Abstract Alcohol use disorder is a chronically relapsing disorder that involves aspects of compulsivity in alcohol seeking and taking, difficulty limiting alcohol intake, and the emergence of negative emotional states, such as dysphoria, anxiety, irritability (e.g., hyperkatifeia), in the absence of alcohol. Alcohol addiction encompasses a three-stage cycle that intensifies with continued alcohol use: binge/intoxication, withdrawal/negative affect, and preoccupation/anticipation. These stages engage neuroadaptations in brain circuits that involve the basal ganglia (incentive salience), extended amygdala (reward deficit/stress surfeit), and prefrontal cortex (executive dysfunction). Here, we discuss key neuroadaptations in stress systems in alcohol addiction. These neuroadaptations contribute to negative emotional states and negative urgency that are hypothesized to powerfully drive alcohol drinking and seeking and promote relapse. Changes in stress systems, combined with the disruption of prefrontal cortex function that leads to cognitive deficits, impairments in inhibitory control, and poor decision making, contribute to the chronic relapsing nature of alcohol addiction.

Introduction

Alcohol use disorder (AUD), also termed alcohol addiction, is a medical condition that is characterized by an impaired ability to stop or control alcohol use despite adverse social, occupational, or health consequences. Currently, three medications—disulfiram, acamprosate, and naltrexone—are approved by the United States Food and Drug Administration (FDA) for the treatment of AUD [1]. However, although these medications are effective, they are underutilized. Like the treatment of mental illness in general, more individually targeted, practical, affordable, and acceptable treatments would alleviate suffering and increase wellbeing.

In individuals who are not diagnosed with AUD, the consumption of alcohol typically causes pleasurable effects (e.g., euphoria). These pleasant effects increase the probability of drinking, which is defined as positive reinforcement. However, AUD involves aspects of compulsive alcohol seeking and drinking, difficulty limiting alcohol intake, and the emergence of a negative emotional state, such as dysphoria, anxiety, and irritability (hyperkatifeia), during alcohol abstinence. These negative emotional states can persist long into alcohol abstinence and are hypothesized to help perpetuate compulsive alcohol drinking and seeking via negative reinforcement. Negative reinforcement is defined as the process by which the removal of an aversive state, such as somatic and motivational signs of withdrawal, increases the probability of a response (e.g., alcohol is consumed to alleviate anxiety, pain, and dysphoria). Negative reinforcement is conceptually distinct from punishment, which involves the presentation of an aversive stimulus contingent to a behavior.

Alcohol addiction encompasses a three-stage cycle [2]: binge/intoxication (heavy alcohol drinking), withdrawal/negative affect (hyperkatifeia), and preoccupation/anticipation (craving; Fig. 36.1). These stages are interconnected and intensify with continued alcohol misuse. They involve neuroadaptations in numerous brain circuits that include the basal ganglia (incentive salience), extended amygdala (reward deficit/stress surfeit), and prefrontal cortex (PFC; executive dysfunction). Here, the extended amygdala is defined as a supra-structure that includes the central nucleus of the amygdala (CeA), the bed nucleus of the stria terminalis (BNST), the sublenticular substantia innominata, and a transition zone in the medial part of the nucleus accumbens (e.g., shell) [4].

The multidimensional nature of AUD involves a complex interaction between alterations in brain reward and stress systems and executive function that engage multiple neurocircuits and neurotransmitter systems [5, 6]. Much work has focused on incentive salience and repetitive behavior (often described as habits) that are associated with the alcohol binge/intoxication stage. However, repeated cycles of alcohol intoxication and withdrawal produce neuroadaptations in reward and stress systems and cognitive function that in turn drive alcohol drinking. Thus, stress systems have an important effect on driving alcohol misuse and precipitating craving and relapse in later phases of AUD [2].

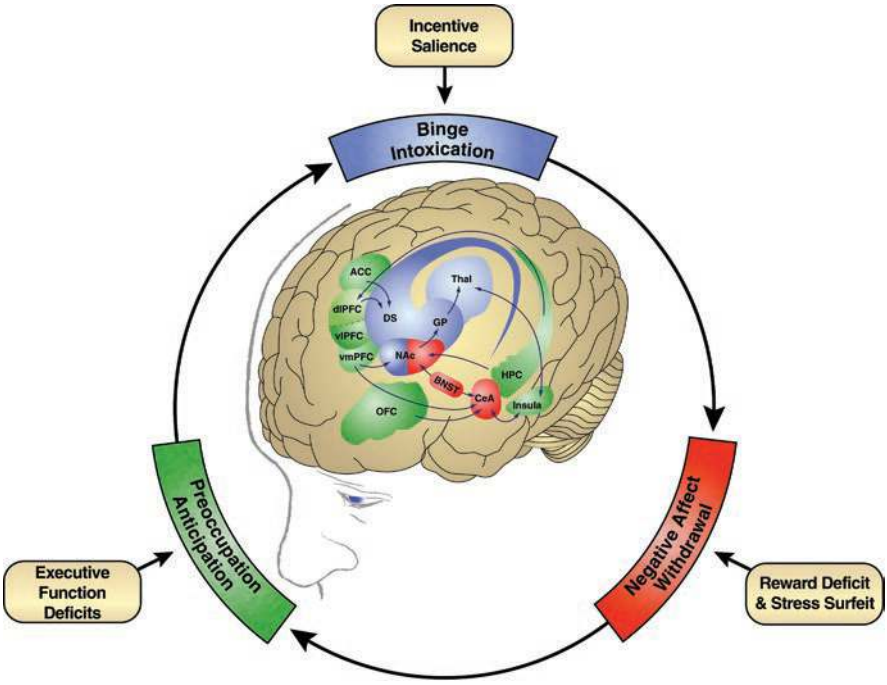

Fig. 36.1 Conceptual framework for the neurobiological basis of addiction. In the *binge/intoxication* stage, reinforcing effects of drugs may engage neurocircuits of the basal ganglia (blue structures). Reward neurotransmitter activation and associative mechanisms engage the nucleus accumbens shell and core, and then stimulus-response habits engage the dorsal striatum. Two major neurotransmitters that mediate the rewarding effects of addictive drugs are dopamine and opioid peptides. In the *withdrawal/negative affect* stage, the negative emotional state of withdrawal may engage activation of the extended amygdala (red structures). The extended amygdala is composed of several basal forebrain structures, including the bed nucleus of the stria terminalis, central nucleus of the amygdala, and possibly a transition zone in the medial portion (or shell) of the nucleus accumbens. Major neurotransmitters in the extended amygdala that are hypothesized to function in negative reinforcement are corticotropin-releasing factor, norepinephrine, and dynorphin. There are major projections from the extended amygdala to the hypothalamus and brainstem. The *preoccupation/anticipation* (craving) stage involves neurocircuitry of the cortex and allocortex (green structures). The processing of conditioned reinforcement involves the basolateral amygdala, and the processing of contextual information involves the hippocampus. Executive control depends on the prefrontal cortex and includes the representation of contingencies, the representation of outcomes, and their value and subjective states (i.e., craving and, presumably, feelings) that are associated with drugs. The subjective effects, termed "drug craving" in humans, involve activation of the orbital and anterior cingulate cortices and temporal lobe, including the amygdala. A major neurotransmitter that is involved in the craving stage is glutamate that is localized in pathways from frontal regions and the basolateral amygdala that project to the ventral striatum. (Modified from [3])

The biological mechanisms of alcohol addiction can be investigated using animal models. These models provide critical information about the etiology and pathophysiology of AUD and will continue to guide the discovery and development of new treatments for AUD. The use of experimental animals in preclinical alcohol research gives the experimenter control over several factors, such as genetic background, the environment, and exposure to alcohol, which are all difficult to control in humans. Although no animal model fully recapitulates AUD in humans, experimental animals exhibit behaviors that have predictive validity in the domains of alcohol drinking that persists despite negative consequences, motivational withdrawal, hyperkatifeia, and hyperalgesia [7–9].

Here, using rodent models as a framework, we argue that repeated, intense cycles of alcohol intoxication and withdrawal elicit neuroadaptations first at the level of the hypothalamic-pituitary-adrenal (HPA) axis, a primary neuroendocrine stress system, and subsequently in extrahypothalamic brain regions (i.e., basal ganglia, extended amygdala, and PFC). These physiological and neural adaptations lead to hypofunctional brain reward systems (reward tolerance, hypohedonia), stress surfeit (anxiety, irritability, and pain), and executive dysfunction (cognitive deficits, poor decision making, and poor judgment) that are associated with AUD. These neuroadaptations are hypothesized to maintain alcohol misuse via negative reinforcement and contribute to relapse risk even long into protracted abstinence.

Neurocircuitry Perspective of Allostatic Stress System Changes in Addiction

Our hypothesis is that as motivational dependence on alcohol develops, reward systems are compromised, and brain stress systems are recruited in the extended amygdala. We further hypothesize that these brain stress neurotransmitters that are known to be activated during the development of excessive drug taking comprise a between-system opponent process, and this activation is manifest when the drug is removed, producing such negative emotional symptoms as anxiety, depression, irritability, and pain (both emotional [hyperkatifeia] and physical) that are associated with acute and protracted abstinence. Between-system neuroadaptations can also impact within-system neuroadaptations to further exacerbate negative emotional states by suppressing reward function, which was originally hypothesized for dynorphin by Carlezon et al. [10]. The activation of cyclic adenosine monophosphate response element binding protein (CREB) by excessive dopamine and opioid peptide receptor activation in the nucleus accumbens is hypothesized to trigger the induction of dynorphin to feedback to suppress dopamine release. Thus, we argue that anti-reward circuits are recruited as between-system neuroadaptations [11] during the development of addiction and produce aversive or stress-like states via the direct activation of stress systems (e.g., corticotropin-releasing factor [CRF] in the

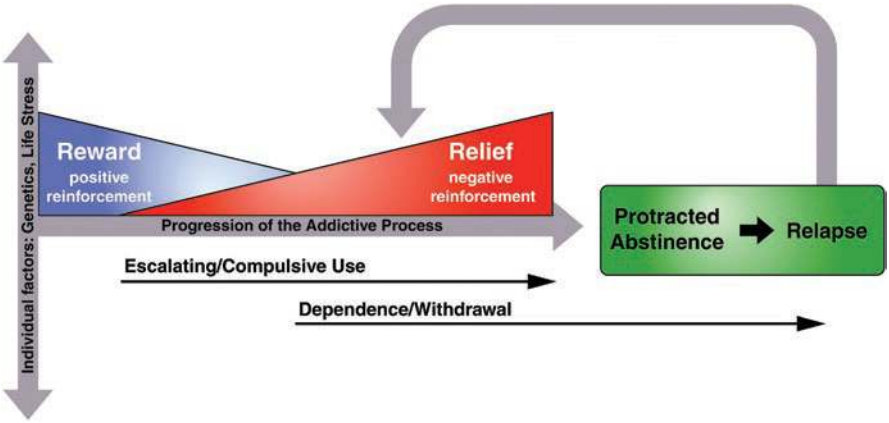

Fig. 36.2 Conceptual framework of sources of reinforcement in addiction. Positive reinforcement, in which the drug typically engenders positive hedonic effects, is defined as an increase in the probability of responding that is produced by the presentation of a drug. Positive reinforcement is associated with the early stages of addiction as part of the binge/intoxication stage but persists throughout the addiction cycle. Negative reinforcement is defined as an increase in the probability of responding for a drug to relieve hyperkatifeia or stress, in which drug withdrawal during the withdrawal/negative affect stage of the addiction cycle typically engenders hyperkatifeia and stress. Both sources of reinforcement can co-exist and be perpetuated by protracted abstinence and cue-, drug-, and stress-induced reinstatement in the preoccupation/anticipation stage of the addiction cycle. (Figure modified from an original diagram from Dr. Loren Parsons)

extended amygdala) and the indirect activation of a hypohedonic state by suppressing dopamine.

The long-lasting neuroadaptations in stress and reward systems that lead to motivational symptoms during acute withdrawal and protracted abstinence may provide the basis by which drug priming, drug cues, and acute stressors acquire additional power to elicit drug-seeking behavior. Notably, multiple alcohol detoxifications and relapses can further enhance withdrawal that is increasingly less responsive to treatment [12]. This "kindling" effect may be reduced by the blockade of brain stress systems, suggesting a key role for brain stress systems in this phenomenon [13] (Fig. 36.2).

Dysregulation of the Hypothalamic-Pituitary-Adrenal Axis in Alcohol Addiction

The endocrinologist Hans Selye conceptualized stress and HPA axis function as adaptive responses to environmental challenges, termed "general adaptation syndrome" [14]. The HPA axis is a primary neuroendocrine system that is engaged in response to environmental stimuli [15, 16]. Knowledge of such an HPA axis, with glucocorticoids as an endpoint, encouraged the search for hypothalamic releasing

factors (i.e., CRF) [17] that control adrenocorticotropic hormone (ACTH), which in turn drives glucocorticoid release from the adrenal gland [18]. Stress stimulates the paraventricular nucleus (PVN) of the hypothalamus to release CRF that acts in the anterior pituitary to release ACTH into the bloodstream, which then activates melanocortin receptor 2 (an ACTH receptor) in the cortex of the adrenal glands. This causes the rapid production and release of glucocorticoids into the blood circulation. Glucocorticoids have physiological effects on many tissues and alter behavior. In situations of high or chronic stress, negative feedback mechanisms along the HPA axis, including the PVN, pituitary, and hippocampus, prevent further glucocorticoid release.

In the brain, glucocorticoids bind to two types of receptors: mineralocorticoid receptors (type I) and glucocorticoid receptors (type II). Mineralocorticoid receptors have high affinity for glucocorticoids, whereas glucocorticoid receptors have lower affinity for glucocorticoids. Thus, at normal circulating levels of glucocorticoids, the occupancy of mineralocorticoid receptors is already substantial, and high circulating glucocorticoid levels are necessary to activate glucocorticoid receptors. Activation of the HPA axis is adaptive and critical for survival. However, intense and sustained HPA axis activation may lead to long-lasting detrimental neuroadaptations that contribute to the development of mental disorders [15, 16].

Like stress, acute exposure to alcohol activates the HPA axis [19]. In nondependent rats, adrenalectomy decreased alcohol drinking, which was restored by corticosterone replacement [20]. Glucocorticoid receptor antagonism blocked alcohol-induced conditioned place preference (a measure of reward) in mice [15, 21]. These findings suggest that glucocorticoids contribute to alcohol's acute rewarding/reinforcing effects in a nondependent state. By extrapolation, glucocorticoids contribute to incentive salience [22]. The effects of glucocorticoids on alcohol's motivational effects may involve the release of dopamine in the mesolimbic system [23]. Extracellular dopamine levels decreased in the nucleus accumbens shell [24] in rats that were subjected to adrenalectomy to suppress endogenous glucocorticoids. Thus, glucocorticoids may contribute to reward/incentive salience function in response to alcohol in the binge/intoxication stage.

Excessive activation of the HPA axis by repeated alcohol exposure and withdrawal leads to the dysregulation of HPA axis activity [25–28]. Activation of the HPA axis by alcohol is blunted (i.e., neuroendocrine tolerance) in alcohol addiction [27, 29] (Fig. 36.3). An injection of alcohol increased blood ACTH and corticosterone levels in nondependent rats but much less so in alcohol-dependent rats [27]. This blunted HPA axis response to alcohol may contribute to the decrease in alcohol-induced rewarding effects in alcohol addiction. Dysregulation of the HPA axis in alcohol addiction is associated with alcohol craving and relapse [28]. The opioid receptor antagonist naltrexone, which activates the HPA axis, has anti-craving effects [33]. Activation of the HPA axis may be a consequence of the naltrexone-induced blockade of tonic inhibitory effects of endogenous opioids [29] on the PVN and other modulatory stress-related regions (e.g., locus coeruleus). However, naltrexone can also cause a direct aversive/stressful response in rats and humans that

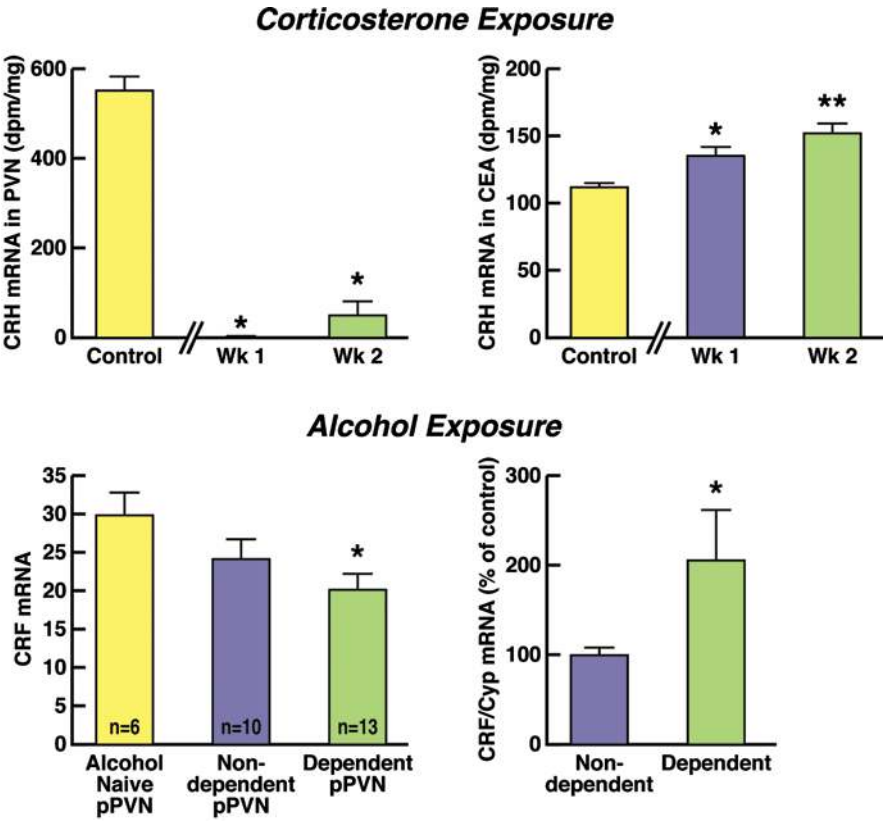

Fig. 36.3 Corticosterone blunts hypothalamic-pituitary-adrenal axis and sensitizes the central nucleus of the amygdala. (Top left) Corticotropin-releasing hormone (CRH; the nomenclature for the CRF gene) mRNA hybridization levels in the paraventricular nucleus induced by corticosterone pellet (200 mg) implantation. Control rats ($n = 12$) were obtained from the pool of rats that were euthanized at the same time points as the experimental group ($n = 7$ for each time point). The data are expressed as the mean + SEM. $*p < 0.001$, *vs*. control (Taken with permission from [30]). (Top right) CRH mRNA hybridization levels in the central nucleus of the amygdala induced by corticosterone pellet implantation over 2 weeks. Control rats ($n = 12$) were obtained from the pool of rats that were euthanized at the same time points as the experimental groups ($n = 7$ for each time point). The data are expressed as the mean + SEM. $*p < 0.01$, $**p < 0.001$, *vs*. control (Taken with permission from [30]). (Bottom left) CRF mRNA significantly decreased in the pPVN in dependent animals compared with alcohol-naive controls ($*p = 0.01$) but not compared with nondependent animals. The groups did not differ in CRF mRNA levels in the magnocellular division of the PVN (mPVN; data not shown). The data are expressed as the mean ± SEM. (Taken with permission from [31]). (Bottom right) In alcohol-dependent rats ($n = 8$), levels of CRF mRNA, normalized to cyclophilin A, significantly increased in CeA punches ($*p < 0.05$) compared with naive controls ($n = 11$), measured by quantitative real-time polymerase chain reaction. (Taken with permission from [32])

consume high levels of alcohol [34]. Furthermore, alcohol-associated cues stimulate glucocorticoid release in humans with a history of AUD who are abstinent from drinking [35] and produce craving, suggesting that glucocorticoids contribute to conditioned responses [36] to promote relapse.

The blunting of HPA axis responses in alcohol addiction may be attributable to CRF downregulation in the PVN [27, 30, 37]. Concomitantly with the downregulation of CRF in the PVN, there is a paradoxical upregulation of CRF levels in extrahypothalamic brain regions (see Fig. 36.3), such as the CeA and BNST, following chronic exposure to either glucocorticoids or alcohol [30, 32, 38]. This bidirectional regulation of CRF has been hypothesized to depend on the interaction between glucocorticoid receptors and various steroid-related co-regulators [39]. Functionally, these neuroadaptations in the extended amygdala may mediate hypohedonia and stress sensitization in alcohol addiction.

Role for CRF and Vasopressin in Alcohol Addiction

The dysregulation of brain CRF and vasopressin systems is hypothesized to underlie the enhanced anxiety-like behavior and enhanced alcohol self-administration that are associated with alcohol withdrawal and protracted abstinence. The pharmacological blockade of CRF_1 receptors or vasopressin (a co-regulator of the HPA axis that potentiates CRF's effects) V_{1b} receptors reduced alcohol drinking, especially in dependent rodents [32, 38, 40–47]. In mice [48] and high-intake nondependent rats [49], CRF receptor antagonists reduced binge-like drinking and stress-induced alcohol drinking. Electrophysiological studies of the CeA showed that the effects of alcohol on the presynaptic activation of γ-aminobutyric acid (GABA) interneurons were enhanced in dependent rats. These effects were abolished by CRF_1 receptor antagonists [32]. Moreover, a CRF_1, but not CRF_2, receptor antagonist normalized the long-term potentiation/intrinsic excitability of BNST neurons in rats during protracted abstinence [50]. There are prominent CRF projections from the CeA to the BNST. The optogenetic inactivation of CRF neurons in the CeA that project to the BNST during alcohol withdrawal reduced dependence-induced alcohol intake [51]. The blockade of CRF_1 receptors (systemic or intra-CeA) also decreased anxiety- and depression-like behavior [52–55] and attenuated hyperalgesia (i.e., an exacerbated tactile response) in alcohol-dependent rats [56] (Fig. 36.4). Anxiety and pain are both hypothesized to contribute to alcohol drinking [59, 60] in the withdrawal/negative affect stage.

Two double-blind, randomized, placebo-controlled, human laboratory studies with treatment-seeking subjects with AUD failed to support the efficacy of CRF_1 receptor antagonists in reducing craving for alcohol [61, 62]. However, based on these studies that have several limitations, one cannot conclude that CRF_1 receptor antagonists, or other drugs that target the CRF system, are ineffective for the treatment of AUD. Several reasons may explain the apparent lack of efficacy of CRF_1 receptor antagonists in humans. These include inadequate pharmacodynamic

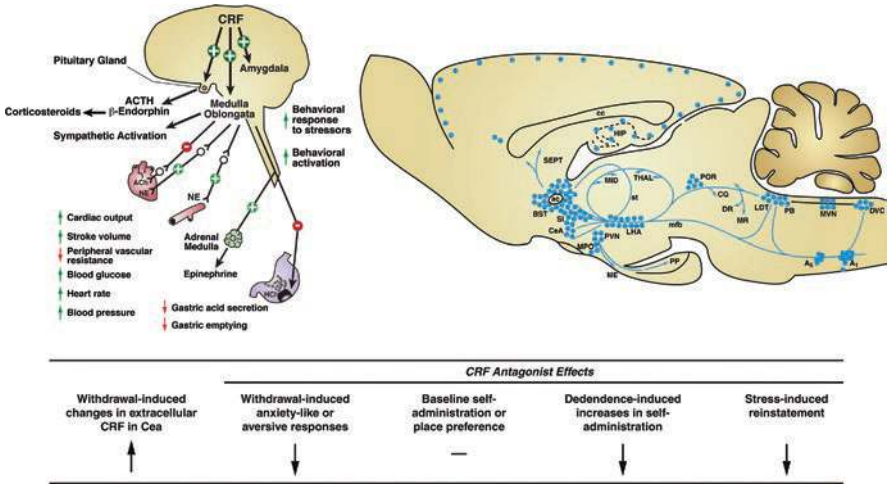

Fig. 36.4 Interactions between CRF and stress systems. (Left) Diagram illustrating the multiple actions of CRF in mediating stress responses in the body. CRF drives the hypothalamic-pituitary adrenal axis by acting to release adrenocorticotropic hormone (ACTH) in the portal system of the pituitary. CRF activates the sympathetic system by actions in the brainstem and mediates arousal and behavioral responses to stressors by actions in the amygdala, other basal forebrain regions, and ventral midbrain, such as the ventral tegmental area. Ach, acetylcholine; NE, norepinephrine (Taken with permission from [57]). (Right) Localizations and projections of brain stress systems. Corticotropin-releasing factor. The major CRF-stained cell groups (dots) and fiber systems in the rat brain. Most of the immunoreactive cells and fibers appear to be associated with systems that regulate the output of the pituitary and the autonomic nervous system and with cortical interneurons. Most of the longer central fibers course either ventrally through the medial forebrain bundle and its caudal extension in the reticular formation or dorsally through a periventricular system in the thalamus and brainstem central gray. The direction of fibers in these systems is unclear because they appear to interconnect regions that contain CRF-stained cell bodies. Three adjacent CRF-stained cell groups—laterodorsal tegmental nucleus, locus coeruleus, and parabrachial nucleus—lie in the dorsal pons. Uncertain are which of these cell groups contributes to each of the pathways shown and which of them receives inputs from the same pathways. ac, anterior commissure; BST, bed nucleus of the stria terminalis; cc, corpus callosum; CeA, central nucleus of the amygdala; CG, central gray; DR, dorsal raphe; DVC, dorsal vagal complex; HIP, hippocampus; LDT, laterodorsal tegmental nucleus; LHA, lateral hypothalamic area; ME, median eminence; mfb, medial forebrain bundle; MID THAL, midline thalamic nuclei; MPO, medial preoptic area; MR, median raphe; MVN, medial vestibular nucleus; PB, parabrachial nucleus; POR, perioculomotor nucleus; PP, peripeduncular nucleus; PVN, paraventricular nucleus; SEPT, septal region; SI, substantia innominata; st, stria terminalis. (Modified from [58])

profiles (e.g., fast receptor off-rates, inability to block ligand-independent CRF_1 signaling or other CRF system elements [CRF-BP, CRF_2]), plasticity/sensitization in mechanisms downstream of the CRF_1 receptor, heterogeneous or incomplete experimental populations (one study only involved women; subgroups defined for genetic or endophenotypic vulnerability, such as hyperkatifeia, might respond), and the temporal challenge of experimentally intervening in dynamic, motivational withdrawal symptoms [63]. Another important consideration is the brain site of

action of receptor blockade. The doses of antagonists that were used in these clinical studies were possibly not sufficiently high for complete CRF_1 receptor blockade in all relevant regions of the forebrain, even if some target engagement was demonstrated. As discussed elsewhere [64], high doses could produce such side effects as Addison's disease-like symptoms by the complete blockade of CRF_1 receptors in the anterior pituitary (outside the blood-brain barrier). Additional well-designed studies with novel anti-CRF compounds or, perhaps even better, the indirect modulation of CRF activity, such as with glucocorticoid receptor antagonists and steroid receptor coregulators [39, 65], may facilitate the discovery of drugs with clinical efficacy (see below).

A recent double-blind, placebo-controlled, multisite clinical trial investigated the role of vasopressin, which is known to modulate HPA axis activity and potentiate CRF's effects, in treating AUD. Vasopressin V_{1B} receptor antagonism increased the percentage of days abstinent compared with placebo [66].

In summary, like stress (e.g., life adversities), repeated alcohol exposure is hypothesized to lead to a delayed hypofunctional HPA axis and decreased reward/incentive-salience system and brain (extended amygdala) stress sensitization in vulnerable individuals. These adaptations may contribute to negative emotional states that are hypothesized to drive alcohol drinking and seeking via negative reinforcement (i.e., "self-medication"). Similar neuroadaptations may underlie the vulnerability to reward- and stress-related mental disorders, such as anxiety, depression, and pain, which are highly comorbid with AUD.

Increased Glucocorticoid Receptor Activity in Alcohol Addiction

Alcohol addiction is associated with glucocorticoid-dependent plasticity in brain reward and stress regions. Acute alcohol withdrawal (i.e., 6–24 h after the end of alcohol exposure) was accompanied by the downregulation of glucocorticoid receptor mRNA in the PFC, nucleus accumbens, and BNST, results that were interpreted as a compensatory effect of receptor overactivation in alcohol withdrawal [67]. Consistent with this hypothesis, glucocorticoid receptor signaling in the CeA, measured by levels of phosphorylated glucocorticoid receptors, increased in dependent rats compared with nondependent rats [68]. Notably, neurophysiology and regulation of the HPA axis and glucocorticoids are complex. Plasma levels of glucocorticoids do not necessarily reflect levels in the brain. Little et al. [69] reported that corticosterone levels increased in several brain regions in alcohol-dependent mice compared with nondependent mice, whereas both dependent and nondependent mice had similar blood corticosterone levels. These findings again suggest the greater activation of glucocorticoid receptors in the brain during acute alcohol withdrawal. Higher corticosterone levels in the brain in animals that are made dependent on alcohol may involve the activity of 11β-hydroxysteroid dehydrogenase 1, which colocalizes with glucocorticoid receptors and converts inactive glucocorticoids

(e.g., cortisone and 11β-dehydrocorticosterone) into active glucocorticoids (e.g., cortisol and corticosterone). The inhibition of 11β-hydroxysteroid dehydrogenase 1 with carbenoxolone reduced escalated alcohol drinking in both rats and mice [70].

The functional role of glucocorticoid receptors in alcohol drinking during acute withdrawal was evaluated using both acute and chronic glucocorticoid receptor antagonism. Chronic mifepristone (also called RU-38486 or RU-486) administration blocked the escalation of alcohol drinking in alcohol-dependent rats at doses that did not affect drinking in nondependent rats [67] (Fig. 36.5). Acute systemic or intra-CeA treatment with mifepristone or the more selective glucocorticoid receptor antagonist CORT113176 decreased escalated alcohol drinking in dependent rats but not in nondependent rats [68] and decreased binge-like alcohol drinking but not low drinking levels in mice [71]. Mice that exhibited high alcohol drinking, compared with mice that exhibited low drinking, exhibited alterations of the expression of several genes that are related to the glucocorticoid system in the nucleus accumbens [72]. The glucocorticoid receptor modulators CORT118335, CORT122928, and CORT125134 reduced alcohol self-administration in alcohol-dependent and nondependent rats, whereas CORT108297 had no effect on alcohol drinking in either

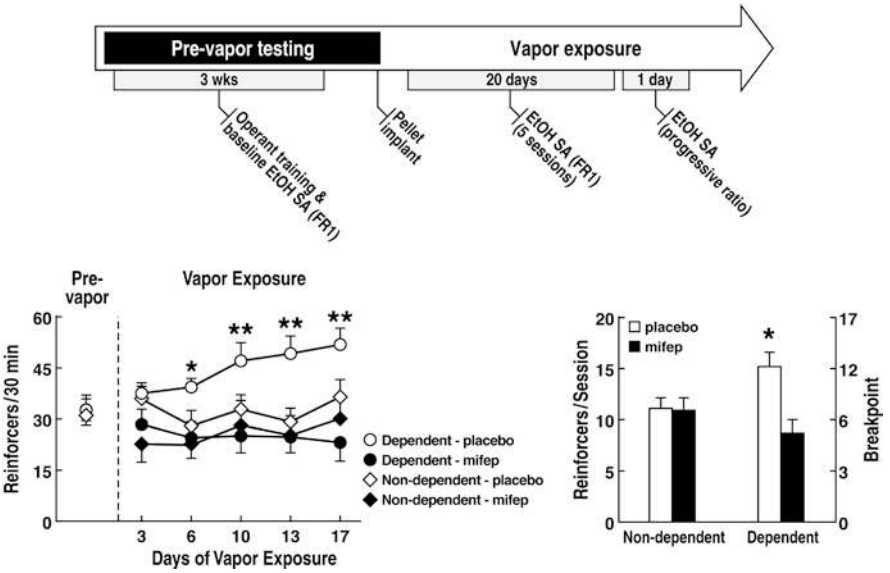

Fig. 36.5 Chronic glucocorticoid receptor blockade by mifepristone prevented the escalation of alcohol intake and motivation for alcohol in vapor-exposed animals. (**a**) Timeline of the experiment. Dependent and nondependent rats were implanted with pellets for the chronic release of mifepristone (150 mg for 21 days) or placebo before exposure to alcohol vapor. Mifepristone-treated vapor-exposed rats did not exhibit an escalation of alcohol intake (**b**) or an increase in progressive-ratio responding (**c**) compared with placebo-treated vapor-exposed rats. Mifepristone did not influence alcohol intake in nondependent rats. The data are expressed as the mean ± SEM. $^{*}p < 0.05$, difference from mifepristone-treated vapor exposed rats; $^{+}p < 0.05$, difference from placebo-treated nondependent rats. n = 9–10/group. (Taken with permission from [67])

group [73]. Acute systemic treatment with mifepristone reduced heavy alcohol drinking in rhesus macaques but did not block alcohol-induced relapse-like behavior in early abstinence [74].

In contrast to dependent rodents, mifepristone did not affect alcohol drinking in nondependent male rodents [20, 67, 68, 75–78] or baboons [79]. However, mifepristone reduced alcohol consumption in female rats [76] and the stress-induced reinstatement of alcohol seeking in male rats [78]. The intra-CeA (but not intrabasolateral amygdala) administration of mifepristone also suppressed the stress-induced reinstatement of alcohol seeking in nondependent rats [78]. Mifepristone prevented the increase in alcohol drinking in mice [80] and decreased alcohol drinking and seeking in rodents under stress conditions [80, 81]. Additionally, a systemic mifepristone injection reduced alcohol self-administration in nondependent male and female Wistar rats, but mifepristone had less of an effect in Marchigian-Sardinian alcohol-preferring rats. CORT113176 decreased alcohol self-administration in male and female Wistar rats and in female Marchigian-Sardinian alcohol-preferring rats [82]. Mifepristone did not affect anxiety-like behavior in Marchigian-Sardinian alcohol-preferring rats [83]. Altogether, these findings suggest that glucocorticoid receptor antagonism reduces alcohol drinking and seeking under conditions of binge-like drinking, stress, and dependence.

During protracted alcohol abstinence (i.e., several weeks of abstinence from alcohol), glucocorticoid receptor mRNA expression levels were upregulated in the nucleus accumbens, BNST, and CeA in dependent rats compared with nondependent rats [67]. These findings suggest that HPA axis activity may be at least temporarily reduced during protracted abstinence [26, 84] and indicate that the expression of glucocorticoid receptors is dynamically regulated in alcohol-dependent and post-dependent states. These neuroadaptations may contribute to long-lasting symptoms of anxiety, craving, and irritability that persist into protracted abstinence.

During protracted abstinence, the gene that encodes glucocorticoid receptors, *Nr3c1*, was identified as a master regulator of gene expression in multiple brain regions, including the medial PFC, nucleus accumbens, CeA, and ventral tegmental area, in rats that were made dependent on alcohol [77]. The chronic systemic administration of mifepristone and acute administration of mifepristone in the nucleus accumbens and ventral tegmental area decreased the escalation of alcohol drinking in rats with a history of alcohol dependence but not in nondependent rats [67, 77]. Furthermore, rats that were chronically exposed to alcohol drinking and dependence exhibited robust cue/context-induced reinstatement of alcohol seeking during protracted abstinence, an effect that correlated with higher glucocorticoid receptor activity in the medial PFC [85]. These results suggest that the dysregulation of glucocorticoid receptor function may be a mechanism by which negative emotional states persist into protracted abstinence in the preoccupation/anticipation stage.

In electrophysiological studies of neurons in the CeA, mifepristone reduced the frequency of spontaneous inhibitory postsynaptic currents (sIPSCs) without affecting postsynaptic measures, suggesting a decrease in GABA release, with the largest effect in dependent rats compared with nondependent rats. The glucocorticoid receptor modulator CORT118335 did not significantly alter GABA transmission in naive

rats but decreased sIPSC frequency in dependent rats. Mifepristone decreased amplitudes of evoked inhibitory postsynaptic potentials only in dependent rats and during protracted withdrawal. These findings suggest that the efficacy of mifepristone and CORT118335 increases in rats that are made dependent on alcohol [86].

Glucocorticoid receptors and glucocorticoids are implicated in other alcohol-related behaviors. During alcohol withdrawal, circulating glucocorticoid levels positively correlated with the severity of cognitive deficits in individuals with AUD [87]. In rodents, glucocorticoids contributed to alcohol withdrawal-induced brain neurotoxicity via the activation of glucocorticoid receptors [49, 88–90]. Treatment with mifepristone during acute withdrawal attenuated memory deficits in mice during protracted alcohol abstinence [88]. The dentate gyrus of the hippocampus exhibits robust neurogenesis and is affected in animals that are made dependent on alcohol [91]. Mifepristone exerted a neuroprotective effect in this brain region in rats that were exposed to binge-like alcohol [49]. Mifepristone also attenuated motor cross-sensitization between stress and alcohol in mice [92] and reduced somatic signs of alcohol withdrawal [88, 90], indicating that the decrease in glucocorticoid receptor function via receptor antagonism normalized several signs of enhanced stress and alcohol addiction-like behaviors.

The positive results of the role of glucocorticoid receptors in animal models of AUD encouraged studies in humans. The effect of mifepristone on alcohol drinking and seeking was tested in a double-blind, randomized, placebo-controlled human laboratory study that included 56 non-treatment-seeking individuals who were diagnosed with AUD [68]. Mifepristone treatment (600 mg daily, orally, for 1 week) lowered craving for alcohol compared with placebo treatment. Craving was precipitated by the presentation of cues that were associated with alcohol-containing beverages in the laboratory. Mifepristone also reduced self-reported alcohol drinking during pharmacological treatment and at least for 1 week after treatment cessation compared with placebo. Mifepristone caused few adverse effects and appeared to improve liver function.

The methylation of the NR3C1 exon variant 1H increased and glucocorticoid receptor mRNA and protein levels decreased in the PFC in individuals with AUD compared with controls. Additionally, the expression of other stress-related genes, such as *CRF*, *POMC*, and *FKBP5*, was altered in the PFC in individuals with AUD compared with controls [93].

Alcohol-Induced Sensitization of Glucocorticoid Receptor Systems

The glucocorticoid receptor is a transcription factor that belongs to the nuclear receptor superfamily. When activated by glucocorticoids, glucocorticoid receptors translocate from the cytoplasm to the nucleus. The process of intracellular glucocorticoid receptor trafficking is regulated by a host of chaperones. In the nucleus, glucocorticoid receptors bind directly to glucocorticoid response elements in the DNA

or indirectly by tethering to other transcription factors to cause the activation or repression of gene expression [94]. Chronic alcohol exposure and withdrawal downregulate CRF in the PVN (i.e., HPA axis tolerance that contributes to reward deficits). CRF upregulation in extrahypothalamic regions (e.g., extended amygdala) contributes to stress sensitization. Thus, an intriguing question is how glucocorticoid receptor activation causes opposite effects in the regulation of CRF expression in two distinct brain regions. A potential mechanism is that the valence of glucocorticoid receptor actions on gene transcription largely depends on co-regulators, and the expression of these regulators is site-specific.

Steroid receptor coactivator 1 (SRC-1) has been implicated in glucocorticoid receptor-mediated CRF transcription, with two isoforms (SRC-1a and SRC-1e) playing opposite roles in CRF transcription. SRC-1a, which represses CRF transcription, is abundantly expressed in the PVN, whereas SRC-1e, which is more highly expressed in the CeA [95], has been shown to lack repressive function [96]. Antisense oligonucleotides, which are synthetic single-stranded strings of nucleic acids that interfere with gene expression by binding to RNA, were used to regulate SRC-1 splice variants *in vivo* [96]. An antisense oligonucleotide infusion in the CeA that favored the expression of SCR-1a over SRC-1e repressed CRF expression and decreased anxiety/fear-like behavior in mice [96]. The effect of manipulating SRC-1 splice variants in alcohol drinking remains to be determined, but a decrease in opioid addiction-like behaviors has been reported [65]. This is an exciting new therapeutic possibility, given that antisense oligonucleotides have already been successfully used in humans for the treatment of neurodegenerative disorders. Furthermore, the indirect and opposite actions of glucocorticoid receptors in different brain regions represent a potential novel mechanism of CRF regulation that may have advantages compared with direct CRF_1 receptor blockade.

Potential Role of Mineralocorticoids in Alcohol Addiction

Much less is known about the role of mineralocorticoids in alcohol addiction [97]. Both glucocorticoids (centrally and peripherally) and aldosterone (mainly peripherally) bind to mineralocorticoid receptors. Aldosterone is a mineralocorticoid steroid hormone that is produced in the zona glomerulosa of the adrenal gland. Aldosterone controls blood pressure and electrolyte levels through the mineralocorticoid receptor, which is encoded by the *NR3C2* gene. However, mineralocorticoid receptors are also expressed in the brain, including the CeA, hippocampus, and PFC. In the brain, mineralocorticoid receptors are preferentially activated by glucocorticoids. The expression of mineralocorticoid receptor mRNA in the CeA but not PFC negatively correlated with anxiety-like behavior and aversion-resistant alcohol drinking in dependent rats but not in nondependent rats [59]. Similarly, alcohol drinking negatively correlated with mineralocorticoid receptor

expression in the CeA but not PFC in long-term drinking rhesus macaques [59]. Both alcohol-drinking rhesus macaques and humans with AUD exhibited higher plasma aldosterone levels compared with controls, and aldosterone levels correlated with craving, anxiety, and the number of drinks consumed by humans with AUD [59].

Systemic or intracerebroventricular administration of the nonselective mineralocorticoid receptor antagonist spironolactone and the more selective mineralocorticoid receptor antagonist RU28318 did not reduce alcohol drinking in male rats [20, 75] or mice [80] in a continuous (24 h) two-bottle (water vs. alcohol) choice model or in a limited (1 h) two-bottle choice model following fluid restriction [81]. However, 7 days of oral spironolactone treatment decreased alcohol drinking (and blood pressure) in high drinking but not low drinking male rats that were given continuous two-bottle choice access [98]. In nondependent male and female rats, the systemic administration of spironolactone reduced operant alcohol self-administration [99]. In nondependent male and female mice, spironolactone dose-dependently reduced binge-like alcohol drinking [100]. In male and female alcohol-dependent and nondependent rats, spironolactone dose-dependently reduced operant alcohol self-administration [100]. Intra-CeA infusion of the selective mineralocorticoid receptor antagonist eplerenone and mineralocorticoid receptor knockdown in the CeA transiently reduced alcohol intake in nondependent rats [101]. In humans, two pharmacoepidemiological studies that used high-dimensional propensity score matching found that spironolactone dispensation was associated with a decrease in alcohol drinking [100, 102]. These findings suggest that mineralocorticoid receptors may be implicated in alcohol reinforcement and that spironolactone may be further studied as a potential pharmacotherapy for AUD.

Brain Stress Systems: Beyond Glucocorticoids and Corticotropin-Releasing Factor

The central role of glucocorticoids and CRF in the brain in behavioral responses to alcohol and stressors does not exclude the role of other brain stress systems. There is strong evidence for norepinephrine, dynorphin, hypocretin (also called orexin), substance P, and neuroimmune modulators in the higher alcohol intake that is associated with alcohol addiction-like behaviors in animal models (for review, see [5, 103]; Fig. 36.6). Thus, the activation of a pro-stress, pro-negative emotional state system is multidetermined and comprises the neurochemical bases of hedonic opponent processes. However, one may hypothesize that there is a multidetermined anti-stress buffer neurocircuitry that may help return the organism to homeostasis. The vulnerability to AUD may also involve hypoactive anti-stress circuitry. Indeed, neuropeptide Y, endocannabinoids, and possibly nociceptin may contribute to such circuitry [5, 103].

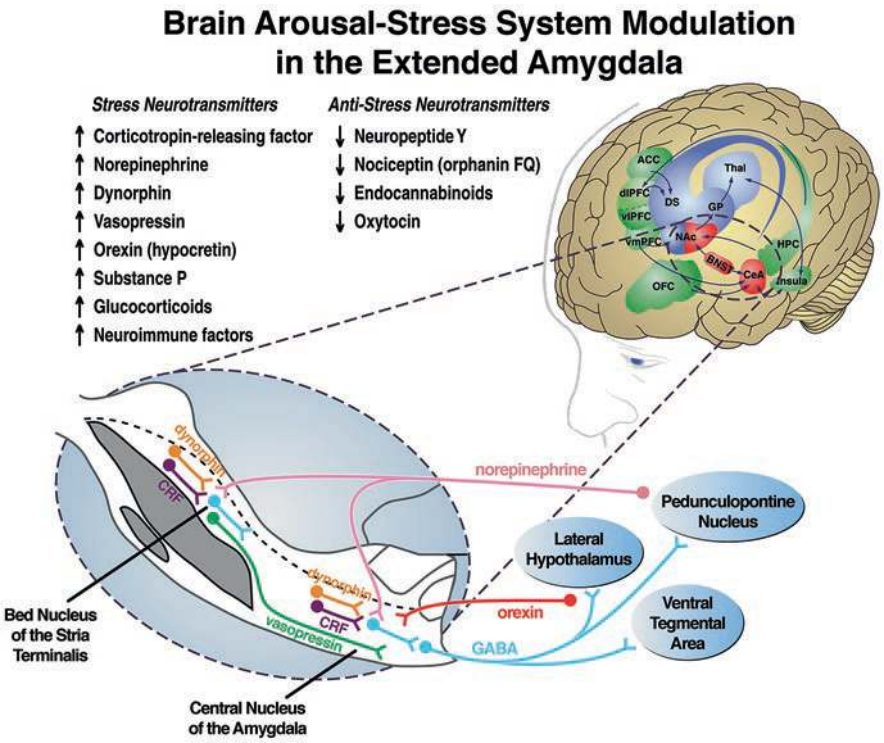

Fig. 36.6 Targets for hyperkatifeia in the withdrawal/negative affect stage (Modified from [104]). Shown is a representation of limbic cortical and associated striatal circuitry, with tentative localization of functions involved in drug addiction. Key structures include the medial prefrontal cortex (mPFC), which also includes the anterior cingulate (AC), orbitofrontal cortex (OFC), hippocampus (Hippo), ventral striatum (VS), nucleus accumbens, dorsal striatum (DS), globus pallidus (GP), amygdala (AMYG), and thalamus (Thal). The zoomed section shows the extended amygdala and its afferent and major efferent connections and modulation via brain arousal-stress systems. Note that dynorphin may activate CRF neurons or be activated by CRF neurons, that norepinephrine and CRF are hypothesized to be involved in a feed-forward circuit, and that vasopressin for the central nucleus of the amygdala is hypothesized to derive from the bed nucleus of the stria terminalis. Neuropeptide Y and nociceptin are not depicted in this figure but may act either via modulation of the CRF system or independently, directly on the output of the central nucleus of the amygdala. (Taken with permission from [105])

Construct and Measurement of Negative Urgency

The construct of negative urgency (i.e., the disposition to act rashly under extreme distress) [106] may further link opponent-process affective dysregulation to greater use in the stress surfeit model of AUD. Negative urgency involves impairments in inhibitory control while under stress [106]. In humans, negative urgency is measured via the validated Negative Urgency subscale of the Urgency, Premeditation (lack of), Perseverance (lack of), Sensation Seeking, Positive Urgency, Impulsive

Behavior Scale (UPSS-P) [106–108]. The Negative Urgency subscale includes negative reinforcement-oriented items, such as "When I feel bad, I will often do things I later regret in order to make myself feel better now." Accordingly, individuals who are high in negative urgency are high in negative reinforcement efficacy and motive [109–111], initiate substance use during stressful life situations [112], and are predisposed to use alcohol to reduce negative affective symptoms of abstinence [113].

A second set of Negative Urgency items measures impairments in inhibitory control during distress or craving, such as (*i*) "I have trouble resisting my craving" and (*ii*) "It often makes matters worse when I act without thinking when I am upset." Accordingly, individuals who are high in negative urgency show impairments in executive function performance in neuropsychological tests [114]. Twin studies showed that negative urgency predicted externalizing psychopathology, including substance use disorders. In these studies, impairments in executive function showed phenotypic correlations with impulsivity and had genetic and environmental bases [115]. A third set of negative urgency items suggests impairments in the negative-outcome-feedback control of behavior, a compulsivity-like construct [113] (e.g., "Sometimes when I feel bad, I can't seem to stop what I am doing even though it is making me feel worse").

Negative Urgency and Alcohol Use

Negative urgency often co-occurs with alcohol misuse [116] and may be an endophenotype of AUD [106, 116]. Negative urgency is a risk factor for the initiation and exacerbation of alcohol use in young people during stress or depression, exemplified in studies of school- and college-age transitions [112, 117–122]. Meta-analyses have found that among UPPS-P impulsivity dimensions, negative urgency is the strongest predictor of problematic alcohol use, especially during late adolescence [123, 124]. Each point increase in negative urgency predicts a fourfold higher rate of alcohol use problems [125], such as driving under the influence [126, 127].

Several additional findings support a role for negative urgency in promoting the negative reinforcement use of alcohol. For example, daytime anxiety in individuals with dependence symptoms predicted subsequent alcohol intoxication only in individuals who were high in negative urgency [128]. In undergraduates with a history of self-harm, negative urgency was associated with greater affective lability, impairments in self-control, problematic alcohol use, and eating problems [129]. In community-dwelling adults, negative urgency predicted greater mood changes, alcohol craving, alcohol seeking, and blood alcohol levels in response to negative mood induction [116]. In college students, path analysis found that the relationship between negative urgency and alcohol drinking was mediated by alcohol outcome expectancies and affect enhancement motives [111], consistent with the hypothesis that individuals who are high in negative urgency drink alcohol to enhance their positive affect and relieve their emotional distress.

Several findings also suggest a differential role for negative urgency relative to other aspects of impulsivity. Urgency (more than sensation seeking, the lack of premeditation, and the lack of perseverance) mediated the relationship between alcohol addiction symptoms and adult symptoms of attention-deficit/hyperactivity disorder [130], linking it to comorbid AUD and attention-deficit/hyperactivity disorder. In Australian young adults, only negative urgency and the lack of premeditation were unique predictors of binge drinking when UPSS-P impulsivity dimensions were regressed simultaneously. Similarly, only negative urgency and positive urgency were unique predictors of alcohol-related problems [131]. In the Rockland Study of community-dwelling adults, negative urgency, not positive urgency, was a unique mediator of relationships between depressive symptoms and problematic alcohol use [132].

Several findings similarly point to a key role for negative urgency in AUD. A study of 454 participants found that negative urgency was 50% higher in participants with AUD than those without AUD and loaded strongly on an impaired inhibitory control factor and also, less so, on a negative emotionality factor [133]. In a structural magnetic resonance imaging study of 33 patients with AUD compared with 32 healthy controls, negative urgency was significantly greater in AUD patients in association with increased anxiety [134]. In a study of 793 patients with AUD by the National Institute on Alcohol Abuse and Alcoholism Clinical Neurogenetics team, negative urgency, more than other UPPS-P dimensions, was related to a greater severity of alcohol addiction symptoms. This relationship was seen across physical ("hangovers, shakes, vomiting"), perceptual ("seen, heard, or felt things not there"), and neurobiological ("passed out, stumbling drunk") domains [135]. Consistent with the reviewed recent findings, an earlier meta-analysis of 2381 individuals found that negative urgency had the strongest relationship to alcohol addiction among all UPPS-P impulsivity dimensions (effect size r = 0.38) [123].

Sex, Age, and Negative Urgency

Negative urgency is a relevant construct in both men and women [136]. Although no consistent sex differences in negative urgency have been reported at the population level [136], negative urgency might still play differential roles between sexes for specific phenotypes [137]. Perhaps accordingly, levels of negative urgency were higher in women with AUD than in men with AUD [135]. This finding is especially salient because clinical and population studies also indicate an increase in the comorbid prevalence and symptom severity of many anxiety and depressive disorders in women with AUD compared with men [138–142]. Altogether, the results potentially suggest a greater role for negative urgency in the pathophysiology of AUD in women.

Levels of negative urgency vary across the lifespan. They increase across puberty [143, 144], and these increases may predict higher drinking frequency and binge eating [145, 146]. Conversely, urgency levels inversely correlated with age in

adulthood, decreasing in older and elderly adults ($r = -0.17$); these findings might account for the "aging out" of drinking for some individuals [147].

Neurocircuitry Implicated in Negative Urgency and Addiction

Initial neuroimaging data [132] support the hypothesis that negative urgency involves impairments in "top-down" cortical control over both basal ganglia and extended amygdala function, leading to a loss of control over pathological habits [148–153] and greater attention to, incentive salience of, or cognitive resource interference from emotion-evoking stimuli.

As summarized in Fig. 36.7, alterations of the structure, function, or connectivity of orbitofrontal cortex (OFC) and ventromedial PFC (vmPFC) projections to the basal ganglia and extended amygdala have been proposed to underlie negative urgency [106, 136, 154]. Accordingly, urgency was associated with the amplitude of resting-state low-frequency fluctuations in the lateral OFC and vmPFC in healthy volunteers [155]. In social drinkers, negative urgency predicted greater activation of the vmPFC in response to an alcohol odor cue and mediated the relationship of vmPFC activation with alcohol craving and problematic drinking [156]. Negative urgency also predicted greater OFC and amygdala activation in response to negative visual stimuli in direct relation to higher levels of risky behavior [157]. In tasks that require inhibition, such as Go/No-Go and gambling tasks, negative urgency predicted differential activation in other cortical regions that are associated with self-regulation and decision making, including the dorsolateral and ventrolateral PFC, anterior insula, and cingulate [155, 158–161]. Greater insula activation predicted real-world substance use in subjects who were high in negative urgency [158]. Finally, negative urgency correlated directly with larger amygdala and thalamus volumes bilaterally in patients with AUD relative to healthy controls [134].

Neurochemically, negative urgency may reflect deficient 5-hydroxytryptamine (5-HT) and dopamine activity in the OFC and vmPFC [106, 162], leading to the disinhibition of basal ganglia- and extended amygdala-subserved impulses. Thus, a composite polygenic 5-HT risk score predicted alcohol use problems via greater negative urgency rather than other aspects of impulsivity [125, 163]. Variants of the *GABRA2* gene, which encodes the $GABA_{A\alpha 2}$ receptor subunit and influences dorsolateral PFC GABA levels, were associated with alcohol use problems via urgency [164] and alterations of insula activation responses [165]. Future work should study the role of glucocorticoid receptors, CRF, hypocretin, dynorphin, and other molecular systems that were reviewed in the stress surfeit model as underlying individual differences in, or chronic alcohol use-induced adaptations in, negative urgency circuitry.

Although traditionally viewed as a stable, trait-like construct that potentiates responses to stress and distress, negative urgency itself is subject to change. Situational factors can increase urgency, potentially by impairing inhibition from

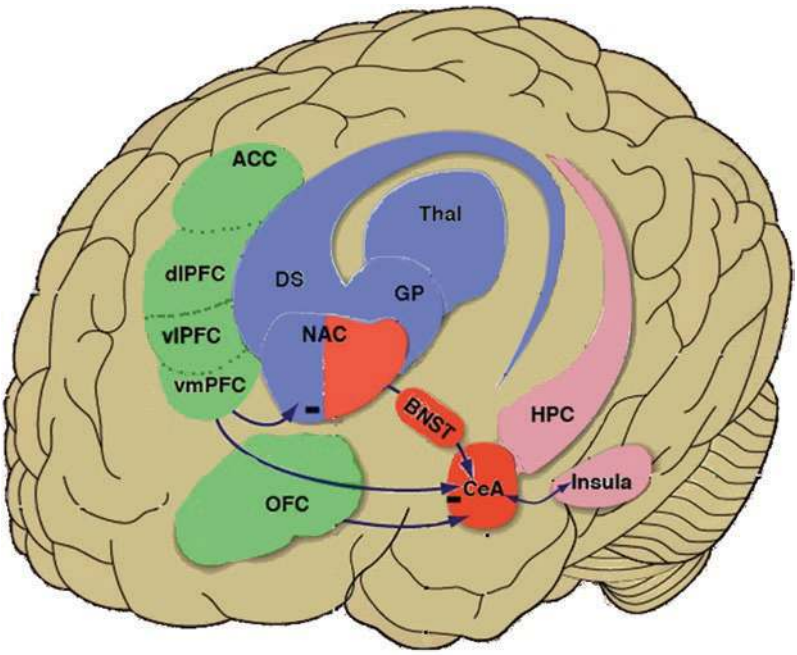

Fig. 36.7 Negative urgency circuitry in the neurobiology of alcohol use disorder. Simplified relationships are shown between higher-order cortical regions (green regions: orbitofrontal cortex and prefrontal cortex, including anterior cingulate cortex, dorsolateral prefrontal cortex, ventrolateral prefrontal cortex, and ventromedial prefrontal cortex) that normally exert top-down regulation over the extended amygdala. Red regions: central nucleus of the amygdala, bed nucleus of the stria terminalis, a portion of nucleus accumbens shell, and basal ganglia. Blue regions: nucleus accumbens core, dorsal striatum, and globus pallidus. Under conditions of stress and extreme negative affect, individuals who are high in negative urgency are hypothesized to exhibit impairments in the efficacy of higher-order inhibitory control from such regions as the orbitofrontal cortex and ventromedial prefrontal cortex over the basal ganglia and extended amygdala, the latter leading to an increase in alcohol use and seeking behaviors that are motivated by negative reinforcement. Negative urgency is also hypothesized to reflect alterations of cortico-amygdalar and cortico-striatal modulation by the insular cortex (representing interoceptive state and context) and other prefrontal cortical regions, including the prelimbic and anterior cingulate cortices. Chronic alcohol use is hypothesized to increase negative urgency progressively by further disrupting top-down control of the OFC and vmPFC over the extended amygdala, thereby increasing the vulnerability to engage in negative reinforcement drinking under conditions of stress or hyperkateifia. Note that regions boundaries are heuristic and not anatomically precise. ACC, anterior cingulate cortex; dlPFC, dorsolateral prefrontal cortex; vlPFC, ventrolateral prefrontal cortex; vmPFC, ventromedial prefrontal cortex; OFC, orbitofrontal cortex; CeA, central nucleus of the amygdala; BNST, bed nucleus of the stria terminalis; HPC, hippocampus; NAC, nucleus accumbens; GP, globus pallidus; Thal, thalamus; DS, dorsal striatum. (Modified with permission from [104])

the OFC/vmPFC to the amygdala [166]. More enduringly, childhood abuse persistently increased amygdala activation and reduced prefrontal cortical control over amygdala responses [167]. Conversely, effective psychological interventions can reduce negative urgency [168, 169].

Relevant to alcohol use, greater activation in response to alcohol and drug cues occurs within the hypothesized negative urgency network across the course of the addiction process (i.e., basal ganglia, amygdala, OFC, cingulate cortex, vmPFC, dorsolateral PFC, and anterior insula) and may reflect use-associated plasticity [158, 170–174]. In contrast, in nondependent subjects, neither alcohol images nor negative urgency was associated with activity of the lateral PFC [158]. Relevant to the stress surfeit model, alcohol cue-induced activation in negative urgency circuitry is hypothesized to involve not only reward processing, as is often interpreted (e.g., [175–177]), but also an increase in aversive stress processing [103].

As further possible evidence of alcohol use-related changes in negative urgency circuits, opponent-process decreases in striatal dopamine D_2 receptor availability in individuals with AUD correlated with lower glucose metabolism in frontal cortical regions that subserved inhibitory control, such as the dorsolateral and anterior cingulate cortices [178]. These relationships were not seen in non-AUD controls. Similarly, negative urgency correlated directly with larger amygdala and thalamus volume in patients with AUD but not in healthy controls [134].

Animal Model of Negative Urgency?

Some attempts have been made to back-translate the negative urgency concept to animal models. Many of these have utilized unexpected reward omission as a probe, based on findings that human subjects who were high in negative urgency exhibited greater behavioral responding and self-reported frustration following reward omission in a monetary-based task compared with subjects who were lower in negative urgency [179]. Accordingly, unexpected reward omission increased subsequent operant responding for intravenous amphetamine and sucrose pellets in rats [179] at levels that were greater than after the contingent delivery of an expected reward [180]. In this animal model, higher V_{max} uptake values for the dopamine transporter in the nucleus accumbens and serotonin transporter in the OFC correlated positively with responding following omission. The results suggest that rats that exhibited higher responding after reward omission (i.e., a putative index of negative urgency) had greater dopamine transporter function in the nucleus accumbens and serotonin transporter function in the OFC [180].

Similarly, Cifani and colleagues showed that the unexpected nonreward of being placed in a context where a previously available, preferred food could be seen and smelled but no longer eaten elicited behavioral and neuroendocrine signs of stress and subsequently greater binge eating of palatable food [181, 182]. The increase in responding was accompanied by CRF activation in the extended amygdala and reduced by local CRF receptor antagonist pretreatment [183, 184]. The results highlight the animal modeling potential of reward omission and frustrative nonreward, which resemble translationally relevant “frustrative” alcohol and drug cues [185]. Remaining to be shown is whether unexpected alcohol reward omission can “drive forward” alcohol use impulsively, meaning (*i*) rapidly, (*ii*) prioritizing immediate

vs. later outcomes (e.g., in a delayed-discounting task framework) [186], and (*iii*) in a risky fashion without behavioral consideration to negative outcomes [187, 188].

From a "negative emotional side" perspective, changes in negative urgency circuits may represent a stress-related mechanism through which impulsivity and deficits in inhibitory control gain prominence in the transition to negative reinforcement-based drinking, away from positive reinforcement and reward motive use. Analogously, Belin and colleagues showed that high impulsivity in the 5-choice serial reaction time task predicted the development of compulsive-like cocaine self-administration and compulsive-like adjunctive behavior in a manner that was mitigated by the norepinephrine transporter inhibitor atomoxetine [149, 189, 190]. Negative urgency impulsivity may similarly ultimately potentiate the development of compulsive alcohol use and relapse in the stress surfeit model of AUD.

The collective results suggest how negative urgency contributes to alcohol use-related behavior in the opponent-process, stress surfeit disorder framework. From a bottom-up perspective, negative urgency may potentiate the experience of self-medicating and urge to self-medicate negative emotions that result during the withdrawal/negative affect stage, thereby increasing negative reinforcement. From a top-down perspective, impairments in executive control and outcome feedback that are associated with negative urgency may decrease the ability to resist urges to pursue alcohol use in the preoccupation/anticipation stage.

Summary

The complex nature of AUD involves multiple neurotransmitter systems that mediate stress sensitization, dysphoria, and hypohedonia (hyperkatifeia) and mediate executive dysfunction (reward, pro-stress and anti-stress neurotransmitter systems). Here, we focused on the role of the HPA axis and extrahypothalamic stress systems in AUD, largely via results from animal models of AUD. Repeated episodes of alcohol intoxication promote neuroadaptations that underlie incentive salience, reward hypofunction, stress sensitization, and impairments in executive function. These neuroadaptations contribute to the development of negative emotional states (i.e., hyperkatifeia: anxiety, dysphoria, pain, irritability) and negative urgency that are hypothesized to drive alcohol drinking and seeking via negative reinforcement in moderate to severe AUD. The HPA axis is necessary for alcohol reinforcement during the initial phase of alcohol use in the binge/intoxication stage of addiction that involves the basal ganglia. In the transition to alcohol addiction, the HPA axis becomes blunted (neuroendocrine tolerance), and extrahypothalamic stress systems (e.g., extended amygdala) become concomitantly sensitized. These changes are accompanied by the disruption of PFC function, which compromises executive function (i.e., inhibitory deficits and poor decision making) that may contribute to craving and relapse in the preoccupation/anticipation stage.

Part VII
Alcohol-Related Liver Disease: Diagnosis

Chapter 37
Laboratory Parameters in Heavy Drinkers

Sebastian Mueller

Abstract Alcohol-related liver disease (ALD) is the most common liver disease in the Western world and for many reasons underestimated and underdiagnosed. Its early diagnosis is essential since it helps to identify patients at an increased genetic risk for disease progression and to initiate screening programs to prevent life-threatening complications such as bleeding from varices, spontaneous bacterial peritonitis, or hepatocellular cancer (HCC). The prediction and early diagnosis of ALD is still insufficiently solved although routine laboratory parameters in combination with abdominal ultrasound, liver elastography and clinical observation can establish the diagnosis and disease stage with high accuracy. This chapter focuses on the typical laboratory findings in chronic alcohol consumers and presents novel data from a large cohort of more than 1000 heavy drinkers. Moreover, the dependence of laboratory data on fibrosis stage are demonstrated and discussed in detail. Typical laboratory profile of ALD patients encompasses elevated levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST), GGT, ferritin and mean corpuscular volume (MCV) of red blood cells (RBC). Already in medium fibrosis stages, levels of transferrin, albumin and RBC count can be decreased. While transaminases and ferritin typically resolve rapidly within 1 week or at least after 4 weeks of abstaining from alcohol, normalization of RBC and MCV can take many months.

Introduction

Alcohol-related liver disease (ALD) is the most common liver disease in the Western world and for many reasons underestimated and underdiagnosed. Its early diagnosis is essential since it helps to identify patients at an increased genetic risk for disease progression and to initiate screening programs to prevent life-threatening complications such as bleeding from varices, spontaneous bacterial peritonitis or hepatocellular cancer (HCC). The prediction and early diagnosis of ALD is still insufficiently solved although routine laboratory parameters in combination with abdominal ultrasound, liver elastography and clinical observation can establish the diagnosis and disease stage with high accuracy. This chapter focuses on the typical laboratory findings in chronic alcohol consumers and presents novel data from a large cohort of >1000 heavy drinkers. Moreover, the dependence of laboratory data on fibrosis are demonstrated and discussed in detail. Typical laboratory profile of ALD patients encompasses elevated levels of AST, ALT, GGT, ferritin and mean corpuscular volume (MCV) of red blood cells (RBC). Already in medium fibrosis stages, levels of transferrin, albumin and RBC count can be decreased. While transaminases and ferritin typically resolve rapidly within 1 week or at least after 4 weeks of abstaining from alcohol, normalization of RBC requires longer and normalization of MCV can take many months.

General Diagnostic Aspects of ALD

The diagnosis of ALD is further complicated by three major challenges: (1) underreporting by patients (2) lack of good biomarkers for alcohol consumption and (3) a rather diverse clinical presentation. These are the reasons why ALD is routinely underestimated both by physicians and health statistics [1, 2]. The diagnosis of ALD relies on a combination of clinical, laboratory, elastographic and imaging findings. For several reasons, despite their high frequency, ALD is often overlooked in daily clinical practice. Although diagnosis requires some experience, the combination of laboratory parameters and experienced clinical observation normally allows an almost certain diagnosis. This chapter will rather focus on the typical laboratory parameters. What complicates the interpretation of laboratory parameters in ALD and contributes to the confusion is the fact that almost all **laboratory markers depend on fibrosis stage**. Since elastography is increasingly available and should actually be available in the near future even in peripheric medical centers and for general practitioners, the changes of laboratory with increasing fibrosis stages are discussed in more detail. To better illustrate the diagnostic findings, data from the Heidelberg cohort of heavy drinkers will be shown in some tables. Table 37.1 shows patient characteristics of important laboratory parameters of this cohort. More details are shown in Tables B.1 and B.4. More details about fibrosis screening are separately discussed in Chaps. 40 and 42 in this book part.

The early and exact diagnosis of ALD and namely the manifestation of fibrosis/cirrhosis are important since:

1. patients receive an explanation for their symptoms and complaints.
2. prognostic information can be obtained.
3. the diagnosis ALD can be separated from other comorbidities (e.g., viral hepatitis) or disease modifying factors (e.g., obesity, drugs).
4. a targeted search for potential complications such as varices or HCC can be started and surveillance intervals, e.g., for HCC can be defined.
5. by understanding of disease mechanisms, the patient gets the opportunity to control disease progression through change of life style, avoidance of alcohol and reducing other potentially harmful factors such as obesity.

Liver diseases are in general hardly to detect and commonly show no or unspecific symptoms. Even end-stage liver cirrhosis remains undetected in routine laboratory testing or ultrasound screening in ca. 40% (see Table 37.2) [3]. For instance, if one considers bilirubin, INR and signs of cirrhosis by abdominal ultrasound as easily accessible parameters that are widely available, Table 37.1 demonstrates that, despite advanced fibrosis, these parameters can be normal in 43% of a large cohort of heavy drinkers. Here, elastography really fills the gap. Although ALD follows the typical sequence of chronic liver diseases including alcoholic fatty liver, steatohepatitis, fibrosis and eventually cirrhosis, the early recognition of severe steatohepatitis and alcoholic cirrhosis is most important since it will save lifes, prevent complications and initiate follow up programs (Fig. 37.1). Most critical and life-threatening

Signs of liver cirrhosis	>0	1.6	59.1	0.02	0.41

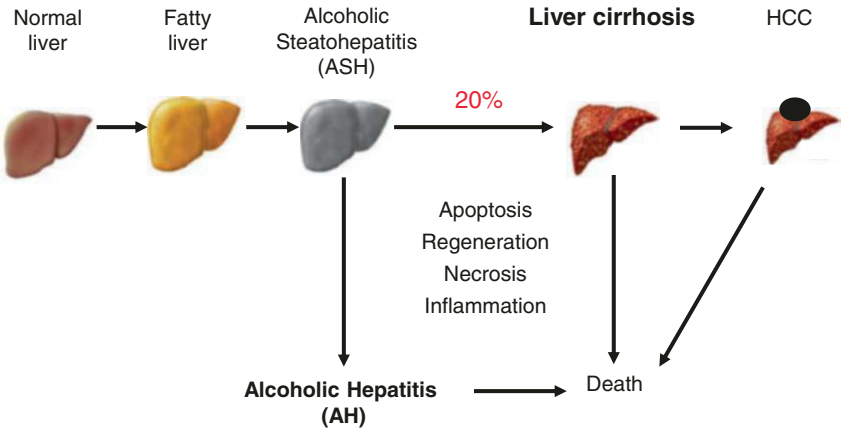

Fig. 37.1 Natural course of ALD and major end points

end points are **decompensated alcoholic liver cirrhosis** and the rare and clinically defined **alcoholic hepatitis (AH)**. Fibrosis screening and AH will be separately discussed in respective book chapters.

The slow progression of ALD towards liver cirrhosis can be undetectable and unnoticed for many years. For these reasons, patients who are sensitive to alcohol-mediated liver damage but diagnosed too late may have an unfavourable outcome. These patients are listed late for transplantation and are at high risk of dying from complications while waiting for a transplant. Of course, modern imaging techniques are absolutely essential for HCC screening and are continuously improved. Liver biopsy still remains an important option for some patients to confirm the relative contribution of alcoholic liver damage in relation to other potential causes. The reader is referred to the book chapters on liver histology (Chap. 38) and AH (Chaps. 64–68).

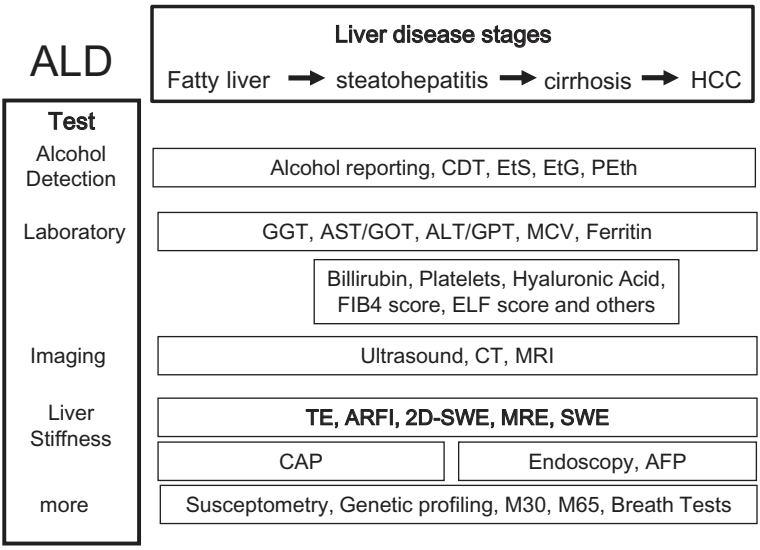

Fig. 37.2 General non-invasive approaches for patients with suspected ALD. The various tests will help to establish alcohol as cause and the progression stage of the disease

Clinical Approach to ALD

The diagnosis of ALD has first to establish the consumption of alcohol as cause of the liver disease. Then, the different clinical stages of ALD should be ascertained such as fatty liver, alcoholic steatohepatitis, fibrosis and eventually cirrhosis (Figs. 37.1 and 37.2) [1]. Reported alcohol consumption of more than 20–30 g alcohol per day for females/males is a prerequisite although genetic background or other comorbidities play also an important role. Except direct measurement of alcohol in serum as sign of acute alcohol intake within the last 20 h, no single laboratory marker definitively monitors chronic alcohol consumption. Alcohol biomarkers such as ethylglucuronide (EtG), ethylsulfate (EtS) and phosphatidylethanol (PEth) are highly specific. EtG levels in the urine (up to 3 days) and, more widely, carbohydrate deficient transferrin (CDT) are used frequently to detect previous alcohol consumption (4–21 days). However, CDT has only a moderate sensitivity of 60% at a daily alcohol consumption of more than 50 g. A rather new and longer tracking of alcohol consumption is provided by determination of EtG in the hair. Especially PEth, although covering a rather long period of alcohol consumption of the last 3 weeks, has distinct degradation kinetics that varies strongly inter-individually. For instance, novel data show that PEth levels, typically produced within the red blood cell, are strongly affected by red blood cell degradation [4]. Moreover, patients with cirrhosis have delayed elimination kinetics of alcohol and, hence, blood alcohol concentration and levels of alcohol biomarkers can be elevated (see Table 37.1) [4]. More information of biomarkers is also provided in the Chap. 40. The diagnosis of ALD sometimes requires a more extended clinical experienced view on the patient

symptoms. Thus, alcohol consequences may manifest first in the brain (see Chap. 72), in the peripheral nerves (polyneuropathy) or as alcoholic cardiomyopathy (Chaps. 70–71) to name only a few. Likewise, rib fractures are common on X ray images and may be even more diagnostic for ALD than an elevated GGT. Some other clinical symptoms more specific for ALD include parotid enlargement, Dupuytren's contracture, and especially signs associated with feminization.

Histology and ALD

Detailed features of liver histology in ALD are described in Chap. 38. Histological characteristics of heavy drinkers are shown in Appendix Table B.9. It should be pointed out, however, that a single histological slide does not allow the diagnosis of ALD, alcoholic hepatitis nor non-alcoholic fatty liver disease (NAFLD) nor does it allow to discriminate between them. Moreover, it is long known that typical hallmarks of ALD such as Mallory bodies (now MDBs) do also occur in other liver diseases (Wilson's disease, NAFLD). Especially in the light of liver elastography, biopsies should not any longer be performed to screen for liver fibrosis stage as it has a quite high sampling error of up to 30% [5–9]. Further, it is invasive with mild (pain and small bleedings in 6%) or severe (0.1%) complications and rarely fatal perforations and bleedings. The most important role of biopsy remains to dissect and identify comorbidities in addition to ALD.

Alcohol-Related Hepatic Steatosis

As shown in Fig. 37.1, the majority (>90%) of moderate and heavy drinkers have hepatic steatosis, but only 15% progress to fibrosis. Therefore, it remains actually an open question to what extent steatosis is indeed a necessary prerequisite for liver fibrosis or even hepatitis (see also Chap. 49). Already in the mid nineteenth century, Theodor Ferichs showed (before actually being able to obtain photographs of microscopic images) that feeding dogs transiently a high fat diet induces a reversible fatty liver [10]. However, as steatosis may be one of the early signs of ALD and may be present in the absence of inflammation or fibrosis, it may be the only sign to show that "at least the liver responds to alcohol intake". Therefore, screening for steatosis may add to the diagnosis and may be the only parameter that can be followed up if other parameters are normal. Table 37.3 shows actual correlation between histology, MRI, controlled attenuation parameters (CAP) and ultrasound. Figure 37.3 shows comparison for all non-invasive techniques with histology. Abdominal ultrasound is quite robust in identifying steatosis [11]. But as seen in Fig. 37.3, it is not linear, especially at higher degrees of steatosis. Recent ultrasound-based techniques such as CAP are promising. They are reproducible and quantitative with an AUROC up to 90% for fatty liver [12]. In clinical

Table 37.3 Spearman correlation between different methods to assess hepatic steatosis from the Heidelberg cohort (n = 41)

	Histological degree of steatosis	Hepatic fat fraction (MRI)	CAP	Steatosis (US)
Histological degree of steatosis	–	0.836***	0.604***	0.358*
Hepatic fat fraction (MRI)	0.836***	–	0.577***	0.304**
CAP	0.604***	0.577***	–	0.408**
Steatosis (US)	0.358*	0.403**	0.408**	–

*$p < 0.05$, **$p < 0.01$, ***$p < 0.001$

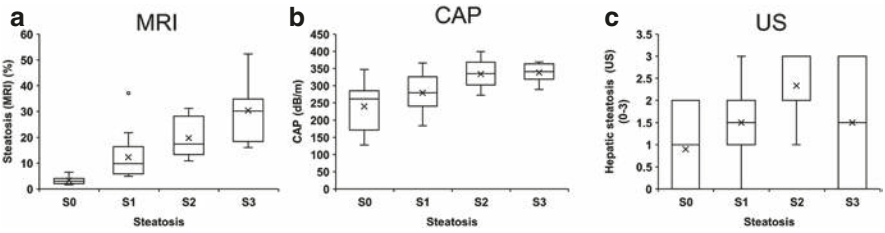

Fig. 37.3 Boxplots with medians to assessing histological steatosis with MRI, CAP and ultrasound. Data are based from an ongoing study in Heidelberg (n = 42). MRI is highly linear, while both ultrasound-based techniques show a saturation and higher steatosis degrees

practice, ultrasonography may be proposed in heavy drinkers as a screening procedure for steatosis [13]. US has the advantage of being already available everywhere. CAP is excellent in ruling in any steatosis and as a quantitative parameter it allows real follow-up studies. Even 1 week of alcohol detoxification, for instance, decreased reliably hepatic steatosis by 30 dB/m [14]. The limitation is that cut-offs between S1–3 are quite narrow and in the light of the importance of steatosis mentioned above, US remains useful for daily practice. In addition, as shown in Fig. 37.3, it becomes "saturated" at higher steatosis degrees. MRI, as also shown in Table 37.3, is the most accurate and correlates best with histology. It is highly quantitative and its only limitations are costs and availability. However, in the future, it may be used more frequently [15, 16]. Table 37.4 shows typical US parameters in patients with ALD and different fibrosis stages.

Introduction to Routine Laboratory Markers in Alcohol Consumers

Alcohol consumers show typical changes of routine laboratory markers. They are dependent on genetic background, disease and fibrosis stage and show a great variability. As already mentioned earlier, an ultrasound and additional liver

elastography are the best prior to laboratory evaluation. Major and typical changes affect the blood count (erythrocytes, MCV, platelets, leukocytes), liver parameters (AST, ALT, GGT, AP, bilirubin), iron-related parameters (Ferritin, Transferrin). Many other routine parameters (Uric acid, creatinine, LDH) or more specific markers (M30, M65) may also be useful to evaluate the disease stage. With some experience, ALD stage can be quite well diagnosed based on routine laboratory and ultrasound. The combination of these routine blood tests further increases the diagnostic accuracy for ALD with a sensitivity and specificity >90% for GGT, MCV, IgA, CDT, and AST/ALT ratio.

Blood Count

As shown in Table 37.1, RBC count decreases with fibrosis stage in ALD. Although full criteria of anemia are only reached in ca. 12% of cirrhotics, a significant decrease of the RBC mass of ca. 20% can be observed quite frequently and the hemoglobin is about 1–2 g/L lower as compared to the mean of a normal population. The underlying mechanisms are discussed in more details in Chaps. 57 and 58. A typical feature of the blood count is an elevated MCV. In the large Heidelberg cohort (see Table 37.1), almost 25% of non-cirrhotic drinkers have an elevated MCV, in cirrhotics more than 50%. Platelet count is also affected by alcohol-related bone marrow toxicity and, at later stages, by portal hypertension and splenomegaly. After alcohol detoxification, RBC count, hemoglobin and MCV even worsen in the first week due to aggravated ineffective erythropoiesis for not yet clear reasons (see Chap. 57 on ALD and iron). While RBCs normalize typically after 4 weeks of abstinence, MCV may take much longer, even many months or even years. However, in a series of 15 patients from Heidelberg, blood count completely normalized even in patients with manifest cirrhosis after an abstinence of 5 years. As can be seen in Table B.29, B12 levels are typically increased in ALD patients with macrocytosis

while folic acid levels are still in the normal range. There are first indications that these patients may still have a relative deficit of folic acid and the elevated B12 levels seems to be due to compensatory adaptations. The exact mechanisms have not been clarified yet.

Gamma Glutamyl Transferase (GGT)

GGT has an important function for replenishing the glutathione pool in cholangiocytes (see also Figs. A.49 and A.50). GGT is one of the best markers of ALD with a combined sensitivity and specificity of >70%. Elevation of GGT is not due to liver damage but induction of enzymatic activity. GGT loses its alcohol specificity in more advanced stages. GGT activity can be also caused by other conditions namely cholestatic liver disease, cardiac insufficiency, drugs and many more. Figure 37.4a shows mean GGT levels dependent on fibrosis stage in comparison to a large population with portal liver disease (hepatitis C infection). Data are taken from a large multicenter cohort with biopsy proven fibrosis stages [17]. It is clearly visible that

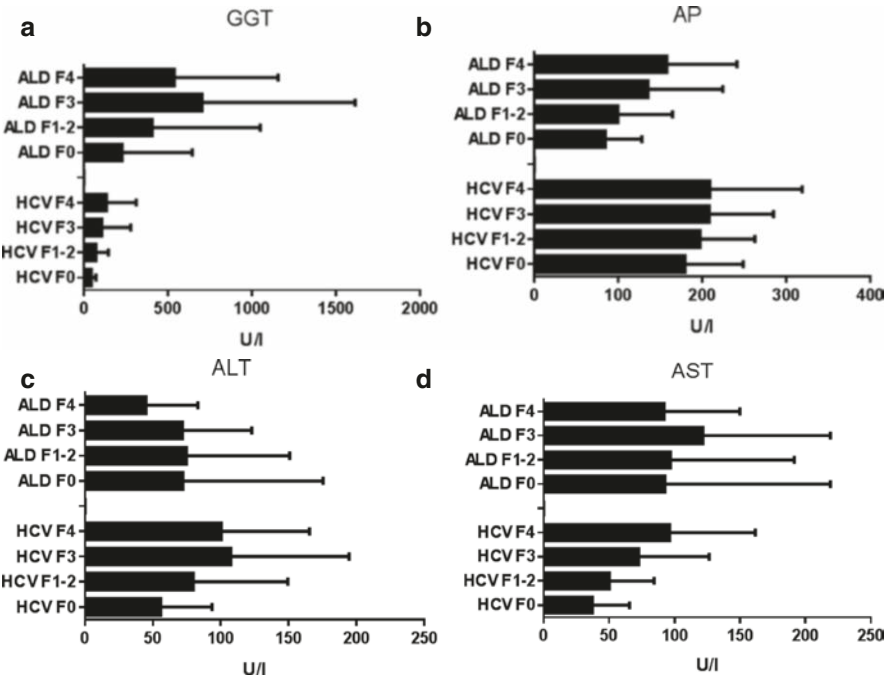

Fig. 37.4 Mean laboratory values for ALD and HCV for respective fibrosis stages (biopsy proven). For (**a**) GGT, (**b**) AP, (**c**) AST (**d**) ALT. Data are from a multicenter study based on 1391 biopsy-proven HCV and 677 ALD samples [17]

GGT levels are higher in ALD patients for all fibrosis stages as compared to HCV. According to Table 37.1, however, about 30% of heavy drinkers without advanced liver disease have no elevated GGT. In contrast, in advanced stages, only ca. 10% have a normal GGT.

Alkaline Phosphatase (AP)

AP's biochemical reaction is shown in Fig. A.49. Its exact role in ALD is not completely clear. As shown in Fig. 37.4b, as compared to GGT, it gradually increases in ALD with fibrosis stage. This may be also the reason why AP has a highly prognostic values with regard to long-term mortality (see Chap. 7). However, levels are still lower as compared to portal HCV and this may one reason why, in daily practice, with limited information, AP has not gained too much attention. It should be noted, however, that a continued increase of AP, even in patients with complete abstinence, is a prognostically unfavorable development.

Liver Transaminases (AST/GOT and ALT/GPT)

AST is typically elevated to a level of two to six times the upper limits of patients with ALD or patients with alcoholic hepatitis (AH) while AST levels of more than 300 IU/L are rarely seen. In about 70% of patients, the AST/ALT ratio is higher than two. This development is especially seen in cirrhotics. As is discussed in more detail in Chap. 41, however, AST level remain elevated throughout all fibrosis stages, in contrast to ALT. Figure 37.4c, d shows AST and ALT for each fibrosis stage both for ALD and HCV [17]. In contrast, in patients with viral hepatitis, AST continuously increase with fibrosis stage. As is discussed in detail in Chap. 41, AST in alcohol consumers is most likely not derived from the liver but rather from red blood cells. The existence of AST in RBCs has already been described early on and seems to have been neglected over the years [18].

Bilirubin

Bilirubin elevation in drinkers is typically an indication of cirrhosis, alcoholic hepatitis or ACLF. The difficulties to discriminate clearly between these entities is discussed in the respective book chapters and still difficult to comprehend. Typically, more than 90% of the total bilirubin in ALD is conjugated bilirubin. It is often ignored that indirect bilirubin is also elevated and an expression of the hemolytic anemia as discussed in Chaps. 57 and 58. Bilirubin has an important prognostic value and is part of many prognostic scores whether for cirrhosis or AH (see Appendix Tables A.9 and A.11).

Iron Related Parameters

Alcohol also causes typical iron changes that are still not very much appreciated and that depend on fibrosis stage. As is discussed in more detail in Chap. 57 on ALD and iron, serum ferritin is typically elevated in drinkers. It is higher than 400 ng/mL in non-cirrhotics in ca. 40% and in cirrhotics in more than 50%. Levels higher than 1000 ng/mL, a typically screening cut-off value for hereditary iron overload disease, is also frequently seen in drinkers, in cirrhotics in up to 25% (see Table 37.1). In contrast to hereditary iron overload diseases, however, ferritin rapidly decreases with a half time of 2 days. Significant decreases can already be seen after 1 week of abstaining from alcohol and ferritin usually completely normalizes after 4 weeks. Ferritin seems to be elevated due to masked hemolytic anemia and ineffective erythropoiesis. As mentioned above, B12 levels can be even elevated, and folic acid levels are normal in most patients. Another typical configuration about iron in ALD patients are significantly decreased transferrin levels and elevated transferrin saturation. This makes it rather difficult per se to differentiate between hereditary iron overload and ALD. Haptoglobin levels are also typically difficult to interpret since they may be elevated in inflammation, reduced in fibrosis and levels also depend on the degree of hemolysis.

Markers of Inflammation

As can be seen in Table 37.1, in this large population of heavy drinkers, levels of inflammation markers are rather moderate. For instance, mean CRP levels are in the normal range with 4.2 mg/L (normal <5 mg/L) for patients without advanced liver fibrosis (<F3). Only ca. 15% have pathologically elevated CRP. In patients with F3–4 fibrosis stage, mean CRP levels are higher with 12.9 mg/dL, but these levels are still moderate and cannot be compared to levels of patients with viral or bacterial infections that can easily reach levels of 50 or higher than 100 mg/dL. Independent of fibrosis stage, mean leukocyte count was always within the normal range and only elevated in ca. 15% (see Tables B.1 and B.4). Of note, levels of important cytokines such as TNFalpha, IL6 or TGFbeta are typically in the upper normal range or just slightly elevated [19]. Only IL8 levels were significantly increased with ca. 120 pg/mL as compared to median levels of healthy donors (below 20 pg/mL). Cytokines were only slightly higher in cirrhotics [19] and decreased after alcohol detoxification. Taken together, markers of inflammation are typically only slightly elevated in large cohorts of heavy drinkers.

Prognosis and New Biomarkers in ALD

Among the many potentially useful markers to be used in ALD in the future, cytokeratins have emerged as markers of hepatocyte damage. Mallory bodies, the hallmark of alcoholic hepatitis, contain cytokeratin-18 and cytokeratin-19 [20]. Serum

levels of CK-18 and CK-19 are increased in patients with AH compared to fatty liver or controls [20]. In a recent study, Bissionette and colleagues reported higher levels of total and microvesicle-bound M65 and M30, circulating fragments of cytokeratin-18 in the circulation in biopsy-proven AH [21]. A cutoff of 2000 U/L for M65 has a positive predictive value of 91% and a cutoff of 642 U/L had a negative predictive value of 88% [21]. It should be noted that CK-18 fragments are markers of hepatocyte apoptosis, thus, are not specific for AH [22]. Furthermore, high levels of CK-18 were reported in non-alcoholic hepatitis and toxin-related steatohepatitis [23, 24]. Of note, M30 levels (caspase3-cleaved Cytokeratin-18) is induced in response to alcohol detoxification [25]. These data suggest that alcohol suppresses apoptosis which is unchained after alcohol withdrawal.

Chapter 38
Histology of Alcohol-Related Liver Disease

Stephan Sygulla and Carolin Lackner

Abstract This chapter describes the typical histologic features of compensated and decompensated alcohol-related liver disease (ALD). Connotations are provided to put pathogenesis and morphologic alterations into context. In addition, an ALD-specific and prognostically relevant semiquantitative scoring system for grading and staging is presented that has been recently developed by the SALVE Histopathology Group.

Keywords Alcohol-related liver disease (ALD) · Steatohepatitis due to ALD · Histology · Fibrosis due to ALD · Pathogenesis · Semiquantitative grading and staging · Ballooning

Histological Types and Natural History of Alcohol-Related Liver Disease

Alcohol-related liver disease (ALD) [1] covers a spectrum of liver diseases ranging from alcohol-related steatosis to steatohepatitis (ASH) and fibrosis/cirrhosis due to alcohol consumption. These types of ALD are defined by histology. The natural course of the disease has not been described in detail. However, a summary of data from the literature indicates that approximately 90–100% of people who consume more than 40 g of alcohol per day over a longer time (many months to years) will develop fatty change of hepatocytes (steatosis due to alcohol). A minority of these individuals, between 10–35% progress to ASH which is an inflammatory condition associated with liver injury and fibrogenesis. Of the individuals with ASH 8–20% develop cirrhosis which provides the basis for progression to hepatocellular carcinoma in another 2% of patients [2].

Histology of ALD: General Remarks

The histologic key features of ALD comprise four types of lesions which in pre-cirrhotic stages of the disease are typically present in centrilobular regions of the hepatic lobules and which either occur as single features or in any combination in individual patients. These features include steatosis of macrovesicular and eventually microvesicular type(s) (see below), lobular inflammation, a certain form of hepatocellular injury termed hepatocellular ballooning (Fig. 38.1) which can be combined with necrosis, and fibrosis [3].

The centrilobular distribution of liver lesions is promoted by the zonation of the hepatic lobules. Pericentral hepatocytes exhibit increased expression of lipogenesis- and reduced expression of fatty acid ß-oxidation genes as compared to periportal hepatocytes thus contributing to the fatty change (i.e., macrovesicular steatosis) in centrilobular hepatocytes. In addition, cytochrome P450 genes such as Cyp2 E1, one of the major ethanol-metabolizing enzymes is increased in centrilobular hepatocytes as compared to the periportal ones. The alcohol-mediated oxidative stress in centrilobular hepatocytes presumably plays an important role promoting hepatocellular injury leading to the disintegration of the intermediate filament cytoskeleton and impaired mechanical stability of hepatocytes eventually resulting in the ballooning change, hepatocellular necrosis, and inflammation [2].

Other characteristic findings include visible bile pigment in hepatocytes (hepatocellular cholestasis), canalicules (canalicular cholestasis) and ductules (ductular cholestasis) as well as perivenular fibrosis, sclerosing hyaline necrosis and fibro-obliteration of hepatic veins [4].

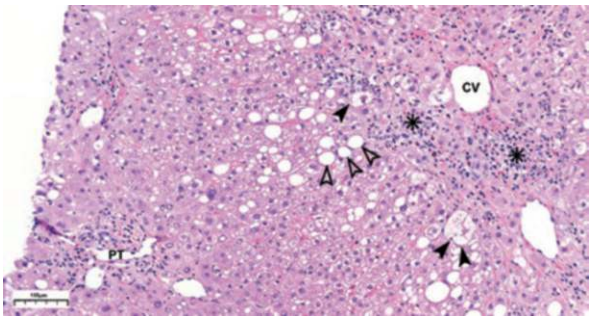

Fig. 38.1 The key features of ASH are accentuated in central and intermediate portions of hepatic lobules. Hepatocytes with macrovesicular fat and ballooned hepatocytes are marked with open and black arrow heads, respectively. The inflammatory infiltrates are indicated by asterisks (H&E; PT, portal tract; CV, central vein)

Alcohol-Related Steatosis

Macrovesicular Steatosis

Macrovesicular steatosis is the most frequent type of fatty change in ALD. Alcohol-associated enhanced lipolysis and uptake of free fatty acids into the liver, increased hepatocellular lipogenesis and reduced lipolysis as well as decreased secretion of lipids via very low density lipoproteins are among the main mechanisms leading to the accumulation of lipid, mainly triglycerides, phospholipids and cholesterol ester deposited in membrane-coated vesicles in the cytoplasm of hepatocytes. Lipid vesicles are dynamic structures involved in the distribution and metabolism of lipids [5–7]. After periods of abstinence, alcohol-related steatosis is fully reversible [8]. Macrovascular steatosis is considered a benign condition with low potential for disease progression. However, in 10% of people alcohol-related steatosis may progress to cirrhosis also in the absence of ASH [9].

In the early stages, small lipid vesicles are typically located around the nucleus of centrilobular hepatocytes. Macrovesicular forms of steatosis are thought to result from confluence of smaller lipid vesicles and comprise most of the hepatocellular cytoplasm. They lead to dislocation of the organelles and nucleus to the periphery of the cell [10, 11]. In settings of ongoing alcohol consumption also hepatocytes of the intermediate and eventually periportal portions of the hepatic lobules are affected by steatosis (Fig. 38.2). Isolated hepatocellular steatosis is a rare finding. Frequently, a mild inflammatory reaction is present. A local inflammatory response consisting of Kupffer cells and few mononuclear cells termed microgranulomas may result from the rupture of lipid-laden hepatocytes (Fig. 38.3). However, there may also be larger lesions termed lipogranulomas with extrahepatocellular lipid droplets surrounded by Kupffer cells, lymphocytes and few eosinophils or neutrophils.

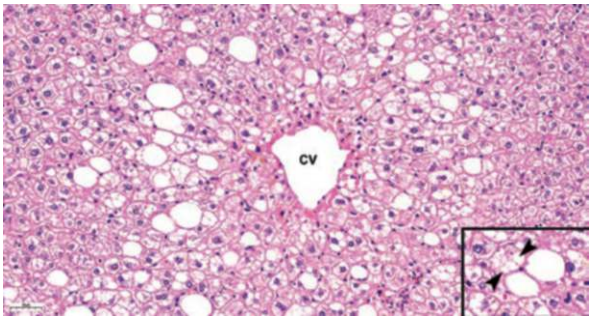

Fig. 38.2 Alcohol-related macrovesicular steatosis: Hepatocytes in intermediate and central portions of the hepatic lobules contain large lipid vesicles taking up most of the hepatocellular cytoplasm and dislocating the nucleus to the periphery of the cell (inset). The large macrovesicles may result from confluence of several smaller ones (marked by arrow head in inset) (H&E; CV, central vein)

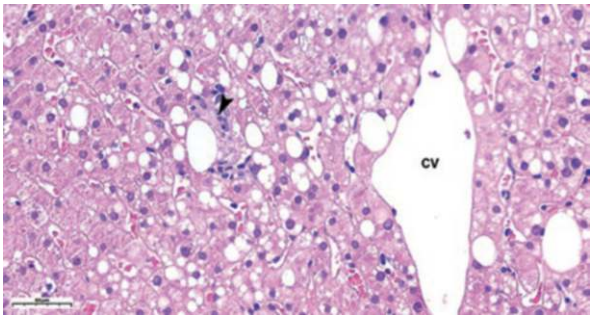

Fig. 38.3 Macrovesicular steatosis and lobular inflammation. Small microgranuloma consisting of Kupffer cells and few lymphocytes is present adjacent to a hepatocyte with large lipid vesicle (arrow head) (H&E; CV, central vein)

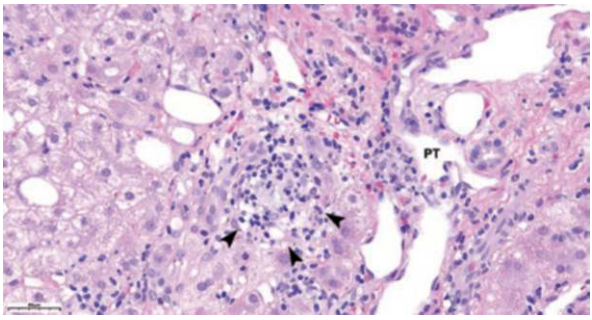

Fig. 38.4 Lipogranuloma adjacent to portal tract consisting of fat vacuoles surrounded by histiocytes and lymphocytes (arrow heads) (H&E; PT, portal tract)

Lipogranulomas can also occur in portal tracts and may be surrounded by collagen fibers (Fig. 38.4) [11, 12].

Sudden death of unknown cause affecting mostly middle-aged females has been described as a rare complication of heavy drinking associated with massive hepatomegaly, macrovesicular steatosis and bilirubinostasis (visible bile pigment) [13].

Microvesicular Steatosis

Microvesicular steatosis is defined as minute lipid droplets only visible at high magnification on H&E histology filling and extending the cytoplasm of hepatocytes. The nucleus is often pycnotic and located in central position within the hepatocytes (Fig. 38.5). It is an infrequent type of steatosis as compared to macrovesicular steatosis which is present in most cases of ALD. Macrovesicular and microvesicular steatosis can also coexist as so-called mixed type steatosis which seems to be associated with higher risk of disease progression [9]. An extensive form of microvesicular steatosis affecting large portions of the parenchyma is termed alcoholic foamy degeneration (AFD) [14] and is believed to represent a type of acute alcohol-related toxicity in chronic drinkers [15]. On histology, AFD is typically not associated with lobular inflammation or fibrosis. Megamitochondria (Fig. 38.6) are

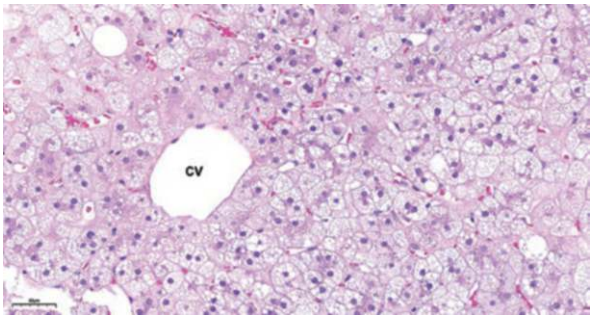

Fig. 38.5 Microvesicular steatosis. Hepatocytes adjacent to central vein are filled and expanded by minute lipid droplets. The pycnotic appearing nucleus is situated in central position in the cytoplasm. Few hepatocytes with macrovesicular fat are present. Lobular inflammation is absent (H&E; CV, central vein)

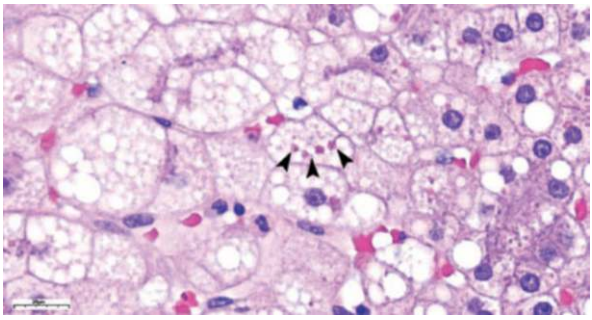

Fig. 38.6 Megamitochondria are seen as globular-shaped eosinophilic cytoplasmic inclusions (arrow heads) in a case of alcoholic foamy degeneration (H&E)

frequently, and bile pigment is occasionally found in the cytoplasm of affected hepatocytes.

In a recent study, Spahr and colleagues investigated patients with AFD in comparison to patients with ASH [16]. In patients with AFD, a pronounced downregulation of genes associated with inflammation, fibrogenesis and detoxification was found and may contribute to mechanisms underlying the non-inflammatory and fibrogenic nature of this condition as suggested by the histological pattern. In addition, upregulation of genes associated with lipid metabolism and mitochondrial function including among others mitochondrial glycerol-3-phosphate acyltransferase (GPAM) was found. GPAM catalyzes the first committed step in triglyceride and phospholipid biosynthesis. Increased expression of GPAM in the mouse model leads to massive accumulation of triglycerides in hepatocytes and to impaired ß-oxidation of fatty acids [16]. Non-esterified fatty acids such as amphiphilic compounds may be involved in the formation of an emulsifying rim around a core of triglycerides thus linking the overexpression of GPAM to the morphological feature of microvesicular steatosis seen on histology [17, 18].

The clinical course differs among individuals. A spectrum of conditions ranging from an asymptomatic condition to a clinical syndrome resembling alcoholic hepatitis [16]. Rare cases of microvesicular steatosis and liver failure have been described and AFD seems to be reversible after alcohol withdrawal [14, 15].

Steatohepatitis Due to ALD (ASH)

The correlation between the clinical syndrome of alcoholic hepatitis (AH) based on anamnestic and biochemical parameters only and ASH defined by histology is not optimal. It has been estimated that approximately 25% of patients with AH do not have ASH on histology [19]. The exact incidence of ASH in people with ALD is uncertain [20–23]. Most clinical studies to date are based on clinical diagnosis of ALD and/or AH without histological analysis. In a large cohort of patients with alcohol abuse, 44% of patients with cirrhosis and 12% of those without cirrhosis had ASH on histology [24].

Most cases of ASH are defined by three key features including macrovesicular steatosis, hepatocellular ballooning, and lobular inflammation [4, 25, 26]. After periods of abstinence or in severe ASH or cirrhosis, macrovesicular steatosis can be very limited. Therefore, the minimum requirement for the histological diagnosis of ASH is based on the presence of hepatocellular ballooning and lobular infiltration by neutrophils [27].

Hepatocellular ballooning is an ill-defined morphological term. It designates a presumably degenerative hepatocellular change characterized by a significantly enlarged pale staining (also referred to as cytoplasmic clarification) and rounded cytoplasm on H&E histology (usually >2× normal sized hepatocytes). Ballooned hepatocytes may contain garland shaped hyaline eosinophilic cytoplasmic inclusions termed Mallory Denk bodies (MDB) (Fig. 38.7) [28]. Compared to normal sized hepatocytes ballooning is also associated with loss of cytoplasmic staining with antibodies against the intermediate filament (IF) components Keratin (K) 8 and 18 and marking with antibodies against sonic hedgehog (see below) [29]. Ballooning can be very severe in ALD. Typically, the ballooned hepatocytes harbour very large MDB (Fig. 38.8).

The mechanisms underlying the ballooning change are not known in detail. Based on the results from in vitro experiments and mouse models it can be concluded that alcohol-related oxidative stress is involved in the upregulation of K8 and

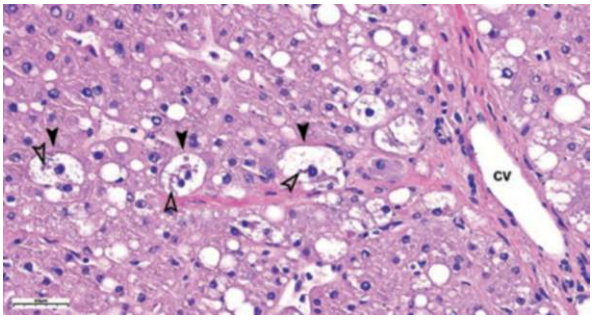

Fig. 38.7 Ballooned hepatocytes with cytoplasmic enlargement, rounding and clarification (examples are marked by black arrow heads) and Mallory Denk bodies present as eosinophilic garland shaped hyaline inclusions (open arrow heads) (H&E; CV, central vein)

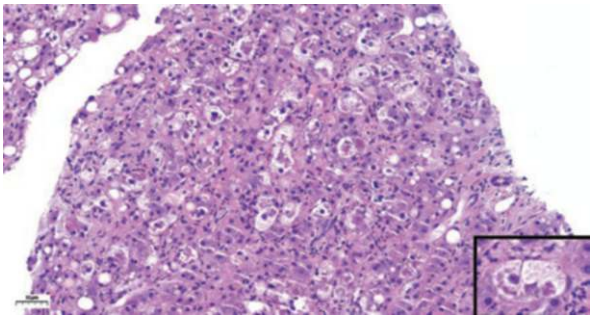

Fig. 38.8 Parenchymal area with massive ballooning. The ballooned hepatocytes contain large Mallory Denk bodies present as eosinophilic garland shaped hyaline inclusions (inset) and are surrounded by neutrophils (H&E)

to a lesser extent K18 as well as hyperphosphorylation, transamidation and crosslinking of these proteins. Furthermore, the keratins become partially degraded and ubiquitinated. These modifications promote disintegration of the IF detectable as loss of cytoplasmic K8/18 staining on immunohistochemistry (Fig. 38.9). The decreased mechanical stability of hepatocytes presumably contributes to the ballooned phenotype. In addition, p62, which is a stress- inducible ubiquitin binding protein is overexpressed. It binds the modified keratin species and targets them for degradation by the proteasome or autophagosome. However, oxidative stress also causes an accumulation of other misfolded proteins. Large amounts of modified proteins overwhelm proteasomal and autophagic capacities resulting in the aggregation of crosslinked and ubiquitinated K8 and 18, p62 and ubiquitin and the formation of MDBs [28, 30, 31]. The role of impaired proteasomal and autophagic degradation for the generation of MDBs was recently also confirmed in mouse models and humans [32, 33]. Hepatocellular ballooning is not specific for ASH. It can also be a feature of other chronic liver diseases associated with chronic oxidative stress like non-alcoholic steatohepatitis (NASH), conditions of chronic cholestasis, copper storage disorders, apha-1-antitrypsin deficiency, and ischemia-reperfusion injury [34]. Loss or regularly structured keratin in ballooned hepatocytes may render them prone to apoptosis [35].

Lobular inflammation by neutrophils is one of the key components of ASH. In some cases, neutrophils surrounding hepatocytes that contain MDBs can be found, a feature referred to as satellitosis (Fig. 38.10). In the early literature it was postulated that MDBs have leukotactic properties. Recently this hypothesis was supported by results from a study by Liu and colleagues using a MDB-inducing cell model. They showed that compounds which can induce MDB in vitro also produce IkappaB alpha loss. Furthermore, IkappaB alpha is sequestered into proteinaceous aggregates mostly consisting of p62, which is also a component of MDBs (see above). Because of the sequestration of IkappaB, NFkappaB signalling is activated, and inflammation is enhanced. The authors also identified another 10 IkappaB alpha- interacting and -aggregating proteins using four different proteomic approaches [36]. The presence of protein aggregates such as MDBs in ASH may therefore be regarded as indicators of oxidative stress-associated propensity of

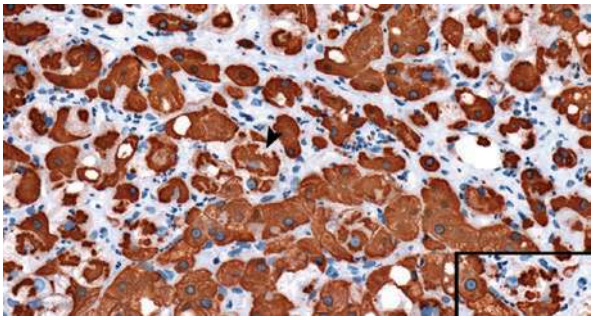

Fig. 38.9 Ballooned hepatocytes characterized by a loss of cytoplasmic staining by antibodies against keratin (K) 8 and K18. Mallory Denk bodies contain the aggregated forms of K8 and 18 as well as other proteins and are therefore stained with the respective antibodies (arrow head) (immunohistochemical stain with antibodies against K8/K18)

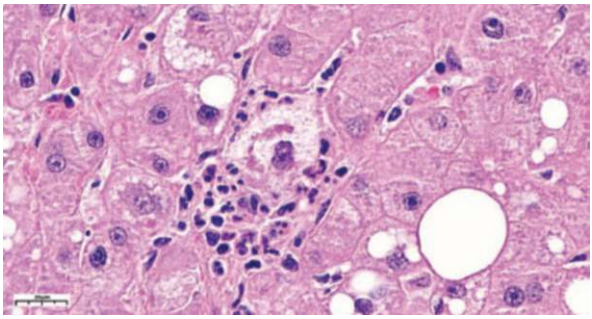

Fig. 38.10 Satellitosis. Ballooned hepatocyte with Mallory Denk body surrounded by neutrophils (H&E)

protein aggregation and a proinflammatory setting promoted by activated NFkappa B signalling.

In decompensated stages of ALD, characterized by bilirubin levels >3 mg/dL and/or signs of liver decompensation (new onset jaundice, ascites, hepatic encephalopathy, portal hypertensive gastrointestinal bleeding), cholestasis can be also a feature in the pre-cirrhotic setting. Visible bile pigment is seen in the hepatocellular cytoplasm (hepatocellular cholestasis), canalicules (canalicular cholestasis) (Fig. 38.11a) and ductules (Fig. 38.11b) (ductular cholestasis) of the so called ductular reaction (see below). However, it is a very rare feature in compensated clinical stages of ALD. Canalicular and/or ductular cholestasis are associated with sepsis [21, 23, 37, 38], unfavourable prognosis and higher short-term mortality rates [27]. Ductular cholestasis has also been identified as an independent predictor of treatment response to corticosteroids in patients with severe AH. The pathomechanism(s) underlying cholestasis are not well described. Some of the factors responsible could include ballooning-associated obstruction of bile radicles [39], impaired bile formation and secretion via the canalicular transport systems [40] and reduced bile flow. Some of these pathways could be implicated in the sepsis-associated ductular cholestasis [41, 42].

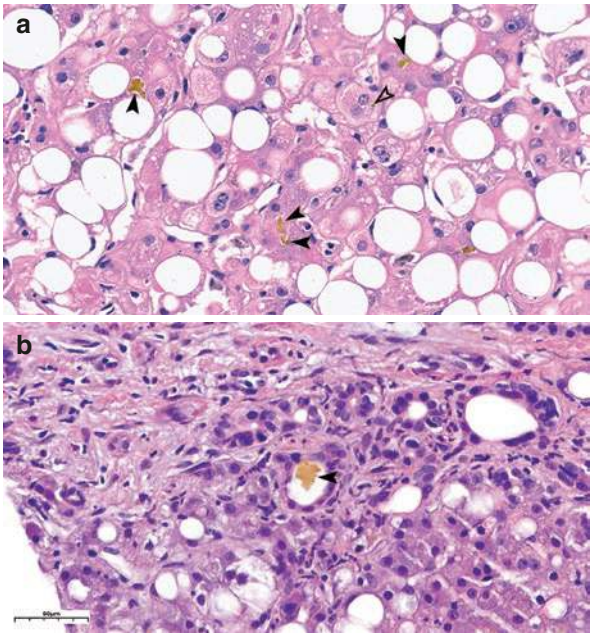

Fig. 38.11 Hepatocellular, canalicular and ductular choleastasis. (**a**) Bile pigment is present in hepatocytes (open arrow head) and canalicules (black arrow head) in a case with the clinical syndrome of alcoholic hepatitis (AH) and severe steatohepatitis due to alcohol-related liver disease (ASH) (H&E). (**b**) Ductular cholestasis with bile pigment in the lumen of a ductule at the mesenchymal-parenchymal interface in a case with AH and sepsis. The ductules are surrounded by some neutrophils (H&E)

Canalicular cholestasis is also a feature of Zieve-syndrome which is characterized by jaundice, hyperlipidemia and hemolytic anemia in a background of cirrhosis and steatosis in patients with ALD [43].

Other Histologic Changes in ALD

Megamitochondria

Mitochondria play a central role in the pathogenesis of fatty liver diseases as a source of reactive oxygen species triggering proinflammatory and fibrogenesis signals via the activation of Kupffer and stellate cells. In ALD mitochondria are damaged by oxidative stress due to induction of cytochrome P450 2E1 and hydroxyl radicals from the Fenton reaction [44].

Normal sized mitochondria are too small to be detected on light microscopy. In ALD they are often enlarged and appear as pink or bright red globular or needle shaped structures in the cytoplasm of hepatocytes in H&E (Fig. 38.6) and chromotrope-aniline-blue (CAB) stained sections, respectively. On electron microscopy, mitochondrial enlargement is accompanied by a reduced number of cristae, intramitochondrial cristalline inclusions and multilamellated membranes [4]. More recently a reduced number of mitochondria of stunted shape have also been described in patients with severe AH.

Megamitochondria appear to be an adaptive phenomenon. Their decreased capacity of oxygen consumption and phosphorylation may be associated with decreased production of reactive oxygen species (ROS) in hepatocytes with beneficial consequences for survival [37].

Megamitochondria are not specific for ALD. They can also be found in other liver diseases like diabetes mellitus or Wilson disease.

Other Adaptive Hepatocellular Changes

Eosinophilic homogenization of the cytoplasm of the liver cells morphologically resembling ground glass inclusions of hepatitis B virus infection are considered a reactive hepatocellular change in ALD caused by an increased smooth endoplasmic reticulum [45, 46]. Another change is so called mitochondriosis due to a proliferation of mitochondria giving rise to an eosinophilic granular cytoplasm (Fig. 38.12) [46]. Adaptive changes are more frequent in cirrhotic than compared to pre-cirrhotic stages of ALD.

Iron Storage

Iron storage in hepatocytes (parenchymal siderosis) as well as in sinusoidal lining and Kupffer cells (mesenchymal siderosis) is a common finding in patients with ALD (Fig. 38.13) [4, 25, 47, 48]. In some cases, particularly in the cirrhosis stage, the extent of parenchymal siderosis can be comparable to siderosis in hereditary hemochromatosis. Iron storage in ALD is due to an increased uptake of iron from the intestine resulting from decreased production of hepcidin in hepatocytes. However, hepcidin expression is upregulated due to alcohol-related ER stress and

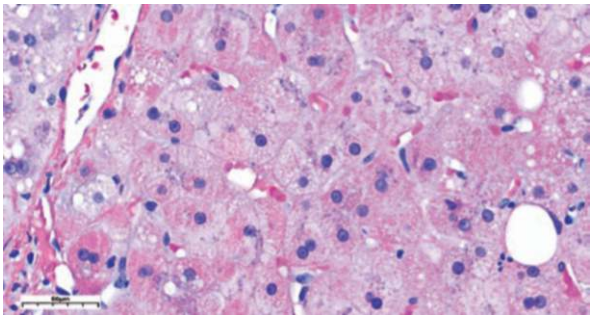

Fig. 38.12 Eosinophilic and granulated cytoplasm of hepatocytes in mitochondriosis is presumed to be due to a proliferation of mitochondria (H&E)

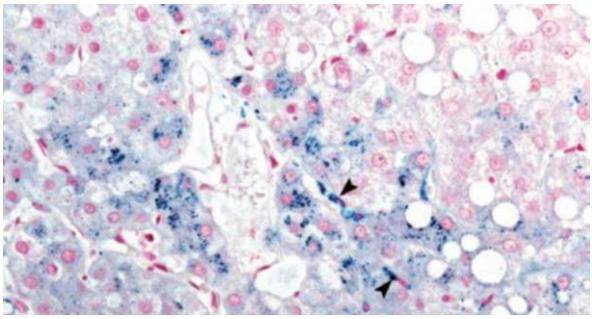

Fig. 38.13 Mixed type siderosis in a case with steatosis due to alcohol-related liver disease. Iron deposits are stained blue in the hepatocellular cytoplasm as well as in Kupffer and sinusoidal endothelial cells (arrow heads) in the Prussian blue stain

inflammation promoting the retention of iron in Kupffer cells. The extent of iron storage may be determined by the ratio of hepcidin suppression and induction in hepatocytes and Kupffer cells, respectively [49]. In addition, comorbidities, genetic factors, fibrosis stage and inflammation may also influence the extent of iron storage [49]. Free iron promotes liver injury and inflammation via oxidative stress and increased production of TNF-alpha [50–52]. In patients with ALD parenchymal siderosis has been shown to correlate with fibrosis stage [53], the development of HCC [54], and prognosis [55].

Ductular Reaction

Ductular reaction (DR) is a frequent histopathological feature in ALD and other chronic liver disease associated with parenchymal loss or mechanical obstruction of bile flow [4, 25, 45, 56, 57]. The ductules consist of epithelial cells with cholangiocellular differentiation set in a loose inflamed fibrous stroma at the mesenchymal parenchymal interface (Fig. 38.14). DR may arise from stem cell proliferation or ductular metaplasia of periportal hepatocytes. The ductules are capable of differentiation into mature cholangio- or hepatocytes and are presumed to contribute to restoration of hepatocellular mass. Transcriptomic analysis of DR revealed a proinflammatory profile with expression of CXC and C-C motif chemokine ligand chemokines [58] as well as fibrogenic factors which activate stromal myofibroblasts, promote the recruitment of neutrophils and the development of periportal fibrosis [59].

DR may also result from mechanical obstruction of bile flow, e.g., related to fibrosis of the papilla of Vater in cases with alcohol-related chronic pancreatitis.

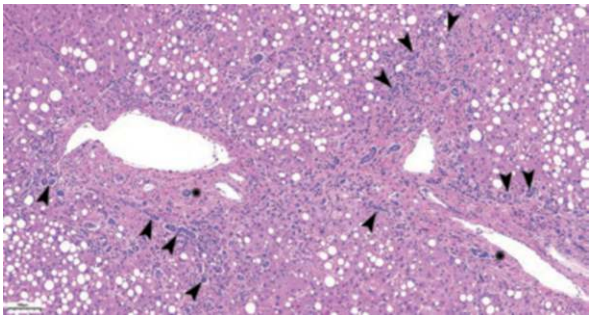

Fig. 38.14 Ductular reaction in a case with severe fibrosis due to alcohol-related liver disease. The interlobular bile ducts of the original portal tracts (marked by asterisks)are located adjacent to the A. hepatica and portal vein branches whereas the ductular structures of ductular reaction are present at the mesenchymal-parenchymal interface (examples marked by arrow heads) (H&E)

Fibrosis and Cirrhosis Due to ALD

Alcohol or acetaldehyde-associated liver injury promotes ballooning degeneration of centrilobular hepatocytes. Ballooned hepatocytes release hedgehog ligands and, in a paracrine fashion, induce hedgehog-responsive genes in hepatic stellate cells (HSC) residing in the space of Disse`. Activated HSCs are involved in the production of extracellular matrix and collagen deposits along sinusoids and around ballooned hepatocytes, giving rise to a particular type of fibrosis typically seen in fatty liver diseases like non-alcoholic fatty liver disease (NAFLD) as well as ALD. According to the characteristic pattern of collagen deposits, the term pericellular fibrosis (PCF) has been coined (Fig. 38.15). Profibrogenic hedgehog ligands can also be released from dying hepatocytes, hepatic progenitor cells and a few other cell types of the injured liver. Furthermore, HSC can also be activated by growth factors secreted by Kupffer cells which are activated by damage-associated molecular patterns (DAMPs) and ROS from dying hepatocytes as well as pathogen-associated molecular patterns (PAMPs) and lipopolysaccharides (LPS) resulting from ethanol-associated gut injury (so called leaky gut). In addition, fibrogenesis is propelled by components of the extracellular matrix (ECM), like collagen-1 and integrin promoting HSC survival which is also enhanced by alcohol-mediated inhibition of natural killer cell (NK)-associated removal of HSC. Activated HSC produce tissue inhibitors of metalloproteinases (TIMPs) and thus inhibit the fibrolytic activity of matrix metalloproteinases (MMPs). Maturation of fibrous tissue is accompanied by loss of hepatocytes from areas with fibrosis, the formation of condensed collagen and accumulation of elastic fibers as well as clusterin resulting in dense, scar-like fibrous septa that resemble septa in chronic viral hepatitis (reviewed in [60]).

Zonation of the hepatic lobules may also play an important role in the shaping of central-based fibrosis patterns. HSC just like hepatocytes differ with respect the expression of zonation-specific protein markers. In a mouse model of centrilobular

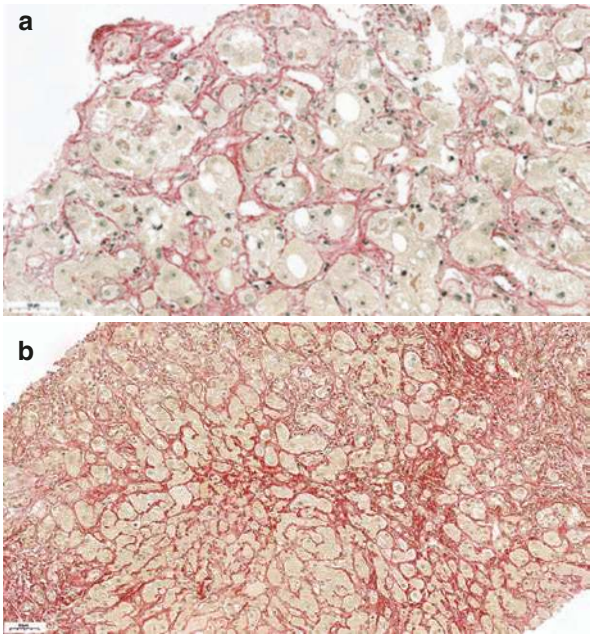

Fig. 38.15 Pericellular fibrosis. (**a**) Single or small groups of hepatocytes are surrounded by collagen fibers giving rise to a chicken wire pattern of fibrosis (sirius red). (**b**) Severe pericellular fibrosis is dissecting the parenchyma (sirius red)

fibrotic injury the central stellate cell type contributed most to the injury-related collagen production whereas the periportal stellate cells are less involved [61].

Compared to normal liver (Fig. 38.16a), in ALD, fibrosis is restricted to perivenular areas and around centrilobular hepatocytes in the early stages of the disease (Fig. 38.16b). In settings of ongoing alcohol abuse, PCF can extend to the intermediate portions of the hepatic lobules. In some cases, the entire lobules are dissected by PCF and/or septa consisting of PCF with admixed hepatocytes (septal PCF) forming bridges between central veins and the portal tracts (bridging fibrosis) (Fig. 38.16e, f). This pattern is often associated with the fibro-obliteration of central veins [27]. Fibro-obliterated veins are typical for ALD and have not been described in NAFLD. A particularly severe form of centrilobular fibrosis is termed sclerosing hyaline necrosis. It designates severe perivenular fibrosis in the setting of lobular inflammation and hepatocellular ballooning [62]. Although central-based fibrosis is the common fibrosis type in ALD, portal-based fibrosis has also been described in a minority of cases [63] (Fig. 38.16c). Portal-pased fibrosis may occur together with central-based PCF (Fig. 38.16d). Ongoing liver injury finally leads to the destruction of the lobular architecture and the formation of parenchymal nodules surrounded by fibrous septa characterizing the cirrhosis stage (Fig. 38.17a–f). In cases of actively drinking patients, PCF may be very severe, dissecting the parenchymal nodules and causing an indistinct nodular outline (Fig. 38.17b, d, f). In such cases the term parenchymal nodularity may be used. Again, this pattern of fibrosis is also typical for ALD and has not been described in NAFLD [27].

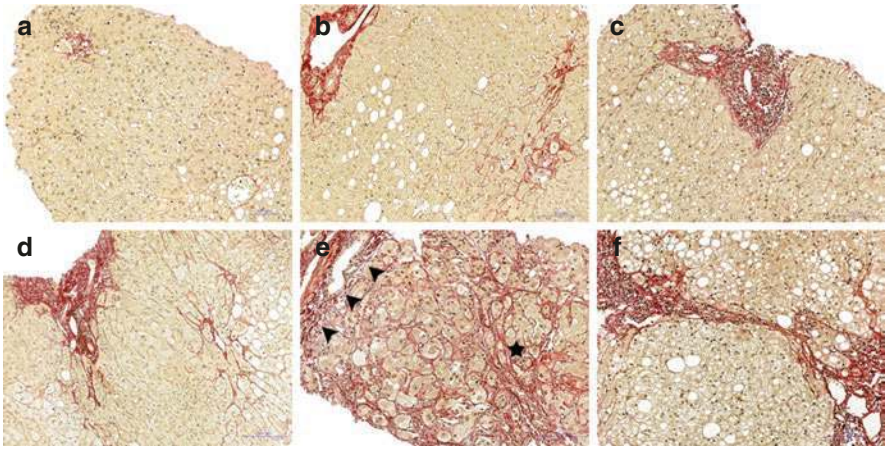

Fig. 38.16 Fibrosis progression in precirrhotic stages of alcohol-related liver disease. (**a**) Normal lobular architecture. Fibrous tissue is restricted to portal tracts (SFS 0). (**b**) Fibrogensis starts in centrilobular areas as pericellular fibrosis withe deposits of collagen fibers around single or groups of hepatocytes (SFS 1P) (**c**) In some cases there is a predominantely periportal fibrosis type (SFS 1). (**d**) With progressive disease both, cetrilobular and periportal fibrosis may be seen (SFS 2) and (**e**) can progress to severe pericellular fibrosis dissecting the lobules or bands of pericellular fibrosis connecting portal tracts and central veins (i.e. bridging fibrosis) (SFS 3P). This fibrosis stage is often associated with obliteration of central veins, a pattern not decribed in NAFLD. (**f**) Bridging fibrosis (SFS 3) ca also present in the form of dense septa resembling septa in chronic viral hepatitis

Even in the cirrhosis stage, there can be disease progression with parenchymal loss and increase of fibrous septa giving rise to different stages of cirrhosis severity (see below) (Fig. 38.17a–f). Notably, most patients with decompensated ALD are in the cirrhotic stage at the time of diagnosis. Substages of cirrhosis severity have been shown to be of prognostic relevance [64, 65] in all clinical settings of ALD including compensated and decompensated ALD as well as patients with the clinical diagnosis of AH and histological ASH [27, 66].

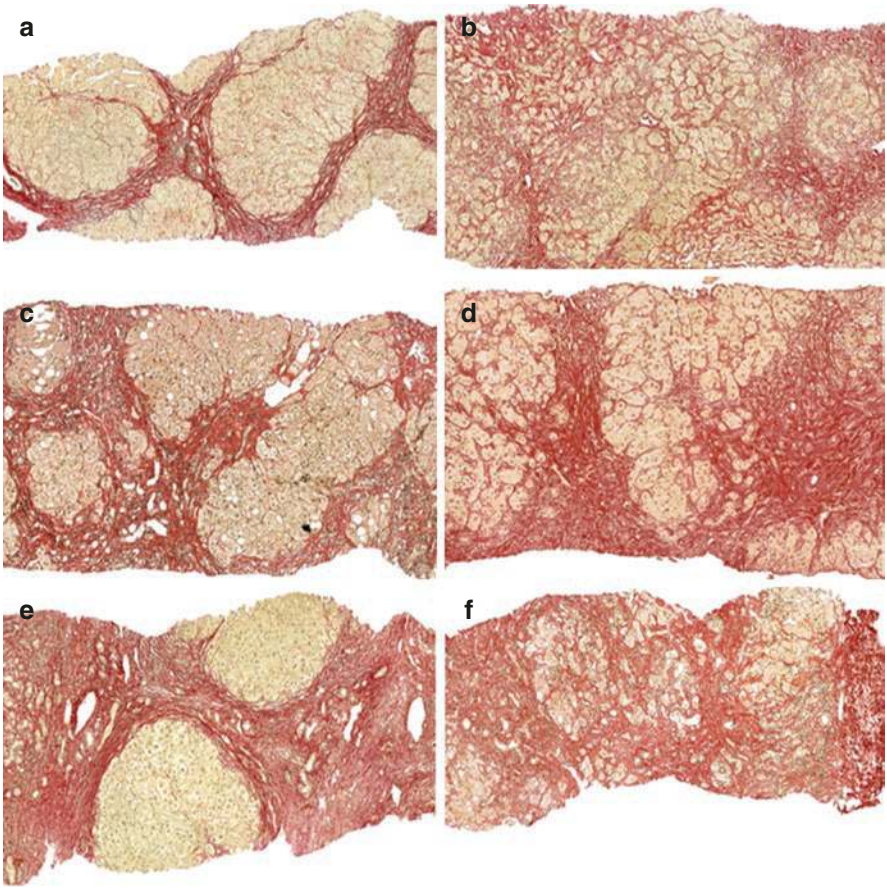

Fig. 38.17 Fibrosis progression in cirrhostic stages of alcohol-related liver disease. (**a**, **c**, **e**) Progresssive disease leads to the destruction of the lobular architecture and the formation of parenchymal nodules surrounded by fibrous septa. The progression of fibrosis leads to thin (SFS 4A) to broad (SFS 4B) and very broad septa (SFS 4C). In all stages of cirrhosis (**b**, **d**, **f**) severe pericellular fibrosis (comprising more than 50% of the parenchyma)

Histologic Grading and Staging of ALD

Histologic methods for the semiquantitative assessment of disease activity (grade) and non-structural collagen, i.e., fibrosis (stage) have been developed and validated for many chronic liver diseases including chronic hepatitis, biliary disease and NAFLD and are widely used in clinical practice and clinical trials for the standardized histological assessment and prognostication. Recently an ALD-specific histological grading and staging system was developed by an international group of pathologists [27], members of the Consortium for the Study of Alcohol-related Liver Disease in Europe (SALVE). The design of this histological method was based on characteristic and prognostic histologic parameters of ALD.

Semiquantitative Assessment of Disease Activity (SALVE Grading)

The histological scoring system for the assessment of grade was defined using numerical scores representing the extent of macrovesicular steatosis, hepatocellular ballooning, MDB, lobular neutrophils as well as canalicular and ductular cholestasis (Table 38.1). Macrovesicular steatosis is assessed on a three-step scale according to the percentage of parenchymal involvement ranging from less than 5% of hepatocytes with macrovesicular steatosis to severe steatosis with more than 66% of parenchymal involvement. Activity is defined as the sum of semiquantitative scores for ballooning or MDBs depending which of these features is more pronounced to avoid overrating of hepatocellular damage, and scores for lobular infiltration by neutrophils, both assessed on a two-step scale. Canalicular and ductular cholestasis is scored as absent or present. SALVE grade is then described by itemization of the scores for steatosis (range 0–3), activity (range 0–4) and canalicular as well as ductular cholestasis (range 0–1, respectively).

Table 38.1 SALVE grading [27]

Steatosis (S) grade: Macrovesicular steatosis[a]; % parenchymal involvement
Score 0: <5%
Score 1: 5–33%
Score 2: 34–66%
Score 3: >66%
Activity (A) grade: Sum of scores for hepatocellular injury (Ballooning [B] *or* Mallory-Denk bodies [MDB][b]) and lobular inflammation
Score 0: None-rare
Score 1: Few[c]
Score 2: Many[d]
Lobular neutrophils (LN)
Score 0: None-rare
Score 1: Few[c]
Score 2: Many[d] and/or satellitosis[e]
Cholestasis type
Canalicular cholestasis (CC)
Score 0: None
Score 1: Present
Ductular cholestasis (DC)
Score 0: None
Score 1: Present
SALVE grade is described by itemization of each of the component scores:
S 0–3**, A (B/MDB** 0–2 **+ LN** 0–2**), CC** 0–1**, DC** 0–1

[a]Lipid vacuoles in the cytoplasm of hepatocytes larger than the hepatocellular nucleus
[b]If scores for ballooning and Mallory-Denk bodies are unequal the higher score is applied
[c]Feature is appreciated after a reasonable search and is present in few microscopic fields
[d]Feature is frequent and easy to find without searching and present in many microscopic fields
[e]Neutrophils surrounding ballooned hepatocytes

Semiquantitative Assessment of Non-structural Collagen (SALVE Staging)

SALVE staging comprises seven main fibrosis stages (SALVE fibrosis stages, SFS) ranging from no fibrosis, SFS 0 to severe cirrhosis, SFS 4C (Table 38.2). SFS 1 can have two different patterns of periportal or centrilobular PCF. In SFS 2 periportal and centrilobular fibrosis is present. Bridging fibrosis (SFS3) is characterized by complete septa that can consist dense fibrous septa devoid of hepatocytes resembling septa in chronic viral hepatitis or consist of PCF (septal PCF) connecting central veins and portal tracts.

SALVE cirrhosis stages are defined by destruction of the lobular architecture and the occurrence of parenchymal nodules surrounded by fibrous septa by the diameter of fibrous septa in relation to the diameter of the smallest distinct parenchymal nodule present in a biopsy. In SFS 4A the diameter of the septa measured at the minimal distance between two parenchymal nodules is less than 50% of the diameter of the smallest parenchymal nodule, whereas broad septa of SFS 4B are wider than 50% and very broad septa of SFS 4C are wider than the complete diameter of the smallest nodule. In all cirrhosis stages, variable amounts of PCF can be seen.

Table 38.2 SALVE fibrosis stage (SFS) [27]

Stage	Fibrosis	Definition
SFS 0	No	No fibrosis
SFS 1	Mild	**1A**: Portal & periportal fibrosis
		***1P**: PCF[a] in zone 3 ± zone 2*[b]
SFS 2	Moderate	**2**: PCF in zone 3 ± zone 2 and periportal fibrosis
SFS 3	Bridging	**3A**: ≥1 complete dense septum[c]
		***3P**: >50% of the parenchyma with PCF up to zone 1, no distinct nodules*
SFS 4	Cirrhosis	**4A**: ≥1 distinct parenchymal nodule[d], most septa are thin[e], 1 broad septum[f] allowed
	Thin septa	***4AP**: >50% of parenchyma with severe PCF[g] and indistinct parenchymal nodules[h]; thin dense septa allowed*
	Severe PCF	
	Broad septa	**4B**: Distinct parenchymal nodules, >1 broad septum; 1 very broad septum[i] allowed
		***4BP**: 4B and >50% of parenchyma with severe PCF*
	Very broad septa	**4C**: Distinct parenchymal nodules, >1 very broad septum[i]
		***4CP:** 4C and >50% of parenchyma with severe PCF*

[a]Pericellular fibrosis: Collagen fibers surrounding single or small groups of hepatocytes
[b]*P stages: optional, for use in research settings*
[c]Dense septum: Septum consisting mainly of collagen fibers and eventually very occasional hepatocytes
[d]Distinct nodule: Parenchymal nodule without portal-central relations surrounded by dense septa
[e]Thin septum: Dense septum, <25% of diameter of smallest distinct nodule
[f]Broad septum: Dense septum, >25% and ≤50% of the diameter of smallest distinct nodule
[g]Severe PCF: PCF visible at 4× magnification
[h]Indistinct nodule: Parenchymal area of indistinct nodular shape dissected by severe PCF
[i]Very broad septum: Dense septum >50% of the diameter smallest distinct nodule

The Diagnostic and Prognostic Relevance of PCF in ALD

PCF is devoid of elastic fibers typically present in dense septa. In mouse models it has been shown that dense septa with elastic fibers are more resistant to degradation than septa without elastic fibers [67, 68]. Therefore, it can be speculated that PCF is an immature type of fibrosis prone to degradation in settings of disease regression and thus may be useful to monitor early antifibrotic effects of therapeutic interventions. Furthermore, because severe PCF affects large proportions of the parenchyma it may be correlated with higher liver stiffness than compared to only septal fibrosis in a particular stage and could affect the interpretation of non-invasive fibrosis tests such as elastography. Finally, severe PCF also characterizes two distinct ALD-specific fibrosis patterns which are part of the spectrum of bridging fibrosis and cirrhosis with thin septa. Bridging fibrosis can be present as panlobular or septal PCF associated with fibro-obliterative lesions of central veins (see above) and destruction of the lobular architecture mainly due to PCF can be seen in early cirrhosis. These fibrosis patterns have not been described in NAFLD and may therefore also be of diagnostic relevance. Data from a recent study also indicate that severe PCF in cases with bridging fibrosis and cirrhosis was associated with significantly worse survival at 5-years compared to cases without PCF [27]. Because of these reasons an ALD-specific staging system should provide the possibility to also record severe PCF.

Expanded SALVE Fibrosis Staging with Emphasis on PCF

The SALVE staging system has also been adapted and expanded by the so called P-stages to represent severe forms of PCF. These stages are shown in the grey insets in Table 38.2. The P-stages are optional and may be used in study settings which require a more detailed description of fibrosis. Stage 1P is for cases with centrilobular fibrosis only, stage 3P is characterized by predominantly panlobular or septal forms PCF with bridging. In the cirrhotic stages 4AP, BP and CP severe PCF is seen in more than 50% of the parenchyma.

Chapter 39
Non-invasive Fibrosis Assessment in Alcohol-Related Liver Disease

Maria Silva and Emmanuel A. Tsochatzis

Abstract Non-invasive identification of advanced stages of fibrosis is of crucial importance in ALD in order to define preventive actions against the occurrence of liver related events. Several non-invasive tests have been tested in ALD populations with high diagnostic yield. Serum biomarkers are valuable tools, mostly to exclude severe fibrosis in low cirrhosis prevalence populations. In case of positive results, the sequential use of a liver elastography to measure liver stiffness (LS) is recommended, provided that alcohol consumption and biochemical evidence of inflammation are excluded or minimized. In high prevalence scenarios, elastographic techniques are preferable. Transient elastography is the most validated LS measurement method, despite the increasing evidence for other SWE techniques with important practical advantages. Disease-specific threshold values for advanced fibrosis/cirrhosis have been proposed, with dual cut-offs providing optimal sensibility and specificity. In terms of prognosis assessment, both biomarkers and LS methods have displayed value, however, sufficient evidence for disease-specific recommendations is lacking.

Keywords Fibroscan · ELF · FIB4 · Cirrhosis · Prognosis · HCC

Introduction

In chronic liver disease, fibrosis develops as a response to repeated liver injury with excess extracellular collagen deposition [1]. Cirrhosis, the most extreme stage of fibrosis, is characterized by abnormal liver architecture with fibrous tissue circumscribing parenchymal nodules and hepatic vasculature alterations [2]. Alcohol consumption is a dominant cause of cirrhosis, with an increasing mortality and morbidity burden worldwide [3]. Alcohol-related liver disease (ALD) patients have

higher risk of cirrhosis complications and death at an early age in comparison with another aetiologies [4]. The risk of cirrhosis development increases in a cumulative alcohol dose-dependent manner [5], which highlights the importance of early diagnosis and prompt life-style interventions.

The standard method for liver fibrosis assessment is liver biopsy. However, it displays several limitations including potential non-representability of the specimen [6], reproducibility difficulties among pathologists [1], limited availability and a small risk of serious complications [7]. These issues have led to the development of non-invasive tests (NITs) for the assessment of liver fibrosis. The term "cirrhosis" implies a pathological diagnosis with the above-mentioned limitations. For that reason, and considering severe fibrosis and cirrhosis as part for a continuous spectrum, the concept of compensated advanced chronic liver disease (cACLD) has been introduced at the Baveno VI conference, as a stage of disease with significant risk of cirrhosis complications [8]. The Baveno VII workshop reinforced the importance of identifying patients with cACLD with NITs and, among those, the ones with clinically significant portal hypertension (CSPH), defined as hepatic venous pressure gradient (HVPG) ≥10 mmHg [9].

NITs are divided into two main categories (Table 39.1): serum biomarkers, that directly or indirectly are associated with liver fibrosis, and liver stiffness (LS) measurement tools [10]. Most NITs were developed in chronic viral hepatitis cohorts

Table 39.1 Advantages, limitations and specificities of non-invasive tests on alcohol-related liver disease

	Serum biomarkers		Liver stiffness measurement tools		
	Direct/ patented	Indirect/ non-patented	Transient elastography	pSWE/2D-SWE	MRE
Advantages	High reproducibility; High applicability; Prognostic value		High accuracy for diagnosis (advance fibrosis/cirrhosis)		Uses regular MRI machine
			Prognostic value (best validated for TE)		Entire liver examination
	Accuracy (> non-patented)	High availability	Most validated technique	Uses regular echography device	Low failure rate
		Low cost	Good reproducibility	Selectable area of interest	
			Fast learning curve	Low failure rate	
			Well defined quality criteria	Higher accuracy in milder fibrosis stages (2D-SWE)[a]	

Table 39.1 (continued)

	Serum biomarkers		Liver stiffness measurement tools		
	Direct/ patented	Indirect/ non-patented	Transient elastography	pSWE/2D-SWE	MRE
Limitations	Non-liver-specific		False positives (inflammation, congestion, extra-hepatic cholestasis, food and alcohol intake)		MRI machine required
	Inferior accuracy compared to TE				Time-consuming
	False positives (extra-hepatic inflammatory conditions)[b]	False positives (inflammation)[c]	Dedicated device required	Less validated than TE	High cost
	Low availability	Lower accuracy	Highest failure rate (obesity, ascites, inexperience)	Compatible device required	Not applicable if iron overload, non-compatible prothesis and claustrophobia
	High cost			Not well stablished quality criteria	Uncertain prognostic value
Specificities on ALD	Lower accuracy for milder fibrosis stages		High accuracy for diagnosis (advance fibrosis/cirrhosis)		High accuracy for diagnosis
	Uncertain value in CSPH		Prognostic value (liver related events > mortality)[b]		Lack of experience
	Accuracy detecting severe fibrosis (best: ELF® and FibroTest®)	Accurate ruling out severe fibrosis in low prevalence populations (best: Forns index and FIB-4)	Higher false positive risk (steatohepatitis/alcohol intake)		Uncertain prognostic value
	Prognostic value (ELF® and FibroTest®)[a]	Prognostic value[a]	Uncertain value in CSPH		

pSWE point shear wave elastography, *2D-SWE* 2D-shear wave elastography, *MRE* magnetic resonance elastography, *TE* transient elastography, *CSPH* clinically significant portal hypertension, *ELF* enhanced liver fibrosis score

[c]False positive for FIB-4 and NFS if age > 65 years

[10]. However, there is increasing evidence regarding their application on ALD [11]. In this chapter, we review the available NITs for liver fibrosis assessment in ALD, focusing on their diagnostic and prognostic applicability.

Considerations on Accuracy and Limitations of Non-invasive Tests

An ideal Non-Invasive Test (NIT) should be cheaper than LB, accessible, reproducible, and reliable in providing prognostic information [11]. Frequent NITs limitations include lack of accuracy in identifying early fibrosis stages, discriminating between adjacent stages of fibrosis and diagnosing CSPH [10].

The performance of NITs is usually evaluated through an area under the receiver operator characteristic curve (AUROC) taking liver biopsy as the reference. However, as previously stated, liver biopsy is not a perfect standard, meaning that an AUROC >0.90 may not be achieved even by a perfect NIT [12]. The AUROC varies according to the prevalence of fibrosis and the distribution of each fibrosis stage [13]. Thus, the choice of NITs must take into account the clinical scenario. Most NITs were developed in secondary/tertiary settings where advanced fibrosis prevalence may reach >50% in ALD [14], contrasting with <10% in risk patients from the general population [15]. In addition, the AUROC does not inform about the clinical impact of false negatives and false positives [16]. This was addressed by Majumdar et al. who integrated decision tree and curve models to define the minimum acceptable accuracy of NITs compared to liver biopsy in terms of 2-year mortality, in function of cirrhosis prevalence [17]. The authors reported minimal sensitivity and specificity of 89% and 88%, 94% and 85%, and 94% and 87% in populations with 5%, 20% and 50% cirrhosis prevalence, respectively.

Serum Biomarkers of Liver Fibrosis

A wide variety of biomarkers have been proposed for the assessment of liver fibrosis [10]. FibroTest® [18] was the first algorithm combining direct fibrosis markers, followed by four additional patented tests (FibroMeter® [19], FibroSpectII® [20], Enhanced Liver Fibrosis score® (ELF) [21] and HepaScore® [22]). Non-patented methods use algorithms that combine indirect routinely available markers. Serum biomarkers have the practical advantages of reproducibility, applicability and, for non-patented scores, availability at low cost. However, they are not liver-specific and may include parameters that are predominantly altered in advanced disease stages, that vary in other conditions and/or in healthy individuals [23]. Most biomarkers were validated in chronic hepatitis C (HCV) patients in secondary/tertiary settings [10]. However, there are increasing data on their use in other populations.

A large systematic review addressed the diagnostic performance of biomarkers in ALD concluding that they could identify severe fibrosis/cirrhosis but not milder stages of fibrosis [24]. The most common single marker was hyaluronic acid (n = 1360) which presented consistent high yield in excluding severe fibrosis/cirrhosis, despite of a wide range of cut-off values and of reported inferiority when compared to panel markers [25]. The patented panels FibroTest®, FibroMeter®, HepaScore® and ELF® showed excellent accuracy in detecting cirrhosis with AUROCs >0.9, while one non-patented test (PGA: prothrombin time, gamma-glutamyl transpeptidase and apoliprotein AI score [26]) showed similar diagnostic yield to patented tests in an 103-patient cohort [25]. Importantly, due to heterogeneity, the definition of pooled cut-off values was not possible in this review. A more recent 289-participant study evaluating eight biomarkers, in both primary and secondary facilities, concluded that ELF® and FibroTest® were excellent markers of advanced fibrosis, with similar diagnostic yield as LS measurements in the intention-to-diagnose analysis [15]. Cut-offs of 10.5 for ELF® and 0.58 for FibroTest® had 94% and 90% negative predictive value (NPV) to rule out advanced fibrosis in all patients, which rose to 98% and 97% in primary care patients, respectively. Among indirect markers, Forns index [27] was the best identifying advanced fibrosis, with a NPV of 91% at a threshold of 6.8, that increased to 97% in primary care settings, suggesting that it might be useful in sequential NITs strategies (see below). FIB-4 [28] was a close second. In a high-cirrhosis prevalence cohort of 193 participants, however, these scores did not perform well and were outperformed by PGAA (PGA and α-2-macroglobulin score) [29] that came close to FibroTest® accuracy [30].

Biomarkers may also be valuable in defining CSPH and prognosis in ALD. In a cohort of 219 cirrhotic ALD patients, biomarkers were outperformed by LS measurements and LS–spleen diameter to platelet ratio score (LSPS) in defining CSPH [31]. However, the non-patented biomarkers FIB-4 [32] and Lok index [33] were the only NITs independently associated with mortality in this analysis. Regarding patented tests, a 462-participant study with 4-year median follow-up showed that ELF® outperformed FibroTest® and other biomarkers in prognostic value, being only inferior to elastography [34]. ELF® and FibroTest® could independently group patients according to rates of liver-related events during follow-up, with minimal risk for ELF® <9.8 (5%) and FibroTest® <0.31 (8%) and maximal for >10.5 (53%) and >0.58 (55%), respectively. Forns index, NFS [35] and FIB-4 had good prognostic accuracies, however, they were not able to define risk groups. The prognostic value of FibroTest® had been previously addressed in a 218-patient cohort where it independently predicted 10-year mortality, performing better than other biomarkers and similarly to histological defined fibrosis stages [36].

In general, biomarkers are reliable tools in ALD, mainly for the exclusion of severe fibrosis/cirrhosis. Patented scores haver higher diagnostic accuracy and are recommended to rule-out advanced fibrosis when TE is not available, with FIB-4 as an alternative [11]. Serum markers appear to have promising prognostic value, however further validation is necessary to advice their use in that regard.

LS Measurement Tools

Transient Elastography

Transient elastography (TE) is the most stablished LS assessment tool. More details are provided in Chap. 42. Briefly, it is based on the propagation of low-frequency shear waves through the liver translated in 1-dimention ultrasounds [37], with higher propagation velocities in stiffer tissues. Measurements are expressed in kilopascal (kPa). TE is reproducible, rapidly obtained and regarded as a fast learning curve technique [38]. However, reliable measurements are not always attainable, mainly due to patient obesity and/or operator inexperience, but also to narrow intercostal spaces [37]. Large series have reported rates of failed/technical unreliable results up to 19% [39]. In addition, TE results are influenced by inflammation [40, 41], hepatic congestion [42], extra-hepatic cholestasis [43] and steatosis [44], as well as by food and alcohol intake [45]. TE has shown better results ruling out cirrhosis than making a positive diagnosis or identifying milder stages of fibrosis [11]. It has been applied to multiple causes of chronic liver disease and disease-specific LS cut-offs for staging fibrosis have been proposed, with generally higher thresholds for ALD [46]. Regardless of the aetiology, according to the Baveno VI consensus, LS between 10 and 15 kPa is suggestive of cACLD and LS >15 kPa is highly suggestive [8].

There are several aspects to take into account when applying TE to ALD. In the presence of steatohepatitis and alcohol consumption, TE may significantly overestimate fibrosis stages. During alcohol detoxification, decreases in transaminases, particularly aspartate aminotransferase (AST), correlate with lower LS values [47–49]. In a cohort of 101 participants with alcohol abuse, the exclusion of patients with AST >100 IU/L increased TE specificity for cirrhosis from 80% to 90% [47]. Interestingly, significant decreases in LS after alcohol withdrawal, occur even if baseline AST is <100 IU/L [48]. In another cohort of 677 patients, LS exponentially increased with AST baseline levels and 16% of patients showed decrease in LS after 5 days of alcohol withdrawal [49]. Surprisingly, with normal AST, LS cirrhosis thresholds in ALD were quite similar to HCV, suggesting that LS may be comparable among aetiologies in the absence of inflammation. In the presence of AST elevation though LS increased much more in ALD. Importantly, LS only increased in 30% of patients with AST >100 IU/L which may help explain the wide range of cirrhosis cut-offs previously reported in ALD, from 11.5 [47] to 25.6 kPa [50].

In ALD, the most robust evidence favors TE use in identifying advanced fibrosis in secondary/tertiary settings, with AUROCs consistently ≥0.9 [11, 15, 46]. A 834-participant meta-analysis concluded that TE is valuable in ruling out significant fibrosis, severe fibrosis and cirrhosis (cut-off: 7.0–7.8 kPa, sensitivity 94%, specificity 89%; 9.5 kPa, 92%, 70%; 12.5 kPa, 95%, 71%, respectively), in high cirrhosis prevalence scenarios [51]. This cut-off values were the most frequently reported by individual studies, since pooled cut-offs could not be defined. A more recent 1026-patient meta-analysis obtained pooled LS thresholds for each fibrosis stages,

reporting 12.1 and 18.6 kPa for severe fibrosis and cirrhosis, respectively [46]. Increased AST and bilirubin values, as well as histological features of alcoholic hepatitis, were associated with increments in LS. If AST >75 IU/L, LS was twice as high and if bilirubin >16 μmol/L, it was three times higher than if both were normal. The reported cut-off values for cirrhosis ranged from 12.1 kPa, if AST <38.7 IU/L and bilirubin <9 μmol/L, to 25.9 kPa, if AST >75 IU/L and bilirubin >16 μmol/L. Inflammation-adjusted cut-off values had been previously proposed regarding AST but not bilirubin [49].

The LS thresholds for cACLD recommended by Baveno VI were challenged by a >5000-patient multi-aetiology meta-analysis with 946 ALD participants that proposes dual cut-offs of <8 kPa to exclude cALCD (93% sensitivity) and >12 kPa for its diagnosis (92% specificity) [52]. Following these results, recently published EASL guidelines propose a general dual cut-off of 8–10 kPa to exclude and 12–15 kPa to diagnose advanced fibrosis in the absence of inflammation [11].

Regarding CSPH, TE performed better than biomarkers in a study on 88 compensated alcoholic cirrhosis patients, with similar accuracy to LSPS [31]. Importantly, none of the NITs was reliable in predicting high-risk varices and LS/LSPS were not independently associated with mortality, being outperformed by Lok index and FIB-4. Nevertheless, in an analysis of 462 compensated ALD patients, TE had de highest accuracy among NITs in predicting liver-related events, with a 28-fold increased risk for LS >15 kPa, when compared with <10 kPa [34]. Notably, 21% of patients with LS between 10 and 15 kPa developed liver-related events, which might reflect a faster disease progression in ALD. The results regarding mortality were less accurate. Despite being the most validated NIT for the diagnosis of severe fibrosis/cirrhosis, further validation is needed to advice TE use for prognostic definition in ALD.

Shear Wave Elastography

Other LS measurement techniques include point shear wave elastography (pSWE) [53], also known as acoustic radiation force impulse imaging (ARFI), and 2D-shear wave elastography (2D-SWE) [54]. They are implementable on commercially available ultrasonography devices and enable the selection of the region of interest under B-mode echography visualization. The measurements are expressed in m/s or kPa. Like TE, these techniques are influenced by food intake [55] and inflammation [56]. However, they perform better in the presence of ascites and obesity and have reported failure rates of around 2–4%, significantly lower than TE [57–60].

The accuracy of pSWE/ARFI and 2D-SWE was addressed in large meta-analyses with 3951 and 1134 participants, respectively, concluding that both had good to excellent yield in detecting advanced fibrosis and cirrhosis [59, 61]. The comparison between pSWE/ARFI and TE performances has also been systematically analyzed, in a 1163-patients study, that did not report significant differences [57]. A prospective 349-participant study comparing 2D-SWE, pSWE/ARFI and TE

concluded that 2D-SWE was superior to TE in identifying severe fibrosis but not cirrhosis, in which all three methods were similar [62]. There was a tendency towards 2D-SWE being better predicting milder stages of fibrosis, a finding that had been previously reported [63]. In the majority of these studies, ALD was not frequently represented nor separately analyzed.

Regarding specifically ALD, a 99-participant study found pSWE/ARFI to be accurate in identifying severe fibrosis/cirrhosis in the presence of normal alanine aminotransferase (ALT), with a threshold of 1.41 m/s for cirrhosis [64]. This cut-off rose to 1.65 m/s when ALT was elevated, with much lower diagnostic yield. These results are in line with a 82-patient study on alcoholic detoxification that reports a cirrhosis cut-off of 1.94 m/s [65]. The fact that these patients had continuous alcohol consumption and elevated baseline AST may explain the higher cirrhosis threshold values. A more recent cohort of 251 participants reported higher diagnostic yields with cut-offs for severe fibrosis and cirrhosis of 1.47 and 1.66 m/s, respectively [66]. Contrary to previous evidence, pSWE/ARFI had excellent accuracy in detecting significant fibrosis. The authors included 138 patients with histologically diagnosed alcoholic steatohepatitis (ASH), in whom LS was higher, with a 2.52 m/s cut-off for cirrhosis with ASH. However, there was an important overlap between patients with cirrhosis without ASH and patients with ASH without cirrhosis, which highlights the limitations of SWE in identifying ASH when cirrhosis is not previously confirmed. Nevertheless, in known cirrhotic patients, SWE might help obviate liver biopsy as well as unnecessary corticosteroid treatment.

There are few studies evaluating 2D-SWE accuracy on ALD patients. A prospective study of 199 participants with alcohol abuse history concluded that 2D-SWE and TE had equally high accuracy in detecting severe fibrosis and cirrhosis, with high NPV in both secondary and primary care settings [60]. The authors propose dual thresholds with optimal cut-off values of <12.1 kPa to exclude and >27.3 kPa to rule in cirrhosis. Regarding CSPH diagnosis by elastography, a 328-participant meta-analysis, with more than half ALD patients, could not report reliable LS cut-offs, probably because the majority of patient had previously experienced cirrhosis decompensation [67]. The authors concluded, nevertheless, that a 2D-SWE LS cut-off of <14 kPa should be further studied in cACLD. Subgroup analysis of ALD and comparing abstinent versus non-abstinent patients did not reveal significant differences.

Despite suboptimal results in CSPH, 2D-SWE has revealed prognostic value in ALD. In a cohort of 462 patients with 4-year median follow-up, 2D-SWE predicted liver-related events with excellent accuracy, similar to TE [34]. In a cohort of 1827 chronic liver disease patients (including 414 with ALD), a 2D-SWE LS cut-off ≥20 kPa combined with model for end stage liver disease (MELD) score ≥10 was associated with 36.9% 2-year mortality and 61.8% 2-year decompensation rate, contrasting with rates of 1.1% and 3.5%, respectively, if none of the two criteria was fulfilled [68]. This model displayed similar results for cACLD, for patients with previous decompensations and for specific aetiologies, including ALD.

Overall, pSWE/ARFI and 2D-SWE show similar diagnostic and prognostic value as TE, with the above-mentioned practical advantages. Technical guidelines have been published, standardizing both techniques and recommending their use in viral hepatitis [69]. Further validation is needed to advice their practice in ALD.

Magnetic Resonance Elastography

Magnetic resonance elastography (MRE) uses a modified MR phase to image the propagation characteristics of shear waves, translating the results in kPa [70]. Contrary to other methods, MRE has the ability to examine the entire liver and is not limited by obesity and ascites. However, it is a time-consuming expensive method not routinely available in clinical practice. In a study with 90 ALD patients, MRE showed excellent accuracy in detecting severe fibrosis and cirrhosis with 3.31 and 4.0 kPa cut-offs, respectively, using TE as the reference [71]. AST values did not influence these results, however, since biopsy was not preformed, the influence of inflammation is uncertain. No further disease-specific studies were conducted.

Combined and Sequential Non-invasive Tests Strategies

Given the higher applicability and availability of biomarkers and the general higher diagnostic accuracy of LS measurement methods, it has been postulated that strategies combining these groups of NITs could be beneficial. A previously mention analysis regarding the minimum acceptable accuracy of NITs concluded that sequential NITs performed better than isolated ones, regardless of cirrhosis prevalence [17].

In low prevalence scenarios, like patients with harmful use of alcohol in primary care, the evidence aligns towards the use of a serum biomarker to rule out advanced fibrosis, with further testing needed to make a positive diagnosis. This strategy increases diagnostic yield and reduces unnecessary referrals to liver specialists [11]. Sequential NITs also proved to be cost-effective in ALD when severe fibrosis/cirrhosis prevalence is taken into account [72]. Sequential strategies have been proposed with high accuracy for ALD in low cirrhosis prevalence populations, including: ELF® followed by a LS measurement if ELF® >10.5 [72]; Forns index, ELF® if Forns >4.1 [15] and LS if ELF® >10.5 [15, 72]. In contrast, in secondary/tertiary settings with high cirrhosis prevalence, the sequential use of biomarkers followed by LS measurement is not superior to direct referral for a LS method and might result in increased false positive risks and higher health costs [15, 25, 30].

There is lack of evidence concerning the prognostic value of combining NITs. Combinations of MELD with LS measurements and with biomarkers have been proposed with interesting results in liver-events prediction, but inconsistent ones regarding mortality [31, 68].

Conclusions

Non-invasive identification of advanced stages of fibrosis is of crucial importance in ALD in order to define preventive actions against the occurrence of liver related events. Several NITs have been tested in ALD populations with high diagnostic yield. Serum biomarkers are valuable tools, mostly to exclude severe fibrosis in low cirrhosis prevalence populations. In case of positive results, the sequential use of a LS method is recommended, provided that alcohol consumption and biochemical evidence of inflammation are excluded or minimized. In high prevalence scenarios, LS techniques are preferable. TE is the most validated LS method, despite the increasing evidence for other SWE techniques with important practical advantages. Disease-specific threshold values for advanced fibrosis/cirrhosis have been proposed, with dual cut-offs providing optimal sensibility and specificity. In terms of prognosis assessment, both biomarkers and LS methods have displayed value, however, sufficient evidence for disease-specific recommendations is lacking.

Chapter 40
Noninvasive Biomarker Screening and Alcohol-Related Liver Disease in the General Population

Ellen Lyngbeck Jensen and Maja Thiele

Abstract Alcohol-related liver disease is present in 4–9% of the population and occurs after years of excessive drinking. Liver cirrhosis develops after decades of heavy drinking, but the accumulation of liver fibrosis which accumulates into cirrhosis is asymptomatic and not detectable by either clinical acumen or the routine liver blood tests available to primary care. Consequently, 75% of patients are diagnosed when symptoms and decompensation occur. At this time, prognosis is poor, and the effect of alcohol rehabilitation diminished. Consequently, there is a need for case-finding efforts in primary care or the population. This could be in the form of population-based screening programs, or opportunistic testing when patients visit their general physician for other reasons. There are clear advantages of early disease detection of alcohol-related liver disease, most notably the opportunity to deliver effective interventions to treat harmful use of alcohol or alcohol dependence, thereby improving health and quality of life. Yet, there are also possible negative consequences of screening, for example in the form of overdiagnoses and anxiety/worry induced by fear of disease. Unfortunately, we still lack evidence for the benefits and harms of screening for alcohol-related liver disease in the population. In line with this, the biomarkers commonly used for screening for fibrosis in low prevalence populations such as primary care lack diagnostic accuracy. In the future, more accurate biomarkers such as patented blood-based tests or elastography may be available to screening programs, but this would require reduced costs, improved knowledge for their use by general practitioners, and wider availability.

The Burden of Alcohol-Related Liver Disease

In a global context, excessive use of alcohol has become an increasing problem, with 1.3 billion of the adult world population consuming levels of alcohol that poses a possible risk to their health (above the non-drinker equivalent) [1]. Europe has the highest alcohol consumption in the world [2]. More information is available in part I of the book. The liver is the most common organ to be affected by alcohol-related harm, with 335,000 annual deaths from alcohol-related cirrhosis, corresponding to one in eight of all deaths attributed to alcohol [3]. Depending on the amount and duration of alcohol consumption, 5–15% will develop severe liver fibrosis or cirrhosis, making alcohol-related liver disease (ALD) the most frequent cause of severe liver disease in Europe [4, 5].

ALD in the population includes steatosis, steatohepatitis, progressive liver fibrosis, and cirrhosis [6]. All the types of ALD suffer from increased all-cause, liver-related and cancer mortality [7, 8]. Patients with cirrhosis experience the highest rates of liver related complications and mortality, but even in patients with moderate fibrosis (Kleiner fibrosis stage F2, where F0 is no fibrosis and F4 is cirrhosis), one study found a 20% the rate of liver related events within 4 years [9]. Further, patients with ALD and concomitant metabolic comorbidity in the form of obesity, insulin resistance and dyslipidaemia exhibit two to three times the risk of progressive fibrosis and development of decompensation as those without [10, 11].

The age-standardised prevalence of alcohol dependence is 1.3% globally, ranging from <1% in most of Asia and 1.9% in North America, up to 4.2% in Eastern Europe [11]. Beyond dependence, far more are excessive drinkers: 4–9% of Europeans report weekly drinking above the recommended limits [2, 12–14]. Despite the large burden of disease and the availability of effective treatments in the form of behavioural and pharmaceutical alcohol rehabilitation, most cases of ALD are diagnosed at a late stage, for 75% of patients when decompensation occurs [15–17]. When ALD is discovered this late, the survival benefit of alcohol abstinence is substantially attenuated, quality of life is severely impaired, and only 12% of patients will still be employed or under eduction, compared to 59% 10 years before the diagnosis [18, 19].

Consequently, there is an urgent need to detect asymptomatic ALD patients with presence of moderate or severe fibrosis before transition to decompensated cirrhosis has occurred. Accurate case finding of these patients, for example through screening or referral programs, will allow for timely promotion of abstinence, treatment of comorbid risk factors, socioeconomic interventions, and monitoring for progression, which, in the end, may improve survival [20].

Arguments for Screening in the General Population

One of the major problems with current referral pathways for ALD is that they rely on the general practitioner's (GP) clinical acumen in combination with routine liver blood tests [21]. These methods are characterised by poor sensitivity and specificity

for detecting fibrosis and compensated cirrhosis [22]. As a result, less than one-third of referrals from primary to secondary care are on time, while 54% are futile referrals having no or mild fibrosis, and 17% are referred too late, with decompensated cirrhosis [23]. This pattern of wasteful use of health care resources, high rate of overdiagnoses, and high rate of missed diagnoses continue despite ample opportunities for case finding among patients with an alcohol use disorder. For example, 5% of patients with any contact to the healthcare system with problems related to alcohol, from intoxication to dependence, develops cirrhosis within 11–12 years [24]. Beyond hospital care, it is highly likely that patients at risk of progressive ALD even more frequently visit their GP. A UK survey found that men who died from alcohol-related causes, mostly cirrhosis, had seen their GP on average 24 times in their lifetime, 5 times for women. One in five had no record of ever having been advised to abstain from alcohol [25]. This emphasizes the need for (a) improved detection of alcohol use disorder in primary care and subsequent use of validated alcohol-rehabilitation treatments; (b) systematic detection of those with severe fibrosis, or at highest risk of progressing to liver-related outcomes, for people with a harmful use of alcohol in general population or in primary care practices, followed by referral to secondary care.

Some evidence suggests that unselected, broad population-level screening for liver fibrosis may not be practical or accurate due to many false positives and false negatives when using the currently available tests. An example is FIB-4, which is cheap, but has a low discriminative accuracy for detecting significant fibrosis (fibrosis-4 algorithm, consisting of age, platelet count, AST and ALT) [26]. However, more accurate tests such as transient elastography may be cost-effective both in the general population and in patients at risk of ALD [27, 28].

The main advantage of case finding on a population level is timely referral to alcohol rehabilitation. Today, less than 10% of people who are eligible for alcohol rehabilitation treatment receives such treatment [29]. Participation in an opportunistic screening program may lead to higher disease awareness among both patients and physician, potentially increasing delivery of brief interventions or referral to alcohol treatment. There are also some indications that the screening result in itself may be used as biofeedback and increase motivation for and adherence to alcohol treatment [30]. A UK pilot study showed that a higher proportion of screened patients with evidence of liver fibrosis by a simple algorithm (the Southhamptom traffic light score) had decreased AUDIT during follow up than the group with a negative screening test [31]. Of interest, the group with a negative screening test also decreased alcohol intake and AUDIT score. Improved delivery of effective alcohol interventions has a particular advantage for patients with severe ALD, where alcohol rehabilitation rapidly improves survival [32, 33].

Pitfalls of Screening for Alcohol-Related Liver Disease in the population

When considering implementing a screening program, the negative consequences of screening need to be investigated [34]. Negative consequences of screening include overdiagnoses, unnecessary invasive diagnostic procedures, and psychological stress or anxiety for participants, the latter especially in case of a positive test. Those aspects are not yet determined for ALD screening in the population.

Another pressing issue is the question of effects. All studies on screening programs so far have case finding of advanced fibrosis or compensated cirrhosis as their primary outcome [12, 35]. None have shown improved survival or reduced liver-related morbidity in the screened group, compared to a non-screened group. These hard outcomes are best evaluated in a randomized controlled trial, as known from cancer screening [36]. This has not been done yet. Unfortunately, progression time from severe fibrosis to clinical events or death is longer than for premalignant lesions or small cancers, why a randomized screening trial would likely need at least 5 years of follow up to show any effect on clinical outcomes. Similarly, in contrast to cancer, it is difficult to establish what the screening target should be, as a form of "premalignant" condition: advanced fibrosis? Significant fibrosis? Compensated cirrhosis? For this to be evaluated, we need more detailed information on the natural history of ALD in an unselected background population, rate of competing risks in the form of non-liver related death, and progression rates from each fibrosis stage according to age, gender, level of drinking and comorbidities.

From a health economic perspective, a screening program can be very costly, and the costs and benefits of screening must therefore be thoroughly examined. The few health economic studies conducted so far suggest that screening for ALD will be highly cost-effective [27, 28, 37].

Furthermore, unselected screening or opportunistic screening for ALD will likely lead to more health inequality, as it is known that people of low socioeconomic status more often opt out of screening [38]. As ALD already suffer from substantial health inequality, a screening program may not find those at highest need for investigations and treatment [18]. A further worry regarding adherence to screening is the misconceptions regarding the ability and availability of interventions to 'do something' about ALD, not just among physicians, but also among ALD patients [39]. Stigma towards alcohol and ALD likely contributes to the pessimistic expectations to interventions [40, 41].

Finally, screening programs depend on the availability of non-invasive tests with very high negative predictive values (NPV) to ensure low false negative rates, but without losing diagnostic ability to rule in, to avoid a high number of false positives. In a low prevalence population with for example 10% cases, flipping a coin will have a NPV of 90%. Consequently, tests with NPV's of 90% should not be celebrated, as high NPV is an overestimation of a test's discriminative ability. Rather, the NPV should be appraised in the context of the disease prevalence. Opposite to NPV, the positive predictive value (PPV) will be low in low prevalence populations. If disease prevalence is 10%, the PPV of a test with a 95% sensitivity and specificity

will still only be 68%. Consequently, a confirmatory diagnostic test should be planned in all screening positive cases.

Who to Screen for Alcohol-Related Liver Disease?

As in other screening programs, considerations about the target group should be discussed. In at-risk populations with a self-reported history of long-term excessive drinking, the prevalence of ALD ranges between 2% and 5%, but there are big differences depending on drinking history, age, gender, and metabolic or genetic risk. Selecting participants based on such predictors increases pre-test risk of disease, thereby increasing PPV of a screening test.

For drinking history, a cut-off for average alcohol intake of 30 g/day for a minimum of 1–5 years will likely suffice as decision threshold for conducting a non-invasive liver screening test [42, 43]. Women are more susceptible to alcohol-induced liver damage, but there are more heavy drinkers among men, so a selection based on gender is likely not effective. Most patients with ALD cirrhosis are diagnosed at age 50–60 years. Consequently, screening could be initiated at age 30–40 years. In line with this, a Swedish population study found that excess drinking in adolescent adults aged 18–20 years investigated at conscription to military service predicted later occurrence of cirrhosis [44]. The cumulative incidence of cirrhosis in high-risk drinkers departed from controls 5 years after inclusion, but only after 15 years had 1% developed cirrhosis. As mentioned above, concomitant metabolic and genetic comorbidity also increases the risk of advanced fibrosis in ALD patients and could be considered as means to increase disease prevalence prior to testing [10].

An opportunistic screening program where patients with a history of harmful drinking from age 30 or 40 are offered non-invasive testing for liver fibrosis when they visit their general practice would fit in the primary health care system. However, such set up require accurate, effective non-invasive tools to either detect significant or advanced fibrosis, or risk stratify according to prognosis for liver-related events.

Non-invasive Biomarkers for Screening in the Population

Liver biopsy is the gold standard for staging fibrosis in ALD [21]. However, this method is not suited for a screening program because it is invasive, require costly specialist healthcare resources, is time consuming, and far from point of care. Fortunately, several non-invasive methods to assess liver fibrosis have been validated for use in ALD [21, 45]. These are based on either a physical methodology with liver stiffness measurements (LSM) by elastography, or a biological methodology using blood-based biomarkers alone or combined in algorithms [46]. The commonly used non-invasive biomarkers have different advantages and disadvantages for use in primary care or the population, most notable differences in availability, cost, and existence of cut-offs which are validated for ALD (Table 40.1).

Table 40.1 Promising biomarkers for risk stratification and fibrosis staging in early alcohol-related liver disease

Test	Description	Proposed cut-off	Costs	Availability in primary care	Disadvantages
Blood-based tests: Algorithms from routine liver blood tests					
FIB-4	Simple algorithm from age, AST, ALT, platelet count	<1.30 to rule out and ≥2.67 to rule in advanced fibrosis.	$	Good; can be calculated automatically in electronic laboratory systems.	Many false positives. Not accurate for diagnosis. False negatives if age < 35, false positives if age > 65.
APRI	Simple algorithm from AST and platelet count	<0.5 to rule out and ≥1.50 to rule in advanced fibrosis.	$	Good; can be calculated automatically.	Less accurate as FIB-4 in head-to-head comparisons, especially in ALD.
Forn's index	Regression algorithm from age, GGT, cholesterol and platelet count	<4.2 to rule out and ≥6.9 to rule in advanced fibrosis.	$	Good; can be calculated automatically.	Few studies in ALD and in low prevalence populations. Cut-offs not well-validated
NAFLD fibrosis score	Regression algorithm from age, BMI, presence of diabetes, AST, ALT, albumin and platelet count	<−1.455 to rule out and ≥0.676 to rule in advanced fibrosis.	$	Good	Targets NAFLD, not ALD. Need for dedicated calculators to include BMI and diabetes.
Blood-based tests: biomarkers which directly reflect fibrosis					
FibroTest	Patented algorithm of age, gender, bilirubin, GGT, a2-macroglobulin, apolipoprotein A1, and haptoglobin	<0.48 to rule out and ≥0.58 to rule in advanced fibrosis.	$$	Moderate; used in France and marketed in US as FibroSure (company Biopredictive)	Few studies in ALD. One study in low prevalence population. Cut-offs not well-validated
FibroMeter	Patented algorithm of age, body weight, glucose, AST, ALT, ferritin and platelet count	0.254< to rule out and 0.585≥ to rule in advanced fibrosis [47]	$$	Moderate, commercially available (company Echosens)	No studies for screening in low prevalence populations. Cut-offs from tertiary healthcare.

Table 40.1 (continued)

Test	Description	Proposed cut-off	Costs	Availability in primary care	Disadvantages
HepaScore	Algorithm of age, gender, bilirubin, GGT, a2-macroglobulin, and HA	No widely agreed cut-offs	$$	Used in Australia	No studies for screening in low prevalence populations
ELF test	Patented algorithm of PIIINP, HA, TIMP1	No accepted cut-off to rule out; ≥9.8–10.5 to rule in advanced fibrosis.	$$$	Moderate, used in UK and authorized by FDA for US (company Siemens Healthcare)	No studies for screening in low prevalence populations
ProC3	Propeptide of type 3 collagen	No widely agreed cut-offs	$$$	Low, only recently made available on a Roche Cobas (company Nordic Bioscience)	Few studies in ALD. No studies for screening in low prevalence populations
Elastography methods					
pSWE	Also known as Acoustic radiation force impulse, ARFI. Software addition to regular ultrasound.	No widely agreed cut-offs due to many manufacturers, but <1.3–1.7 m/s to rule out and ≥1.7–2.1 m/s to rule in.	$$$	Moderate, available in most medium- and high-end ultrasound equipment	Few studies in ALD and in low prevalence populations. Cut-offs not well-validated
TE	Transient elastography (Fibroscan, Echosens)	<8 kPa to rule out, and ≥15 kPa to rule in advanced fibrosis	$$$$	Moderate, available in some nurse-led FibroScan clinics	False positives in case of liver inflammation (disadvantage of all elastography techniques)
2D-SWE	Software addition to some high-end ultraound equipment	No widely agreed cut-offs to rule in and rule out	$$$$	Low	Few studies in ALD. No studies for screening in low prevalence populations. Cut-offs not well-validated

(continued)

Table 40.1 (continued)

Test	Description	Proposed cut-off	Costs	Availability in primary care	Disadvantages
MRE	Magnetic resonance	No widely agreed cut-offs to rule in and rule out	$$$$$	Low	Few studies in ALD. No studies for screening in low prevalence populations. Cut-offs not well-validated

Based on publications: [45, 46, 48, 49]
2D-SWE 2-dimensional shear wave elastography, *ALT* alanine transaminase, *APRI* AST-platelet ratio index, *AST* aspartate transaminase, *ELF* enhanced liver fibrosis test, *GGT* gamma-glutamyl transpeptidase, *HA* hyaluronic acid, *PIIINP* propeptide of collagen type 3 N-terminal, *pSWE* point shear-wave elastography, *TE* transient elastography, *TIMP1* tissue inhibitor om metalloproteinase-1

Transient elastography (TE) has emerged as the referral standard for non-invasive markers due to its validation for ALD in several diagnostic studies [9, 45, 50, 51]. More details are provided in the respective chapter within this book part. TE has also been investigated for describing fibrosis prevalence in large, low-prevalence populations from mostly Europe, but also North America and Asia [27, 35, 52–56]. These studies often use 8 kPa as the screening cut-off, because, with a sensitivity of 93%, it rules out advanced fibrosis with very high accuracy [57]. The advantages of TE consist of the technique being ultrasound-based which makes it fully non-invasive, and point-of-care, providing the answer immediately. The disadvantage of TE is that the equipment is expensive, both for purchase costs and for an annual calibration fee. However, the FibroScan equipment for TE requires less experience and not dedicated ultrasound knowledge is necessary as compared to 2D-SWE. Finally, elastography may suffer from larger variability than the blood-based tests, especially for patients with elevated LSM [52, 58].

The current recommendation by European guidelines is to initiate case finding in people at risk of liver disease by a history of excess drinking [21]. Next, usage of a cheap algorithm calculated from routinely available liver blood tests, preferably the FIB-4, which seems to perform best among the const-moderate, non-patented blood tests. In case of a FIB-4 above 1.30, the physician may consider referring the patient to LSM by TE. However, this approach was recently criticised, since one-third of patients with FIB-4 $\geq$ 1.30 have liver stiffness below 8 kPa, leading to over-referrals, and FIB-4 was below 1.30 in up to half of patients with highly elevated LSM indicative of severe fibrosis, leading to false negatives [26]. Consequently, a future approach may be a more expensive, but more accurate blood test to select patients

from primary care to referral for LSM [59]. An alternative future approach is to use one of the cheap algorithms first, for example FIB-4, followed by a confirmatory more expensive blood test in case of elevated FIB-4, and only refer those where both blood tests are elevated for LSM [60].

Chapter 41
Evidence for Red Blood Cell-Derived Aspartate Aminotransferase in Heavy Drinkers

Sebastian Mueller

Abstract Serum transaminase aspartate transaminases (AST/GOT) and alanine transaminase (ALT/GPT) are frequently elevated in alcohol-related liver disease (ALD) and show a typical profile in heavy drinkers with AST being higher as ALT. So far, this has been attributed to the hepatic mitochondrial isoform of AST. Based on recent novel findings in humans and animals, this chapter, however, demonstrates that AST is rather derived from hemolyzed red blood cells (RBC). First, prospective mortality data in heavy drinkers identify hemolytic anemia as novel and most important long-term predictor of survival. Second, in difference to patients with viral hepatitis, AST levels are elevated constantly in ALD throughout all fibrosis stages. Of note, AST-derived from human RBCs not only matches basal serum AST levels in healthy volunteers but also their daily RBC turnover due to RBC recycling. In addition, and third, in a mouse model of mild hemolysis using phenylhydrazine, AST levels are significantly and transiently elevated and follow the kinetics of hematocrit and LDH. Almost no changes of ALT are observed in this model. Finally, during alcohol detoxification of heavy drinkers, AST levels resolve much faster than ALT and correspond to other hemolytic markers. In conclusion, these data suggest that elevated AST and de Ritis ratio in drinkers are likely due to hemolysis and enhanced RBC turnover. These observations should be further confirmed in in vitro erythrophagocytosis studies. The potential ingestions of senescent RBCs by hepatocytes (efferocytosis) also requires further attention as well as the possible contribution of RBC-AST to hepatocyte transamination.

Keywords AST · ALT · Liver transaminases · Red blood cell · Hemolysis · De Ritis ratio

Introduction to Serum Transaminases

Elevation of transaminases are commonly seen in patients with alcohol-related liver disease (ALD) [1]. Two major transaminases are known: Aspartate aminotransferase (AST), formerly called glutamic oxaloacetic transaminase (GOT, EC 2.6.1.1) and alanine aminotransferase (ALT), formerly known as glutamic-pyruvic transaminase (GPT, EC 2.6.1.2). Both names are still widely used throughout the world. Transaminases or aminotransferases are enzymes that catalyze a transamination reaction between an amino acid and an α-keto acid (Fig. A.48). In the following, the biochemistry of transaminases and their medical use for diagnosis is briefly described. Serum transaminases are elevated in alcohol-related liver disease (ALD) and show a typical profile in heavy drinkers with AST being higher as ALT. So far, this has been attributed to the hepatic mitochondrial isoform of AST.

Data presented in this chapter suggest that elevated AST in drinkers is likely due to hemolysis and enhanced RBC turnover which has important clinical and pathophysiological implications.

Biochemistry of Transaminases

AST and ALT were discovered in 1954 [2]. The transaminases are important for the production of various amino acids. Determination of transaminases in the blood is important for diagnosing many diseases. Transaminases require the coenzyme pyridoxal phosphate (PLP, Vitamin B6), which is converted into pyridoxamine in the first half-reaction (see also Fig. A.48). In this process, the cofactor shuttles between PLP and the pyridoxamine phosphate (PMP) form [3]. Enzyme-bound pyridoxamine in turn reacts with pyruvate, oxaloacetate, or alpha-ketoglutarate, giving alanine, aspartic acid, or glutamic acid, respectively. Many transamination reactions occur in tissues, catalyzed by transaminases specific for a particular amino/keto acid pair. The amino group transfer catalyzed by this enzyme is crucial in both amino acid degradation and biosynthesis. In amino acid degradation, following the conversion of α-ketoglutarate to glutamate, glutamate subsequently undergoes oxidative deamination to form ammonium ions, which are excreted as urea. In the reverse reaction, aspartate may be synthesized from oxaloacetate, which is a key intermediate in the citric acid cycle. Animals metabolize proteins to amino acids, at the expense of muscle tissue, when blood sugar is low. The preference of liver transaminases for oxaloacetate or alpha-ketoglutarate plays a key role in guiding nitrogen from amino acid metabolism to aspartate and glutamate for conversion to urea for excretion of nitrogen. In a similar manner, in muscles, the use of pyruvate for transamination gives alanine, which is carried by the bloodstream to the liver (the overall reaction being termed **glucose-alanine cycle**). Here other transaminases regenerate pyruvate, which provides a valuable precursor for gluconeogenesis. This alanine cycle is analogous to the **Cori cycle**, which allows anaerobic metabolism by muscles [4].

Transaminases in ALD and De Ritis Ratio

The **AST/ALT ratio** or **De Ritis ratio** is the ratio between the concentrations of AST to ALT in the blood of humans or animals [5]. It is useful in medical diagnosis for elevated transaminases to differentiate between causes of liver damage, or hepatotoxicity [6]. An AST to ALT ratio of 2:1 or greater is suggestive of alcohol-related liver disease, particularly in the setting of an elevated gamma-glutamyl transferase [7]. The AST to ALT ratio can also occasionally be elevated in patients with nonalcoholic steatohepatitis (NASH). In addition, patients with Wilson's disease or cirrhosis due to viral hepatitis may have an AST that is greater than the ALT, though the ratio typically is not greater than two. AST may be also elevated due to cardiac ischemia or muscle inflammation. For example, muscle inflammation due to dermatomyositis may cause AST > ALT. It is important to note that, besides clinical information, additional laboratory parameters such as creatine kinase or troponins will help to further dissect the origin of the transaminases. Intense exercise is also able to increase ALT to 50–200 U/L, and AST to 100–1000 U/L [8]. Most causes of liver cell injury are associated with a greater increase in ALT than AST.

Tissue Distribution of AST/GOT

Two isoenzymes of AST are present in a wide variety of eukaryotes. In humans: AST1/GOT1/cAST, the **cytosolic** isoenzyme derived mainly from red blood cells and heart. Already in the first report [2], the high abundance of AST in RBCs had been described. AST2/GOT2/mAST, the **mitochondrial** isoenzyme, is present predominantly in liver. These isoenzymes are thought to have evolved from a common ancestral AST via gene duplication, and they share a sequence homology of approximately 45% [9]. ALT is found predominantly in the liver, with clinically negligible quantities found in the kidneys, heart, and skeletal muscle, while AST is found in the liver, heart (cardiac muscle), skeletal muscle, kidneys, brain, and red blood cells. As a result, ALT is considered to be a more specific indicator of liver inflammation than AST, as AST may be elevated also in diseases affecting other organs, such as myocardial infarction, acute pancreatitis, acute hemolytic anemia, severe burns, acute renal disease, musculoskeletal diseases, and trauma. The half-life of total AST in the circulation approximates 17 h and, on average, 87 h for mitochondrial AST. Aminotransferase clearance is carried out within the liver by sinusoidal cells [10].

Transaminases in Patients with ALD: Is AST Rather RBC Derived?

In contrast to common believe, AST in alcohol consumers seems to be most likely not derived from the liver but rather from red blood cells. The existence of AST in RBCs had already been described in the first publication and seems to have been

neglected over the years [2]. In most text books, this is not mentioned anymore and AST is usually related to the mitochondrial isoenzyme form. However, it has been always somehow contradictory, why, in the context of hepatotoxicity, AST should be higher based on mitochondrial localization. If mitochondria are damaged the hepatocyte will also die and, eventually be taking up through efferocytosis by neighbouring cells. Even most medical laboratories do not provide anymore specific information as to which isoform is actually measured in patient sera.

Differences between AST and ALT can be seen in the large Heidelberg cohort of heavy drinkers depending on fibrosis stage (see Table B.5). AST elevation is seen in ca. 60% of all patients, more in patients with advanced fibrosis stages (69% vs. 52%). In contrast, ALT is elevated in F0-2 in 42%, and in 37% in patients with F3-4. In line with these observations, the de Ritis ratio increases in this cohort from 1.3 for patients with F0-2 fibrosis to almost 2 for F3-4 fibrosis. Notably, AST has almost no prognostic value in heavy drinkers (see Table B.10 and Chap. 7).

In contrast to ALT, AST rather remains stably elevated throughout all fibrosis stages (Fig. A.79 and Chap. 37). Figure 41.1 shows AST and ALT for each fibrosis stage both for ALD and hepatitis C (HCV) as an example of portal liver disease [11]. As can be seen, in contrast to portal HCV, patients who consume alcohol show an almost constant elevation of AST throughout all fibrosis stages. Only in fibrosis stage 3 (F3), which is a rather transient period and normally a small fraction in study cohorts, it is elevated. In contrast, in patients with viral hepatitis, AST continuously increases with fibrosis stage. Thus, Fig. 41.1 demonstrates important differences between HCV and ALD. While AST is almost constantly elevated in heavy drinkers throughout all fibrosis stages, it continuously increases in HCV. Since the liver mass and function is considered to decrease at higher fibrosis stages, the rather constant levels of AST even in cirrhosis stage F4 may indirectly suggest that AST is not directly derived from hepatocytes.

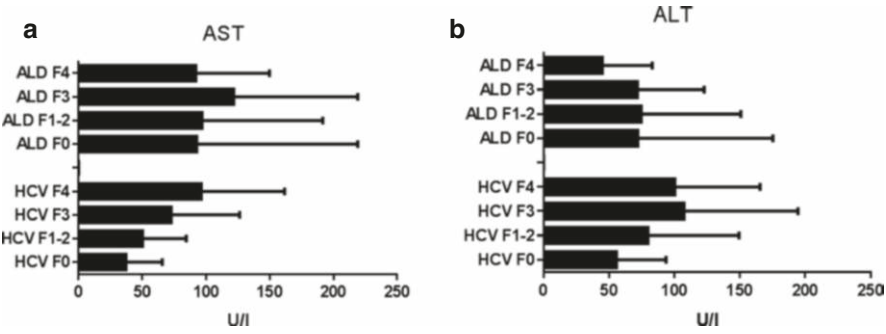

Fig. 41.1 Levels of (**a**) AST and (**b**) ALT in patients with alcohol-related liver disease (ALD) and viral hepatitis C (HCV) depending on fibrosis stage. Note, that AST levels remain rather constant throughout all fibrosis stages in ALD while they continuously increase in HCV. Data are from a multicenter study based on 1391 biopsy-proven HCV and 677 ALD samples [11]

Direct Assessment of AST in Red Blood Cells

The existence of AST in RBCs has already been described in first publications of AST and seems to have been neglected over the years [2]. In a next series of experiments, RBCs from healthy human donors were washed in 0.9% iso-osmotic saline solution three times, then lysed in water, and both AST and ALT activities were measured at the medical laboratory of the University of Heidelberg. As can be seen in Fig. 41.2, at a hematocrit of 1% which corresponds to the daily RBC turnover during physiological RBC recycling, AST levels were 50 U/L, at 5% hematocrit, 200 U/L were reached. In contrast, ALT levels were almost negligible. These data demonstrate that RBC contain significant amounts of AST. It is also interesting to note that AST from an amount of RBCs that are daily recycled due to physiological senescence, already corresponds to basal AST levels in the serum of healthy volunteers.

Tables B.27 and B.28 show Spearman correlations with AST from the 1200 patients of the Heidelberg prospective cohort of heavy drinkers. Only significant correlations are shown in descending order (according to the absolute correlation coefficient r). Accordingly, there are also strong indications that AST is mainly derived from RBCs. AST is highly correlated with hemolysis markers (LDH, indirect bilirubin, CD163 and Haptoglobin). On the other side, it is also clearly associated with liver damage such as liver stiffness (LS), ALT, M65 and M30, histological ballooning and markers of iron overload. These data support the notion discussed in Chap. 57 on iron and ALD, that RBC turnover by erythrophagocytosis and efferocytosis lead to liver damage under conditions of ethanol consumption.

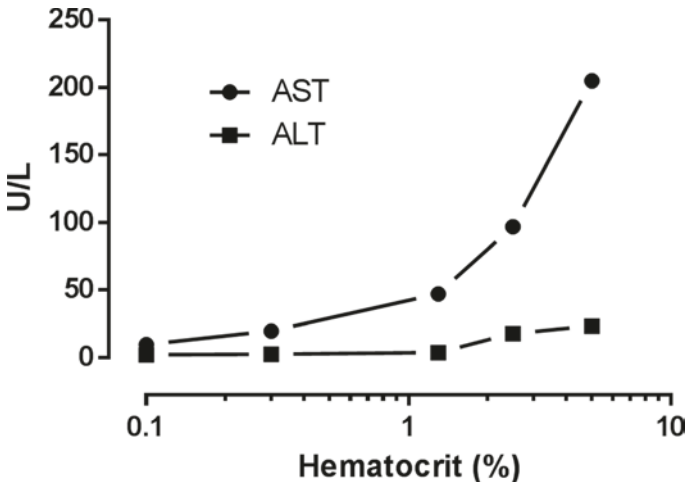

Fig. 41.2 Levels of AST and ALT in washed human red blood cells from healthy volunteer. Representative example. Note that RBCs contain significant AST while ALT is negligible. At a hematocrit of 1% which corresponds to physiological daily RBC turnover, AST levels are in the range of normal basal levels. This suggests that even normal AST levels are mostly derived from RBCs

Transaminase Levels in a Murine Model of Hemolysis

We next studied transaminase levels in mice exposed for 48 h to one injection of 60 mg of the hemolytic agent phenyl hydrazine (PHZ) per kg mouse weight. As can be seen in Fig. 41.3a, hematocrit fell from 48% to 35% in this mild hemolysis model while LDH transiently increased to 1300 U/L (Fig. 41.3b) peaking at ca. 12 h. In line with this (Fig. 41.3c), AST levels increased to almost 600 U/L while almost no change of ALT was observed. Figure 41.3d shows that the heme-binding protein haptoglobin was strongly reduced in response to hemolysis. Of note, in this mice model of hemolysis, mRNA of heme degrading hemoxygenase 1 (HO1) was primarily elevated in the spleen, and so was spleen stiffness. Only a marginal elevation of hepatic HO1 was observed. These data demonstrate that non-toxic hemolysis in mice translates primarily into AST elevation and almost no change in ALT. It should be noted that ethanol exposure of both mice and rats result in higher AST levels and even basal AST levels are already higher as compared to ALT in these animals (not shown).

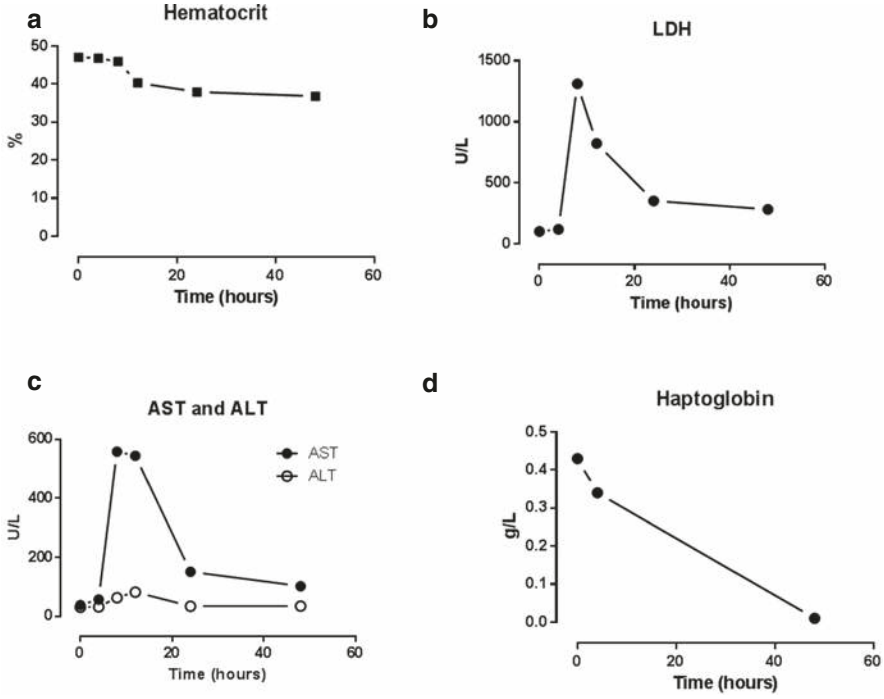

Fig. 41.3 Time course of (**a**) hematocrit (**b**) LDH (**c**) levels of AST and ALT and, (**d**) Haptoglobin in an experimental mouse model of mild hemolysis. Hemolysis was induced using 60 mg per kg phenylhydrazine. Serum was taken at 0, 4, 12, 24 and 48 h. Note that only AST levels increase drastically and transiently during hemolysis, going along with hematocrit, LDH and haptoglobin, but not ALT

Resolution Kinetics After Alcohol Detoxification: Correlation of AST with Hemolysis Parameters

We also analyzed in 19 heavy drinkers the kinetic of AST and various other blood parameters after 1 week of alcohol detoxification. More details about patient characteristics are described in Table B.1. Laboratory parameters were measured in each patient on day 1, 2, 7 and 28. As discussed in more detail in the chapter on bone marrow toxicity, hemoglobin (Fig. 41.4a) slightly decreased after detoxification but recovered after 28 days. During this time, serum LDH and ferritin deceased continuously (Fig. 41.4b, c). A significant difference was seen between AST and ALT. AST fell much faster, already significantly between day 1 and 2, while ALT showed a slower decreased during the whole time period. AST kinetics also corresponded better to kinetics of hemoglobin and LDH that already showed stabilization after 1 week. In contrast, ALT continued to significantly improved in the final weeks of detoxification. We finally, as shown in in Fig. 41.5 and Table B.24, analyzed the association of the erythrophagocytosis marker CD163 with various other laboratory markers. As can be seen in this table, CD163 is highly correlated with indirect bilirubin and shows a twice as high correlation with AST as compared to ALT.

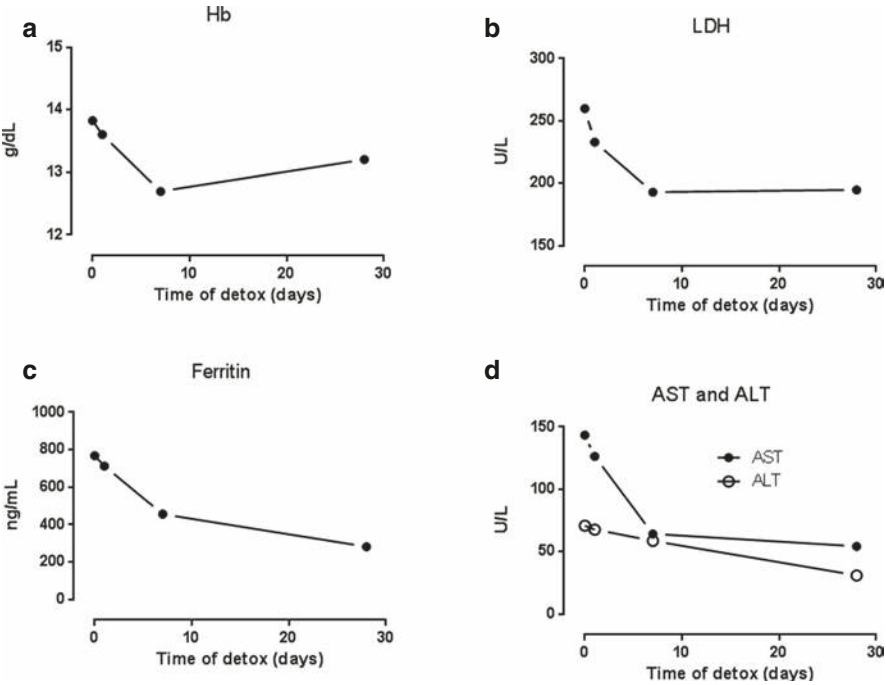

Fig. 41.4 Kinetics of (**a**) hemoglobin (Hb), (**b**) LDH, (**c**) ferritin, (**d**) AST and ALT during alcohol detoxification. Heavy drinkers were withdrawn from alcohol and laboratory parameters were obtained at day 1, 2, 7 and 28 after detoxification. Note that AST levels match the time course of other parameters while ALT shows a very different kinetics. Lab tests are from 19 heavy drinkers

Fig. 41.5 Correlation analysis (Spearman Rho) of the hemolysis marker CD163 with other laboratory parameters. Data are from 304 heavy drinkers. Left panel shows positive correlations, right shows negative correlations. Parameters are sorted according to P value in descending order. Note that CD163 is correlated highly with hemolysis markers (e.g., indirect bilirubin) and AST. The association with ALT is much weaker. The relation between hemolysis and liver damage, namely under ethanol exposure, needs to be studied further

Conclusions and Future Directions

As is discussed and shown in this chapter, RBCs have been described already initially as important source of serum AST. In addition, recent prospective mortality data in heavy drinkers identify hemolytic anemia as important long-term predictor of survival (Chap. 7). Several human and animal data are presented here that suggest that AST is also mainly derived from RBCs in heavy drinkers. Thus, as compared to patients with viral hepatitis, AST levels are elevated constantly throughout all fibrosis stages in patients with ALD. Of note, the AST-derived from 1% washed human RBCs correspond to basal AST levels in healthy volunteers thus matching daily RBC turnover due to RBC recycling. In addition, in a mouse model of mild hemolysis caused by phenyl hydrazine, AST levels are significantly elevated matching the kinetics of hematocrit and LDH while almost no changes of ALT are observed. Finally, during alcohol detoxification of heavy drinkers, AST levels also match the course of hematocrit and LDH, in contrast to ALT. In conclusion, these data suggest that elevated AST and De Ritis ratio in drinkers is likely due to hemolysis and enhanced RBC turnover rather that of mitochondrial origin from hepatocytes. To further confirm these observations, direct specific assessment of erythrocyte AST would be helpful. Moreover, the course of AST should be studied during erythrophagocytosis. It can also not be ruled out that some erythrocyte AST is taken up by hepatocytes directly during so-called efferocytosis (see also Chap. 57). It also remains to be solved how enhanced RBC turnover translates into liver damage during ethanol consumption. Finally, like LDH during hemolysis, it remains to be studied whether AST serves additional purposes after the release into the serum.

Chapter 42
Fibrosis Screening of Alcohol-Related Liver Disease Based on Elastography

Sebastian Mueller and Ioan Sporea

Abstract In alcohol-related liver disease (ALD), transient elastography (TE) to measure liver stiffness (LS) has been demonstrated to have an excellent performance to detect advanced fibrosis and cirrhosis. It correlates well with histological fibrosis stages with a $r > 0.7$ and AUROCs for F3 and F4 fibrosis are typically higher than 0.9. Point and 2D- shear wave elastography (SWE) combine elastography with conventional ultrasound imaging and is also increasingly used in clinical practice for the assessment of LS in ALD. However, the number of published studies is still limited. The initial confusion and controversial debates about varying elastographic cut-off values for fibrosis stages F0–4 in ALD patients is mainly due to inflammation as important confounder of elevated LS. Several studies could show that resolution of liver inflammation due to alcohol withdrawal leads to ca. 20% decrease of LS, within 1 week of alcohol detoxification. Long-term abstinence of more than 5 years seems to further improve LS suggesting partial reversibility of fibrosis. So far, levels of liver transaminases (especially levels of GOT/AST) are providing the best estimate whether LS overestimates histological fibrosis stages due to inflammation. For these reasons, a more accurate fibrosis assessment is obtained either by 1–4 week of alcohol withdrawal and re-measurement of LS or so-called AST-adapted cut-off values that allow for instant fibrosis staging. Moreover, first long-term follow-up data indicate that LS seems to be the best univariate predictor of long-term survival in heavy drinkers. Taken together, liver elastography has drastically improved the screening, early diagnosis and follow-up of fibrosis in patients with ALD. It is expected that the future broader availability of elastographic methods to ALD patients will not only significantly improve the management of the disease, but also help us to finally obtain true prevalence data of this popular, but still underestimated

Introduction

In alcohol-related liver disease (ALD), transient elastography (TE) to measure liver stiffness (LS) has been demonstrated to have an excellent performance to detect advanced fibrosis and cirrhosis. It correlates well with histological fibrosis stages with a $r > 0.7$ and AUROCs for F3 and F4 fibrosis are typically higher than 0.9. Point and 2D-shear wave elastography (SWE) combine elastography with conventional ultrasound imaging and is also increasingly used in clinical practice for the assessment of LS in ALD. However, the number of published studies is still limited. The initial confusion and controversial debates about varying elastographic cut-off values for fibrosis stages F0–4 in ALD patients is mainly due to inflammation as important confounder of elevated LS. Several studies could show that resolution of liver inflammation due to alcohol withdrawal leads to ca. 20% decrease of LS, within 1 week of alcohol detoxification. Long-term abstinence of more than 5 years seems to further improve LS suggesting partial reversibility of fibrosis. So far, levels of liver transaminases (especially levels of GOT/AST) are providing the best estimate whether LS overestimates histological fibrosis stages due to inflammation. For these reasons, a more accurate fibrosis assessment is obtained either by 1–4 week of alcohol withdrawal and re-measurement of LS or so-called AST-adapted cut-off values that allow for instant fibrosis staging. Moreover, first long-term follow-up data indicate that LS seems to be the best univariate predictor of long-term survival in heavy drinkers. Taken together, liver elastography has drastically improved the screening, early diagnosis and follow-up of fibrosis in patients with ALD. It is expected that the future broader availability of elastographic methods to ALD patients will not only significantly improve the management of the disease, but also help us to finally obtain true prevalence data of this popular, but still underestimated disease. There are also preliminary indications that the non-invasive and interactive setting of LS assessment is supporting alcohol withdrawal. Additional schemes and data on elastography/liver stiffness can be found in Figs. A.80, A.81, A.82, A.83, A.84, A.85, A.89, A.90, A.92, and A.93.

Specific Diagnostic Challenges in Patients with ALD

ALD is the most frequent cause of severe liver disease in Europe and according to WHO, more than 40% of the liver deaths are attributed to alcohol consumption [1]. In addition, the number of liver transplantation for patients with ALD-related cirrhosis has increased over the past two decades, both in Europe and in the USA [2, 3]. Despite this high burden of ALD, it is unfortunate that most patients with ALD are diagnosed at the decompensation stage, normally presenting with ascites or jaundice. Moreover, a large proportion of newly diagnosed cirrhosis had recent consultations in primary care or emergency units [4], without any intervention. Alcohol-related liver disease includes a wide spectrum of lesions ranging from steatosis to steatohepatitis, progressive liver fibrosis, cirrhosis and its complications [1]. Although steatosis is almost constant in heavy drinkers, it is estimated that only 10–20% will eventually develop cirrhosis [5]. Since the presence of advanced fibrosis or cirrhosis in compensated patients is the main predictor of long-term survival, it is of clinical importance to diagnose those patients with advanced fibrosis before the decompensated stage, in order to promote abstinence and improve survival [6]. Liver diseases are in general hardly to detect and commonly show no or only mild symptoms. Even end-stage liver cirrhosis remains undetected in routine laboratory testing or ultrasound screening in ca. 40% [7]. The diagnosis of ALD is further complicated by three major challenges: (1) underreporting by patients (2) lack of good biomarkers for alcohol consumption and (3) a rather diverse clinical presentation. These are the reasons why ALD is routinely underestimated, both by physicians and health statistics [8, 9]. Therefore, the diagnosis of ALD normally must rely on a combination of clinical, laboratory, elastographic and imaging findings (Fig. 42.1), where ***liver elastography*** has gained and important novel role for early screening and follow-up [10]. For other non-invasive, e.g., serum tests see other chapters in this book part.

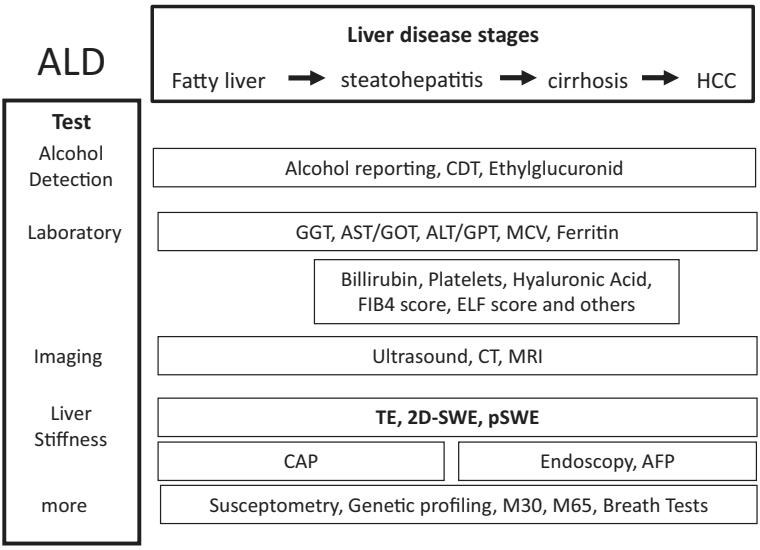

Fig. 42.1 Role of liver elastography within the context of assessing patients with ALD in different disease stages. Note that various clinical, laboratory and imaging tools are used to assess and diagnose ALD patients. Ultrasound-based liver elastography whether 1D-SWE such as TE or 2D- or pSWE elastographic techniques (highlighted in bold) have revolutionized the screening and management of the disease and its complications. There are also indications that elastography is a useful feedback tool for many patients in order to abstain from drinking or cut-down drinking levels

Brief Introduction to Liver Elastography

Ultrasound-based elastographic methods, namely Transient Elastography (TE), have been first introduced in 2003 [10]. Elastography has rapidly gained importance as it allowed within minutes and in a non-invasive manner the accurate screening for liver cirrhosis. Elastography has been so successful as it directly assesses one of the early and most sensitive consequences of liver cirrhosis, an increased stiffness of the liver. Due to the non-invasive nature of elastographic techniques, replicative measurements are possible allowing follow-up studies. First larger cohort studies in patients with ALD were published as of 2008 [11].

In this chapter, we are focusing on quantitative shear wave elastographies (SWE) that should not be mismatched with the qualitative strain elastography (SE) [10, 12, 13].

Transient Elastography was first introduced in 2003 [14] and, consequently, most published data on liver elastography have been based on TE [10]. TE can be also considered a 1D-SWE in comparison to 2D-SWE methods that are integrated or work together with conventional ultrasound imaging devices. Although TE does not allow a simultaneous ultrasound imaging of the liver, it is still the easiest to use system and the most standardized. Typical TE probes and the screen with an actual

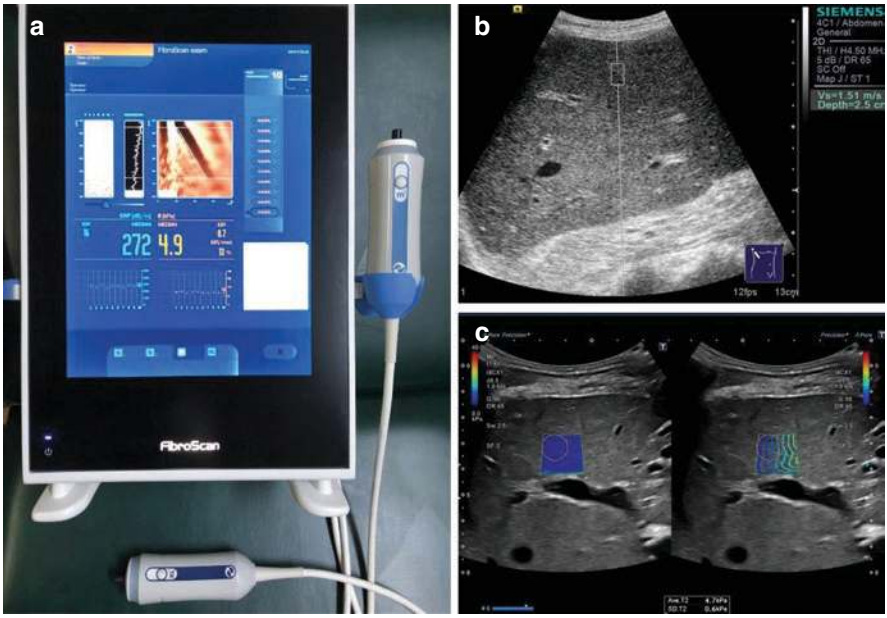

Fig. 42.2 Examples of 1D and 2D ultrasound-based liver elastographies to assess liver fibrosis. (**a**) TE (FibroScan, Echosense) was the first elastographic technic to assess liver stiffness. It does not require dedicated ultrasound knowledge and measurements are highly standardized and interobserver independent. Various probes are available (here shown M and XL probes) and a hepatic steatosis parameter called CAP (controlled attenuation parameter) are also run on the platform. Examples of two 2D-SWE platforms (**b**) pSWE (VTQ from Siemens) and (**c**) 2D-SWE with propagation map from Canon. These platforms have the advantage of being integrated in a conventional ultrasound imaging device but dedicated ultrasound knowledge is required. In addition, elastography can be measured in other tissues but standardization is still a challenge

measurement is shown in Fig. 42.2a. Briefly, in TE, a 50 Hz probe induces a shear wave within the liver whose propagation is quantified with a co-integrated 3.5 MHz ultrasound probe. The liver stiffness is directly and automatically calculated from the shear wave speed. In cases of measuring artifacts or low quality measurements, TE usually will not deliver any LS data. Together with the early well standardized conditions for LS measurements, these criteria have been responsible for the rather low inter- and intraobserver variability with TE. Recently, a liver fat-assessing parameter has been introduced on the TE platform which is called CAP (Controlled Attenuation Parameter). In contrast, 2D-SWE methods have been later introduced to the market and a provide a much larger freedom to the examiner. On the other side, this increased freedom requires experienced ultrasound knowledge and increases the risk of errors. In addition, elastographic platforms have drastically increased on the marked while standardization is significantly lacking behind which has created some confusion with regard to comparability between various techniques. 2D-SWE platforms now also provided fatty liver-assessing parameters. Two examples are shown in Fig. 42.2b, c. For more details, the reader may be referred to

recent publications or guidelines [10, 12]. Since most studies on ALD have been performed with TE, this chapter focuses mainly on this elastographic technique and uses TE-based cut-off values. An update of the first 2D-SWE data will be provided at the end of the chapter.

Elastography in Comparison to Other Alternative Methods to Assess Fibrosis

Although ALD follows the typical sequence of chronic liver diseases including alcoholic fatty liver, steatohepatitis, fibrosis and eventually cirrhosis (Fig. 42.3), the early recognition of severe steatohepatitis and alcoholic cirrhosis is most important since it will save lives, prevent complications and initiate follow-up programs [7]. Most important clinical end points are alcoholic liver cirrhosis and the rare and clinically defined severe alcoholic hepatitis (AH). AH should not be mismatched with the commonly and histologically detectable steatohepatitis (ASH) (Fig. 42.2). Since AH is very rare, typically presents clinically with pronounced jaundice (see also part X) and there are still no early predictors, screening for liver problems in heavy drinkers should primarily focus on the screening for fibrosis [7]. Although liver biopsy is still essential in some patients with liver diseases in establishing the definite diagnosis or in ruling out additional or other causes of the disease, elastographic techniques are the novel gold standard in assessing liver fibrosis. First, liver biopsy is invasive and can cause significant complications in up to 7% [15]. Complications can encompass mild (pain and small bleedings in 6%) or severe

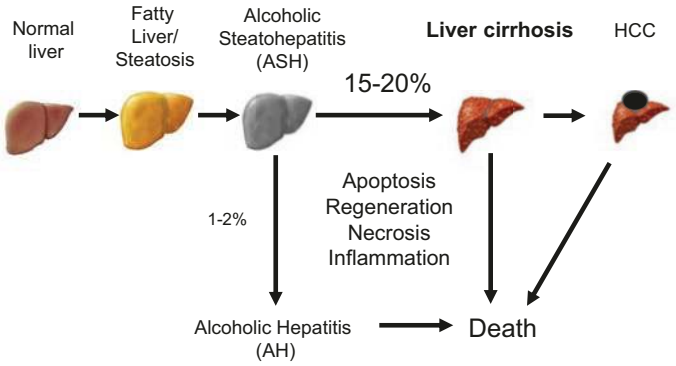

Fig. 42.3 Natural course of alcohol-related liver disease and importance to early detect liver. About 15–20% of heavy drinkers (>80 g alcohol per day) will develop cirrhosis over a period of 15–20 years. Most drinkers will eventually die from cirrhosis or its complications while only very few (<2%) will die due to the rare alcoholic hepatitis (AH). In the compensated state, liver cirrhosis will remain undetected for many years although patients are already at high risk to die from complications of cirrhosis such as bleeding, infections or primary liver cancer (HCC). Consequently, the early detection of those who are going to progress to cirrhosis is essential in order to early screen them for complications, to enroll them in screening programs, and, of course, to motivate them to abstain from alcohol

(0.1%) complications and rarely fatal perforations and bleedings [16, 17]. Moreover, due to the small needle, with regard to fibrosis assessment, the sampling error of a liver biopsy is larger and can reach up to 30% [18–22]. In addition, and the context of ALD, heavy drinkers are typically less likely to see doctors and to undergo invasive diagnostic procedures. With respect to fibrosis assessment, all imaging techniques must rely on so called sure morphological signs of cirrhosis, such as nodular aspects of the liver or recanalization of the umbilical vein, while splenomegaly or ascites are not specific. These imaging signs are only available in about half of ALD patients, with manifest cirrhosis [7]. Serum markers have been long thought to allow for easy fibrosis screening [7, 23]. In ALD, however, a previous study clearly showed superiority of TE with regard to various serum markers [11]. Moreover, this was achieved without sophisticated algorithms. Although this will not be the discussed in detail here, serum markers have important advantages (see also other chapters in this book part), when, e.g., looking for affordable screening tools to be applied worldwide, especially in third world countries.

Fibrosis Screening Using Elastography and Role of Inflammation

Early direct comparison with serum fibrosis markers showed a better performance of TE in patients with ALD [11] and AUROCs are typically >0.9 to detect F4 cirrhosis. The initial major biopsy-proven studies on LS in patients with ALD are listed in Table 42.1. Although an excellent performance could be shown in all

Table 42.1 List of initial biopsy proven studies using transient elastography (TE) to assess fibrosis stage

Reference	Number of patients (n)	Correlation	AUROC F4	Cut-off F4
Nahon et al. [24]	174	0.70, $p < 0.0001$	0.87	22.6
Nguyen-Khac et al. [11]	103	0.72, $p < 0.014$	0.92	19.5
Kim et al. [25]	45		0.97	25.8
Boursier et al. [26]	217	0.87, $p < 0.02$	0.91	17.3
Mueller et al. [27]	101	0.72, $p < 0.001$	0.92	11.5[a]
Janssens et al. [28]	49		0.86	21.1
Fernandez et al. [29]	15		0.93	18.0
Thiele et al. [30]	199		0.94	16.9
Voican et al. [31]	217	0.73, $p < 0.0001$	0.93	20.8

AUROCs and Cut-off values are shown for F4 fibrosis stage (cirrhosis). Note the large difference of cut-off values between different study cohorts. The differences are mainly due to the degree of inflammation and inflammation-associated LS elevation. Consequently, cut-off values should be corrected for inflammation to avoid overestimation of fibrosis stage. This can be done by alcohol-withdrawal and re-measurement of LS after resolution of inflammation or by using co called AST-adapted cut-off values. For more details see text

[a] Patients with AST > 100 U/L were excluded

Table 42.2 Changes of liver stiffness in response to alcohol withdrawal or relapse

Reference	Mean alcohol consumed per day	Patient number/ intervention	LS decrease before and after abstinence	Mean LS change (%)	Time of abstinence/ relapse
Mueller et al. [32]	190 g/day	50/detoxification	Mean LS 20.1–16.5 kPa	17% decrease	5.3 days
Gelsi et al. [34]		23/abstinence relapse		21.7% decrease	7 days
				20% decrease	9 weeks
				32% increase	9 weeks
Trabut et al. [33]	150 g/day	137/abstinence	Median LS 7.2–6.1 kPa		7 days
Mueller et al. [36]	98 g/day	Reduction of 42 g/day total alcohol consumption under Selincro	Mean LS 10.5–8.7 kPa	17%	8 weeks
			Median LS 6.0–5.4 kPa		
Mueller [37]	181 g/day	23/abstinence	Mean LS 20.5–10.5 kPa	48%	5.7 years
Mueller et al. [37]	194 g/day	23/continued drinking	Mean LS 14.8–18.1 kPa	22% increase	5.3 years

Note that absolute and relative LS decreases of 20 kPa or 80% can be observed including complete normalization. LS decrease also depends on initial LS and duration of abstinence. Note that long-term abstaining from alcohol seems to further improve liver stiffness even after 2 years of abstinence potentially suggesting fibrosis reversal in these patients

studies, cut-off values for F3 and F4 fibrosis differed quite significantly between the studies, ranging from 11.5–25.8 kPa. These differences initially caused some confusion, but it was rapidly learnt in an alcohol withdrawal study in 2010, that the cut-off values were strongly dependent on the degree of inflammation in a single patient or the total study cohort [32]. Thus, within 1 week of alcohol withdrawal, LS rapidly decreased independent of fibrosis stage [32]. This study could also show that LS decrease after alcohol withdrawal was inflammation-related and could be best estimated using initial transaminase levels [27]. The importance of inflammation for LS elevation in patients with ALD has been later confirmed by other studies including a meta-analysis [33–35].

Table 42.2 summarizes the data on alcohol withdrawal/relapse and LS. Typically, alcohol withdrawal in heavy drinkers (>80 g alcohol per day) leads to ca. 20% decrease of LS within 1 week of alcohol detoxification [38]. This algorithm has direct implication for fibrosis stages which change in ca. 27% after alcohol withdrawal. Even a 2 months reduction of alcohol consumption by 40% significantly

reduced LS by 17% [36]. In this study, LS decreased significantly in 62 patients (45.3%), and there was a reduction in the estimated stage of fibrosis in 32 (23.3%). In contrast, an increase of LS was observed in 11.7% [33]. The proportion of patients with a significant decrease of LS after alcohol withdrawal increased from 41.7% to 66.7% with the duration of abstinence, from 1 to 9 weeks [34]. There are preliminary observations that long-term abstinence is even more beneficial as LS decreased by 50% if abstained from alcohol for 5 years [39].

Figure 42.4a shows the now widely used algorithm to interpret LS in patients with ALD. When using 1D-SWE such as TE, a concomitant ultrasound is recommended to rule out liver congestion, obstructive cholestasis or nodular masses of the liver. Using 2D-SWE techniques, one platform allows both imaging analysis and elastography using one platform. In addition, as discussed here, the actual AST/GOT levels should be available taken within hours of the elastography. If AST levels are normal, cut-off values from Fig. 42.4a can be directly used to assess fibrosis stage with high accuracy. In case of elevated AST levels, patients should withdraw from alcohol for at least 1–2 weeks, and LS should be re-measured to avoid an overestimation of fibrosis stage due to inflammation.

To avoid the hassle of remeasuring ALD patients after alcohol withdrawal, so called AST-adapted cut-off values can be used [40]. Using the graph shown in Fig. 42.4b, fibrosis stage can be directly read using the measured LS and AST value. AST is indeed the best routine laboratory parameter which allows to estimated LS-elevation due to inflammation and AST performs best both in metabolic but also viral liver disease [40] although different graphs should be used for viral hepatitis. It is still not completely clear why AST has this special impact on LS and not, e.g., ALT? It remains to be addressed in future studies whether this may also be related to extrahepatic conditions, as AST also occurs in muscle cells and erythrocytes. The role of AST was also confirmed in a recent meta-analysis [35]. In this study, also additional levels of bilirubin were found to be useful although we have not been able to confirm this in our Heidelberg cohort. It remains to be confirmed whether bilirubin levels really add to the overall performance of LS, since ALD patients develop jaundice at end stage cirrhosis, where LS normally is higher than 30 kPa and the status of cirrhosis remains undoubted. In contrast, the so called clinical alcoholic hepatitis may develop high levels of bilirubin, in the absence of drastic LS elevation. The correction for AST levels is certainly relevant in daily clinical practice as, in ALD, AST levels are typically higher as compared to ALT and in ca. 70% of patients the AST/ALT ratio is higher than two [41]. On the other side, AST levels higher than 300 IU/L are rarely detected. In cirrhotic stages, transaminases may normalize, while AST levels may be continuously increased despite the absence of alcohol consumption [40].

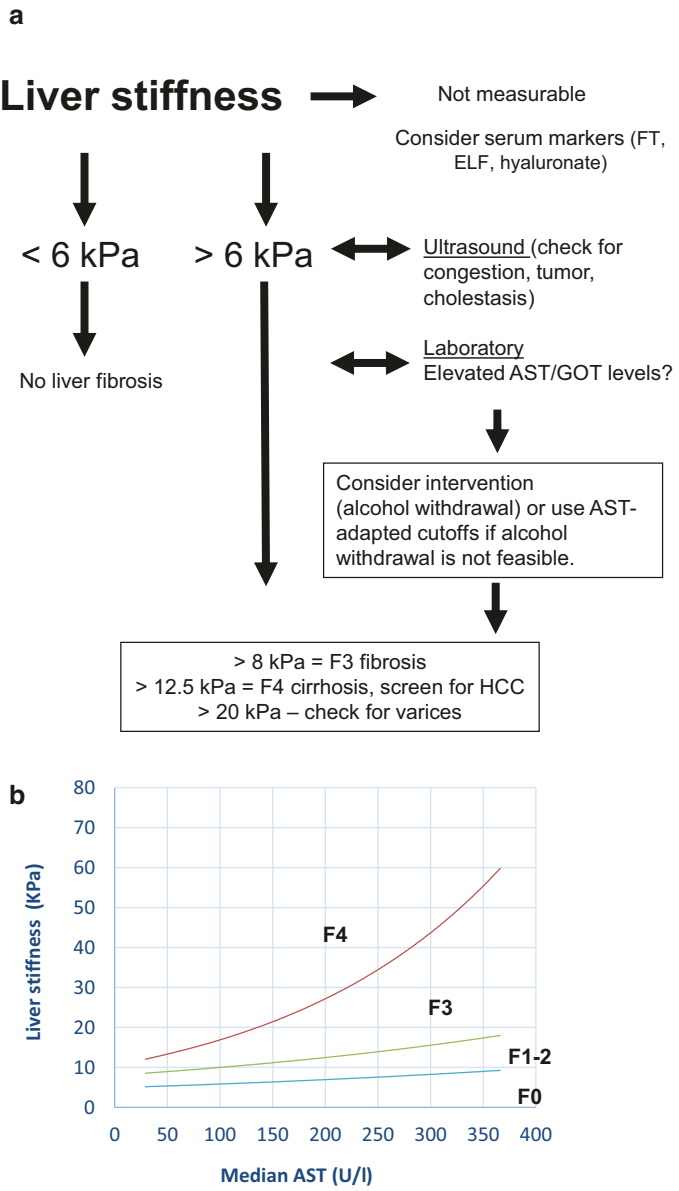

Fig. 42.4 Algorithm to assess fibrosis stage using elastography in patients with excessive alcohol consumption. (**a**) LS is measured and onside ultrasound is performed in order to exclude other potential confounders of elevated LS such as tumors, liver congestion or cholestasis. In addition, actual AST/GOT levels are required to estimate the role of inflammation. If AST levels are highly elevated, patients should abstain from alcohol for 1–2 weeks to allow resolution of inflammation. LS should then be measured in order to accurately apply the indicated cut-off values in the absence of inflammation. (**b**) In addition, so called GOT/AST-adapted cut-off values can be applied for ALD patients without the necessity to abstain from alcohol. Based on the actual LS and AST measurement, the fibrosis stage can be directly read from this graph. Note that other graphs should be used for, e.g., viral liver disease (see also [40])

ARFI Technology for the Evaluation of ALD Patients

ARFI (Acoustic Radiation Forces Impulse) technology is used for the evaluation of liver stiffness in point and 2D-SWE. The advantage of this technology is that this system is implemented inside an ultrasound machine. Consequently, standard ultrasound evaluation of the liver can be performed at the same time of ultrasound-based elastography. The probe produces the ultrasound beam that induce the lateral displacement of the tissue that is used for stiffness measurement. Depending on the platform, results are expressed in kPa and m/s. The ARFI technology is implemented in many ultrasound systems (Siemens, General Electric, Canon, Philips, Samsung, Mindray, Fujifilm, Esaote and others) and published papers about the value of the method in the assessment of liver stiffness are numerous. What are advantages of the ARFI systems? Obviously, it is space saving as no additional ultrasound machine is required, e.g., next to the TE device. As with TE, the measuring time of ARFI devices is less than 5 min. Usually, 5–10 measurements are performed and the criterium of IQR/median < 30 is used for valid measurements. pSWE and 2D-SWE can be performed in patients with ascites as compared to TE. Although ARFI technology is implemented in the high-prize machines of most companies, increasingly middle class ultrasound machines also provide elastographic modules (e.g., Philips Affiniti, Siemens Juniper or General Electric P10) and the technology may be both, pSWE or 2D-SWE.

Once dedicated ultrasound knowledge is available, the ARFI is straightforward and very simple. First, the liver is displayed by ultrasound and important additional information can be rapidly acquired such as tumor masses, signs of cirrhosis, ascites, biliary tree dilatation etc. To measre LS with an ARFI device, a box (region of interest—ROI) of ca. 5–10 mm is placed in an area at least 1–2 cm below the liver capsule (that must be avoided) and free of any larger vessels. The patient is asked to briefly stop the breath in a neutral position and then the button is push and one measurement is obtained. Usually 10 measurements are performed, although some studies point out that 5 measurements may be sufficient for valid LS measurement [42]. Like TE, the pSWE methods are simple and reproducible. For 2D-SWE some experience in field of ultrasound is necessary [43] to obtain the best liver image through the intercostal approach. A box of ca. 2–3 cm is placed at least 1–2 cm bellow the liver capsule avoiding larger vessels. The patient is then invited to stop breathing in neutral position and some measurements are recorded. After this, a region of interest (ROI) of ca. 1 cm is placed in every frame, in the area of the most homogenous image to obtain the final LS values. The advantage of 2D-SWE method is that it is colour-coded and numeric method and for many systems, a quality control of the acquisition exist. Unfortunately, due to a lack of standardization, machine-specific cut-off values are required for each different systems. Some years ago, the SRU (Society of Radiologist in Ultrasound) proposed the “Rule of 4” for different degrees of fibrosis, that are now widely used [44]. In this classification, which has been mostly based without ALD patients, but on patients with viral hepatitis or NAFLD, the following cut-off values can be used:

Table 42.3 Published cut-off values in pSWE and 2D-SWE studies in patients with ALD

Reference	Number of patients (*n*)	Elastography technique	Cut-off values for different fibrosis stage		
			F2	F3	F4
Kiani et al. [45]	69	pSWE	>1.63 m/s	>1.84 m/s	>1.94 m/s
Zhang et al. [46]	112	pSWE	>1.27 m/s	>1.40 m/s	>1.65 m/s
Cho et al. [47]	251	pSWE	>1.46 m/s	>1.47 m/s	>1.66 m/s
Thiele et al. [30]	199	2D-SWE	>10.2 kPa	–	>16.4 kPa

Note that platforms are not standardized and different units are provided. For pSWE, values are typically expressed in m/s

(A) <5 kPa means: normal liver
(B) 5–9 kPa: rule out cACLD (compensated advanced chronic liver disease)
(C) 9–13 kPa: suggestive for cACLD
(D) >13 kPa: rule in cACLD
(E) >17 kPa: suggestive for clinical significant portal hypertension (CSPH).

For ALD, the number of published papers with ARFI technology are rather limited and only one study has been published based on 2D-SWE. These studies are shown in Table 42.3. Point SWE are typically provided in m/s, but can converted into the Young's modulus using a simple formula [10]. 2D-SWE are normally given in kPa like TE and do also correlate well with TE [10].

Practical Example of Fibrosis Assessment by Elastography

After suspicion of ALD either by patients reporting, clinical or laboratory signs, 1D or 2D-SWE is performed directly after the abdominal ultrasound and routine blood tests. A **minimum time of 5–10 min in horizontal position** should be allowed for stabilization of hemodynamics and LS. We normally do the elastography right after the abdominal ultrasound, so the patient has already rested in horizontal position a couple of minutes. During the **abdominal ultrasound**, liver size, antero-posterior diameter of caudate lobe (normal <35 mm), liver morphology, abnormalities such as congestion, cholestasis, morphological signs of cirrhosis, spleen size, the presence of ascites and the diameter of the inferior vena-cava are assessed. In case of TE, LS is measured first with the M probe or in cases of M probe failure due to obesity [48] with the XL probe [48, 49]. If LS is elevated and patients have **AST > 100 U/mL**, alcohol withdrawal for at least 2 weeks (optimal 4 weeks) is recommended, followed by a second LS measurement. In patients with LS > 30 kPa, the diagnosis of cirrhosis is settled despite steatohepatitis as measured by elevated transaminase levels. At these levels, the development of ascites is very likely. This approach will allow definitive non-invasive assessment of fibrosis stage in ca. 95% of patients.

Compared to conventional routine ultrasound, TE identifies almost twice as many patients with advanced fibrosis/cirrhosis (Mueller S, unpublished) and has a smaller sample error as compared to histology (3–5% vs. 20–50%). In a recent French elastography screening study on more than 1000 apparently healthy people older than 45 years, 7.5% had a pathologically increased liver stiffness >8 kPa, with 36% of them eventually being due to ALD [50]. Therefore, it is anticipated that these novel non-invasive screening tools will improve the early recognition and follow up of patients with ALD, the most common and unfortunately too often underestimated liver disease.

Long-Term Liver Stiffness Follow-Up in Patients with ALD

LS measurement allows to monitor drinking activity and ALD progression since LS encompasses the sum of all pathological features from inflammation, ballooning to fibrosis. LS improved shortly after alcohol withdrawal in more than 80% [32]. As shown in Table 42.2, first unpublished preliminary data indicate that LS continues to decrease after further abstaining from alcohol up to 5 years. Thus, in 23 heavy drinkers who were followed-up for 5.5 years, LS decreased by almost 50%. Preliminary unpublished mortality data from 10 year survey in heavy drinkers also shows that LS seems to be the best univariate predictor of death in heavy drinkers [37]. More details are described in Chap. 7. Accordingly, LS predicts mortality independently from bilirubin and INR. A LS >12.5 is associated with 64% survival after 5 years [51].

Additional Information from Spleen Stiffness Measurements in ALD Patients

In addition to liver stiffness (LS), spleen stiffness (SS) is now widely used as novel non-invasive parameter to screen for portal hypertension [52, 53]. Moreover, SS has been demonstrated to outscore liver stiffness or platelet count in **predicting complications of portal hypertension**, such as the presence of **esophageal varices** and the risk of variceal bleeding [54–60]. SS can be easily measured with 2D-SWE or pSWE and also Transient Elastography can well be explored to assess SS [52, 61]. Limitations are: small normal sized spleens and obesity. In addition, since SS is typically higher as LS, the upper detection limit of the Fibroscan device at 75 kPa is more rapidly reached, which has presently resulted in commercially available technically modified dedicated spleen examinations [62].

However, the impact of disease etiology namely the localization of inflammation (portal vs. lobular) has only recently been appreciated. We recently conducted a study that analyzed and compared SS and LS in patients with portal (HCV) and lobular (ALD) chronic liver disease [63]. Our findings clearly showed that SS is

significantly higher in patients with hepatitis C (HCV) as compared to alcohol-related liver disease (ALD) (42.0 vs. 32.6 kPa), $p < 0.0001$), despite a lower mean LS in HCV. Consequently, the **SS to LS ratio** was significantly higher in HCV (3.8 vs. 1.72) through all fibrosis stages. Notably, spleen length linearly increased with SS and the relation between SS and SL was identical in HCV and ALD. In contrast, livers were much larger in ALD at comparable LS. In a prognostic cohort, **ALD patients** had higher LS values, predominantly presented for jaundice and liver failure was the major cause of death [63]. In contrast, spleens were larger in **HCV** with variceal bleeding was the major cause of decompensation. Thus, combined LS and SS measurements provide additional information about disease etiology and disease-specific complications. Figure 42.5 shows SS (in kPa) and spleen size (in cm) both for HCV and ALD in cohorts matched for LS (19 kPa). Cohorts were also matched for age and gender. Although no significant differences were observed with regard to LS, Fig. 42.5 demonstrates that spleens/SS are significantly larger in HCV. Since mean SS/LS ratio did not overlap between ALD and HCV, the SS/LS ratio may be also a useful tool to better emphasize the role of alcohol consumption in HCV patients.

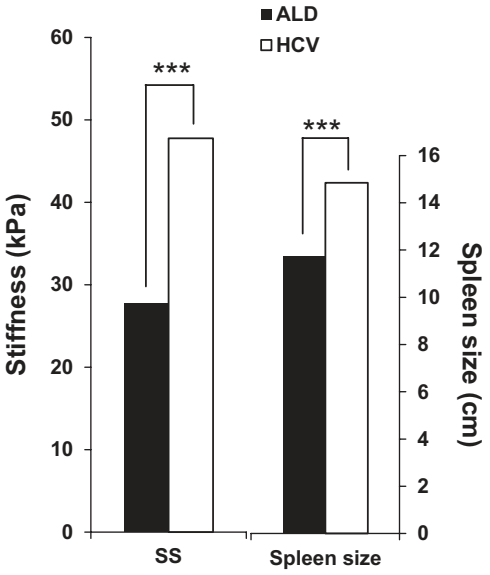

Fig. 42.5 Spleen stiffness (SS) and spleen length are not only highly correlated with portal hypertension but also depend on disease etiology. As shown here, spleen stiffness and spleen length is higher in patients with hepatitis C virus infection (HCV) has compared to patients with ALD. Consequently, the SS/LS ratio can be used to confirm the disease etiology or to assess the relative importance of one disease in patients that present with co-morbidities. More needs to be learnt in future studies about these novel insights

Shear Wave Attenuation Parameters to Assess Liver Steatosis on Elastography Platforms

Controlled Attenuation Parameter (CAP) is a novel tool to non-invasively assess liver steatosis, which measures ultrasound attenuation when travelling through fatty liver tissue, compared to normal liver [64]. It is run on the 1D-TE (Fibroscan) platform (see also Fig. 42.2a). In an individual data meta-analysis, CAP technology was shown to diagnose moderate and severe steatosis with diagnostic accuracies between 0.85 and 0.90 in 2735 patients with mixed liver disease etiologies (mainly viral hepatitis and NAFLD) [65]. In a recent European multicenter prospective study including 562 ALD patients who underwent CAP, regular US and liver biopsy [66], CAP diagnosed mild, moderate and severe steatosis with AUC of 0.77, 0.78 and 0.82, respectively. A CAP value above 290 dB/m ruled in any steatosis with 88% specificity. Moreover, CAP was shown to be superior to regular US to diagnose steatosis in ALD patients. CAP technology appears therefore as an interesting tool to diagnose steatosis and is performed concomitentely with TE, using the FibroScan device: the procedure is non-invasive, non-ionizing, easy to perform and provides immediate results. In addition, CAP can be performed simultaneously to liver stiffness measurement, making possible the simultaneous evaluation of both fibrosis and steatosis [67]. However, diagnostic accuracy appears to be poorer at low steatosis stages and seems lower in ALD compared to other liver disease etiologies. Moreover, optimal cut-offs to rule in, rule out and stage steatosis are varying in the different studies performed. One reason of this variation of CAP within multicenter studies seems to be the rapid response of CAP to drinking dynamics [66]. In case of sequential measurements of CAP in the same cohort, much better accuracy has been observed. It is therefore assumed that specific challenges of ALD study design has also contributed to the rather poor performance of CAP in ALD as compared to NAFLD.

On the other hands, in the last years, **QUS (quantitative ultrasound measurement of steatosis)** have been also implemented on other ultrasound/2D-SWE/pSWE platforms. Examples are the ATI module (Attenuation Image from Canon), or the UGAP module (Ultrasound Guided Attenuation Parameter from General Electric), TAI or TSI (from Samsung) or UDFF (Ultrasound derived Fat Fraction from Siemens). According to the increasing publications, the AUROC of these QUS can reach 0.90–0.95 with some systems, in comparison with liver biopsy [68].

Conclusion

At present, the market of elastographic platforms is continuously expanding and changing. Moreover, there is a certain need for standardization and formal use of units and training that can even confuse experts. Even cut-off values are still controversially used and most likely, some basic training will be required in the near future

in order to help to standardize the "elastographic science" that goes beyond interpretation of "radiological images".

While, already today, liver elastography outscores any other non-invasive fibrosis marker and has significant advantages in comparison to the former gold standard liver histology, a certain knowledge of **confounding factors** that elevate liver stiffness is required.

A **normal liver stiffness of <6 kPa rules out liver fibrosis** since even artifacts are always causing LS elevation but no LS decrease. In ALD patients, liver inflammation is the most important confounder of LS elevation and this is best done by having an actual AST/GOT level available. In cases of highly elevated transaminase levels, elevated liver stiffness is very likely a result of inflammation and either AST-adapted cut-off values should be applied or liver stiffness should be re-measured after an abstaining period of at least 1–2 weeks. If done so, cut-off values of 8 and 12.5 kPa can used to assess for F3 and F4 cirrhosis [10]. A cut-off value of >20 kPa is indicative for significant portal hypertension and patients should be screen for esophageal varices and primary liver cancer (HCC). Future discussion will show whether the "rule of four" (4, 8, 12, 16 kPa for ARFI methods) or the "rule of five" (5, 10, 15, 20 kPa for TE) are more easily applicable in clinical activity. The EFSUMB, WFUMB and EASL Guidelines recommend mainly this methods to rule out liver cirrhosis or advanced fibrosis [69]. Why confounding factors of elevated liver stiffness apply to all elastographic techniques whether 1D or 2D-SWE, there are certain differences to be considered. In 1D-TE, and extra-ultrasound needs to be organized, while 2D-SWE platforms already contain an conventional ultrasound device which facilitates detection of confounders, additional stiffness measurements, e.g., in the spleen. These latter platforms are ideal for hepatologists in order to perform both an abdomincal ultrasound and a Point of Care Elastography (POCE). With the new ultrasound system with the module of elastography (and QUS) inside, after a clinical examination and a standard ultrasound examination, an ultrasound based elastography can be performed (pSWE or 2D-SWE). Both methods can typically be performed successfully in more than 90%. We also have to keep in mind that health care systems are differently organized in different countries. While in some, general practitioners and internists are doing abdomincal ultrasound and are certainly and ideally qualified for performing elastography, ultrasound is restricted in other countries to radiologists. ALD patients will certainly benefit from a future great availably of elastography, due to competition on the market and there may be many niches for stand alone 1D-elastographic platforms and high end 2D-SWE module. Finally, elastography can be explored in a simple "**screening mode**" in search for any elevated LS and the more sophisticated "**expert mode**" that take account of all potential confounders as described above.

Part VIII
Medical Aspects of Alcohol Consumption and Alcohol-Related Liver Disease

Chapter 43
Portal Hypertension in ALD

Benedikt Silvester Hofer and Thomas Reiberger

Abstract Alcohol-related liver disease (ALD) is among the leading causes of liver-related mortality worldwide. Patients who progress to alcohol-related cirrhosis are at risk for developing portal hypertension (PH), a key pathophysiological driver of disease progression and hepatic decompensation. PH following chronic alcohol consumption develops as a consequence of chronic changes to the hepatic architecture and functional disturbances within intra- and extrahepatic vascular beds. Additionally, acute alcohol intake aggravates PH by increasing intrahepatic resistance as well as portal venous and portosystemic collateral blood flow, thus further increasing the risk of hepatic decompensation. The diagnosis of PH and clinically significant portal hypertension (CSPH) should be based on non-invasive tests, including liver stiffness measurements, or on the invasive gold-standard hepatic venous pressure gradient (HVPG) measurement. As the risk of experiencing PH-related complications is directly related to the severity of PH, any reduction in HVPG results in a risk reduction. Clinically, non-selective betablockers are the therapeutic mainstay for ALD patients suffering from CSPH, as they not only reduce the risk of hepatic decompensation, but also improve survival. Additionally, alcohol abstinence has been shown to significantly reduce HVPG and decrease the risk for PH-related complications in patients with alcohol-related cirrhosis.

Abbreviations

acetyl-CoA	Acetyl-coenzyme A
ACLD	Advanced chronic liver disease
ALD	Alcohol-related liver disease
AMP	Adenosine monophosphate
CSPH	Clinically significant portal hypertension
eNOS	Endothelial nitric oxide synthase
FHVP	Free hepatic vein pressure
HSC	Hepatic stellate cell
Hsp90	Heat shock protein 90
HVPG	Hepatic venous pressure gradient
LSEC	Liver sinusoidal endothelial cell
MAP	Mean arterial pressure
NO	Nitric oxide
NSBB	Non-selective betablocker
PH	Portal hypertension
vWF	von-Willebrand factor
WHVP	Wedged hepatic vein pressure

Introduction

Alcohol-related liver disease (ALD) encompasses a spectrum of distinct disease stages, ranging from simple steatosis, to steatohepatitis, fibrosis and eventually alcohol-related cirrhosis [1]. Patients who progress to advanced fibrotic stages of ALD are subsequently at risk for developing portal hypertension (PH), which represents the primary pathophysiological driver of disease progression and hepatic decompensation [2, 3].

Hepatic Haemodynamics and Pathophysiology of Portal Hypertension in ALD

PH is a syndrome defined by an increased pressure within the portal vein, which collects blood from the splanchnic area. The pathogenesis of increased pressure levels in the portal venous system and subsequent PH can be described using a modification of Ohm's law, which defines pressure as the product of the resistance to flow and the flow rate. In the case of cirrhosis, functional and structural pathological changes that affect the hepatic (sinusoidal) microcirculation lead to an increase in resistance, while vasodilatory changes in the splanchnic vascular bed increase the amount of blood inflow into the portal vein [4]. While the overall pathophysiology of increased portal pressure is similar between different aetiologies of

cirrhosis, the haemodynamic profile of PH in alcohol-related cirrhosis demonstrates numerous distinct features. Furthermore, multiple components of the hepatic haemodynamic system are significantly modified by acute alcohol intake. These distinct haemodynamic characteristics of PH in ALD will be covered by this chapter.

Intrahepatic Resistance

The increase in intrahepatic resistance in cirrhosis arises as a consequence of both structural and functional changes, which decrease the calibre of hepatic sinusoids and subsequently hinder portal blood flow.

Intrahepatic Structural Changes

Structural changes originate from cirrhosis-associated alterations of the hepatic architecture, including the formation of regenerative nodules and fibrotic septa [4]. In addition to these macroscopic changes, the intrahepatic resistance is further increased by sinusoidal disturbances, which seem to be particularly pronounced in ALD and are caused by a complex interplay of multiple factors [5].

One key aspect that contributes to distorted blood flow on a sinusoidal level is hepatomegaly, which is caused by hepatocyte hypertrophy and ballooning [6–10]. Importantly, while hepatomegaly can already be observed in early stages of ALD, it is also found in advanced stages of alcohol-related cirrhosis [6]. Mechanistically, hepatomegaly following chronic ethanol consumption is the result of an intracellular accumulation of proteins and lipids, as well as increased levels of intracellular water [8, 11, 12]. In the setting of acute alcohol intake, hepatocyte size may be further increased via a mechanism which is thought to be mediated by the intracellular oxidation of ethanol to acetaldehyde and a subsequent activation of Na-K-2Cl cotransporters [8]. This hypothesis is underlined by the fact that hepatocyte swelling following ethanol exposure can be significantly reduced by inhibiting either alcohol dehydrogenase or the Na-K-2Cl cotransporter [8]. Importantly, this ethanol-induced cell swelling may further inhibit hepatocyte proteolysis and the secretion of proteins and thus further increase hepatocyte volume [8, 9, 13, 14].

The effects of cell swelling and sinusoidal compression on portal pressure levels have been investigated in a pig model of acute PH following intragastric ethanol administration. In this study, the authors observed a marked increase in portal pressure levels upon administration of ethanol, which was paralleled by significant hepatocyte swelling and a subsequent restriction of hepatic sinusoids, as analysed by electron thin-section phase-contrast microscopy [10].

In humans, a number of studies have observed enlarged hepatocytes in histological analyses of liver tissue from ALD patients and linked this phenomenon to increased portal pressure levels [5, 7, 15]. In order to provide pathophysiological

insights regarding this increase in portal pressure, one study demonstrated that the enlarged surface of hepatocytes was directly linked to a significant decrease in relative sinusoidal area [5]. Furthermore, this study revealed that the decreased relative sinusoidal area was significantly more pronounced in patients with ALD compared to patients with non-alcohol-related aetiologies of liver disease [5]. Importantly, in those ALD patients who demonstrated a significant sinusoidal disturbance, the reduction in sinusoidal area was directly correlated to increased portal pressure levels [5]. However, as patients did not abstain from alcohol in this study, the direct (acute) effects of ethanol on hepatocyte volume might have played a significant role.

The presence of a more pronounced sinusoidal disturbance in alcohol-related cirrhosis compared to non-alcohol-related aetiologies of liver disease has been further investigated by assessing hepatic haemodynamics and liver weight in patients with either alcohol-related or viral cirrhosis immediately before and after liver transplantation [16]. As this study was performed in a transplant setting, ALD patients were abstinent for at least 6 months [16]. Liver weight was significantly higher in ALD compared to viral liver disease, regardless of disease severity, thus underlining the increase in hepatocyte volume and sinusoidal resistance in ALD, even in abstinent patients [16]. Furthermore, by using Doppler ultrasound, a significantly reduced portal perfusion rate per gram of liver tissue could be detected in patients with alcohol-related cirrhosis compared to viral cirrhosis, despite a comparable degree of liver fibrosis [16]. The hypothesis of decreased portal perfusion in ALD patients is further supported by liver perfusion assessments using xenon computed tomography, which demonstrated a significantly decreased portal venous tissue blood flow in Child-Pugh A patients with alcohol-related cirrhosis compared to hepatitis C virus-associated cirrhosis [17].

In addition to enlarged hepatocytes, the intrahepatic resistance to blood flow is further increased by significant changes in and around the perisinusoidal space of Disse. In a healthy liver, hepatic sinusoids and the perisinusoidal space of Disse form a complex network within the liver parenchyma and represent the main site of interaction between cellular and liquid blood components and the liver parenchyma [18]. This interaction is facilitated by liver sinusoidal endothelial cells (LSECs), which line the hepatic sinusoids [18]. Importantly, LSECs lack a continuous basal lamina and thus form a netlike structure [18]. In cirrhosis, alterations in the sinusoidal microstructure are caused by the accumulation of collagen in the space of Disse [15, 19] and the formation of a continuous LSEC basal membrane, a process termed "sinusoidal capillarisation" [20]. Hepatic stellate cells (HSCs), which can be found within the space of Disse, are the primary cell type responsible for these perisinusoidal alterations [21]. Upon activation, which can occur due to multiple factors, including transforming growth factor β, as well as various cytokines and chemokines, HSCs transform into fibrogenic myofibroblasts and produce extracellular matrix proteins such as collagen, which subsequently accumulate inside the space of Disse [21]. While this pathomechanism is present in all aetiologies of cirrhosis, studies have shown that metabolites of ethanol, including acetaldehyde and acetaldehyde by-products, directly activate HSCs [22, 23]. Furthermore, the severity of

fibrotic changes, as assessed by serum markers of fibrogenesis including type IV collagen and laminin, has been linked to the amount of ethanol intake in ALD patients [24].

Overall, these alterations not only significantly impair the interaction between hepatocytes and hepatic sinusoids [25], but also increase pressure levels [15]. More information on hepatic fibrogenesis and cirrhosis formation in ALD can be found in a separate chapter within this book.

Intrahepatic Functional Changes

Functional changes that impair the intrahepatic circulation via vasoconstriction are a consequence of HSC activation, LSEC dysfunction and an imbalance between the release of vasodilators and vasoconstrictors [4].

While the activation of HSCs and the subsequent transdifferentiation into myofibroblasts that produce extracellular matrix (i.e., scar tissue) form the key structural resistance factor to portal blood flow, myofibroblasts also contribute to the functional intrahepatic alterations occurring in cirrhosis [4, 21]. These functional changes are facilitated by the fact that HSCs/myofibroblasts line the abluminal sinusoidal wall inside the space of Disse. Thus, a contraction of activated HSCs decreases the sinusoidal lumen and increases the intrahepatic resistance to blood flow [4].

In addition to HSC activation, endothelial dysfunction is another key aspect in the pathogenesis of PH. In healthy liver tissue, LSECs are crucial for maintaining homeostasis and controlling the hepatic vascular tone via the production of vasodilatory nitric oxide (NO) by the endothelial NO synthase (eNOS) [4]. In cirrhosis, however, LSECs become dysfunctional, resulting in a significantly impaired NO production [4]. Simultaneously to the decreased production of vasodilators, there is also an overproduction of vasoconstrictors, including adrenergic stimulants, thromboxane and endothelin, which induce HSC contraction and thus further increase the intrahepatic vascular tone [4]. While LSEC dysfunction is crucial for the pathogenesis of PH regardless of liver disease aetiology, novel evidence suggests that specific causes of cirrhosis may have additional modes of action in terms of modifying eNOS activity [26]. More specifically, it has recently been demonstrated that ethanol intake induces LSEC dysfunction through an interaction with heat shock protein 90 (Hsp90) [26]. Physiologically, Hsp90 is able to induce eNOS activation and, in turn, the production of NO. [27] However, increased levels of acetyl-coenzyme A (acetyl-CoA), which arise from the metabolization of ethanol by LSECs, can lead to the acetylation of Hsp90 [26]. This process decreases the ability of Hsp90 to activate eNOS and thus, the acetylation of Hsp90 decreases eNOS-related NO production [26]. Hence, ethanol directly impacts hepatic vasoconstriction via the induction of LSEC dysfunction.

Splanchnic Vasodilation

Splanchnic vasodilation increases hepatic blood flow and thus the pressure in the portal venous system [4]. The pathophysiology of vasodilation in the splanchnic region in patients with PH is based on the activation of multiple vasoactive systems and the production of vasoactive molecules. One such vasoactive molecule is NO. [28] While reduced NO production within the liver parenchyma induces vasoconstriction, NO production is increased within the splanchnic region [28]. The increased production of NO is primarily a result of the increased shear stress within the splanchnic system due to PH and the translocation of bacteria from the gut into the splanchnic blood stream [28, 29]. As a consequence of these vasodilatory changes, blood pools within the splanchnic region, eventually leading to central hypovolemia [30]. Central hypovolemia and the accompanying decrease in mean arterial pressure (MAP) induce neurohumoral response mechanisms, including the renin-angiotensin-aldosterone system and the sympathetic nervous system [30–32]. Since these response mechanisms aim to increase MAP, they cause an increase in cardiac output and lead to the retention of sodium and water [30]. Overall, these alterations are summed up by the term "peripheral arterial vasodilation hypothesis", which establishes systemic and splanchnic vasodilation as a key factor in the progression of advanced chronic liver disease (ACLD) [30]. Potential differences in the severity of systemic haemodynamic changes in distinct aetiologies of cirrhosis were assessed in a small study by Momiyama et al., which demonstrated a more pronounced decrease in the systemic vascular resistance in alcohol-related cirrhosis compared to hepatitis C virus-associated cirrhosis [33].

While the clinical relevance of these aetiology-specific differences remains insufficiently explored, the impact of acute alcohol consumption on systemic haemodynamics and the ensuing increase in portal pressure is undisputed and has been the topic of numerous previous studies. More than 40 years ago, Villeneuve et al. described the increase in hepatic blood flow in dogs following an acute intragastric or intravenous administration of ethanol [34]. Importantly, haemodynamic assessments in this study were performed without prior anaesthesia and thus, the blunting effects of anaesthetics on the vasodilatory response to ethanol was avoided [34, 35]. These findings were subsequently further investigated in rat studies, which detected a progressive increase in portal pressure following the infusion of increasing amounts of ethanol [36], as well as a dose dependent increase in portal venous blood flow [35].

In subsequent years, the impact of acute ethanol administration on portal venous and splanchnic haemodynamics could also be confirmed in human patients with chronic alcohol consumption, with [37] and without liver cirrhosis [38]. In a study performed in patients without underlying liver cirrhosis and without PH, the intravenous administration of ethanol led to a significant increase in portal pressure, portal blood flow and hepatic vascular resistance [38]. Similar findings were obtained in patients with underlying alcohol-related cirrhosis, who demonstrated a significant increase in hepatic venous pressure gradient (HVPG) and azygos blood

flow following oral ethanol administration [37]. Importantly, both the increase in portal pressure and the increase in azygos blood flow indicate that ethanol consumption might increase the risk of suffering an oesophageal variceal bleeding event [37].

The pathophysiology of increased portal blood flow following ethanol ingestion is based on the metabolization of ethanol and the subsequent production of vasoactive mediators, but not ethanol itself. This is highlighted by the fact that inhibiting alcohol dehydrogenase, the primary enzyme in the degradation of ethanol, using 4-methylpyrazole leads to a suppression of the ethanol-induced increase in portal blood flow [39]. Furthermore, blocking the conversion of acetaldehyde to acetate also suppressed the increase in portal blood flow in response to ethanol [40]. These findings suggest that acetate might be a key metabolite in conveying the vasoactive effects of ethanol. This is in line with the observation that the intravenous administration of acetate causes a dose-dependent rise in portal blood flow [41]. Nevertheless, studies have also indicated that the acetate-induced vasodilation is still dependent on the metabolization of acetate to acetyl-CoA, which is paralleled by the production of adenosine monophosphate (AMP) from adenosine triphosphate [41, 42]. AMP is subsequently further metabolised to adenosine via the enzyme 5′ nucleotidase [42]. The hypothesis that the vasoactive effects of acetate are caused by the subsequent production of adenosine is reinforced by two key observations. Firstly, adenosine is a potent vasodilator [43] with an ability to increase portal blood flow [44]. Secondly, the acetate-induced increase in portal blood flow can be inhibited by administering an adenosine receptor blocker [41]. Of note, hypoxia occurring during the metabolization of ethanol might additionally propagate the increase in adenosine levels [45, 46].

Hepatofugal Blood Flow and Formation of Porto-Systemic Shunts

Hepatofugal blood flow, i.e., a reversal of blood flow within the portal vein, is a phenomenon that has been observed in previous studies using Doppler ultrasound and has been linked to a worse prognosis and the presence of porto-systemic shunts [47–49]. Potential differences in distinct aetiologies were assessed by Hirata and colleagues [49]. The authors observed a high prevalence of hepatofugal blood flow in patients with alcohol-related cirrhosis, while this phenomenon was not observed in patients with viral cirrhosis [49]. A potential explanation for the increased prevalence of hepatofugal blood flow in ALD patients might be found in the increased prevalence of porto-systemic shunts [49]. Porto-systemic collaterals develop as a response to increased pressure levels in the portal vein and shunt blood away from the portal system and into the systemic circulation [49]. As demonstrated by Simón-Talero et al., the prevalence of collaterals increases as portal pressure rises and hepatic function worsens [50]. Importantly, a significantly higher prevalence of

large shunts and paraumbilical collaterals was found in patients with alcohol-related cirrhosis compared to non-alcohol-related aetiologies of cirrhosis [50]. This finding is in accordance with the previously described higher prevalence of paraumbilical vein patency in alcohol-related cirrhosis when compared to viral cirrhosis [16, 51].

Diagnosis of Portal Hypertension in ALD

Invasive Assessment of Portal Hypertension

The invasive measurement of HVPG is the current gold standard method to assess the severity of PH and diagnose clinically significant portal hypertension (CSPH) [52]. HVPG is the most precise surrogate parameter of PH available and has been shown to enable risk stratification, help monitor the treatment response to portal pressure lowering medication and facilitate personalised therapeutic decision-making [3, 52–55]. The current approach to measuring HVPG is based on the insertion of a balloon-tipped catheter into a large hepatic vein and is performed according to a standardised protocol [56]. Specifically, the hepatic blood flow is inhibited by inflating the attached balloon [57], thus forming a static blood column between the hepatic sinusoids and the catheter tip. Therefore, the wedged hepatic vein pressure (WHVP) corresponds to the sinusoidal pressure level. Following the assessment of the wedged pressure, the occlusion is reversed and the free hepatic vein pressure (FHVP) can be measured. Subsequently, the HVPG is calculated by subtracting the mean FHVP from the mean WHVP. While HVPG measurements are considered the gold standard regardless of aetiology, the ability of HVPG to mirror the severity of PH might vary in distinct disease entities [58]. This is highlighted by data on the agreement of the directly measured portal pressure with the WHVP [59, 60]. Of all cirrhosis aetiologies, the correlation between portal pressure and WHVP is the highest in alcohol-related cirrhosis [59]. In patients with non-alcohol-related cirrhosis on the other hand, the correlation performs significantly worse and portal pressure, as assessed by WHVP, may be underestimated [59, 60]. A possible explanation for this discrepancy is the pre-sinusoidal component of PH found in patients with non-alcohol-related cirrhosis [60], as shown for cirrhosis due to cholestatic liver disease [61] or non-alcoholic steatohepatitis [62].

Non-invasive Tests of Portal Hypertension

Due to the invasiveness and the required expertise, HVPG measurements are currently limited to specialised centres and thus, non-invasive tests for the assessment of PH are required. According to the Baveno VII guidelines, the presence of CSPH in patients without previous hepatic decompensation can be assessed using liver

elastography and platelet count [52]. More specifically, liver stiffness values ≤15 kPa, combined with a platelet count ≥150 G/L can be used to rule out CSPH with a negative predictive value and sensitivity of more than 90% [52]. Stiffness values ≥25 kPa on the other hand can be used to rule in CSPH [52]. In patients who do not fall into any of these two categories, the ANTICIPATE model can be employed to assess the likelihood of CSPH [63]. Importantly, non-invasive tools can not only be used to diagnose CSPH, but also to evaluate the presence of fibrotic changes in patients with chronic alcohol intake—a topic which is discussed in depth in a different chapter of this book. More details on PH and measurements of liver stiffness and additional spleen stiffness and important differences between ALD and other liver disease aetiologies are discussed in Chap. 42.

Prognostic Impact of Portal Hypertension in ALD

Regardless of liver disease aetiology, PH only occurs after advanced disease and/or cirrhosis has developed. Thus, the presence of PH itself already indicates a more advanced disease stage that, by definition, is associated with a worse prognosis than non-advanced stages [52]. However, with the concept of using non-invasive liver stiffness measurements to stage liver disease, rather than conducting invasive liver biopsies, the clinical strategy to risk-stratify patients has also changed [64]. A key factor in improving risk stratification in patients with compensated ACLD. following the diagnosis of ACLD via a confirmed liver stiffness measurement of ≥15 kPa, is to assess the presence of CSPH (i.e., HVPG ≥10 mmHg) [52]. CSPH is the main driver of hepatic decompensation [3]. Importantly, liver stiffness measurements can not only be used to detect compensated ACLD in ALD patients, but also to non-invasively classify their risk of suffering from CSPH [63, 65] and to assess PH severity [64]. Nevertheless, the invasive assessment of HVPG still represents the gold-standard for diagnosing CSPH in ALD [56], as it is able to accurately assess the severity of PH in ALD cirrhosis [66] and is thus an important tool for clinical risk stratification [67].

Traditionally, screening for CSPH was mostly conducted by screening for varices using gastroscopy, with the presence and size of varices being associated with prognosis in patients with ALD cirrhosis [68, 69]. However, as the therapeutic focus in patients with (ALD) cirrhosis has shifted from only treating PH once varices have developed (i.e., primary prophylaxis) to treating CSPH (i.e., as soon as HVPG surpasses 10 mmHg regardless of the presence of varices), endoscopic screening for varices should be replaced by other means of diagnosing CSPH [52, 70]. As mentioned above, while HVPG remains the diagnostic gold standard for CSPH, non-invasive surrogates of PH severity are also of prognostic relevance. In this regard, we want to highlight the importance of the liver stiffness-to-platelet ratio score [71], the von-Willebrand factor (vWF) antigen [72] and the vWF-to-platelet count ratio (VITRO) [73, 74] to predict PH-related complications in alcohol-related cirrhosis.

Ultimately, all of the abovementioned studies, which assessed HVPG and non-invasive surrogates of PH, have confirmed that the presence of CSPH, as well as the severity of PH beyond CSPH, are key prognostic factors in patients with alcohol-related cirrhosis.

Treatment of Portal Hypertension in ALD

Despite ongoing research efforts, the current pharmacological treatment options for PH in patients with alcohol-related cirrhosis are limited to non-selective betablockers (NSBBs) [4, 75, 76]. Even though the administration of NSBBs in patients with CSPH has been shown to effectively reduce the incidence of hepatic decompensation, decrease systemic inflammation and improve prognosis, they do not cure the underlying pathophysiological alterations present in cirrhosis [70, 76, 77].

Thus, a particular focus in the treatment of PH in ALD patients should be set on curing the underlying aetiology via sustained alcohol abstinence. The clinical impact of maintaining abstinence from alcohol has been assessed in numerous studies and has been shown to improve the prognosis regardless of disease severity and across all stages of PH [78–82].

Furthermore, persistent abstinence has been shown to significantly decrease the Child-Pugh score, portal pressure and oesophageal variceal size in patients with alcohol-related cirrhosis [67, 83]. Since NSBB therapy was not administered within the context of these studies, their findings were not confounded by a potential difference in treatment adherence between patients with active alcohol intake and abstinence [67]. Importantly, resuming alcohol consumption has been shown to be associated with a renewed increase in PH [83].

Overall, these findings highlight the importance of remaining abstinent on the disease course in patients with alcohol-related cirrhosis and indicate the potential for a regression of PH that warrants further investigation.

Conclusions

Patients with ALD and ongoing pathological alcohol intake are at a high risk of ultimately progressing to cirrhosis, developing CSPH, and subsequently suffering from CSPH-related complications, including variceal bleeding, ascites and hepatic encephalopathy. The diagnosis of CSPH in these patients should no longer rely on screening for the presence of varices by gastroscopy, but rather be non-invasively assessed via liver stiffness measurements and other non-invasive surrogates, or evaluated invasively through HVPG measurements. Patients are at risk of experiencing PH-related complications as soon as CSPH develops and this risk is directly related to the severity of PH, i.e., the level of HVPG. Thus, any reduction in PH severity,

achieved through treatments that decrease HVPG, will result in a risk reduction for PH-related complications. Clinically, NSBBs should be used in patients with alcohol-related cirrhosis as soon as CSPH develops, since NSBBs not only reduce the risk of hepatic decompensation, but also improve survival. In addition to NSBB therapy, alcohol abstinence is a key factor in reducing HVPG and decreasing the risk of CSPH-related complications in patients with alcohol-related cirrhosis. Nevertheless, more effective treatment options for CSPH in patients with alcohol-related cirrhosis are urgently needed in order to improve their prognosis independently from strategies used to treat alcohol use disorders.

Chapter 44
The Impact of Alcohol Consumption on Inflammatory Bowel Disease

Ioana Duca

Abstract Controversial effects of alcohol have been described for patients with inflammatory bowel diseases (IBD) which mainly consists of Crohn's disease (CD) and ulcerative colitis (UC). Besides direct toxic or immunomodulatory effects of alcohol, non-alcoholic ingredients may also show protective effects or modulate relapse induction and exacerbation of symptoms. After a comprehensive literature search, 179 articles were retrieved from Pubmed with the searching terms UC, CD, IBD, and alcohol. Although interpretation remains difficult, studies suggest that chronic heavy drinkers have a higher incidence of abdominal pain, risk of relapse and of colon cancer, while non-smoking moderate drinkers seem to be protected against UC. Moderate alcohol consumption is also safe in inactive IBD patients. The preliminary reports with potentially beneficial effects of non-alcoholic agents in low-to moderate wine consumers warrant further confirmative studies.

Keywords Ulcerative colitis · Crohn's disease · Relapse · Alcohol · Alcohol consumption

Introduction

Inflammatory bowel disease (IBD) is a group of inflammatory conditions of the colon and small intestine consisting mainly of Crohn's disease (CD) and ulcerative colitis (UC). IBD is a complex disease which arises as a result of the interaction of environmental and genetic factors. Although a wide range of treatment modalities have been established ranging from probiotics to surgery, immunosuppressive therapy can be considered the workhorse. Despite scientific efforts over many decades, the pathophysiology of IBD is still not completely understood. This chapter is not addressing the pathology, diagnosis or treatment of IBD but rather the impact of

https://doi.org/10.1007/978-3-031-32483-3_44

alcohol consumption on the pathogenesis and progression of the disease including important severe complications such as cancer and malnutrition [1]. Altogether, 179 articles were identified reviewed in literature search for the years 1991–2022 in Pubmed using the following terms: UC, CD, IBD, alcohol. Full articles or abstracts in English, German and Italian (systematic reviews, original articles, observational studies, multicenter studies, randomized controlled trials, experimental studies on humans and animals, metaanalysis) were included. Excluded were those articles which did not contain precise data about exact effect on IBD nor the type or ingested quantity of alcohol.

Interactions of Alcohol with IBD Pathology

Alcohol consumption is known to increase the transfer of microbiota from gut to blood ultimately being able to cause endotoxemia [2]. The effects on pro-inflammatory cytokine production seems to depend on the level of drinking [3]; while heavy intake inhibit their production, moderate and chronic drinking stimulates them [3]. Growth factors are also inhibited *in vivo* by heavy chronic alcohol abuse. Alcohol also negatively affects the hypothalamic-pituitary-adrenal axis and the cell-mediated and humoral immunity. For instance, hyperproduction of pro-inflammatory factors (IL1, IL6, TNF-α) has been described in response to chronic alcohol consumption due to increased activity of leucocytes and Kupffer cells [3].

Overall, there was a protective effect of alcohol consumption on three autoimmune diseases mediated by Th1 (IBD, rheumatoid arthritis, multiple sclerosis), but excessive drinking did not lead to decrease of risk of autoimmune diseases [4]. No risk between the alcohol consumption and risk of UC (OR 0.85)/CD (OR 0.95) was observed in two meta-analysis by Nie [5] and Yang [6]. Controversial data have been reported with regard to IBD development after 10 years of heavy alcohol consumption. An increased risk has been reported from Taiwan [7], while no elevated risk was seen in a European study with 262,451 participants [8].

Light drinkers (less than 3 days/week with 0.5–1 drinks per day and corresponding to 1–19 g alcohol per day) seem to be protected against UC (see Table 44.1), if they do not smoke [15]. This protection cannot be seen in smokers [27]. Magee et al. described the lack of association between UC activity and intake of spirits (with no content of sulphites) [26]. Casey et al. proved in a cohort study on 237,835 people that moderate (>1–4/week) intake of beer was associated with low risk of CD, while consumption of >4 portions liquor/week led to increased risk of UC [18].

A genetic predisposition of alcohol consumption and IBD risk has been described, independently of polygenic risk score and in the absence of substance use. SULT1A2 is involved in alcohol metabolism and responsible for regulating alcohol consumption. Gene variants of SULT1A2 were negatively associated with CD risk in children (with no alcohol intake); Chr 16 locus was identified as being connected to

Table 44.1 Summary of alcohol-modulated effects in IBD patients

Study	Year	Consumption	Alcohol dose (wine)	Effect on IBD
Tabasco [9]	2011	low	≤3 days/week, 0.5–1 portions alcohol/day, 1–19 g alcohol/day	prebiotic
Dolara [10]	2005			
Biasi [11]	2014			antimicrobial
Singh [12]	2010			antioxidant, antiinflammatory
Cheah [13]	2013			
Giovanelli [14]	2000			reduces colorectal cancer risk
Jiang [15]	2007			protective in non-smokers (UC)
Cho [16]	2018			higher bone mineral density vs. nondrinkers/big drinkers
Swanson [17]	2011	moderate	1–3 glasses/day; 30 g alcohol/day (men), 15 g/day (women)	safe (inactive IBD), increased risk of flares
Casey [18]	2021		beer (>1–4/week) >4 liquor/week	decreased risk of CD increased risk of UC
Stermer [19]	2002	high	238 g/day	increased colorectal cancer risk
Siegmund [20]	2003			
Swanson [21]	2010		sustained	increased risk of flares (UC)
Jiang [15]	2007		sulfite-containing drinks	increased risk of flares (UC)
Berg [22]	2008			higher risk of hip fracture
Hsu [7]	2016		>10 years (Taiwan)	increased IBD risk
Bergmann [8]	2017		>10 years (Europe)	no IBD risk
Niccum [23]	2021		wine	increased risk of microscopic colitis
Chiba [24]	2000	not mentioned	chronic	complications (malnutrition, diarrhea)
Piovenzani Ramos [25]	2021		gin	increased risk of flares (*Clostridium, Bacteroides)*
Jiang [4]	2021		not excessive amount	protective
Magee [26]	2005		spirits	no association with UC activity

predisposition to alcohol drinking and IBD risk [28]. Ramos et al. identified 240 IBD susceptibility loci in a study including 60,000 people [29]. The anti-inflammatory diet proposed in IBD patients should not contain alcohol [30].

Effect of Alcohol in IBD Relapse

Sustained consumption of high doses of alcohol (238 g/day) leads to increased rate (OR 2.71) of relapses in IBD (Table 44.1) compared to spirits [15, 21] especially due to the sulphite content (component of red and white wine, bitter, beer), but also

a high risk of colorectal cancer [19, 20]. Regarding the complications of chronic alcohol intake in IBD, diarrhoea and malnutrition would be the most important, due to improper absorption of vitamins, folate and thiamine [24]. Alcohol represents a modifiable risk factor of relapse, through formation of crypt micro abscesses, mucosal ulceration, colonic epithelial damage and sulphite-rich (wine, beer) beverages [8]. Although consumption of moderate quantities of red wine (1–3 glasses/day, corresponding to 30 g alcohol/day in men and 15 g/day in women) proved an increased risk of flares in IBD [17], this amount is considered safe in inactive IBD patients, without exposing them to relapse (Table 44.1).

Consumption of alcohol increases the relapse-risk by 2.7 times [31]. Alcohol is the most avoided dietary factor in IBD patients (in 22% patients) [32] and especially women were more likely to avoid alcohol [33]. Among adults with IBD from USA, Xu et al. described a percentage of 57.8% of current drinkers in 2015 (vs. 65.1% among people without IBD) and 16.3% remained all life abstainers (vs. 20.8% in non-IBD people) [34]. Mechanisms that lead to IBD relapse after alcohol intake are complex and include increased permeability, endotoxemia, increased proinflammatory cytokines [25].

Interaction of IBD Treatment with Ethanol

In the context of IBD medication (methotrexate, biologics, 5-aminosalycylates), several interactions with alcohol are of concern, e.g., due to induction or competition with the cytochrome P450 system or adverse events (disulfiram-like reactions) in combination with antibiotics (metronidazole, cephalosporin) [25, 35]. Decreased efficacy of 5-ASS, low levels of cyclosporine (salvage treatment in severe UC) and progression of liver fibrosis after methotrexate/azathioprine have been reported in association with concomitant alcohol abuse [36, 37].

Non-alcoholic Content of Alcoholic Beverages

Beneficial effects of wine have been mainly attributed to non-alcoholic ingredients including antioxidant properties of a wide variety of phenolics, also called polyphenols. Wine phenolics may prevent or delay the progression of intestinal diseases. They act both as free radical scavengers but also modulate specifically inflammation-related genes involved in cellular redox signalling. In addition, the importance of wine polyphenols has recently been stressed for their ability to act as prebiotics and antimicrobial agents. Although questionable with regard to the cancerogenic effect of alcohol in large human studies, low levels of wine have been experimentally shown to reduce inflammatory infiltrates in piglets, rats and mice [12–14].

Conclusions

Chronic heavy drinkers have higher incidence of abdominal pain, risk of relapse and of colon cancer, while non-smoking light drinkers are protected against UC. Moderate alcohol consumption is safe in inactive IBD patients. The preliminary reports with potentially beneficial effects of non-alcoholic agents in low-to moderate wine consumers on reducing the histopathological, endoscopic and immunohistochemical scores in IBD warrant further confirmative studies.

Chapter 45
Coagulation Disorders in Patients with Alcohol-Related Liver Cirrhosis

Liana Gheorghe and Speranta Iacob

Abstract In patients with liver cirrhosis, the hemostatic cascade is rebalanced at a low levels and its equilibrium is extremely fragile. It can be easily destabilized by various triggers (e.g., infection, alcohol, uremia, anemia, medications etc.) toward either an anticoagulant or procoagulant phenotype. Conventional coagulation tests do not fully reflect the abnormalities of hemostasis and do not accurately predict the risk of bleeding. Commercially available global coagulation tests (viscoelastic tests), including thromboelastography, rotational thromboelastometry and sonorheometry analyze all components of hemostasis including the dynamics of clot formation, clot strength, and clot stability and represent a promising point-of-care tool for assessing bleeding risk and guiding therapy in these patients. In the setting of bleeding, blood product transfusions should be used judiciously because they increase portal pressure and carry a risk of transfusion-associated circulatory overload, transfusion-related acute lung injury, infection transmission, alloimmunization, and/or transfusion reactions. The following transfusion thresholds may optimize clot formation: hematocrit ≥25%, platelet count >50,000/mmc and fibrinogen >120 mg/dL. In the setting of thrombotic complications, systemic heparin infusion is recommended for symptomatic deep vein thrombosis, thromboembolism and portal or mesenteric vein thrombosis. Therapy with low-molecular-weight heparin, vitamin K antagonists, and direct-acting oral anticoagulants improve portal vein re-permeabilization versus observation alone.

Introduction

The liver plays a pivotal role in hemostasis by synthesizing all coagulation factors and their natural anticoagulants, except for von Willebrand factor (vWF), as well as several fibrinolytic proteins. As a consequence, liver cirrhosis is commonly associated with profound alterations of coagulation by simultaneous reduction in plasma levels of both procoagulant and anticoagulant factors. Coagulation abnormalities in liver cirrhosis pose important clinical consequences representing a key variable of most prognostic scores in liver cirrhosis [1].

Pathophysiology of Coagulation Abnormalities in Patients with Alcoholic Cirrhosis

Liver cirrhosis, irrespective of etiology, is characterized by a state of *re-balanced low-level hemostatic equilibrium* due to the concordant reduction in pro- and anticoagulant components. This balance is extremely fragile and can be easily destabilized by various triggers and superimposed conditions (e.g., infection, alcohol, uremia, anemia, medication, variceal bleeding, decompensated liver cirrhosis, invasive procedures, or inadequate hemotherapy) toward either a procoagulant or anticoagulant phenotype [2, 3]. The resulting clinical state is bleeding or thrombosis according to the predominant complex hemostatic mechanisms [4].

Several well characterized mechanisms are involved in the rebalanced hemostasis that occurs in advanced chronic liver disease [5]: hepatic synthetic dysfunction resulting in decreased levels of liver-derived coagulation, anticoagulation, and fibrinolytic factors; the combination of decreased synthesis of thrombopoietin (TPO) and splenomegaly leading to thrombocytopenia and platelet dysfunction; increasing synthesis of endothelial-derived hemostatic proteins; low-grade activation of the hemostatic system resulting in consumption of hemostatic proteins [6]; posttranslational changes of hemostatic proteins such as fibrinogen associated with functional alteration [7]. Alcohol itself impairs directly or indirectly hemostasis inhibiting platelet aggregation and reducing key components such as vWF, factor VII and fibrinogen levels.

Coagulation disorders may occur in all three phases of hemostasis—primary hemostasis, coagulation (clot formation) and fibrinolysis. Alcoholic cirrhotic patients specifically present multiple alterations of *primary hemostasis* characterized by quantitative (thrombocytopenia attributed to impaired production by decrease in thrombopoietin, splenic sequestration, accelerated turn-over, myelosuppression, and ethanol toxicity) and qualitative (platelet dysfunction resulting in hypo-aggregability) platelet defects, counterbalanced by high vWF and disintegrin and metalloproteinase with thrombospondin type 1 motif 13 (ADAMTS 13) levels [4, 8]. Similarly, in the *coagulation phase,* the low level of liver-derived procoagulant factors, such as fibrinogen and factors II, V, VII, IX, XI, XII, causing

Hemostasis phase	Antihemostatic changes (favoring bleeding)	Prohemostatic changes (favoring thrombosis)
Primary hemostasis	- Thrombocytopenia (splenic sequestration decreased TPO, myelosuppression, ethanol toxicity) - PLT dysfunction (hypo-aggregability)	- High vWF levels - Low ADAMTS 13 levels
Coagulation phase	- Low liver-derived procoagulant factors II, V, VII, IX, XI, XII - Low fibrinogen, Dysfibrinogenemia	- High factor VIII - Low liver-derived anticoagulant proteins S, C, antithrombin III
Fibrinolysis phase	- Low antiplasmin - Low TAFI - High tPA	- Low plasminogen - High PAI1

Fig. 45.1 Hemostasis is rebalanced at unstable low levels in patients with liver cirrhosis

prolongation of the prothrombin time are counterbalanced by a parallel decline in liver-derived anticoagulant proteins C, S, antithrombin III and high factor VIII, while during the *fibrinolysis phase,* to maintain a normal fibrinolytic balance, increase in tissue plasminogen activator (t-PA) is compensated by increase in plasminogen activator inhibitor type-1 (PAI-1) concentrations [2–4] (Fig. 45.1).

Coagulopathy Assessment in Cirrhosis

Simultaneous changes of procoagulant and anticoagulant pathways in patients with cirrhosis result in complex hemostatic changes that are not adequately captured by standard coagulation tests for identifying and monitoring coagulopathy such as platelet count, activated partial thromboplastin time (aPTT), prothrombin time (PT) and international normalized ratio (INR). All currently available laboratory tests of hemostasis have significant limitations in patients with liver cirrhosis and do not reliably predict the risk of bleeding. They do not fully reflect the complex derangement in hemostasis in advanced chronic liver disease since they usually measure procoagulant factors (I, II, V, VII, and X) and do not reflect the reduction in liver-derived anticoagulant factors or the complex interactions between cells and coagulation factors in whole blood [9].

The INR is calculated from the PT ratio (patient PT/control PT) adjusted for the international sensitivity index (ISI). Largely used in clinical practice, the INR was developed to standardize PT reporting for patients on stable anticoagulation with vitamin K antagonists (VKA) and it is not validated for patients with liver disease [4, 9]. Patients with cirrhosis have a more complex and less predictable coagulation profile than patients on VKA with similar INR values. Moreover, there is substantial interlaboratory variability of the INR in patients with cirrhosis across laboratories, especially at high INR, largely due to differences in the thromboplastin used. To

overcome this problematic setting, an alternative INR system has been proposed for patients with cirrhosis (ISI_{liver}) using plasma samples from patients with liver disease for calibration [10]. However, implementation of the INR_{liver} presents logistical challenges that prevent its routine use; for example, a requirement for the manufacturer to provide 2 ISI values (ISI_{VKA} and ISI_{liver}) for each thromboplastin translates into extra-costs and may raise confusion among the laboratory personel [4].

Alternative tools reflecting the interaction between procoagulants, natural anticoagulants, platelets, and the fibrinolytic system (global tests of hemostasis) have been investigated as potentially more reliable for assessing global coagulation in patients with cirrhosis. Global tests of hemostasis, such as thrombin generation or whole-blood viscoelastic tests better capture the general hemostatic status of a patient with cirrhosis but have not been clinically validated.

The thrombin generation test (TGT) dynamically measures the total amount of thrombin generation during *in vitro* coagulation. TGT reflects the balance between pro- and anticoagulant factors in advanced chronic liver disease (ACLD), but remains primarily a research tool, not ready to be translated into a viable clinical instrument and not validated for predicting bleeding risk in patients with ACLD [11, 12].

Recently, whole-blood viscoelastic methods of assessing the clotting mechanism have been showed to be of clinical value in patients with liver cirrhosis. The commercially available viscoelastic methods are: (1) Thromboelastography (TEG, Hemonetics Corporation, Braintree, MA) (2) rotational Thrombelastometry (ROTEM, TEM International GmbH, Munich, Germany) and (3) Sonoclot analysis (SCA; Sienco Inc., Morrison, CO) [13]. These methods are global tests of hemostasis analyzing from a single sample of blood all phases of hemostasis, including the dynamics of clot formation (balance of procoagulant and anti-coagulant factors), clot maturation and strength (platelet and fibrinogen), and clot stability and lysis (fibrinolysis and FXIII) [4, 13].

The principle of the assay consists of (1) *measuring the force* exerted on a small metal rod suspended in whole blood during clot formation while either the cuvette ("resistance to motion") (TEG, ROTEM) or the rod is rotated (ROTEM) or (2) *measuring ultrasound density* during clot formation (sono-rheometry; SONOCLOT). A small amount of whole blood (less than 5 mL) at body temperature (37 °C) is placed in an oscillating cup. A pin suspended from a torsion wire couple with the blood as fibrin form, and the result is increased wire tension as detected by an electromagnetic transducer. The resulting electrical signal is converted to the TEG trace, which can be displayed in real time on a computer monitor allowing the analysis of the TEG curve and variables. Key elements of the whole blood TEG include the reaction time (R time), which reflects the quantity of available factors; clot formation time (K); alpha angle (α) reflecting the rate of clot formation and indirectly indicating fibrinogen levels; maximum amplitude (MA), which is an indicator of platelet activity; and finally, a measure of clot lysis [13, 14] (Fig. 45.2).

Global viscoelastic tests (TEG, ROTEM, and Sonoclot) provide a more physiological assessment of coagulation and should be considered a practical guidance for

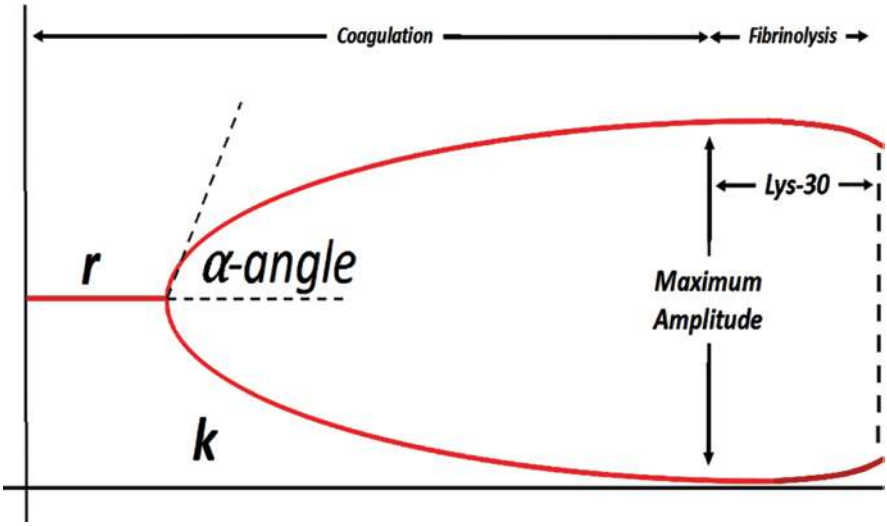

Fig. 45.2 Thromboelastogram curve analysis to assess the bleeding risk in patients with advanced alcohol-related liver disease. (Adapted from Stravitz [13] and Premkumar [14])

blood transfusion requirements in patients undergoing liver transplantation and other major surgeries. TEG is now widely used in cirrhotic patients during surgery and liver transplantation to guide transfusion, coagulation factor replacement, and antifibrinolytic therapy. Only limited data also suggest that TEG more accurately reflects the balance of hemostasis in patients with chronic liver disease outside of surgery [15]. A major limitation in the interpretation of these tests is that they assess *in vitro* hemostasis and cannot express the entirely *in vivo* hemostatic milieu engaging endothelium, tissue factors, portal pressure and flow.

Common Clinical Scenarios of Coagulopathy in Alcoholic Cirrhosis

The unstable *re-balanced* hemostatic state in the setting of liver cirrhosis and portal hypertension could be easily destabilized and tipped toward either a bleeding or a thrombotic phenotype by various triggers. The clinician is facing with two common clinical scenarios (1) *bleeding, related to portal hypertension, spontaneous or procedure-related,* and (2) *thrombosis, either splanchnic or systemic*. Patients with cirrhosis and liver failure are often concurrently coagulopathic, hypercoagulable and hyperfibrinolytic. The resulting clinical state (bleeding or thrombosis) is depends on which hemostatic mechanisms predominates. Moreover, the simultaneously hypercoagulable and hypocoagulable features in an individual patient may

contribute to a complex scenario consisting of concomitant bleeding at one site and thrombosis to another (eg. acute portal vein thrombosis followed by variceal variceal bleeding) [9].

Hypocoagulable/Bleeding Complications in Alcoholic Cirrhosis

Clinical Scenarios

Although considered the dominant clinical problem in cirrhosis, bleeding phenotype is less frequent than generally assumed and may be encountered in several clinical scenarios. Bleeding complications in cirrhosis are infrequently related to abnormal hemostasis. Most clinically significant bleeding episodes are due to increased portal pressure rather than to the deranged hemostasis.

Portal Hypertension-Related Bleeding

In patients with cirrhosis, bleeding is usually the consequence of portal hypertension and primarily related to hemodynamic and mechanical factors, with less relevance of hemostatic mechanisms. Portal hypertension-related bleeding events consist of acute variceal (esophageal, gastric, or ectopic) and non-variceal (portal-hypertensive gastropathy, enteropathy or colopathy) gastrointestinal bleeding. Approximately 50% of cirrhotic patients develop gastroesophageal varices and one-third of them will experience variceal bleeding with an in-hospital mortality rate of approximately 15% per episode [8].

Bleeding Induced by Hemostatic Failure

Bleeding events instigated by hemostatic failure usually occur spontaneously. Spontaneous mucosal or puncture wound bleeding (hematomas, oozing from oropharyngeal or genital mucosa), results from premature clot disolution and hyperfibrinolysis and it is named in the setting of advanced liver disease *accelerated intravascular coagulation and fibrinolysis—AICF*. Although similar to consumptive coagulopathy of disseminated intravascular coagulation (DIC), it can can be

distinguished by the high FVIII level [16]. Apart of these intrinsic alterations, alcohol and drugs (aspirin, AINS, antibiotics, cardiovascular, anti-depression, lipid-lowering drugs) have an important contribution to *acquired platelet dysfunction* in our (overmedicated) society, aggravating hemorrhagic diathesis.

Procedure-Related Bleeding Episodes

Various invasive liver and nonliver specific procedures may be necessary in patients with liver cirrhosis. Procedure-related bleeding events in cirrhosis result from the combination between hemostatic failure, portal hypertension and mechanical factors such as incision, puncture or vascular trauma (vessel rupture/puncture). Accurately determining procedural bleeding risk is a complex process and requires collaboration between specialists to determine the level of bleeding risk before procedures, as well as the periprocedural hemostasis management.

Prediction of the Risk of Bleeding

A procedure-related risk stratification in *low-risk* and *high-risk* procedures (Table 45.1) is accepted based on expert opinion and the overall bleeding risk reported in the literature so far, where low-risk procedures have been defined as procedures associated with significant bleeding in less than 1.5% of cases, that can be easily controlled, while high-risk procedures have a risk of major bleeding higher than 1.5%, can be difficult to control or may lead to catastrophic consequences, even in small amounts (eg, central nervous system bleeding) [17–19]. In clinical practice, it is admitted that several low-risk procedures do not routinely require coagulation assessment in patients with cirrhosis before their performance, including diagnostic and therapeutic paracentesis, thoracentesis, upper endoscopy to screening for and banding esophageal varices, and diagnostic colonoscopy [9]. Assessment of bleeding risk for an individual procedure in patients with cirrhosis is a complex process influenced by numerous interdependent factors grouped into *procedural and technical factors* (such as technique and operator skills and experience), *factors related to liver disease* (severity of liver dysfunction, low fibrinogen levels and advanced portal hypertension are independent risk factors for procedure-related bleeding) and *systemic factors* (comorbidities such as chronic kidney disease, medication such as antiplatelet therapy and anticoagulation which should be carefully considered in the periprocedural period).

Table 45.1 Classification of procedure-related risk of bleeding in patients with cirrhosis

	Low risk procedures	High-risk procedures
Percutaneous	Paracentesis	Biliary interventions: percutaneous biliary drainage
	Thoracentesis	Liver and non-liver intra-abdominal solid organ biopsy
	Drainage catheter exchange	Tumor ablation
		Intrathoracic organ biopsy
		Central nervous system procedures
		Intra-articular injections
Vascular	Central venous catheter line placement and removal	Transjugular intrahepatic porto-systemic shunt (TIPS)
	Diagnostic coronary angiography and right heart catheterization	Transjugular liver biopsy
	HVPG measurement	Locoregional therapies for hepatocellular carcinoma: transhepatic arterial chemo or radio-embolization, radiofrequency or microwave ablation
		Lumbar puncture
		Therapeutic coronary angiography
Endoscopic	Diagnostic upper gastrointestinal endoscopy	Endoscopic polypectomy
	Routine band ligation	Endoscopic stricture dilatation and endoscopic mucosal resection/dissection
	Enteroscopy and colonoscopy (including mucosal biopsy)	Balloon-assisted enteroscopy
	Endoscopic retrograde cholangiopancreatography without sphincterotomy	Endoscopic retrograde cholangiopancreatography with sphincterotomy
	Capsule endoscopy	Percutaneous endoscopic gastrostomy placement
	Endoscopic ultrasound without fine-needle aspiration	Endoscopic ultrasound with fine-needle aspiration
	Transesophageal ecocardiography	Cystgastrostomy
	Diagnostic bronchoscopy without biopsy	Diagnostic bronchoscopy with biopsy or therapeutic bronchoscopy
Others	Skin biopsy	
	Dental non-extraction procedures	Dental extraction

TIPS transjugular intrahepatic porto-systemic shunt
Adapted from Northrup [5], Davidson [17] and Patel [18]

Therapeutic Interventions to Prevent or Control Bleeding

Blood product transfusion can be lifesaving, but the risks and complications of this practice are often underestimated. Transfusion reactions, exacerbation of portal hypertension due to transfusion-associated circulatory volume expansion, bacterial and viral infection transmission, transfusion-related acute lung injury, potential hypercoagulable complications (eg, portal vein thrombosis), as well as long-term

immunologic complications (eg, development of HLA antibodies impacting subsequent transplantation or impairing the ability to receive further transfusions) may alter patient's prognosis by increasing intensive care unit stay, hospitalization, and mortality.

Therefore, it is mandatory to reconsider the practice patterns of blood product transfusion, incorporating agents that have lower volume and risk as well as standardizing the process. A standardized protocol of utilization of blood products and pro-coagulants should be implemented and followed in every unit. The recent AGA Clinical Practice Expert Review on Coagulation in Cirrhosis [1] summarized the current recommendations for active bleeding and bleeding prophylaxis management. Despite the shortcomings of standard coagulation tests, measuring platelet count and fibrinogen level still represent the standard of care assessment of coagulation for all patients with cirrhosis before a procedure.

Hemostatic Strategy and Targets: Utilization of Procoagulant Factors Including Blood Products

In both active portal hypertension-related or spontaneous bleeding, as well as for the prophylaxis of bleeding associated with high-risk procedures, the recommended targets of hemostatic strategy consist of maintaining hematocrit ≥25%, platelet count >50,000/mm^3, and fibrinogen >120 mg/dL in order to optimize clot formation in patients with advanced liver disease [1, 5].

Platelet Transfusion and Oral Thrombopoietin Agonists

Studies have shown that a target platelet count of 56,000/mm^3 suffices to control variceal bleeding because of intact platelet dependent thrombin generation in cirrhosis [11, 15]. There is a consensus that the platelet count should be maintained above 50,000/mm^3 during acute bleeding, the level shown to ensure adequate thrombin generation in vitro.

Given the low-risk of bleeding of many common procedures, potential risks of platelet transfusion, lack of evidence that elevating the platelet count reduces bleeding risk, and ability to use effective interventions, including transfusion and hemostasis if bleeding occurs, it is reasonable to perform low-risk procedures without prophylactically correcting the platelet count [1]. Platelet transfusion derived from single or multiple donors (250 mL of platelet-rich plasma/unit) is expected to increase the platelet count by 5000–10,000/mm^3 [1]. The increment in platelets is often poor in patients with hypersplenism, active bleeding and/or coexistent infection [15]. Oral thrombopoietin agonists (Avatrombopag, Lusutrombopag) are a good alternative to platelet transfusion, but require time (10 to 20 days) to elevate platelet levels and are indicated in patients scheduled to undergo a procedure in elective setting [20, 21].

Red Blood Cell Transfusions

Raising the hematocrit above 25% by red blood transfusion (total volume 250 mL/unit) may improve the margination of platelet and hemostasis and is recommended especially in the setting of renal dysfunction and severe anemia [1].

Cryoprecipitate

Low fibrinogen levels (<100 mg/dL) are associated with spontaneous and procedure-related bleeding in patients with cirrhosis [22]. Recently, fibrinogen levels have emerged as potentially useful tool to couple with platelet count as a measure of bleeding risk, with target levels 120–150 mg/dL. This level is best achieved with cryoprecipitate, a low-volume product having vWF, fibrinogen and fibronectin that does not need cross-matching. Cryoprecipitate is administered on a weight-base dose (1 U of cryoprecipitate per 10 kg body for a volume of 10–20 mL/U). The average dose is 5–10 U resulting from 50–200 mL cryoprecipitate. The increase in plasma fibrinogen from 1 U of cryoprecipitate per 10 kg body weight will be approximately 50 mg/dL.

Fresh Frozen Plasma

Standard doses of fresh frozen plasma (FFP) (approximately 250 mL/U dosed at 10 mL/kg) are not recommended to correct any coagulation factor deficiency [9]. FFP transfusion before procedures is associated with risks and no proven benefits. Increased infused volume of FFP predisposes to transfusion-associated circulatory overload and transfusion-related acute lung injury (TRALI) and determine a substantial increase in portal pressure directly proportional to the volume transfused [23]. For every 100 mL rapid expansion of blood volume, portal pressure increases by 1 mmHg, potentially leading to portal collateral-related bleeding [24].

Concentrated Vitamin K–Dependent Clotting Factors

Prothrombin complex concentrates (PCCs) are plasma-derived products that contain vitamin K-dependent coagulation factors (II, IX, X, VII) and anticoagulant proteins (protein C and protein S). PPCs are available as three-factor (containing factors II, IX, X, very low concentration of FVII and little/no protein C and S) and four-factor (II, IX, X, with the addition of FVII, protein C and S) products. PCC show advantages over FFP including delivery of a smaller volume with a 25-fold higher

concentration of coagulation factors and more rapid correction of hemostatic parameters. In the absence of evidence confirming benefit, the routine use of PCC is not recommended for bleeding complications and may increase the risk of thrombotic events in patients with liver cirrhosis.

Recombinant Factor VIIa (rFVIIa)

Although rFVIIa normalizes a prolonged PT/INR, there is no evidence that it reduces bleeding. Several randomized studies found the use of rFVIIa in addition to standard pharmacologic therapy and endoscopy [25, 26], as well as a Cochrane systematic meta-analysis [27] found that rFVIIa did not reduce mortality in patients with liver disease and upper GI bleeding concluding that there is insufficient evidence to support the use of rFVIIa in this setting.

Antifibrinolytic Agents

Diagnostic laboratory tests for hyperfibrinolysis are not available in clinical practice, and current viscoelastic testing is not sensitive for moderate or mild hyperfibrinolysis. Therefore, the diagnosis of hyperfibrinolytic postprocedural bleeding is made clinically; typical manifestations include continuous venous oozing from skin puncture sites and persistent mucosal or submucosal bleeding. Epsilon-aminocaproic acid (EACA) is a lysine analogue that prevents plasminogen and tissue plasminogen activator (tPA) fibrin binding. Administered for a short period of time either by oral (3 g times per day) or intravenous route (4–5 g in 250 mL by infusion over 1 h, followed by 1 g/h in 50 mL of saline, continued for 8 h or until bleeding is controlled) [1], it has shown benefit in controlling fibrinolytic bleeding without major toxicity. Tranexamic acid is recommended at a dose of 1 g IV every 6 h. Antifibrinolytic agents are commonly used as rescue therapy in major bleeding events that occur after procedures [5].

Vitamin K

Vitamin K will take more than 12 h to correct the hemostatic defect in vitamin K–deficient patients and typically has only a minor impact on the prothrombin time. It can be administered either orally as a 10-mg tablet or 10-mg IV (iv administration carries risk of anaphylaxis), the latter should be mandatory in patients with impaired bile flow, e.g., at bilirubin levels higher than 2 mg/dL. It can be effective when patients have history of prolonged antibiotic therapy, poor nutrition, or severe malabsorption [1].

Hypercoagulable/Thrombotic Complications in Alcohol-Related Cirrhosis

Hypercoagulation in liver disease results from the complex interplay of three pathophysiologic factors: low velocity of portal flow, endothelial dysfunction, and decreased synthesis of the naturally occurring anticoagulant proteins. Therefore, thromboembolic events occur with an increased incidence among patients with cirrhosis, irrespective of etiology, despite standard coagulation tests revealing a prolonged PT/INR [28].

Three main clinical scenarios consisting of thrombotic complications may be encountered: (1) venous thromboembolism (VTE) including peripheral deep vein thrombosis (DVT) and pulmonary embolism (PE), (2) portal vein thrombosis (PVT), and (3) thrombin activation and occlusion of small intrahepatic vessels.

Deep Vein Thrombosis and Pulmonary Embolism

Incidence and prevalence of DVT and PE among patients with cirrhosis have been estimated in several case-control, retrospective and cross-sectional studies reporting an incidence varying from 0.5% to 8.2% [29–33]. A systematic review and meta-analysis of literature evaluating the risk VTE associated with cirrhosis, showed a significantly increased risk in cirrhotic patients as compared with non-cirrhotic controls with a cumulative odds ratio for all venous tromboembolic events of 1.7 for patients with cirrhosis [34]. These results were confirmed when specifically considering the risk of DVT (odds ratio 2.038) and the risk of PE (odds ratio 1.655). Despite this risk, prophylactic anticoagulation for VTE in hospitalized cirrhotics is significantly lower than in non-cirrhotic patients [35], although current evidence supports the use of routine DVT prophylaxis in cirrhotic patients in the absence of evident contraindications [36].

Patients with cirrhosis and VTE may share the same risk factors as other non-cirrhotic patients with thrombotic complications such as venous stasis, infection, congestive heart failure, acute respiratory disease and immobilization. Surgery is one of the major risk factors for VTE in cirrhotic patients [31]. Among the liver-related risk factors, hepatocellular carcinoma (HCC) has been shown to correlate with a higher incidence of thrombotic complications. Although liver disease etiology has not been demonstrated as a risk factor for VTE [37], patients with cholestatic liver disease (including patients with alcohol-related liver disease) show enhanced thrombin generation and platelet adhesion as compared to non-cholestatic etiologies as a result of chronic exposure to high levels of bilirubin. Moreover, patients with non-alcoholic fatty liver disease and metabolic syndrome have been associated with a greater risk of atherosclerosis and endothelial dysfunction contributing to the prothrombotic state [38].

Portal Vein Thrombosis

PVT is the most common and challenging thrombotic event occurring in cirrhotic patients being increasingly recognized due to improvement of diagnostic imaging methods and better awareness amongst clinicians. Incidence of PVT ranges from 5% at 1 year to 40% at 10 years [39]. The relative risk of developing PVT in cirrhosis is sevenfold higher as compared to the risk observed in the general population; it increases with the degree of liver failure and in the presence of HCC, being as low as 1% in patients with compensated disease and rising to 8–25% in patients with end-stage liver disease awaiting liver transplantation and to 40% in patients with HCC [40]. The multicenter prospective study PRO-LIVER (PVT Relevance On Liver Cirrhosis: Italian Venous Thrombotic Events Registry), including 753 Caucasian cirrhotic patients, reported a prevalence of US-documented PVT of 17% and an annual incidence rate of 6.05% [41].

Low portal vein flow velocity, malignancy, prior VTE, thrombophilia, intra-abdominal infection, and history of recent interventions increase the risk for PVT; emerging data suggest that non-alcoholic etiology may be an independent risk factor for thrombotic events, including PVT [42].

PVT classification and terminology are standardized for clinical and research purposes using combined criteria including time course (acute or chronic—if less or more than 6 months), extension (intra- or extrahepatic splenic or mesenteric veins), degree of occlusion (minimal, partial, complete or cavernoma formation), and time change (stable, progressive, regressive) [39].

Most cirrhotic patients are diagnosed with PVT incidentally, during routine ultrasound (US), computed tomography or magnetic resonance imaging evaluation, while some other cases may present with abdominal pain, fever or hepatic decompensation (ascites, encephalopathy, jaundice). The first-line technique for PVT detection is Doppler US (sensitivity about 90% for complete PVT and about 50% for partial PVT) and high operator-dependence. Contrast-enhanced imaging techniques have comparable sensitivity for PVT diagnosis and are used for a better characterization of PVT (extension, degree of occlusion, cavernoma formation).

The most common evolution of acute PVT is spontaneous resolution or disease stability, which have been described in 45–70% of cases [43]. Progression has been reported especially in extensive thrombosis, in one-third of patients at 2 years follow-up.

PVT is associated with a negative impact on the outcome of liver cirrhosis due to the further increase in portal hypertension which may lead to potentially life-threatening bleeding events and worsening of cirrhosis and decompensation caused by decreased hepatic perfusion [44]. Moreover, it definitely increases the technical complexity of liver transplant surgery and may negatively impact transplant outcomes [45]. Improvement in medical and surgical strategies over the last decade overcomes surgical difficulties and, as a consequence, PVT is no longer considered an absolute contraindication for liver transplantation.

An ideal strategy for the treatment of PVT in patients with cirrhosis should have reasonable success rate in reestablishing physiologic flow in the portal system, minimal risk of therapy-induced complications related to the therapy, and be simple and convenient to administer and monitor. The two currently available options include (1) long term anticoagulation therapy and (2) transjugular intrahepatic portosystemic shunt (TIPS) with mechanical or intraprocedural thrombolysis in selected cases.

Anticoagulation is an attractive therapeutic option of PVT since it is widely available, does not require specific procedural interventions, can be started and stopped promptly as needed and has low rates of complications. Pharmacologic agents include vitamin K antagonists (VKAs), low molecular weight heparins (LMWHs), and more recently, the direct acting oral anticoagulants (DOACs) inhibiting factor X or thrombin [46].

Old anticoagulant agents, VKAs and LMWHs, are widely used and appear to be equally effective in cirrhotic patients with PVT. VKAs (warfarin, acenocoumarin) are oral agents that require close monitoring using INR, have a narrow therapeutic window (a target INR of 2.0–3.0), not validated in cirrhotic patients, and are perceived as associated with an increased risk of bleeding in the setting of cirrhosis. Anticoagulation with LMWHs has been extensively studied in cirrhotic population and appears to be safe and effective. Once the risk of bleeding from esophageal varices is controlled by using beta-blockers or band ligation, the rate of bleeding complications in cirrhotic patients with PVT on therapeutic anticoagulation seems to be similar to the non-cirrhotic population. Of note, a significantly lower rate of variceal bleeding in anticoagulated patients was reported in some studies compared to untreated patients [47]. The main limitation of using LMWHs for PVT consists of repeated subcutaneous injections making this therapy poorly acceptable for a long period and causing a high rate of non-adherence; in addition, their efficacy may be compromised by the low plasma level of antithrombin in patients with cirrhosis.

DOACs that inhibit thrombin (dabigatran) or activated factor X (rivaroxaban, apixaban, edoxaban) recently emerged as potential alternatives to VKAs and LMWHs in patients with PVT, because they are oral drugs that do not require laboratory monitoring for dosage [48]. However, they are currently prescribed *off-label* in this setting because patients with cirrhosis were excluded from clinical trials comparing DOACs versus VKAs and LMWHs for prophylaxis or treatment of VTE or atrial fibrillation [49–51].

There are limited data on the pharmacodynamics of DOACs in cirrhosis, rising significant concerns of bleeding and other adverse events. Clinical experience with DOACs in patients with cirrhosis remains sparse and limited to highly select cohorts with well-compensated cirrhosis. Overall, DOACs appear to have a similar safety profile in patients with compensated cirrhosis compared to patients without cirrhosis, and their use is expanding in all indications for anticoagulation, including PVT [48]. Moreover, the availability of direct reversal agents for DOACs (idarucizumab for dabigatran and andexanet alfa for all the others) may attenuate the concerns of bleeding.

Anticoagulation induce reduction in thrombus volume as early as 2 weeks on therapy. The recommended duration of anticoagulant therapy resulting from the

meta-analysis by Loffredo et al. [47] is 6 to 12 months and is associated with 71% of partial and 53% of complete recanalization after 6 months of therapy. Portal vein recanalization (PVR) (thrombolysis) followed by TIPS should be considered in patients with chronic PVT and recurrent bleeding and/or refractory ascites not manageable medically or endoscopically. TIPS insertion was successful in more than 90% of the patients with partial or complete occlusive thrombi with similar rates of complications and mortality compared with patients without PVT [52, 53]. Key recommendations for anticoagulant therapy, but also for controlling bleeding in patients with cirrhosis are shown in Table 45.2 [1, 4].

Table 45.2 Key recommendations for thrombotic complications and bleeding in cirrhosis

Thrombotic complication	Specific management	Comments
Acute setting: acute portal or peripheral vein thrombosis or extension of prior thrombosis (especially if symptomatic)	Systemic anticoagulation with therapeutic dose of I.V. heparin or LMWH	High INR does not indicate an auto-anticoagulant state, and patients will still require anticoagulation
	In acute PVT and superior mesenteric vein thrombosis, catheter-mediated thrombolysis may be indicated	Heparin-induced thrombocytopenia and appearance of new-onset clinically evident bleeding may be challenging
Chronic PVT or history PVT or mesenteric thrombosis	Anticoagulation is indicated in Yerdel grades ≥2, especially in patients who are listed for liver transplantation	Patients with portal cavernoma are less likely to benefit
	Systemic anticoagulation with therapeutic LMWH is indicated	Asymtomatic incidentally discovered PVT does not invariably require anticoagulation
	Oral anticoagulants recommended include VKAs (problematic due to uncertainty of targeting therapeutic INR) and DOACs (safe and effective in Child-Pugh class A and early class B cirrhosis)	Conflicting data are available on primary prophylaxis of PVT to prevent decompensation
DVT therapy or prophylaxis in hospitalized patients if indicated (venous stasis, history of DVT and PE, immobilization, surgery etc.)	In the absence of bleeding, routine DVT prophylaxis is recommended	Variceal eradication is necessary
	Prophylaxis with LMWH should be offered	Anticoagulation is considered for at least 6 months or lifelong in cases of multiple episodes
	Therapeutic anticoagulation should be with oral anticoagulants	

(continued)

Table 45.2 (continued)

Thrombotic complication	Specific management	Comments
Bleeding complication	*Specific management*	*Comments*
Portal hypertension-related bleeding	Timely endoscopic management (variceal banding/sclerotherapy, glue injection etc.)	• Maintain Hb ~ 7 g/dL in all patients and 8 g/dL in cardiac patients (hematocrit >25%)
	Minimize volume expansion during resuscitation	• platelet transfusion for >50,000/mm^3
	Discuss role of emergency TIPS	• Fibrinogen level > 100–120–140 mg/dL
Wound/mucosal oozing suspicious for accelerated intravascular coagulation or hyper-fibrinolysis	Control infection (active infections release endothelial derived heparinoids which can have anticoagulant effect)	• platelet ≥50,000/mm^3, fibrinogen ≥ 120 mg/dL
	Optimize renal function (uremia-associated platelet dysfunction	• Consider anti-fibrinolytic agents (aminocaproic and tranexamic acid)
		• Role of prothrombin complex concentrates not yet defined
Invasive procedures prophylaxis	Risk-benefit ratio and local expertise should be considered	• High-risk: PLT > 50–60,000/mm^3
		• Very high-risk: PLT > 100,000/mm^3

LMWH low molecular weight heparins, *INR* international normalized ratio, *PVT* portal vein thrombosis, *VKAs* vitamin K antagonists, *DOACs* direct acting oral anticoagulants, *DVT* deep vein thrombosis, *PE* pulmonary embolism, *Hb* hemoglobin, *platelet* platelet, *TIPS* transjugular intrahepatic portosystemic shunt

The Role of Hypercoagulability in Hepatic Fibrogenesis and Decompensation: Thrombin Activation and Occlusion of Small Intrahepatic Vessels

Local thrombin generation in portal and hepatic branches triggered by adjacent necroinflammation results in intrahepatic microvascular thrombosis which in turn causes ischemia-induced tissue injury (known as parenchymal extinction). This pathogenic mechanism plays an important role in cellular death and liver atrophy, activates stellate cells, and promotes fibrogenesis emerging as an important mediator of fibrogenesis. Anticoagulation prophylaxis in this setting may be beneficial on disease progression and parenchymal extinction/atrophy [54].

The detrimental effects of hypercoagulability were further documented in a prospective trial of enoxaparin therapy for patients without PVT [55], which demonstrated that enoxaparin treatment lowered the incidence of PVT, decreased the incidence of decompensation, and improved overall survival.

Conclusions

The hemostatic cascade is rebalanced at low levels and its equilibrium is extremely fragile in patients with cirrhosis. It can be easily destabilized by various triggers (e.g., infection, alcohol, uremia, anemia, medications etc.) toward either an anticoagulant or procoagulant phenotype. These complex hemostatic changes are not adequately captured by standard coagulation tests for identifying and monitoring coagulopathy. Further studies of global assessment of coagulation, such as TEG and ROTEM, are needed to determinate appropriate cut-offs for therapeutic interventions. Blood products transfusions should be used judiciously because they increase portal pressure and carry a risk of transfusion-associated circulatory overload, transfusion-related acute lung injury, infection transmission, alloimmunization, and/or transfusion reactions. The following transfusion thresholds for management of active bleeding or high-risk procedures may optimize clot formation in advanced liver disease: hematocrit ≥25%, platelet count >50,000/mmc and fibrinogen >120 mg/dL. In the setting of thrombotic complications, systemic heparin infusion is recommended for symptomatic DVT thromboembolism and portal and mesenteric vein thrombosis. Prophylaxis therapeutic strategy consists of LMWHs, VKAs, and DOACs according to the specific setting. Therapeutic intervention for incidental portal and mesenteric vein thrombosis should be based on careful clinical judgement and estimation of impact on transplantation surgical complexity versus risks of bleeding.

Chapter 46
Hepato-Renal Syndrome in Patients with Alcohol-Related Liver Disease

Cristina Muzica, Camelia Cojocariu, Tudor Cuciureanu, and Anca Trifan

Abstract Hepatorenal syndrome (HRS) is defined as impaired renal function in the context of both acute or chronic liver failure. HRS is considered one of the most dreaded complications in chronic liver diseases. In the context of alcohol consumption, HRS can occur in the acute setting of alcoholic hepatitis (AH) or, in most cases, in alcohol-related liver cirrhosis. It can drastically worsen their prognosis especially for severe AH. This book chapter discusses the new classification of HRS, its diagnosis and underlying pathophysiology with regard to alcohol exposure, and, finally, the therapeutic management ranging from general measures, application of vasoactive drugs, hemodialysis, transjugular intrahepatic stent shunt (TIPS) till Molecular Adsorbent Recirculating System (MARS), and liver transplantation. HRS is considered a frequent complication that arises in cirrhotics and AH causing death in more than 90% of the patients in the first 3 months after the onset of the symptoms, in the absence of liver transplantation.

Keywords Hepatorenal syndrome · Alcoholic hepatitis · Terlipressin · Pathophysiology · Diagnosis · Management · Albumin

Introduction

Hepatorenal syndrome (HRS) is a dreaded complication which develops in patients with liver cirrhosis and has a negative impact on the survival rates. The early recognition of HRS and prompt initiation of specific treatment is mandatory because it may change the prognosis in any cirrhotic patient. The epidemiology of HRS

differs worldwide, but in the United States, HRS affects between 9000 and 35,000 patients annually. It is considered that approximately 20% of the hospitalized patients with cirrhosis are diagnosed with HRS [1].

Definition of HRS

HRS is defined as the impairment of renal function occurring in the context of both acute liver failure, alcohol or non-alcohol related, and chronic liver failure such as liver cirrhosis [2, 3]. The pathophysiology of kidney failure in HRS is not very well defined, but the most studied mechanism which could induce the malfunction of kidneys in liver diseases is represented by renal vasoconstriction caused by an important decline in effective circulating volume in a setting of systemic and splanchnic vasodilatation, which consequently will lead to a decrease in kidney perfusion [4, 5]. Patients with HRS typically have decreased arterial pressure combined with an elevated cardiac output. The release of circulating vasodilators from the endothelium is one of the leading causes for arterial vasodilatation, and consequent activation of endogenous vasoconstrictor systems resulting in a reduced glomerular filtration rate [6]. The definition of HRS has changed over the years, traditionally including two types. HRS type-1 is characterized by a doubling of the serum creatinine with values higher than 2.5 mg/dL within 2 weeks. HRS type-2 is defined as a slower increase in serum creatinine higher than 1.5 mg/dL [7] (see also Table 46.1). In order to establish the diagnosis of HRS, other causes of kidney injury have to be excluded such as the absence of cardiovascular shock or nephrotoxic drugs. Second, no improvement should be observable after diuretics withdrawal or volume expansion with albumin for 2 days. Third, kidney morphology should be normal in ultrasound, and, finally, no hematuria defined by more than 50 erythrocytes per high power field in urine and absence of proteinuria >500 mg/24 h should be confirmed.

An important change regarding HRS definition emerged with the acceptance of the new definition of Acute Kidney Injury (AKI). The definition of AKI was proposed by the Hepatology community and the International Club of Ascites [8]. The definition of HRS now relies first and foremost on the definition of AKI. The new concept of AKI was introduced because the old definition of HRS had several shortcomings which contributed to delays in establishing the diagnosis, or even misdiagnosis. In the last few years, the Kidney Disease Improving Global Outcome (KDIGO) criteria were modified in relation to AKI. These changes were necessary since serum creatinine-based criteria turned out to be important for estimating mortality rates in patients with liver cirrhosis and deciding early treatment initiation [8]. KDIGO criteria helped to understand HRS and mortality risk stratification according to AKI stage and to speed up the time for diagnosis [9, 10]. After the consensus of the ICA, HRS is now specified by the presence of AKI. Consequently, conventional HRS type-1 is now referred to as HRS-AKI being defined by changes in serum creatinine and/or urine output along to the criteria shown in Fig. 46.1. To

Table 46.1 The evolution of diagnosis criteria for hepatorenal syndrome

	1996 ICA	2007 ICA	2012 KDIGO/2015 ICA	2022 ICA and KDIGO accepted criteria's
Criteria for HRS diagnosis	– Serum creatinine >1.5 mg/dL or 24-h creatinine clearance <40 mL/min. – Absence of shock, nephrotoxic drugs, GI fluid loss, renal fluid loss – No improvement after diuretic withdraws and plasma expansion volume – No US-signs of renal disease – Proteinuria <500 mg/dL	– Type 1 HRS defined by rapidly progressive renal impairment – Doubling sCr at a value >2.5 mg/dL in less than 2 weeks – Type 2 HRS defined by moderate renal failure with sCr between 1.5 and 2.5 mg/dL – Slowly progressive course	– Criteria remove the absolute creatinine value of at least 1.5 mg/dL as a requirement. – Use of acute kidney injury (AKI) criteria. – The importance of having a baseline sCr for diagnosis. Baseline - a prior sCr within 3 months	– Cirrhosis and ascites – Diagnosis of AKI according to ICA- AKI criteria – Absence of shock – No response to diuretic withdrawal and plasma volume expansion – No use of nephrotoxic drugs – No macroscopic signs of structural kidney injury

AKI acute kidney injury, *AKI* acute kidney injury, *GI* gastrointestinal, *HRS* hepatorenal syndrome, *ICA* international club of ascites, *KDIGO* kidney disease improving global outcome, *sCr* serum creatinine, *US* ultrasound

improve early treatment efficiency, the new classification removes the cut-off values for serum creatinine of ≥1.5 mg/dL and suggests treatment even in cases of small increases. HRS type-2 is now defined as HRS without AKI and manifest chronic kidney disease [8].

Pathophysiology of HRS in ALD

Alcohol-related liver disease (ALD) is an umbrella term that includes several disease stages ranging from simple steatosis to steatohepatitis, acute alcoholic hepatitis, and liver cirrhosis. Severe alcoholic hepatitis (AH) develops in a minority of patients (typically <2%) with heavy alcohol consumption and is characterized by the onset of jaundice and signs of liver inflammation. Severe AH has a high mortality rate, with approximately 40% patients dying within the first 6 months after hospital admission [11]. Several factors contribute to the high mortality such as sepsis, variceal bleeding, liver failure, and HRS, respectively. Although HRS as long been considered as a specific complication restricted to cirrhotic patients with ascites, it is nowadays considered a frequent complication that also arises patients with severe AH, complicates the course of the disease, and, in the absence of liver transplantation, causes death in more than 90% of the patients in the first 3 months after the onset of the symptoms [12]. Similarly, in patients with liver cirrhosis, HRS is a dreaded complication with a median survival of about one-month [13].

As already mentioned above, HRS is defined as a renal dysfunction which arises in patients with chronic liver diseases – especially in advanced cirrhosis, or in acute liver failure. There are several mechanisms that have been proposed to cause HRS, the most accepted includes splanchnic vasodilation due to portal hypertension which predisposes to peripheral and subsequently renal vasoconstriction leading to a decrease in glomerular filtration rate (Fig. 46.2) [14]. Although this mechanism is the hallmark of HRS, there is evidence for several other contributors, such as systemic inflammation, cirrhotic cardiomyopathy, and adrenal insufficiency.

The Uncompensated Hyperdynamic Circulation

Due to liver inflammation, increased vascular resistance and portal hypertension, several vasodilatory mediators are released into the splanchnic and later systemic circulation which finally lead to arterial vasodilatation. The most known mediators that can induce significant vasodilatation are nitric oxide, carbon monoxide, prostacyclin and endogenous cannabinoids [15, 16]. The splanchnic vasodilation will cause a decrease of effective circulating volume, a decrease of systemic arterial pressure and, ultimately, an activation of systemic vasoconstrictor pathways such as the renin-angiotensin-aldosterone system (RAAS). The sympathetic nervous system acts by releasing angiotensin II, norepinephrine, and antidiuretic hormonein order to increase the effective circulating volume. These mechanisms results in Na^+ retention, water retention through reduced water excretion and renal vasoconstriction which subsequently determines a decreased renal perfusion. In the early stages of liver cirrhosis, the kidneys are able to maintain an adequate blood flow and thus a normal glomerular filtration rate, but with the progression of the disease the glomerular pressure is impaired and leads to renal disfunction [17].

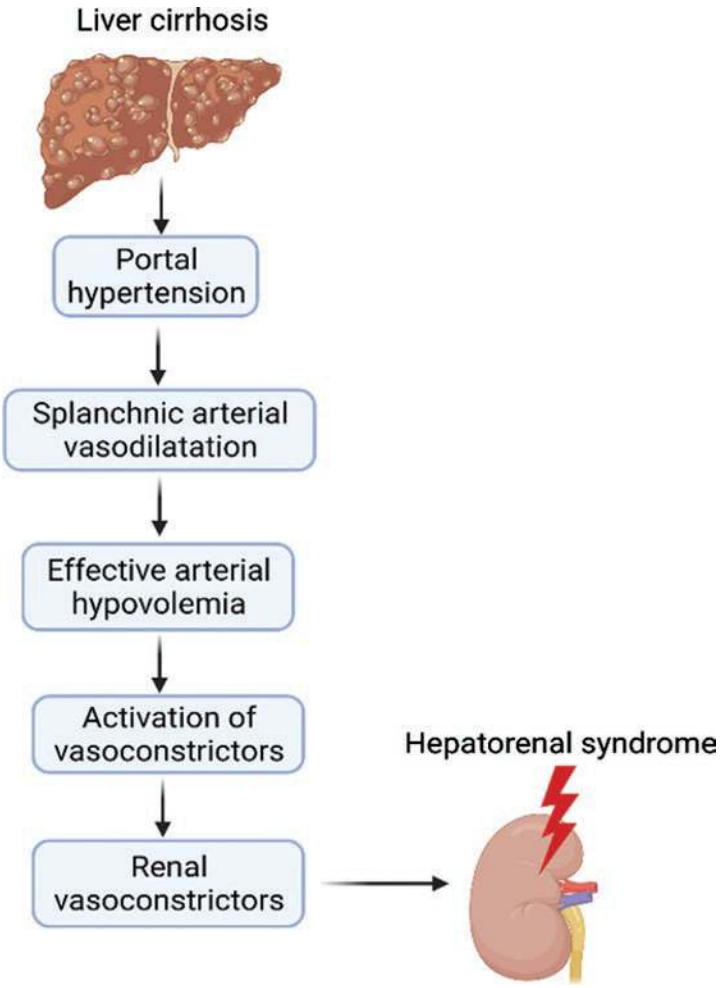

Fig. 46.2 The mechanism of hepatorenal syndrome due to portal hypertension

Systemic Inflammatory Response Syndrome

The systemic inflammatory response syndrome occurring in liver cirrhosis encompasses two types of patterns, the pathogen associated molecular patterns (PAMPs) and damage associated molecular patterns (DAMPs). PAMPs are bacterial-released products which result during bacterial translocation whereas DAMPs are cellular products originating from damaged hepatocytes. PAMPs and DAMPs will produce an inflammatory state and release of cytokines by activating toll-like receptors. These events will eventually lead to a systemic inflammatory response which stimulates the arterial production of vasodilators, resulting in a decreased systemic vascular resistance (Fig. 46.3). Data from current literature show that, in patients with

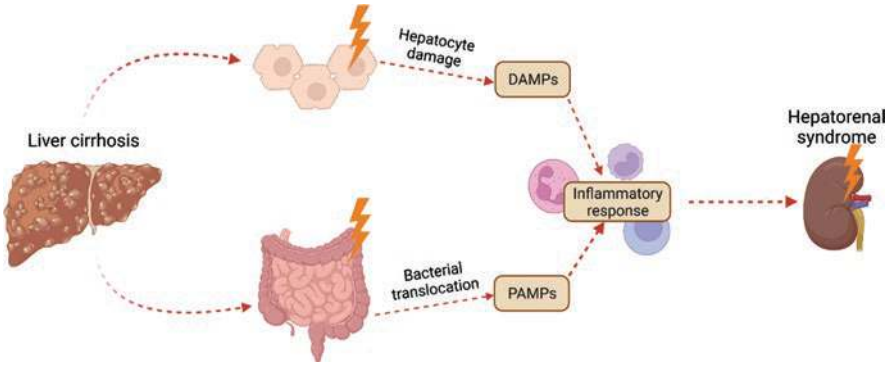

Fig. 46.3 The role of PAMPs and DAMPs in inducing hepatorenal syndrome (*created with* BioRender.com)

liver cirrhosis and impairment of renal function, there is an overexpression of toll-like receptor 4 (TLR4), which has been linked to a prolonged exposure to PAMPs [18]. Furthermore, it has been demonstrated that renal ischemia due to reduced blood flow in HRS induces an increase of TLR4 [19]. There are other possible mechanisms related to innate immune system that can promote HRS, but there is no scientific evidence yet to sustain these theories.

Hepato-Adrenal Syndrome

In about 50% of the patients with decompensated liver cirrhosis and ascites, there is a relative adrenal dysfunction which can be a risk factor for HRS. This category of patients has low blood pressure values, important circulating levels of renin and noradrenaline, and, secondary to the unavailability of cortisol substrates and the disturbance of the hypothalamus pituitary axis in response to cytokines and PAMPs. Patients with decompensated liver cirrhosis and developing HRS have high risks of sepsis and short-term mortality [20].

Bile Cast Nephropathy

Bile cast nephropathy (BCN), known under several terms such as cholemic nephropathy, biliary nephrosis and jaundice-related nephropathy, is frequently found in patients with liver cirrhosis and other cholestatic liver diseases. It seems that BCN affects most patients with high bilirubin levels and HRS and has a negative impact on therapy response and prognosis [21]. Morphologically, it is represented by the

formation of bile acid casts which cause tubular obstruction and toxicity, as well as an altered kidney perfusion. The tubular obstruction has been demonstrated by several histopathologic studies through the presence of intratubular bile acid casts in up to 75% of HRS cases [21]. Furthermore, experimental studies have demonstrated that hyperbilirubinemia can cause "jaundice heart" due to chronotropic and inotropic effects which lead to renal hypoperfusion, corticomedullary junction ischemia and tubular injury, all related to HRS [22]. The diagnosis of BCN can be suggested by elevated urinary bilirubin and urobilinogen levels. Serum bilirubin levels of more than 10 mg/dL are usually associated with a poor response to vasoconstrictors and high mortality rates in HRS [21]. Therefore, targeting bile acids by agents such as ursodeoxycholic acid or norursodeoxycholic acid are thought to improve the response to treatment in patients with HRS and BCN.

Intra-Abdominal Hypertension (IAH)

An important role of a high intra-abdominal pressure (above 12 mmHg) in the pathophysiology of AKI has also been demonstrated. Furthermore, in patients with refractory ascites, IAH seems to be an underestimated cause of HRS. A recent study demonstrated that reduction of intra-abdominal pressure by large volume paracentesis (LVP) short-term improved creatinine levels in patients with HRS [23]. However, it is important to carefully monitor the diameter of the lower caval vein in order to prevent post-paracentesis circulatory dysfunction by applying albumin and plasma expanders.

Direct Alcohol Effects on Kidneys

Although the mechanisms resulting in alcohol-related kidney injury are yet to be established, the role of alcohol in inducing renal dysfunction is well known. Several studies have demonstrated harmful effects of chronic alcohol consumption on kidneys termed "alcoholic kidney injury" [24]. The pathophysiologic mechanisms that have been linked to kidney damage are caused both directly by the toxicity of alcohol and by the increased amounts of the metabolites including acetaldehyde, or the release of NADH and free radicals from damaged cells. Reactive oxygen species (ROS) are thought to trigger alcohol-related tissue injury. Recent data show that alcohol stimulates mitochondrial protein hyperacetylation in the kidney, which may interfere with the function of some mitochondrial proteins involved in alcohol metabolism or defense against oxidative stress which can significantly contribute to alcohol-induced mitochondrial dysfunction in the renal tissue [25].

Predictors of HRS in ALD

In HRS, there are several predictors that could guide the management of these patients. The major risk factors for HRS are low blood sodium, a high level of plasma renin activity, liver size, and the degree of ascites [26, 27]. There are very few cases of unprecipitated HRS, usually it develops in the setting of infections or LVP without standard albumin administration. Data from current literature shows that HRS occurs in more than one quarter of patients with spontaneous bacterial peritonitis (SBP) and has a strong negative impact on survival rates [28]. The prevention of HRS associated to infections could be achieved by administrating albumin in combination with specific antibiotics in patients with SBP or other types of infections, which can significantly improve overall mortality. Furthermore, it has been demonstrated that albumin infusion in patients with infections has a positive impact on effective circulatory volume which is favors an adequate renal function. Other advantages of albumin are represented by the ability to inactivate endotoxins and by the potential immunomodulatory effects [29].

Diagnosis of HRS

As mentioned above, the new diagnostic criteria of HRS allow an earlier diagnosis and specific treatment initiation (Table 46.1, Fig. 46.1). Accordingly, the specific treatment for HRS should be started immediately after the documentation of a lack of response to fluid challenge, without the need to wait for a doubling of creatinine levels. Furthermore, it is important to know that most patients with HRS stage 1A will respond to fluid challenge because it is frequently caused by hypovolemia. In patients with HRS stage 1B, only half will have a favorable response to repletion therapy and therefore current guidelines state that vasoconstrictors should be used only in this category of patients.

The exclusion of structural kidney injury is very important and is stipulated as a diagnostic criterion. Prerenal kidney failure azotemia is the most common cause of AKI in liver cirrhosis, and it develops as a complication to diuretics and LVP without albumin infusion or gastrointestinal bleeding. Thus, for establishing the diagnosis of HRS, the following should be confirmed: the absence of shock or nephrotoxic drugs, no improvement after diuretics withdrawal or volume expansion with albumin for 2 days, normal kidney ultrasound, and the absence hematuria of proteinuria.

Management of HRS

Despite the progresses and standardization of the pharmacological therapy in the last three decades, HRS is considered as one of the cirrhosis complications with the poorest outcome. The immediate goal of treatment in cirrhotic patients with HRS is reversal of the acute kidney injury. Ideally, therapy should include a short-term

improvement of the liver function which most often not possible [30–32]. Numerous confounding factors are known to precipitate HRS. Their prevention can often be achieved by prompt action and close monitoring. HRS regularly develops in patients with systemic bacterial infection (especially, SBP) and/or severe alcoholic hepatitis.

In addition, HRS prophylaxis is an extremely important element and identification, and treatment of precipitating factors is mandatory, given that the prevalence of unprecipitated AKI is low (1.8%) [10]. The following recommendations are mandatory for any patient with liver cirrhosis and ascites: In cases of SBP, a combination of albumin (1.5 g albumin/kg body weight on the first day and 1 g albumin/kg body weight on day 3, up to a total amount of 100–150 g/24 h) with antibiotic therapy has been shown to reduce the incidence of HRS and mortality in patients with PBS [14, 17, 33]. AKI-HRS appears in more than 30% of patients with SBP and is associated with worse outcomes [34]. Patients who benefit particularly from the administration of albumin are those with bilirubin over 4 mg/dL and serum creatinine over 1 mg/dL. Administration of norfloxacin 400 mg/day to patients with proteins in ascites <15 g/L, with bilirubin>3 mg/dL, Child-Pugh score > 10, serum sodium <130 mEq/L and/or serum creatinine>1.2 mg/dL reduces the risk of HRS and improves survival [17, 35]. Regarding therapeutic paracentesis, any paracentesis over 5 L requires an efficient administration of albumin with 8–10 g of albumin for each eliminated liter of ascites [14, 17]. Maintaining the hemodynamic balance, renal perfusion, prophylactic antibiotherapy are mandatory measures in cirrhotic patients with upper GI bleeding, since these measures have been shown to reduce the frequency of infectious complications, HRS, reducing both mortality and length of hospitalization. Generaly, nephrotoxic medication should be avoided in cirrhotic patients despite NSAIDs are required. These drugs should be stopped and replaced by therapeutic classes that do not affect the kidney function. In patients undergoing investigation with iodinated contrast agents, renal injury prophylaxis is recommended. The risk of impaired renal function occurs 72 h after administration of the contrast agent, which is why, after this time, clinical monitoring of serum creatinine is mandatory.

General Measures

Patients with HRS require:

- Monitoring of BP, HR, fluid intake, diuresis, weight.
- Discontinuation of diuretics (spironolactone or other potassium-sparing diuretics are contraindicated due to the risk of hyperkalemia; furosemide may be useful in some patients with low diuresis);
- Central/peripheral venous supply (at least two venous lines).
- The initial assessment includes blood counts, coagulation tests, liver tests, serum albumin, electrolytes, urea, serum creatinine (for calculating the Child Pugh and MELD scores, assessment of renal function and hydroelectrolyte imbalances).
- Exploratory paracentesis is mandatory (albumin, nuclear polymorphism, bacteriology);

– Urine examination - urinary electrolytes, osmolarity, sediment, cultures.
– Excessive fluid administration should be avoided to reduce the risk of dilution hyponatremia and acute pulmonary edema.

Subsequently, every 48 h, urea, creatinine, serum ionogram will be monitored. Patients with ALD need more careful supervision and monitoring because at hospitalization/during hospitalization they may present/develop evolving neuropsychiatric manifestations related to alcohol consumption: delirium tremens, withdrawal syndrome, exacerbations of neuropsychiatric manifestations, etc. Any of these manifestations are often associated with hemodynamic and hydro electrolytic changes that must be closely monitored and psychiatric/neurological consultation is mandatory for each patient.

Specific Treatment of HRS

Therapeutic options for patients with HRS include pharmacological therapy (administration of vasoconstrictor and albumin), hepatic dialysis, transjugular porto-systemic shunt (TIPS) and liver transplantation. Pharmacological therapy, although without a well-defined pathogenic basis, often remains the only therapeutic option for patients who are not candidates for liver transplantation.

Systemic vasoconstrictors are the only therapeutic class with a therapeutic effect demonstrated in randomized studies in HRS. There are three classes of systemic vasoconstrictors: (a) vasopressin analogues (ornipressin, terlipressin) that induce smooth muscle vasoconstriction and decrease portal pressure (b) somatostatin analogues (octreotide) that may inhibit the release of systemic vasodilators [36], and (c) alpha-adrenergic agonists - midodrine and norepinephrine (NE) that act to constrict the smooth muscle and increase systemic vascular resistance. Terlipressin, a vasopressin analog with greater affinity for the vasopressin V1 receptor (V1R:V2R 2-6:1) [37] is the most studied vasoconstrictor in the treatment of HRS and the most utilized vasoconstrictor in Europe, Asia, and Latin America; it is not approved by the Food and Drug Administration (FDA) in North America [37]. The combination of octreotide, midodrine and albumin improves renal function in patients with HRS type 1, without ischemic side effects. These three vasoconstrictors should be mixed with human albumin infusion given at a dose of 20–40 g/day [38].

Clinical experience, efficacy and superior safety profile have made terlipressin the first therapeutic option in patients with HRS type 1. Standard treatment in HRS is terlipressin and albumin, with a minimum duration of 3 days and a maximum duration of 14 days. In single administration, the efficacy of terlipressin in HRS remission is inferior to the combined administration of terlipressin and albumin, suggesting that albumin is a mandatory component of the regimen. The mechanism of action of albumin is not only the effect of plasma expansion but is associated with

a vasoconstrictor effect in the peripheral arterial circulation. The combination of terlipressin with albumin has maximum efficacy, causing improvement in renal function in 65–70% of cases of type 1 HRS.

Terlipressin can be administered as an intravenous bolus (i.v.) at a dose of 0.5–1 mg every 4–6 h or as a continuous infusion; continuous administration is preferred because, although the efficacy is similar, the side effects are less than bolus administration. Treatment is initiated with terlipressin 2 mg/day in continuous infusion, plus albumin 20–40 g/day; terlipressin dose is increased by 2 mg/day if creatinine does not decrease by more than 25% of baseline within 3 days, and may be increased to a dose of 12 mg terlipressin/day (patients who do not respond to 12 mg/day, do not respond to additional dose increases). In patients responding to treatment, it should be continued until serum creatinine drops below 1.5 mg/dL. The only contraindication to terlipressin is ischemic coronary heart disease and during treatment it is recommended to carefully monitor for possible side effects: arrhythmias, mesenteric ischemia; their appearance requires dose modification or even discontinuation of administration, adequate hydration. Vasoconstrictors that can be used in the treatment of HRS are presented in Table 46.2.

After discontinuation of treatment, HRS recurs in a small number of cases (less than 15%) compared to non-specific patients (volume correction with saline or albumin, dopamine, octreotide). Resumption of treatment in case of recurrence has the same effectiveness, and ischemic complications do not exceed 5%.

Transjugular Porto-Systemic Shunt

Although there are data showing that TIPS can be effective in normalizing renal function (creatinine ≤1.5 mg/dL) in a substantial proportion of patients with HRS, its use in practice is usually limited by the fact that HRS usually occurs in patients with severe hepatic impairment (which contraindicates TIPS). The indication is reserved for patients without hepatic encephalopathy, with bilirubin <15 mg/dL and Child Pugh score <12.

Table 46.2 Vasoconstrictor drugs indicated in the treatment of HRS

Drug	Administration
Terlipressin	Continuous iv infusion - 2 mg/day, with the dose increasing by 2 mg/day every 2 days if the creatinine does not decrease by more than 25% of the initial value; maximum dose - 12 mg terlipressin/day
Norepinephrine	Continuous iv infusion with 0.5–3.0 mg/h; the patient should be supervised in an intensive care unit, with careful monitoring of BP and heart rate
Midodrin and Octreotid	7.5–12.5 mg/day midodrin p.o. plus 100–200 μg octreodide, administered subcutaneously every 8 h (the effectiveness of this combination is quite limited, being used in countries where terlipressin is not available)

Renal and Hepatic Replacement Therapy

Hemodialysis is indicated in patients with HRS who are on the waiting list for liver transplantation, in whom renal function is nonresponsive to medical treatment. MARS (Molecular Adsorbent Recirculating System) is indicated in patients without a vasoconstrictor response and with severe liver dysfunction on the transplant list, but the results are contradictory. Liver transplantation is the ideal, curative treatment for patients with end-stage liver cirrhosis, and therefore of those with HRS. In practice, however, performing the liver transplant for HRS is extremely rare, as most patients with HRS type 1 die before the transplant can be performed and in those with HRS type 2, although they manage to survive the transplant, poor control of refractory ascites may contraindicate transplantation. Patients transplanted for HRS have a higher proportion of postoperative complications, increased length of hospitalization in intensive care and significantly higher short-term mortality. In the long term, survival is about 60% at 3 years, compared to 70–80% in transplant patients without HRS. In patients with type 2 HRS, several remarks should be made: treatment with vasoconstrictors is less effective than in type 1 HRS due to the high recurrence rate (although the initial resolution can be obtained in almost 80% of cases, recurrence is the rule in almost all patients); TIPS appears to be an effective therapeutic alternative for the management of HRS type 2 and refractory ascites.

Chapter 47
Acute Liver Failure Due to Alcohol Intoxication—Therapeutic Options

Carmen Fierbinteanu-Braticevici and Vlad-Teodor Enciu

Abstract Acute liver failure is a relatively common complication of patients with alcoholic hepatitis (AH) and it is characterized by severe liver cell dysfunction. AH can be seen as Acute-on-chronic liver failure (ACLF), as most patients have preexisting liver damage. ACLF is characterized by acute deterioration, multiple organ failure, evidence of systemic and hepatic inflammation and a high risk of mortality. Patients with AH benefit from therapies directed towards reducing liver injury and suppressing inflammation. Traditional, established approaches focus on nutritional support while some patients benefit from corticosteroids. Other therapeutic strategies warrant further confirmation in larger controlled trials. For instance, the addition of intravenous N-acetyl cysteine (NAC) to prednisolone may improve the survival of patients with severe AH. Several studies have demonstrated the efficacy of Granulocyte–Colony Stimulating Factor in mobilizing stem cells from bone marrow to liver, with improvement of clinical, biochemical, and histological profile in patients with liver failure. Some pilot studies suggest that healthy donor fecal microbiota transplantation has a beneficial effect on the outcome of patients with ACLF. In selected cases, the time to liver transplantation may be bridged with liver-assist devices (artificial livers). Liver transplantation has also been shown to improve survival in these patients but acute alcohol intake usually prevent organ allocation.

Introduction

For a very long time, alcohol consumption has been an accustomed practice in many cultures. Due to increased availability and globalization, alcohol abuse has become a worldwide health concern. Alcohol-related liver diseases (ALD) includes a wide range of hepatic disorders, from hepatic steatosis to episodic steatohepatitis, alcoholic hepatitis, progressive liver fibrosis and lastly alcoholic cirrhosis.

Acute liver failure (ALF) is a syndrome characterized by an acute deterioration of liver function on an otherwise healthy liver, causing different degrees of hepatic encephalopathy and elevated prothrombin time/international normalized ratio (INR), with onset in under 26 weeks [1]. This definition originates from the studies and observations of drug related liver toxicity [2]. Untreated, ALF has a high mortality and, consequently, early recognition and prompt management are crucial. Considering the severity of the disease, it should be treated in an intense care unit with the possibility for liver transplantation [3].

Based on the debut of **hepatic encephalopathy (HE)** and the onset of jaundice, ALF can be subcategorized in three forms: **hyperacute** (<7 days), **acute** (7–21 days) or **subacute** (>21 days and <26 weeks). Patients with hyperacute presentations usually develop cerebral edema, while patients with subacute forms have renal failure or portal hypertension. These subcategories have different prognoses, reflected more by the underlying cause and not the duration of the disease. For instance, patients with hyperacute liver failure usually have a better long-term prognosis, related to the fact that these patients often have acetaminophen intoxication or ischemic hepatitis, which have a better outcome once the disorder has been recognized. On the other hand, subacute liver failure, secondary to Wilsons disease, comprises a poor long-term prognosis [4].

Recently, **acute-on-chronic liver failure (ACLF)** has been recognized as a distinct disorder, especially in ALD (see also Chap. 67). ACLF involves an acute decompensation of an underlying chronic liver disease, association with other organ failures, and has specific pathogenic mechanism, evolution, and treatment [5]. Regardless of being diagnosed in under 26 weeks, ALF due to alcohol consumption is considered in cases of **severe alcoholic hepatitis (sAH)** even though most patients have a pattern of chronic drinking, with different degrees of subclinical hepatic injury [6]. Particularly, the term ALF due to alcohol intoxication accounts for a minority of cases and should not be used in this context since alcohol intoxication refers more to neurologic or cardiac complications. Nevertheless, since the underlying pathomechanisms are still not completely understood, further studies are needed regarding the terminology. In this chapter we will present the management of ALF due to alcohol consumption as an integrated subgroup of ACLF and sAH. Related chapters on alcoholic hepatitis can be found in Part X (Chaps. 64, 65, 66, 67 and 68).

Assessing Disease Severity

Early assessment of patients with ALF and sAH is vital. Identifying patients who are unlikely to respond to standard therapy and may require liver transplantation is based on severity scores that are poorly standardized. Many patients develop multiple organ failures with rapid deterioration while waiting on the transplant list, hence a readily identification of transplant candidates should be achieved as soon as possible. Clinical and paraclinical features that indicate a poor prognosis include presence of hepatic encephalopathy, extrahepatic organ failure, coagulopathy, and high bilirubin levels. Those have been combined in the classic prognostic and severity scores for alcoholic hepatitis (AH) such as Maddrey's discriminant function, model for end-stage liver disease (MELD), Glasgow alcoholic hepatitis score, ABIC score and Lille score [7–9]. A Maddrey score >32 indicates a severe form of AH, poor prognosis, important hepatic and extrahepatic inflammation, with high risk of organ failure [9]. While the MELD score can be used for severity assessment, it is normally used for liver transplant list stratification [10].

ALF in critically-ill patients can be assessed using scoring systems such as sequential organ failure assessment (SOFA) score and other scores that are used in intensive care units [11]. This score has been also the basis for establishing the CLIF-OF score in the CANONIC study and the definition of ACLF [12]. The clinical prediction scores in ACLF, particularly CLIF-OF, is showing superiority in assessing severity and predicting outcome in this disease category. CLIF-OF includes organ assessment: liver function (bilirubin levels), kidney function (creatinine levels), brain function (hepatic encephalopathy), coagulation (INR), circulatory system (mean arterial pressure), and respiratory function (PaO_2/FiO_2) [12–14]. The CLIF-OF score also helps to determine short and long-term mortality in patients with ACLF, based on the number of organ failure(s) [12].

Diagnosis of Acute Liver Failure

ALF is a rare syndrome with highly specific characteristics consisting of acute modifications of liver blood tests in an individual without an underlying chronic liver disease [4]. While ALF is a characteristic of sAH and ACLF, they are recognized as acute decompensations of chronic liver diseases with particularly higher morbidity and mortality due to concomitant multiple organ failure(s) [14]. **ALF includes the following criteria**:

1. Increased hepatic enzymes,
2. Presence of hepatic encephalopathy and
3. Prolonged prothrombin time (PT) or International Normalized Ratio (INR, higher than 1.5) [15].

Although, INR > 1.5 is still accepted for defining ALF, there is a debate that higher cut-off values should be used or only PT since INR is not standardized and it is used for monitoring Warfarin therapy [16]. The timing of evaluation and diagnosis is crucial as early treatment initiation may improve the patient's outcome. Moreover, a timely evaluation stratifies patients that may benefit from liver transplantation [17].

Key Histologic Features in AH

Details are provided in the histology chapter in this book but are briefly recapitulated within the context of this chapter. Liver biopsy is sometimes needed to advance the diagnosis. In ALF it is a risky maneuver due to the presence of coagulopathy and bleeding complications, especially in the acute episode of liver failure [18]. Moreover, the histologic features are not specific as they can also be found in patients with nonalcoholic steatohepatitis. Histologic finding in AH include: steatosis, hepatocellular ballooning, megamitochondria, lobular inflammation with neutrophilic PMN cells, canalicular and/or ductal cholestasis, Mallory-Denk bodies, fibrosis disposed pericellular, perisinusoidal and perivenular [19, 20]. From these, the presence of neutrophils is more often seen in AH. Mallory-Denk bodies (previously called Mallory bodies) are eosinophilic intracellular protein deposits, which are cytokeratins, a normal component of the hepatocyte cytoskeleton. Mallory-Denk bodies do not appear to play a role in the pathogenesis of the hepatic injury, they are not specific, and can also be found in other liver pathologies [21, 22].

A histological score has been proposed for the severity stratification of AH which includes stage of fibrosis, extent of bilirubinostasis, grade PMN infiltration and presence or absence of megamitochondria. The extent of fibrosis and bilirubinostasis is directly linked to the severity of AH. On the other hand, high PMN infiltration and megamitochondria have been seen in mild cases [19].

Therapeutic Options

General Management

Patients with ALF should be admitted in centers with liver transplantation availability. More than half of alcohol-induced ALF do not recover with standard therapy and require liver transplantation [23]. Patients benefit from early transfers to a liver transplantation center since later transports can become difficult due to clinical deterioration, aggravation of coagulopathy and increased intracranial pressure [24]. Patients are usually managed in intensive care units (ICU) but can also be admitted on a general medical ward provided they have grade I encephalopathy and frequent

neurologic checks. Neurologic stimulation should be minimized, patient's room should be quiet, without audible monitors and dimly lit in order to prevent increased intracranial pressure [4].

Laboratory testing is used to follow the patients' evolution and to monitor for complications. Hepatic enzymes should be tested daily. More frequent lab tests include (up to three times a day) coagulation parameters, complete hemogram, ionogram and arterial blood gas [1]. Glycemia is monitored every 6 h. It is highly recommended that ammonia levels are tested daily, as high values are associated with cerebral herniation [25]. Plasma supplementation should only be used in cases of severe coagulopathy since it can prevent the usage of prognostically important prothrombin/INR monitoring. Increasing bilirubin and INR levels indicate worsening of liver failure. Amelioration of transaminase levels (ALT/AST) should be interpreted with caution since this can indicate either recovery or worsening of ALF as a result of loss of hepatocyte mass [1].

Hemodynamic homeostasis is perturbed in patents with ALF due to low systemic vascular resistance. Glucose levels and intravascular volume are decreased as a result of low oral intake and extravasation of fluid in the interstitial space [26, 27]. Consequently, patients may be either hypotensive or hypoglycemic and fluids should be renewed accordingly using IV saline and glucose fluids. However, fluid supplementation should be managed carefully, as overhydration may worsen cerebral edema [27].

Patients who do not respond to fluid supplementation alone require vasopressor support. Norepinephrine is the preferred agent as it facilitates peripheral organ perfusion with lesser cardiac impact and better preservation of splanchnic blood flow than other vasopressors. The goal is to maintain a mean arterial pressure of 70-75 mmHg. Vasopressin can be added to obtain as it potentiates the effect of norepinephrine [28].

Nutrition is essential in the management of ALF. Early initiation prevents catabolic status and decreases risk of stress ulcers in critically-ill patients. As a result, protein restriction is not recommended and a daily intake of 50–60 g of protein is required to compensate protein catabolism. Oral and enteral nutrition is preferred since this maintains the intestinal barrier and prevents bacterial translocation. Nasogastric tube placement should be done with care as it can increase intracranial pressure through gag reflex, so it should only be performed in intubated and sedated patients [29, 30].

The risk of hemorrhage should be assessed as patients with ALF can develop severe coagulopathy due to decreased coagulation factors synthetization. Conventional indices of coagulation (INR) have been shown to be not accurate in determining bleeding risk in patients with liver diseases. For these reasons, additional tests may be required for patients who require invasive procedures or who develop bleeding, like thromboelastrography or thromboelastrometry such as rotational thromboelastometry (ROTEM), which, unfortunately, are not widely used [3]. Prophylactic administration of fresh frozen plasma has been shown to not

improve survival in a small, randomized trial and can cause fluid overload or interference with liver function assessment [31, 32]. As the gastrointestinal tract is the major site of bleeding in these patients, prophylaxis of stress ulcers should be taken into consideration using proton pump inhibitor or blockers of histamine-2 receptors.

Infection Management and Prevention

Patients with ALF have a high risk of infection and sepsis so close monitoring and prompt actions are necessary. The most common sites of infection are (in descending order of their prevalence) infections of the respiratory tract, the urinary tract and the circulatory system [33]. Symptoms are usually diminished, fever or sputum production may be absent, and the only indication of an infection may be the appearance/worsening of encephalopathy or kidney function. AASLD and EASL guidelines suggest that all patients with ALF, including those without signs of infection undergo routine urine, sputum, blood cultures and chest radiographs to detect a possible infection [4, 27]. This approach is still controversially discussed among specialists in the light of the limited data regarding the prognostic importance of bacterial cultures and imaging surveillance. Moreover, positive cultures, in the absence of infectious signs, may be due to bacterial or fungal colonization or contamination [3].

Patients with ALF and concomitant ascites should undergo diagnostic paracentesis [3]. Antibiotic prophylaxis have shown mixed results. In a randomized trial with 59 patients with ALF who were not infected, antibiotic administration reduced the rate of infection, but did not improve overall survival rate [34]. In a retrospective study on 1151 patients with ALF, antibiotic prophylaxis did not reduce neither bloodstream infection (sepsis) nor short-term mortality [35]. In presence, it is general consensus to give antibiotic therapy in case of any sign of infection and the threshold for initiating antifungal treatment is kept low since many of these patients are at high risk due to prolonged hospitalization, parenteral nutrition and glucocorticoid treatment. If antibiotic therapy is indicated, broad spectrum antibiotics are used, avoiding hepatotoxic and nephrotoxic antibiotics, particularly aminoglycosides. Piperacillin/tazobactam or a fluoroquinolone could be used without the need of culture surveillance [4, 27].

Organ Failure Targeted Therapy

Severe forms of alcohol-induced ALF involve multiple organ failure due to a systemic inflammatory response. Cardiovascular failure should be treated with vasoactive agents preferentially with Norepinephrine. Respiratory failure should be managed with standard sedation and invasive or non-invasive ventilation techniques.

Neurological manifestation due to intracranial hypertension should be treated using mannitol or hypertonic saline solutions. Renal failure often requires extracorporeal renal replacement therapy to correct electrolyte and metabolic imbalances [4].

Treatment for ALF as a Complication of Severe AH

Corticosteroids (CS) remain the first line therapy for severe forms of alcoholic hepatitis (Maddrey>32). For more details, chapters in the AH part of this book are recommended. The response rate is calculated using the Lille model which includes a series of static parameters and bilirubin as a dynamic parameter at the start of treatment and at day 7. A Lille score >0.45 after 7 days predicts failure of corticosteroid treatment and other therapeutic options should be considered. It is interesting to note that the response rate seems to be linked to the degree of ACLF. In other words, the higher the degree of ACLF is the lower will be the response rate [36]. This observation highlights the importance to carefully screening for other organ failure(s) prior to corticosteroid treatment.

Pentoxifylline alone or in combination with CS has been shown to not improve short term survival at day 28, nor does it improve the survival of CS non-responders [37]. Granulocyte colony stimulation factor (G-CSF) has been thought to promote liver regeneration through mobilizations of bone marrow stem cells and proliferation of hepatic progenitor cells [38]. However, as discussed in a recent systematic review, while G-CSF improved survival in steroid non-responders and reduced short-term mortality in patients with ACLF, this could not be confirmed in a prospective multicenter phase 2 study. Here, G-CSF, at a dose of 5 μg/kg per day for 5 days and then every third day until day 26, failed to improve the CLIF-OF score, the MELD score or the incidence of infections [39].

Another important question is centered around intestinal microbiota. Alcohol consumers are knows to have dysbiosis of the intestinal microbiome which contributes to the development of liver injury and maintains liver inflammation [40]. In a pilot study, 1 week of fecal transplantation was effective and improved survival in patients with sAH-ACLF at 1.5 years follow-up [41]. Many patients with alcohol-induced ALF, especially those with ACLF, do not respond to standard therapy. Since liver transplantation is not readily available, new therapeutic options have been studied. Artificial liver support systems are extracorporeal nonbiological dialysis machines are designed to remove albumin-bound toxins (bile acids, bilirubin) and circulating cytokines, thus limiting systemic inflammation. There are five artificial liver support systems: molecular adsorbent recirculating system (MARS), single-pass albumin dialysis (SPAD), fractioned plasma separation, adsorption and dialysis (FPSA)- Prometheus System, selective plasma filtration therapy and hemodiafiltration. While these dialysis systems improve survival in non-alcohol induced ALF, all studies have shown that they do not improve survival patients with sAH and ACLF. However, they transiently reduce pathological levels of liver

biomarkers and are occasionally used for bridging to curative liver transplantation [42–44]. High volume plasma exchange has shown some benefit in patients who are treated early and will not undergo liver transplantation [45].

Liver Transplantation

Patients with sAH usually fail to respond to most therapeutic options including CS, hence liver transplantation remains the only viable treatment option [46, 47]. All causes of ALF are given the highest priority on the transplant list, except ALD (United Network for Organ Sharing [UNOS] status 1). The transplant list stratification is still made based on MELD-Na score which assesses liver and renal function. The newer concept of ACLF highlights the importance of multiple organ failure and increased infection risk in this syndrome. Thus, the CLIF-OF scoring system offers an additional means to assess wait-list mortality and futility of transplantation [48]. Due to the ethical dilemma arising from a high proportion of relapse among ALD patients and the limitation in predicting alcohol relapse, most countries abide by the 6-month abstinence rule [49]. Moreover, these patients must adhere to a rehabilitation and abstinence program. In addition, social support is required maintain sobriety. On the other hand, most of them are critically-ill and would not survive without liver transplantation. For these reasons, and as is discussed in the AH part of thi book, liver transplantation is also performed in alcohol-induced ALF or sAH in highly selected patients with good short and long-term survival rates [50–52].

While continuation of alcohol abuse is associated with post-transplant morbidity and mortality, the prediction of alcohol relapse lacks data and may be similar to patients who follow the six-month abstinence period [52]. In addition, while inflammatory and coagulation disturbances associated with AH could increase perioperative complications, long-term morbidity is more tied to recurrent alcohol abuse rather than complications of transplantation [53, 54]. Overall, there are increasing efforts directed towards establishing liver transplantation protocols in order to facilitate graft allocation in sAH non-responders. Ultimately, patients with sAH who do not respond to conventional treatment, have more than four organ failures and do not meet the criteria for liver transplantation and they are considered for palliative care [55].

Alcohol Withdrawal Treatment

Alcohol withdrawal is only briefly mentioned here, as it is discussed in more detail in other chapters of this book. Alcohol abstinence outweighs any other type of targeted therapeutic approach in patients who have ALD. This usually comes along with a high probability of alcohol withdrawal syndrome, particularly in acute phases. Minimally symptomatic or asymptomatic patients can be prophylactically

treated with oral benzodiazepines, while IV administration is reserved for severe cases with delirium tremens and seizures. Attention is required while administering iv benzodiazepines in patients with ALF as it can worsen pulmonary function and develop acute respiratory distress syndrome. Symptom-triggered approached is favored over front-loading therapy [36].

Conclusions

Excessive alcohol consumption is a world-wide healthcare problem with enormous socio-economic and clinical consequences. ALF consists of an acute deterioration of liver function on a previously healthy liver. Alcohol consumption induces subclinical hepatic steatosis, hence, ALF in drinkers can be seen as deterioration of a chronic disease. The accepted terms are sAH or ACLF that cause ALF and have specific pathomechanisms, prognosis and treatment. Risk stratification and severity is poorly defined due to lack of specific prognostic biomarkers and a yet insufficiently understood underlying disease mechanisms, further complicating the therapeutic management. Despite many previous studies with different agents, corticosteroids are momentarily the only approved option for a limited number of patients. Liver transplantation remains difficult to access in an era of organ-donor shortage and stigma towards a disease that is considered self-inflicted in many countries. While the general management strategies for ALF can also be applied to sAH and ACLF, treatment of associated organ failures and infections are of an additional high priority.

Chapter 48
Management of Acute Alcohol Withdrawal

V. Enatescu, R. Kalinovic, A. Pascariu, and G. Vlad

Abstract Alcohol use disorders (AUD) are the most prevalent psychoactive substance use disorders worldwide, caused by several biological, psychological, and socio-cultural factors.

Alcohol withdrawal syndrome (AWS) is a frequent complication of those who met the criteria for alcohol dependence. Its intensity may vary from symptoms such as insomnia, tremors, sweating, and tachycardia up to more severe complications such as delirium or seizures, implying 5–15% mortality.

Currently, there are two main directions in the pharmacological management of AWS. First, symptom-triggered therapy is when treatment is provided if the symptoms are severe but not if the symptoms are mild. In this latter case, simple continuous monitoring without medication is sufficient. Therefore, the unnecessary use of benzodiazepines or phenobarbital is avoided. Secondly, in those being delirious or having a prior history of Delirium Tremens (DT) or seizures, a fixed-dose regimen of some type needs to be administered.

On the other hand, the pharmacological treatment of AWS should cover three symptomatic domains: neuropsychiatric symptoms, autonomic symptoms, and motor disturbances. Considering the complexity of AWS, treatment should be individualized according to the physiological and pathological particularities of each case.

Finally, the mainstay of alcohol withdrawal management is early adequate treatment.

Introduction

Alcohol is the most widely used psychoactive substance worldwide and across the different cultures dating back to 3150 BC in Ancient Egypt [1]. As societies have emancipated, the differences in alcohol consumption have diminished in regard to gender, age of onset, geographical region, and even socio-cultural affiliation [2].

In line with WHO data, in 2016, 2.3 billion (42%) people aged 15 or over were current drinkers meaning at least one use of alcohol in the past 12 months. Based on traditional and cultural considerations, in some low-income and middle-income countries, this data should be cautiously interpreted, as a significant quantity of alcohol is produced in a domestic setting so that official statistics overlook it [3]. On the other hand, due to the high level of stigma associated with Alcohol Use Disorder (AUD), at least a part of patients are often diagnosed with other psychiatric or medical conditions [4]. As a result, AUD could become either a secondary diagnostic or, in some cases, even a hidden or masked condition.

According to a systematic analysis for the Global Burden of Disease Study 2016 that has considered diseases attributable to alcohol and drug use in 195 countries between 1990 and 2016 revealed that globally, in 2016, 99.2 million disability-adjusted life-years (DALYs) (95% UI 88.3–111.2) and 4.2% of all DALYs (3.7–4.6) were attributable to alcohol use. The authors concluded that alcohol significantly contributes to the global disease burden [5].

Alcohol withdrawal syndrome (AWS) is a life-threatening condition that occurs in up to 50% of patients who are affected by AUD when they cease or diminish their alcohol intake [6]. Undoubtedly, AWS needs to be promptly detected and treated, especially in critically ill patients admitted to an intensive care unit (ICU) or referred to the emergency room (ER) when other underlying medical conditions may significantly increase the risk of death [7]. Generally, based on the literature data, AWS implies a 5–15% mortality [8].

Finally, AWS is a severe condition that can evolve to delirium tremens (DT), a state of altered consciousness that often requires higher doses of medications and sometimes physical restraints, making clinical practitioners confront ethical issues [9].

Neurobiological Basis of Alcohol Withdrawal Syndrome

Harmful and chronic alcohol drinking alters the brain's structure and neurotransmitter systems. The main two neurotransmitters that play a key role in AWS are glutamic acid or glutamate (Glu) and gamma-aminobutyric acid (GABA). Glu has an excitatory effect on the central nervous system (CNS), whereas GABA has an opposite inhibitory neurobiological effect. Glutamate acts on both metabotropic and ionotropic receptors; of the latter, N methyl aspartate (NMDA) plays a major role in several neurodegenerative and psychiatric conditions. Glu stimulates all neurotransmitters including catecholamines (dopamine and norepinephrine) contributing to

the increased autonomic sympathetic symptoms of AWS. In a few cases, dopaminergic hyperactivity may result in hallucinatory experiences during DT. Normally, the two neurotransmitters are in a steady balance, GABA being synthesized from glutamate via glutamic acid decarboxylase (GAD) [10, 11]. From a psychoactive standpoint, alcohol stimulates GABA neurotransmission to the detriment of Glu which will lead to the upregulation of NMDA glutamate receptors and glutamatergic hyperactivity if abruptly cessation or significant reduction of alcohol intake happens. The AWS symptoms result from the imbalance in brain receptors between GABA and NMDA that develop on the discontinuation of chronic and harmful alcohol consumption [12].

On the other hand, repeated withdrawal episodes lead to the so-called "kindling," in which neuronal hyperexcitability causes an increased severity of AWS over time that may be complicated by seizures and DT [13].

Symptomatic Polymorphism of Alcohol Withdrawal Syndrome

The clinical picture of AWS is characterized by an intricate combination of signs and symptoms with varying degrees of severity influenced by the time elapsed from the moment of alcohol intake cessation/reduction, the quantity, frequency and duration of the dependence syndrome, number and severity of previous AWSs, patient's age, comorbidities, and concurrent medication or drug use [14–17].

Given the polymorphism of AWS clinical presentation, two approaches can be considered in understanding the symptomatic complexity of this syndrome, a categorial one, respectively a quantitative one.

The categorial approach aims to identify and arrange symptoms into clusters and attribute them, as much as possible into nosologic entities, in order to encompass the effects this pathology exerts on different physiological systems. According to this, the AWS symptoms can be classified in autonomic, motor, neuropsychiatric and related to underlying medical conditions, as detailed in Fig. 48.1 [8, 14–16].

The quantitative approach regards symptomatology as a continuum, with the purpose of quantifying AWS severity. The literature classifies the natural evolution of this syndrome into four main degrees which develop and partially overlap over the course of the first few days [14, 16] as follows:

Mild AWS: is characterized by the presence of autonomic hyperactivity symptoms (see Fig. 48.1), insomnia, anxiety, irritability and general malaise [14–16].

AWS hallucinosis: in this stage patients experience transient auditory (voices, sometimes persecutory), visual (zooscopies) and tactile (formication) hallucinations that develop on a clear field of consciousness, which can increase anxiety to the point of psychomotor agitation [14–16].

AWS seizures: generalized tonico-clonic seizures occur in some patients, and are usually self-limited but in some cases, especially if untreated, they can evolve into DT [15, 16].

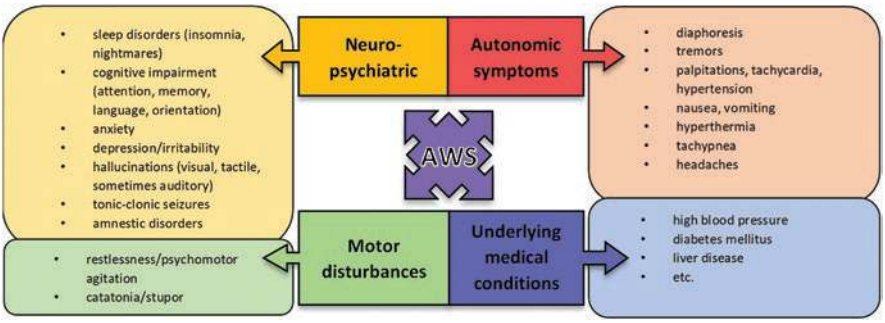

Fig. 48.1 The categorial approach of AWS symptoms

Delirium Tremens: is the most severe form of AWS, manifested by abrupt fluctuations in consciousness, a significant worsening of the aforementioned symptoms (especially the autonomic ones), confusion, disorientation and hallucinations or delusions [14–17].

While the natural evolution of AWS tends to follow this spectrum, clinicians should keep in mind that for some patients the duration and severity of these stages can vary according to the presence or absence of efficient treatment [8, 15, 16, 18].

Measures of the Severity of Alcohol Withdrawal Syndrome

Regarding the assessment of the severity of AWS, the most relevant tool is the revised Clinical Institute Withdrawal Assessment for Alcohol-Revised (CIWA-Ar) scale, which is required for decision-making in AWS management. It must be administered by a trained caregiver, and consists of 10 items, all of which are scored from 0 to 7, except for the orientation category, scored from 0 to 4. The summation of the scores yields an aggregate value that correlates to the severity of alcohol withdrawal, with ranges of scores designed to prompt specific management decisions such as the administration of benzodiazepines. The CIWA-Ar should be used to adjust dosage, detect complications, and identify patients who require more intensive therapy [16].

Risk Factors Associated with the Neuropsychiatric Complications of Alcohol Withdrawal Syndrome

A number of general risk factors are known to predispose patients to developing complications during AWS, such as: advanced age (>65), heavy and regular ethanol use for long periods of time, medical and surgical comorbidities (traumatic brain

injury in particular), marked autonomic symptoms at presentation (especially elevated blood pressure, tachycardia), history of multiple withdrawal episodes (kindling) [16], a positive history for DT or seizures during a withdrawal episode (DT having a stronger predictive value), seizures during the current AWS episode, physiological dependence on drugs that act as GABAergic agents (benzodiazepines, barbiturates) [8, 15, 17].

There are also several individual risk factors: concomitant use of additional addictive substances, active signs and symptoms suggesting at least a moderate severity of psychiatric comorbidity (Dual Diagnosis), concomitant presence of AWS signs and symptoms and a positive blood alcohol concentration (BAC) at presentation [17].

The predictive value of the general and individual risk factors is additive, consequently the more risk factors are identifiable in a patient, the more chances that DT will develop [17].

Thrombocytopenia, low albumin, elevated blood urea nitrogen (BUN) and aspartate aminotransferase (AST) levels could also play a part in identifying patients at risk for developing DT [8, 19].

Although not a direct complication of AWS but rather of thiamine (vitamin B1) deficiency, Wernicke-Korsakoff Syndrome (WKS) often manifests during a withdrawal episode, therefore clinicians should assess if the patient requires thiamine replacement. Besides alcohol dependence, other risk factors include malnutrition and medical conditions which either reduce thiamine absorption or enhance its excretion/consumption [20, 21].

Treatment of Alcohol Withdrawal Syndrome

Objectives

The goals of AWS treatment are to provide symptomatic relief, normalize vital signs, control psychomotor agitation, decrease the risk of seizures, monitoring complications, detection of complications and underlying comorbidities and halt progression to severe withdrawal and prevent death [22–24].

Basic Principles of Acute Alcohol Withdrawal Treatment

It is recommended to administer medication before significant withdrawal symptoms emerge. GABA agonists are the medicines of choice. Delaying the start of treatment can result in withdrawal symptoms that may become difficult to control. Nevertheless, it should be kept in mind that the use of benzodiazepine sedation while the patient is still intoxicated can lead to respiratory depression and death.

For patients with signs of acute alcohol withdrawal on admission, an initial dose of 30 mg chlordiazepoxide is recommended (ideally 6–8 h after the last drink). The patient should then be assessed hourly [25].

Pharmaceutical Compounds and Supplements Used in the Treatment of AWS

Benzodiazepines

Benzodiazepines are the "gold standard" for moderate to severe forms of AWS, given their effectiveness in reducing both withdrawal symptoms and the risk of developing seizures/DT. Benzodiazepines bind allosterically at GABA receptors and increase GABA activity, increase inhibition, and therefore alleviate withdrawal signs and symptoms. The activity of benzodiazepines appears to require some native GABA for benzodiazepines to be effective. Because these drugs have anticonvulsant activity, they are useful in active seizing withdrawal patients. Benzodiazepines have also been shown to reduce mortality associated with AWS. Long-acting benzodiazepines, such as chlordiazepoxide and diazepam provide more protection against delirium and seizures. Short-acting benzodiazepines with renal metabolism (oxazepam, lorazepam) have a better safety profile in the elderly or in those with impaired liver function [16, 26]. The most frequently used BZDs in alcohol withdrawal treatment/prevention are diazepam, lorazepam and chlordiazepoxide.

Administration algorithm: Benzodiazepines are available in different forms (orally, intramuscularly or intravenously) [6]. Oral formulations are preferred in most outpatient settings. Following IV administration, patients should be switched to oral dosing as soon as possible, based on their clinical response. Intramuscular administration should be avoided due to absorption variability [6, 27].

Symptom-triggered regimen: patients are continuously monitored using a structured assessment scale and are given medication only when symptoms exceed a severity threshold. The CIWA-Ar score may also determine the frequency of reevaluation and subsequent dosing until the patient is no longer in weaning and detoxification is complete [27].

Fixed-schedule regimen: fixed-dose administration at predefined intervals (based on AWS severity) according to a schedule. Doses are usually lowered gradually over a few days.

Front-loading regimen: it is recommended for patients at high risk of severe AWS and medical or psychiatric comorbidities. Early control of symptoms with a lower total dose and a lower rate of seizures is achieved by the front-loading therapy method. Starting doses of benzodiazepines should be: diazepam 5–10 mg IV, (lorazepam 2–4 mg IV in patients with severe liver disease) or chlordiazepoxide 25–100 mg orally (oxazepam 10–30 mg orally in patients with severe liver disease) [26]. Loading doses of benzodiazepines should be 5–20 mg of diazepam every

5–10 min, or 2–4 mg of lorazepam every 10–15 min (lorazepam requires a longer time between doses to avoid dose stacking and sudden deep sedation) [22].

Barbiturates

The action of ethanol is replaced by the activity of benzodiazepines, barbiturates and propofol which act on the physiological cause of AWS, thus creating inhibition in an overexcited system. Barbiturates also provide an inhibitory effect caused by the activation of the GABA receptor like benzodiazepines, by a slightly different mechanism at the receptor, which works in the absence of any native GABA receptor. The most used barbiturate is phenobarbital due to its onset and duration of action. The appropriate dose is 65–260 mg every 15–30 min until symptoms are controlled [22].

Thiamine and Folic Acid

The levels of thiamine and folic acid deserve special attention, as long-term malnutrition is common in alcoholic patients. Chronic folic acid deficiencies can lead to the development of megaloblastic or macrocytic anemias, which is why supplementation is recommended [3, 6].

The administration of oral thiamine 100 mg is initiated at the same time as the administration of intravenous therapy and is recommended for a period of 3–6 months in case of abstinence or indefinitely if alcohol consumption is continuous [25].

Anticonvulsants

Antiepileptics such as phenytoin, valproic acid and levetiracetam, do not treat or effectively prevent alcoholic seizures, therefore they are considered adjuvant drugs. Carbamazepine has been shown to have a particular benefit in the treatment of AWS, although it is not available in IV form [22].

While carbamazepine, gabapentin, and valproic acid may be useful in the outpatient management of mild alcohol withdrawal, there is no evidence that this class of drugs can be used effectively in patients with severe AWS [27].

Antipsychotics

When agitation, delirium and hallucinations are not controlled with benzodiazepines, antipsychotics are used as adjunctive therapy. First generation antipsychotics, especially haloperidol, have often been used in patients with psychotic symptoms.

The recommended dose of haloperidol is 2–5 mg intravenously every 0.5–2 h, with a maximum dose of 0.5 mg/kg/24 h. The main disadvantage is that haloperidol is a dopaminergic antagonist and has no effect on GABAergic or glutamatergic systems. It should only be given to patients who have already received benzodiazepine treatment. Intravenous administration of haloperidol may cause QTc prolongation, torsades de pointes, and death. Although a small number of studies have been performed on atypical antipsychotics, it appears that they may have some benefit in reducing withdrawal symptoms, Risperidone and Quetiapine have been shown to be most effective [15].

Alpha-2-Agonists

Alpha-agonists and beta-agonists are used primarily to treat AWS somatic symptoms such as tachycardia or hypertension, but they do not treat the cause [22].

Dexmedetomidine is used to decrease sympathetic overdrive by decreasing norepinephrine release. Some of the more common adverse effects are bradycardia and hypotension, but these have no additive effect to the usual treatment with benzodiazepines, propofol or opioids. Dexmedetomidine is superior to clonidine due to its rapid onset of action and shorter half-life. Studies show that an infusion rate of 0.7 1 g/kg/h is sufficient for most patients, but standardization of dosage for AWS has not been established. It produces light sedation while keeping the patient easily aroused, this helps with routine assessments. Because dexmedetomidine does not prevent withdrawal seizures or DT, they are recommended as adjunctive therapy only if the autonomic symptoms cannot be controlled by benzodiazepines [15].

Clonidine can be used instead of dexmedetomidine but it produces more sedation therefore it is only used as adjunctive therapy in AWS for reducing autonomic sympathetic symptoms [7].

Beta-Blockers (Beta-Adrenergic Antagonists)

Beta-blockers (atenolol) should not be used to prevent or treat AWS, but they are useful for tremors, hypertension and tachycardia, the downside of choosing beta-blockers is that they could mask AWS symptoms and should only be used when the patient is already under treatment with BZDs and presents persistent hypertension or tachycardia [16].

Rehydration and Electrolytes Rebalance

Most patients have hydro-electrolyte imbalances and need to be evaluated and corrected as necessary. Magnesium has received special attention for its potential role in the treatment of AWS since it is an NMDA antagonist. Studies show that there is

a correlation between symptomatic hypomagnesemia and the severity of DTs. Magnesium alone has no beneficial effect on AWS [22].

Sodium oxybate/sodium salt of c-hydroxybutyric acid (GHB) is a natural fatty acid structurally similar to GABA. Alcohol withdrawal symptoms are thought to be suppressed by indirect activation of GABA receptors by GHB. Increased dopamine release in the CNS has been described as an alcohol 'mimicking' effect of GHB [15].

Management of Poorly Controlled AWS

Benzodiazepine-resistant alcohol withdrawal (RAW) is a notion that gained attention in the recent years, even though there is no clear consensus among clinicians regarding the threshold that defines it, the most accepted view defines it as AWS non-responsive to the administration of 40 mg Diazepam (or another benzodiazepine equivalent) in the first 2 h, most often accompanied by seizures and tachycardia [28–31].

Literature suggests that treatment with other agents such as phenobarbital, propofol, dexmedetomidine and ketamine might provide better clinical outcomes, but only as adjunctive therapy to benzodiazepines [31–33].

Phenobarbital is the most commonly used but it has a narrow therapeutic index and requires close monitoring in intensive care settings [33].

Propofol is also considered a viable option, but it is recommended mainly for intubated patients, and it might prolong the need for clinical care [30, 33].

Dexmedetomidine and ketamine yielded promising results in this field but more studies are needed to confirm their reliability for this group of patients [33].

In patients with resistant delirium other etiologies should be screened for [25, 34]. Besides anamnesis, data from caregivers and additional biological and neuroimaging investigations might be needed for identifying a secondary cause or potential medical complications [34]. The importance of a thorough investigation is confirmed by the fact that patients with RAW are more likely to have a psychiatric history, thrombocytopenia, lower potassium and chloride levels and higher values for AST and alanine aminotransferase (ALT) [35]. A cooccurring withdrawal from GABAergic agents such as Gabapentin and a history of repeated AWSs (kindling) might be the cause for the lack of response to benzodiazepines through complex alterations of the GABA receptors therefore considering an alternative strategy is advised [27, 36, 37].

Current literature suggests that for diazepam-resistant delirium or agitation lorazepam and po/im haloperidol should be considered as rescue medication. Clinicians should be careful of contraindications such as CNS depression, coma, long QT syndrome, etc. [25, 34, 36, 38].

Treatment of Alcohol Withdrawal syndrome's Neuropsychiatric Complications

Alcohol-Induced Amnestic Disorders (Wernicke's Encephalopathy and Korsakoff's Syndrome WKS)

The combination of Wernicke's Encephalopathy (WE) and Korsakoff's Syndromes (KS) is a neurological disorder caused by thiamine (vitamin B1) deficiency mostly found in patients with AUD because alcohol is poor in nutrients and high in calories, also patients with AUD tend to have a poor diet, vomiting, diarrhea and liver problems that can lead to improper absorption and storage of thiamine [39]. It can also occur in other diseases that are not associated with alcohol consumption. WE is an acute syndrome characterized by three main clinical symptoms: mental status changes (confusion), ataxia and eye abnormalities (diplopia, nystagmus, ophthalmoplegia and rarely ptosis). Symptoms develop over a few days or weeks and are often reversible [40]. While WE is an acute condition, KS is a chronic condition that can be preceded by WE and that can evolve to dementia, it is characterized by permanent or serious amnesia along with confabulation [41]. Treatment involves stopping alcohol consumption, rehydration and replacing thiamine. Given that oral absorption is compromised in alcoholic patients, it is preferred to administer thiamine IV or IM. IM preparations have a lower incidence of development of anaphylactic reactions. Diagnosed patients should be given parenteral thiamine 200–500 mg three times a day for 3–5 days, followed by oral administration of 250–1000 mg/day. In patients with suspected WE, parenteral thiamine 250–300 mg two times a day for 3–5 days, then oral thiamine 250–300 mg/day [42, 43]. When glucose infusion is required, thiamine is given before or at the same time as glucose to prevent precipitation of WE, because thiamine as a coenzyme that plays a fundamental role in glucose metabolism.

Alcoholic Hallucinosis

Alcoholic hallucinosis can occur both during acute intoxication or during withdrawal [44]. The onset is usually 48 hours after the last alcohol consumption and can last for days [45]. Therapeutic measures involve abstinence and, in some cases, high potent neuroleptic drugs (haloperidol) [46]. Valproate has been shown to be effective and well tolerated [47]. In the case of alcohol abstinence, the prognosis is good, but in 10–20% of cases, alcohol hallucinosis may persist for a long time.

Alcoholic Withdrawal Induced Seizures

Prevention of seizures is an important goal in the treatment of acute AWS syndrome. Alcohol withdrawal seizures usually occur within 6–48 h after cessation of ethanol consumption and are usually generalized tonico-clonic seizures, partial

seizures can also occur [48]. Literature indicates that seizures are more severe in elderly patients or drug users. In cases of recurrent or prolonged seizures, the aetiologies should be investigated. In addition to blood tests, it is recommended to perform electroencephalography (EEG), cranial computed tomography (CT) and in some cases lumbar puncture [48]. Alcohol sudden cessation destabilizes balance between excitatory (glutaminergic) and inhibitory (GABA) neurotransmitters in the brain which decreases the convulsive threshold. Other possible causes of seizures in AWS are hypoglycemia, electrolyte imbalances, blunt head trauma or associated diseases. Benzodiazepines are the drug of choice in treating and preventing seizures in AWS [49]. In some cases it has been shown that anticonvulsants (carbamazepine, valproate) may be effective [50].

Delirium Tremens

Delirium Tremens is a medical emergency and the most severe complication of AWS that significantly increases the morbidity and mortality of patients [51]. DT appears after a period of heavy drinking followed by acute reduction or cessation of alcohol, typically begins about 3 days after the last drink and lasts from 1 to 8 days or more, in some cases the disorder may occur during an episode of heavy consumption [6]. One of the first treatment goals for patients with DT is to control agitation and decrease the risk of injury and death. Non-pharmacological interventions involve a quiet and protective environment, frequent monitoring of vital signs, acid-base rebalancing and liver enzymes, ensuring adequate hydration, and establishing of an intravenous line. In case of extreme agitation, mechanical restrains may be temporarily applied, for as short as possible and under medical supervision, respecting the applicable laws of each country regarding mechanical restraint [6]. This measure is applied to protect the patient and the people around him. Benzodiazepines used to prevent more severe withdrawal symptoms and to control psychomotor agitation and insomnia. Intravenous administration is preferred, BDZs with long half-time (e.g. diazepam, chlordiazepoxide) have the advantage of self-tapering and constant drug serum levels. For patients with hepatic impairment, short half-life benzodiazepines with no active metabolites are preferred [52]. Suggested treatment of DT consists of controlling agitation, promoting sleep and raising the seizure threshold. Benzodiazepines are used in a high enough dosage to achieve sedation or even light sleep, but still have the patient in an arousable state. The recommended starting dosage depends on the severity of the symptoms. Controlling the symptoms must be done on day 1 with a high enough dose of either lorazepam or diazepam. The recommended dosage of diazepam is 10–20 mg intravenously (IV) or orally every 1–4 h, as needed while the recommended dosage of lorazepam is 8 mg IV, intramuscular (IM) or orally every 15 min, as needed. If the patient received 16 mg of lorazepam and the delirium is still severe, a bolus of 8 mg lorazepam IV is recommended, after that a dose of 10–30 mg/h can be maintained. If the patient presents uncontrolled agitation or hallucinations it is recommended to administer an adjunctive antipsychotic such as haloperidol 0.5–5 mg IV or IM every 30–60 min as

needed, without exceeding 20 mg. Thiamine should be administered to prevent WE, 500 mg IV over the course of 30 min once or twice daily for 3 days. IV glucose and fluids with electrolytes are used for rehydration and to restore the normal levels of electrolytes. In the case of refractory DT, propofol should be given in an intensive-care unit if the clinician has experience with treating DT [6]. It should be noted that clinicians need to differentiate early between DT and WE, as it is a neurological emergency with vital risk.

Treatment of Alcohol Withdrawal Syndrome in Particular Patients

Liver Impairment/Disease

Alcohol use disorder is a common cause of advanced liver disease, and some pharmacological agents are likely to be hepatocytotoxic. Several direct and indirect biomarkers can help clinicians detect and quantify alcohol consumption. Since they can be modified in several pathological processes, they have indicative value when correlated with other clinical data, anamnestic and in some cases heteroanamnestic data (Table 48.1).

Pharmacological treatment for AWS is limited in patients with liver disease based on the underlying illness as well as drug interaction, metabolism, bioavailability, and excretion route [53]. Due to their different metabolic pathways, oxidative metabolism and conjugation, the choice of benzodiazepine is made depending on the degree of liver damage. Patients with alcoholic liver cirrhosis have reduced BZD clearance that undergoes oxidative hepatic metabolism. Diazepam undergoes oxidation in the liver and is therefore prone to impairing the metabolic rate in this group of patients while the clearance of lorazepam is assumed to be unchanged [43]. Therefore, in those with moderate liver damage and those who require close monitoring halving the dose of diazepam/chlordiazepoxide or using lorazepam is recommended. Considering potential side-effects of benzodiazepines in patients with advanced liver disease (risk of sedation and drug accumulation), GABAergic non-benzodiazepine drugs such as baclofen are useful in managing withdrawal symptoms, based on their safety hepatic profile [54].

Elderly Patients

In the elderly, clinicians need to be especially careful because these patients often face multiple comorbidities: cardiovascular, renal or liver impairment, dehydration, infections and hydro-electrolyte imbalances. It is essential to evaluate and identify these conditions. In the elderly benzodiazepines should be administered with caution, because these patients may have liver disease or kidney disease, which increase

Table 48.1 Biomarkers for alcohol use and abuse [52]

Biomarker	Clinical significance
Blood alcohol concentration	Useful in detecting acute alcohol intoxication, it shows limited utility in evaluating alcohol abstinence
γ-Glutamyltransferase	The daily consumption of ethanol for several weeks increases the serum γ-glutamyltransferase level, this is an early indicator of liver disease
The mean corpuscular volume (MCV)	Chronic alcohol abuse increases the size of red blood cells. MCV levels normalize, in general, after 3–4 months after alcohol abstinence.
Carbohydrate-deficient transferrin (CDT)	Heavy drinkers have higher levels of the CDT version than non-drinkers
n-acetyl-β-hexosaminidase (Beta-hex)	Found to be increased in heavy drinkers, subsides to normal levels after 7–10 days of abstinence
Fatty acid ethyl esters (FAEE)	Used for distinguishing social drinkers from heavy or alcoholic drinkers, has also been used as a postmortem marker of alcohol consumption
Aspartate Transaminsase (AST)/ alanine transaminase ratio > 2	A ratio of 2:1 or greater is suggestive for alcohol-related liver disease
Uric acid	Indicator of alcoholism through two mechanisms, dehydration and purine intake
Albumin	Marker of liver function and useful for quantifying the severity of chronic liver disease: a decrease in serum albumin is a sign of a poor prognosis
Prothrombin time test	Sensitive indicator in both acute and chronic liver disease

the risk of drug accumulation and sedation, with subsequent risk of falls and fractures, respiratory depression and cognitive impairment. BZD with short half-life (lorazepam, oxazepam) are preferred, and sometimes it is necessary to lower the doses or to increase drug dosing intervals [55].

Pregnant Patients

The first step in approaching women at childbearing age involves performing a pregnancy test. The diagnosis of AWS in pregnant women is difficult to establish, given that certain symptoms are present in pregnancy but also in AWS. Certain items on the CIWA-Ar scale that assess withdrawal symptoms (nausea, headache or seizures) may overlap with symptoms of pregnancy or preeclampsia. There have been case-control studies suggesting that benzodiazepines administered during pregnancy may cause foetal malformations [56]. Most studies disprove this claim. Careful foetal monitoring is recommended in case of administration of BZD. The use of benzodiazepines in the last trimester of pregnancy has been associated with an increased risk of floppy infant syndrome and benzodiazepine withdrawal syndrome [57].

Conclusions

AWS is a prevalent condition in people with long-term alcohol consumption and is often underdiagnosed and undertreated, with short and long-term consequences. Psychometric assessment (AUDIT test) should become a routine practice not only in psychiatric units but in all medical specialties. The global burden of disease (GBD) is very high in the case of AUD and especially AWS. Therefore, evaluation or screening at the level of primary care would substantially contribute to the prophylaxis of complications caused by AUD, which would significantly reduce the costs associated with GBD. The therapeutic management should be established according to biomolecular markers, rating scales and clinical data about the patient's psychiatric and somatic comorbidities, especially age and the presence of pregnancy. The treatment setting is chosen based on the severity of AWS and life-threatening medical comorbidities (outpatient, inpatient units or even ICU). Treatment is individualized respecting the guidelines and therapeutic protocols. Given the pathophysiology of AWS, the most recommended medications are GABAergic agonists, of which BZD represent the first line of treatment, due to their efficacy and safety profile. While long half-life BZDs are preferred for young patients or in those without medical comorbidities, shorter half-life BZDs are the drugs of choice for elderly patients and for those with severe medical comorbidities because they have little hepatic metabolization and no active metabolites so there is no risk of accumulation. Other medications used to manage AWS are antiepileptics, a-blockers, beta-blockers, barbiturates and new drugs like dexmedetomidine and levetiracetam. Thiamine supplementation is widely recommended. In conclusion, AWS is a widespread neuropsychiatric condition that clinicians should be aware of as it often requires an interdisciplinary approach, timely diagnosis and prompt treatment.

Part IX
Molecular Mechanisms of Alcohol-Related Liver Disease

Chapter 49
Pathophysiology of Ethanol and Unexplained Observations

Sebastian Mueller

Abstract The mechanisms underlying alcohol-related liver disease (ALD) are still poorly understood despite decades of scientific efforts. Ethanol interacts with all structural levels in organisms making the number of interactions difficult to handle. This chapter identifies six larger topics that require more attention to resolve overlooked clinical, partly controversial observations. Briefly, these topics include (a) the role of fat and intermediary metabolism, (b) competition of ethanol metabolites with enzymes, (c) protein retention and endocytosis as adaptive response, (d) enhanced heme and red blood cell (RBC) turnover, in association with reactive oxygen species, erythrophagocytosis and efferocytosis (e) their role for cell death, ferroptosis and regeneration, and (f) biomechanic aspects such as sinusoidal pressure, hepatic arterialization and mechano-signaling. For instance, many enzymes involved in ethanol metabolism such as acetaldehyde dehydrogenases and the P450 systems have other essential substrates. Such a competitive inhibition has been shown to cause teratogenic malformations in early embryonic stage by specifically interacting with retinol aldehyde dehydrogenase 2, thus modulating retinoic acid levels, an important growth factor. Ethanol also interferes with the metabolism of amino acids, steroids, lipids and so-called specialized pro-resolving mediators. Novel prospective survival data clearly link hemolytic anemia and ineffective erythropoiesis to mortality in heavy drinkers. Preliminary data also suggest that hepatocytes can directly engage in RBC turnover (efferocytosis), involve mitochondria, which may open up novel insights with regard to heme metabolism. More targeted strategies will help to dissect the underlying mechanisms of ALD, namely its astonishing histological similarity to non-alcoholic fatty liver disease.

Keywords Alcohol-related liver disease · NAFLD · CYP2E1 · Liver disease · Liver pathophysiology · Mechanic stress · Shear stress · Hemolysis · Nrf2 · AST · Efferocytosis · Erythrophagocytosis

Introduction

Although ethanol is a relatively simple molecule it undergoes multiple interactions at all structural and organizational levels when exposed to the human organism. As shown in Fig. 49.1, this renders potential interactions rather complex and is one of the reasons that limit our deeper understanding of alcohol-mediated disease mechanisms. The figure also visualizes that many effects of alcohol require the total integrity of a living organism. Although being justifiable to study ethanol-mediated interactions in a solution of isolated proteins, organelles or in cultured cells, the limitations of such approaches should always be kept in mind.

Especially the 60 and 70ies of the last centuries saw an enormous progress in the understanding of alcohol-related diseases. Ethanol as disease causing factor was established. The important role of the liver in the elimination and metabolism of ethanol and its definite role in causing cirrhosis could be demonstrated. However, a couple of years later, in 1995, Peter Scheuer noted in a Foreword to the book entitled "Alcoholic liver diseases" edited by Pauline Hall that he did not understand why "there is an apparent latent period, supported by examination of serial liver biopsies, between the onset of heavy drinking and the development of steatohepatitis". He further asked "why alcohol-related steatohepatitis is so very similar morphologically to non-alcoholic steatohepatitis (NAFLD)? [1].

Today, almost 30 years later, these statements still hold true. In fact, we have noted almost a stagnation over the last two decades. The reasons are manifold. They may also lay in the complexity of ethanol interactions shown in Fig. 49.1. They may also be related to a general change of societies, some stigmata, with which alcohol remains to be associated, the structure how biomedical science is organized and funded etc. It becomes also clear that novel technological achievements, as fascinating as they are such as OMICS will not spare us from synthesizing the vast amount of data into a meaningful story. What is also missing is the classical, successful strategy in biomedical sciences, the tight interaction between clinical observation and basic research at the organ and cellular level. Alcohol-related diseases are primarily human diseases and, despite many other important interactions of ethanol in the living world such as yeast and bacteria, it should not lose its contact to the diseased human body.

Especially ALD offers more unanswered questions, in addition to the above-mentioned stunning similarity between diabetes- and overweight-induced NAFLD. Almost no progress has been made in diagnosing and treating the often-fatal alcoholic hepatitis (see also part X of the book). Modest benefits are seen in only a fraction of patients with steroids. Although the microbiome has gained great attention, simple antibiotic treatment seems not to halt ALD. Moreover, the pathophysiology of ALD is often explained with quite complex and methodologically challenging topics such as reactive oxygen species that require deep physical,

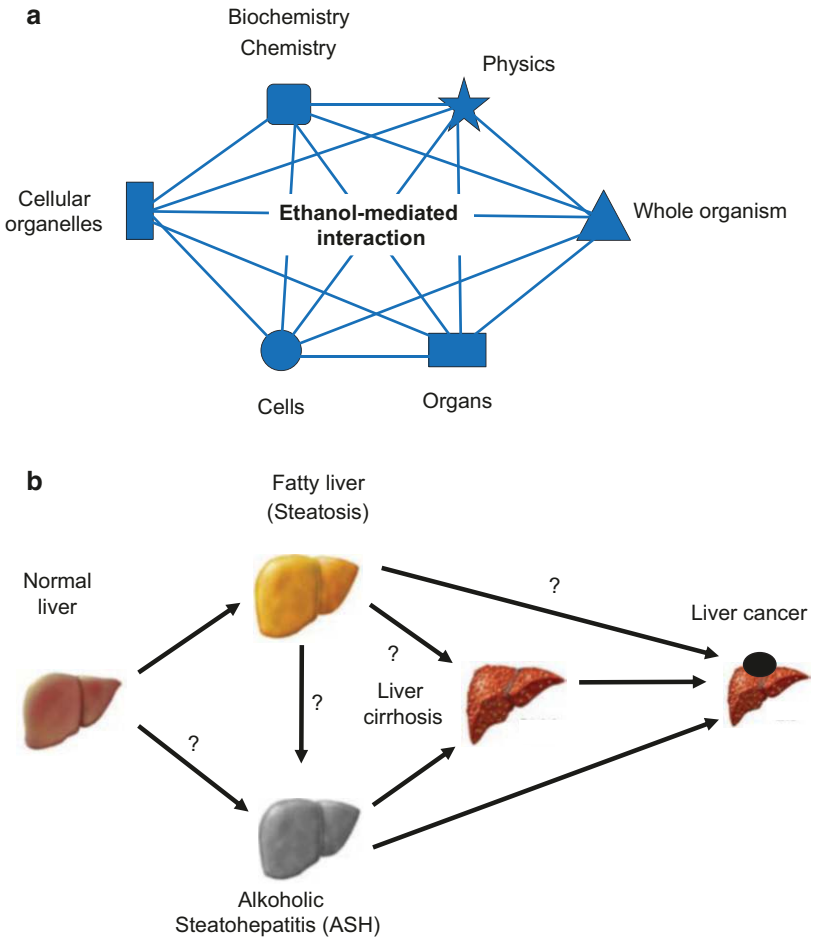

Fig. 49.1 Enhanced intermediary metabolism provides a possible common link between alcohol-related liver disease (ALD) and non-alcoholic fatty liver disease NAFLD. (**a**) Alcohol (ethanol) shows multiple interactions at various organizational levels in humans which complicates the understanding of alcohol-related diseases such as ALD. (**b**) Under ethanol exposure, the transition from normal to steatosis and steatohepatitis to cirrhosis and cancer is established. However, it is still debated whether steatohepatitis can be induced in normal liver or whether steatosis can directly progress to inflammation, cirrhosis and cancer. Moreover, it is still not clear whether steatosis is a bystander or a mandatory step towards the progression of ALD. (**c**) Progression of NAFLD and ALD share many confounding factors. Factors in black are essential for the progression of either NAFLD or ALD while factors marked in blue represent important modulating factors. An enhanced intermediary metabolism with a shift towards reduced NADH, enhanced lipogenesis and elevated glucose could be the joint link of both diseases, potentially better called **metabolic liver disease (MLD)**

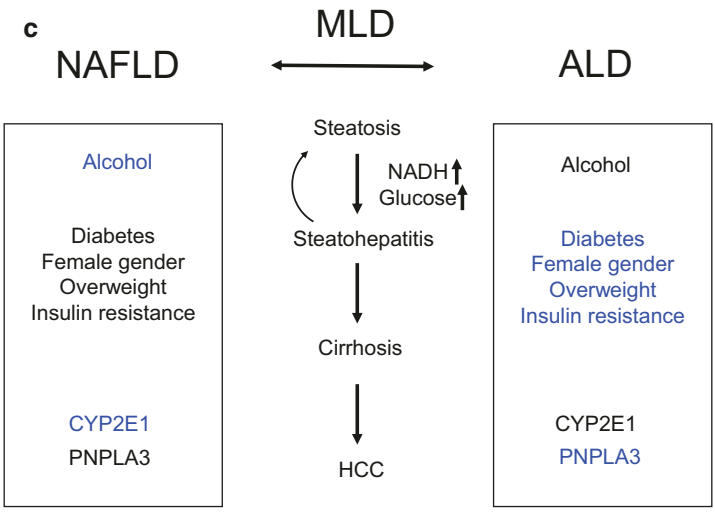

Fig. 49.1 (continued)

chemical and biochemical knowledge. On the other side, enzyme systems such as the p450 system localized in the endoplasmic reticulum are attributed to mediate major disease mechanisms but both knockout animals or pharmacological blockage show less convincing effects. And again, meanwhile, we are used to typical laboratory changes of heavy drinkers although we have no real explanation. What is alkaline phosphatase really doing? Why is GGT frequently elevated in patients with ALD? Where are transaminases originating from? Why are levels of AST always higher than levels of ALT? How about the changes of typical iron-related parameters such as ferritin that are even proposed by guidelines to search for the much rarer hereditary iron overload diseases? In other words: What are the real mediators of ALD?

There can be no doubt that **acetaldehyde** is one of the most important toxic intermediates of ethanol toxicity. As described in another chapter, gene variants that cause a homeostatic elevation of acetaldehyde cause clinical symptoms such as flushing syndrome or hangover. The worse combination is a rapid ADH combined with an almost inactive ALDH. It is also interesting to appreciate that slow ADH metabolizers are more prone to develop alcohol dependence. It seems that, to gain the joy of ethanol, the organism has to cope with the obligatory burden of its oxidation products, especially acetaldehyde. This chapter will not claim to be complete, but it aims at describing in a few rather short paragraphs some basic principles of ethanol-related diseases mechanisms. It also aims at describing some newer clinical and experimental observations in order to continue our journey in better understanding the pathology of alcohol.

Hepatic Steatosis-Bystander or Mandatory Disease Stage?

Steatosis is considered one of the hallmarks of ALD and, indeed, as shown in Fig. A.7 and Table B.7, it is present in more than 90% of heavy drinkers. However, exactly this number has generated a continued debate on whether steatosis is indeed a mandatory precursor of liver cirrhosis or a bystander or even a physiological way of interim storage of fat. If only 20% of heavy drinkers progress to liver cirrhosis, the majority of patients with fatty liver will obviously not undergo any disease progression. As shown in the prospective data in Tables B.21, B.22 in the Appendix B, no significant association can be found between steatosis and death in heavy drinkers. In addition, although discussed controversially, there have been observations of "protective" fat accumulation [2]. Already Theodor Ferichs described in the mid-nineteenth century, that feeding with a high fat diet could induce reversible hepatic steatosis in dogs, and liver fat is typically used by hibernating animals during winter periods to store fat without known negative consequences [3]. As shown in Fig. 49.1b, the transition of the liver to steatosis and of inflammation to cirrhosis are established beyond any doubt. It is, however, surprising to see that the transitions from fat to inflammation and the role of fat for fibrogenesis are still not clearly understood. Based on studies on patients with non-alcoholic fatty liver disease (NAFLD), it is even increasingly discussed whether steatosis can also directly contribute to cancer development.

In summary, liver fat and the role of fatty acids for disease progression is still poorly understood. It is hoped that the identification of the new role of enhanced red blood cell (RBC) turnover in ALD which is presented within this book (chapters on mortality, iron and bone marrow), will provide novel impulses. This "masked hemolysis" is highly associated with steatosis and RBCs uptake by macrophages but also hepatocytes (see Figs. A.33, A.34, A.35, A.36). It is often forgotten that RBC cholesterol primarily accounts for serum cholesterol levels and is in tight homeostasis with it. Moreover, the role of poly unsaturated fatty acids (PUFAs), especially the arachidonic acid metabolism, can give rise both to pro-inflammatory and anti-inflammatory pathways that are still poorly understood. Almost no data are available on these signaling pathways in the context of ethanol metabolism (see also Figs. A.53, A.54, A.55, and A.56). First preliminary data on lipidomics and mortality in heavy drinkers is presented in Table B.10.

Is the Intermediary Metabolism the Link Between ALD and NAFLD?

Why can alcohol-related liver disease be replicated by diabetes and obesity? One of the major cause-specific deaths is liver related mortality with alcohol-related liver disease as one of the famous hallmarks of alcohol consumption. Already in 1995 it was discussed "why alcohol-related steatohepatitis is so very similar morphologically

to non-alcoholic steatohepatitis (NAFLD)? [1] with no clear answers today, almost 30 years later.

Although the oxidation intermediated acetaldehyde is beyond any doubt crucial to explain alcohol-related disease mechanisms, it cannot be the major link to obesity and diabetes.

Rather, both alcohol, diabetes and overweight are characterized by an excess of energy. As can be seen from the original data (see Tables B.4, B.5, B.6, B.7, B.8, B.9) of the Heidelberg cohort followed-up over 15 years, heavy drinkers, despite having access to normal nutrition, cover about 50% of their energy supply by ethanol. In this cohort, during a mean daily consumption of ca. 180-gram alcohol, a mean blood alcohol concentration of 1 °/°° (1 g/L) was reached, corresponding to a mean elimination of ca. 7.5 g alcohol per hour.

Although ethanol, comparable to sugars, only contains the three elements carbon, oxygen and hydrogen, it is neither chemically nor biochemically a carbohydrate and human metabolism is strikingly different. As mentioned above, ethanol is an energy supplier containing almost the double energy as compared to glucose (7 versus 4 kcal per gram). Similar to other physiological energy suppliers such as fatty acids or sugars, oxidation of ethanol leads to NADH which can be further used for mitochondrial respiration. However, in contrast to glucose and fructose, **ethanol metabolisms rather prevents gluconeogenesis** simply due to a balance shift towards reduced NADH (see also Fig. A.38). This shifts the lactate/pyruvate ratio towards lactate and, consequently, away from gluconeogenesis. Through the malate aspartate cycle, reduced NADH is also shifted across the mitochondrial membrane and used for ATP production [4]. First data suggest that the same holds true for other organelles such as peroxisomes [5]. Ethanol also provokes a fast and efficient depletion of glycogen stores (see Fig. A.47). Of note, however, heavy drinkers are characterized by elevated serum glucose levels (see Tables B.2, B.6) which further increase at later fibrosis stages. Due to the enhanced hemoglobin and red blood cell turnover, the diabetic marker HbA1C is often underestimated in heavy drinkers and the diagnosis of diabetes remains obscure (see also Chap. 57).

Glucose is central to energy consumption. Carbohydrates, lipids, and proteins can all ultimately break down into glucose, which then serves as the primary metabolic fuel of mammals and the universal fuel of the fetus. It serves as the major precursor for the synthesis of different carbohydrates like glycogen, ribose, and deoxyribose, galactose, glycolipids, glycoproteins, and proteoglycans [6]. Unlike glucose, which is directly metabolized widely in the body, fructose is almost entirely metabolized in the liver in humans, where it is directed toward replenishment of liver glycogen and triglyceride synthesis [7]. Ca. 40% of fructose is converted in liver to glucose, and about 25% is converted to lactate and ca. 20% is converted to glycogen [8]. Glucose and lactate are then used normally as energy to fuel cells all over the body [9].

Thus, it seems that although not being a carbohydrate, ethanol shares with sugars the immediate energy supply within the intermediary metabolism (see also Fig. 49.1c). They also share to some extent the lack of a negative feedback loop. As mentioned in the Chap. 50, human metabolism can neither escape an excess of glucose/fructose or ethanol and will metabolize it under excess conditions. In this scenario, fatty acid accumulation is the bodies only option to rapidly eliminate carbohydrates or ethanol and store the excess energy through lipogenesis in adipose tissue. Hence, in this context, **fatty liver** may rather be a bystander and a metabolic consequence to quickly remove the excess of energy but not the primary cause of steatohepatitis. Consequently, it is the **uncontrolled excess of rapidly-available energy that may link NAFLD with ALD**. Figure 49.1c shows the common progression factors of NAFLD and ALD, where steatohepatitis results from enhanced intermediary metabolism, most likely due to mitochondrial damage, while steatosis is both a results of the mitochondrial damage (decreased fat elimination) and enhanced lipogenesis in order to rapidly eliminate the energy excess in "safe adipocyte stores".

Since lipogenesis, in this context, would be more a solution than a problem, fatty liver may not be the actual disease hallmark but rather the mitochondrial damage and inflammation due to excess energy supply and mitochondrial damage. The development of mitochondrial damage will later impair the mitochondrial ß-oxidation and, subsequently, further increase steatosis due to decreased fat elimination. More research on carbohydrate metabolism and its relation to ethanol and its hormonal control is needed. Ultimately, with regard to the terminology debate, **metabolic (dysfunction) associated fatty liver disease (MAFLD)** [10] may not be optimal for paving a future path of better understanding the underlying mechanism. As shown in Fig. 49.1c, a potential more optimal alternative could be then broader term **"Metabolic Liver Disease" (MLD)** which would only encompass patients with signs of liver damage and fibrosis while fatty liver would be an important diagnostic feature but not necessarily part of the pathology. Finally, the intermediary metabolism would also provide a novel bridge to **interlink energy and ethanol metabolism to addiction**, whether it is food addiction or alcohol dependence. Here, more detailed studied are needed in the future.

Competition of Ethanol with Important Ethanol-Metabolizing Enzymes

It is important to note that all ethanol-metabolizing enzymes including ADH, ALDH or CYPs are highly evolutionary conserved despite nutritional intake of alcohol. As mentioned in the Chap. 50, this is because gastrointestinal fermentation causes significant intestinal production of ethanol, and, more importantly, these enzymes are involved in the oxidation of other alcohols and substrates such as retinols. The

most impressive example, in my opinion, has been observed in experimental frog embryo models to study Fetal Alcohol Spectrum Disorder (FASD) [11]. For more details, reading of part IV is recommended. In this work, first evidence was provided of a competitive inhibition of **retinoic acid (simplified for all-trans-retinoic acid, abbreviated RA**) biosynthesis under conditions of ethanol metabolism. RA synthesis required the enzymatic activity of RALDH2 (ALDH1A2), the main retinaldehyde dehydrogenase expressed at that stage. As can be seen in Tables A.39, A.40 and A.41 in the Appendix, RALDH2 (ALDH1A2) is also an important acetaldehyde dehydrogenase. Under physiological conditions, in the embryo, RALDH2/ALDH1A2 converts retinal to RA. RALDH2/ALDH1A2 thus provides a molecular link between growth and ethanol metabolism with both substrates, retinal/retinaldehyde and acetaldehyde, competing for the enyzme.

Normally, RA is a metabolite of vitamin A1 (all-trans-retinol) that mediates the functions of vitamin A1 required for growth and development. RA is required in chordate animals, which includes all higher animals from fish to humans. During early embryonic development, RA generated in a specific region of the embryo helps determine to position along the embryonic anterior/posterior axis by serving as an intercellular signaling molecule that guides development of the posterior portion of the embryo [12]. It acts through Hox genes, which ultimately control anterior/posterior patterning in early developmental stages [13].

In the embryo, RA production by RALDH2 (ALDH1A2), the main retinaldehyde dehydrogenase expressed at that stage, is inhibited by ethanol exposure. Pharmacological inhibition of the embryonic alcohol dehydrogenase activity prevents the oxidation of ethanol to acetaldehyde that in turn functions as a RALDH2 inhibitor. Acetaldehyde-mediated reduction of RA can be rescued by RALDH2 or retinaldehyde supplementation [11]. Enzymatic kinetic analysis of human RALDH2 shows a preference for acetaldehyde as a substrate over retinaldehyde. RA production by RALDH2 is efficiently inhibited by acetaldehyde but not by ethanol itself. Thus, these studies elegantly demonstrated that acetaldehyde is the teratogenic derivative of ethanol responsible for the reduction in RA signaling and induction of the developmental malformations characteristic of FASD. It is assumed that this competitive mechanism will affect tissues requiring RA signaling when exposed to ethanol throughout life.

The study [11] also showed that ethanol was only harmful in a specific vulnerable time window, where teratogenic malformations could be observed. The conclusion may even be extended to carcinogenesis and much more work is needed to better understand ethanol interactions with cellular growth by competitive enzyme inhibition. Table 49.1 lists a few ADHs, ALDHs and CYPs with at least some of their known physiological substrates. It becomes rapidly evident that ethanol or, more likely, acetaldehyde can compete with these pathways and cause highly specific interferences.

Finally, with regard to microsomal ethanol oxidation by CYP2E1, it should be noted that other CYPs also metabolize ethanol to a similar or lower extent. There are

Table 49.1 Potential competition of ethanol with physiological substrates of selected ethanol metabolizing enzymes. The competitive inhibition of these enzymes provides a mechanistic rationale for ethanol-mediated disease mechanisms such as the teratogenic effects during embryonic phases involving ALDH1A1-3 (RLDH2). A more complete list is shown in Appendix Figs. A.39, A.40, A.41 and A.42

Enzyme	Substrates or conversion
ADH	
ADH1A	Metabolizes a wide variety of substrates, including ethanol, retinol, other aliphatic alcohols, hydroxysteroids, and lipid peroxidation products. Major role in ethanol catabolism
ADH5	Glutathione-dependent formaldehyde dehydrogenase, has virtually no activity for ethanol oxidation, but exhibits high activity for oxidation of long-chain primary alcohols and for oxidation of S-hydroxymethyl-glutathione, important for the elimination of formaldehyde
ALDH	
ALDH1A1	Converts retinaldehyde to retinoic acid
ALDH1A3	Converts 10-formyltetrahydrofolate to tetrahydrofolate
ALDH1L1	Converts 10-formyltetrahydrofolate to tetrahydrofolate
ALDH1L2	Converts aldehydes from lipid peroxidation to their corresponding carboxylic acids
ALDH6A1	Converts malonate and methylmalonate semialdehydes to acetyl- and propionyl-CoA
ALDH8A1	Converts 2-aminomuconate semialdehyde to 2-aminomuconic acid
ALDH9A1	Oxidizes gamma-aminobutyraldehyde and other amino aldehydes
ALDH18A1	Reduction of glutamate to delta1-pyrroline-5-carboxylate
CYP	
CYP2E1	
	ω-1 hydroxylation of fatty acids
Monooxygenase activity	Metabolizes arachidonic acid to 19-hydroxyeicosatetraenoic acid (19-HETE)
Epoxygenase activity	Metabolizes docosahexaenoic acid to epoxides
CYP1A2	Metabolizes polyunsaturated fatty acids into signaling molecules
Monoxygenase activity	Arachidonic acid to 19-hydroxyeicosatetraenoic acid (19-HETE)
Epoxygenase activity	Metabolizes docosahexaenoic acid to epoxides, primarily 19R,20S-epoxyeicosapentaenoic acid and 19S,20R-epoxyeicosapentaenoic acid isomers (termed 19,20-EDP) and similarly metabolizes eicosapentaenoic acid to epoxides, primarily 17R,18S-eicosatetraenic acid and 17S,18R-eicosatetraenic acid isomers (termed 17,18-EEQ)

still many open questions. The literature focuses on hepatic CYP2E1, but its expression has been noted in macrophages, adipose tissue, intestine. Moreover, it remains unclear why CYP2E1 is typically expressed in the pericentral region (see Fig. 49.2c) and why its expression decreases or is almost abolished in patients with manifest cirrhosis (see mRNA data from ALD patients in Appendix B Table B.13.

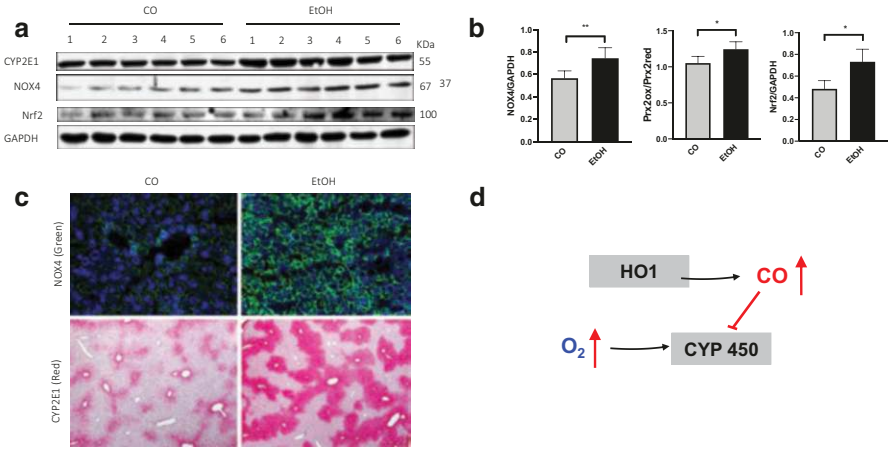

Fig. 49.2 Novel role of redox-sensitive factors to produce reactive oxygen species such as hydrogen peroxide by NADPH-dependent oxidase 4 (NOX4). Mice were exposed for 4 weeks to ethanol. (**a**) Protein expression of CYP2E1, NOX4 and Nrf2. (**b**) Densitometric data. (**c**) Immunostaining of CYP2E1 and NOX4 prior and after 4 weeks of ethanol in mouse liver. (**d**) Possible inhibition of heme-containing CYP2E1 by HO1-released carbon monoxide (CO). Both enzymes are located in the endoplasmic reticulum. CO may also inhibit other heme enzymes such as peroxisomal catalase and mitochondrial cytochromes. This inhibition would finally cause elevation of intracellular oxygen which could be more efficiently processed by NOX4 to yield hydrogen peroxide. More details are provided in the Appendix

Role of Enhanced RBC Turnover, Iron, and Reactive Oxygen Species

The recent novel finding that enhanced red blood cell (RBC) degradation and increased erythropoiesis drive long-term mortality in heavy drinkers (see Chaps. 7, 57 and 58 on mortality, iron and bone marrow) [14] provides a better understanding of the role of hepatic iron accumulation but also reactive oxygen species. Systemic hormonal and cellular control of iron accumulation has long been considered the major reason for pathological iron deposition in livers of drinkers [15]. However, the new insight of enhanced RBC turnover and the importance of hepatocytes in guiding heme degradation and being even able to perform efferocytosis of RBCs (see chapter on "Hepatic iron overload and ALD" and preliminary data in Figs. A.34, A.35, A.36) strongly underline that iron overload is a direct consequence of this heme turnover.

These findings have multiple implications for long known pathological aspects in ALD such as the generation of reactive oxygen species (ROS) or the changes in the methionine, glutathione, vitamin B6 and B12 metabolism. They are especially interesting with regard to the evolutionary role of mitochondria as ancient bacteria (**endosymbiosis theory**). It is quite striking to see that important steps of the heme synthesis only occurs in mitochondria while heme degradation through HO1 is

performed in the ER (see also Fig. A.74). Moreover, first electron micrograph images from Figs. A.33, A.34, A.35, A.36 suggest that RBCs may not only be uptaken directly by hepatocytes (**efferocytosis**) (also shown in Fig. 49.7) but may later fuse with mitochondria. More studies are needed but these impulses are highly fascinating and go beyond the role of ethanol in liver injury but touch fundamental physiological cellular processes. They are especially interesting with the evolutionary conserved **tight link between iron and bacteria**, the high demand of bacterial growth for iron, the high content of iron in mitochondria, the still important role of iron for bacterial infections in humans (see e.g. transferrin versus lactoferrin), and the still unclear role of **megamitochondria** in ALD.

Reactive oxygen species (ROS) have been established to be involved in ALD, however, ROS methodology is challenging and can be easily misinterpreted [16–22] . Important antioxidative systems such as glutathione (GSH) are decreased under exposure to ethanol and oxidative fingerprints such as lipid peroxidation products are increased. All animal cells are capable of synthesizing GSH, and GSH synthesis in the liver has been shown to be essential as Glutamate-cysteine ligase (GCLC) knockout mice die within a month of birth due to the absence of hepatic GSH synthesis [23]. Unfortunately, it tells little about the real underlying molecular mechanisms. Often, unphysiological high ROS concentrations (e.g. hydrogen peroxide) are explored in experimental models while the use of appropriate low and steady state levels show opposite findings [18]. For instance, the redox-sensitive systemic iron masterswitch hepcidin is downregulated at toxic ROS levels [24] while non-toxic H_2O_2 level upregulate [25]. Moreover, under physiological hypoxia levels of 5%, hepcidin is further upregulated [19]. For details see also Figs. A.70, A.71, A.72. There is also the misconception about "physiological oxygen" levels. While human require appropriate oxygen levels in the air of about 21%, single cells are exposed to much less oxygen tension [21, 22, 26].

It has also been less appreciated that either between cells or between organelles within a single cell, there may be important and specific interactions with regard to ROS and oxygen. As an example, Fig. 49.2a shows typical moderate upregulation of CYP2E1 in a 4-week mice model exposed to ethanol in drinking water. As can be seen, NAPDH-dependent oxidase **NOX4** that is readily expressed in hepatocytes, is induced in line with the redox-sensitive transcription factor **Nrf2 (Nuclear factor erythroid 2-related factor 2, or Nuclear factor erythroid-derived 2-like 2)** [27–29]. Figure 49.2b shows the typical pericentral induction of CYP2E1 upon ethanol exposure while NOX4 shows a clear membrane associated, basolateral expression. Figure 49.2d schematically demonstrates that enhanced heme turnover, as is observed in heavy drinkers (see chapters on mortality and iron), will generate **carbon monoxide through HO1 action**, which should block efficiently the heme enzyme CYP2E1. Both enzymes, HO1 and CYP2E1, are localized in the same compartment (endoplasmic reticulum, ER). Figure A.76 goes one step further. If carbon monoxide is released from the ER, it may not only block the mitochondrial respiratory chain but also peroxisomal catalase. In both cases, this will result in less oxygen consumption, increased cellular oxygen levels which then could serve as substrate for NOX4 and lead to elevated hydrogen peroxide levels. The strong

expression of NOX4 rather suggests that oxidase-released H_2O_2 may significantly contribute to elevated ROS in ALD. It is also interesting to note that the redox-sensitive transcription factor Nrf2 is elevated upon ethanol exposure (Fig. 49.2a). **Nrf2** controls many other important target genes such as HO1, Glutamate-cysteine ligase (GCLC), Glutathione S transferase (GST), UDP glucuronosyltransferase (UGT) and Multidrug resistance-associated proteins (MRPs) that are all involved in heme degradation and elimination through the bile. Figure A.75 shows the regulatory network with **KEAP1** including the feedback loop with KEAP1. More detailed studies on this topic will be highly fascinating and hopefully shed more light on the fact that, while NOX1 and 4 are upregulated by ethanol, macrophage NOX2 is downregulated. As shown recently, NOX enzymes induce different target genes and cytokines depending on macrophage or hepatocyte localization [19, 30]. NOX1 and 4 upregulation but NOX repression has also been confirmed in liver specimen from human heavy drinkers (not shown).

Enhanced RBC turnover is also interesting with regard to **vitamin disturbances in ALD. Thiamine (Vitamin B1)** and its thiamine phosphate derivatives are involved in many cellular processes. The best-characterized form is thiamine pyrophosphate (TPP), a coenzyme in the catabolism of sugars and amino acids. **Thiamine deficiency** causes Wernicke Korsakoff syndrome and is more pronounced in patients with ALD (see respective chapter in this book).

Manufactured folic acid, which is converted into **folate** in humans, is required to make DNA and RNA and metabolize amino acids necessary for cell division. Although not completely clear, it is quite intriguing that ethanol metabolism in liver and RBCs (where **folic acid** is stored) causes increased folate utilization and RBC turnover. As can be seen from heavy drinkers (see Chap. 58 on "Bone marrow" and original data in Table B.29), folate decreases in patients with macrocytic anemia. Consequently, a relative folate deficiency may exist due to enhanced RBC turnover. It is also interesting to see, that, most likely in a compensatory manner, **vitamin B12** is elevated in heavy drinkers with elevated MCV. As B12 is controlled by secretion of the gastric intrinsic factor, this could suggest that ethanol specifically blocks certain pathways that require folate and B12 (betaine, methionine). In this context, biochemical pathways of transsulfuration and methionine metabolism are of highest interest (see Figs. A.50 and A.51 and Chap. 55 on methionine metabolism). In conclusion, the role of vitamins, namely the B series, deserve special attention in the light of the important prognostic role of hemolytic anemia (see Chaps 7, 57 and 58 on mortality, iron and bone marrow).

Regeneration, Cell Division and Cell Death

Cell division and regeneration is another important cellular function that is strongly affected by ethanol. On the other side, regeneration is important for cancer development, especially, if cells divide rapidly in a toxic environment that exposes the DNA to genotoxic intermediates such as acetaldehyde. Liver regeneration is also required to recover from alcoholic liver injury and it is long know that a

continuous exposure to alcohol is more detrimental than same quantities that are provided intervals allow phases of recovery. Alcohol-related fatty liver demonstrate increased rates of hepatocyte death, the latter providing a regenerative stimulus. However, unlike mature hepatocytes in healthy adult livers, most surviving mature hepatocytes in alcoholic fatty livers cannot replicate. Therefore, less mature cells (progenitors) must differentiate to replace dead hepatocytes. Little is known about the general mechanisms that modulate the **differentiation of liver progenitors** in adults requiring a better molecular and cellular clarification [31].

In this context, data from patients undergoing alcohol detoxification on growth factors but also on apoptosis are quite elucidating. As shown in Fig. 49.3a, **important growth factors (HGF, hepatocyte growth factor, EGF, epithelial growth factor, and IGF, insulin-dependent growth factor)** are all significantly increased after alcohol detoxification within the first 7 days. IFG even continues to increase thereafter. Figure 49.3b demonstrates that serum erythropoietin (EPO) but also apoptosis as measured by serum M30 levels is transiently upregulated. Induction of liver apoptosis after withdrawal from alcohol had been reported previously [32]. These data, in humans, readily demonstrate that ethanol primarily blocks regeneration and cell division, most likely due to the genotoxic environment. However, under another vital stimulus, such as severe anemia or functional loss of hepatic tissue, the DNA protecting mechanisms that block regeneration may be counteracted by survival signals to maintain a critical cells mass.

This can be studied e.g. by phlebotomy or hepatectomy both of which remove vital tissue mass and, consequently, induced tissue proliferation despite the presence of toxic ethanol metabolism. As ethanol causes both ineffective erythropoiesis (see chapters on iron and bone marrow) and liver damage (see Chap. 38 on histology), these changes can be regarded as "virtual phlebotomy or hepatectomy). As shown in Fig. 49.4, this will result in enhanced RBC turnover, enhanced heme degradation and processing of toxic heme degradation end products by the liver with final excretion of bilirubin. Hence, an ambivalent situation ("signaling conflict") is created that

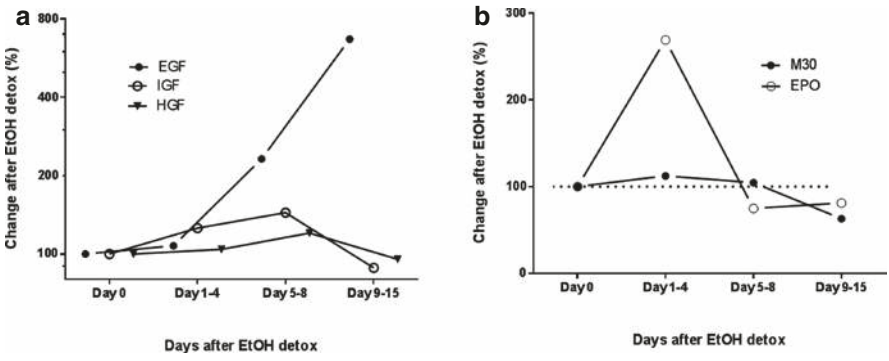

Fig. 49.3 Elevation of important (**a**) growth factors (EGF, IGF, HGF) and (**b**) erythropoietin (EPO) and apoptosis marker M30 after alcohol detoxification. These data demonstrate that ethanol is a strong blocker of growth factors and apoptosis

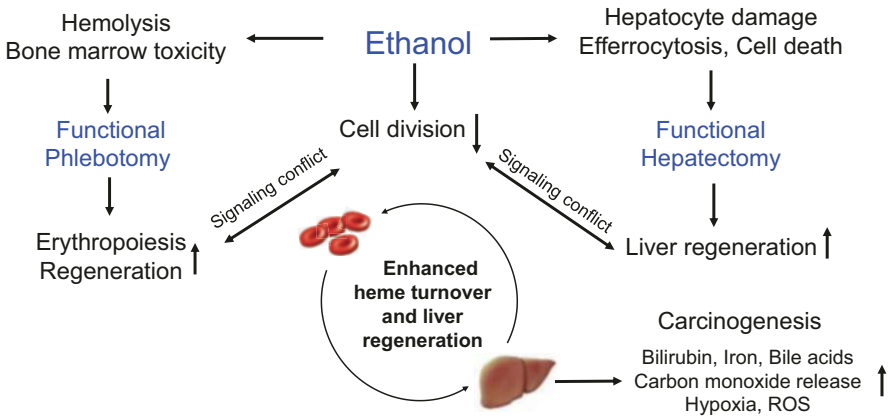

Fig. 49.4 Ethanol provides ambivalent signals to the regeneration machinery and cell division. It is blocking cell division due to toxic ethanol metabolism but stimulates regenerative signals through functional loss of tissues such as hemolysis or liver damage

forces tissues to regenerate and process toxic end products in a genotoxic environment.

Mice and human data suggest that the RBC cycle is modulated by alcohol in a complex manner. As hemolytic anemia is a major driver of mortality in heavy drinkers (see mortality and iron Chaps. 7 and 57) and due to compensatory mechanisms at various levels, it takes several years to develop macrocytosis and liver damage. The transient deterioration of hemolytic anemia after alcohol detoxication demonstrates that ethanol is not alone responsible for the vicious cycle but other cofactors may also contribute. **For instance, accumulation of toxic iron in hepatocytes, macrophages, and erythroblasts could contribute to this mechanism**. Further studies are needed to better understand the exact kinetic response. It is a sign of hope that continued abstaining from alcohol, even after years, can both improve the hematological parameters (MCV, RBC count) and liver parameters (liver stiffness). Preliminary data after 5 years of continued abstaining from alcohol are shown in Figs. A.89 and A.90.

The **mechanisms of cell death regulation** in ALD remain also to be clarified. As is shown in Fig. 49.3, after alcohol detoxification, liver apoptosis increases, so do liver regeneration markers [32]. However, various types of cell death such as **pyroptosis, necroptosis, apoptosis and ferroptosis** (see Fig. A.58) have been identified. So far, it remains unclear whether these death pathways are distinct forms or overlapping events of a general and fundamental death cascade. Moreover, for each classified death type, many open questions remain. It is interesting that reactive and toxic molecules such as ROS (apoptosis) and iron (**ferroptosis**) have been implicated [33–35]. Preliminary data in the Heidelberg cohort of heavy drinkers indicate that markers of ferroptosis such as GPX4 and ACLF are elevated (see Figs. A.3 and A.12). It is intriguing to speculate that ferroptosis is connected to heme turnover,

most likely through efferocytosis of RBCs (see also electron micrographs in Figs. A.34, A.35, and A.36. An interaction of Nrf2 (see above) and ferroptosis has also been discussed [29].

Ethanol, Endocytosis, and Protein Retainment

Alcohol consumption causes hepatomegaly, both in rodents and humans, associated with enlargement of the hepatocytes. Largely overseen today, already Lieber and Baraona showed clearly, almost 50 years ago, that enlarged livers during heavy alcohol consumption are not only due to retention of lipids (steatosis) but also proteins (see Fig. 49.5) [36, 37]. Protein deposition also contributes to a similar extent to hepatomegaly as observed in chronic alcohol consumption. In control rats, lipids represented 15.7% of dry weight and proteins 55.2%. After alcohol consumption, hepatic dry weight increased by ca. 31%, protein by 31% and fat by 83%. Although increasing organelle proteins (mitochondria and microsomes) do contribute to the total increase, the **major fractions of proteins is deposited in the cytosol, including export proteins such as albumin and transferrin** [38]. They also showed that synthesis of liver protein and **proalbumin** were enhanced by chronic ethanol feeding, but this was not associated with a corresponding rise in serum albumin output. There was a significant retention of liver albumin and transferrin with delayed appearance in the serum of ethanol-fed rats. This indicated

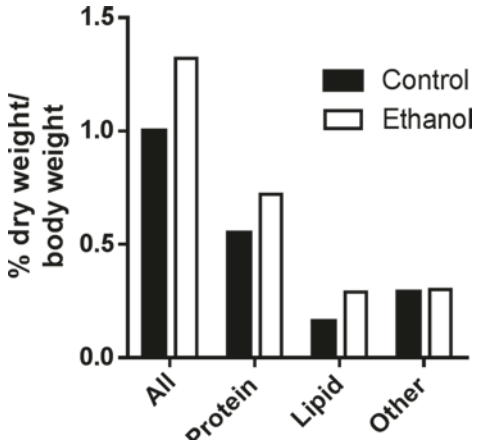

Fig. 49.5 In humans and animals, ethanol not only increases hepatic fat content but also causes protein accumulation. The bars show amount of protein, lipid and other content in control rats and rats treated with alcohol. The underlying mechanisms have been poorly studied but seem to be rather due to an adaptive response in order to e.g. prevent iron uptake in the case of transferrin than a toxic blockage. In support of this hypothesis, some specific proteins are released to the serum compartment such as alpha-macroglobulin. Modified from [36]

that, regardless of the changes in synthesis, the export of protein from the liver into the plasma was impaired. This alteration in export was associated with a decreased amount of polymerized tubulin in the liver of ethanol-treated animals. Thus, both enhanced protein synthesis and defective export contribute to the ethanol-induced accumulation of liver protein, and the decrease in **liver microtubules** represents a possible site for impairment of protein export [38]. **Triglycerides and cholesterol** also decrease after alcohol exposure [39, 40].

As is shown in chapter and Appendix (e.g. Fig. A.57), many important and liver synthesized carrier proteins (albumin, transferrin, haptoglobin, Apo A1) are decreased in serum of heavy drinkers with progressing liver disease. This is not the case for total protein.

It remains to be answered whether protein accumulation is due to ethanol-mediated damage to the protein elimination machinery, microtubule apparatus, cytoskeleton and membranes associated vesicle generation used for endo-, trans- and exocytosis or, whether this could be due to an adaptive response. As is discussed in detail in Chap. 57 on "ALD and iron", due to hemolysis and ineffective erythropoiesis, serum iron typically increases, in line with transferrin saturation and ferritin. As can be seen in the Kaplan Meier plots (Figs. A.86, A.87) from the ongoing survival study in heavy drinkers, **transferrin** is one of the most suppressed serum proteins. This appears logical since the liver is overwhelmed with iron from the erythrophagocytosed/efferocytosed RBCs and it could downregulate transferrin to prevent further iron delivery. More work is needed here that also includes the relation to ferroptosis.

Is Albumin Synthesis Really Impaired in Patients with Liver Cirrhosis?

The strongest argument against a mere toxic or damage-related decrease of serum proteins such as albumin comes from clinical studies of a continued removal of albumin in patients with liver cirrhosis. Thus an **implanted ascites pump** (alfapump®) [41] has been recently introduced for the treatment of therapy-refractory ascites that continuously pumps ascites from the peritoneal cavity into the urinary bladder. The study recruited initially 40 patients of whom the majority (43%) had ALD. In average, the pump removed 1 L ascites per day. As ascites contains significant amounts of albumin (at least 20 g albumin/L ascites), after 6 months, the pump had removed 180 l ascites corresponding at least to ca. 3.6 kg albumin. However, albumin levels were only reduced from 31.9 to 27.2 g/L (by 14.7% or from 0.5 to 0.4 mM)) while, at the same time, bilirubin levels decreased by 20.7% [41]. In other words, while the serum albumin amount decreased by 5 g/L, more than 3 kg had been removed and, consequently, had been replaced by the cirrhotic liver. Even if ascitic concentrations of albumin would be some grams less as compared to the serum, these clinical data clearly suggest that the cirrhotic liver replaces

albumin if it is removed by other means. It also suggests that there could be a signal of the "old albumin" to not further release/secret fresh albumin to the circulation.

One obvious reason of decreased albumin could be that hepatocytes are loaded enough with molecules carried by albumin such as bilirubin. It is often forgotten that albumin not only serves to maintain oncotic pressure but has many other functions. It not only binds thyroid and steroid hormones, vitamin D, fatty acids, but above all, **unconjugated bilirubin**. The amount of bilirubin released from heme degradation can be estimated from novel data of enhanced RBC turnover in heavy drinkers. Each hemoglobin molecule is made up of four heme groups surrounding a globin group, forming a tetrahedral structure. During normal daily erythrophagocytosis, ca. 1% of RBC are recycled which corresponds to 25 ml RBC volume, 8 g or 0.12 mmol hemoglobin. As four heme groups are contained by each hemoglobin, this results in ca. ca. 0.5 mmol or 250 mg bilirubin released every day. Since bilirubin is bound to albumin at a 1:1 ratio [42], and assuming a single path removal of bilirubin by albumin, ca. 0.5 mmol albumin or ca. 30 g albumin total serum albumin would be required. This corresponds to about 20% of the total serum albumin if a total serum volume of 3 L is assumed. In ALD patients with enhanced RBC turnover, a much higher bilirubin release can be estimated potentially by a factor of 3–4 times higher the normal value. These calculations underline how important albumin is for bilirubin removal and that a **blocked albumin uptake by hepatocytes could be seen as a likely adaptive response** to prevent further bilirubin uptake and toxic heme degradation.

Unconjugated bilirubin is typically taken up by the **Organic anion transporting polypeptide called OATP1B3** which is most strongly expressed in pericentral regions of the hepatic lobule. In addition to endogenous substrates (examples include bile salts, thyroid hormones, conjugated steroid hormones, prostaglandins), OATP1B3 transports unconjugated bilirubin from the blood to the liver [43]. See also Fig. A.60. However, how albumin is entering hepatocytes, still remains an open discussion [44]. In an average human, about 13.3 g albumin are lost per day. An **putative albumin-uptake receptor** has been described (Albondin) that allows transcytosis through endothelial cells. Transcytosis of albumin through endothelial cells has been shown to only last 15 s. The strong inhibition of albumin release by colchicine clearly suggests that microtubules are required for albumin excretion [36, 38, 45]. The putative albumin receptor may play an important role in the bidirectional transfer of many classes of endogenous and exogenous substances between albumin and cells [46]. In addition, **lysosomes** also contain a considerable amount of serum albumin and it has been shown in the regenerating liver that partial hepatectomy activates endocytosis and facilitates delivery of endocytosed serum albumin to lysosomes, where albumin is digested to yield amino acids for possible use in protein synthesis during liver regeneration [47].

In conclusion, the long known protein and albumin retention in hepatocytes during alcohol exposures could rather be an adaptive response to prevent further uptake of toxic excretion products such as iron and bilirubin from heme degradation and enhanced RBC turnover. An additional direct efferocytosis of red blood cells by hepatocytes (see Fig. 49.7) would be an additional more efficient strategy

to remove RBC content. Additional electron micrographs both from livers of ALD patients and rodent models of hemolysis are shown in Figs. A.34, A.35, and A.36. These figures suggest that **RBCs could be directly taken up by hepatocytes, and potentially fuse with mitochondria**. In summary, enhanced RBC turnover in ALD, the specific role of mitochondria in heme synthesis, iron and energy metabolism, provide novel highly interesting areas of basic research not only to understand the pathophysiology of alcohol, but physiological routes of iron trafficking between cells, RBCs and organelles.

Biomechanic Aspects for ALD

Finally, studies on ALD and liver pathology should consider recent developments obtained by liver stiffness measurements [48]. The Sinusoidal Pressure Hypothesis (SPH) has been introduced which identifies an elevation of **sinusoidal pressure** (SP) as cause of fibrosis and liver cirrhosis [49–51]. SPH has been a novel concept to better explain macroscopic changes during liver cirrhosis development and the so-called point of no return, at which fibrosis progression becomes irreversible. Normally pressure changes in the context of cirrhosis are associated with portal hypertension which is a consequence of cirrhosis. According to the SPH, however, an elevated SP is the major upstream event that initiates fibrosis (initiation). In healthy liver, liver stiffness (LS) corresponds to SP and increases in response to many pro-fibrogenic stimuli such as inflammation, cholestasis or liver congestion. SPH postulates that extracellular matrix is produced in response to elevated SP to withstand the underlying pressure. Both duration (>4 weeks) and degree (>10–12 mmHg or 10–12 kPa) of SP/LS elevation are critical. While fibrosis can still reverse if the underlying cause of SP elevation is eliminated, the increased matrix deposition causes an increasing blood supply through the hepatic artery. This elevated hepatic arterial flow and the final arterialization of the liver permanently causes pathologically high pressures. A vicious cycle is initiated with further matrix deposition and increased arterial pressure. Thus, **arterialization** defines the **so-called 'point of no return' with irreversible fibrosis progression**. At the cellular level, SP is the actual driving force for the production of collagen by stretching of perisinusoidal cells, pressure-related increase in tissue stiffness and stretch forces transduced via cellular and intercellular bio-mechanic signaling. SPH is able to explain the macroscopic changes of the cirrhotic liver (trajectory forces), the uniform fibrotic response to various etiologies and the point of no return in advanced stages despite elimination of the cause. According to SPH, future treatment options should be targeted at lowering the sinusoidal pressure.

The hepatic artery is directly connected to the sinusoidal bed via arteriole inlets and provides about 20% of blood in a normal healthy liver. The stiffer the liver becomes due to inflammation or fibrosis the more pressure is required to maintain sufficient blood flow. Although the elevation of portal pressure (portal hypertension

>12 mmHg) can partly maintain some portal flow it will hardly reach values higher than 30 mmHg. Under these conditions, the hepatic artery will be the only vessel with sufficiently high pressure to maintain hepatic blood supply. Elevation of hepatic arterial flow and subsequent arterialization is mainly driven by the HABR [52] and hypoxia signaling [53]. SPH postulates that this arterialization defines the so-called **'point of no return'.** It provides a pressure-based rationale to explain the self-perpetuation of fibrosis progression and the uniform, etiology-independent progression of fibrosis. Arterialization of the fibrotic liver ultimately leads to a sustained exposure of the low-pressure organ liver (typically <6 mmHg) to higher pressures. In ca. 7% of patients with cirrhosis, extreme flow changes can be observed such as complete reversal of the portal flow (so called hepatofugal portal flow) [54]. At the end, the arterialized liver (high oxygen, high pressure) together with massive matrix deposition will cause self-inflicted ischemia (see Fig. 49.6a). The combination of these events stimulates the **formation of regenerative nodules** finally causing the typical nodular aspect of cirrhotic livers. High pressure in combination with cell

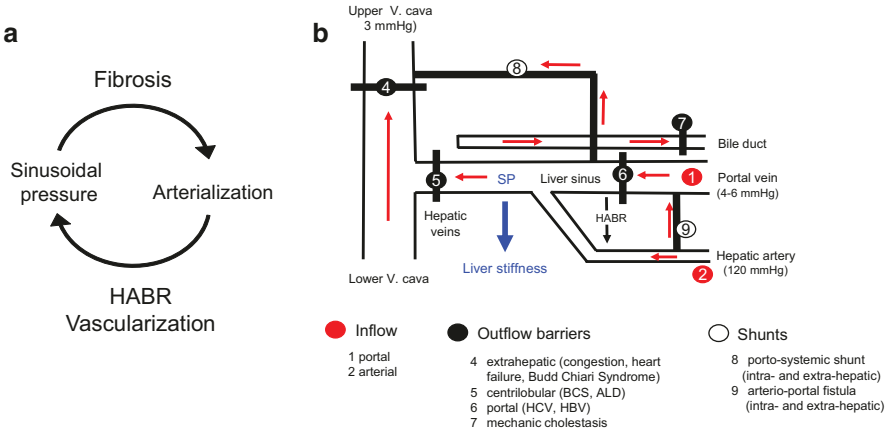

Fig. 49.6 (**a**) Vicious cycle of pressure elevation, matrix generation and arterialization according to the sinusoidal pressure hypothesis [49, 50]. The arterial response is mainly driven by hypoxia signaling and metabolic demand. The hepatic arterial buffer response (HABR) is the first and most rapid step in increasing arterial blood flow in response to decrease portal flow according to the adenosine wash out theory [52]. Later, other vascularization signals establish and secure arterial blood supply. (**b**) Simplified scheme of the hepatic vascular architecture and conditions that result in elevated sinusoidal pressure (SP) and liver stiffness (LS). A normal liver is supplied with blood from the hepatic artery (25%) with arterial pressure (AP) and the portal vein (75%) with the portal pressure (PP). Hepatic blood then leads into the hepatic veins with a central venous pressure (CVP). The hepatic venous pressure gradient (HVPG) determines the flow through the sinusoidal bed. In contrast, the SP is determined by the outflow/inflow ratio and ultimately increases LS. According to the hepatic arterial buffer response (HABR), a reduced portal flow causes compensatory arterial blood supply in a liver-autonomous unidirectional fashion [52]. Arterialization of the liver may have further consequences such as enhanced mechanic shear stress to red blood cells and enhanced RBC uptake by macrophages and hepatocytes in the pericentral region with reduced sinusoidal blood flow. Modified from Mueller S. World J Gastroenterol. 2016;22 (48):10482–10,501

death and enhanced regeneration ultimately provides an ideal environment of genetic instability and formation of cancer (HCC).

The concept of pressure further facilitates to understand typical differences between e.g. portal viral hepatitis (HCV) and lobular disease such as ALD. Figure 49.6b shows a simplified scheme of the vascular and biliary architecture of the liver to better illustrate the role of the various inflow, outflow and shunt factors on sinusoidal pressure. In general, the liver is a low-pressure organ. Pressure in the portal vein is ca. 5 mmHg, while blood leaves the liver through the veins and is ca. 2 mmHg in the caval vein (CVP) [55–57]. Close to the right atrium, this pressure can even reach negative values. Despite this low hepatic venous pressure gradient (HVPG) of ca. 3–6 mmHg, the liver is supplied with ca. 25% of the total cardiac output [57]. According to Ohm's law of streaming fluids it also demonstrates the very low vascular resistance of the healthy liver that easily adapts to flow changes e.g. from the splanchnic side [52]. The sinusoidal pressure (SP) is determined by static and dynamic components (see also Fig. 49.3). The **static part** of the SP is determined by the intravasal pressure and the elastic properties of the vessel walls and also exists in the absence of a functioning blood circulation. Osmotic, oncotic pressure as well as gravitational forces related to the body positioning further contribute to this component. In contrast, the **dynamic component** is represented by the kinetic energy of the blood flow and becomes only relevant under conditions of an operating blood circulation. The flow resistance of the liver, blood viscosity and the blood flow rate all affect this dynamic component. The flow resistance however, will be modulated by many conditions including cellular swelling or infiltration of inflammatory cells. Importantly, the localization of inflammation will increase the vascular resistance locally either in the portal or central areas. It explains why both a rapid increase of arterial [58] or portal [59] inflow or outflow barriers within the venous outflow tract (congestion) [60], bile ducts (mechanic cholestasis) [61] or the sinusoidal bed [62] are able to increase LS. Taken together, the introduction of pressure into the pathology of fibrosis allows various novel insights to understand fibrogenesis at the hemodynamic level.

At the cellular level, sinusoidal pressure elevation induces stretch forces within the per-sinusoidal cells that include hepatic stellate cells (HSC), endothelial cells, hepatocytes and macrophages. Notably, fibroblasts and HSCs are known for a long time to contract and to respond to mechanic forces [63–65]. Taken together, the concept of SPH postulates, that collagen deposition is a result of pressure-elevation. The so-called pericellular fibrosis is not in contrast to SPH. **Pericellular fibrosis** describes collagen deposition around single ballooned hepatocytes and is commonly observed in heavy drinkers. This pericellular fibrosis could be also explained by a pressure-stretch force concept. In contrast to perisinusoidal fibrosis, pressure inside the ballooned hepatocyte causes stretch forces in pericellularly aligned HSC or fibroblasts and finally lead to mechanically induced collagen deposition. Thus, both intravascular and intracellular pressure can cause stretch forces at the hepatocyte membrane with consequent stretching of HSC and/or elevation of cellular stiffness.

A Novel Link Between Enhanced RBC Turnover and Shear Stress to RBCs in ALD?

This novel link could consist of the **increased mechanic stress to red blood cells during the arterialization of the liver**. It is also postulated that the typical laboratory finding of cirrhotic livers, an increased AST/ALT ratio and a slight GGT elevation [66] is indicative for the stage of arterialization [49]. It is long known from patients with artificial heart valve implantation, that mechanic stress can increase RBC turnover or even cause direct hemolysis with AST elevation. As discussed in Chap. 41 on "AST levels in ALD", AST/GOT seems to be primarily derived from RBCs (and not mitochondria) and there is enough clinical evidence (see also Table B.4) that RBC turnover further increases with fibrosis stage. Although speculative, the predominant perivenular hepatic injury could be due to **shear stress damage of RBCs in arterialized livers** when entering the liver through the artery. The perivenular bed would then be the first vascular section with decreased blood flow which would increase the likelihood to take up damaged RBCs either by **erythrophagocytosis** or **efferocytosis** (see also Fig. 49.7 and Figs. A.31, A.34, A.35). This would be in line with the **uptake of bilirubin in the perivenular region by OATP1B3**. Nrf2 could be primarily seen to orchestrate degradation of RBCs (see Figs. A.60 and A.75) as it controls transport, conjugation and glutathione

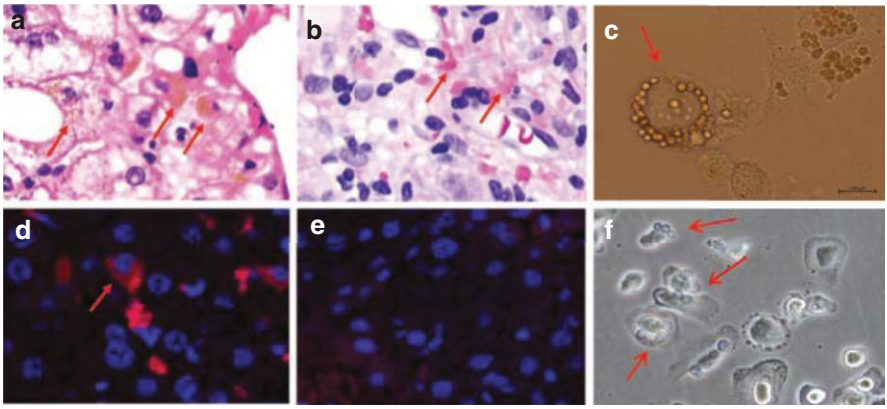

Fig. 49.7 Histological indications of hepatocellular heme degradation in alcohol-related liver disease or during hemolysis. (**a**) HE stain of a liver section from a heavy drinker. Note the intrahepatocellular bilirubin accumulation in ballooned hepatocytes. (**b**) HE stain of a liver section from a patient with ALD. RBCs are seen in red. Some hepatocytes seem to show ingested RBCs suggestive for efferocytosis. (**c**) Efferocytosis of oxidized human RBCs in cultured human hepatoma cells (huh7). Data can also be reproduced in primary hepatocytes. (Zheng C and Mueller S, 2023, unpublished) (**d**, **e**) RBC autofluorescence in a mouse phenylhydrazine model of mild hemolysis (**d**). Control livers are shown in (**e**). Note that heme autofluorescence is also seen inside hepatocytes, partly in the cytosol, but also in vesicles. Nuclei are stained blue. More studies are needed to comprehend RBC processing by hepatocytes under (patho) physiological hemolysis (**f**) Erythrophagocytosis of human oxidized RBCs by human macrophages (THP1) (Mueller S, unpublished)

metabolism, among many other pathways linked to RBC and heme degradation. With RBC turnover, cholesterol, phospholipid and triglyceride metabolism come into play which could be tightly linked to bile acid synthesis and bile formation. Highly fascinating, RBC turnover either through erythrophagocytosis or efferocytosis could provide novel links between iron metabolism, cytosol and mitochondria. As proposed above, RBC could be not only taken up by hepatocytes, but could also fuse with mitochondria, which contain high levels of iron. Such a potential fusion is highly interesting with regard to evolutionary conserved pathways, since mitochondria are considered ancient bacteria and bacteria require iron for growth and have developed sophisticated strategies to acquire iron. Not by chance, enzymes and molecules such as AST, peroxiredoxins such as PRX2 or glutathione are both existing in RBCs and mitochondria. These considerations open also other novel interactions such as the role of the malate aspartate shuttle to transport NADH from the cytosol into mitochondria. It also remains fascinating to study why, at least to some extent, heme degradation and heme synthesis are strictly separated in humans. Finally, as already mentioned above, the role of HO1-released carbon monoxide could profoundly link energy and oxygen metabolism with heme degradation. I truly hope that detailed and concerted mechanistic studies will soon shed more light on all of these exciting and potential options that go far beyond simple ethanol metabolism but the heart of life per se.

Chapter 50
Ethanol Metabolism

Sebastian Mueller

Abstract Ethanol, an alcohol found in nature and in alcoholic beverages, is metabolized through complex catabolic pathways. Ethanol is amphiphile and, thus, distributes in all compartments. In addition, there are no negative feedback loops, so that the organism cannot escape from ethanol oxidation. This chapter introduces to major metabolic pathways and its consequences on energy metabolism, addiction, but also the development of alcohol-mediated diseases and cancer. The liver is the major elimination side of ethanol through alcohol dehydrogenases which convert it to the highly toxic and carcinogenic acetaldehyde. Acetaldehyde dehydrogenases ultimately transform acetaldehyde to acetic acid. This oxidation cascade also leads to an excess of NADH/lactate with important biochemical implications such as enhanced lipogenesis and decreased gluconeogenesis. Ethanol is also oxidized to acetaldehyde in the endoplasmic reticulum by the inducible cytochrome P450 system, especially the subtype CYP2E1. To a minor extent, catalase can also oxidize ethanol although its contribution in compartments such as red blood cells or brain are still poorly studied. The genetics of ethanol metabolism is increasingly uncovered, varies significantly between geographic regions and contributes to both the risk for alcohol-dependence and alcohol-related disease. Important features of ethanol metabolism such as the accumulation of fatty acids (steatosis) is considered a hallmark. Although, in contrast to carbohydrates, ethanol limits the availability of glucose, both lead to an enhanced energy flow through the mitochondrial respiratory chain, mitochondrial damage and enhanced lipogenesis. Thus, intermediary metabolism not only interlinks ethanol consumption, diabetes mellitus, and overweight to hepatic steatohepatitis but also tightly to addiction.

Introduction to Ethanol Metabolism

Ethanol, an alcohol found in nature and in alcoholic drinks, is metabolized through a complex catabolic Ethanol is amphiphile and can dissolve both in water and lipid phases (see Fig. A.2). Ethanol is readily absorbed from the gastrointestinal tract. Major elimination side is the liver which can be seen after either functional or physical hepatectomy [1]. Using the elastographic methods to characterize fibrosis stages precisely, it has been recently shown that elimination of ethanol is decreased in higher fibrosis stages [2]. Thus, drinkers with manifest cirrhosis achieve both higher blood alcohol levels and biomarkers of ethanol such as ethyl glucuronide despite lower alcohol consumption [2] (see Table B.7). The extrahepatic metabolism of ethanol is relatively small [3]. However, extrahepatic metabolism remains important in order to understand ethanol-mediated organ damage e.g. in brain or red blood cells. Only 2–10% is eliminated through kidney and lungs while the rest is oxidized within the body, mostly in the liver.

As shown in Fig. 50.1, in the liver, ethanol is largely metabolized via alcohol dehydrogenases (ADH), cytochrome P450 (CYP) 2E1, and to a minor degree by catalase, resulting primarily in the generation of acetaldehyde. Acetaldehyde is further metabolized via acetaldehyde dehydrogenases (ALDH) to acetate. Acetate is

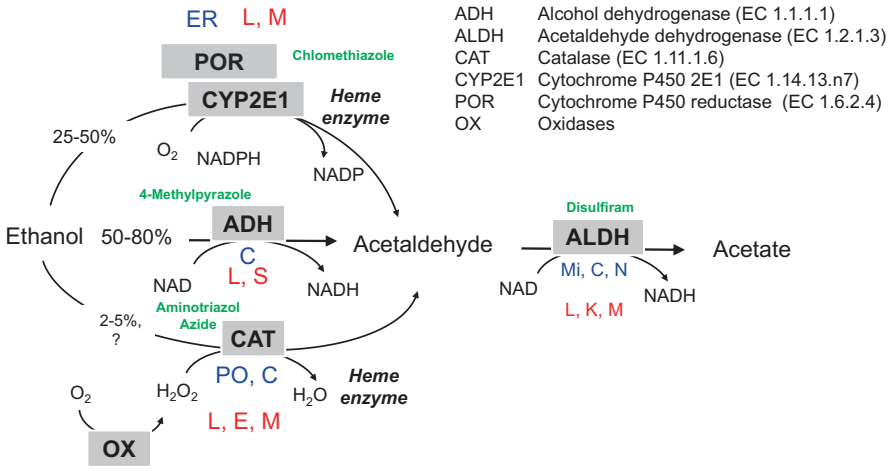

Fig. 50.1 Major enzymatic ethanol oxidation pathways. ADH and ALDH convert ethanol to acetic acid by transforming NAD to NADH. This causes an important shift of the redox potential and is responsible for many biochemical consequences including enhanced lipogenesis. Also note that CYPs require NADPH. They directly use oxygen which can lead to ROS formation through uncoupling. The proximity to carbon monoxide releasing HO1 in the endoplasmic reticulum has less well been studied but suggests a potential inhibitory interaction between CYPs and HO1. Abbreviations: subcellular localization are indicated in blue: *C* cytosol, *ER* endoplasmic reticulum, *Me* membrane, *Mi* mitochondria, *N* nucleus, *PO* peroxisome, inhibitors are given in green. Tissue distribution is given in red: *E* erythrocyte, *K* kidney, *L* liver, *M* many tissues, *S* stomach, enzyme abbreviations are provided in figure

then channeled as acetyl-CoA into the citric acid cycle. Since multiple isoenzymes exist for ADH and ALDH (see Figs. A.39, A.40, A.41) and some variants with reduced activity, ethanol metabolism varies considerably inter-individually. This results in different metabolic flows and the generation of different homeostatic acetaldehyde concentrations. Due to differences in enzyme presence and availability, human adults and fetuses process ethanol through different pathways.

Acetaldehyde is highly reactive, toxic, and carcinogenic, and the rate of its generation and of its degradation predicts the individual risk for organ toxicity and cancer development. This can be best seen in the high risk of local oropharyngeal cancers (see also Chap. 73–75 on cancer) in heavy drinkers. The oxidation cascade **tightly links addiction and alcohol dependence to general ethanol metabolism**. For instance, ADH variants with decreased activity increase the risk for addiction while variants with increased ADH and decreased ALDH activity result in acetaldehyde accumulation and rather prevent alcohol intake due to severe clinical symptoms. It seems that the brain-sensed joy primarily originates from ethanol and its intermediary metabolism while the negative consequences are mostly caused by the toxic ethanol oxidation intermediates.

In humans, several enzymes are involved in processing ethanol first into acetaldehyde and further into acetic acid and acetyl-CoA (see Fig. A.38). Once acetyl-CoA is formed, it becomes a substrate for the **citric acid cycle** ultimately producing cellular energy and releasing water and carbon dioxide (see Figs. A.43 and A.44). In addition to acetaldehyde, **reducing equivalents in the form of NADH** are also generated via the ADH reaction, resulting in a severe change of the intracellular redox state and leading to severe alterations of the intermediary metabolism. Due to its equilibrium with NADPH (see also Figs. A.46, A.47, NTH - $NAD(P)^+$ transhydrogenase), both reduced nicotine adenine dinucleotides (NADH and NADPH) are cumulating during ethanol metabolism leading to characteristic metabolic consequences such as enhanced lipogenesis, mitochondrial respiration, metabolism of galactose, serotonin, steroids, amines and other NADH dependent metabolism. NADPH is also required for the non-NADH mediated oxidation of ethanol by the microsomal multifunctional P450 cytochrome system in the endoplasmic reticulum, especially the subtype CYP2E1. CYP2E1 is not only induced by ethanol but also fatty acids, ketones and drugs and it can significantly contribute to ethanol elimination. CYPs are ubiquitously distributed in many tissues and are important for ω-1 hydroxylation of fatty acids but also have monooxygenase and epoxygenase activity. Although ethanol metabolism via CYP2E1 is quantitatively lower, it can be strongly induced by chronic alcohol consumption. Consequently, the rate of ethanol metabolism via CYP2E1 increases in the chronic alcohol abuser.

Ethanol metabolism via CYP2E1 also generates **reactive oxygen species (ROS)** through one electron reduction of oxygen, resulting in tissue toxicity and DNA damage (see Figs. A.67, A.68). Since CYP2E1 is not only responsible for ethanol metabolism, but also for the metabolism of various drugs, xenobiotics, and procarcinogens, alcohol metabolism can strongly interact with these substances which has clinical importance. Thus, ethanol metabolism is not only an important prerequisite

to explain ethanol toxicity in various organs such as the liver, but also plays an important role to explain the interaction with drugs, xenobiotics, procarcinogens, and retinoids.

Endogenous Ethanol Production and Evolution

Ethanol is produced endogenously during bacterial fermentation in the gut reaching up to levels of ca. 1 mM in the portal vein [4, 5]. Gastric bacterial overgrowth observed in atrophic gastritis may lead to the generation of ethanol within the stomach. In addition, Candida species may also generate ethanol, resulting in relatively high concentrations of blood alcohol up to 25 mM [6, 7]. The average human digestive system produces approximately 3 g of ethanol per day through fermentation. This is considered a potential evolutionary reason for the expression of ADHs both in stomach and liver. Regional differences of ethanol-metabolizing enzymes, however, suggest that the ability of humans to produce alcoholic beverages have also modulated the genetic background of ethanol metabolism. Catabolic degradation of ethanol is essential to life, not only in humans, but of most other organisms.

Certain amino acid sequences in the ethanol oxidation enzymes are highly conserved going back to the last common ancestor over 3.5 billion years ago [8]. Organisms including humans also produce several types of other alcohols in small amounts, primarily through fatty acid synthesis, retinol metabolism, glycerol lipid metabolism, and bile acid biosynthesis pathway, many of them in the liver. This may explain why the liver is also the main target organ of the negative side effects of ethanol metabolism. Importantly, **there is no feedback inhibition of ethanol metabolism** and most metabolizing enzymes are rapidly saturated. In other words, once exposed to ethanol, the metabolic machinery must metabolize it.

Energetic Considerations

As is also demonstrated in Fig. A.2, the exothermic reaction of the complete catabolism of alcohol yields about 1325 kJ or 317 kcal energy per mol [9]. With an molecular weight of 46 g/mol, this corresponds to 29 kJ or **6.9 kcal per gram ethanol**. Therefore, ethanol-bound energy is higher as the caloric content of sugars and proteins, but slightly lower as the one in fats. More complexity is added due to the different pathways to convert energy into heat or anabolic processes such as lipogenesis. Roughly, however, 5–6 L beer or 2–3 liters of wine are sufficient to cover the daily calory intake of a standard person (see also Figs. A.1, A.2 and A.3). In addition, in a standard person, at saturated levels, about **8 g pure alcohol are eliminated per hour** corresponding to about 230 kJ or 55 kcal per hour. Importantly, as already mentioned above, the organism cannot escape ethanol metabolism, and there is no negative feedback mechanism. In the 60ties of the last century there has been an intensive

debate to whether negative side effects of ethanol are due to caloric intake or ethanol per se. The now classical 4 year-long standardized feeding studies in non-primate monkeys by Charles Lieber could eventually establish once and for all that it is primarily the ethanol and its metabolism that causes liver damage [10]. As can be seen from the original data (see Table B.2) of the Heidelberg cohort of heavy but well-nourished Caucasian heavy drinkers, about **50% of their energy supply is covered by ethanol**. In this cohort, ca. 1200 patients consumed ca. 180-g pure alcohol per day during a heavy drinking period of about 14 years reaching a mean blood alcohol concentration of 1 °/°° (1 g/L). One can calculate from these data that this corresponds to a mean elimination of 7.5 g/h. With a mean size of 174 cm and weight of 78 kg (mean BMI 25.5), this corresponds to 0.01 g eliminated alcohol per kg body weight and hour. As is discussed at the end of this chapter, there are several emerging arguments to suggest that it is the energy availability of ethanol that, similar to excess carbohydrates, may explain the **steatohepatitis** caused by conditions such as chronic alcohol consumption, diabetes mellitus and overweight. In this concept, fat accumulation is rather seen as escape way to eliminate ethanol more rapidly than as a prerequisite for liver damage.

Ethanol Absorption and Ethanol Blood Levels

Blood alcohol concentrations (BACs) reflect gastrointestinal absorption, diffusion, metabolism, and unchanged excretion of ethanol. Thus, absorption of ethanol associated with increasing BAC has to be distinguished from elimination with decreasing BAC. At the end of alcohol absorption, a peak is detectable, which may change to a plateau if alcohol is further consumed continuously. As mentioned above, this plateau is reached in heavy drinkers e.g. from the Heidelberg cohort as described in Table B.2.

Alcohol is absorbed from the upper gastrointestinal tract by simple diffusion. Delayed gastric emptying and food in the upper gastrointestinal tract may lead to lower BAC, while a higher BAC is observed after gastrointestinal bypass surgery and after consumption of highly concentrated alcoholic beverages such as liquors compared to low concentrated beverages like beer and wine [11, 12]. Gastrointestinal absorption of ethanol depends on various factors, including the ethanol concentration of the beverage, blood perfusion of the stomach and duodenum, simultaneous food intake, rate of gastric emptying, body temperature, and menstrual cycle [11, 12]. Twenty percent of alcohol is absorbed from the stomach and 80% from the upper small intestine. In the gastric mucosa, alcohol can be metabolized by various ADHs. This is called gastric **first-pass metabolism (FPM)** of alcohol [13]. The rest of the ethanol enters the liver via the portal vein. Ethanol is metabolized to more than 90% in the liver after multiple passages through the liver, to 5–10% in the gastric mucosa, and approximately 3–5% of the orally absorbed ethanol is excreted unchanged through the lungs, skin, and kidneys [11, 12]. It should be noted that hemodynamics completely change in patients with liver cirrhosis where the hepatic artery increasingly takes over the blood supply of the whole liver. More of these

biomechanic considerations are discussed in the Chap. 49 on the "pathophysiology of alcohol and unexplained observations".

Calculation of Ethanol Elimination

A mathematical estimation of blood alcohol content is useful when blood alcohol is not currently detectable, or for the prediction of alcohol levels. While there are several ways to calculate it, the simplest is Widmark's equation [14–16]:

$C_o = A/[p \times r]$

C_o is the theoretical maximum concentration of alcohol in blood (mg/g). A is the amount of alcohol in the body (g). p is the body weight (kg). r is the correction factor corresponding to the ratio of total body water and blood water (0.6 for females and 0.7 for males).

Gender plays an important role in the total amount of water in the body. In general, men have less fatty tissue and a higher percentage of water (58%) than women (49%), thus the volume of distribution (V_d) for ethanol is higher in men. According to its partition coefficient (Poct/water is 0.1), ethanol is 10 times more soluble in water than in lipids. Thus, upon ingestion of the same amount of ethanol, the BAC will be higher in females than in males. The Widmark's equation has been improved subsequently by introducing individual r, based on the multiple linear regression equations:

for females:

rFI = 0.31223 – 0.006446 × body weight (kg) + 0.004466 × body height (cm)

for males:

rMI = 0.31608 – 0.004821 × body weight (kg) + 0.004632 × body height (cm).

There is no absolute accurate blood alcohol calculator because numerous factors influence the BAC, such as gender (male/female), rate of metabolism/elimination, health status, medications, drinking frequency, amount and the type of food in the stomach and small intestine, the time of food intake, and others [17].

Ethanol Oxidation to Acetaldehyde in Humans

Chemical properties of ethanol are listed in Fig. A.2. In human adults, ethanol is oxidized to acetaldehyde using NAD^+, mainly via the hepatic enzyme alcohol dehydrogenase IB (class I), beta polypeptide (ADH1B, EC 1.1.1.1). (see Fig. 50.1). The gene coding for this enzyme is located on chromosome 4, in 4q22 [12]. Members of this enzyme family metabolize a wide variety of substrates, including ethanol, retinol, other aliphatic alcohols, hydroxysteroids, and lipid peroxidation products. An actual complete list of the 7 ADHs is provided in Figs. A.39, A.40, A.41, A.42. ADH consists of several homo- and heterodimers of alpha, beta, and gamma subunits (see also Fig. A.42). It plays the major role in ethanol catabolism. Three genes encoding alpha, beta and gamma subunits are tandemly organized in a genomic segment as a gene cluster.

In human **embryos and fetuses,** ethanol is not metabolized via this mechanism as ADH enzymes are not yet expressed to any significant quantity in human fetal liver. In fact, induction of ADH starts after birth, and requires years to reach adult levels. Consequently, in fetuses, ethanol is metabolized at much slower rates by different enzymes from the cytochrome P-450 superfamily (CYP), in particular by CYP2E1. The low fetal rate of ethanol clearance is responsible for the important observation that the fetal compartment retains high levels of ethanol long after ethanol has been cleared from the maternal circulation by the adult ADH activity in the maternal liver [18]. CYPs, in contrast to ADH, directly use oxygen and uncoupled one electron reduction of oxygen can lead to the release highly reactive superoxide anion radicals that are able to initiate lipid peroxidation. These mechanisms render the fetus especially vulnerable to alcohol. The resulting **Fetal Alcohol Spectrum Disorders (FASD)** are discussed in detail in Part IV of this book (Chaps. 23–25).

Most of the alleles of ADH are single nucleotide polymorphisms. Table B.10 in the Appendix also shows kinetic parameters such as K_M and V_{MAX} for selected enzymes. Class I ADH – the major ADH in the liver –becomes quickly saturated at low millimolar ethanol concentrations. ADH4 contributes to ethanol oxidation at higher concentrations and is only expressed in the liver. ADH5 has virtually no affinity for ethanol with an extremely high K_M. ADH6 mRNA is also expressed in the liver, but the protein has not been isolated so far. ADH7 is primarily localized in the stomach and in the retina, and responsible for gastric FPM of ethanol and retinol oxidation [19].

ADH1B and ADH1C show polymorphisms, resulting in the production of enzymes with different kinetic properties and different ethanol-oxidizing capacities. There are three different ADH1B alleles that alter the amino sequence of the encoded β subunit. In both the β2 and β3 subunit, the amino acid substitution occurs at an amino acid that contacts with NAD. This substitution results in enzymes that have a 70- to 80-fold higher turnover rate than the β1 subunit [12]. ADH1B1 contributes ca. 20% to ethanol metabolism in the liver. ADH1C has also three alleles. While the ADH1B2 allele encodes for an enzyme that is approximately 40 times more active in producing acetaldehyde as compared to the enzyme encoded by the ADH1B1 allele, the ADH1C1 allele encodes for an enzyme with 2.5 times more acetaldehyde production as compared to the ADH1C2 allele.

This has severe consequences with respect to ethanol drinking behavior and ethanol-associated cancer development. With respect to alcoholism and liver disease, the presence of the ADH1B2 allele seems to be strongly protective, since individuals with this gene produce enormous amounts of acetaldehyde following alcohol ingestion [20–23]. Under these circumstances severe side-effects of acetaldehyde such as tachycardia, sweating, flushing, nausea, and vomiting occur (flush syndrome), and therefore these individuals avoid alcohol. With respect to ADH1C polymorphism, individuals homozygous for the ADH1C1 allele with a small but significant greater production of acetaldehyde do not show such side-effects. However, they seem to be at increased risk for the development of cancer of the upper aerodigestive tract, breast, and colorectum [19, 24–26]. ADH1C1 contributes approximately 40% to ethanol metabolism in the liver.

Metabolic consequences of the ADH reaction are either due to an increase in NADH or acetaldehyde. Production of NADH leads to a change in the cellular redox potential and has a severe influence on the intermediary cell metabolism. This is especially pronounced in the liver and include [27] a shift towards lactate and an inhibited gluconeogenesis, an increase in NADPH with **enhanced lipogenesis** [28], a change in transcriptional regulation by affecting C-terminal binding protein and the silent information regulator, resulting in enhanced histone acetylation and reduced deacetylation associated with epigenetic changes and activation of certain inflammatory genes [28] and, finally, an effect on signaling proteins such as NF-κB, c-Jun N-terminal kinase (JNK), and p38 mitogen-activated protein kinase [28]. Clinical consequences of a change in the redox state are [27, 28]:

- Activation of the nuclear transcription factor SREBP-1c and inhibition of peroxisome proliferator-activated receptor-α, resulting in a stimulation of fatty acids and triglyceride synthesis, and inhibition of β-oxidation of fatty acids. As a result, fatty liver and also hyperlipoproteinemia type IV and V according to Fredricksen may occur.
- Decreased pyruvate and increased lactate concentrations in the liver. As a consequence, an inhibition of hepatic gluconeogenesis due to a lack of pyruvate with hypoglycemia may occur especially in individuals with liver disease in the fasted state. Also, lactic acidosis occurs followed by low urinary pH and increased tubular reabsorption of uric acid leading to hyperuricemia. The increase in lactate also stimulates hepatic stellate cells (HSCs) to produce collagen.
- A rapid depletion of hepatic glycogen due to enhanced glycogenolysis
- Disturbed porphyrin metabolism with the occurrence of secondary porphyria [29]
- Decreased production of testosterone in the Leydig cells of the gonads resulting in feminization (body fat, gynecomastia, body hair) [30].
- Reduced generation of UDP-glucuronic acid from UDP-glucose, and thus inhibition of hepatic glucuronidation of phenolphtalein, trichloroethane, and diethyldithiocarbamate [31].

The generation of acetaldehyde and acetate has several consequences that are shown in Table 50.1 [27, 28, 39]. Since ethanol metabolism primarily via ADH effects hepatic intermediary metabolism, the occurrence of various metabolic diseases is favored by chronic ethanol consumption, including hypoglycemia, hyperlactatemia (lactic acidosis), hyperuricemia, hyperhomocysteinemia, porphyria, and an altered testosterone to estrogen ratio. Ethanol competes with some substrates at the ADH binding site. Most importantly, the conversion of retinol to retinal and retinoic acid is inhibited in the presence of ethanol. This is one mechanism to explain low levels of retinoic acid in the liver after chronic ethanol consumption [40]. As is discussed at the end of this chapter, the important changes on intermediary metabolism may be the major reasons why ethanol leads to the same histological characteristics as an excess of carbohydrates does under condition of diabetes mellitus or overweight.

Table 50.1 Generation of acetaldehyde and acetate and its consequences

	References
Effects of acetaldehyde	
• Mitochondrial damage with alteration of the respiratory chain and decreased ATP production. As a morphological consequence hepatic megamitochondria may occur	[27, 28, 32, 33]
• Damage of the microtubular system with an altered secretion of proteins, such as albumin, transferrin, and very-low-density lipoproteins. As a morphological equivalent, ballooning of the hepatocyte may occur	
• A decrease in glutathione, and thus an alteration of the detoxification of xenobiotics and ROS	
• An inhibition of the nuclear repair systems with an enhancement of carcinogenesis	[34]
• A disturbed methyl transfer with decreased levels of the active methyl donor *S*-adenosylmethionine and an increase of homocysteine, which produces endoplasmic reticulum stress resulting in fatty liver, as well as a decrease in mitochondrial glutathione and increased apoptosis. As a consequence, membrane damage and hypomethylation of DNA may occur. Aberrant methylation causes an inflammatory response and tissue injury, and DNA hypomethylation may cause liver cancer	[35]
• Binding of acetaldehyde to proteins with generation of neoantigens, activation of the immune system, and production of antibodies	[36]
• Binding of acetaldehyde to DNA and generation of mutagenic DNA lesions	[37]
• Stimulation of fibrogenesis by activation of stellate cells	[27, 38]
Effects of acetate	
• Increased acetylation of histones associated with epigenetic changes (see above).	[39]
• Increased acetylation of certain compounds such as sulfanilamide	

Oxidation of Acetaldehyde to Acetic Acid

The second oxidation step by acetaldehyde dehydrogenases (ALDH) is also shown in Fig. 50.1 and Figs. A.40, A.41 show the actual, still growing list of the known ALDHs. Acetaldehyde is a highly unstable compound (see Fig. A.2) and an electrophile that readily engages in condensation reactions. It can also conjugate with glutathione and rapidly deplete this important antioxidative defense system [41]. Acetaldehyde is considered one of the major toxic intermediates of ethanol oxidation. A major ALDH is aldehyde dehydrogenase 2 family (ALDH2, EC 1.2.1.3, see also Figs. A.41 and A.42) which is found on chromosome 12, locus q24.2. Among the 19 known human ALDHs, mitochondrial ALDH2 and, to a lesser extent, cytosolic ALDH1 play a major role in acetaldehyde oxidation and elimination [42]. Both enzymes exhibit low K_M constants for acetaldehyde (i.e., 3.2 and 180 μM for human ALDH2 and ALDH1A1, respectively) [43]. Acetaldehyde is also considered to injure mitochondria and decrease the activity of ALDH2. Ultimately, this will further increase acetaldehyde levels and initiate a vicious cycle.

A coding variant known as ALDH2*2 allele leads to the substitution of Lys for Glu at position 504. This substitution results in a virtually inactive ALDH2 enzyme [12] which is present either in homo- or heterozygous form in almost 50% of Asians. For instance, in 10% of the Japanese population, this mutation is homozygous and associated with zero ALDH activity. These individuals cannot drink ethanol at all since they develop severe side-effects such as flushing, tachycardia, nausea, and vomiting. Forty percent of Japanese, however, are heterozygotes. They may consume alcohol with an ALDH2 activity of approximately 10–15% compared to those of normal Caucasians. They also develop a flushing syndrome, however, this can be tolerated, so that they continue to drink. As a result, acetaldehyde levels increase in the blood, in the liver, and in the saliva [6]. Since acetaldehyde is a carcinogen, these individuals have a high risk for alcohol-associated cancer development, such as cancer of the upper alimentary tract and the colon [44]. The presence of even a single ALDH2*2 allele is **strongly protective against alcohol dependence**. Compared with an individual carrying two active ALDH2*1 alleles and two copies of the normal ADH1B*1 allele, the odd ratios for the risk for alcohol dependence for a man carrying one inactive ALDH2*2 allele and two ADH1B*1 alleles is 0.33. If, in addition to the ALDH2*2 allele, the man also carries at least one overactive ADH1B*2 allele, the odds ratio declines further to 0.05 [12].

The protective effect of the ALDH2*2 allele can, however, be modulated by the environment. In Japan, the percentage of alcoholics with the ALDH2*2 allele has increased over the years from less than 3% to over 12% due to a sociological change of increased alcohol consumption [12]. ALDH2 can also be inhibited by various drugs leading to a flush reaction and Disulfiram has been used in alcoholics to obtain abstinence (see Fig. 50.1). Most recently, another human low-K_M ALDH has been characterized as ALDH1B1, being actively involved in ethanol metabolism, especially in the intestinal mucosa [45]. Similar to the ADH genes, many noncoding variations in the ALDH2 gene exist and several promoter polymorphisms in the ALDH1A1 gene affect gene expression *in vitro*.

Alternative Ethanol Oxidation in the Smooth Endoplasmic Reticulum

The **microsomal ethanol oxidizing system (MEOS)** is an alternate pathway of ethanol metabolism that occurs in the smooth endoplasmic reticulum in the oxidation of ethanol to acetaldehyde. While playing only a minor role in ethanol metabolism in average individuals, MEOS activity increases after chronic alcohol consumption. The MEOS pathway requires the CYP2E1 enzyme, part of the cytochrome P450 family of enzymes, to convert ethanol to acetaldehyde. Cytochrome P450 2E1 (abbreviated CYP2E1, EC 1.14.13.n7) is a member of the cytochrome P450 mixed-function oxidase system. It is involved in numerous physiological reactions and synthesis steps in humans, but also highly important for the

metabolism of xenobiotics. This class of enzymes is divided into a number of subcategories, including CYP1, CYP2, and CYP3 [46]. While CYP2E1 itself carries out a relatively low number of these reactions (~4% of known P450-mediated drug oxidations), it and related enzymes CYP1A2 and CYP3A4 are responsible for the breakdown of many toxic environmental chemicals and carcinogens, in addition to basic metabolic reactions such as fatty acid oxidations [47]. CYP2E1 is a membrane protein expressed in high levels in the liver, where it composes nearly 50% of the total hepatic cytochrome P450 mRNA [48] and 7% of the hepatic cytochrome P450 protein [49].

The activity of the MEOS is gender-dependent with higher activities in the male gender. Castration, ovariectomy, and substitution with sex hormones affect the MEOS activity. The MEOS activity decreases with age, and may depend on diets with higher activities following hypocaloric carbohydrate-deficient diets and lower activities following protein malnutrition [38]. The MEOS activity can also be induced by certain drugs. Major components of the MEOS are CYP2E1 and NADPH, cytochrome *c* reductase as well as phospholipids. The reaction occurs within the smooth endoplasmic reticulum and involves P450 reductase [13, 50, 51]. This protein transfers electrons to the CYP2E1 heme iron after first accepting them from the reduced NADPH. CYP2E1 catalyzes the oxidation of small organic compounds such as the production of glucose from ketones such as acetone during starvation [52].

The MEOS metabolizes not only ethanol, but also other primary aliphatic alcohols such as methanol, propanol, butanol, and pentanol, as well secondary alcohols such as isopropanol and tertiary alcohols such as *t*-butanol [27, 50, 51]. CYP2E1 also plays a role in several important metabolic reactions, including the conversion of ethanol to acetaldehyde and to acetate in humans [53]. In the conversion sequence of acetyl-CoA to glucose, CYP2E1 transforms acetone via hydroxyacetone (acetol) into propylene glycol and methylglyoxal, the precursors of pyruvate, acetate and lactate [54–56]. CYP2E1 also carries out the metabolism of endogenous fatty acids such as the **ω-1 hydroxylation** of fatty acids such as arachidonic acid, involving it in important signaling pathways that may link it to diabetes and obesity [17].

Thus, it can act as a **monooxygenase** to metabolize arachidonic acid to 19-hydroxyeicosatetraenoic acid (19-HETE), and as an epoxygenase to metabolize docosahexaenoic acid to epoxides [57]. 19-HETE is an inhibitor of 20-HETE, a broadly active signaling molecule, e.g. it constricts arterioles, elevates blood pressure, and it promotes inflammation responses. The EDP (see Epoxydocosapentaenoic acid) and EEQ (see epoxyeicosatetraenoic acid) metabolites also have a broad range of activities. In various animal models and in vitro studies on animal and human tissues, they decrease hypertension and pain perception; suppress inflammation; inhibit angiogenesis, endothelial cell migration and endothelial cell proliferation [58–61]. CYP2E1 is not regarded as being a major contributor to forming the cited epoxides but could act locally in certain tissues [61].

The ethanol metabolism via CYP2E1 produces first a *gem*-diol – an unstable product that disintegrates to acetaldehyde [52]. Since oxygen is used in this

CYP2E1-dependent reaction, ROS can occur. CYP2E1 also catalyzes the formation of hydroxyethyl radicals directly from ethanol. Importantly, when oxygen is used in the reaction, sometimes the reaction does not continue, and ROS may be generated [62–64]. The amount of CYP2E1 in the liver and in other tissue is variable and may vary up to eight-fold. Induction of CYP2E1 by chronic ethanol ingestion occurs not only in the liver, but has also been reported in the mucosa cells of the small and large intestine, in the pancreas, in the lung, and in the brain [65]. CYP2E1 is also induced by 4-methylpyrazole – an ADH inhibitor – and by acetone and free fatty acids, which may possibly be of importance in the pathogenesis of nonalcoholic fatty liver disease [66].

Chronic ethanol ingestion even at relatively low doses such as 40 g ethanol/day and even after a short period of time such as 1-week results in a significant induction of CYP2E1 which varies inter-individually [67]. The enhanced metabolism of ethanol after chronic alcohol consumption is due the induction of CYP2E1, and it is important to note that CYP2E1 activity needs NADPH and reutilizes reducing equivalents from the ADH reaction as NADPH from NADH. The mechanisms for regulating the enzyme concentration are complex. CYP2E1 is lower in the fed sate and higher during starvation or in obesity. In addition to control mechanisms for translation and transcription, an inhibition of CYP2E1 degradation by the ubiquitin–proteasome pathway may additionally contribute to the increase of CYP2E1 following ethanol consumption [68]. Thus, various factors contribute to the large variation of CYP2E1 after alcohol ingestion. The metabolic and clinical consequences of ethanol metabolism via MEOS are multiple and described in Table 50.2. The interaction with drugs is beyond the scope of this chapter and described in more detail elsewhere [72].

Table 50.2 Metabolic and clinical consequences of ethanol metabolism via MEOS

Effects of CYP2E1 (MEOS) induction	References
• Production of ROS including hydroxyl-ethyl radicals, superoxide anions, and hydroxy peroxide, which contribute to liver damage and cancer. ROS results in lipid peroxidation with lipid peroxidation products such as 4-hydroxynonenal or malondialdehyde. 4-Hydroxynonenal binds to DNA, forming highly carcinogenic exocyclic etheno–DNA adducts.	[69, 70]
• Interaction of the microsomal ethanol metabolism with the metabolism of various drugs, leading to decreased drug blood levels and increased drug toxicity.	[27, 38]
• Interaction of CYP2E1 ethanol metabolism with the metabolism of various xenobiotics and carcinogens, leading to increased toxicity and carcinogenesis.	
• Interaction of CYP2E1 ethanol metabolism with the metabolism of retinol and retinoic acid, leading to vitamin deficiency and increased toxicity, including enhanced carcinogenesis.	[69, 71]

P450 Subtype CYP2E1 and its Regulation

CYP2E1 exhibits structural motifs common to other human membrane-bound cytochrome P450 enzymes and is composed of 12 major α-helices and 4 β-sheets with short intervening helices interspersed between the two [17]. Like other enzymes of this class, the active site of CYP2E1 contains an iron atom bound by a heme center which mediates the electron transfer steps necessary to carry out oxidation of its substrates. The active site of CYP2E1 is the smallest observed in human P450 enzymes, with its small capacity attributed in part to the introduction of an isoleucine at position 115. The side-chain of this residue protrudes out above the heme center, restricting active site volume compared to related enzymes that have less bulky residues at this position [17]. Its hydroxyl group is well-positioned to donate a hydrogen bond to potential acceptors on the substrate, and its methyl group has also been implicated in the positioning of fatty acids within the active site [73, 74].

In humans, the CYP2E1 enzyme is encoded by the CYP2E1 gene [75]. As mentioned above, the enzyme has been identified in fetal liver, where it is considered to be the predominant ethanol-metabolizing enzyme, and may be connected to ethanol-mediated teratogenesis [76]. In rats, within 1 day of birth, the hepatic CYP2E1 gene is activated transcriptionally. CYP2E1 expression is easily inducible, and can occur in the presence of a number of its substrates, including ethanol [51], isoniazid, [51] tobacco, [77] isopropanol, benzene, toluene, and acetone [47]. For ethanol, specifically, there seem to exist two stages of induction, a post-translational mechanism for increased protein stability at low levels of ethanol and an additional transcriptional induction at high levels of ethanol [51]. CYP2E1 is inhibited by a variety of small molecules, many of which act competitively (see Fig. 50.1). Inhibitors include diethyldithiocarbamate [78], and disulfiram [79]. CYP2E1 and other cytochrome P450 enzymes can inadvertently produce reactive oxygen species (ROS) in their active site when catalysis is not coordinated correctly, resulting in potential lipid peroxidation as well as protein and DNA oxidation [17]. CYP2E1 is particularly susceptible to this phenomenon compared to other P450 enzymes, suggesting that its expression levels may be important for negative physiological effects observed in a number of disease states [17].

CYP2E1 expression levels have been correlated with a variety of dietary and physiological factors, such as ethanol consumption [80], diabetes [81], fasting [82], and obesity [83]. It appears that cellular levels of the enzyme may be controlled by the molecular chaperone HSP90, which upon association with CYP2E1 allows for transport to the proteasome and subsequent degradation. Ethanol and other substrates may disrupt this association, leading to the higher expression levels observed in their presence [84]. The increased expression of CYP2E1 in these health conditions is thought to contribute to their pathogenesis by production of ROS [17]. A study in rats revealed a eight- to nine-fold elevation of CYP2E1 with fasting alone, compared to a 20-fold increase in enzyme level accompanied by a 16-fold increase in total catalytic capacity in rats who were both fasted and given large quantities of ethanol for three consecutive days [85]. However, a previous study in humans with

detailed characterization of fibrosis stage by elastography revealed that other CYPs may also be expressed highly in drinkers. Of note, **expression of all CYPs drastically decreases once cirrhosis stage is reached** (Figs. A.65 and A.66). In fetuses, ethanol is instead metabolized at much slower rates by different enzymes from the cytochrome P-450 superfamily (CYP), in particular by CYP2E1. The low fetal rate of ethanol clearance is responsible for the important observation that the fetal compartment retains high levels of ethanol long after ethanol has been cleared from the maternal circulation by the adult ADH activity in the maternal liver [18]. CYP2E1 expression and activity have been detected in various human fetal tissues after the onset of organogenesis (ca. 50 days of gestation). Exposure to ethanol is known to promote further induction of this enzyme in fetal and adult tissues. CYPs, in contrast to ADH, directly use oxygen and uncoupled one electron reduction of oxygen can lead to the release highly reactive superoxide anion radicals that are able to initiate lipid peroxidation.

Ethanol Metabolism Via Catalase

Catalase is localized in the peroxisomes of cells, namely hepatocytes, and is able to oxidize ethanol to acetaldehyde by using H_2O_2 (Fig. 50.1). However, due to the low generation of H_2O_2 in the liver (typically at the 0.1 μM level), catalase seems not to contribute significantly to ethanol metabolism. The role of catalase in detoxifying ethanol has been extensively discussed in the past [5]. Physiological rate of H_2O_2 production has been estimated to represents 2% of the in vivo rate of hepatic ethanol oxidation. It has been further considered that catalase could account for 5% of the non-ADH mediated, pyrazole-insensitive ethanol oxidation. Conversely, in brain samples, the presence of the catalase inhibitor 3-amino-1,2,4-triazole induced a concentration-dependent reduction of the amount of acetaldehyde generated after incubation [86]. Moreover, the contribution of catalase for ethanol oxidation in red blood cells, another important side of this enzyme, has not widely been appreciated [87, 88]. As catalase activity is roughly comparable between liver and blood compartment but blood is at least 3 times larger in volume, RBCs could represent an estimated up to 6% of ADH-mediated ethanol oxidation and even up to 15% of the ADH-independent oxidation. Moreover, as shown in brain studies, catalase could play an important role in specific tissues locally. It also remains to be studied, in light of the new prospective all-cause mortality data presented in Part I of this book, how catalase-mediated ethanol metabolism interferes with the RBC metabolism and whether this impairs the physiological role of catalase as major H_2O_2 removing enzyme in human erythrocytes [88]. Recently, it has been suggested that catalase could participate in lactate-stimulated liver ethanol oxidation, where the addition of lactate generates hydrogen peroxide, which is then used by catalase to oxidize ethanol to acetaldehyde [89].

Nonoxidative Metabolism of Ethanol

Nonoxidative metabolism of ethanol includes the **generation of fatty acid ethyl ester (FAEE)** [90, 91], phosphatidyl ethanol (PEth) [92, 93] as well as ethyl glucuronide (EtG) and ethyl sulfate (EtS) [94, 95]. While FAEEs have been implicated in the pathogenesis of organ injury, especially in the pancreas, the later compounds have been used in forensic medicine as markers for chronic or acute alcohol ingestion. PEth is generated from phosphatidylcholine with phospholipase D. PEth has a high specificity for ethanol since it has a low rate of degradation. As already discussed above, however, degradation rate of PEth varies considerably between individuals. New work shows that PEth elimination depends on heme turnover and is enhanced in those drinkers with increased hemolysis [2]. EtG can be found in the urine up to 5 days after alcohol ingestion. EtG can also be determined in hairs (if more than 20 g ethanol/day is consumed). The detection of EtG and FAEE in hairs of more than 1 ng/mg demonstrates excessive ethanol consumption. Since EtG can be degraded by bacteria (urinary tract infection), the measurement of EtS seems superior. Other ethanol metabolites are ethylphosphate and ethylnitrite in very low concentrations. Additional information is further provided in Figs. A.77, A.78 and in the chapter on biomarkers.

Ethanol and Carbohydrate Metabolism—A Common Link to Metabolic Liver Disease?

Why can alcohol-related liver disease be replicated by diabetes and obesity? One of the major cause-specific deaths is liver related mortality with alcohol-related liver disease as one of the famous hallmarks of alcohol consumption. In 1995, more than 25 years ago, in a book edited by Pauline Hall and entitled “Alcoholic liver disease” [96], Peter Scheuer noted in the foreword that he did not understand why “there is an apparent latent period, supported by examination of serial liver biopsies, between the onset of heavy drinking and the development of steatohepatitis”. He further asked “why alcohol-related steatohepatitis is so very similar morphologically to non-alcoholic steatohepatitis (NAFLD)? [96]. Today, almost 30 years later, we have not yet found definite answers to these questions and, rather, a stagnation has been observed over the last two decades in our progress to better understand the underlying molecular mechanisms of ALD.

Moreover, ALD offers more unanswered questions, in addition to the above-mentioned stunning similarity between diabetes- and overweight-induced NAFLD. Almost no progress has been made in diagnosis and treating the often-fatal alcoholic hepatitis. Modest benefits are seen in only a fraction of patients with steroids. Although the microbiome has gained great attention, simple antibiotic treatment seems not to halt ALD. Moreover, the pathophysiology of ALD is often explained with quite complex and methodologically challenging mechanisms such

as reactive oxygen species that require deep physical, chemical and biochemical knowledge. On the other side, enzyme systems such as the p450 system localized in the endoplasmic reticulum are attributed to mediate major disease mechanisms but both knockout animals or pharmacological blockage show less convincing effects. In other words: What are the actual mechanisms of the alcohol-related liver disease and what does it have in common with NAFLD in the setting of overweight and diabetes?

Although the oxidation intermediated acetaldehyde is beyond any doubt crucial to explain alcohol-related disease mechanisms, it cannot be the major link to obesity and diabetes.

Rather, both alcohol, diabetes and overweight are characterized by an excess of energy. As can be seen from the original data (see Tables B.4, B.5, B.6, B.7, B.8, B.9) of the Heidelberg cohort followed-up over 15 years, heavy drinkers, despite having access to normal nutrition, cover about 50% of their energy supply by ethanol. In this cohort, in more than 1200 patients, in average, during a mean daily consumption of ca. 180-gram alcohol, a mean blood alcohol concentration of 1 °/°° (1 g/L) was reached. This corresponds to a **mean elimination of ca. 7.5 g alcohol per hour**. Based on a mean size of 174 cm and mean weight of 78 kg (BMI 25.5), this also corresponds to **0.01 g alcohol per kg body weight and hour**.

Although ethanol, comparable to sugars, only contains the three elements carbon, oxygen and hydrogen, it is neither chemically nor biochemically a carbohydrate and human metabolism is strikingly different. As mentioned above, ethanol is an energy supplier containing almost the double energy as compared to glucose (7 versus 4 kcal per gram). Similar to other physiological energy suppliers such as fatty acids or sugars, oxidation of ethanol leads to NADH which can be further used for mitochondrial respiration. However, in contrast to glucose and fructose, ethanol metabolisms rather **prevents gluconeogenesis** simply due to a balance shift towards reduced NADH (see Fig. 50.2). This **shifts the lactate/pyruvate ratio towards lactate** and, consequently, away from gluconeogenesis (see also Fig. 50.2). It should be also noted that typical ethanol metabolism starts already at 0.4 permille of blood ethanol concentration [97]. Through the **malate aspartate cycle**, reduced NADH is also shifted across the mitochondrial membrane and used for ATP production [98]. Peroxisomes seem also to have such a shuttle system so that peroxisomal ß-oxidation is also closely linked to the cytosolic intermediary metabolism [99].

Ethanol also provokes a fast and **efficient depletion of glycogen stores** (see Fig. 50.2). Although fundamental to ethanol biochemistry, it is still not clear whether these changes are responsible for rapid ethanol-mediated muscular fatigue as muscles obtain glucose from the liver through the Cori cycle. As already mentioned above, it is also highly intriguing that ethanol, which does not have any biochemical feedback loop in human cells, overwhelms the mitochondrial respiratory chain and may simply cause injury by uncoupling reactions leading to release of reactive oxygen species (ROS). Consequently, despite providing enough energy, ethanol metabolism leads to glucose deprivation and glycogen depletion which may become limiting for cells of the brain, red blood cells or muscle cells that are highly dependent on hepatic gluconeogenesis. In contrast to former reports, mitochondria seem

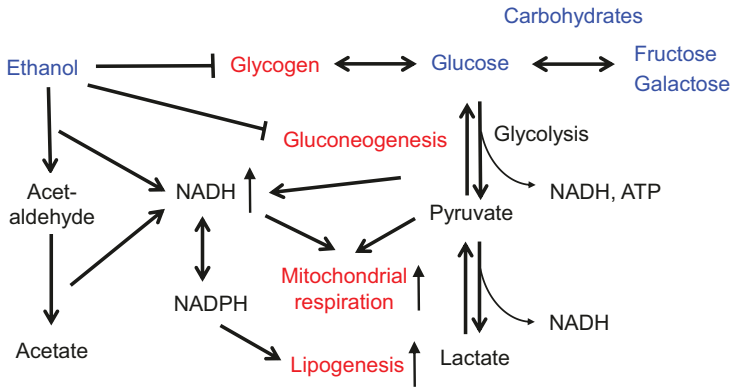

Fig. 50.2 Common pathways and differences of carbohydrate and ethanol metabolism. Both glycolysis and ethanol oxidation lead to formation of NADH. Cytosolic NADH can be transferred to mitochondria through the malate aspartate (Borst) shuttle. Both metabolic pathways also lead to lipogenesis, since NADH and the required NADPH are in balance. The major metabolic difference is that ethanol oxidation ultimately blocks gluconeogenesis most likely due to the redox changes with NADH excess and by shifting the lactate/pyruvate ratio towards lactate. Ethanol also causes rapid and significant glycogen depletion. Hence, glucose becomes limiting. With progression of ALD, however, blood glucose levels increase (see Table B.2). More studies are needed to fully comprehend the underlying hormonal and potentially hemodynamic mechanisms. The similarity of ethanol and carbohydrate metabolism consists in the excess and uncontrolled energy supply which may be one of the major driving forces of mitochondrial damage and liver inflammation. In addition, no metabolic escape exists for both excess carbohydrate and ethanol exposure except elimination by lipolysis or oxidation

first to increase respiration under conditions of ethanol. It would be an attractive scenario that the rapid and uncontrolled "fuel burning" in the cellular powerplants could ultimately be responsible for later observed mitochondrial damage e.g. through uncoupled redox reactions yielding to ROS, another established hallmark in alcohol-related liver and organ damage (see also chapter on "mitochondria and alcohol".

Glucose is central to energy consumption. Carbohydrates, lipids, and proteins can all ultimately break down into glucose, which then serves as the primary metabolic fuel of mammals and the universal fuel of the fetus. It serves as the major precursor for the synthesis of different carbohydrates like glycogen, ribose, and deoxyribose, galactose, glycolipids, glycoproteins, and proteoglycans [100]. However, in terms of evolution, access to small carbohydrates such as glucose, galactose or fructose has been always limiting to humans. Unlike glucose, which is directly metabolized widely in the body, fructose is almost entirely metabolized in the liver in humans, where it is directed toward replenishment of liver glycogen and triglyceride synthesis [101]. Ca. 40% of fructose is converted in liver to glucose, and about 25% is converted to lactate and ca. 20% is converted to glycogen [102]. Glucose and lactate are then used normally as energy to fuel cells all over the body [103].

Thus, it seems that although not being a carbohydrate, ethanol shares with sugars the immediate energy supply within the intermediary metabolism. They also share to some extent the lack of a negative feedback loop. As mentioned above for ethanol, the human metabolism can also not escape an excess of glucose or fructose and will metabolize it under excess conditions. In this scenario, fatty acid accumulation is the bodies only option to rapidly eliminate carbohydrates or ethanol and store the excess energy through lipogenesis in adipose tissue. Hence, in this context, fatty liver may rather be a bystander and a metabolic consequence to quickly remove the excess of energy but not the primary cause of steatohepatitis. Consequently, it is the **uncontrolled excess of rapidly-available energy that may link NAFLD with ALD**. Since lipogenesis, in this context, would be more a solution than a problem, fatty liver may not be the actual disease hallmark but rather the mitochondrial damage and inflammation due to excess energy supply and mitochondrial damage. The development of mitochondrial damage will later impair the mitochondrial ß-oxidation and, subsequently, further increase steatosis due to decreased fat elimination. More research on carbohydrate metabolism and its relation to ethanol and its hormonal control is needed. Ultimately, with regard to the terminology debate (see also Chap. 1), **metabolic (dysfunction) associated fatty liver disease (MAFLD)** [104] may not be optimal for paving a future path of better understanding the underlying mechanism. A potential more optimal alternative could be then broader term **"Metabolic Liver Disease" (MLD)** which would only encompass patients with signs of liver damage and fibrosis while fatty liver would be an important diagnostic feature but not necessarily part of the pathology. Finally, the intermediary metabolism would also provide a novel bridge to **interlink energy and ethanol metabolism to addiction**, whether it is food addiction or alcohol dependence. Here, more detailed studies a needed.

Chapter 51
Modulation of Alcohol-Related Liver Disease by Obesity and Diabetes

Hannes Hegmar and Hannes Hagström

Abstract Current evidence suggests an interactive effect between a high consumption of alcohol, or ALD, and metabolic risk factors, associated with NAFLD, on the risk of development of cirrhosis. Patients with both a high consumption of alcohol and obesity or diabetes should therefore be considered a risk group for cirrhosis. Additional studies regarding the efficacy of screening for advanced liver fibrosis or cirrhosis in such risk groups are needed. The most effective, and established, methods to reduce the risk of progression of ALD is alcohol abstinence, and weight loss in NAFLD.

Keywords NAFLD · Alcohol-related liver disease · Diabetes mellitus · Prediction · Cirrhosis · Epidemiology

Introduction

The use of alcoholic beverages might have started as early as year 10,000 BC [1]. As such, alcohol consumption is highly integrated into most modern societies. The knowledge about the harmful effects of alcohol on the liver, however, is relatively new. Until the 1950s it was thought that malnutrition, and not alcohol itself, caused end-stage liver disease [2]. As opposed to alcoholic beverages, easy access to excess food is rather new to human history and has led to overnutrition in a substantial proportion of the population [3]. This excess in combination with a more sedentary lifestyle is the basis for the obesity pandemic currently affecting most developed and developing countries globally. Even though the harmful effects of obesity were

https://doi.org/10.1007/978-3-031-32483-3_51

known to the ancient Greeks and Hippocrates [4], the association between obesity and liver disease is also relatively new [3]. In 1980, a paper by Ludwig, et al., was published showing that patients abstaining from alcohol could have a histologic picture that mimicked alcohol-related liver disease (ALD). Most of those patients were obese and had diabetes mellitus type 2 [5]. Ludwig termed the condition non-alcoholic steatohepatitis (NASH) which today is part of the broader term non-alcoholic fatty liver disease (NAFLD). Besides the histologic resemblance, ALD and NAFLD share many disease traits, such as a broad spectrum of disease severity, from mild liver damage with steatosis to cirrhosis and end-stage liver disease. Since both ALD and NAFLD, which is closely related to obesity and diabetes mellitus type 2, constitute a large proportion of patients with advanced liver disease in many countries, attention to both diseases is required. In the USA, ALD was the most common indication for liver transplantation in patients without primary liver cancer in 2019, while the second most common indication was NAFLD [6].

Not all patients who drink alcohol, nor all patients with NAFLD, develop severe liver disease such as cirrhosis or hepatocellular carcinoma (HCC) [7–9]. Patients that do develop severe liver disease have certain specific risk factors, known and unknown, putting them at a higher risk. Emerging evidence regarding risk factors of a greater severity in both ALD and NAFLD associates with metabolic as well as genetic traits (see also book Chap. 52). Alcohol use disorder, obesity, and diabetes mellitus type 2, respectively, are identified as risk factors of progression to more advanced liver-related disease. However, there is a growing concern that a combination of these risk factors might act synergistically on the risk of developing liver disease, as well as its progression. This interaction therefore requires attention from both policymakers as well as health care professionals who meet these patients in their everyday care.

Definitions of Liver Disease Related to Alcohol, Obesity, and Diabetes

Since alcohol, obesity, and diabetes mellitus type 2 are independent risk factors for liver disease [10, 11], it is important to know how obesity and diabetes might modify the risk of developing more severe forms of liver disease in people with a high consumption of alcohol. Likewise, it is important to know how consumption of alcohol might modify the risk of liver disease in people with obesity and diabetes mellitus type 2, likely to have NAFLD. Since these conditions are all highly prevalent globally, it is obvious that many patients with ALD also are obese or have diabetes mellitus type 2.

When investigating the risk of liver-related outcomes based on alcohol consumption in obese and diabetic patients, many studies have investigated patients with non-alcoholic fatty liver disease, which is closely related to these conditions. The

definition currently separating ALD and NAFLD is the amount of alcohol consumed. Internationally, a daily intake of less than 20 g alcohol in women, and less than 30 g in men is usually recommended to define presence of NAFLD and rule out ALD in the setting of hepatic steatosis [12], whereas some countries and organizations recommend an even lower threshold, or total abstinence [13]. ALD is generally considered if the patient has an alcohol consumption above the recommended limits and other causes of liver diseases have been ruled out [14]. If alcohol consumption is within the recommended limits, NAFLD should be considered [15]. This cut-off is rather arbitrary. The terms NAFLD and ALD are umbrella terms which include different stages of disease severity. Presence of inflammation in ALD is termed alcohol-related steatohepatitis, or simply steatohepatitis, where the most severe form is termed alcoholic hepatitis (AH). More details are provided in book chapters xxx and xxx. However, it remains a central problem that it is difficult to measure alcohol consumption objectively, and definitions of ALD differ between studies, which must be taken into consideration when interpreting results of the available evidence. With regard to ethanol biomarkers, the reader is referred to chap. xxx.

Epidemiology of Alcohol-Related Liver Disease

It is believed that approximately 80% of adults in the Western world have been drinking alcohol sometime in their life, and that up to 60% of adults in the western world are active drinkers [16]. According to a World Health Organization report from 2018, the average consumption among active drinkers globally is 32.8 g of pure alcohol per day, or 15.1 L of pure alcohol annually, but there are large differences between populations [16]. Furthermore, there are sex differences, where men drink larger amounts of alcohol compared to women [16]. More details can be found in part I of the book.

Approximately 90% of patients who drink more than 60 g of alcohol daily, which equals five or six units depending on the definition of a unit, are thought to develop liver steatosis, but only around 20–30% develop significant fibrosis or cirrhosis [7–9, 17]. Still, ALD is attributable to roughly half of all deaths related to cirrhosis, corresponding to 607,000 deaths per year globally [16]. Apart from the total amount of alcohol ingested, the drinking patterns also seem to affect the risk, and heavy episodic drinking has been associated with an increased risk of ALD and mortality [18]. The global prevalence of regular heavy episodic drinking is estimated to 18% in people 15 years or older, where Europeans and Americans have a higher prevalence estimated to 26% and 22%, respectively [16]. Among current drinkers the prevalence of regular heavy episodic drinking is approximately 40% [16].

Epidemiology of Liver Disease in Obesity and Diabetes Mellitus Type 2

Overweight and obesity, defined as a body mass index (BMI) ≥25, and ≥30 kg/m^2, respectively has a prevalence of 39% globally. In total numbers, this equals to around 1.9 billion overweight people, of which 650 million are obese [19]. In the United States alone, the prevalence of obesity is 35% and is expected to reach 45% in 2030 [20]. Diabetes mellitus type 2 is also a disease of global concern with a prevalence of 10% in 2014 and it is expected to increase to 13% in 2030. The prevalence of diabetes is associated to that of obesity, and follows the increase of obesity prevalence closely [20]. Both diabetes and obesity are associated with NAFLD [21, 22]. Based on previous studies, approximately 70% of persons with obesity have NAFLD with an even higher proportion in those that undergo bariatric surgery (90%), and 55–70% of patients with diabetes mellitus type 2 have NAFLD [21–23]. The duration of obesity and diabetes likely affects risk of liver disease. A population-based study of 1.2 million men showed that a high BMI during late adolescence was associated with an increased risk of severe liver disease later in life [10]. The risk increased non-linearly without evidence of a threshold effect, suggesting that increasing one's BMI already from a low level is associated with some increase in this risk, although the risk in absolute terms was low for those with a mildly increased BMI (overweight). The risk was further enhanced if patients had diabetes mellitus type 2 compared to obese people without diabetes mellitus type 2 [10]. Similar findings have been seen in young women [24].

Diabetes mellitus type 2 has also been shown to increase the risk of severe liver disease [25]. When screened for liver disease with magnetic resonance imaging, almost 64% of patients with diabetes mellitus type 2 had liver steatosis, and 6% had cirrhosis [26]. An increased severity of liver disease in patients with diabetes mellitus type 2 and NAFLD was further seen in a meta-analysis, where 37% were estimated to have NASH, and 17% had advanced fibrosis [27]. That is of prognostic significance as the stage of fibrosis is the best predictor of severe liver disease and overall mortality in patients with NAFLD [28, 29]. This illustrates the increased risk of severe liver disease in patients with diabetes mellitus type 2. A recent meta-analysis combining epidemiological findings showed an association between obesity and type 2 diabetes mellitus and an increased risk of developing severe liver-related outcomes [30]. The combined evidence suggested an increased rate of developing severe liver disease of approximately 2.25 for persons with type 2 diabetes, and a more modest increase in this rate (1.20) in those with obesity [30].

Pathophysiology of Alcohol-Related Liver Disease

The metabolism of alcohol begins in the stomach, where alcohol is oxidated by gastric alcohol dehydrogenase [31]. More details are provided in chapters xxx. Alcohol which is not metabolized by the stomach enters the portal vein through

the lower intestinal tract. It finally reaches the liver where the majority is metabolized by hepatic alcohol dehydrogenase (ADH) and microsomal CYP2E1 [32, 33]. Hepatic ADH normally accounts for most of the ethanol metabolization, but oxidation within the CYP2E1 system can be increased in the setting of a high consumption of alcohol [33, 34]. However, this upregulation also increases the production of reactive oxygen species and DNA damage [35]. Furthermore, the intermediate product in alcohol metabolism, acetaldehyde, is highly reactive, a carcinogen and contributes to the development of ALD [36, 37].

The metabolism of alcohol also affects hepatic lipid metabolism [38]. An increased uptake of fatty acids and increased lipogenesis combined with a decreased fatty acid oxidation and decreased export of very low-density lipoprotein (VLDL) result in an accumulation of lipid droplets in hepatocytes [38]. This condition is then defined as alcohol-related fatty liver, or steatosis related to alcohol. This diagnosis has traditionally been made by liver histology, although currently biopsies are seldomly acquired in ALD. Fat accumulation in hepatocytes is a hallmark of the histologic picture of ALD, and is seen in the histology of most patients with ALD. For more details, see also the book chap. xxx on histology of ALD. ALD typically shows fat infiltration in hepatocytes in mild cases of disease, which can be either macro- or microvesicular [39, 40]. Steatohepatitis is a more severe form of the disease with inflammation and fibrosis. The histology in steatohepatitis displays, in addition to steatosis, lobular inflammation, focal necrosis with inflammatory infiltrates, hepatocyte ballooning, Mallory-Denk bodies, and different stages of fibrosis including cirrhosis [39–41]. Steatosis can be less pronounced in severe steatohepatitis or constitute of less than 5% of the parenchyma, and is therefore not a formal diagnostic criterion in alcohol-related liver disease [42].

Alcoholic Hepatitis

One of the most severe forms of alcohol-related liver disease is termed alcoholic hepatitis (AH) and more details are provided in chapters xxx and xxx. Briefly, AH usually evolves after a period of extended binge-drinking [14]. Cirrhosis is also frequently seen in patients with AH [14]. AH is primarily a clinical diagnosis and patients often present with jaundice combined with fever, weight loss, fatigue, malaise and malnutrition. Signs of decompensation such as ascites and hepatic encephalopathy can also occur. AH can resemble acute-on-chronic liver failure (ACLF) and bacterial infections, why other etiologies must be investigated before a final diagnosis can be made. A liver biopsy is seldom performed and a transjugular approach is recommended to avoid the risk of bleeding. Biopsy should be reserved for cases where the diagnosis is uncertain [14]. Patients with AH typically have a bad prognosis and 6 months mortality can be high as 30–40% [43].

Pathophysiology of Liver Disease in Patients with Obesity and Diabetes

In general, the histologic picture in ALD is not specific, and patients with NAFLD have a similar histologic presentation. Therefore, based on histology, ALD cannot be separated from NAFLD without additional information from laboratory reports or patient anamnesis [42]. There are some specific changes that have mostly been described in alcohol-related liver disease, such as sclerosing hyaline necrosis, alcoholic foamy degeneration among others [42]. However, these are nonspecific and not present in all patients. In patients with obesity and diabetes mellitus type 2 with a non-specific histologic picture of fatty liver disease, and where no secondary causes of liver disease are present, NAFLD is thought to be the cause of the histopathologic picture. The pathogenesis of NAFLD is complicated and beyond the scope of this chapter but is in principle caused by changes in metabolic pathways due to overnutrition. The major causes include increased substrate load directly from the diet, lipolysis of triglycerides in adipose tissue related to insulin resistance, and an increased flow of fatty acids to the liver, as well as increased de novo lipogenesis in hepatocytes [44, 45].

Non-alcoholic Steatohepatitis

Additional contributions to the progression of liver disease and liver inflammation include the formation of lipotoxic lipids, gut-derived lipopolysaccharides, reactive oxygen species, inflammasome activation, and injured hepatocytes which activate liver macrophages [46, 47]. Alone and in combination, this can form an inflammatory environment that trigger stellate cells in the liver to turn into myofibroblasts, these then produce extracellular matrix proteins and ultimately fibrosis [48]. Continuous progression of fibrosis can lead to cirrhosis, the common end-stage of all chronic liver diseases. Furthermore, the activity of the CYP2E1 enzyme has also been found to be induced by diabetes mellitus type 2 and obesity and could therefore contribute to changed alcohol metabolism, with increased oxidative stress and cell damage, in patients with these conditions [49]. An experimental study comparing microbiota in healthy children; obese children without sign of liver disease; or children with NASH found an abundance of ethanol-producing bacteria in the children with NASH, and also higher levels of endogen ethanol in blood [50]. These results have later been confirmed in another study [51]. Thus, low doses of endogenously produced ethanol could be a contributing factor for the progression of NAFLD to NASH and eventually fibrosis, although ethanol levels are significantly lower as those seen in ALD patients.

Genetics Modifiers of ALD and NAFLD

Genetic risk modifiers are present in both ALD and NAFLD, and are to some extent shared between the diseases, suggesting some degree of hereditability of these diseases. More details are provided in book chap. xxx. A study of more than 15,000 male twins showed that presence of alcohol-related cirrhosis was three times more common in monozygotic twins compared to dizygotic twins [52]. This indicates a correlation of genetic risk factors and progression of fibrosis in patients with ALD. Genome-wide association studies have identified mutations that have a strong correlation with ALD and cirrhosis in the genes PNPLA3, TM6SF2, and MBOAT7 [53–55]. The single-nucleotide polymorphism in the PNPLA3 gene, as well as the TM6SF2, have also been associated with NAFLD [56, 57]. Both PNPLA3 and TM6SF2 affect the hepatic lipid metabolism by retaining lipids in the liver through different pathways [58, 59]. A longitudinal study of a large cohort showed an association of mutations in PNPLA3 and an increased risk of liver cancer, hospital admission due to severe liver disease, and death [60]. Additional mutations in genes such as HSD17B13, MBOAT7, MARC1, GCKR and others have also been described [61, 62]. A deeper understanding of the pathophysiology and genetic predispositions are important and promising predictors of future liver-related events. However, currently no genetic data is routinely used in clinical practice.

Amount of Alcohol as a Risk Factor in ALD

ALD is caused by an excess intake of alcohol, and there is a direct association between the amount of alcohol consumed and the risk of developing ALD [63]. Data from meta-analyses suggest the risk of developing cirrhosis is present already in persons consuming more than 25 g of pure alcohol per day, although other studies found an increased risk even in persons consuming between 12 and 24 g of alcohol daily [64, 65]. Women are at an even greater risk of developing ALD, and even one drink a day is associated with an increased risk of developing cirrhosis [66, 67]. This could partly be explained by the higher proportion of body fat in women which leads to higher serum concentrations of ethanol, and by sex differences in gastric alcohol dehydrogenase [31]. A Danish study suggested that the largest risk of cirrhosis development was seen in patients drinking daily, and that this risk was higher in patients with a recent episode of drinking [68].

The presence of alcohol-related fatty liver itself is also a known risk factor of progression to fibrosis and cirrhosis, especially in patients that continue to consume alcohol [9]. The 5-year risk of alcohol-related cirrhosis is estimated to be 7% in patients with pure alcohol-related steatosis, while the 5-year risk of cirrhosis is around 16% in patients with steatohepatitis due to alcohol [69]. All together, these data suggest differences in risk of progression of ALD among people drinking alcohol that is not solely based on the amount of alcohol consumed.

The controlled attenuation parameter (CAP) is a surrogate for liver steatosis that is defined using an ultrasound-based method measuring the attenuation of ultrasound waves [70]. In patients consuming 5–7 drinks per week there was a significant association between the number of units of alcohol per week with steatosis, as defined by an increased CAP. This finding remained after adjusting for quantity and binge-drinking [71]. However, repeated measurements of CAP to investigate changes in liver steatosis might not be as accurate as methods based on magnetic resonance imaging, and its clinical use to monitor steatosis change over time is uncertain, especially in patients reporting periodical drinking, since abstinence of alcohol reduces the level of steatosis in the liver [39, 40, 72]. In a randomized controlled trial performed in healthy students consuming moderate amounts of red wine during 3 months, defined as 33 g daily in men and 16 g daily in women, no steatosis was induced as measured by magnetic resonance spectroscopy [73]. Altogether, this indicates that either a longer duration of consumption or higher dose of alcohol is needed to develop liver steatosis.

Amount of Alcohol as a Risk Factor in NAFLD

The evidence regarding the risk of developing liver disease, or worsening of known liver disease, in people consuming low to moderate amounts of alcohol is inconsistent. A study performed in patients with NAFLD found that moderate consumption of alcohol, defined as less than two drinks daily, was associated with less reduction of steatosis and less resolution of NASH in paired liver biopsies compared to patients who were abstinent from alcohol [74]. In patients with metabolic risk factors correlated to NAFLD, alcohol was a significant independent predictor of liver-related outcomes along with smoking, age, waist circumference, and insulin resistance [75]. A Mendelian randomization study used a mutation in the alcohol dehydrogenase gene as a proxy for long-term alcohol consumption in patients with NAFLD. Patients with the mutation reported less consumption of alcohol and did not have higher stages of fibrosis or a higher prevalence of steatohepatitis on biopsy compared to patients without this mutation [76]. Binge-drinking has been shown to be a risk factor of progression to advanced liver disease. Patients with biopsy proven NAFLD showed an association between heavy episodic drinking and fibrosis progression [77], which was also the result in a population based study where increased risk of decompensated liver disease was seen in patients with weekly and monthly binge drinking [78]. Further, binge-drinking and other behaviors associated with alcohol overconsumption has been showed to associate with increased risk for cirrhosis in healthy young adults later in life [79].

Other studies primary using a cross-sectional design have suggested a protective effect of low to moderate consumption in patients with NAFLD, compared to drinking no alcohol. Patients undergoing bariatric surgery had a reduced risk of non-alcoholic fatty liver disease if they reported a moderate alcohol consumption compared to patients with other drinking habits undergoing surgery [80]. It was

speculated that this was because of reduced insulin resistance. A meta-analysis included studies where patients with total abstinence from alcohol versus low to moderate alcohol consumption, defined as less than 40 g per day, were compared. It showed a protective effect of 31% from getting NAFLD, and a 50% protection from developing NASH in patients consuming low to moderate levels of alcohol [81]. In patients with NAFLD and concomitant diabetes, low to moderate alcohol consumption have been associated with improved insulin resistance and a lower risk of diabetes mellitus type 2 [82, 83]. Also, low to moderate alcohol was not associated with development fibrosis [84].

Several other cross-sectional studies have shown similar results with a reduced risk of advanced liver disease in patients with fatty liver drinking low to moderate amounts of alcohol [84–91]. However, there is a risk of bias in these studies due to methodological issues. Patients with known manifest advanced liver disease have, for example, been included and there is a risk of misclassification bias in patients that report current total abstinence, since many of them could previously have been drinking larger amounts alcohol, so called "sick quitters" [92]. Interestingly, one of the studies also measured phosphatidyl ethanol which is a validated marker for recent alcohol consumption [93–95]. Patients that had reported low to moderate alcohol consumption had an elevated phosphatidyl ethanol >0.3 μmol/L in 11% of the cases, which indicate a larger consumption than reported [90]. This is suggestive of either recall bias or dishonesty in the reported alcohol consumption. Furthermore, in 8300 patients with known liver steatosis, the risk of developing advanced liver disease, defined as liver-related hospital admission, liver cancer or liver-related death, based on low to moderate alcohol consumption was evaluated. The study excluded patients with manifest liver disease at baseline and current abstainers. They found a dose-dependent increase in the risk of incident advanced liver disease in persons consuming more than 10 g of alcohol per day [96].

Interaction Between Alcohol and Diabetes

Table 51.1 lists some important studies to analyze the modulating role of diabetes on ALD. A high chronic consumption of alcohol is associated with increased insulin resistance and the development of diabetes mellitus type 2 [83]. People with an alcohol use disorder have a higher risk of diabetes mellitus type 2 compared to people in the general population [99]. This is most likely due to the progression of insulin resistance seen in patients with ALD, where the insulin resistance is more severe in more advanced stages of fibrosis [61]. Progression to cirrhosis is more common in patients with diabetes and high BMI, compared to people without these diseases who drink the same high amount of alcohol [97].

Even without a known alcohol consumption, patients with diabetes and a severe insulin resistance progress to fibrosis at a higher rate than diabetic patients with other metabolic profiles [100], and an increased blood glucose level is associated with increased fibrosis [101]. Therefore, it is not surprising that a combination of

alcohol and diabetes should have a synergistic effect on the risk of liver disease. This synergistic effect was seen in a population-based study of 6700 persons with a follow-up time of 12 years. Persons with diabetes and a high alcohol consumption had a 20-fold increased rate of progression to liver cancer, hospital admission due to liver disease, or liver-related mortality compared to persons with little or no alcohol consumption and no diabetes. In contrast, there was a 3.5-fold increase in patients with high alcohol consumption alone, and a 2.5-fold increase in patients with diabetes alone [75]. Another study showed a similar synergistic effect where patients with liver steatosis and the metabolic syndrome, who drank excessive amounts of alcohol, had an increased mortality risk compared to people that did not drink excessive amounts of alcohol or did not have the metabolic syndrome [102]. The metabolic syndrome is closely related to insulin resistance, and diabetes was the only component in the metabolic syndrome that was significantly associated with increased mortality in this cohort [102].

Furthermore, patients with diabetes mellitus type 2 who carry mutations in the PNPLA3 gene have a more severe insulin resistance compared to patients with diabetes type 2 that do not carry this genotype [103]. In patients with ALD, presence of increased insulin resistance and mutations in PNPLA3 are associated with more advanced stages of fibrosis, and together with active alcohol consumption they are independent risk factors of inflammatory activity in the liver [61], which is a main driver in the fibrogenesis. Altogether, with the metabolic changes in ALD and diabetes, and the combined effect of alcohol and insulin resistance, screening for insulin resistance and diabetes in patients with manifest ALD might be valuable in clinical practice. Even genetic screening might be a future tool, used in combination with metabolic risk factors, to identify patients with ALD with increased risk of future cirrhosis.

Interaction Between Alcohol and Obesity

Table 51.1 also lists important studies to analyze the modulating role of obesity on ALD. Before the modulation of ALD by obesity is discussed in further detail the effect of alcohol on obesity should be taken into consideration, not the least because of the potential synergistic risk of liver disease between alcohol and obesity. Pure ethanol contains 7 kcal/g and heavy drinking is associated with weight gain [104]. The opposite effect with weight loss is usually seen in patients with severe alcohol use disorder and in cirrhotic patients with sarcopenia [105]. Consumption of 500 mL of beer daily has a weak association with weight gain, whereas a low consumption of wine has been associated with a possible protective effect on weight gain [106, 107]. As above, careful interpretation of such cross-sectional studies must be made, since residual confounding such as a better diet and more exercise might be present in those consuming wine. As mentioned above, obesity is defined by a BMI of 30 kg/m^2 or more, but adipose tissue differently distributed in the body, and a high waist-hip ratio are better predictors of liver disease than a high BMI, suggesting that

Table 51.1 Important studies to study the modulation of alcohol-related liver disease by obesity and diabetes

Reference	Setting and design	N patients	Key exposure	Key outcome	Key finding
Hagström [10]	Sweden, cohort study	1.2 M men	Body mass index	Liver-related outcomes from national registers	Higher BMI early in life associates with higher risk of cirrhosis. Further increase if presence of diabetes.
Jarvis et al. [30]	Multiple countries, meta-analysis	22.8 M	Body composition including BMI, diabetes	Liver-related outcomes	Meta-analysis finding an association between obesity (HR = 1.2) and diabetes type 2 (HR = 2.3) with future cirrhosis
Sahlman et al. [60]	Finland, cohort study	41,260	Patterns of alcohol consumption and metabolic, lifestyle-related, and anthropometric parameters	Liver-related outcomes from national registers	Strong synergism between alcohol and central obesity on the risk of liver-related outcomes
Israelsen et al. [61]	Denmark, cross-sectional	325 patients with alcohol-related liver disease	Metabolic and genetic parameters	Hepatic fibrosis defined by liver biopsy	Insulin resistance strongest risk factor for hepatic fibrosis in patients with ALD
Ajmera et al. [74]	US, cohort study	285 patients with biopsy-proven NAFLD with at least 2 biopsies	Questionnaire-defined alcohol consumption	Biopsy-defined improvement of hepatic steatosis and NASH	Modest alcohol use was associated with less improvement in steatosis as well as lower odds of NASH resolution, compared with no use of alcohol.
Åberg et al. [75]	Finland, cohort study	6732	Alcohol use and metabolic risk factors	Liver-related outcomes from national registers	Interaction between alcohol use and type 2 diabetes, higher risk for liver-related outcomes

(continued)

Table 51.1 (continued)

Reference	Setting and design	N patients	Key exposure	Key outcome	Key finding
Whitfield et al. [97]	UK, case-control study	1293 cases with ALD-cirrhosis and 754 controls with similar alcohol consumption but no cirrhosis	Alcohol use, life-style and metabolic risk factors	Cirrhosis defined as by clinical records	Patients with cirrhosis more commonly had type 2 diabetes and higher BMI
Liu et al. [98]	UK, cohort study	1.2 M women	BMI and questionnaire-defined alcohol consumption	Hospital admissions for cirrhosis	Alcohol and higher BMI interactively increases risk for cirrhosis. 17% of cirrhosis cases attributable to obesity, 42% to alcohol.

it is more important to consider abdominal obesity than only BMI [108]. This was recently also suggested in a paper where waist-hip ratio was also superior to blood-based scores such as FIB-4 and NAFLD fibrosis score in predicting the presence of hepatic fibrosis in a low-prevalence population [109]. Recent longitudinal studies in a Finnish cohort showed a synergistic interaction between high waist circumference or high waist-hip ratio and an alcohol consumption over 210 g per week in men and over 140 g per week with an increased risk of liver-related outcomes [60, 75]. Weekly binge drinking in patients with the metabolic syndrome has also showed a synergistic effect on the risk of developing advanced liver disease with complications such as ascites, esophageal variceal bleeding and hepatic encephalopathy [78]. Similar findings were seen in almost 10,000 British men during 29 years of follow-up. An increased risk of death from liver disease was found if drinking >15 drinks per week across all BMI categories, but the risk in obese men was even greater [110]. Abdominal obesity is further correlated with insulin resistance, which is an important driver of liver disease by increasing lipolysis from adipose tissue and shunting free fatty acids to the liver [111]. This could in part explain why estimations of pathologic fat distribution show a stronger association than BMI with development of liver disease.

In patients with biopsy-proven steatosis due to ALD, independent risk factors of alcoholic hepatitis and cirrhosis were being overweight during more than 10 years, female sex, and the duration of a risky consumption of alcohol [112]. There were similar findings in women consuming more than 150 g of alcohol per week, and the risk of developing cirrhosis was higher if they were obese compared to non-obese women [98].

Animal models have shown different potential pathways as a cause for the synergistic effects of alcohol and obesity on the development of steatohepatitis.

Moderate use of alcohol and obesity together cause an activation in macrophages which accentuates mitochondrial stress, and binge-drinking and obesity together induce the chemokine CXCL1, leading to infiltration of hepatic neutrophils which synergistically increase the risk of steatohepatitis [113, 114].

Risk of Hepatocellular Carcinoma in Patients with Alcohol-Related Liver Disease by Obesity and Diabetes

The risk of hepatocellular carcinoma is increased in patients with alcohol-related cirrhosis. It is estimated that 30% of the mortality in hepatocellular carcinoma is due to alcohol-related liver disease [115]. Diabetes mellitus type 2 and obesity are also independent risk factors of hepatocellular carcinoma [116, 117]. In patients with both alcohol and obesity as risk factors there seems to be a synergistic effect regarding the risk of hepatocellular carcinoma [118, 119]. The effect is also present in patients with diabetes and a high alcohol consumption [75, 120, 121].

Screening and Treatment of Risk Factors

Screening of at-risk individuals have gained more attention in recent years. The European Association for the Study of Liver (EASL) recommend screening for fibrosis with non-invasive methods in patients with potentially harmful alcohol consumption or metabolic risk factors such as diabetes and obesity, but not in an unselected general population [122]. A study investigating screening of liver disease using transient elastography in patients with heavy alcohol consumption or diabetes mellitus type 2 included 900 patients. A total of 230 (26%) patients had signs suggestive of fibrosis, and 27 (3%) had cirrhosis. The study also found that cirrhosis was significantly more common in obese patients with diabetes or heavy alcohol consumption compared to non-obese patients [123].

Alcohol might also indirectly affect the course of diabetes mellitus type 2 by an increased risk of non-adherence to the self-care recommendations and less compliance to anti-diabetic medications [124, 125]. Patients with type 2 diabetes drinking heavy or moderate amounts of alcohol were shown to report less self-glucose monitoring and were more likely to skip diabetes provider visits compared to non-drinkers [126]. At-risk alcohol consumption in patients with diabetes is often inadequately addressed but should be evaluated thoroughly in routine diabetes care [127].

The most effective, and established, methods to reduce the risk of progression of ALD is alcohol abstinence, and weight loss in NAFLD [14, 128, 129]. Treatment guidelines regarding contributing risk factors in ALD and NAFLD would be beneficial, but there is currently no consensus on this topic. The Asian Pacific Association

for the Study of Liver (APASL) as well as the European Society for Clinical Nutrition and Metabolism (ESPEN) recommend patients with diabetes mellitus type 2 and obesity and present liver disease to completely avoid alcohol [130, 131].

Summary

Current evidence suggests an interactive effect between a high consumption of alcohol, or ALD, and metabolic risk factors, associated with NAFLD, on the risk of development of cirrhosis. Patients with both a high consumption of alcohol and obesity or diabetes should therefore be considered a risk group for cirrhosis. Additional studies regarding the efficacy of screening in such risk groups are needed and eagerly awaited. The most effective, and established, methods to reduce the risk of progression of ALD is alcohol abstinence, and weight loss in NAFLD.

Chapter 52
The Genetics of Alcohol-Related Liver Disease

Hamish Innes and Felix Stickel

Abstract Significant advances into the genetics of alcohol-related liver disease (ALD) have been made in the last two decades. Most notably, this includes the discovery of ten common genetic variants associated either with alcohol-related cirrhosis and/or hepatocellular carcinoma. These novel associations provide insight into the pathophysiology of ALD and have led directly to potentially new therapeutic targets, which are the subject of ongoing research. In addition, several genetic risk scores are now available to identify patients at high/low risk of developing cirrhosis, albeit their performance may not yet be adequate to enable risk stratification in the clinic. Prospectively, the increasing accessibility of population-level biobank data together with the emergence of whole genome sequencing data will likely lead to further discoveries in the years ahead. In this chapter, we will review the key genetic association studies performed so far in relation to ALD, discuss the potential clinical applications, and identify areas worthy of future research.

Heritability of Alcohol-Related Liver Disease

Alcohol-related liver disease (ALD) refers to a spectrum of partly overlapping liver tissue alterations with escalating severity attributable to excess alcohol use over time. Clinically, ALD ranges from simple steatosis in nearly all heavy drinkers through to life-threatening conditions such as cirrhosis and hepatocellular carcinoma (HCC) in only a minority of approximately 10–15% [1]. Global mortality from ALD is substantial, with ~350,000 people dying every year from alcohol-related cirrhosis alone [2]. In addition, alcohol consumption leading to ALD or as a cofactor in other non-alcohol-related liver diseases is a major driver of HCC, which causes ~800,000 deaths per year [3].

The quintessential risk factor for ALD is the total volume of alcohol consumed (i.e. greater total volume is associated with a higher ALD risk). However, other risk factors contribute too, including age, sex, diabetes, BMI, coffee intake, features of the metabolic syndrome and potentially drinking patterns and beverage types consumed [4–6]. As most of these factors are influenced by both genetic and environmental factors, it follows that ALD itself is a product of interaction between both genes and the environment (i.e. nature and nurture). Unfortunately, the relative importance of genes versus environment has not been widely quantified. The only significant study to investigate this issue was published >25 years ago by Reed et al. [7]. This analysis included data from 31,848 twins (i.e. 15,924 male twin-pairs), all within the US army veterans' health program. The authors quantified the heritability of three phenotypes: alcoholism, alcohol psychosis and cirrhosis. The overall prevalence of cirrhosis in the sample was 2.2%. The concordance of cirrhosis between twin-pairs was three times higher for monozygotic twins (16.9%) versus dizygotic twins (5.3%). Overall, Reed et al. found that 47% of the variability in cirrhosis status was due to genetic effects, with the remaining 53% attributable to the environment. Nevertheless, Reed et al. suggested that most of this genetic contribution reflected the genetic liability for alcoholism, rather than genetic liability for cirrhosis specifically [7].

Unfortunately, no comparable study has been performed since this landmark publication. Replication studies are fundamentally hampered by the low prevalence of cirrhosis among twins. Indeed, in the twins UK registry, there are only 16 individuals with a cirrhosis diagnosis, and none with HCC [personal communication: Victoria Vazquez; first March 2022]. Thus, meta-analysis of twin studies/registries will be useful to better understand the heritability of specific ALD phenotypes. Although meta-analysis has been performed in relation to alcohol use disorders [8], it has not yet been applied to the heritability of specific ALD phenotypes such as cirrhosis.

Genetic Association Studies: Overview

Although twin studies can establish whether a given phenotype is heritable, they do not indicate which specific genetic factors underpin this heritability [9]. This is the role of genetic association studies. In general, genetic association studies fall into two main categories. First, genome-wide-association studies (GWAS), which typically test up to millions of polymorphisms for association with a single phenotype. The hallmark of a GWAS is that it incorporates polymorphisms throughout the genome. In this way, GWAS is biologically agnostic insofar as it makes no prior assumption about which genetic regions influence disease [10]. However, this hypothesis-free perspective comes at a price. Namely, to guard against false-positive associations, one must use a very low p-value threshold to define statistical significance (typically $P < 5 \times 10^{-8}$). As a result, GWAS inherently favours the discovery of variants that: (a) exhibit very strong associations with the phenotype; or (b) are highly frequent in the population; or (c) exhibit a combination of the two. Rare variants that might very well influence the evolution of disease are less likely to be recognised and can be missed.

On the other hand, candidate gene association studies (CGAS) assess the association between single or a small number of specific variants with a given phenotype [11]. Candidate variants are typically selected on the basis of biological knowledge and/or the results from previous GWAS. A crucial point is that because fewer variants are considered, the p-value threshold used to define statistical significance is much higher, thus, statistical power is greatly increased.

In liver disease, CGAS studies are performed to assess if a variant-phenotype association identified in patients with a particular aetiology (e.g. NAFLD) is generalisable to patients with other aetiologies (e.g. ALD). One example is the discovery of rs429358 in *APOE* as a risk factor for alcohol-related HCC [12]. Also, the importance of rare variants (i.e. loci with a minor allele frequency < 1%) in liver disease is being increasingly recognised [13]. CGAS is the standard approach for investigating rare variant-phenotype associations, as rare variants are typically omitted from GWAS. Thus, new insight into ALD genetics will depend on the interplay between GWAS and CGAS approaches since both can be valuable if applied appropriately.

GWAS for Alcohol Liver Disease

Study Design Overview

Five robust GWAS studies have been performed for ALD phenotypes: three for cirrhosis [14–16] and two for hepatocellular carcinoma [17, 18]. All studies have used a case-control design with separate discovery and validation stages (Table 52.1). Effective sample sizes of the five GWAS have been substantial, ranging from 2942 to 10,209 patients. Crucially, study participants have been recruited from specialist

Buch, Innes et al.	Gut	2022	Europe	HCC	1214	1866	2942	*Case-control*: alcohol-related HCC Vs alcohol-related liver cirrhosis w/o HCC	Principal components	Non-European ancestry	*TERT*

liver centres across Europe, with case definitions based on strict clinical criteria. Moreover, controls have been selected from the same source population in which the study cases have arisen. These stringent selection attributes help to reduce bias. Another salient point is that in the three GWAS for alcohol cirrhosis [14–16], controls were defined not just by the absence of cirrhosis, but by the absence of any significant non-alcohol-related liver disease, such as chronic viral hepatitis and haemochromatosis. This represents an "extreme phenotyping" strategy designed to increase statistical power [19], and thus, maximise the number of statistically significant variant-phenotype associations identified for a given sample size.

The selection of controls requires careful consideration for a GWAS on HCC. This is because cirrhosis, being the strongest risk factor for development of alcohol-related HCC, is a major confounding factor. Thus, it is crucial that cases and controls are balanced with respect to cirrhosis status to ensure variants identified are directly implicated in hepatocarcinogenesis (as opposed to only modifying cirrhosis risk). In a recent HCC GWAS by Buch et al. [18], cases were tightly defined as cirrhosis with HCC, whilst controls were defined as patients with cirrhosis but without HCC. Thereby cirrhosis has effectively been "adjusted for" at the design stage of the analysis. On the other hand, in a GWAS by Trepo and coworkers, cases and controls with different fibrosis stages below the threshold of cirrhosis were included, and in their main analysis, fibrosis stage was not controlled for [17]. Such difference in case-control matching details can lead to different association results between studies unless a number of relevant sensitivity analyses are performed: (1) adjusting for fibrosis stage (F3-F4 vs F0-F2); (2) restricting the analysis to F3-F4 patients; and (3) comparing the association between novel variants with alcohol cirrhosis with data from publically accessible data repositories [14]. These sensitivity analyses are designed to act as a fail-safe to ensure novel associations with HCC were independent of cirrhosis status.

A significant limitation of all previous GWAS for ALD is that they have focused only on persons of Caucasian ancestry. As a result, their generalisability to other ethnic groups is unclear. On this point, an "ALD" GWAS in a Korean population was recently published by Kim et al. [20]. Unfortunately, in this study, ALD was defined by elevated serum liver enzyme tests as a surrogate of alcohol-mediated liver injury alone, which obviously is not a reliable approach. Indeed, a recent study by Innes et al. indicates that the majority of variants associated with liver blood tests are not actually associated with an objective measure of clinical disease [15]. Thus, studies like the one from Korea study should be considered hypothesis-generating at best, and a solid Asian GWAS on ALD is so far lacking.

Novel Identified Variants: Overview and Functional Impact

Previous GWAS have identified ten loci in total, all independently associated with alcohol-related cirrhosis and/or HCC (Table 52.2; Fig. 52.1). Striking are that many variant genes are integrally involved in lipid metabolism and trafficking, and therefore not surprisingly also associate with the progression of non-alcoholic fatty liver

Table 52.2 Detailed overview of the ten polymorphisms identified in previous genome-wide association studies for alcohol liver disease

Variant information						Phenotype association		Functional impact				
rsid	Nearest gene	Chr: position	Ref allele	Minor allele	MAF	Phenotype(s)	Direction of association	Annotation	Amino acid substitution	Impact on protein function	Evidence of regulatory function	Gene ontology enrichment analysis
rs738409	*PNPLA3*	22:43928847	C	G	0.26	HCC + cirrhosis	G allele ↑ risk	Exonic	I148M	Deleterious	None	
rs58542926	*TM6SF2*	19:19268740	C	T	0.07	HCC + cirrhosis	T allele ↑ risk	Exonic	E167K	Deleterious	None	
rs72613567	*HSD17B13*	4:87310241	A	AA	0.18	HCC + cirrhosis	AA allele ↓ risk	intronic	NA	NA	variant is a splicing QTL for HSD17B13 in liver	
rs2642438	*MARC1.*	1:220796686	G	A	0.19	cirrhosis	A allele ↓ risk	Exonic	A165T	Deleterious	None	
rs28929474	*SERPINA1*	14:94378610	C	T	0.02	cirrhosis	T allele ↑ risk	Exonic	E366K	Deleterious	None	
rs15052	*HNRNPUL1*	19:41307470	T	C	0.07	cirrhosis	T allele ↑ risk	3'UTR	NA	NA	Variant lies in enhancer region (GeneHancer ID: GH19J041294). "C" allele is associated with increased expression of TGFB1 in liver.	
rs2242652	*TERT*	5:1279913	G	A	0.17	HCC	A allele ↓ risk	intronic	NA	NA	None	
rs708113	*WNT3A*	1:228005052	A	T	0.40	HCC	T allele ↓ risk	intronic	NA	NA	Variant lies in cis regulatory element (ID: EH38E1428717)	
rs374702773	*FAF2*	5:176467130	(T)24	del(T)7	0.42	cirrhosis	NK	intronic indel	NA	NA	None	
rs641838	*TMC4*	19:54173068	C	T	0.43	cirrhosis	T allele ↑ risk	Exonic	G17E	Benign	Variant lies in enhancer region (GeneHancer ID: GH19J054172). "T" allele associated with ↓MBOAT7 and ↓TMC4 expression in liver.

No significant enrichment

Molecular functions:
No significant enrichment

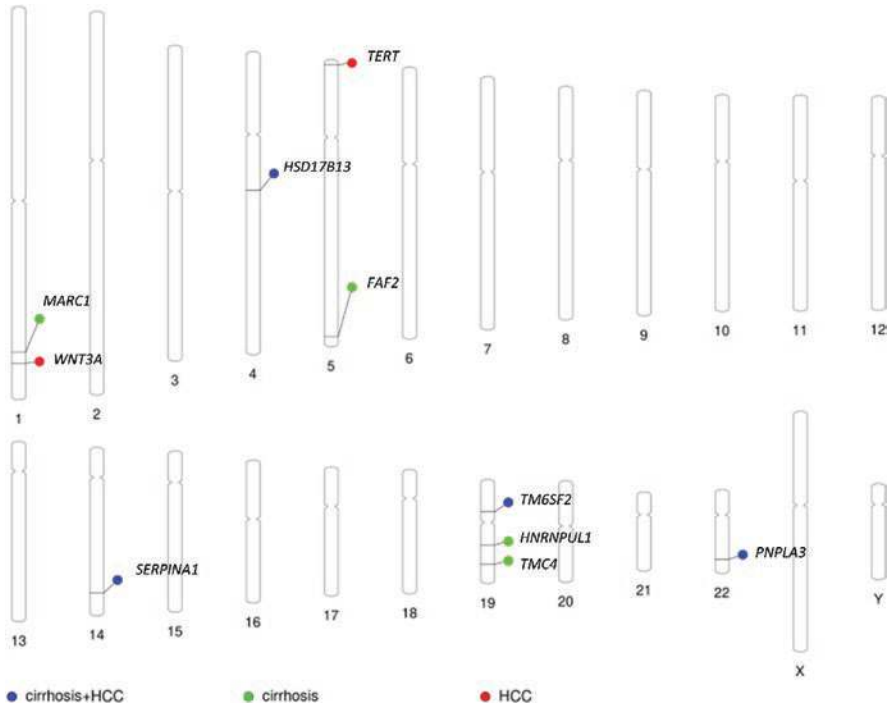

Fig. 52.1 Phenogram representation of loci associated with alcohol-related liver disease phenotypes. Numbers refer to chromosomes, X and Y to sex chromosomes

disease in the context of the metabolic syndrome. The allele frequencies for these variants are highly diverse, ranging from 2% (rs28928474:T in *SERPINA1*) through to 43% (rs641738:T in *TMC*). Importantly, loci that enhance the risk of ALD and cirrhosis in particular have been identified, as well loci that reduce the risk developing ALD, and are therefore considered protective (Fig. 52.2).

Half (5/10) of the identified loci represent missense variants lying in exonic regions, leading directly to an amino acid change in the corresponding protein. *In silico* bioinformatics tools can evaluate the impact of these amino-acid changes on the functioning of the protein product. One such tool – Polyphen2 [21] - predicts that 4/5 of these missense mutations have a deleterious impact on protein function. An exception to this is the rs641738 missense variant in *TMC*, which is predicted to be benign. However, as well as being an exonic variant in *TMC*, rs641738 also regulates the expression of proximal genes. In particular, data from the gene-tissue expression (GTEx) resource shows that rs641738 is associated with expression of *MBOAT7* in liver tissue [22]. Thus, *MBOAT7* is considered to be the causal gene underlying the association between rs641738 and cirrhosis, rather than *TMC*. Another interesting observation is that the rs224652:A missense allele in *MARC1* – despite being predicted to have a deleterious impact on MARC1 function – is in fact associated with a reduced risk of alcohol cirrhosis [15]. This suggests that inhibiting MARC1 may be a promising therapeutic strategy if the protein can be targeted.

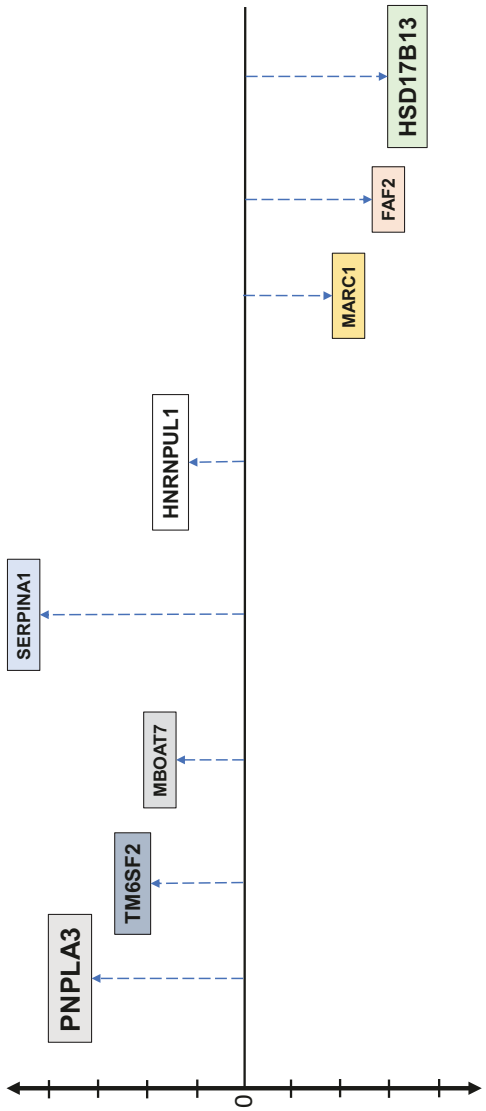

Fig. 52.2 Risk loci and their effect on ALD risk

The remaining 5/10 loci are located in non-coding regions of the genome. Although this means they do not modify protein composition, there is evidence that many exert regulatory functions, such as modifying the expression of proximal genes or splicing. For example, rs72613567 is in fact a splicing variant influencing the balance/abundance of HSD17B13 isoforms in liver tissue (Table 52.2). The rs15052 loci in *HNRNPUL1* lies in an enhancer region of the genome, and is directly associated with the expression of the transforming growth factor beta 1 protein in the liver, a potent profibrogenic cytokine produced by liver mesenchymal cells to stimulate collagen production [23]. Rs708113 also lies in an enhancer, and is associated with expression of mitochondrial genes (*IBA57* and *MRPL55*), albeit these associations are not evident in liver tissue. The rs2642438 variant in *TERT* is strongly associated with telomere length, a frequently altered pathway leading to hepatocarcinogenesis [24, 25]. On the other hand, no obvious regulatory function is apparent for rs374702773 in *FAF2*.

Table 52.3 gives an overview of identified risk loci and their known or putative functional implications.

Table 52.3 Risk loci for ALD and their known or suggested functional implications

Gene	Enzymatic function	Subcellular localisation	Cellular localization	Effect of the mutation
PNPLA3	Triglyceride hydrolase	Lipid droplets	Hepatocytes, mesenchymal cells	Missense mutation: Loss of function
TM6SF2	Unknown	Endoplasmic reticulum and ER-Golgi compartment	Hepatocytes	Retention of VLDL in hepatocytes
MBOAT7	Lysophosphatidyl-inositol acyl-transferase; phospholipid remodeling	Hepatocyte membranes	Hepatocytes	Lower expression
HSD17B13	Hepatic retinol dehydrogenase; activation of the retinoic acid receptor?	Hepatic lipid droplet	Hepatocytes	Insertion mutation: Loss of function
SERPINA1	Protease inhibition	Hepatocyte cytosol	Hepatocytes	Lack of protease inhibition: Loss of function
HNRNPUL1	Regulation of DNA transcription by dual DNA and mRNA binding	Endosplasmatic reticulum	Hepatocytes	Increase of TGFb1 expression
MARC1	Reduction of N-hydroxyl compounds; neutralization of acetaldehyde?	Outer mitocondrial membrane	Hepatocytes, adipose tissue	Gain of function
FAF2	Resistance to apoptosis	Cell membranes	T cells, eosinophils	Gain of function

Notable Findings from Candidate Association Studies

CGAS have succeeded in identifying novel variant-phenotype associations that have been overlooked by genome-wide analyses. In particular, a recent CGAS for ALD demonstrated an association between a missense variant in *APOE* (rs429358) and alcohol-related HCC [12]. Specifically, the rs429358:C allele (versus T allele) was shown to be associated with a reduced risk of HCC in patients with cirrhosis (OR:0.71; 95% CI: 0.61–0.84; $P = 2.9 \times 10^{-5}$). Previously, rs429358:C has been associated with a reduced risk of cirrhosis in patients with hepatitis C, and more recently with lower liver fat content in the UK biobank (UKB) community cohort study [26, 27]. However, the rs429358:C allele is best known for its deleterious impact on the risk of Alzheimer's disease. Indeed, homozygous carriers of rs429358:C are estimated to have >12-fold increased risk of AD relative to rs429358 T homozygotes [28, 29]. This highlights that in some cases, genetic risk factors for ALD exert significant pleiotropic effects. In the same CGAS, the authors also identified a second missense variant in *TM6SF2* (rs187429064:G) as being associated with alcohol-related HCC in cirrhosis patients [12]. Crucially, the rs187429064 locus is in complete linkage equilibrium with the better known rs58542926 locus, also in *TM6SF2*. Although the frequency of the rs187429064:G allele is very low at ~1% in Europeans, it's effect size with HCC is strong. Indeed, the magnitude of association between rs187429064:G and HCC (OR: 2.03) exceeds the equivalent association for rs738409 (in *PNPLA3*) and rs58542926 (in *TM6SF2*) [12].

Alcohol consumption is itself a heritable phenotype, most likely modified by multiple genetic determinants [30]. Previous CGAS have reported associations between loci that influence alcohol intake and ALD. Examples include rs1229984 in *ADH1B*, a gene that is directly involved in alcohol metabolism [31]. It is likely that such variants influence ALD only indirectly, for example through modifying alcohol intake. Nevertheless, these genetic predictors could be harnessed to build more effective risk stratification scores. However, until now, no risk-enhancing variant for alcohol drinking behaviour has been identified.

Clinical Applications

Treatment Discovery

Treatments for ALD have advanced only marginally over the last 50 years, with abstinence remaining the cornerstone of clinical management. Many candidate drugs for ALD have failed due to lack of efficacy [32], including colchizine, silibinine, polyenyl-phosphatidyl-choline, S-adenosyl-L-methionine, TNF-alpha inhibitors or propylthiouracil. Insight into the genetics of ALD could pave the way for innovative treatments for ALD by identifying novel drug targets (see also book chap. xxxx). Indeed, it has been shown that candidate drugs are more likely to

achieve regulatory approval if they are supported by data from genetic association studies [33, 34]. An example par excellence is the development of PCSK9 inhibitors to treat high cholesterol [35].

Data from previous ALD GWAS have already identified several promising therapeutic targets. Of these, PNPLA3 silencing has been a focal point of investigation [36]. In murine models, PNPLA3 silencing leads to reduced inflammation and fibrosis [37], and clinical trials are currently evaluating the safety of PNPLA3 silencers in human subjects [NCT04142424]. However, a fundamental concern about targeting PNPLA3 therapeutically is the potential for off-target effects. This is because the I148M variant exerts pleiotropic effects, particularly with respect to the risk of coronary artery disease. For example, in a general population cohort from Germany, the rs738409:G allele was associated with a higher risk of liver failure, but a lower risk of coronary artery disease and all-cause mortality [38]. Interestingly, a similar pattern may also be apparent for the E167K variant in TM6SF2 [39].

Beyond PNPLA3, the rs72613567 splicing variant in *HSD17B13* is also being widely investigated as a treatment target. Indeed, a phase 1 clinical trial is already underway for a therapeutic agent modifying HSD17B13 expression through RNA interference [NCT04565717]. The study completion date is expected for early 2023. Inhibition of the MARC1 mitochondrial protein could be another viable target given that loss of MARC1 function appears to protect against cirrhosis.

As well as identifying direct targets, GWAS can provide broader insight into the physiological pathways disrupted in disease progression. For example, using the gene ontology resource, it is possible to ascertain if the genes identified in previous ALD GWAS are enriched within specific cellular locations, biological processes, or molecular functions [40, 41]. This analysis indicates that relative to a random gene set, the protein products of the ten genes identified in previous ALD GWAS are more likely to be located in lipid droplets (60-fold enrichment; $P = 0.015$) and the endoplasmic reticulum (seven-fold enrichment; $P = 0.017$) (Table 52.2). These insights align with the therapeutic strategies currently being investigated in the field [36]. For example, the importance of lipid droplets in mediating lipid homeostasis and steatosis is well recognised in ALD and other forms of liver disease [42]. Similarly, ER stress triggers the unfolded protein response, leading to apoptosis and potentially hepatic steatosis onset [43]. Thus, agents acting to restore ER stress are of therapeutic interest.

Risk Prediction and Stratification

Why Risk Stratification Is Needed?

An unfortunate hallmark of ALD is that patients are typically not diagnosed until severe complications such as HCC or decompensated disease emerge [44, 45]. At this point, the damage incurred to the liver is usually advanced, potentially intractable and, thus, treatment options are limited. Therefore, prompt diagnosis of ALD

in the community is crucial to reduce the mortality burden from ALD. At present, clinicians have multiple opportunities to intervene early before patients develop alcohol-related cirrhosis [46]. However, because: (a) the size of the "at risk" population is vast (i.e. excess alcohol intake is relatively commonplace in the general population); (b) a majority of patients with excess alcohol intake show no progression to significant ALD and (c) health care resources are scarce, there is a clear need to focus the finite resources available on the highest risk patients. For these reasons, combating late diagnosis hinges on being able to stratify patients' risk in community/primary care settings [47, 48].

Risk stratification remains equally important even once patients have progressed into secondary care. Ultrasound surveillance for liver cancer is a case-in-point. Currently, clinical guidelines recommend all patients with cirrhosis should receive surveillance every 6 months [49], but in practice, surveillance is poorly implemented [50, 51], meaning that too few patients with HCC go on to be treated with curative intent [52, 53]. Support for "individualised" surveillance is growing [54–57], but this approach similarly hinges on the availability of robust and accessible risk stratification scores.

Risk Stratification through Polygenic Risk Scores

Current risk scores used in ALD are derived from routine blood tests, such as bilirubin, coagulation tests, albumin, and creatinine (e.g. MELD and Lille model for alcohol hepatitis). The falling cost of genotyping however, together with an increasing understanding of genetic predictors for ALD, means that for the first time, it may be feasible to utilise a new class of prognostic factors in clinical practice: namely, the polygenic risk score (PRS). At bottom, a PRS is simply a number reflecting an individual's lifetime genetic susceptibility to a disease. It is calculated by aggregating the effects conferred by multiple genetic variants on a given phenotype (hence "polygenic" as opposed to "monogenic") [58, 59]. PRSs can vary from one another in two main respects: (1) in terms of which genetic loci are included in the score; and (2) by the weighting assigned to each locus. Crucially, because a PRS is based on immutable germline DNA, it provides a measure of lifetime risk that is constant over time. Detailed tutorials explaining the methods used to generate a PRS are available [58, 59].

Studies have already begun to derive and evaluate PRSs for predicting cirrhosis and HCC. In particular, Whitfield et al. proposed a PRS for alcohol cirrhosis combining information on three genetic loci together with information on diabetes status [60]. All three genetic loci included were identified from previous GWAS: rs738409 (PNPLA3); rs10401969 (TM6SF2); and rs72613567 (HSD17B13) [14–16]. The authors reported that individuals with the highest PRS score had between 2.8 and 6.0 times greater risk of cirrhosis compared to individuals the lowest PRS score. The area under the curve (AUC) was between 0.62 and 0.67, indicating moderate discriminative ability. Another important contribution to the field is the HCC PRS developed by Bianco et al. [61]. This PRS is comprised of five variants associated with hepatic fat content: rs738409 (PNPLA3); rs58542926 (TM6SF2); GCKR;

rs641738 (MBOAT7); and rs72613567 (HSD17B13). Here, the AUC was 0.64, again indicative of moderate discrimination. High risk patients generally had >5 times odds of HCC versus lower risk patients. Other PRSs developed have reported similar results in terms of discriminative ability [14, 62, 63].

Clinical Translation of Polygenic Risk Scores

The increasing affordability of genetic sequencing has sparked hope that genetic data could soon be used routinely in liver clinics to advance patient management. However, like any risk score, utility hinges on whether it provides "new" prognostic information beyond what is already available to clinicians [64]. This perspective is crucial because clinicians already enjoy access to a diverse range of prognostic factors for liver disease, which are "free to use". For example, platelet count, alanine aminotransferase, aspartate aminotransferase, albumin, bilirubin etc. are all prognostic factors for ALD that are routinely available to clinicians. Thus, the real utility of a PRS depends less on its absolute performance, and more on its added-value relative to existing alternatives. This "added-value" perspective was explored recently in a study by Innes et al. [65]. The authors examined 20 routinely available risk scores, including the ALT:AST ratio, the fibrosis four index (FIB4) and the aspartate aminotransferase platelet ratio index (APRI). They found that majority of routine risk scores outperformed prediction using genetic data. For example, the C-index for the APRI score was 0.80, whereas the C-index for the PRS was 0.60. Secondly, they found that, for the best performing risk scores (e.g. APRI and Fib4), the addition of genetic risk data added only a very modest amount of "new" prognostic information. For example, the C-index for APRI alone was 0.804 versus only 0.809 when combined with genetic data. This suggests that current PRSs will not fundamentally change the risk stratification landscape. Comparable findings regarding the added-value of PRSs have also been observed in a specialist care context [66]. However, there are two caveats to point out regarding the interpretation of these studies. Firstly, the performance of PRSs are likely to improve as understanding of ALD genetics expands. Secondly, a PRS holds some practical advantages over traditional risk scores, which in some contexts, could outweigh differences in performance. For example, a PRS provides a measure of lifetime risk and so only needs to be calculated once. Conversely, risk scores derived from liver blood tests are dynamic and so must be periodically updated at relevant clinical milestones.

Future Research

Whilst considerable progress has been made in the past 10 years, there is still much to be done to better characterise the genetics of ALD. In particular, this includes translating novel discoveries into tangible patient benefits. In the last section of this review, we discuss specific topics/areas which are particularly likely to deliver research impact in the future.

Increasing Statistical Power

Statistical power is one of the most critical factors to consider when designing a genetic association study. This is because studies with low power are very unlikely to identify novel genotype-phenotype associations if they were missed by previous studies with greater statistical power. Thus, developing and applying new techniques to maximise statistical power will be an important theme of future research.

Meta-Analysis

Meta-analysis of individual genetic association studies is an important route to augmenting sample size, in order to increase statistical power [67]. Recently, this approach was used to verify the association between rs641738 (*TMC/MBOAT7*) and chronic liver disease phenotypes (cirrhosis, HCC, steatosis, etc) [68]. Other equivocal loci that would benefit from a meta-analysis approach include rs2954038 in the region of *TRIB1*. This variant has achieved borderline significance in previous association studies, and exhibits compelling evidence of regulatory function [14].

Exploiting Endophenotypes

An endophenotype is an intermediate variable on the causal pathway between a genetic variant and the disease of interest [69]. For example, elevated alanine aminotransferase (ALT) level is on the causal pathway between: a) rs738409:G in *PNPLA3*, and b) cirrhosis. This is because rs738409:G leads to liver cirrhosis, and in the process ALT levels (a marker of liver inflammation and damage) increase. Interestingly, the rs738409:G allele is easier to "discover" through a GWAS on ALT than a GWAS on cirrhosis. In other words, fewer patients would be required to detect rs738409 at a genome-wide level (i.e. $P < 5.0 \times 10^{-8}$) if ALT were the phenotype compared to if cirrhosis were the phenotype [14]. Essentially, this is because ALT is a continuous variable whereas cirrhosis is a binary phenotype; and in general, continuous variables provide greater statistical power than binary ones [70]. In this way, leveraging endophenotypes can considerably enhance the statistical power of a GWAS. An example of this endophenotype approach was recently illustrated in a GWAS by Innes and Buch et al. [14]. In stage 1, heavy drinkers from UKB were included in a linear regression GWAS against continuous measures of liver fibrogenesis (i.e. APRI, FIB4, Forns, ALT and AST). Loci significantly associated with one or more of these continuous fibrogenesis measures were brought forward into the stage 2 analysis, entailing direct testing for association with cirrhosis status in clinical cohorts. Using this approach, the authors were identified new variants (e.g. rs15052 in *HNRNPUL1*) that would not have been discovered using a conventional binary phenotype design. In the future, studies can extend this approach by leveraging a broader set of endophenotypes.

Harnessing Population-Based Biobanks

As discussed, future insights in ALD genetics will require increasing statistical power and hence increasing sample sizes. Large population-based biobanks will be critical in helping the field to achieve this. Biobanks are repositories of biological samples, stored at low temperatures. Samples are donated by members of the public who crucially also provide information about their health and risk factors for disease. In some cases, longitudinal data on health outcomes are available through linkage to national health registries. The UKB resource is an exemplar par excellence, and provides an excellent template for emerging biobanks to follow. In brief, UKB provides whole-genome sequencing data for 500,000 middle-aged people in the UK, together with detailed lifestyle, disease and biomarker data [70]. Proof of its utility is that UKB has actually supported (directly or indirectly) most of the recent genetic association studies performed so far relation to ALD [14, 15, 17] (see Table 52.1). Many countries are now seeking to develop their own population-level biobanks. Notable examples include: FinnGen (Finland) [71]; All of us (US) [72]; Our future health (UK) [73]; The million veteran program (US); 100,000 genomes (UK) [74]; and CanPath (Canada) [75]. Researchers who succeed in harnessing these population-based resources and integrating then with data from detailed clinical cohorts, are likely to achieve significant new insights.

Polygenic Risk Scores

Although current PRSs provide minimal "new" prognostic information [65, 66], their performance will improve as our understanding of ALD genetics grows. Transforming PRSs into clinically useful tools is likely to be an active area of future research.

One area that may bring about improvements is accommodating rare variants into existing PRSs. Thus-far, GWAS (and by implication PRSs) have focused exclusively on common variants with minor allele frequencies >1%. There is increasing recognition however that rare variants with high penetrance may be major contributors to genetic susceptibility for common diseases [76]. A recent study by Pelusi et al., comparing a PRS comprising rare variants versus a PRS comprising common variants alone, supports this view [77].

Multi-polygenic risk scores (MPS) are another promising avenue [78] The rationale behind this approach is that most disease events have multiple predictors, each of which can themselves be predicted through a PRS. Thus, an MPS is constructed by combining separate PRSs, each relating to a different predictor of the overall phenotype. For example, independent predictors of ALD cirrhosis, include alcohol intake, type 2 diabetes, obesity, telomere length and hepatic fat content. In this context, a MPS would combine five individual PRSs (i.e. one PRS for each predictor) into a single multivariate model. Previous studies generally show that MPSs exhibit better predictive performance than a single PRS alone [79, 80]. In particular, the

recent study by Sinnott-Armstrong et al. reported that an MPS for alcohol cirrhosis derived from PRSs of 35 urine/blood biomarkers exhibited better predictive performance (C-index: ~0.60) than a single PRS based on variants associated with alcohol cirrhosis alone (C-index: ~0.55) [80].

Multi-Omics

Previous studies focus overwhelmingly on the relationship between sequence variants and ALD risk. In the future, studies are likely to shift towards a broader "multi-omics" approach, e.g. considering genetics sequencing data together with data on gene expression and tissue-specific proteomics. Indeed, a very recent study by Niu et al. provides compelling evidence that a proteomics-based risk score outperforms existing diagnostic and prognostic risk models in ALD [81]. Scientific methods for standardising integration of multi-omics data are advancing at pace [82]. Cohorts where patients are characterised in terms of multi-omics data will soon become the new benchmark, and will yield deeper insights into ALD pathophysiology.

Multi-Ancestry Genetic Association Studies

An important limitation of current GWAS for ALD is that they are restricted to individuals of European ancestry. Going forward, multi-ancestry genetic association studies should be adopted. This is important if GWAS findings are to be successfully translated into ethnically diverse "real world" clinical populations. The implementation of PRS is a case-in-point for why GWAS must reflect the ethnic diversity of the "at risk" population. For example, it has been shown that the performance of PRSs - derived pre-dominantly from individuals of European ancestry - are suboptimal in people of non-European descent, particularly individuals of African ancestry [83].

Alcohol Hepatitis

No robust GWAS has been carried out to-date for alcohol hepatitis. This omission is notable given that alcohol hepatitis is a prominent feature of ALD, responsible for significant mortality [84]. In the future, GWAS are expected to emerge for this phenotype, which will provide broader insight into ALD genetics [85].

HCC Driver Genes

As with any form of cancer, HCC arises when healthy liver cells acquire mutations in key genes regulating cell division. In HCC tumours, the most frequently mutated genes are *TERT*, *CTNNB1* and *TP53* [86]. In their recent GWAS of ALD HCC, Buch et al. identified a new germline variant in *TERT* (rs2242652) [18]. This shows in principle that both hereditary and somatic mutations in HCC driver genes (in this case *TERT*) are associated with hepatocarcinogenesis. It is possible that equivalent patterns may hold for other HCC driver genes. Also, in the first French GWAS on HCC, it was reported that the lead variant (rs708113) was associated with somatic mutations in *CTNNB1* in HCC tumour cells [17]. Specifically, HCC patients with the rs708113 T allele were less likely to have somatic mutations in *CTNNB1* compared to carriers of the rs708113 A allele. Further research evaluating the interplay between germline polymorphisms and somatic mutations leading to HCC is warranted. One initial follow-up study could be to carry out a CGAS, systematically assessing the association between germline variants in HCC driver genes and HCC status.

Epistasis

Epistasis is defined as gene-gene interaction – i.e. where the association between a given genetic loci and a phenotype varies according to an individual's genotype at a second loci. Epistatic relationships are notoriously difficult to identify at a genome wide level. Firstly, because they require even greater statistical power than a conventional GWAS. Indeed, even for a very large interaction effect (i.e. the same magnitude as the main effect size), one's sample size would need to be inflated four-fold to detect the interaction effect with 80% power [87]. Where the interaction effect was more modest (i.e. half the size of the main effect), one's sample size would need to increased 16-fold [88]. Moreover, the computational resources required to screen for epistasis at a genome-wide level are another prohibitive factor. Consequently, studies typically only test for epistatic relationships where there is compelling biological information in support of this. Thus, little is known about the importance of epistasis in ALD at present. Currently, there is evidence that rs72613567 (*HSD17B13*) may interact with rs738409 (*PNPLA3*) to modify liver disease risk. Specifically, carriage of rs7613567:TA allele appears to attenuate the deleterious effect of the rs738409:G allele [89, 90]. Many more examples of epistasis are likely to exist. As statistical power increases, uncovering these relationships could be a source of great insight.

Chapter 53
Mechanisms of Alcohol-Related Liver Cirrhosis

Honglei Weng, Yujia Li, and Steven Dooley

Abstract Liver cirrhosis-induced portal hypertension is a major cause for mortality in chronic liver diseases, including alcohol-related liver disease. Anatomically, liver cirrhosis is presented as septa separating hepatocellular nodules throughout the liver. Mechanistically, vascular injury-initiated congestive escalation is the central event to induce parenchymal extinction lesions and for the in-out imbalance of hepatic blood flow, which finally leads to portal hypertension. Parenchymal extinction leads to liver function insufficiency or even liver failure, while portal hypertension results in ascites, and mediates acute renal injury, hepatic encephalopathy, and gastrointestinal bleeding. In comparison with other etiologies, liver cirrhosis arising from long-term alcohol abuse impairs number and composition of gut microbiota and leads to pathological translocation of bacteria and bacterial endotoxins, thus stimulating systemic and liver inflammation. Patients with alcohol-related liver cirrhosis frequently develop spontaneous bacterial peritonitis, sepsis, and acute-on-chronic liver disease.

Keywords Alcohol-related liver cirrhosis · Vascular injury · Portal hypertension · Hepatocyte injury · Inflammation · Liver scarring

Introduction

Liver cirrhosis, severe alcoholic hepatitis and the development of liver cancer, in particular hepatocellular carcinoma (HCC), represent the major causes for mortality in patients with alcohol-related liver disease (ALD). HCC causes around 810,000 deaths annually, and ALD is responsible for approximately 30% of these HCC-related deaths [1], which far exceeds the number of HCC deaths caused by

non-alcoholic fatty liver disease at this time. This chapter starts with an overview on the sequence of cellular events that underly liver damage and fibrosis with disease progression in general, and more specifically as it relates to ALD dynamics.

Pathophysiology

Cirrhosis is defined anatomically by the presence throughout the liver of hepatocellular nodules that are separated by septa [2]. Since its first use, the term "liver cirrhosis" has been a controversial issue [3]. In 1947, Himsworth once proposed to replace the term cirrhosis with "the sclerosed appearance of the liver as fibrosis" [4]. In 2012, an International Liver Pathology Study Group proposed that "this is an appropriate time to consider discontinuing the use of this term (cirrhosis)", given that "recent advances in the diagnosis and treatment of chronic liver diseases (CLD) have changed the natural history of cirrhosis significantly" [3]. However, as stated in the textbook *MacSween's Pathology of the liver*, 'cirrhosis' is a firmly entrenched term, likely to remain in common usage for the foreseeable future" [5]. This chapter describes conception evolution of liver cirrhosis and current knowledge of mechanisms underlying alcohol-related liver cirrhosis. Related chapters include Chaps. 7, 49, 54, 59 and 61.

Conception Evolution of Liver Cirrhosis

The definition of liver cirrhosis has been evolving particularly in the last three decades [6]. Wanless and Huang described evolution of the conception in the *MacSween's Pathology of the liver* [5]. There are three representative definitions in history of liver cirrhosis: (1) The presence throughout the liver of fibrous septa that subdivide the parenchyma into regenerating nodules; (2) The accumulation throughout the liver of confluent parenchymal extinction lesions; and (3) Cirrhosis is the collection of anatomic changes in the liver that result from the presence of widespread imbalance of hepatic blood flow where inflow exceeds the outflow capacity [5]. As explained in the textbook, point (1) of this conception is misleading because it denotes that fibrogenesis is the cause of cirrhosis. Point (2) reveals that parenchymal extinction is a special type of hepatocyte death required for the formation of cirrhosis. This definition leads to the question what causes or has caused parenchymal extinction. Point (3) arrives the core point of the pathogenesis of cirrhosis: it is the "in-out imbalance of hepatic blood flow" that results in parenchymal extinction and architecture distortion in the damaged liver. Point (3) also explains why the measurement of hepatic vein pressure gradient (HVPG) is a reliable tool to assess the progression of cirrhosis [7]. Thus, elucidating the cause and mechanisms of the "in-out imbalance of hepatic blood flow" is critical to understand the pathogenesis of liver cirrhosis.

Vascular Injury and Congestion

Vascular injury and congestion are central events in the pathogenesis of cirrhosis regardless of etiology. Given the central role of the in-out imbalance of hepatic blood flow in liver disease, vascular injury and subsequent vascular remodeling are the central events that result in liver cirrhosis and portal hypertension. In ALD, vascular alteration occurs at the early phase of liver damage. Capillarization of hepatic sinusoids, a term coined by Schaffner and Popper in 1963, is a phenomenon occurring in the perivenular zone following early alcohol-related liver injury [8]. Normal liver sinusoidal endothelial cells (LSEC) are characterized by the presence of pores (fenestrae). The fenestrae are 100–150 nm in size and are clustered in groups, which are termed as sieve plates [9]. In pathological conditions, for example alcohol stimulation, LSEC lose fenestrations and acquisition of a vascular phenotype. In the process of capillarization of hepatic sinusoids, the normal extracellular matrix, mainly type III collagen, in the space of Disse is replaced by mainly type I collagen, as well as basal lamina-like material containing laminin and type IV collagen, which are produced by activated hepatic stellate cells (HSC) [5].

It has been well recognized that maintenance of phenotype of fenestrated LSEC requires nitric oxide (NO), which is stimulated by VEGF secreted by hepatocytes and HSC [9]. VEGF stimulates NO release through endogenous nitric oxide synthase (eNOS) in LSEC [10]. During liver injury due to alcohol abuse, LSEC produce low production of NO due to increased binding to caveolin [11, 12]. Low NO levels in sinusoids diminish eNOS activity and thus result in capillarization of LSEC [11, 12].

Capillarization of hepatic sinusoids is also thought as the early feature of fibrosis. Although the detailed mechanisms remain largely unknown, the fenestrated LSEC play a crucial role in the prevention of HSC activation [13]. Capillarized LSEC lose capacity to maintain HSC quiescence [13]. Besides contributing to fibrosis, capillarization of hepatic sinusoids leads to additional two severe consequences: (1) Establishment of a significant barrier between the blood and the hepatocyte, which results in hepatocyte dysfunction and injury, as well as reduces the transport of solutes from the sinusoidal blood to the hepatocyte via the space of Disse. (2) Changing structure of the sinusoidal endothelial cells and localization of subendothelial basal laminas, which is associated with increased vascular resistance in the sinusoidal bed and the pathogenesis of portal hypertension.

In addition to capillarization of hepatic sinusoids, alcohol abuse leads to local vasculature including thrombosis, lymphocytic phlebitis, phlebosclerosis, veno-occlusive lesions and vascularized septa [14, 15]. These vascular alterations are essential to the formation of cirrhosis and portal hypertension. Wanless showed that obliterative lesions in hepatic veins and portal veins occurred in 70 and 36% of cirrhotic livers, respectively [15]. Goodman and Ishak described three types of venous lesions in ALD: (1) lymphocytic phlebitis; (2) phlebosclerosis; and (3) veno-occlusive lesions [16]. Levels of portal hypertension are associated significantly with the degree of phlebosclerosis and veno-occlusive change [16]. In addition,

Burt and MacSween found that the occlusive venous lesions may contribute to the atrophy of hepatic parenchyma and functional impairment [17]. To date, detailed mechanisms of how alcohol leads to lymphocytic phlebitis, phlebosclerosis and veno-occlusive lesions are largely unknown.

Recently, Wanless proposed a "vascular hypothesis", which clearly demonstrates the key role of vascular injury in the pathogenesis of cirrhosis in humans [2]. The hypothesis comprises four key conceptions: (1) a definition of parenchymal extinction, which emphasizes the importance of sinusoidal destruction; (2) a "congestive escalator" hypothesis, which explains how vascular obstruction occurs, beginning with sinusoidal endothelial cell injury, fluid translocation, and vascular compression by mechanics known as "compartment syndrome"; (3) a "nested cone model" of hepatic vein anatomy that predisposes to compartment syndrome in the human, and (4) a proposal for the mechanism of collagen formation in response to congestion ("congestive fibrosis") [2].

In 1990s, Wanless originally defined parenchymal extinction lesion (PEL) as a region with loss of contiguous hepatocytes [5]. Given the causality between loss of the local microvasculature and PEL, he recently revised the definition as "a region with focal loss of contiguous hepatocytes and adjacent microvascular structures" [2].

During CLD, vascular injury causes vascular obstruction which causes more vascular injury which causes more vascular obstruction in a positive feedback loop. Wanless defines such a loop as "congestive escalator" [2]. Vascular obstruction increases tissue pressure gradients and thus drives transudation of fluid into vessel walls and interstitial tissues, which results in further vascular obstruction. Vascular obstruction caused hepatocellular ischemia results in PELs with collapse of the architecture. Local vascular impairment delays tissue repair so that the regions of injury are repopulated by liver progenitor cells (LPC), which resides in smallest biliary tree [18]. Later, vascular obstructing lesions progresses from smaller branches to larger branches of the hepatic and portal veins, which leads to PELs larger and eventually merge into confluent septa. Collapse, delayed repair, and LPC-mediated regeneration constitutes hepatocellular nodules separated by septa and tissue distortion in cirrhosis [2].

Obstruction in hepatic vein (HV) and small portal vein is a prominent histologic feature in cirrhosis regardless of etiology [15–17, 19–21]. In a recent study, Wanless showed high-grade (>50%) obstruction of HVs in 15.0 and 66.5% of recognizable HVs in mild cirrhosis and severe cirrhosis, respectively. After correction for collapse of tissue, patent HVs were decreased by 59% in mild cirrhosis and 94% in severe cirrhosis. He also measured the involvement of small (20–100 μm) and larger HVs (≥100 μm). In patients with Laennec stage 4A cirrhosis, high-grade obstruction was found in 63.4% of small and 26.5% of larger HVs [2]. These data demonstrate an evolution that HV obstruction begins from small to larger HVs following advance of disease severity.

Following vascular obstruction, obliterative lesions in hepatic veins and portal veins occurred in severe cirrhotic livers [15]. The obliteration of hepatic veins explains the prominent congestive features in cirrhotic livers [2]. Many regenerative nodules have zones of sinusoidal congestion and collapse that lead to subdivision

and remodeling of nodules into two or more smaller nodules. The congested zones also contain red blood cells that have dissected into vein walls, causing luminal compromise. These features indicate that congestion is a mechanism causing progression from mild to severe cirrhosis [2].

Wanless further pointed out that the human liver is particularly vulnerable to this congestive escalator given the "nested cone" architecture in humans. Such a long and branched hepatic vein tree is susceptible to "compartment syndrome" effects [2]. He described the "nested cone" architecture as follows: "In normal human liver, the axial hepatic veins branch dichotomously 4–6 times at acute angles. Many small branches arise at right angles. Each hepatic vein branch drains a cone of parenchyma that is nested inside larger cones drained by larger branches. As collateral pathways are few, each cone has its own pressure environment modified by local venous obstruction and hyperemia. Distal branches have a longer path to the vena cava than side branches of larger axial branches. The shorter path would likely be associated with lower venous pressure. Obstruction is due to luminal reduction as well as external compression. The nested cone architecture facilitates the migration of external compression to involve larger vessels as adjacent tissue expands. In chronic hepatitis, there is widespread mild to moderate inflammation leading to local sinusoidal and venous obstruction. One cone has become more congested than others as its hepatic vein is compromised, with a local rise in pressure. Hyperemia and vascular leak has caused expansion of the affected cone that now is compressing adjacent cones, spreading the pressure rise to them. Vascular obstruction has extended to a larger vein causing three more small cones to expand with more compression of the cones on the right as well as higher in the tree" (Detailed description please see Fig 6 in [2]).

The consequence of extensive congestive injury is the "in-out-imbalance of hepatic blood flow", defined as inflow (hepatic artery and portal vein flow) exceeds the outflow capacity of the system (hepatic vein flow) [2]. Inflow is increased due to reactive hyperemia such as in response to inflammation, ischemia, portal vein obstruction, or shunting. Outflow is reduced by obstruction of hepatic and portal veins.

The in-out-imbalance of hepatic blood flow results in further elevated transmural pressure gradient, which causes endothelial injury, vascular leak, with transudation and edema [2]. Expansion of tissue compresses adjacent tissues including veins that leads to elevated in-out-imbalance and more vascular injury. Besides the in-out-imbalance of hepatic blood flow, an imbalance of vasoconstrictive and vasodilating agents in the intrahepatic circulation results in consistent net vasoconstriction inside the liver [22]. In the cirrhotic liver, the capillarized LSECs produce less nitric oxide [23]. Over time, congestive vasculopathy-induced in-out-imbalance and consistent intrahepatic vasoconstriction cause cirrhosis and portal hypertension [2, 24].

High levels of intrahepatic vascular resistance further lead to the development of splanchnic arterial vasodilation [25]. In contrast to the LSECs with compromised function to produce NO, extrahepatic endothelial cells-produced NO is increased in response to vascular shear stress, which results in vasodilation in the splanchnic capillary beds and arterioles [26]. Progressive splanchnic vasodilation initiates

complications of port hypertension such as ascites, acute renal injury, hepatic encephalopathy, and gastrointestinal bleeding [24]. To counteract progressive splanchnic vasodilation-induced systemic hypotension and arterial underfilling, neurohumoral vasoconstrictive systems such as sympathetic nervous system, renin–angiotensin–aldosterone system, and non-osmotic release of vasopressin are activated. Activation of these systems leads to an increase in plasma volume through sodium and water retention. The excessive plasma volume results in ascites. With the progression of cirrhosis, vasodilation increases and systemic blood pressure progressively decreases, which further activates vasoconstrictors factors. The intense vasoconstriction in the renal circulation causes hepatorenal syndrome [27].

With the progression of portal hypertension, new collateral channels are formed at the sites where systemic and portal circulation come together (such as at the gastrooesophageal junction) to shunt portal pressure [28]. In clinical, patients usually present as gastro-oesophageal varices. When the pressure in these varices exceeds the elastic capacity of the vessel wall, variceal bleeding occurs [24]. When hepatocyte functions such as urea cycle are severely compromised, portosystemic shunting induces hepatic encephalopathy given failing to clear gut-derived ammonia in cirrhotic patients [24].

Liver Cell-Based Mechanisms

The spectrum of ALD comprises steatosis, perivenular fibrosis, alcoholic foamy degeneration (microvesicular steatosis), alcoholic hepatitis, occlusive venous lesions, cirrhosis and hepatocellular carcinoma [5]. Among these pathophysiological alterations, occurrence of cirrhosis is a key step, which largely determines prognosis of a patient. On the other hand, development of cirrhosis is closely associated with early pathophysiological alterations. Besides vascular injury described above, hepatocyte death, inflammation, fibrosis, and extrahepatic pathophysiological alterations are additional important aspects of alcohol-related cirrhosis.

Alcohol-Related Hepatocyte Injury: Sublethal Hepatocytes

Intensive hepatocyte injury or even the loss of contiguous hepatocytes are dominant features of liver cirrhosis. In alcohol-related liver cirrhosis, long-term and excessive alcohol abuse induces hepatocyte apoptosis through oxidative stress and mitochondria stress [29, 30]. In addition, hepatocyte cytochrome P450 2E1 (CYP2E1)-mediated alcohol metabolism also result in hepatocyte necroptosis through receptor-interacting protein kinase (RIPK) 3 and mixed lineage kinase domain–like protein [31].

In addition to cell death, long-term alcohol insults leads to sublethal changes in hepatocytes, which is characterized by ballooning degeneration, Mallory-Denk

body formation and sclerosing hyaline necrosis [5]. Hepatocytes with ballooning degeneration and Mallory-Denk bodies reflect a progressive injury leading to lytic necrosis and are considered as sublethal changes [5]. These hepatocytes are not immediately dead. However, functions in these cells are largely compromised. Animal studies show that these sublethal changes may persist for weeks or even months [32].

When the loss of contiguous hepatocytes and sublethal hepatocytes extend to most of the liver tissue, the liver function is largely compromised, which contributes to the progression of liver cirrhosis. For example, insufficient release of albumin causes formation of ascites while the dysregulation of urea cycle plays a leading role in hepatic encephalopathy [24].

Inflammation and Innate Immunity in ALD

Different forms of inflammatory activities are present throughout the progression of ALD, starting with hepatocellular damage until end stage of disease, where it is characterized as non-resolving inflammation. Inflammation in ALD comprises multiple scenarios, including microbial dysbiosis, loss of barrier integrity in the intestine, hepatocellular stress and death, and inter-organ cell-to-cell communication. Multiple cell types are involved, including Kupffer cells (KC), the resident macrophages, infiltrating monocytes, neutrophils, the inflammatory subpopulation of hepatic stellate cells (iHSCs), LSECS, bile duct epithelial cells, as well as other cell types of the innate and adaptive immune system. Intercellular communication is mediated via the matrisome and cell secreted molecules, including miRNAs and extracellular vesicles. Importantly, the damaged and stressed hepatocytes themselves express chemokines and inflammatory mediators, and finally release damage-associated molecular patterns (DAMPs) during injury and death, which shape the immune and stromal response in the neighbourhood of the damaged region (Fig. 53.1).

In active drinkers, activation of tumor necrosis factor **(TNF)-α**, interleukin **(IL)-1β**, and nuclear factor **(NF)-κB** is found in liver tissue already at early disease stages. Double immunofluorescence staining localizes this proinflammatory response to activated, CD68-positive macrophages. In parallel, down-regulation of **IL-6**, abrogation of the signal transducer and activator of transcription 3 (**Stat3**) pathway, as well as blunted **cyclin D** expression in hepatocytes, reduced proliferation and increased hepatocyte apoptosis is found. Toll-like receptor **(TLR) 7**–interferon **(IFN)** axis in hepatocytes correlates with liver fibrosis markers and disease progression. Two weeks of abstinence attenuates the inflammatory response but does not allow recovery of the defective Stat3 pathway or effects fibrosis associated factors. Therefore, inflammation, activation of the TLR7–IFN axis, and inhibition of Stat3-dependent repair in early ALD pave the way for fibrosis development and ultimately disease progression [33].

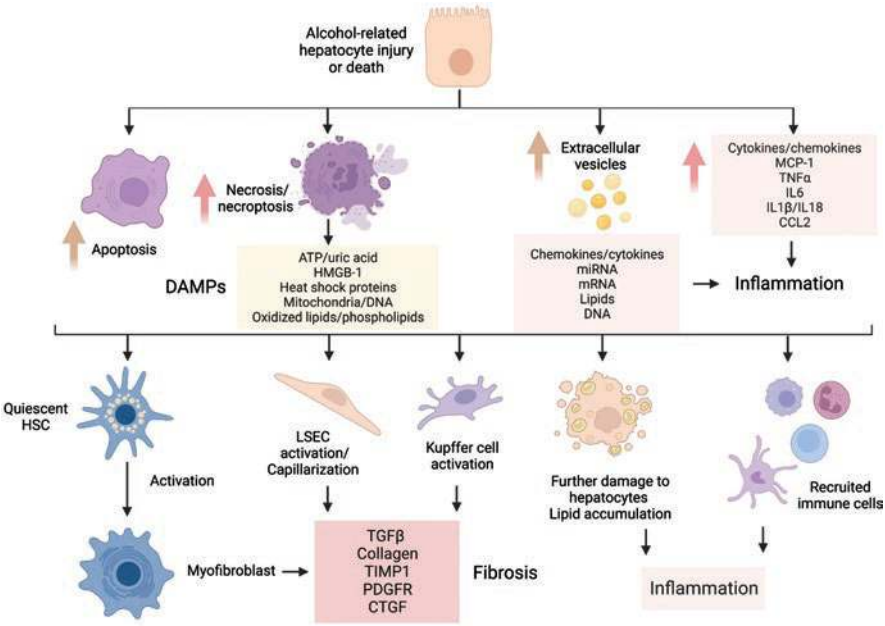

Fig. 53.1 Alcohol-related hepatocyte injury or death signals coordinate cells in the hepatic sinusoids. When alcohol-related hepatocyte injury occurs, the stressed, damaged and dying hepatocytes communicate with other cells that reside in the local hepatic sinusoids through releasing signals. These include apoptotic and necrotic damage associated molecular patterns (DAMPs; e.g. ATP/uric acid, HMGB-1, heat shock proteins, mitochondria/DNA, oxidized lipids/phospholipids), extracellular vesicles packaged with chemokines/cytokines, miRNA, mRNA, lipids or DNA, or directly secreted cytokines and chemokines including MCP-1, TNFα, IL6, IL1β/IL18, CCL2 and so on, therewith initiating and facilitating a protective wound-healing response with subsequent liver regeneration, or upon chronicity, orchestration of ALD progression with fibrosis and inflammation. The signals activate the non-parenchymal cells (NPCs) in the hepatic sinusoids to mediate. These responses include activation of quiescent hepatic stellate cells (HSCs) into myofibroblasts, activation of liver sinusoidal endothelial cells (LSECs) and vessel capillarization, as well as Kupffer cell activation, all of which lead to the secretion of fibrogenic factors like TGFβ, collagen, TIMP1, PDGF or CTGF, inflammatory factors like IL6, IL1β or TNFα, among others, and chemokines like CXCL1 or CCL2, to induce migration and immune cell infiltration to accordingly shape the tissue response to the injury. In the text, we review some of the mechanisms and signals by which hepatocytes and NPCs communicate and orchestrate the local environment to maintain a healthy liver or to develop an ALD

Alcohol metabolism also induces **IRAK4 (interleukin-1 receptor-associated kinase 4)** expression in hepatocytes, which is mediating an acute phase response and release of proinflammatory cytokines/chemokines, along with enhanced hepatocyte cell death. Pharmacological inhibition of IRAK4 kinase activity effectively attenuates alcohol-induced liver injury in mice [34]. Additionally, hepatocytic upregulation of MIF induces an inflammatory response with specific chemokine signatures, as observed in patients with severe AH [35].

Deregulation of the **Hippo/YAP** pathway with uncontrolled activation of YAP in hepatocytes is present in patients with severe AH. YAP activation in hepatocytes from AH patients leads to transdifferentiation towards a cholangiocyte program with loss of the hepatocyte identity, and results in an impaired regeneration in mice. Therapeutic inhibition of YAP activity in patients with AH interfered with hepatocyte transdifferentiation [36].

Hepatocyte **autophagy** is impaired in ALD and AH mouse models and human livers since both present with increased hepatic **p62** and **LC3-II** levels. Alcohol targets multiple steps in the autophagy pathway. Alcohol decreases **mTOR** and **Rheb**, correlates with increased **Beclin1** and **Atg7**, decreased lysosomal-associated membrane protein 1 (**LAMP1**) and lysosomal- associated membrane protein 2 (**LAMP2**). **miR-155**, which targets mTOR, Rheb, LAMP1, and LAMP2 in the autophagy pathway is increased by alcohol. miR-155-deficient mice are protected from alcohol-induced disruption of autophagy. As a result, alcohol impairs autophagic flux at the lysosome level, therewith promoting exosome release [37].

The **complement system** also belongs to the innate immune system and contributes to inflammation mediated liver injury and hepatic regeneration. Canonical factors C2, C4b, C4d, CFI and C5 are reduced in AH patients, whereas components of the alternative CFBa and CFD are increased. Therefrom, AH leads to profound disturbances of the complement and CFI and sC5b9 are valuable diagnostic and prognostic markers for disease severity and risk of mortality for AH patients [38].

Neutrophil infiltration is a frequent feature in severe AH. Immunohistochemistry of explanted livers now identified two variant severe AH phenotypes, one with high intrahepatic neutrophils, but low levels of $CD8^+$ T cells, and vice versa. RNA-Seq analyses demonstrated that neutrophil cytosolic factor 1 (NCF1), a key factor in controlling neutrophilic ROS production, was upregulated and correlated with hepatic inflammation and disease progression. Myeloid-specific deletion of the Ncf1 gene abolished ethanol-induced hepatic inflammation and steatosis in a mouse model of chronic-plus-binge ethanol feeding. Neutrophilic NCF1-dependent ROS promoted AH by inhibiting AMP-activated protein kinase (a key regulator of lipid metabolism) and microRNA-223 (a key anti-inflammatory and antifibrotic microRNA). In conclusion, two distinct histopathological phenotypes based on liver immune phenotyping are observed in severe AH patients, suggesting a separate mechanism driving liver injury and/or failure in these patients [39].

Neutrophils of patients with severe AH are associated with a defect in the **IL-33/ST2** pathway. This defect is associated with lower migration capacities and a higher probability of getting infected. Administration of IL-33 to the neutrophils partly restores this defect and may be effective at reducing the risk of infection in patients with severe alcoholic hepatitis [40]. Upregulated IRF3 increases apoptotic cell death of immune cells that promote the resolution of injury in a mouse model of alcoholic hepatitis [41].

IL-17A regulates inflammatory responses in macrophages (Kupffer cells and bone-marrow derived monocytes) and cholesterol synthesis in steatotic hepatocytes. IL-17 promotes alcohol-induced hepatocellular carcinoma. **IL-17** facilitates tumor necrosis factor/tumor necrosis factor receptor-mediated lipogenesis in

alcohol-damaged hepatocytes via activation of caspase-2-SP1-SREBP1/2-DHCR7 pathway [42].

Interleukin-22 (**IL-22**) biology and its roles of anti-apoptosis, anti-fibrosis, anti-oxidation, anti-bacterial infection and regenerative stimulation in protecting against liver injury in many preclinical models including several recently developed models such as chronic-plus-binge ethanol feeding, acute-on-chronic liver failure (ACLF), C-X-C motif chemokine ligand 1 (CXCL1) plus high-fat diet (HFD) (HFD + Cxcl1)-induced nonalcoholic steatohepatitis (NASH). Finally, clinical trials of IL-22 for the treatment of AH are also discussed, which showed some promising benefits for AH patients [43].

In summary, cellular fate and cell recruitment is orchestrated by the respective pro- or anti-inflammatory environment, either facilitating the wound healing response and liver regeneration, driving the devastating inflammation in the liver, or controlling bacterial infection. In late disease stages, physiological inter-organ crosstalk is heavily disturbed. A nicely illustrated summary of details on the aforementioned can be found e.g. in a recent review article by Bin Gao et al. [44].

Fibrosis in ALD

Accumulation of a fibrillar ECM is the consequence of repeated liver damage induced chronic wound healing reactions towards cirrhosis, the latter morphologically characterised by regeneration nodules of liver parenchyma cells encapsulated in fibrotic septa, and major changes in the vascular system. Initially, the deposited ECM is predominantly found in the subendothelial space of Disse, mainly consisting of collagen types I and III, which is paralleled with capillarisation of the sinusoids [45, 46]. Millions of individuals world-wide are affected by CLD, but only 25–30% progress to significant fibrosis and cirrhosis. Among others, daily alcohol intake is a strong predictor for disease progression. Importantly, in patients with CLD, progression to significant fibrosis in most cases needs a clinical course of between several years and decades, suggesting long latency periods [46, 47].

Depending on the disease etiology and type of insult, variant phenotypes of fibrogenesis are developing that all may progress towards cirrhosis [48]. Biliary fibrosis with significant proliferation of reactive bile ducts and activation of periportal myofibroblasts leads to ECM deposition in the portal–parenchymal interface, forming portal to portal bridges of scar around the liver lobules, preserving the functional linkage between central veins and portal tracts until late disease stages. Viral hepatitis causes portal–central bridging necrosis with corresponding ECM deposition, forming portal to central scar walls. Moreover, viral infections present with interface hepatitis, additionally resulting in portal-to-portal septa and septa ending blind in the parenchyma. This type of scarring leads to a rapid disruption of the vascular connections with the portal system and earlier development of portal hypertension. Central to central septa, also termed “reversed lobulation” [49], are forming due to targeted damage of the hepatocytes located around the central vein,

due to the zonated expression of Cyp2E1, which is responsible for mediating DILI. Besides, venous outflow problems (e.g. during chronic heart failure) lead to that kind of fibrosis pattern. Alcohol-related and metabolic liver diseases display a very distinct fibrosis pattern, where the deposition of ECM is concentrated around the sinusoids and around groups of hepatocytes, termed perisinusoidal, resulting in a so-called chicken-wire archetype. The different fibrosis patterns are induced in dependency of the region of tissue damage, the concentration of pro-fibrogenic mediators, and the prevalent pro-fibrogenic mechanism(s) [45, 47].

Sinusoids are the microvascular units in the liver and the space between hepatocytes and LSEC is termed space of Disse, where the HSCs are located throughout the liver lobules. The physiological basal membrane-like ECM in these spaces is required for physiological cell functions and an efficient metabolic exchange between the sinusoids and the hepatocytes. Hepatic sinusoids originate in the portal tracts from branches of the portal vein and the hepatic artery. The portal tracts further comprise bile ducts and lymphatic ducts as structural elements, and portal fibroblasts and bile duct epithelial cells as cellular components.

Extrahepatic Manifestations of Liver Cirrhosis

The Gut-Liver Axis

Besides intrahepatic disturbances, alcohol-related liver cirrhosis causes severe extrahepatic pathophysiological alterations that contribute to disease progression. The most predominant alterations are microbiota dysregulation-induced pathological bacterial translocation and systemic inflammation. Bacterial translocation is defined as translocation of bacteria and-or bacterial products from the gut to mesenteric lymph nodes [50]. In a healthy individual, bacterial translocation between the gut and the liver is a physiological phenomenon orchestrated by intestine barrier and host immunity [51]. There are three structural and regulatory mechanisms controlling microbiota in healthy condition: (1) stratification of the microbiota by the mucus barrier; (2) intestinal epithelial and the gut-vascular barriers; and (3) immune system control of the microbiota [52]. Excessive alcohol consumption induces gut dysbiosis, impairs the intestinal barrier and increases intestinal permeability, which leads to the gut-associated lymphatic tissues undergoing immune response aiming to eliminate invading bacteria and bacteria products [50]. Patients with chronic alcohol abuse show intestinal overgrowth of aerobic and anaerobic microorganisms, reduced bacterial diversity, and a shift in phyla towards a greater abundance of Proteobacteria and lower abundances of Bacteroidetes and Firmicutes, as well as of Lactobacillus species [53]. In addition to the microbiome alterations, the gut mycobiome such as fungi is also altered in patients with chronic alcohol abuse, which is associated with the severity of liver damage [54]. Alcohol intake impairs gut barrier and increases intestinal permeability at any stage of the disease [55]. Both dysbiosis

and damage of intestinal epithelial cells induce intestinal and systemic inflammation, which plays a critical role in pathological bacterial translocation and the progression of cirrhosis. In alcohol-related liver cirrhosis, pathological bacterial translocation, including bacterial overgrowth and deficiency in secretory and mechanical barrier function, triggers immune response in the gut-associated lymphatic tissue and the liver [56]. These events may lead to spontaneous bacterial peritonitis and acute-on-chronic liver failure (ACLF), a clinical situation characterized by decompensation, organ failure and high short-term mortality. More information can be found in the respective chapter within this book. This dysbiosis, which is present at different sites of our body, is highly associated with bacterial infections, systemic inflammation and poor outcomes. The dysbiosis-dependent constant stimulation of the immune system causes immune dysregulation in cirrhotic patients. The role of dysbiosis, unfavorable microbiota profiles, in the process of liver cirrhosis at the level of the gut and body system have been summarized in several elegant reviews [57–59].

Systemic Inflammation

The importance of systemic inflammation has been recognized and a systemic inflammation hypothesis was proposed by Arroyo and colleagues recently. The hypothesis suggests that "systemic inflammation through an impairment of the functions of one or more of the major organ systems may be a common theme and act synergistically with the traditional mechanisms involved in the development of acute decompensation" [60]. It has been well recognized that immune dysfunction commonly occurs in cirrhotic patients. Cirrhosis-associated immune dysfunction comprises immunodeficiency and systemic inflammation [56]. Immunodeficiency in cirrhosis refers to impaired local immune surveillance function of the liver, reduced synthesis of pattern recognition receptors, and damage at the systemic level of immune response cell function [56]. Cirrhosis-associated systemic inflammation is a dominant feature that is closely associated with consequence of cirrhosis [56]. Patients with alcohol-related liver cirrhosis constantly face challenges from both pathogen-associated molecular patterns (PAMPs) derived from dysregulated gut bacteria and damage-associated molecular patterns (DAMPs) from dead hepatocytes. Given the long-term alcohol consumption-induced gut dysbiosis, bacteria, fungi, and viruses from the gut lumen translocate to the gut-associated lymphatic tissue and the liver and thus result in systemic inflammation. Excessive systemic inflammation plays a leading role in the occurrence of ACLF [61]. Recently, Albillos et al. divided cirrhosis-associated immune dysfunction into two immune phenotypes: (1) the low-grade systemic inflammatory phenotype in the stage of compensated cirrhosis or clinical decompensation with no organ failure and (2) the high-grade systemic inflammatory phenotype in patients with ACLF [61]. In patients with high-grade inflammation, intense immune paralysis following systemic response syndrome increases the risk of infections and worsens prognosis [61].

In summary, vascular injury and congestion are central events in the pathogenesis of liver cirrhosis. Injury of hepatocytes, inflammation, fibrosis and pathological bacteria translocation and systemic inflammation contribute to the progression of this old and severe clinical syndrome. To date, detailed molecular mechanisms underlying liver cirrhosis are largely unknown. Further intensive investigations are required in the future.

Chapter 54
Alcoholic Fibrosis/Cirrhosis and Its Reversibility

Massimo Pinzani

Abstract A consistent percentage of subjects with alcohol abuse develop alcohol-related liver disease (ALD) with the development of liver tissue fibrosis and cirrhosis often associated with hepatocellular carcinoma (HCC). Alcoholic steatohepatitis (ASH) is critical in driving a fast progression of ALD towards cirrhosis. Concurrent factors include age, gender, ethnicity and coexisting clinical conditions such as obesity and diabetes. Development of fibrosis in ALD is characterized by a perisinusoidal/pericellular pattern and by the central pro-fibrogenic role of hepatic stellate cells. In this context, a major pro-fibrogenic and pro-inflammatory role is played by reactive oxygen species (ROS), acetaldehyde, the main metabolite of ethanol, and other reactive aldehydes deriving from membrane lipid peroxidation. A key role is also attributed to bacterial translocation due to increased gut permeability with increased circulating levels of LPS correlating with the severity of hepatic injury. In general terms, it is likely that in ALD the stage of fibrosis, and not the extent of fatty deposition and inflammatory infiltration, determines the long-term outcomes including hepatic and extra-hepatic clinical outcomes. There is extensive evidence that abstinence can rapidly lead to total resolution of liver steatosis with a minimal or no impact on liver fibrosis. However, this is associated with evident clinical benefits particularly in patients with overt cirrhotic decompensation. When compared with patients with HCV-related cirrhosis with sustained viral response (SVR) following treatment, the clinical benefit of abstinence is unlikely to be due to a faster and more comprehensive regression of tissue fibrosis in ALD cirrhosis, and possibly relies in a difference in the mechanisms responsible for the development and the aggravation of portal hypertension. Indeed, ALD is likely characterized by key tissue mechanisms of early resolution which are not necessarily related to significant fibrosis and cirrhosis regression but rather to unique features of portal hypertension in ALD.

Introduction

Alcohol consumption is a major risk factor for chronic liver disease and liver-related deaths in both industrialized and developing countries. Modern research on alcohol-related liver disease (ALD) has its foundation in the pioneer work of Lieber et al., who, in the early 1960s introduced experimental models to show that alcohol is a true hepatotoxin causing hepatocellular damage, and that ALD is not simply caused by malnutrition [1]. Overall, these early studies, as well those published in the following decades, demonstrated that ethanol metabolism-associated oxidative stress, glutathione depletion, abnormal methionine metabolism, ethanol-induced increase in intestinal permeability with endotoxin leakage followed by the activation of Kupffer cells have important roles in the pathogenesis of ALD [2–7].

In broad terms, liver fibrosis, similarly to other forms of tissue fibrosis occurring in chronic inflammatory diseases, is characterized by a chronic wound-healing response to a chronic tissue damage. Tissue scarring, which is the result occurring in general after several years of tissue injury, is not necessarily the worst outcome. Indeed, it is the best compromise to ensure continuity in the tissue structure although at the cost of a progressive loss of function associated to negative mechanical consequences. In very superficial terms it is also assumed that liver fibrosis develops in chronic liver disease (CLD) due to different causes of parenchymal damage (hepatocellular and/or cholangiocellular) according to the same cellular and molecular mechanisms irrespective of the etiology (viral, metabolic, toxic, autoimmune and cholestatic). However, there are important etiology-dependent features which are crucial to understand how fibrosis evolves into cirrhosis in different CLD and how fibrosis can be reversible or irreversible in cirrhotic liver.

General Cellular and Molecular Mechanism of Liver Fibrosis

The main effectors of hepatic fibrogenesis are hepatic stellate cells (HSCs). HSCs are liver-specific pericytes localized in the space of Disse, that, once activated, develop into highly proliferative fibrogenic myofibroblasts [8, 9]. Although HSCs are the main source of myofibroblasts in the liver, other cell types contribute to the pool of fibrogenic myofibroblasts in chronic liver disease. Portal myofibroblasts, located around bile ducts, also play a fibrogenic role particularly for the development of biliary fibrosis [10, 11]. Activation of HSCs is stimulated by damaged and apoptotic hepatocytes through several converging routes. These include: i) disruption of the normal ECM of the space of Disse because of hepatocyte damage and inflammatory infiltration, ii) release of reactive oxygen species (ROS) and other fibrogenic/pro-inflammatory mediators, and iii) recruitment of immune cells, which in turn mediate HSC activation and stimulate collagen secretion through release of cytokines and chemokines. Following the initial activation of HSCs, cytokines secreted by HSCs and by cells of the inflammatory infiltrate, provide signals that

maintain HSC activation/survival and promote the accumulation of fibrillar extracellular matrix (ECM). This leads to a vicious circle, in which mutual stimulation between inflammatory and pro-fibrogenic cells drives hepatic fibrogenesis [12].

The present knowledge concerning the cellular effectors of hepatic fibrogenesis derives from studies performed on primary culture or immortalized cell lines of human or rodent HSC as well as of immortalized rat portal myofibroblasts [13, 14]. The major phenotypic responses and their role can be summarized in the following points [15]:

1. *Synthesis and remodelling of the ECM.* Increased synthesis of ECM components is a disease hallmark in progressive CLD, with TGF-β1 playing a major role in the production of fibrillary collagens (mainly type I and III), laminin and fibronectin. A key counterpart of this feature is the reduced expression of genes involved in ECM remodelling, resulting in increased expression of tissue inhibitors of metalloproteinases (TIMPs) and the consequent inefficient removal of excess fibrillary collagen by metalloproteases (MMPs). Several other mediators have been proposed to be involved, including: (i) reactive oxygen species (ROS) released by injured hepatocytes or overproduced as a consequence of activation of NADPH-oxidase isoforms, associated to the interaction of growth factors, cytokines and other active peptides with their cognate receptors; (ii) aldehydic products like acetaldehyde (during ethanol metabolism) or 4-hydroxy-nonenal, the most relevant aldehydic end-product of lipid peroxidation; (iii) several growth factors, ligand peptides and the relative signalling pathways.
2. *Proliferation, survival, and migration.* Activated HSCs and myofibroblasts are highly proliferating cells because of increased availability of mitogenic growth factors released by surrounding cells in the profibrogenic environment and increased expression of the relative receptors. Indeed, the pro-fibrogenic microenvironment in CLD is characterized by a markedly increased expression of mitogens such as platelet-derived growth factor (PDGF), epidermal growth factor (EGF), thrombin, keratinocyte growth factor, connective tissue growth factor (CTGF), basic fibroblast growth factor (bFGF). Altogether, these mitogenic signals are also responsible for an increased cell survival and resistance to apoptotic stimuli, thus leading to a diffuse and persistent hyperplasia of pro-fibrogenic cells within the diseased liver tissue. Most part of the above growth factors and cytokines also promote cell migration according to concentration gradients which progressively develop in the pro-fibrogenic microenvironment and greatly contribute to tissue scarring.
3. *Pro-inflammatory role.* Activated HSCs are characterized by increased gene expression and release of proinflammatory mediators such as the chemokines CCL2 and CCL21 as well as IL-1β following activation of NLRP3 inflammasome. In these terms they can actively contribute to perpetuate inflammatory response and regulating and/or modulating interactions with cells of innate and adaptive immunity.
4. *Pro-angiogenic role*. Activated HSCs have been reported to synthetize and release proangiogenic mediators like vascular endothelial growth factor A

(VEGFA), Angiopoietin-1 or-2, PDGF-BB and hedgehog ligands. This feature strongly links neo-angiogenesis with the fibrogenic progression since HSCs express receptors for these soluble factors and support the formation of fibrotic septa typical of cirrhotic liver.

Specific Mechanism of Liver Fibrosis in ALD

ALD is characterized by a spectrum of histopathological lesions that range from simple steatosis to alcoholic hepatitis or alcoholic steatohepatitis (ASH). Tissue fibrosis and cirrhosis are key features with a significant risk to develop hepatocellular carcinoma (HCC). ASH is believed to be critical in driving a fast progression of ALD towards cirrhosis and to increase the risk of decompensation and liver failure [16]. ALD shares with non-alcoholic steatohepatitis (NASH) the pattern of perisinusoidal/pericellular fibrosis development and the key pro-fibrogenic role of HSCs [17, 18]. Interestingly, although alcohol abstinence can favour recovery from fatty liver, alcoholic hepatitis, and sinusoidal fibrosis, thus improving the outcome for cirrhosis, no significant regression of established cirrhosis in ALD patients has been convincingly documented [16].

The main pathogenetic determinants of liver fibrosis in ALD are illustrated in Fig. 54.1. In ALD, chronic hepatocellular injury and cell death are closely related to the oxidative ethanol metabolism by alcohol dehydrogenase and the ethanol inducible CYP2E1 cytochrome P450 isoform. This metabolic pathway leads to the

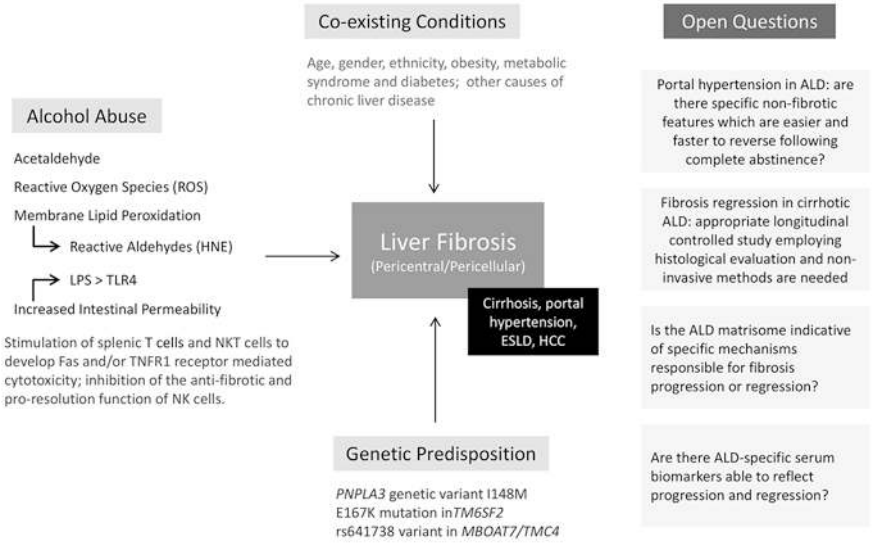

Fig. 54.1 Alcoholic liver fibrosis: pathogenetic determinants and open questions

formation of acetaldehyde and ROS, and to the consequent oxidative stress-mediated injury mainly through lipid peroxidation affecting the integrity of mitochondria and ER membranes [19–21].

Acetaldehyde is produced mainly by hepatocytes and acts on HSCs in a paracrine manner by directly inducing the expression of collagen type I in HSCs via activation of multiple signalling pathways and transcription factors. In addition, acetaldehyde reacts rapidly with cellular components, producing adducts such as malondialdehyde, 4-hydroxynonenal, and malondialdehyde-acetaldehyde, which further contribute to HSC activation and support their pro-fibrogenic role [22, 23]. ROS are the major determinants of ER stress and, together with acetaldehyde, of alcohol-induced steatosis. These features are associated to AMPK downregulation and inhibition of PPAR-α expression via SREBP1c stimulation [16]. DAMPs, released following necrotic cell death, trigger macrophage and neutrophil activation, in a context were senescence (via NK cells) and autophagy act as major regulators of liver inflammation [24].

A major role in the pathogenesis of ALD is also attributed to bacterial translocation due to increased gut permeability with increased circulating levels of LPS correlating with the severity of hepatic injury. LPS not only stimulates Kupffer cells to produce reactive oxygen species and cytokines, that subsequently promote activation of HSCs, but also directly activates HSCs via TLR4 [25]. LPS can also activate TLR4 signalling in liver sinusoidal endothelial cells with the promotion of angiogenesis. Collectively, TLR4 signalling in HSCs, Kupffer cells and endothelial cells provides a major contribution to inflammation, fibrogenesis and angiogenesis in ALD [26].

Adaptive immunity might also contribute to ALD progression, with chronic alcohol consumption leading to increased levels of antibodies directed against lipid peroxidation products. These antibodies can activate an adaptive immune response, likely by stimulating splenic T cells and NKT cells to develop Fas and/or TNFR1 receptor mediated cytotoxicity towards hepatocytes [27]. Finally, ethanol itself can suppress the anti-fibrotic and pro-resolution function of NK cells, which is believed to operate through IFN-γ secretion and the related elimination of activated HSC [28].

Liver Fibrosis in ALD: Incidence, Predisposition, and Natural History

There is a direct relationship between the quantity of alcohol consumed and the risk of ALD [29]. The risk of developing alcohol-related cirrhosis is increased with chronic alcohol consumption of 12–24 g/day compared to not drinking alcohol. Chronic alcohol abuse of more than 60 g/day, results in the development of fatty liver in most individuals with a progression to ASH in 10–35% [30]. In the context of ASH, fibrosis progression can be associated with episodes of alcoholic hepatitis which are key fibrogenesis accelerators. Overall, these numbers suggest that most

alcohol abusers will not develop severe disease with progression to advanced liver fibrosis and cirrhosis.

It is well established that age, gender, ethnicity and coexisting clinical conditions such as obesity and diabetes, are predisposing factors to the development of fibrosis and cirrhosis in ALD. Alcoholism is regarded to be a familial disorder since individuals with a familial history of alcohol abuse are more susceptible to develop alcohol dependence. Irrespective of this, the predisposition to develop ASH and fibrosis seems to be linked to genetic risk loci which are in common with NASH [31]. Along these lines, the non-synonymous genetic variant I148M in the *Patatin-like phospholipase domain containing-3* (*PNPLA3*) gene has emerged as the major risk factor for chronic liver disease progression in general, but particularly in ASH and NASH. In addition, a variant causing an amino acid change (E167K) in the *Transmembrane 6 superfamily member 2* (*TM6SF2*) gene, has been associated with the development and the severity of NASH and likely ASH. More recently, the rs641738 variant in the *Membrane bound O-acyltransferase domain containing 7-Transmembrane channel-like 4* (*MBOAT7/TMC4*) locus has been related to a higher risk of cirrhosis in alcohol abusers and with liver disease progression in NAFLD [32, 33].

It is increasingly established that these genetic variants favour fat accumulation in hepatocytes. In the case of ALD, prolonged ethanol exposure impairs insulin sensitivity with the consequent increase of free fatty acids from the adipose tissue and de novo lipogenesis. In this context, steatosis can be exacerbated by genetic modifiers such as the *PNPLA3 148 M* variant, which increases hepatic triglyceride content upon accumulation of the mutant protein on the surface of the lipid droplets. In addition, the 148 M variant impairs the amount of VLDL released, thus worsening fat deposition. Since the presence of these genetic risk loci is associated not only with the development of steatosis but also with the fibrogenic progression of chronic liver diseases, it is possible that they directly influence cellular and molecular pathways more relevant for fibrogenesis. For example, *PNPLA3* is strongly expressed and synthesized even in primary HSCs, and catalyses the hydrolysis of retinyl esters, regulating retinol release. The I148M could hamper the dismissal of retinol and lipids from intracellular lipid droplets, resulting in a more pronounced fibrogenic phenotype [34]. Current work from our laboratory, employing transcriptomic analysis, confirms that *PNPLA3 I148M* variant is associated with impaired mitochondrial function and antioxidant response in 3D cultured human HSCs and liver tissue from patients with NAFLD [35]. These findings tend to suggest that, in the presence of the *PNPLA3 I148M* variant, the handling of the antioxidant response in fibrogenic cells such as HSCs is markedly impaired, thus leading to an exaggerated fibrogenic response in the presence of acute and chronic oxidative stress conditions.

In addition to genetic determinants, epigenetic modifications have been identified in parenchymal and non-parenchymal cells in the liver and contribute to steatosis, inflammation, and oxidative stress following chronic exposure to excess ethanol. These modifications are hereditable and impact on gene expression without altering nucleotides sequence. Examples include DNA methylation, histone modifications and RNA silencing by microRNAs (miRNAs) [31].

In terms of natural history of ALD, progression from steatosis to cirrhosis is observed at 3%/year and from steatohepatitis (which is a histological diagnosis rather than the clinic syndrome of alcoholic hepatitis) to cirrhosis at 10%/year. This suggests that steatohepatitis is the progressive form of liver disease and is probably a prerequisite for the development of cirrhosis. The risk of HCC in ALD is lower than in cirrhosis due to chronic viral infection with a cumulative HCC incidence of 2.9 per 100 patient-years [36].

Reversibility of Fibrosis and Cirrhosis in ALD

The issue of fibrosis regression/reversibility of cirrhosis originates from evidence obtained in animal models upon the discontinuation of the cause of liver damage or following treatment with a putative antifibrotic agent. While tissue fibrosis in the absence of major changes in the hepatic angio-architecture is potentially reversible upon discontinuation of the cause of damage, the regression of cirrhosis is questionable. Regardless, evidence of cirrhotic regression has been reported in CLD of different etiologies. However, when performing an accurate analysis of the results of these studies, the only prudent conclusion is that, in most cases, there was a variable degree of fibrosis regression in cirrhosis but not a clear reversal of cirrhosis [37, 38]. In particular, there is no convincing evidence that major abnormalities of the intrahepatic vasculature typical of human cirrhotic liver can effectively regress. Along these lines, the available evidence suggests that the so-called veno-portal adhesions and evident "arterialized" sinusoids persist even in cases of extensive fibrosis regression [39].

Similarly, to what shown in NASH, it is also likely that in ALD the stage of fibrosis, and not the extent of fatty deposition and inflammatory infiltration, determines the long-term outcomes including hepatic and extra-hepatic clinical outcomes. However, this distinction is at least in part questionable in ALD, where the mainstay of treatment is alcohol abstinence. There is extensive evidence that abstinence can rapidly lead to total resolution of liver steatosis with a minimal or no impact on liver fibrosis. However, this is associated with evident clinical benefits particularly in patients with overt cirrhotic decompensation. Indeed, abstainers' probability of survival has been reported to be 87% compared to 55% in persistent drinkers within an observation period of about five year [40]. Therefore, the benefit of abstinence appears somehow disproportionated when compared, for example, to patients with HCV after obtaining a DAA-induced sustained viral response. This difference is unlikely to be due to a faster and more comprehensive regression of tissue fibrosis in ALD cirrhosis when compared to HCV-related cirrhosis, and possibly relies in a difference in the mechanisms responsible for the development and the aggravation of portal hypertension. Importantly, when compared to HCV or HBV cirrhosis, in ALD cirrhosis sinusoidal pressure is generally higher, hepatic venous pressure gradient better reflects portal pressure, the portal flow perfusing the liver is reduced despite an increase in liver weight, the prevalence of reversal portal blood flow is

higher, and a patent paraumbilical vein is a more common finding. In addition, signs of hyperdynamic circulations, such as an increased cardiac output and decreased systemic vascular resistance, are more pronounced. Besides, alcohol consumption can acutely increase portal pressure and portal-collateral blood flow. Alcoholic cardiomyopathy, another pathological consequence of prolonged alcohol misuse, may contribute to the hemodynamic changes occurring in alcohol-related cirrhosis [41]. Along these lines, Klein et al. showed that after 1 year of abstinence, portal vein pressure and the size of esophageal varices almost halved [42]. It is conceivable that abstinence, although not significantly affecting the amount and distribution of liver tissue fibrosis within the early time frame when the clinical improvement occurs, is able to reduce factors influencing portal pressure rapidly and efficiently in ALD cirrhosis such as tissue edema and hepatocyte swelling, which are characteristic of ALD and may represent rapidly reversible causes of intrahepatic resistance to portal inflow [43].

Conclusions

In conclusion, in the absence of other hepatic co-morbidities, liver fibrosis and cirrhosis due to alcohol abuse present with unique features which are relevant for the clinical management and the overall treatment. Of particular interest is the clinical evidence of a rapid and persistent clinic improvement observed in many patients following alcohol abstinence that may disentangle key tissue mechanisms of early resolution which are not necessarily related to significant fibrosis and cirrhosis regression but rather to unique features of portal hypertension in ALD. Along these lines, some of the key open questions concerning liver fibrosis in ALD are summarized in Fig. 54.1. See also related Chaps. 7, 49 and 53.

Chapter 55
Alterations in Methionine Metabolic Pathway in the Pathogenesis of Alcohol-Related Liver Disease

Kusum K. Kharbanda

Abstract Alcohol-related liver disease is a major worldwide health care problem. Findings in multiple laboratories, including ours, have demonstrated that ethanol consumption impairs several of the multiple steps in hepatic methionine metabolism, leading to progressive liver injury. Ethanol consumption predominantly inhibits the activity of the vital enzyme, methionine synthase, which catalyzes homocysteine remethylation to form methionine. By way of compensation, chronic ethanol consumption increases the activity of betaine homocysteine methyltransferase. This enzyme catalyzes an alternate pathway in methionine metabolism by utilizing intracellular betaine to remethylate homocysteine to form methionine, thereby maintaining adequate levels of S-adenosylmethionine, the key cellular methylating agent. However, after extended periods of ethanol feeding, alternate pathway for remethylation cannot be maintained, likely due to depletion in hepatic betaine levels. This condition, in turn, results in a decrease in hepatocyte S-adenosylmethionine, while increasing the levels of two toxic metabolites, S-adenosylhomocysteine and homocysteine. These changes cause serious functional consequences, which include lower activities of essential methylation reactions critical to normal liver function and activation of endoplasmic reticulum-dependent stress response. The ultimate outcome of these consequences is enhanced fat deposition, increased apoptosis, accumulation of damaged proteins and alterations in various signaling pathways, all of which, if sustained, cause progressive liver damage.

Of all the therapeutic modalities currently used to attenuate ethanol-induced liver injury, betaine has been shown to be one of the most effective in a variety of experimental models of liver disease. Betaine, as a methyl group donor, remethylates homocysteine, thereby removing both toxic metabolites (homocysteine and

S-adenosylhomocysteine) and restoring S-adenosylmethionine to reverse/prevent many hallmark features of alcohol-induced liver damage. Thus, betaine is a promising therapeutic agent that relieves methylation and other defects associated with alcohol use disorders.

Keywords Alcohol-related liver disease · Betaine · S-adenosylmethionine · S-adenosylhomocysteine · Homocysteine · Methyltransferases

Abbreviations

ALD	Alcohol-related liver disease
BHMT	Betaine-homocysteine-methyltransferase
CBS	Cystathionine-β-synthase
ER	Endoplasmic reticulum
GAMT	Guanidinoacetate methyltransferase
GCL	Glutamate cysteine ligase
GCLC	Catalytic subunit of GCL
GCLM	Modifier subunit of GCL
GSH	Glutathione
ICMT	Isoprenylcysteine carboxyl methyltransferase
K_i	Inhibitor affinity constant
K_m	Michaelis constant
MAT	Methionine adenosyltransferase
MS	Methionine synthase
MTHF	N^5-methyltetrahydrofolate
MTHFR	5,10 methylenetetrahydrofolate reductase
NAC	N-acetylcysteine
PEMT	Phosphatidylethanolamine methyltransferase
PIMT	Protein L-isoaspartate methyltransferase
PRMT	Protein arginine methyltransferase
SAH	S-adenosylhomocysteine
SAHH	S-adenosylhomocysteine hydrolase
SAM	S-adenosylmethionine
SREBP-1	Sterol regulatory element binding protein-1
VLDL	Very-low-density lipoprotein

Introduction

Alcohol-related liver disease (ALD) is one of the most serious medical consequences of ethanol misuse. Clinical and experimental models demonstrate that ethanol administration leads to many adverse functional and structural changes in

hepatic and extrahepatic organs and is associated with over 200 diseases [1]. Alcohol's hepatic effects are the most well characterized, as the liver is one of the most susceptible organs to its toxic effects. Alcohol (a.k.a. ethanol or ethyl alcohol) misuse produces a wide spectrum of hepatic lesions ranging from simple steatosis (fatty liver) that with continued drinking usually progresses to steatohepatitis, fibrosis, cirrhosis and even hepatocellular cancer [2]. These lesions reportedly can occur independently, in combination, or sequentially, with progression from steatosis through alcoholic hepatitis to established cirrhosis. Multiple factors and co-cofactors have been implicated in the pathogenesis of alcohol induced liver injury (reviewed in [3]). In particular, the interaction of ethanol with nutrients and/or their metabolism is believed to contribute significantly to the pathology observed in ALD. In this context, the effects of ethanol administration on methionine metabolism pathway have been studied, based on findings from the early 1950s, that ethanol consumption during dietary methionine or choline deficiency accelerates the onset of liver pathology. Therefore, investigations have focused on ethanol-induced perturbations in hepatic methionine metabolism to gain a clear understanding of the pathogenic mechanisms and to devise appropriate therapeutic interventions.

Methionine Metabolism

Methionine is an essential amino acid, well known for being the initiator (NH_2-terminal) amino acid during cellular protein synthesis. It also serves major roles through its metabolism, which fuels several metabolic pathways. Methionine metabolism is mainly comprised of the methionine cycle and the transsulfuration pathway.

The primary importance of the metabolic cycle is to conserve methionine so that S-adenosylmethionine (SAM), a universal methyl donor, can be generated. This reaction is catalyzed by methionine adenosyltransferases (MAT I and III) both liver-specific enzymes. The *MAT1A* and *MAT2A* genes, respectively encode the MAT catalytic subunits, α1 and α2. The α1 subunit organizes into dimers (MATIII) or tetramers (MATI). The α2 subunit is found in the MATII isoform. A third gene *MAT2B*, encodes beta, a regulatory subunit, that regulates MATII activity by lowering the inhibitor affinity constant (K_i) for SAM and the Michaelis constant (K_m) for methionine. The *MAT1A*-encoded enzyme (MATα1) is mainly expressed in liver hepatocytes and is associated with differentiated phenotype. The *MAT2A*-encoded isozyme (MATα2), expressed in non-parenchymal cells and extrahepatic tissues is associated with rapid growth and de-differentiation [4]. SAM, at its physiological concentration of 60 μM feedback inhibits MATα2 but it minimally inhibits MATα1 at this concentration. Therefore, MATα1 is considered responsible for maintaining adequate SAM levels, whereas MATα2 minimally contributes to the SAM pool in liver cells [4]. Under normal conditions, most of the 6–8 g of SAM generated per day in a healthy human adult serves as a methyl donor for more than 85 percent of all transmethylation reactions that occur in this organ. In SAM-dependent

methylation reactions, a methyl group is transferred from SAM to a variety of acceptors to form methylated acceptors that play vital roles in maintaining important functions in the liver. The other product of the methylation reaction is S-adenosylhomocysteine (SAH), which is hydrolyzed to adenosine and homocysteine by S-adenosylhomocysteine hydrolase (SAHH). Although the equilibrium constant of the SAHH-catalyzed reaction strongly favors SAH synthesis over homocysteine synthesis, the efficient removal of homocysteine and adenosine by multiple pathways (indicated in Fig. 55.1) allows homocysteine synthesis to proceed so that it is rapidly converted to methionine or to glutathione (GSH).

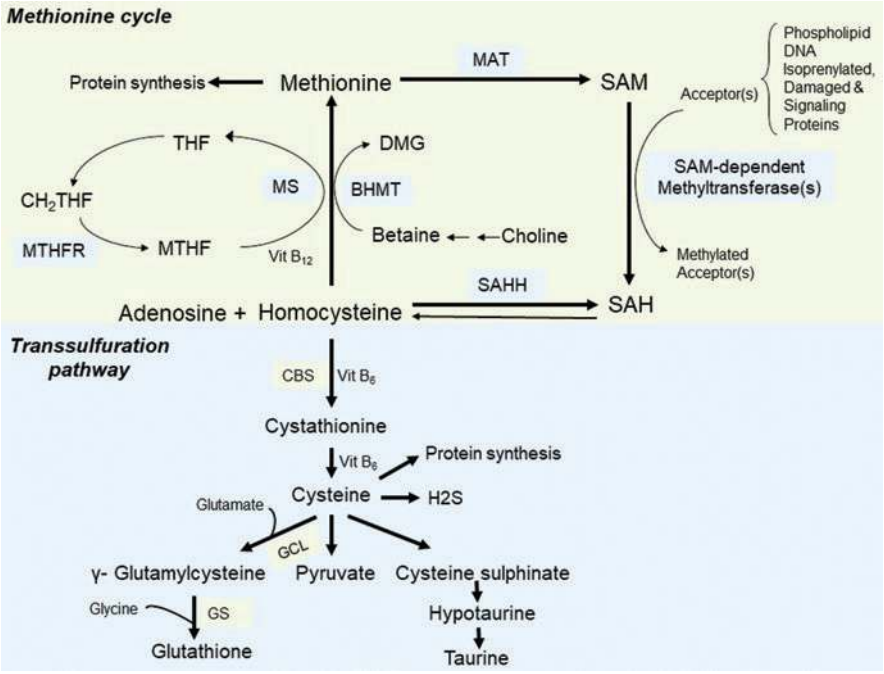

Fig. 55.1 Reactions of methionine metabolism in the liver. There are four main participants of this pathway, which are methionine, S-adenosylmethionine (SAM), S-adenosylhomocysteine (SAH) and homocysteine. Methionine adenosyltransferase (MAT) converts methionine to SAM, which then serves as a methyl-group donor substrate for methyltransferase-catalyzed reactions. The other product of these reactions is S-adenosylhomocysteine (SAH) which is hydrolyzed to adenosine and homocysteine by S-adenosylhomocysteine hydrolase (SAHH). The thermodynamics of this latter reaction favors the formation of SAH if the products (adenosine and homocysteine) are not removed. The methionine cycle is completed when homocysteine is remethylated back to methionine by B_{12}-dependent methionine synthase (MS) using 5-methyltetrahydrofolate (MTHF) as a substrate. MTHF is derived from dietary folate and from endogenous 5,10, methylenetetrahydrofolate (CH_2-THF) by way of its reductase, 5,10 methylenetetrahydrofolate reductase (MTHFR). Homocysteine can also be remethylated to methionine by an alternate pathway in the liver via betaine homocysteine methyltransferase (BHMT)-catalyzed reactions with the formation of dimethylglycine (DMG). Homocysteine can also be catabolized through the transsulfuration pathway initiated by B_6 dependent cystathionine β-synthase (CBS) to generate glutathione (GSH). See also related Appendix Figs. A.49, A.50, A.51 and A.52

There are two pathways in liver that participate equally in converting homocysteine to methionine [5]. One pathway utilizes N^5-methyltetrahydrofolate (MTHF), methionine synthase (MS) and vitamin $B_{12.}$ MTHF is derived from dietary folate and from endogenous 5,10, methylenetetrahydrofolate by way of its reductase, 5,10 methylenetetrahydrofolate reductase (MTHFR). Through the action of MS, a methyl group is transferred from MTHF to vitamin B_{12} to form methylcobalamine. The methylcobalamine in turn transfers the methyl group to homocysteine to produce methionine. In organs such as liver, kidney, pancreas, the eye lens, there is an additional pathway that is folate-independent for remethylating homocysteine. This pathway, catalyzed by betaine-homocysteine methyltransferase (BHMT), is of equal importance as the folate-dependent pathway in these organs. BHMT utilizes choline oxidation derivative, betaine, as a source of methyl group in the reaction to generate methionine and dimethylglycine [5].

Key enzymes of the methionine cycle (except MATIII) share several properties including a low K_m for sulphur-containing substrates, down-regulation by dietary methionine as well as inhibition by methionine and/or SAM. On the other hand, owing to the high K_m of MATIII for methionine, liver is the only tissue capable of synthesizing additional SAM when the concentration of methionine becomes excessive [6].

Homocysteine can also be utilized for the synthesis of cysteine and its derivatives, GSH, taurine and sulfate via the transsulfuration pathway. In this pathway, homocysteine is irreversibly catabolized by the action of cystathionine β-synthase (CBS). The tight regulation of homocysteine metabolism depends on different affinities for homocysteine by MS, BHMT and CBS. While MS and BHMT have high affinities for homocysteine ($K_m < 0.01$ mmol/L), CBS has a > 100-fold higher K_m (>1 mmol/L). Therefore, at low homocysteine concentrations, methionine conservation is favored whereas at higher homocysteine concentrations, the transsulfuration pathway is favored [7]. Through the action of CBS, homocysteine and vitamin B_6 are converted to cystathionine, which is further split to cysteine and α-ketobutyrate by cystathionase, another pyridoxal phosphate-containing enzyme. Cysteine is then incorporated into reduced glutathione (GSH) through several metabolic steps. A rate-limiting enzyme in GSH biosynthesis is glutamate cysteine ligase (GCL), which synthesizes gamma-glutamyl-cysteine. GCL holoenzyme is a heterodimer, consisting of the catalytic subunit (GCLC) and the modifier subunit, GCLM [8]. Gamma-glutamyl-cysteine may be produced by the holoenzyme as well as GCLC; however, the presence of GCLM decreases the K_m for ATP and glutamate to increase the K_{cat} for gamma-glutamyl-cysteine synthesis [8].

GSH is the most abundant non-protein thiol that protects cells against endogenous and exogenous electrophiles and it functions as a major antioxidant. The enzymes of the transsulfuration pathway also share common properties, such as the significantly higher K_m values for the sulphur substrate and induction of these enzymes by dietary methionine and SAM [6, 9].

Since transmethylation reactions and GSH levels regulate various cellular processes and antioxidant status, respectively, changes in methionine metabolism have far reaching detrimental effects in precipitating liver damage.

Defects in Hepatic Methionine Metabolic Pathway Following Ethanol Consumption

Using different animal models and human studies, it is widely recognized that multiple steps in hepatic methionine metabolism are influenced by ethanol consumption.

Effects on MS and BHMT: The first change that occurs by day 6 in livers of male rats fed the Lieber-DeCarli liquid ethanol diet is that MS activity declines by about 50 percent [10, 11]. The latter decrease still persists after 4 weeks of feeding [12]. Similar results have been reported by other investigators using other animal models of ethanol feeding, including female rats and micropigs [13–16]. There is also a decline in MS protein and mRNA that encodes MS in the livers of cirrhotic patients [17], and these changes have been reproduced in animal ethanol feeding models [18, 19]. Furthermore, *in vitro* studies have shown that the activity of purified MS enzyme is significantly and irreversibly inhibited by incubation with the primary ethanol metabolite, acetaldehyde [20]. This could be another contributing mechanism for a decrease in MS activity observed after alcohol exposure.

Another consequence of ethanol ingestion on the methionine metabolic pathway is that there is an adaptive increase in BHMT activity in male rats, which is seen as early as 1 week of ethanol feeding [21]. Subsequent studies showed that this rise in enzyme activity is due to an increase in BHMT protein and the mRNA that encodes BHMT [12]. Similarly, increases in BHMT mRNA are also reported from array analyses of human ALD livers [22]. However, this adaptive increase in BHMT is not observed in mouse models of ethanol exposure [23], which may be the reason for more severe liver injury seen in murine species with the same duration of ethanol exposure as that of rats [23].

The sustained increase in BHMT activity in livers of ethanol-fed rats is protective, in that, by utilizing endogenous betaine helps maintain hepatic SAM levels for up to 8 weeks of ethanol exposure [12, 24, 25]. This occurs despite impaired methionine production via the MS-catalyzed pathway. However, after 8 weeks of ethanol feeding SAM levels decline significantly [11]. This is likely due to depletion of intrahepatic betaine reserves [21, 24, 26] and hence the failure of induced levels of BHMT to compensate for impaired MS-mediated catalysis. Trimble *et al* also reported an adaptive increase in BHMT activity in rats on ethanol diet for 2 weeks but reported an earlier decrease in hepatic SAM after 2 weeks of ethanol feeding [13]. However, because female rats were utilized in their study, the discrepancy may be due to gender differences in hepatic betaine reserves and the inability of adaptive BHMT induction to maintain SAM levels. Rapid declines in SAM levels occur in ethanol-fed micropigs and mice, species in which ethanol-induced BHMT induction does not occur [15, 19]. Depletion of hepatic SAM is also reported in baboons following prolonged periods of ethanol feeding [27].

Effects on methionine adenosyltransferase (MAT) expression/activity: Declines in hepatic levels of SAM also occur because alcohol feeding reduces MAT

activity, the only enzyme that synthesizes SAM from methionine. Patients with alcoholic hepatitis and alcohol-related cirrhosis exhibit diminished hepatic *MAT1A* mRNA expression, lower MAT activity and impaired SAM biosynthesis [28–30]. Similar results were also reported for ethanol-fed micropigs [15, 16]. However, Alvarez *et al* reported normal levels of *MAT1A* mRNA in human cirrhotic livers, as compared to controls [31]. They postulated that post-translational modifications of critical cysteine residues (present only in liver specific MAT) by nitrosative or oxidative stress are responsible for lower MAT activities observed by other investigators. Contrary to these studies, a two-fold increase in hepatic mRNAs encoding both MAT1A and MAT2A occurs in rats after 9 weeks of intragastric ethanol feeding. But, despite similar increases in these mRNAs the protein levels of non-liver MATs were robustly induced [32]. Subsequent studies revealed that liver pathology is associated with a switch from MATα1 to MATα2, causing an overall decrease in MAT activity and SAM depletion [33]. The switch of MATα1 to MATα2 during alcohol exposure is associated with pro-proliferative states [33] that may promote the hepatocellular carcinoma phenotype [34]. Alcohol-induced loss of MATα1 may also have other detrimental consequences unrelated to decreased SAM levels. This is because (i) MATα1 targets the nuclear compartment where it acts as a transcriptional co-factor influencing the activity of several transcription factors [35, 36] and (ii) MATα1 negatively regulates CYP2E1 expression by promoting its degradation through the ubiquitin-proteasome system (UPS) [37]. MATα1 has recently been identified as a mitochondrial-targeted protein that is not only an additional source of mitochondrial SAM, but physically interacts with other mitochondrial proteins involved in the citric acid cycle, oxidative phosphorylation, and fatty acid β-oxidation to preserve mitochondrial function [30]. Ethanol depletes mitochondrial MATα1 via casein-kinase 2 (CK2)-mediated phosphorylation resulting in mitochondrial dysfunction and promoting ALD pathogenesis [30].

Effect on GSH levels and enzymes of transsulfuration pathway: The inactivation of liver-specific MAT has also been correlated to the depletion of reduced GSH levels. This has been observed in some models of ethanol-induced liver injury in rodents and baboons as well as in patients who are alcohol-dependent [27, 38, 39]. The decrease in GSH was suggested to be due to GSH efflux into plasma, decreased GSH synthesis, and accelerated GSH metabolism. Interestingly, there was no change in mRNA encoding CBS, the first enzyme of the transsulfuration pathway [19]. Rather, there was an increase in GCL activity [39]. Yet, reduced GSH levels were observed despite the induction in GCL activity and expression of the two GCL subunits [39]. This was believed to be caused by alterations in other factors important in determining the steady-state GSH level [39].

Notably, a marked and selective decrease in the intramitochondrial GSH pool was reported in rats chronically fed ethanol using either the Lieber-DeCarli diet for 4–6 weeks or by intragastric feeding for 3–16 weeks [40–46]. This reduction in GSH was attributed to defective transport of GSH into mitochondria following ethanol consumption that occurs preferentially in mitochondria of perivenous hepatocytes, which surround the central vein, an area of the liver lobule where

alcohol-induced liver injury initiates. The mechanism underlying the transport defect appears to be due to changes in kinetic parameters of the GSH carrier, which, in turn, is sensitive to changes in the physical properties and fluidity of the inner mitochondrial membrane [47, 48]. Further, *in vitro* studies documented that metabolically derived acetaldehyde causes depletion of mitochondrial GSH pools in a time- and dose-dependent fashion, without any change in cytosolic GSH levels [49]. These changes, like those reported in livers of long-term ethanol-fed rats [40–46], were ascribed to increased mitochondrial microviscosity due to enhanced cholesterol deposition. However, one laboratory reported no mitochondrial GSH depletion after chronic ethanol feeding [50], but instead, a rise in mitochondrial GSH. This finding was corroborated in unpublished work from Kharbanda laboratory [51]. Yet, others reported no change in mitochondrial GSH after alcohol exposure [19, 52]. Despite these controversial findings, likely related to ethanol exposure models, species and/or analytical assays, the pathogenic role of GSH depletion in ALD remains to be fully defined.

However, a series of recent studies, using a mouse model of GSH deficiency demonstrate that the status of chronic oxidant stress (resulting from GSH deficiency) may be beneficial. *GCLM*-null mice have about 15% of normal GSH levels in their livers [53] and despite exhibiting increased oxidant stress are resistant to alcohol-induced lipotoxicity [54]. Mechanistic studies revealed that *GCLM*-null mice exhibit constitutive activation of liver AMP-activated protein kinase (AMPK) signaling and nuclear factor-erythroid 2 related factor 2 antioxidant response. In addition, these mice display acetyl-CoA enrichment, diversion of acetyl-CoA flux from lipogenesis to alterative metabolic pathways, an elevation in glutamate levels, and inductions of the glucuronate pathway and nucleotide biosynthesis [54, 55]. Taken together, the molecular and metabolic features observed in the livers of these mice reflect low GSH-elicited hepatic reprogramming to cope with alcohol-induced cellular stress.

Effects on Homocysteine levels: Experimental and clinical studies of chronic alcohol consumption have consistently documented elevated plasma homocysteine levels [15, 19, 56–62]. That this increase was due to an ethanol-induced impairment in remethylation of homocysteine in hepatocytes was verified by observations of higher secretion by hepatocytes from ethanol-fed rats compared with those of pair-fed controls [63]. Additionally, when isolated hepatocytes were challenged with a methionine load, much higher levels of homocysteine were released from hepatocytes of ethanol-fed rats [63]. The latter-described conditions were used because supplemental dietary methionine elevates plasma homocysteine levels [64] and methionine loading in fasting patients has been used to stress the homocysteine remethylation pathways to detect disturbances in methionine metabolism [65].

Effects on Hepatic SAH Levels: Recent investigations have addressed whether ethanol consumption influences intrahepatic SAH levels. Results have consistently shown a ~ two-fold rise in hepatic SAH levels after ethanol exposure in several experimental models [12, 13, 15, 19, 32, 66, 67].

Detrimental Consequences of Altered Hepatic Methionine Metabolism

Of all the alterations in methionine metabolism by chronic ethanol consumption, the most detrimental changes in liver cells are: (i) increased levels of homocysteine and (ii) Reduction in SAM:SAH ratio, which occurs due to rising hepatocellular SAH levels, which may or may not be accompanied by decreases in hepatic SAM levels.

Defects in Crucial Methylation Reactions: The intracellular SAM:SAH ratio is an important metabolic indicator of cellular methylation status and is also called the methylation potential. A decrease in SAM:SAH ratio in the presence of increased SAH is associated with impaired activities of many of the 120 SAM-dependent methyltransferases [68]. These occur because SAH has a high affinity for binding to the catalytic region of many SAM-dependent methyltransferases, thereby enabling it to act as a potent end product inhibitor; the K_i values for SAH are in the submicromolar to low micromolar range. In fact, recorded K_i for SAH are often lower than the K_m for SAM for many of the methyltransferases [68]. The ethanol induced perturbations in the SAM to SAH levels specifically impairs methyltransferase(s)-catalyzed addition of a methyl group to diverse biologically active molecules that normally serve vital roles in biosynthesis, regulation, repair and detoxification [68]. This ultimately results in compromised liver function and progressive liver injury. Of particular interest is the inhibition of several important enzymes. These are phosphatidylethanolamine methyltransferase (PEMT), isoprenylcysteine carboxyl methyltransferase (ICMT), protein L-isoaspartate methyltransferase (PIMT), protein arginine methyltransferase (PRMT), guanidinoacetate methyltransferase (GAMT) and lysine methyltransferase. PEMT catalyzes the three sequential transfers of methyl groups to phosphatidylethanolamine to generate phosphatidylcholine, an important constituent of very-low-density lipoproteins [69–71]. ICMT is involved in carboxyl methylation of isoprenylated proteins [72], a step that is crucial for activation of these proteins to enable their participation in anti-apoptotic signaling pathways [73]. PIMT is required for catalyzing the repair of isoaspartyl sites of spontaneously damaged proteins, thereby preventing the consequences of their accumulation, as these atypical aspartyl residues compromise the biological function and modify the immunogenicity of the protein [74–77]. PRMT catalyzes the addition of monomethyl or dimethyl groups to the guanidine nitrogen atom of arginine. These methylated arginine proteins regulate protein-protein interactions and signaling events [78]. GAMT catalyzes the transfer of a methyl group from SAM to guanidinoacetate to form creatine in the liver [79] that is transported to distal "creatine requiring" organs where it serves as an important cytosolic phosphorylation potential buffer and energy shuttle [80]. Lysine amino acids on several histones and non-histone proteins are methylated by specific lysine methyltransferases, which modulate protein activity, stability, localization, and/or interaction, resulting in specific downstream signaling and biological outcomes [81]. Our studies have shown that decreased activities of these enzymes results in fat accumulation [12], elevated

apoptosis [82, 83], accumulation of damaged proteins [84, 85], altered signaling [86], reduced creatine synthesis [87] and impaired proteasome activity [88], respectively—all of which are characteristic features of alcohol-related liver injury.

Homocysteine Toxicity: High homocysteine levels contribute to a variety of diseases including cardiovascular disease, diabetes, seizures and neurodegenerative disorders [89]. However, recent studies indicate that SAH is a more reliable predictor of cardiovascular disease than homocysteine [90].

Regarding, its effect on the liver, Torres et al. suggested a possible role of homocysteine in liver fibrosis, based on their observations that increased collagen production and induction of tissue inhibitor of metalloproteinases occurs in cultured hepatic stellate cells exposed to homocysteine [91]. Seminal studies conducted ~20 years ago revealed that ethanol-induced hyperhomocysteinemia activates endoplasmic reticulum (ER) stress-dependent apoptosis and lipid synthesis in hepatocytes [59]. Of 1176 toxicology-related genes examined, they reported increases in glucose-regulated proteins-78 and -94, growth arrest/DNA damage-inducible protein 153 and caspase-12, all indicating that an ER stress response was prominent among the alcohol-responsive genes. Sterol regulatory element binding protein (SREBP-1) and HMG-CoA reductase were also enhanced by alcohol administration [59, 92]. Evidence from ethanol-fed micropigs also supports a correlation between the ER stress response and pathogenesis of alcohol-related liver injury [93]. Homocysteine also enhances production of several proinflammatory cytokines, it generates a procoagulant state and it increases oxidant stress [94–96]. All these hyperhomocysteinemia-induced changes may explain the cellular defects in the liver [19, 59, 97, 98] and brain atrophy observed with ethanol exposure [99].

Interestingly, in alcohol-dependent patients the plasma homocysteine concentration is associated with the degree of alcohol craving and hazardous and harmful patterns of its consumption [100]. Taken together, it appears that alcohol induced hyperhomocysteinemia in addition to causing organ toxicity simultaneously enhances alcohol consumption by increasing the severity of craving in a circular self-reinforcing mechanism.

One question that needs to be clarified is which of the two conditions (decreased intracellular SAM:SAH ratios or elevated homocysteine levels) is more critical to the pathogenesis of alcohol-related liver injury. Arguably, increases in both SAH and homocysteine following ethanol exposure are related. Higher homocysteine levels result in higher levels of SAH by mass action effects via the SAHH reaction, where the equilibrium favors the condensation of homocysteine and adenosine to form SAH (Fig. 55.1). However, some of the reported effects of these two conditions are diverse. Even though both hyperhomocysteinemia and altered SAM:SAH ratios appear to play a role in producing fat accumulation and apoptosis, previous research suggested differing mechanisms of action. Specifically, the altered SAM:SAH ratio appears to predominantly inhibit VLDL secretion via impaired PEMT activity, thereby generating steatosis [12, 101, 102], while hyperhomocysteinemia likely promotes fat accumulation by enhancing lipid synthesis [59].

We portend that elevated SAH levels have a greater impact in the pathogenesis of liver injury. This is because more than 85% of all SAM-dependent transmethylation

reactions occur in the liver. While not all methyltransferases are affected by low SAM:SAH ratios, some of the very important ones including PEMT, PIMT, PRMT, GAMT and lysine methyltransferases, have a lower K_i for SAH compared to the K_m for SAM [68]. All these methyltransferases have a broad range of functions [68], there is a myriad of detrimental consequences when their activities and that of many other critical SAM-dependent methyltransferase are inhibited in the liver. Indeed, the ethanol-induced decline in SAM:SAH ratio via inhibiting specific methyltransferases causes the generation of specific hallmark feature of ALD [12, 82–88, 101] as shown in Fig. 55.2. Further, studies have shown that ethanol-induced DNA and histone methylation changes alter the expressions of several susceptible genes [103–105] and epigenetic memory in relation to liver pathology and Mallory bodies [106, 107]. These studies add a new dimension to potential consequences of defective methylation.

The impact of elevated hepatocellular SAH was further demonstrated by conducting *in vitro* studies by exposing isolated hepatocytes to agents that selectively elevate intracellular SAH levels (without affecting homocysteine levels), such as after exposure to adenosine or deazaadenosine [82, 83]. In such a setting, increased

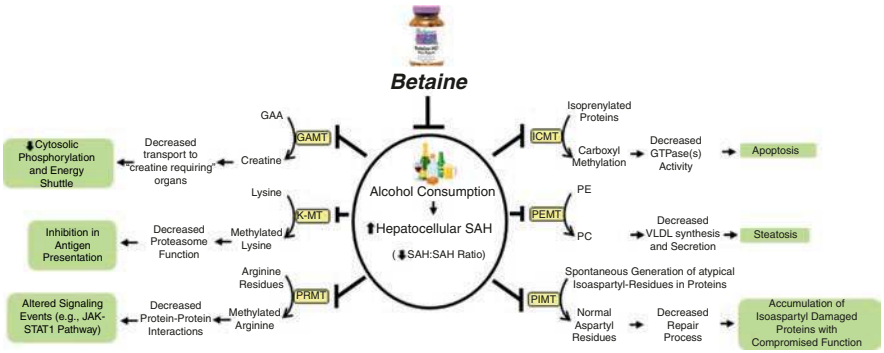

Fig. 55.2 Current scheme of our working hypothesis. Increased hepatocellular S-adenosylhomocysteine (SAH) levels generated by chronic ethanol exposure can negatively affect the activities of the several methyltransferases, phosphatidylethanolamine methyltransferase (PEMT), isoprenylcysteine carboxyl methyltransferase (ICMT), protein-isoaspartate methyltransferases (PIMT), protein arginine methyltransferase (PRMT), guanidinoacetate methyltransferase (GAMT) and lysine methyltransferase. These methylation defects, in turn, lower the synthesis and secretion of very-low-density lipoproteins (VLDL), impaired activation of GTPases, diminished protein repair processes, decreased protein-protein interactions due to reduced arginine methylation, reduced guanidinoacetate methylation and impaired lysine methylation on critical proteins (histones, proteasome), respectively. These deficiencies ultimately contribute to the development of steatosis (fatty liver), increased apoptosis (cell death), accumulation of isoaspartyl-damaged/dysfunctional proteins, altered signaling events, reduced creatine synthesis in the liver and its transport to "creatine-requiring" organs and impaired proteasome activity. Betaine administration prevents the increase in SAH and also prevents these ethanol-induced pathologies. The consequences of alterations in DNA and histone methylation, which influence gene expression and epigenetic memory as well as effects of elevated SAH on many other crucial methylation reactions are not depicted in this figure

apoptosis, steatosis, damaged protein accumulation, altered signaling, reduced creatine synthesis and impaired proteasome activity as seen after alcohol consumption, was observed [82, 83, 85–88]. Recent studies, using similar approaches to selectively elevate intracellular SAH levels, showed that the rise in intracellular triglycerides seen was accompanied by decreased lipolysis and increased expression of factors involved in lipogenesis and fatty acid mobilization [108].

Further support for the role of increased SAH in hepatic injury comes from case-reports of patients with inherited SAHH deficiency. The low liver SAHH activity in the first two cases was reported of brothers who exhibited over 100-fold higher SAH levels that accompanied histological macrovesicular steatosis, "piece-meal" necrosis, and signs of hepatitis and moderate fibrosis. These changes occurred despite only slight elevations in their plasma homocysteine levels [109, 110]. There are other case reports of two sisters with inherited SAHH deficiency that were born with fetal hydrops and had developmental abnormalities [111]. While SAHH deficiency typically presents in infancy, it can remain asymptomatic in childhood but when manifests in adulthood is associated with advanced liver damage, including early onset of HCC [112].

Interestingly, SAHH has recently been shown to have other functions including regulating DNA methylation maintenance at replication sites, mRNA cap methylation at transcriptionally active chromatin regions [113] and controlling circadian gene transcription by interacting with the core clock regulator [114]. This latter aspect illustrates a yet unexplored connection between alcohol-induced circadian rhythm disruption and SAHH.

Role of Altered Methionine Metabolism in Extrahepatic Organs that Promote ALD Pathogenesis

Recent studies demonstrate that ethanol-induced perturbation of hepatic methionine metabolism also occurs in adipose tissue and intestine, two organs whose dysfunction promotes and exacerbates ALD pathogenesis (reviewed in [115–118].

Ethanol consumption elevates adipose SAH levels and consequently decreases adipose SAM:SAH ratio [119, 120]. Mechanistic *in vitro* studies revealed that selective increase of SAH levels in adipocytes caused increased secretion of pro-inflammatory cytokines, accelerated lipolysis to increase the release of free fatty acids while decreasing the production and release of protective adipokines. All these effects mimic those seen after alcohol consumption *in vivo* [120]. Similarly, when intestinal cells were exposed to the intracellular SAH elevating agent, it caused a significant decrease in the localization of the important tight junction protein, occludin, to the apical junctional complex [121]. The consequent loss of tight junction integrity accompanied reduction in transepithelial electrical resistance and increased dextran influx—two endpoints frequently used for measuring epithelial

barrier function [122–124]. Collectively, these studies indicate that alcohol-induced alterations in the methionine metabolic pathway in adipose tissue and the intestine, contributes to the pathogenesis and progression of ALD.

Treatment Strategies

Elevated hepatic levels of SAH or homocysteine are both rectified by inclusion of betaine in the diet [63, 66]. These findings revealed that betaine is a promising therapeutic agent. Furthermore, betaine, by reversing/preventing elevated SAH and hyperhomocysteinemia, also prevents downstream consequences such as steatosis, apoptosis, accumulation of damaged proteins and signaling defects in the liver. These protective effects of betaine have been shown in a variety of rodent models of alcohol toxicity [12, 25, 59] as well as *in vitro* studies [63, 66, 82, 125]. While betaine is well known as an intracellular osmolyte [126], its protective effects in the liver are exerted through the BHMT-catalyzed reaction [82]. Although findings in other laboratories, including ours do not show restoration of GSH levels after betaine treatment [19, 51], there have been reports that betaine treatment may alleviate both the ethanol-induced decline of hepatic GSH and the elevation in oxidant stress [127–129].

Similarly, SAM administration reportedly prevents alcohol-related liver injury, which has been reported rather widely [130–134]. But there are several disadvantages of using SAM to ameliorate liver injury: Because of its rather high molecular weight and its low membrane permeability, SAM has very low bioavailability if given orally or parenterally [135]. Another disadvantage is SAM's prohibitive cost.

Additionally, it should be noted that studies in our laboratory demonstrate that betaine treatment generates SAM *in vivo,* eliminating the need for exogenous SAM supplementation. Specifically, we have shown that betaine feeding doubled hepatic levels of SAM in control rats and increased the levels of SAM four-fold in ethanol-fed rats [12]. This occurs despite continued MS inhibition by ethanol which is not improved by betaine treatment [25]. More important, unlike SAM treatment as reported above, the consumption of betaine by humans has had no adverse effects [126, 136].

Although antioxidants in general, have shown little benefit in the treatment of alcoholic hepatitis, a double-blind randomized control trial of patients with severe alcoholic hepatitis treated with N-acetylcysteine (NAC) and corticosteroids, demonstrated improved 28-day survival, primarily related to lower infection rates. However, no long-term benefits were observed [137]. A meta-analysis of 22 randomized control trials noted that the addition of NAC to corticosteroids may be superior to corticosteroids alone for reducing short-term mortality [138]. Further studies using NAC in alcoholic hepatitis are reportedly underway.

Summary and Future Studies

Ethanol consumption alters multiple steps in hepatic methionine metabolism. These alterations result principally in a decrease in the vital liver metabolite, SAM, while two toxic metabolites, homocysteine and SAH rise. The decline in SAM and increase in SAH leads to a plethora of detrimental functional consequences in the liver particularly those affecting hepatic methylation reactions. Betaine has the unique ability to remethylate homocysteine, thereby restoring hepatic SAM levels and lowering SAH levels. Thus, by correcting defective methylation and decreasing homocysteine levels, betaine prevents or attenuates alcohol-induced steatosis, apoptosis, protein damage, and altered signaling events. In addition, betaine treatment can also prevent ethanol-induced adipose dysfunction and increased gut barrier permeability [139].

To date, no clinical trials have been conducted for treatment of ALD with betaine. However, SAM has been used in several clinical studies, but the outcomes have been unclear and its efficacy in liver diseases continues to be debated [140, 141]. In the future, new treatment modalities for ALD should consider supplementation with betaine which will likely prove to be a promising protective agent. For further reading, see also related chapters encompass Chaps. 49, 58 and 66 on e.g. bone marrow toxicity and the management of alcoholic hepatitis.

Chapter 56
Mitochondria and Alcohol

Sandra Torres, Paula Segalés, Laura Conde de la Rosa, Carmen Garcia-Ruiz, and Jose C. Fernandez-Checa

Abstract Alcohol-related liver disease (ALD) is a spectrum of liver alterations both at the structural and functional levels that begins with the deposition of lipids in hepatocytes defining the first stage of steatosis, which can progress to alcohol-related steatohepatitis and culminate in cirrhosis and hepatocellular carcinoma. The deleterious effects of alcohol consumption in liver function are determined by the oxidative metabolism of ethanol, which triggers multiple mechanisms, including oxidative and endoplasmic reticulum stress, disruption of methionine metabolism and alterations in mitochondrial function that contribute to the progression of ALD. Being mitochondria essential hubs for energy production and metabolism, alterations of mitochondria at the structural and functional levels are considered a driving force for the onset of steatosis and its progression towards more advanced stages of ALD. Thus, understanding the mechanisms that trigger the alterations of mitochondrial function may open novel opportunities for the identification of poten-

tial therapies to manage ALD. In the present chapter, we briefly outline the players involved in mitochondrial dysfunction and their impact in ALD, which may stand as promising new targets for intervention.

Keywords Alcohol · Hepatotoxicity · Mitochondria · Oxidative stress · Glutathione

Abbreviations

OGC, SLC25A11	2-oxoglutarate
APAP	Acetaminophen
ASMase	Acid sphingomyelinase
ATP	Adenosine triphosphate
ADH	Alcohol dehydrogenase
ASH	Alcoholic steatohepatitis
ALD	Alcohol-related liver disease
ALDH2	Aldehyde dehydrogenase 2
AMPK	AMP-activated protein kinase
CO_2	Carbon dioxide
CK2	Casein kinase
CYP2E1	Cytochrome P450 2E1
CYP27A1	Cytochrome P450 family 27 subfamily a member 1
CYP7A1	Cytochrome P450 family 7 subfamily a member 1
DAMPs	Damage-associated molecular patterns
DIC	Dicarboxylate
DRP1	Dynamin-related protein 1
ETC	Electron transport chain
ER	Endoplasmic reticulum
ERAD	ER-associated degradation
FA	Fatty acid
GI	Gastrointestinal
GSH	Glutathione
Gpx	Glutathione peroxidase
HO-1	Heme oxygenase
HSC	Hepatic stellate cell
HCC	Hepatocellular carcinoma
HMGB1	High-mobility group box 1 protein
H_2O_2	Hydrogen peroxide
HHCy	Hyperhomocysteinemia
iNOS	Inducible nitric oxide synthase
IMM	Inner mitochondrial membrane

ICAM-1	Intercellular adhesion molecule-1
IL	Interleukin
IMS	Intermembrane space
KCs	Kupffer cell
LPS	Lipopolysaccharides
LDL	Low-density lipoprotein
mTOR	Mammalian target of rapamycin
MAT	Methionine adenosyl transferase
MS	Methionine synthase
MEOS	Microsomal Ethanol-Oxidizing System
MAMs	Mitochondria-associated membranes
mtDNA	Mitochondrial DNA
mGSH	Mitochondrial GSH
Mfn1/2	Mitofusin 1 and 2
MSP	Mitochondria shaping proteins
NAC	N-acetyl-L-cysteine
NAD^+	Nicotinamide adenine dinucleotide
NASH	Nonalcoholic steatohepatitis
Nrf-2	Nuclear factor erythroid 2-related factor 2
Opa-1	Optic atrophy 1
OMM	Outer mitochondrial membrane
OXPHOS	Oxidative phosphorylation
O_2	Oxygen
PA	Palmitic acid
PAMPs	Pathogen-associated molecular patterns
PP	Periportal
PV	Perivenous
Prx	Peroxiredoxin
PPARs	Peroxisome proliferator-activated receptors
PIN1	Peptidyl-prolyl cis/trans isomerase
(PAI)-1	Plasminogen activator inhibitor
PDGF	Platelet derived growth factor
ROS	Reactive oxygen species
SAM	S-adenosylmethionine
StARD1	Steroidogenic acute regulatory protein 1
SREBPs	Sterol regulatory element-binding proteins
SOD	Superoxide dismutase
Trx2	Thioredoxin2
TGF-β	Transforming growth factor beta
TNFα	Tumor necrosis factor alpha
UPR	Unfolded protein response
VLDL	Very-low-density lipoprotein
VDAC	Voltage-dependent ion channel

Introduction

Alcohol-related liver disease (ALD) is the most prevalent type of chronic liver disease in the world (see also part I of the book). Disproportionate alcohol drinking is a global healthcare concern with immense social, economic, and clinical consequences, accounting for up to three million deaths per year worldwide according to the World Health Organization. Excessive alcohol consumption over decades harms practically every organ in the body. However, the liver undergoes the earliest and the greatest tissue impairment grade from excessive drinking since it is the principal organ involved in ethanol metabolism [1]. Ethanol is an important source of energy, with 7.1 kcal (29.7 kJ) per gram, an amount that exceeds the energy content of carbohydrates or proteins. On average, ethanol represents half of the caloric intake of a chronic drinker, displacing normal nutrients, which causes malnutrition, and vitamin deficiencies. In addition, malnutrition is also due to malabsorption and nutrient impaired hepatic metabolism, as a consequence of a direct hepatotoxic effect of ethanol, as recognized over 6 decades ago [2].

Although ALD pathogenesis is still incompletely known, which has limited the availability of effective therapies, there have been important milestones in the identification of mechanisms involved in ALD progression, from the initial stage of hepatic steatosis towards its final stage of hepatocellular carcinoma (HCC). The oxidative metabolism of alcohol triggers a variety of players that elicit an unbalance between the biogenesis and catabolism of lipids, what translates in the initial stage of hepatic steatosis, that along with other mechanisms, such as oxidative and endoplasmic reticulum (ER) stress, disruption of methionine metabolism and mitochondrial dysfunction, contribute to the development of advanced stages of ALD, such as alcohol-related steatohepatitis (ASH), characterized by hepatocellular injury, inflammation and fibrosis. The combination of these ethanol-derived mechanisms with other players, including innate immunity, epigenetics and inflammasome activation drive the onset towards the final stage of ALD, such as alcohol-related HCC development.

Clinical and Histological Characteristics of ALD

Stages

ALD is worldwide recognized as a complex disease provoked by alcohol excessive intake over years comprising a range of stages including simple steatosis, steatohepatitis, cirrhosis and end-stage HCC (Fig. 56.1), although an overlap between them can generally be observed [3–5].

An accumulation of fat in the liver is induced by just a few days of drinking large volumes of alcohol. Fatty liver, the earliest liver response to alcohol abuse, rarely

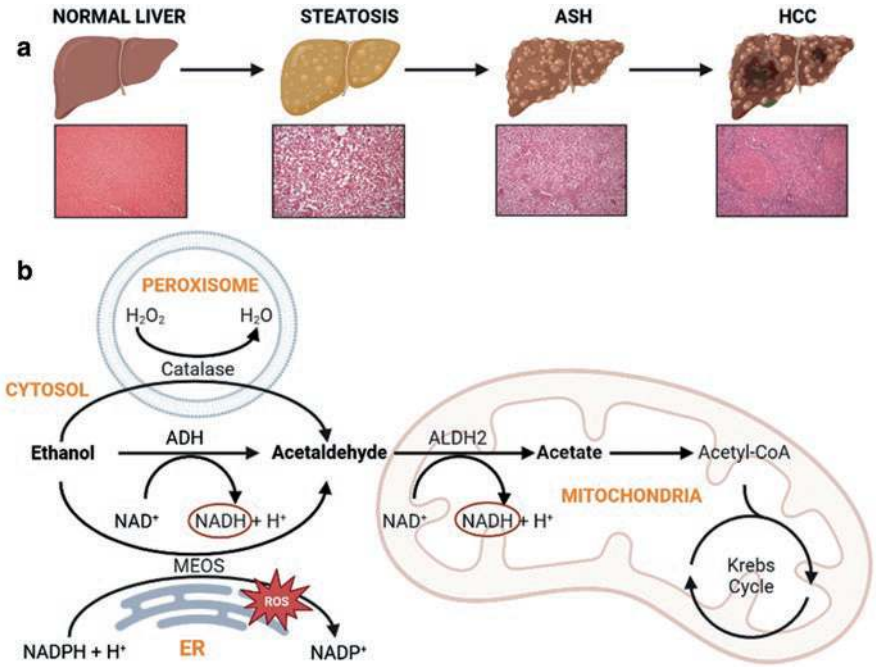

Fig. 56.1 (**a**) Stages of ALD. Alcohol intake induces a wide spectrum of hepatic lesions. Fatty liver (steatosis) is the earliest liver response to alcohol abuse. Although it develops in more than 90% of heavy drinkers, rarely causes any symptoms and it is often reversible with abstinence or moderation in alcohol intake. Continued alcohol consumption induces the progression of ALD to liver inflammation (ASH), fibrosis and even HCC. (**b**) Alcohol metabolism pathways in hepatocytes. Ethanol is metabolized mainly in hepatocytes of the liver. The enzymes ADH, the main ethanol detoxification pathway located in the cytosol, and ALDH2, located in the mitochondria, catalyze sequential oxidations, which convert ethanol to acetate, forming two mole equivalents of NADH. The major inducible pathway in ethanol metabolism is the CYP2E1, a major component of the MEOS, located in the endoplasmic reticulum, which oxidizes ethanol in the presence of molecular oxygen (O_2) to acetaldehyde and transforms reduced NAD phosphate (NADPH) to NADP+ and generates water. Peroxisomal catalase is a minor hepatic pathway of ethanol metabolism that utilizes H_2O_2 to oxidize ethanol to acetaldehyde and water. Ethanol metabolism elevates ROS production, which contribute to oxidative stress and can interact with other cellular molecules forming adducts (proteins, lipids or DNA). *ADH* alcohol dehydrogenase, *ALDH2* aldehyde dehydrogenase 2, *ASH* alcoholic steatohepatitis, *CYP2E1* cytochrome P450 2E1, *H_2O_2* hydrogen peroxide, *HCC* hepatocellular carcinoma, *MEOS* microsomal ethanol-oxidizing system, *ROS* reactive oxygen species

causes any symptoms and it is often reversible with abstinence or moderation in alcohol intake [6]. Alcohol promotes hepatic fatty acid (FA) uptake, FA oxidation impairment, induction of *de novo* lipid synthesis and neutral lipid storage, inhibition of lipid export and lipid droplet catabolism, driving hepatic fat accumulation.

Alcoholic steatohepatitis (ASH) is a potentially serious condition that can be caused by alcohol after years of heavy consumption. It is associated with hepatocyte ballooning and reactive oxygen species (ROS) production [7, 8]. In addition, excessive alcohol intake induces intestinal bacterial overgrowth, endotoxins accumulation and increased intestinal permeability by impairing the intestinal barrier function, which allow the translocation of bacterial products from the intestine to the liver, driving the activation and recruitment of inflammatory cells to this organ, and increasing inflammation. Approximately 20–40% of patients with steatosis present liver biopsies with additional histological changes showing hepatocellular damage accompanied with fibrosis and inflammation, indicative of ASH. Unlike ASH, which can be reversible upon abstinence or moderating alcohol drinking, severe alcoholic hepatitis (AH or sAH), characterized by massive inflammation and multiple organ failure is a life-threatening illness with a high probability of death within a few months of diagnosis [9, 10].

Alcohol-related liver fibrosis and cirrhosis are advanced stages in ALD and occur when the liver has been inflamed for a long period of time, driving to scarring and loss of function. Excessive and long-term alcohol oxidation damages hepatocytes structure, causing microtubule dysfunction and disruption in the transport of nutrients. Moreover, hepatic stellate cell (HSC) activation is a key step in the pathogenesis of alcoholic liver fibrosis, in which collagen synthesis is induced and extracellular matrix proteins accumulate. This event compromises the ability of the liver to detoxify and metabolize xenobiotics and it becomes more sensitive to medications and continued alcohol drinking. Cirrhosis stage is irreversible, and although exacerbated organ damage can be controlled by preventing continued alcohol intake, the only treatment available to increase life-expectancy is liver transplantation [11]. The onset of alcohol-related cirrhosis with obesity, diabetes and active alcohol drinking or viral-hepatitis increases the odds of developing ALD-driven HCC [12–15].

Risk Factors

The probability to develop ALD increases with augmenting daily alcohol intake with a threshold of 12–22 g/day in women and 24–46 g/day in men [16], although correlation is not dose-dependent [17]. Among heavy drinkers up to 90% develop steatosis, but only a minority progresses to steatohepatitis, and 10–20% eventually suffer cirrhosis. Many factors influence the development of ALD, in particular age [18], gender, pattern, duration and type of alcoholic beverage consumed, and ethnicity factors [19–22]. Other associated risk factors include nutritional factors [23], obesity [24], iron overload, concomitant infection with viral hepatitis [15], smoking and genetic factors. More details are find in other parts of the book, especially in Part IV.

Hepatic Zonal Pattern in ALD

Several liver pathologies display specific patterns that can be attributed to the functional zonation of hepatocytes [25]. ALD develops in a zonal pattern beginning from the pericentral or perivenous (PV) area, which disseminate into the periportal (PP) zone as the disease progresses [26–28]. ALD progression starts with the accumulation of lipid droplets, promoting hepatic steatosis. Alcohol-promoted lipid accumulation might be faster in PV regions than in PP zone due to the increased expression of lipogenesis genes and reduced expression of FA β-oxidation genes in PV hepatocytes compared to those in PP regions [25, 28]. Accordingly, in models of ethanol intoxication in rats, the overload of lipid droplets is detected in first place in the PV zone compared to the PP area [29]. Analogous PV zonation patterns have been observed in human ALD patients [30]. Furthermore, an elevated activity of the key alcohol metabolizing enzymes alcohol dehydrogenase (ADH) and cytochrome P450 2E1 (CYP2E1) has been found in the PV zone, not only in basal conditions but also after long-term alcohol intake [31]. Thus, alcohol detoxification principally occurs in the PV area being the most affected zone in early stages of the disease. Thus, it is of critical importance to consider liver zonation when investigating specific liver diseases.

Hepatic Alcohol Metabolism and Pathological Effects

Alcohol Metabolism

Alcohol is a polar substance soluble in both water and lipid. After being consumed, it is absorbed through the gastrointestinal (GI) tract into the blood circulation. Following absorption in the GI, only 2–10% of total consumed alcohol is directly removed through the lungs, kidneys and sweat in its untransformed form. Thus, more than 95% of the alcohol ingested will experience metabolic processing in the liver.

Hepatocytes are responsible for alcohol metabolism, as they possess the principal ethanol oxidizing enzymes, ADH, which resides in the cytosol, and CYP2E1, which is located in the smooth ER. Hepatocytes also express high catalase levels, an enzyme located in peroxisomes.

In the liver, ADH is the most catalytically effective ethanol-oxidizing enzyme. ADH oxidizes ethanol using nicotinamide adenine dinucleotide (NAD+) as a cofactor, producing reduced NAD+ (NADH) and acetaldehyde, which is highly reactive and toxic. Acetaldehyde can covalently bind to proteins [32], lipids [33], and nucleic acids [34] to produce acetaldehyde adducts, which, in turn, can affect the structure and function of these macromolecules [35, 36], promoting mutations and carcinogenesis [37]. To minimize acetaldehyde toxicity, hepatocytes quickly oxidize it to acetate via aldehyde dehydrogenase 2 (ALDH2) inside mitochondria, producing

NADH and acetate. The elevated production of NADH by both ADH and ALDH2 reduces the cellular redox potential (intra hepatocyte NAD+ /NADH ratio), which alters from oxidative metabolism toward reductive synthesis, favoring the formation of FAs and causing fatty liver development [38].

Microsomal Ethanol-Oxidizing System (MEOS) is an alternative pathway to oxidize ethanol to acetaldehyde, which depends on cytochrome P450 (CYP450) enzymes, particularly CYP2E1. The catalytic efficiency of CYP2E1 is substantially slower than that of ADH, but it has a ten-fold higher affinity towards ethanol. Under normal physiological conditions, CYP2E1 oxidizes a small amount of ethanol (about 10%) into acetaldehyde. Remarkably, CYP2E1 is an inducible enzyme and its hepatocellular content increases during chronic ethanol intake [39, 40], accumulating in the smooth ER. CYP2E1 induction has diverse important effects in heavy drinkers, as they develop a metabolic tolerance to alcohol. In addition, together with acetaldehyde CYP2E1 also generates ROS, such us hydroxyethyl radicals, superoxide anions and hydroxyl radicals. Constant ROS production overcomes the detoxifying capacity of the liver driving to oxidative stress. Indeed, different animal studies described that chronic ethanol intake reduces the activities and/or amount of diverse antioxidant enzymes [41–43]. The dynamic imbalance of antioxidant systems affects the crucial antioxidant regulatory gene nuclear factor erythroid 2-related factor 2 (Nrf-2) in ALD [44], superoxide dismutase (SOD), glutathione (GSH), catalase, peroxidase-1, metallothionein, and heme oxygenase (HO-1) [45, 46]. Moreover, ROS endure secondary reactions with proteins and unsaturated lipids, which, in turn, react with each other and acetaldehyde exacerbating oxidative stress and triggering an immune response [47, 48]. Of clinical relevance, the induction of CYP2E1 by chronic alcohol drinking can accelerate/enhance xenobiotic metabolism, especially from drugs that are actively biotransformed by the CYP2E1 like acetaminophen (APAP) [49]. This convergence of alcohol and APAP on CYP2E1 metabolism implies that alcohol drinking can sensitize to APAP hepatotoxicity.

The third metabolic pathway system that relies on NADPH for alcohol oxidative metabolism to acetaldehyde involves the enzyme catalase, which, in the presence of ethanol, uses hydrogen peroxide (H_2O_2) to form acetaldehyde [50, 51]. Ethanol metabolizing role of catalase is minor in the liver, but has an important function in the brain [52] (Fig. 56.1).

Pathological Effects

The pathogenesis of ALD is multifactorial and involves several events such as steatosis, hepatotoxicity and inflammation. Chronic alcoholic consumption affects primarily hepatocytes and other liver cells, such as activated HSCs that proliferate and produce collagen that contributes to liver alcoholic fibrosis [53] (Fig. 56.2). In the following section, we will briefly describe the main effects of ethanol metabolism.

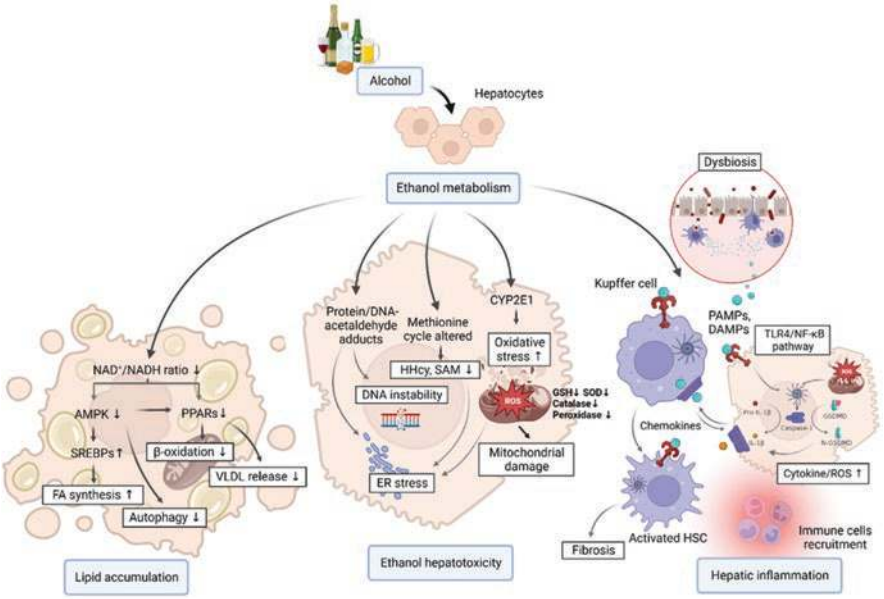

Fig. 56.2 Mechanisms involved in ALD. Lipid accumulation, hepatotoxicity and inflammation are the multiple effects involved in the development of ALD. Ethanol metabolism produces a decrease in NAD^+ /NADH ratio, an increment of SREBPs, and a reduction of AMPK, PPARs and autophagy pathways, leading to FA synthesis, and a decrease of beta-oxidation and VLDL release in hepatocytes. Furthermore, ethanol-induced protein and DNA-acetaldehyde adducts formation causes DNA instability and ER stress. In addition, the methionine cycle is altered with the reduction of SAM levels and HHcy. Moreover, the increase of CYP2E1 expression produces an increment of ROS and ends up in mitochondrial damage. Not only the hepatocytes are affected by the alcohol metabolism, the enteric dysbiosis produces PAMPs and DAMPs that activate KCs and HSC cells and cause the recruitment of immune cells producing hepatic inflammation that can progress to advanced stages of ALD. *ALD* alcohol-related liver disease, *AMPK* AMP-activated protein kinase, *CYP2E1* cytochrome P450 2E1, *DAMPs* damage-associated molecular patterns, *ER* endoplasmic reticulum, *FA* fatty acid, *HHCy* hyperhomocysteinemia, *HSCs* hepatic stellate cells, *KCs* kupffer cells, *PAMPs* pathogen-associated molecular patterns, *PPARs* peroxisome proliferator-activated receptors, *ROS* reactive oxygen species, *SAM* S-adenosylmethionine, *SREBPs* sterol regulatory element-binding proteins, *VLDL* very-low-density lipoprotein

Lipid Accumulation

One of the earliest responses of the liver during alcohol consumption is the lipid accumulation that involves molecules and regulatory pathways related to lipid synthesis, oxidation and very-low-density lipoprotein (VLDL) release [51]. Among the myriad well-known key players in lipid alteration by alcohol abuse are the decrease in NAD^+/NADH ratio, the increment of the expression of sterol regulatory element-binding proteins (SREBPs), the downregulation of peroxisome proliferator-activated receptors (PPARs) and AMP-activated protein kinase (AMPK), and in long-term ethanol consumption a decrease in autophagy is promoted.

A decreased NAD^+/NADH ratio is a main direct consequence of alcohol intake. The coenzyme NAD^+ is used as a cofactor for the transfer of hydrogen in the oxidation of ethanol to acetaldehyde and acetate and produces NADH. Since many of the enzymes of FA oxidation are pyridine nucleotide dependent NAD^+/NADH ratio promotes triglyceride accumulation in the liver by reducing FA oxidation and enhancing FA synthesis [54–56].

Another ethanol-impaired signaling pathway involved in hepatic steatosis is the downregulation of PPARs. PPARs are members of steroid/retinoid nuclear receptor superfamily involved in the regulation of lipid and lipoprotein levels, and consequently the transcription of genes involved in the esterification and VLDL release to be oxidized in the mitochondria, peroxisomes and microsomes. Once the heterodimer with retinoid-X receptor is formed, PPARα binds to DNA and interferes in the transcriptional activity and decreases PPARα target genes related to VLDL export, overall leading to the accumulation of FAs [57–60].

Another important player in ethanol-induced steatosis is the induction of SREBPs. SREBPs are a family of transcription factors that regulate the synthesis of FAs, triglycerides and cholesterol. These transcription factors undergo a proteolytic processing involving a crosstalk between the ER and Golgi. SREBPs are ER-resident proteins and ER stress caused by alcohol intake (see below) promotes the generation of mature SREPPs. SREBP-1 plays an important role regulating the genes of hepatic triglyceride synthesis [61] and SREBP-2 is responsible for regulating genes of cholesterol metabolism [62]. Activation of SREBP-1 by ethanol feeding and the production of acetaldehyde promote the synthesis of FAs in the liver which results in FA accumulation in hepatocytes [61, 63].

In addition to the outcomes described above, through the downregulation of AMPK, chronic ethanol exposure downregulates PPARα, decreasing FAs beta-oxidation and inflammation by acting on acetyl Coenzyme A carboxylase and carnitine palmitoyltransferase [64], which complement the lipid storage effect of alcohol intake [65–67]. Moreover, AMPK can be activated by ROS and promotes cell survival by inducing autophagy, mitochondrial biogenesis and increasing the expression of the genes involved in antioxidant response. Autophagy is a genetically programmed degradation of damaged organelles and proteins, with mammalian target of rapamycin (mTOR) as a key regulator [68, 69]. Chronic ethanol feeding decreases AMPK and thus, reduces autophagy activity and consequently it produces lipid accumulation through an impaired lipophagy [70, 71].

Hepatic Inflammation

Hepatic inflammation has a central role in the pathogenesis of ALD. Ethanol feeding causes imbalance of intestinal flora that produces gut-derived pathogen-associated molecular patterns (PAMPs), such as lipopolysaccharides (LPS), from the bacterial overgrowth and enteric dysbiosis. Alcohol consumption also causes hepatocyte death, producing damage-associated molecular patterns (DAMPs), such

as mitochondrial DNA (mtDNA) and high-mobility group box 1 protein (HMGB1) [72]. DAMPs and PAMPs activate the innate immunity and the release of cytokines and chemokines from KCs, macrophages and neutrophils. Aside from this, the alcohol metabolism occurs primarily in the gram-negative bacteria and intestinal epithelial cells, leading to acetaldehyde accumulation, which damages the intestinal barrier. In addition, alcohol also increases adaptive immune responses such as protein adducts with acetaldehyde and ROS.

PAMPs derived from gut microbiota and DAMPs from damaged cells are recognized by Toll-like receptors and stimulate the production of a large number of nuclear transcription factors (e.g., NF-κB) and inflammatory cytokines, but also induce overproduction of NO by the inducible nitric oxide synthase (iNOS), and this disrupts the barrier integrity and its function [73]. The increase of endotoxins that can across the intestinal barrier can activate KCs, HSC and other inflammatory cells, which produce pro-inflammatory cytokines such as tumor necrosis factor alpha (TNFα), interleukin IL-1β, IL-17, IL-6, MCP1, CXC chemokines, osteopontin and inflammatory factors and free radicals [3]. The neutrophils migration is a histological hallmark in ALD, promoted by the chemokines produced by KCs and HSC, which have an increased expression of intercellular adhesion molecule-1 (ICAM-1) on the surface and is accompanied by E-selectin expression on sinusoidal endothelial cells [74]. The recruitment of neutrophils by KCs, induces the release of key fibrosis markers from HSC, such as transforming growth factor beta (TGF-β), platelet derived growth factor (PDGF), IL-1β and TNFα, among them, overall leading to a fibrogenic response, mitochondrial dysfunction, intrahepatic inflammation and hepatocyte damage [75, 76].

Mechanisms of ethanol's Deleterious Effects

Chronic alcohol consumption affects different molecules, pathways and subcellular compartments that play significant roles in alcohol-derived hepatotoxicity. Acetaldehyde is the first metabolite derived from the oxidative metabolism of ethanol. Acetaldehyde is extremely toxic and a carcinogen by its reactivity to form adducts with proteins and DNA, causing damage to hepatocytes. Acetaldehyde can bind to structural and functional proteins, such as albumin, tubulin, collagen and microsomal enzymes, leading to a defective assembly of microtubules, protein excretion and enzymatic activity. In advanced ALD, these protein-acetaldehyde adducts are found in HSC and myofibroblasts, being associated with fibrosis and cirrhosis [77]. As mentioned above, chronic alcohol use results in oxidative stress through the CYP2E1 metabolism not only producing acetaldehyde but also generating ROS, which induce ER stress and increase hepatocyte sensitivity to TNF-α [78].

Besides acetaldehyde, ethanol metabolism recruits and activates other important pathways involved in the progression of ALD from its initial stage of steatosis.

– *Oxidative stress and antioxidant systems*: In physiological conditions, the homeostasis of ROS involves different cellular pathways and functions. In

chronic alcohol users, the sustained oxidative metabolism directly induces an excessive accumulation of ROS in the hepatocytes, such as H_2O_2 and superoxide anions. Moreover, alcohol-induced ROS are also generated through inflammation and the recruitment of immune cells and the generation of pro-inflammatory cytokines. Furthermore, ROS can bind proteins and generate neoantigens that induce a host immune response [79]. As indicate above, in alcohol exposure, the Nrf-2, a factor that regulates the expression of antioxidant proteins, is upregulated to counterbalance the stimulation of ROS generation due to the induction of important antioxidant genes, such as SOD, GSH, catalase, peroxidase-1, metallothionein and heme oxygenase [11, 44, 45]. However, the constant generation of ROS due to chronic alcohol intake can exceed the antioxidant strategies leading to the onset of oxidative stress. In addition, increased prooxidant species (e.g. H_2O_2) can also generate an unbalance between antioxidant enzymes, such as MnSOD and the GSH redox cycle in mitochondria, resulting in a net onset of oxidative stress [80].

– *Methionine cycle*: Methionine is an essential amino acid, substrate for methionine adenosyl transferase (MAT1A) to produce S-adenosylmethionine (SAM), which is the methyl donor for methylation reactions (DNA, proteins, lipids and histones) and polyamine synthesis (see also respective chapter on methionine metabolism in Part IV and biochemical pathways in Appendix). In ALD, methionine metabolism is affected by decreased activity of the enzymes MAT1A and methionine synthase (MS), causing a reduction of SAM, hyperhomocysteinemia (HHcy) and with resultant nucleotide imbalance and DNA instability [81]. The reduction of SAM levels impact in the liver function [82]. In transsulfuration reactions, homocysteine is metabolized to produce cysteine and GSH, the principal antioxidant for the defense against oxidative liver injury [83]. HHcy has been shown to activate ER stress in the pathogenesis of ALD [84], promoting apoptosis, steatosis and inflammation [85, 86].
– *ER Stress*: The ER regulates posttranslational protein processing, trafficking and maturation of membrane and secretory proteins. ER stress is induced in conditions of accumulation of unfolded or misfolded proteins in the ER lumen, thereby leading to lipid accumulation, inflammation and cell death [87]. ER stress triggers unfolded protein response (UPR) that acts to inhibit protein synthesis and to increase the efficiency of chaperone proteins. Ethanol exacerbates ER stress responses by different mechanisms such as acetaldehyde-protein adduct formation, oxidative stress and alcohol-induced HHcy, and promotes liver damage [88]. Ethanol aggravates palmitic acid (PA)-induced ER stress response in primary rat hepatocytes and in a high-fat diet-treated mouse model [89]. Furthermore, other studies showed that CHOP knockout mice, one of the ER stress and apoptosis involved genes, have an attenuated liver damage and a reduced steatosis after ethanol exposure [90]. As mentioned above, ER stress is also a trigger for the activation of transcription factors SREBPs, and thus, besides promoting liver damage and inflammation, alcohol-induced ER stress also contributes to the accumulation of lipids.

– *Mitochondrial damage*: Alcohol overconsumption alters mitochondrial function in the liver, which has a wide-range impact due to the crucial role of these organelles in energy production and metabolism [91], which is described in the following section.

Mitochondria and ALD

Mitochondria are the energy centers of the cell designed to generate energy for myriad cell functions and critical hubs for metabolism and a strategic center of cell fate decisions. Mitochondria functions are affected by the oxidative metabolism of alcohol, and hence this event is considered as a causal role in the progression of ALD. In the following sections, we will briefly review the properties and structure of mitochondria and summarize what functions of mitochondrial physiology are altered in ALD.

Mitochondrial Properties and Structure

Mitochondria are specialized compartments found in most eukaryotic organisms. Their size is variable but the area is commonly between 0.75 and 3 μm^2. This organelle is known for being the main source of energy metabolism within cells. Their main function is to convert O_2 and nutrients into carbon dioxide (CO_2) and water in order to produce adenosine triphosphate (ATP), the main energy source of the cells.

To accomplish these roles, mitochondria rely on a cross-talk between nuclear genome and the mitochondrial circular DNA (mtDNA). Most of the mitochondrial proteins that sustain mitochondrial function derive from the nuclear DNA, with the mtDNA encoding for just a handful of components of the respiratory chain. The mtDNA shows substantial similarity to bacterial genomes and it is hypothesized to originate from an endosymbiotic event occurring 1.5 billion years ago in which an archaea host engulfed an α-proteobacterium ancestor. Mitochondria have retained their small genome throughout evolution in order to drastically improve cell energy production. Human mtDNA is a 16.5 kb circular dsDNA lacking introns and residing within the mitochondrial matrix [92, 93].

Structurally, mitochondria are composed of two membranes and two compartments, each one carrying out specialized functions [94, 95].

Outer mitochondrial membrane (OMM): the outer membrane separates mitochondrial content from the cytosol. Regarding membrane composition, the OMM is smooth and very similar in lipid composition to eukaryotic cell membranes. It is mainly formed by phospholipids of unsaturated FAs such as phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol. Another main component of this membrane are the membrane proteins called porins. Their main function is to allow the freely passage of ions and small molecules in order to allow mitochondrial

signaling events. The main transporter of these small molecules from the cytosol to the intermembrane space is the voltage-dependent ion channel (VDAC) [96]. The import of larger proteins (more than 5000 Da) required to be tagged with an amino-terminal sequence, which binds to a subunit called translocase that actively moves the proteins into the mitochondria. An example of this receptor system is the commonly known as TOM20 [97].

The outer membrane also hosts a number of enzymes with a wide variety of functions. In addition, the OMM establishes membrane contact sites with other subcellular compartments, including the ER, lysosomes, peroxisomes, endosomes, melanosomes, lipid droplets and the plasma membrane.

Inner mitochondrial membrane (IMM): Unlike OMM, the IMM is fairly impermeable to solutes due to the lack of porins, and this event requires specific carriers for transport into the matrix. This property is exemplified by the transport of GSH from cytosol to mitochondrial matrix (see below), which is of significant relevance for ALD. IMM has a unique lipid composition, characterized by low cholesterol content and enriched in cardiolipin (10–20%). This exclusive lipid of the IMM is characterized by four unsaturated fatty acyl chains and is essential in the performance of mitochondrial energy generation in the respiratory chain and in the maintenance of mitochondrial IMM structure [98]. While impermeable to most solutes, the IMM is permeable to O_2, CO_2 and water. The IMM is characterized by its invaginations called cristae that penetrate the mitochondrial matrix providing a large surface area for chemical reactions to occur. The cristae of the IMM are the principal site of oxidative phosphorylation (OXPHOS), since they host all the complexes implicated in mitochondrial respiration, including the mitochondrial respiratory chain and the ATP synthase. Hence, the primary function of the IMM is linked to bioenergetics, where the free energy stored in the reducing equivalents produced in the Krebs cycle is converted into ATP. Cristae organization ensures the optimal conditions for ATP production, minimizing the diffusion of metabolites, protons and ADP during respiration. Apart from being a chemical barrier, IMM is also an electrical insulator since it insulates the membrane potential generated by the action of the enzymes of the electron transport chain (ETC) [99].

Intermembrane space (IMS): This is a ~ 20 nm space that lies between the OMM and IMM. All matrix proteins imported into the mitochondria from the cytoplasm must pass through the OMM and IMM and therefore also through the IMS. Because the OMM is freely permeable to small molecules, the concentrations of ions and sugars in the IMS is more similar to that of cytosol. However, the protein composition of this space is different from the protein composition of the cytosol. It has a high concentration of protons due to their pumping by the ETC. This region allows oxidative phosphorylation to occur in it.

Mitochondrial matrix: This is the innermost compartment surrounded by the IMM. It contains a highly concentrated mixture of enzymes, mitochondrial ribosomes, RNA and several copies of the mtDNA. Most of the crucial metabolic pathways for mitochondrial function (Krebs cycle, FAs β-oxidation, alternative bile acid synthesis and steroid synthesis) take place in this compartment. It is a site for the

production of ATP with the help of the enzyme ATP synthase present in the IMM and is also the site of organelle DNA replication, transcription and protein biosynthesis.

Alterations of Mitochondrial Function in ALD

Mitochondrial Dynamics and ALD

Mitochondria are highly complex organelles, which can also move along the cytoskeleton and regulate their morphology by fusion and fission in a process named mitochondrial dynamics. This process is important not only for maintaining mitochondrial performance but also for coordinating metabolism and cell signaling [94]. Mitochondria move to specific destinations by attaching to the microtubular apparatus. Their proper distribution within the cell allows the correct execution of mitochondrial functions. Apart from being transported within the cell, mitochondria can also modulate their shape with fusion and fission events. The balance between fission and fusion has critical roles in maintaining mitochondrial homeostasis in response to metabolic or environmental stresses, and is linked to cell division, apoptosis, and autophagy. A high fusion activity leads to mitochondrial elongation, promotes the capacity of OXPHOS and allows redistribution of mtDNA between damaged and healthy mitochondria. This fragmentation and shape of mitochondria are precisely controlled by mitochondria shaping proteins (MSP). These include mitochondrial proteins such as Mitofusin 1 and 2 (Mfn1/2), Optic Atrophy 1 (Opa1) and the cytosolic dynamin-related protein 1 (Drp-1). These proteins influence not only the shape of mitochondria, but also the functions and cellular signaling cascades. Mfn1/2 and Opa1 are the proteins involved in the process of organelle fusion, whereas cytosolic Drp1 has a main role in mitochondrial fission [100–102].

One of the earliest features of mitochondrial structure alterations reported in patients with ALD was the presence of **megamitochondria** (see also Appendix Figs. A.33, A.34 and A.35), which were associated with a mild form of liver disease [103]. The significance of this characteristic feature was not understood until the uncovering of the machinery responsible for the regulation of mitochondrial dynamics. In an elegant study, using cell lines and knockout mice Palma et al., uncovered a critical role for Drp-1 in shaping the size of mitochondria and in the control of alcohol-induced liver injury [102]. While exposure of VL-17A cells exhibited hyperfragmentation of mitochondria, the deletion of Drp-1 in this cell line prevented this effect and increased cell growth. Moreover, mice with liver-specific Drp-1 deletion exhibited the presence of megamitochondria and decreased alcohol-induced liver injury, lending strong support for a role of Drp-1 in the control of mitochondrial dynamics in ALD. In line with these findings, patients with alcoholic hepatitis exhibited increased expression of Drp-1, findings that paralleled the outcome reported in human precision-cut liver slices exposed to increases doses of alcohol

[101]. Thus, overall, these findings suggest that alcohol intake promotes mitochondrial hyperfragmentation, which translates in a more severe state of liver injury, and indicate that the modulation of mitochondrial dynamics can be a novel target for ALD management.

Mitochondrial Respiration and ALD

Exposure to ethanol has been demonstrated to alter mitochondrial OXPHOS. Early studies in rats revealed that oral alcohol intake decreases mitochondrial respiration (state III) and lowered the respiratory control ratio (state III/state IV) in isolated mitochondria [105]. The findings were accounted for by the downregulation of the synthesis of subunits of the main respiratory complexes such as NADH dehydrogenase, cytochrome b-c1 (Complex III) and the ATP synthase complex (Complex V) [104]. Although these pioneering findings in alcohol-exposed rat liver mitochondria have documented impaired respiration due to different mechanisms [105], recent findings in mice fed alcohol showed opposing effects, in which alcohol feeding either in oral or in intragastric models increased state III respiration in liver mitochondria from mice fed alcohol [106]. Interestingly, the increase in state III respiration was more robust in the intragastric alcohol-feeding model, and correlated with enhanced liver injury, compared to the milder outcome seen in the oral alcohol intake model. This finding was associated with enhanced levels of complexes I, IV and V incorporated into the respiratory chain and reflected the effects of alcohol in increasing the expression of PGC1α, a master regulator of mitochondrial biogenesis. While the effect of alcohol intake in eliciting enhanced mitochondrial biogenesis remains to be formally demonstrated, these findings suggest that the stimulatory effect of alcohol intake in mitochondrial function is related to the replenishment of NAD^+ from NADH oxidation to accelerate the oxidative metabolism of ethanol. Feeding the electrons from NADH to the respiratory chain to oxidize NADH to NAD^+ in mice mitochondria would stimulate the generation of ROS from the enhanced consumption of O_2 in the ETC. Of interest, the increased stimulation of respiration in mice versus rats parallels the species-dependent sensitivity towards alcohol induced liver injury, being greater in mice than in rats, and parallels the enhanced replenishment of NAD^+ from NADH in the mitochondria, suggesting that an increased respiration couples alcohol intake with enhance metabolism and subsequent ROS generation. The relevance of the putative alterations of mitochondrial respiration to human ALD remains to be determined. Although systematic studies addressing the status of liver mitochondrial function in patients with ALD have not been established, there has been indirect evidence suggesting decreased mitochondrial function in patients with ALD. Using assays determining the decarboxylation state of ketoisocaproate as a surrogate way to measure mitochondrial function [107], pioneering observations indicated that alcoholic patients exhibited reduced peak exhalation of $^{13}CO_2$ from 2-keto[1-^{13}C]isocaproic acid while aminopyrine breath test and galactose elimination capacity were not altered, suggesting that the

impaired mitochondrial ketoisocaproate decarboxylation is not a consequence of decreased functional hepatic mass. Moreover, ALD in patients with active drinking was associated with the expression of a mtDNA deletion fragment in human liver tissue [108, 109]. Thus, these findings indicate that alcohol intake is associated with the disruption of mitochondrial respiration, which parallels the susceptibility towards ALD progression.

Mitochondrial Membrane Composition in ALD

As lipid composition determines membrane structure and affects the function of embedded proteins, it is conceivable that alcohol intake impacts in the lipid composition of mitochondria. Two major changes in the mitochondrial lipid composition of liver mitochondria from rodents fed alcohol have been described, such as an increase in the cholesterol content and reduced cardiolipin status. The cholesterol/phospholipid molar ratio is a critical determinant of the fluidity of membrane bilayers and the accumulation of cholesterol disrupts lipid organization and decreases the transition of liquid-ordered to liquid-disordered phases of membranes, leading to a higher membrane rigidity and alteration of the mitochondrial membrane proteins [110]. As described below, alcohol consumption increases the mitochondrial cholesterol levels due in part to the stimulated expression of a specific carrier involved in the trafficking of cholesterol to mitochondria. This event has important functional consequences mainly derived from the alteration in mitochondrial membrane fluidity, which impairs the action of specific carriers located in the IMM that affects the strategic antioxidant defenses, exemplified by the loss of mitochondrial GSH (mGSH) content (see below). In addition, early studies indicated that chronic alcohol intake affects the homeostasis of cardiolipin [111], which is known to play an essential role in the maintenance of cristae and in the function of respiratory chain organization [98]. While these changes have been mainly reported in experimental animal models, whether or not alterations in mitochondrial cholesterol and cardiolipin status contribute to human ALD remains to be further explored.

Mitochondrial DNA in ALD

As shown above, chronic alcohol ingestion and subsequent oxidative metabolism perturbs mitochondrial structure and function and hence promotes mitochondrial ROS generation (in part due to increased leakage of electrons from the transport chain to molecular oxygen and decreased antioxidant defenses), which can target macromolecules, including mtDNA. As mtDNA encodes for 13 components of the respiratory chain complexes, alcohol-induced mtDNA damage via mitochondrial ROS stimulation can impair mitochondrial respiratory chain [112]. Besides, alcohol decreases mitochondrial protein synthesis by impairing mitochondrial ribosomes and ROS irreversibly oxidize intramitochondrial proteins [104]. The inactivation of

proteins is critical for mitochondrial function and this contributes to alcohol-induced liver injury. Consistent with the susceptibility of mtDNA to ROS attack, it has been described in patients with ALD the presence of mtDNA deletion fragments, which likely reflects the severity of disease progression.

Mitochondrial ROS Production and Impaired Antioxidant Defense

Although the oxidative metabolism of alcohol is known to generate ROS as subproducts, as described above, the regeneration of NAD^+ from NADH, which is required for continued alcohol metabolism, feeds electrons to the respiratory chain. One of the consequences of this process is the increase of electron transfer directly to molecular oxygen to generate superoxide anion [113]. As mitochondria are the main consumers of oxygen, the likelihood to stimulate superoxide anion increases with the burden of oxidizing alcohol, particularly by CYP2E1. Moreover, although CYP2E1 is associated with the ER, it has been also shown to be present in mitochondria [114, 115] and potentiates alcohol injury by stimulating mitochondrial ROS generation. Although the main line of defense against superoxide anion generation in mitochondria is MnSOD, its status in ALD is controversial and not well-defined with studies reporting an increase, decrease or not change in expression/activity [116–118]. The action of MnSOD on superoxide anion results in the formation of hydrogen peroxide, which although is not strictly a free radical it is a potent oxidant that can generate reactive radicals through the Fenton reaction. The detoxification of hydrogen peroxide occurs mainly through the GSH redox cycle, for which the level of reduced GSH is essential, as well as by peroxiredoxin (Prx)-III, the Prx isoform located exclusively in mitochondria, which upon oxidation by hydrogen peroxide is reconstituted by thioredoxin2 (Trx2) [119]. Since mitochondria do not synthesize GSH *de novo* from its constituent aminoacids, mitochondria rely on cytosol GSH after being transported into the mitochondrial matrix to act as the cofactor for GSH peroxidase (Gpx) to detoxify hydrogen peroxide as well as other fatty acids-derived peroxides [105]. The transport of GSH into mitochondria has been a subject of intense investigation, with recent findings showing a role for the dicarboxylate and particularly 2-oxoglutarate (OGC, SLC25A11) transporters playing a key role in the import of GSH into mitochondria from cytosol. Importantly, the enrichment of mitochondria in cholesterol lowers mitochondrial membrane fluidity and affects the function of OGC to transport GSH (see below), resulting in mGSH depletion. Although alcohol induces mGSH depletion [105, 119], the status of Prx-III is not well-established raising the question about the relative importance between mGSH vs Prx-III in the detoxification of hydrogen peroxide in ALD [120, 121]. While differences in K_m for hydrogen peroxide, catalytic efficiency and K_{cat} between mGSH/Gpx and Prx-III/Trx-2 may exist, it has been shown that depletion of mGSH results in Trx-2 oxidation [122], which limits the reduction of oxidized

Prx-III, compromising the Prx-III/Trx-2 system to continue elimination of hydrogen peroxide.

Endoplasmic Reticulum (ER) Stress and Mitochondria Crosstalk in ALD

As mentioned above, ER stress is known to regulate hepatic steatosis via SREBPs activation, and hence ER stress plays a pivotal role in metabolic liver diseases, including ALD. The ER is an organelle responsible for the synthesis, folding, maturation and secretion of proteins and lipids and Ca^{2+} homeostasis. Disruption in protein folding or alterations in lipid homeostasis results in the activation of the unfolded protein response (UPR) that selectively increases the transcription of chaperones (GRP78/BiP) and the ER-associated degradation (ERAD) processes [123–125] with the ultimate goal to restore homeostasis. Alcohol intake induces ER stress through the onset of different mechanisms, including the generation of ceramide via acid sphingomyelinase (ASMase) activation, the generation of acetaldehyde due to the formation of protein adducts in the ER and the onset of oxidative stress [126]. A critical mechanism in alcohol-induced ER stress is the perturbation of the methionine metabolism with the subsequent increase in homocysteine levels (see above). In line with the role of homocysteine in mediating alcohol-induced ER stress, it has been shown that feeding mice with betaine decreased HHcy preventing alcohol-mediated ER stress, hepatic steatosis and liver injury [63].

Besides the impact of ER stress in protein and lipid homeostasis, ER stress can regulate mitochondrial function. The disruption of Ca^{2+} homeostasis in the ER is translated in mitochondria via the import of this cation, which promotes mitochondrial membrane permeability transition and subsequent cell injury [111]. ER and mitochondria exhibit physical contact through mitochondrial-associated membranes (MAMs), as specific membrane subdomain encompassing ER and mitochondria bilayers, which serve as a freeway for the movement of ions (e.g. Ca^{2+}) and lipids. In this regard, besides the movement of phospholipids synthesized in the ER moving to mitochondria, ER stress can signal the accumulation of cholesterol in mitochondrial membranes through the upregulation of steroidogenic acute regulatory protein 1 (StARD1), an OMM protein responsible for the transport of cholesterol into IMM, which has been recently described to be regulated by ER stress [120] and has emerged as a critical player in metabolic liver diseases, including nonalcoholic steatohepatitis (NASH) and more recently in ALD [127, 128]. As mentioned before, disruption in methionine metabolism is a key player in ALD pathogenesis via decreased MAT1A and MS expression and increased homocysteine levels, which is causally linked to ER stress. An additional link between methionine metabolism and mitochondrial cross-talk has been recently described in

ALD. Although MAT1A is found in the cytosol and nucleus, recent findings uncovered that MAT1A is localized in mitochondria, where it preserves mitochondrial proteome and promotes mitochondrial function [129]. Alcohol feeding to mice and liver samples from patients with ALD results in a striking decrease in the localization of MAT1A in mitochondrial mediated by the isomerase peptidyl-prolyl cis/trans isomerase (PIN1) and the casein kinase (CK2). Blocking PIN1-MAT1A interaction increased mitochondrial MAT1A levels and protected against alcohol-induced mitochondrial dysfunction and fat accumulation. Whether the beneficial effects of targeting MAT1A in mitochondria is due to the local generation of SAM levels to promote higher methylation and increased expression of mitochondrial proteins remains to be established. This is of particular interest vis a vis the known transport of SAM from cytosol to mitochondria by a specific carrier that is insensitive to the changes in mitochondrial membrane fluidity [130].

Inflammasome and Mitochondria Crosstalk in ALD

As discussed in the Sect. 3.2.2., pathogenesis of ALD involves inflammasome activation [131]. The disruption of the intestinal barrier integrity that allows the translocation of DAMPs and PAMPs to the circulation leads to the activation of the inflammasome cascade in the liver cells. Inflammasomes are a group of intracellular multicomplexes (NLRP3, caspase-1, IL-1β) located in the cytosol, which detect the PAMPs and DAMPs, such as ATP, pore-forming toxins, RNA viruses, cholesterol crystals, uric acid, and amyloid β [132, 133], and produce the release of the pro-inflammatory cytokines, such as IL-1β and IL-18 [134, 135]. There are different hypotheses regarding the activation of NLRP3 inflammasome, among them the release of ROS by damaged mitochondria produced by excessive electron flow [136], inhibited mitophagy [137], mtDNA oxidation [132]. In the context of the disruption of the balance between antioxidants and free radicals/oxidants, the onset of net ROS generation in mitochondria increases the risk of damaging mitochondrial components, such as the oxidation of mitochondrial DNA (ox-mtDNA) which are released to the cytosol and bind NLRP3 inflammasome [138]. The NLRP3 inflammasome complex activation is produced in MAMs, where cardiolipin is found and translocates from the IMM to the OMM and triggers the activation of the NLRP3 [139]. Furthermore, MAMs constitute the site where the transfer of lipids and Ca^{2+} influx between ER and mitochondria occurs mediated by VDAC [140] and facilitates the assembly of the NLRP3 inflammasome [141]. In this regard, the link between alcohol metabolism and NLRP3 activation is mediated via mitochondrial dysfunction, since mitochondria contributes to the oxidative metabolism of alcohol, the onset of ROS generation and oxidative stress, consequently the crosstalk between mitochondria and inflammasome contributes to the progression of ALD and emerges as a potential target for intervention.

Mitochondrial Cholesterol and Alcohol

Cholesterol is an important component of cell membranes, which determines membrane physical properties. Despite this structural role, cholesterol plays an important functional role by the regulation of multiple signaling pathways [142]. Cells meet their need for cholesterol either through the diet or synthesized *de novo* in the ER in the so-called mevalonate pathway. Once synthesized in the ER or delivered into lysosomes from diet-derived low-density lipoprotein (LDL), cholesterol is distributed to different membrane bilayers, particularly plasma membrane and mitochondria. Although the latter pool of cholesterol is considerably lower compared to the presence of cholesterol in the plasma membrane, the mitochondrial cholesterol plays important physiological roles, including the synthesis of bile acids in the liver in an alternative pathway to the classic one regulated by cytochrome P450 family 7 subfamily a member 1 (CYP7A1). The trafficking of cholesterol to mitochondria for metabolism is governed by StARD1, whose expression increases in metabolic liver diseases, such as NASH and ALD [143]. StARD1 is located in the OMM and has a cholesterol-binding domain. Being regulated by ER stress, alcohol consumption leads to the upregulation of StARD1, which has been shown to act as the rate-limiting step in the mitochondrial metabolism of cholesterol into oxysterols and bile acids. Thus, the induction of StARD1 by alcohol exceeds the capacity of cytochrome P450 family 27 subfamily a member 1 (CYP27A1) to initiate cholesterol metabolism into 27-hydroxycholesterol resulting in the next accumulation of cholesterol in the IMM. The accumulation of mitochondrial cholesterol results in a wide-range impact on mitochondrial function due to perturbation of mitochondrial membrane fluidity, which affects the activity of: (a) IMM solute carriers, such as the SLC25A11, involved in the transport of cytosolic GSH into mitochondrial matrix, which cause mGSH depletion [144, 145], and (b) oxidative phosphorylation by causing defective assembly of respiratory chain super-complexes [146] (Fig. 56.3). Although the activity of the SLC25A11 carrier has been shown to be sensitive to cholesterol-mediated changes in membrane fluidity resulting in impaired transport of GSH into the mitochondrial matrix [105, 145, 147], a novel mitochondrial carrier SLC25A39 has emerged as a putative GSH transporter [148]. However, whether SLC25A39 is sensitive to the disruption of membrane fluidity imposed by the accumulation of cholesterol or not remains to be established, and constitutes an essential mark for the mGSH transport activity. As ALD exhibit zonal dependent features, as mentioned above, it has been reported that the depletion of mGSH is preferentially seen in the PV area of alcohol-fed mice [149]. Interestingly, this outcome reflects a zonal-dependent induction of StARD1 by alcohol intake in which mice fed alcohol exhibit a preferential expression of StARD1 in PV hepatocytes [150]. While the direct determination of mitochondrial cholesterol levels in human ALD has not been determined, there was evidence indicating that patients with ALD exhibit increased expression of StARD1 [120].

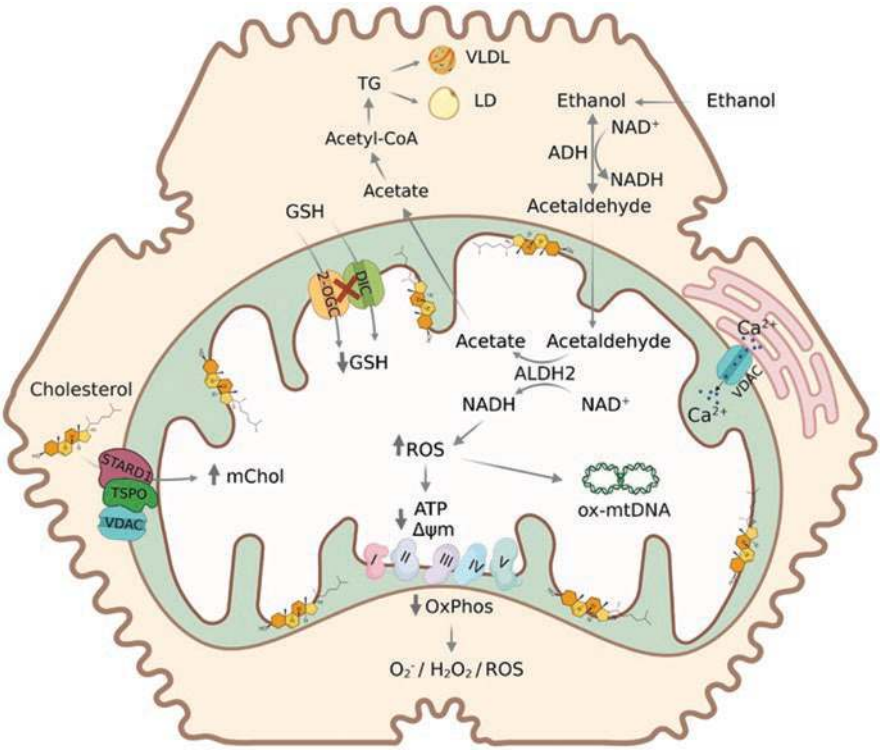

Fig. 56.3 Mitochondrial alterations in ALD. Ethanol is metabolized in the liver by ADH enzyme which converts it into acetaldehyde. This molecule is metabolized to acetate in the mitochondria by the ALDH2. Acetate is then converted to Acetyl-CoA which can be the energy source for other tissues or can be stored as triglycerides. The reaction catalyzed by the ALDH2 produces NADH that increases ROS production. ROS oxidize the mtDNA and interfere with the ETC. Ethanol intake increases the cholesterol into mitochondria through StARD1 protein. Cholesterol increases the membrane rigidity altering the membrane proteins and also the antioxidants (GSH) transport into mitochondria in order to reduce ROS. All this contributes to ALD progression. *ADH* alcohol dehydrogenase, *ALDH2* aldehyde dehydrogenase 2, *ETC* electron transport chain, *GSH* glutathione, *mtDNA* Mitochondrial DNA, *ROS* reactive oxygen species, *StARD1* steroidogenic acute regulatory protein 1

Conclusions and Future Perspectives

From the pioneering observations of the presence of megamitochondria in patients with ALD, it has become clear that mitochondria are not only involved in the metabolism of alcohol but are also targets of alcohol-derived metabolites. Mitochondria are important hubs for the energy production and metabolism and hence alterations in mitochondrial function are likely an important culprit of ALD pathophysiology. The nature of the alterations in mitochondria by alcohol consumption is multifactorial and involves changes at the structural and functional levels, most of which have

been described in experimental models of the disease. Although the translational side of these findings in patients with ALD has been limited there have been important developments, in which perturbations of mitochondrial dynamics has been described in human alcoholic hepatitis, a severe form of ALD, with an increased expression in the levels of Drp-1 that likely contribute to the hyperfragmentation of mitochondria and correlated with disease severity. At the functional level, limited information regarding the status of mitochondrial respiration in patients with ALD is available although indirect assays of mitochondrial functional activity indicated a possible impaired mitochondrial performance in human ALD, an aspect that deserves further effort and progression in the future. The increased expression of StARD1 in liver samples from patients with ALD [120] suggests that two important features of ALD seen in experimental models, namely increased mitochondrial cholesterol accumulation and mGSH depletion, are likely present in human ALD. Giving the role of mGSH in the detoxification of hydrogen peroxide and ROS attenuation, strategies boosting the mitochondrial pool of GSH may be of potential interest. Unfortunately although the role of N-acetyl-L-cysteine (NAC) has been shown to be ineffective in human ALD, NAC is not expected to recover the mitochondrial pool of GSH due to the defective transport from cytosol GSH, suggesting that other permeable GSH prodrugs, such as SAM may be more effective in treatment [151]. In addition to decreasing mitochondrial membrane fluidity, increased StARD1 expression may contribute to enhanced burden of bile acids production. Consistent with this possibility, which needs to be explored in the future, recent observations indicated increased total and conjugated bile acids in alcoholic hepatitis in patients with alcoholic hepatitis, although paradoxically this output did not derive from *de novo* synthesis based on a decreased expression of CYP7A1 and C4 serum levels [152]. Thus, although significant progress needs to be made to define the causal role of mitochondrial alterations in human ALD, the availability of new genetic models with liver-specific StARD1 deletion and humanized models with StARD1 overexpression may be useful to increase translational application of the impact of increased StARD1 in ALD pathogenesis. For related information on mitochondria and ALD see also Chap. 49 and Appendix Figs. A.33, A.34, A.36, A.43, A.74 and A.76.

Chapter 57
Hepatic Iron Overload in Heavy Drinkers: Molecular Mechanisms and Relation to Hemolysis and Enhanced Red Blood Cell Turnover

Sebastian Mueller, Johannes Mueller, Siyuan Li, Chaowen Zheng, and Cheng Chen

Abstract About half of all heavy drinkers show pathological hepatic iron overload that is part of the developing alcohol-related liver disease (ALD). The underlying mechanisms have been remained largely obscure until now. We here review previous work, but also present novel long-term studies on iron parameters both in heavy drinkers but also animals and in vitro models. We show that enhanced red blood cell (RBC) turnover and hemolysis is strongly associated with mortality in heavy drinkers and seems to be a key mechanism responsible for the long-observed iron accumulation in alcohol drinkers. In line with this, ca. 50% show an enhanced erythrophagocytosis and ineffective erythropoiesis as evidenced by increased elevation of the hemoglobin-haptoglobin scavenger CD163 and serum ferritin. In general, and in contrast to former acute ethanol exposure models in mice, heavy drinkers have elevated hepcidin levels as compared to non-drinking human controls. Our preliminary data both in humans and animal indicate that hepcidin is primarily upregulated due to continued physiological heme turnover rather than excessive inflammation or cytokine production. This regulatory loop is not only disrupted by HFE mutations, but also cirrhosis development or severe hemolysis that causes toxic hepatocyte iron overload. There is also first indications that ethanol blocks erythropoiesis. Taken together, enhanced RBC recycling provide a first comprehensive but complex rational for iron overload in ALD linking iron metabolism tightly to liver, blood and bone marrow. The data also provide new insights into our understanding of alcoholic hepatitis.

Introduction

About half of all heavy drinkers show pathological hepatic iron overload that is part of the developing alcohol-related liver disease (ALD) [1–3]. The underlying mechanisms have been remained largely obscure until now. We here review previous work, but also present novel long-term studies on iron parameters both in heavy drinkers but also animals and in vitro models. We show that enhanced red blood cell (RBC) turnover and hemolysis is strongly associated with mortality in heavy drinkers and seems to be a key mechanism responsible for the long-observed iron accumulation in alcohol drinkers. In line with this, ca. 50% show an enhanced erythrophagocytosis and ineffective erythropoiesis as evidenced by increased elevation of the hemoglobin-haptoglobin scavenger CD163 and serum ferritin. In general, and in contrast to former acute ethanol exposure models in mice, heavy drinkers have elevated hepcidin levels as compared to non-drinking human controls. Our preliminary data both in humans and animal indicate that hepcidin is primarily upregulated due to continued physiological heme turnover rather than excessive inflammation or cytokines. This regulatory loop is not only disrupted by HFE mutation, but also cirrhosis development or severe hemolysis that causes toxic hepatocyte iron overload. There is also first indication that ethanol blocks erythropoiesis. Taken together, enhanced RBC recycling provide a first comprehensive but complex rational for iron overload in ALD linking iron metabolism tightly to liver, blood and bone marrow. The data also provide new insights into our understanding of alcoholic hepatitis.

Hepatic Iron Overload in Alcohol-Related Liver Disease

Gradual hepatic iron accumulation over years is an important key feature of alcohol-related liver disease (ALD) [1–3]. Hepatic iron accumulation and chronic alcohol consumption have been associated for a long time [4] and it has been recently confirmed in larger cohorts with non-invasive iron detecting methods [5]. Iron also represents an independent factor for disease progression and long-term survival [6]. Already a first look at typical laboratory parameters of a large cohort of heavy drinkers (see Table 57.1) shows that e.g. serum ferritin levels are higher than 1000 ng/mL in more than 20%. Other iron-related parameters such as transferrin or transferrin saturation are also changed significantly.

Figure 57.1a shows a Prussian blue stain with typical pathological iron deposits in a patient with ALD. Figure 57.1b shows a more quantitative analysis of the histological iron stain from 156 liver biopsies in heavy drinkers. The percentage of positive iron stains is shown separately for macrophages (Kupffer cells) and hepatocytes. The data show that ca. half of both cell types show hepatic iron loading. When looking into more details, macrophages always seem to have more iron load. Figure 57.1c shows how often pathological iron stain is found in both cells or isolated in either macrophages or hepatocytes.

Table 57.1 Typical laboratory parameter findings in heavy drinkers

Parameter	Units	Normal range	Normal (F0–2)		Fibrosis F3–4	
			Mean	Patholog (%)[a]	Mean	Patholog (%)[a]
Demographics and drinking history						
Male gender			71.30%		68.20%	
Duration of heavy drinking	Years	0				
Death in mean 3.8 years	Yes = 1	%	12.50%		34.90%	
Liver-related death		%	16.20%		56.80%	
Laboratory						
Erythrocytes	/pL	4.5–5.9	4.8	47.50%	3.9	76.50%
Hemoglobin	g/dL	12–16	14.5	6.10%	12.8	33.00%
Hemoglobin<10 (anemia)	g/dL	12–16	14.5	0.80%	12.8	12.90%
Bilirubin (total)	Mg/dL	<1.2	0.7	11.10%	3.3	50.30%
Bilirubin (indirect)	Mg/dL	<0.3	0.3	33.70%	0.7	55.20%
LDH	U/L	<250	223.6	26.30%	260.5	41.80%
Haptoglobin	g/L	0.3–2.0	1.5	2.90%	1.2	15.20%
CD163	Ng/mL	<800	1118	63.00%	2218.8	94.40%
Iron-related parameters						
Ferritin>150	Ng/mL	50–150/400	567	75.80%	674.4	75.90%
Ferritin>400	Ng/mL	50–150/400	567	41.70%	674.4	50.30%
Ferritin>1000	Ng/mL	50–150/400	567	17.20%	674.4	25.60%
Serum iron	Ug/dL	95–158	129.2	25.60%	117.9	25.10%
Transferrin	g/dL	2.0–3.6	2.5	2.30%	2	44.80%
Transferrin saturation	%	16–45	40.7	31.10%	48.3	44.50%
Iron stain macrophages	0–2	0	0.6	43.00%	0.632	46.10%
Iron stain hepatocytes	0–2	0	0.575	40.50%	0.526	36.80%
Liver iron concentration (AAS)	Mg/g dw	<0.8	1.4	5.60%	1.3	19.60%

[a] Underlined if decreased

Data are obtained from the Heidelberg cohort of heavy drinkers and stratified according to fibrosis stage (n = 1185). More parameters are shown in Tables B.1 and B.2 in the Appendix. Note that ca. 20% have ferritin levels >1000 ng/mL and more than 10% of F3/4 patients develop anemia

Figure 57.1d shows hepatic iron levels as assess with a non-invasive method (room temperature susceptometry [5]) in a large cohort of 154 ALD patients as compared to patients with non-alcoholic fatty liver disease (NAFLD) and patients with genetic iron overload. These data also confirm that ALD patients have significantly higher hepatic iron levels as compared to controls. Figure 57.1e further demonstrates that, in difference to common believe, hepatic iron not linearly increases with disease progression and fibrosis stages, but shows a peak at F1–2 fibrosis, while reduced iron levels are observed in patients with F4 cirrhosis. A similar pattern is observed when looking at serum ferritin levels (Fig. 57.1f).

In ALD, in previous reports, histological iron accumulation has been identified as independent risk factor both for survival and HCC development [7] comparable

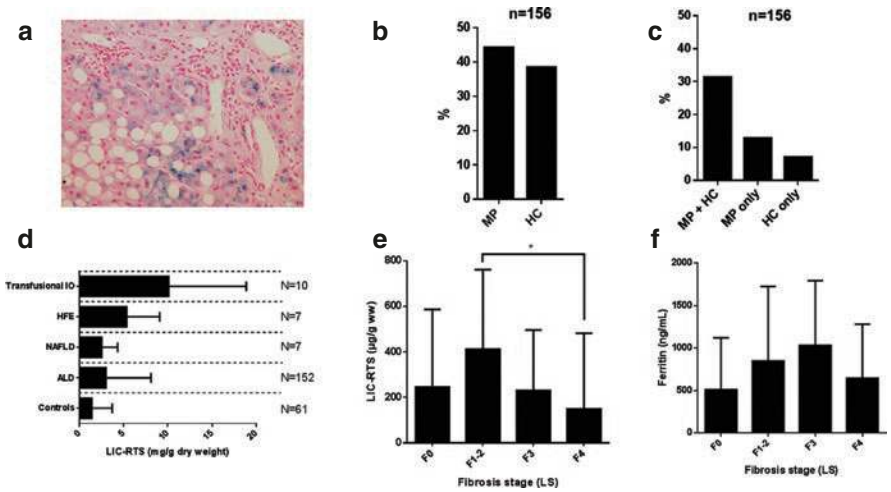

Fig. 57.1 Hepatic iron accumulation in ALD. (**a**) Liver stain with iron marker Prussian blue indicating pathological iron accumulation in hepatocytes and macrophages in a typical patient with ALD (counter stain Nuclear Fast Red). (**b**) Percentage of ALD patients with pathological iron deposits in liver biopsies for macrophages (MP) and hepatocytes (HC). Almost 50% have pathological iron overload, macrophages (Kupffer cells) slightly more than hepatocytes. (**c**) Percentage of pathological iron overload in both MP and HC, only MP and only HC. hepatocytes. (**d**) Comparison of liver iron concentration (LIC) as measured with non-invasive room temperature susceptometry (RTS) in patients with ALD, non-alcohol-related liver disease (NAFLD), hemochromatosis (HFE) and transfusional iron overload (IO). Both LIC-RTS (**e**) and serum ferritin levels (**f**) show characteristic changes with fibrosis stage in ALD. They increase from F0 to F3, but a decrease in F4 (cirrhosis)

to patients with hereditary iron overload [8]. These observations have led to intensive research activities aimed at better understanding molecular iron homeostasis, since iron is not only essential for hemoglobin synthesis, many iron containing enzymes and essential metabolic functions but also known to be highly toxic. To maintain an adequate iron supply, humans and other vertebrates have evolved effective mechanisms to conserve and finely regulate iron concentration, storage, and distribution to tissues. The carcinogenic potential of tissue iron accumulation is attributed to Fenton-like reactions which occur in the presence of reduced, ferrous iron and H_2O_2, yielding to highly reactive hydroxyl radicals [2]. In addition, excessive iron accumulates in lysosomes that originates from auto-phagocytosed ferritin and hemosiderin. It often leads to fragile membranes via lipid peroxidation and subsequent lysosomal dysfunction with the loss of free iron into the cytoplasm [9]. Taken together, the actual role of iron (in particular non-protein Fe complexes) and how alcohol favors iron accumulation is still under intensive investigation. Interestingly, recent preliminary data from our ongoing prospective, long-term mortality study in heavy drinkers has identified masked hemolysis, enhanced RBC turnover and ineffective erythropoiesis as important hitherto underestimated feature and predictor (see also book chapter on mortality and bone marrow toxicity). These new

insights also shed new light on our understanding of disturbed iron balance in patients with ALD. Consequently, besides established molecular pathways of iron regulation, this chapter will also introduce the very likely role of an impaired red blood cell cycle in heavy drinkers that seems to be the most likely reason for hepatic iron overload and other know changes of serum iron parameters in drinkers.

Control of Iron Homeostasis and Red Blood Cell Recycling

In the last decades, an enormous progress has been made to better comprehend the molecular mechanisms of iron regulation and homeostasis at the systemic and the cellular level [10, 11]. The human body contains ca. 5 g iron, of which ca. 2.5 g is used in the oxygen-carrying hemoglobin of erythrocytes (Fig. 57.2) and ca. 2.0 in liver, bone marrow and macrophages in the iron-storage protein ferritin and iron-containing proteins such as cytochromes. The liver serves as interim iron storage organ and can store up to 1 g. Circa 0.4 g are devoted to cellular proteins and enzymes in other cells. Iron is typically stored (ferritin, transferrin, enzymes) in the ferric state (Fe^{3+}) but crosses membranes through transporters in the highly reactive reduced, ferrous state (Fe^{2+}). Iron circulates bound to transferrin to be released to all organs/tissues through transferrin receptor 1. The transferrin bound ferric iron is relatively small only representing 2–3 mg. Most iron (20–25 mg) is recycled by

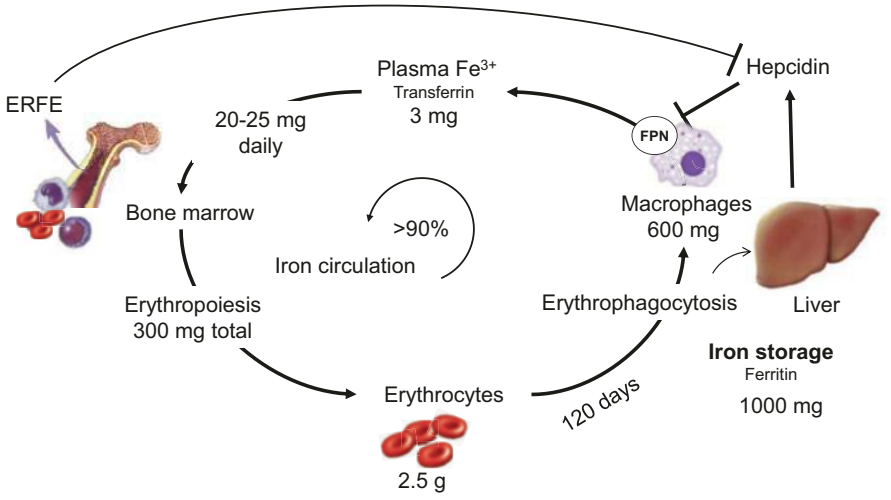

Fig. 57.2 Iron homeostasis and utilization in the body. Dietary iron is absorbed in the duodenum and binds to transferrin. Iron is then delivered to the bone marrow for erythropoiesis the major utilization pathway. Senescent RBCs are phagocytosed by macrophages (erythrophagocytosis) and ca. 90% of iron is recycled for heme synthesis. Excess iron is stored in ferritin in the liver. Regulation of iron metabolism by hepcidin and factors which influence hepcidin expression is also shown

macrophages, which phagocytize senescent red blood cells (RBC). In addition, as will be shown later in this chapter, hepatocytes are also able to directly uptake senescent RBCs, a function termed efferocytosis (see below). Most of this recycling occurs mainly in spleen and liver through the reticuloendothelial system, which initiates erythrophagocytosis. Macrophages can also directly recycle iron for new RBC production in the bone marrow. The daily uptake of dietary iron by duodenal enterocytes compensates for net loss or iron and is relatively small with 1–2 mg [10]. In contrast to general believe, iron is not only lost through cell desquamation and blood loss but also through the bile and urinary tract [12]. Excess iron is stored in ferritin of hepatocytes and macrophages as a reserve. As shown in Fig. 57.2, altogether about 90% of iron is recycled from senescent erythrocytes that typically have a mean survival of 120 days [13]. In other words, and considering that an average individual has 5 L total blood (2.5 g iron, ca. 0.5 mg per ml blood) ca. 40 mL blood are recycled every day which equals to ca. 20 mg iron. Likewise, these 20 mg of iron are required daily for erythropoiesis in the bone marrow.

Cellular Regulation of Iron

Each cell tightly controls iron homeostasis through sophisticated mechanisms. For instance, erythroid cells as well as all other cell types depend on the delivery of iron via the iron carrier serum **transferrin**, a glycoprotein with two affinity sites for ferric iron. Transferrin binds with high affinity to cell surface transferrin receptor 1 (TfR1) and with lower affinity to transferrin receptor 2 (TfR2) [14]. Genetic deletion of TfR1 in mice demonstrates its endocytic role and ability to import iron into several cell types [15]. In non-erythroid cells, iron is safely stored in ferritin complexes or can be incorporated into hemoglobin of erythrocytes, being later reused for various synthesis pathways [16]. Ferric iron stored in ferritin complexes (non-toxic form) must be subsequently released for biological use via lysosomal degradation of ferritin [17]. This mechanism of autophagy dominates during iron deficiency and is mediated by the nuclear receptor coactivator 4 (NCOA4) [18]. It has been described that NCOA4 interacts with ferritin heavy chain targeting ferritin for degradation. In iron overloaded cells, NCOA4 expression decreases leading to suppression of ferritin autophagy [19]. A recent study described the retention of iron within ferritin in NCOA4 KO mice, which led to iron-deficiency anemia, highlighting the important role ferritin autophagy mechanism on cellular and systemic iron homeostasis [20]. At the cellular level, central regulators of iron homeostasis are controlled post-transcriptionally by **iron responsive proteins** (IRP1 and IRP2) which are able to bind to the **iron responsive elements** (IREs) of the RNA encoding for various iron-related proteins. While binding to the IRE located in the 5′ untranslated region of the mRNA results in a translational inhibition, the bind of IRPs to the 3′ untranslated region stabilizes and protects the transcripts from degradation. In particular, IRPs can cause upregulation of TfR1 or suppress the translation of mRNA encoding

other proteins involved in iron metabolism, such as ferritins or ferroportin [21]. During cellular iron deficiency, IRPs are in the active form (apo-IRP) and this results in TfR1 induction stimulating the acquisition of iron from plasma Tf. In contrast, to counteract iron overload, IRPs become inactive (holo-IRP) for IRE binding leading to degradation of TfR1 mRNA and translation of ferritin mRNA [22]. The interactions IRE-IRP allow an autonomous independent control of iron homeostasis at the individual cell level. TfR1 expression is also regulated at the transcriptional and translational levels [23, 24]. Interestingly, IRP1 is regulated in a complex manner by various ROS linking iron homeostasis to oxygen metabolism [25–27].

Systemic Iron Control by Hepcidin

Systemically, iron is mainly controlled by the **hormone hepcidin** (Fig. 57.2). This 25 amino-acid peptide is primarily expressed in hepatocytes and to a lesser extent in macrophages [28, 29] representing about 10% of total serum hepcidin [30]. By binding to the unique iron exporter, **ferroportin**, hepcidin efficiently inhibits duodenal iron absorption, iron recycling from macrophages and iron mobilization from hepatic stores. Hepcidin blocks the iron efflux into the plasma by binding ferroportin and consequently inducing the phosphorylation, internalization and lysosomal degradation of the complex by the proteasome [31]. Deletion of hepcidin in mice or hepcidin deficiency in humans results in severe hepatic iron overload, increased serum iron levels and loss of iron in macrophage stores, caused by hyperabsorption of iron [32]. In contrast, transgenic overexpression of hepcidin causes decreased serum iron leading to anemia by blocking the iron absorption in enterocytes and the release of iron from the hepatic stores [33, 34].

The levels of circulating hepcidin are mostly controlled at the transcriptional level. Hepcidin promoter activity can be induced by iron signals, including serum iron concentrations and liver stores, or by inflammatory signals and suppressed during increased erythropoietic activity. In general, the transcriptional control of hepcidin by iron occurs via the bone morphogenic protein-SMAD (BMP/SMAD) pathway. High circulating concentrations of transferrin-bound iron (Tf-Fe) are the extracellular signal for transcriptional induction of hepcidin [35]. Tf-Fe modulates the interaction between the transferrin receptors (TFR) 1 and 2 and **hemochromatosis protein** (**HFE**) by inhibiting the binding of HFE to TFR1. Consequently, HFE stabilizes activin receptor-like kinase 3 (ALK3), which activates BMP/SMAD signaling cascade [36]. Increased Tf-Fe [37] concentrations can also promote the association between HFE and TFR2 that can further form a membrane complex with the BMP the co-receptor HJV, promoting hepcidin transcription via BMP/SMAD pathway [38]. Besides the iron, inflammatory signals as TGF-β, activin B and BMPs are also inductors of BMP/SMAD signaling while matripase-2 and furin act as suppressors by cleavage of the cell surface hemojuvelin (HJV) protein [39–43].

Hepcidin Regulation by Bleeding, Erythropoiesis, and Inflammation

Figure 57.3 shows the major pathways of hepcidin regulation. More details about iron homeostasis and erythropoiesis are provided in book chapter on bone marrow xxx. A complex interplay exists between liver and blood system and require a fine-tuned coordination that allows the maintenance of iron homeostasis. Increased **erythropoiesis**, caused by exposure to high altitude, anemia, or other physiological conditions, is so far described as the major inhibitory stimuli of hepcidin synthesis. Increased erythropoietin (EPO) release by the kidney is the major erythropoietic factor, which has been also implicated in downregulating hepcidin [44]. Despite many efforts over the last decade, there are still many open questions on how EPO suppresses hepcidin. Years ago, several studies have associated the suppression of hepcidin with two **erythroid regulators (GDF15 and TWSG1)**, which are normally increased during erythropoiesis. However, the direct link between these proteins and hepcidin regulation is still missing [35]. A more recent study has identified another erythroid regulator as part of the hepcidin-EPO axis, called **erythroferrone (ERFE)** [45, 46]. ERFE has been identified as main erythroid regulator of hepcidin and, in contrast to many other hepcidin stimuli but seems not to be responsible for the complete hepcidin suppression (see Fig. 57.2) [47]. When the release of erythropoietin from the kidney stimulates the production of new red blood cells, it also

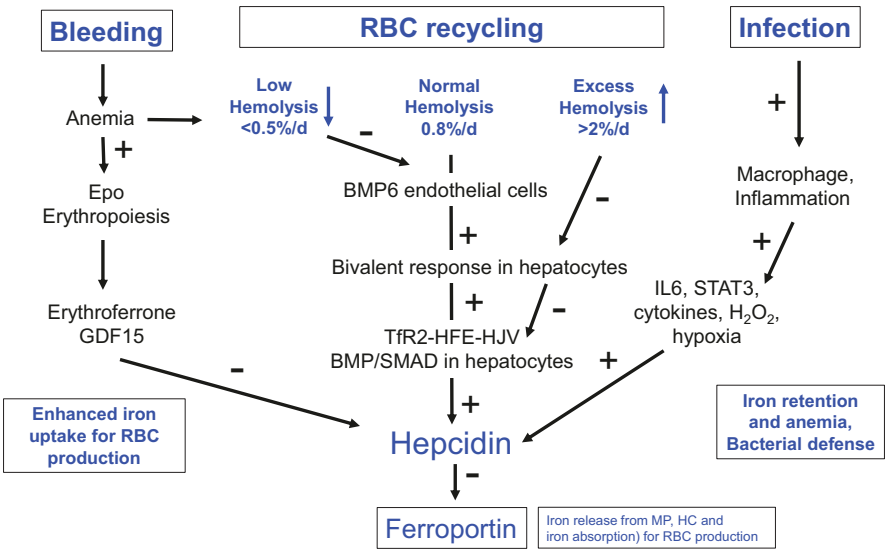

Fig. 57.3 Important signaling pathways on hepcidin: Bleeding, red blood cell recycling and inflammation/infection. Note that RBC recycling seems to control basal hepcidin levels which is HFE dependent and also depends on the rate of heme turnover. While physiological low hemolysis stimulates hepcidin, severe hemolysis strongly suppresses hepcidin

increases the synthesis of ERFE in bone marrow erythroblasts. Increased ERFE then suppresses hepcidin synthesis, thereby mobilizing cellular iron stores for use in heme and hemoglobin synthesis. Recent mechanistic studies have shown that ERFE suppresses hepcidin transcription by inhibiting bone morphogenetic protein signaling in hepatocytes. During ineffective erythropoiesis, pathological overproduction of ERFE by an expanded population of erythroblasts suppresses hepcidin and causes iron overload, even in non-transfused patients. Finally, it has been recently demonstrated that excess non-toxic iron and heme, *in vitro* and in the absence of erythroid cells, is able to suppress hepcidin expression [48]. In contrast, low levels of heme stimulate hepcidin both in hepatocytes and macrophages, which is further potentiated through endothelial derived BMP6 [49].

The induction of hepcidin during **inflammation or infection** constitutes an important evolutionary conserved mechanism known as "anemia of chronic disease" (ACD) see also Fig. 57.3). This mechanism describes a host defense response against invading extracellular pathogens by decreasing the availability of iron, an important bacterial growth factor. In ACD, IL-6 plays a key role as a major upstream regulator via STAT3 pathway leading to hepcidin induction [50]. Recently, H_2O_2 has been suggested as additional important inflammatory cofactor and second messenger capable of upregulating hepcidin by activation of the STAT3 signaling cascade [51]. In particular, hepcidin can be strongly induced by exposing hepatoma cells to sustained H_2O_2 concentrations similar to that released by inflammatory cells [51]. Subsequent studies have confirmed the role of STAT3 in the H_2O_2-mediated hepcidin induction [52, 53]. Other studies reported contrary findings and demonstrated a suppression of hepcidin in alcohol-fed mice by ROS [54]. However, no mechanistic details were provided, and we had earlier shown that the concentration of peroxide is crucial for hepcidin transcription [51]. While low levels induce hepcidin, toxic levels drastically block hepcidin most likely through unspecific inhibition of the transcription machinery. In the context of ALD, H_2O_2 has been shown to have a complex, concentration-dependent and bivalent action on hepcidin. Since ethanol metabolism strongly affects hepatic oxygen homeostasis, liver hypoxia is thought to have an important impact on hepcidin regulation *in vivo* and *in vitro* [55].

Erythrophagocytosis and Efferocytosis

Erythrocytes are either be directly phagocytosed by macrophages – termed **erythrophagocytosis**- or released toxic heme is bound to either haptoglobin (Hp) or, after release of heme, hemopexin (Hpx) and internalized through the hemoglobin- haptoglobin (Hb-hp) complex-CD163 or the heme-hemopexin (Heme-Hx) complex-CD91 [56, 57]. As we will describe later, hepatocytes are even able to quickly uptake oxidized red blood cells. The exact underlying mechanisms and how RBCs reach hepatocytes are not fully understood. During erythrophagocytosis, **heme oxygenase (HO)** catalyzes the enzymatic degradation of heme and produces equimolar amounts of carbon monoxide (CO), biliverdin and iron [58–61]. In a coupled

reaction, biliverdin is converted into bilirubin (BR) via biliverdin reductase [62] (see Fig. 57.4a). Of the two genetically distinct HO isoforms, HO2 is constitutively expressed and mainly found in brain and testis [63], whereas the inducible HO **isozyme HO-1** is expressed at low levels in most cells and tissues [60]. HO-1 is markedly up-regulated by its substrate heme and a variety of oxidative stress stimuli [64, 65] and HO-1 induction has been considered a general adaptive response to protect against the toxicity of oxidative stress [66–69]. Of note, Nrf2 is a major upregulator of HO1 that also orchestrates the transcriptional induction of various enzymes of the hepatic elimination and detoxification phases 0–3. More details are shown in a scheme in Fig. A.75. HO-1 deficient mice develop a chronic inflammatory disorder and are highly vulnerable to an experimental sepsis induced by the classical proinflammatory mediator endotoxin [70]. Second, these animals exhibit a marked hemosiderosis of solid organs such as the liver and kidney [71]. Finally, the liver is also the only location for bilirubin glucuronidation and excretion through canaliculi

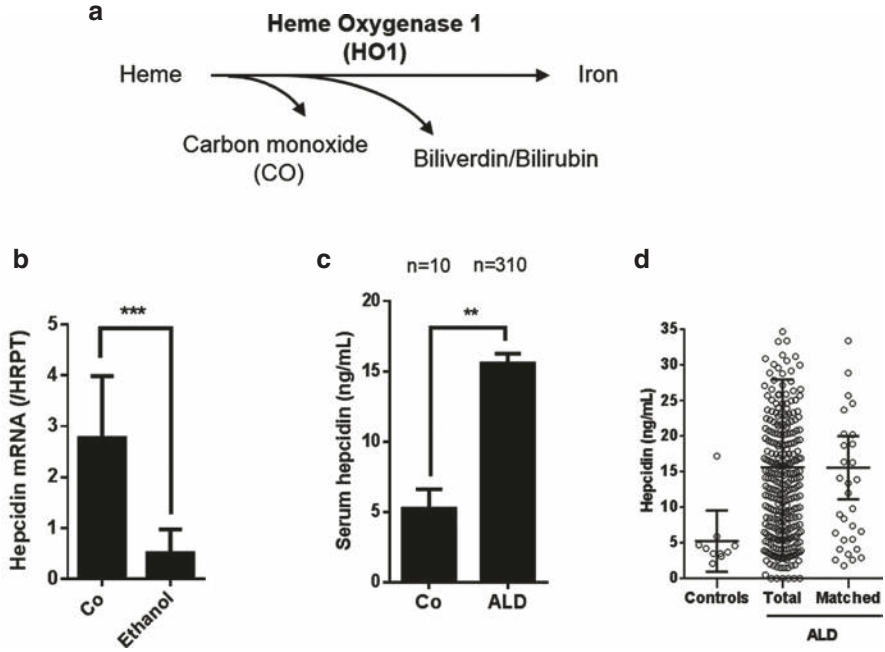

Fig. 57.4 (**a**) **Heme degradation by HO1.** Notably, the heme binding respiratory chain-blocker carbon monoxide CO is produced and toxic iron is release. In addition, bilirubin is ultimately conjugated in the liver and excreted through the biliary system. Bilirubin and bile acids can both cause eryptosis and hemolysis at higher concentrations. (**b**) Strong suppression of hepcidin mRNA in mice in response to acute ethanol exposure. Liver hepcidin expression in untreated (white) and 10% ethanol, gavage-fed male 129/Sv mice for 24 h as determined by real-time PCR (n = 7). (**c**) Elevated serum hepcidin levels in heavy drinkers as compared to controls. Serum hepcidin in healthy controls (n = 10) and ALD patients (n = 310) from the Heidelberg ALD cohort. (**d**) Hepcidin is also elevated when drinkers are matched for age and gender

and bile ducts. Mechanic obstruction of canaliculi or small bile ducts or direct hepatocyte damage through e.g. alcoholic liver injury/ballooning will also cause accumulation of bile content including bilirubin and bile acids. It is often overlooked that hepatocytes are also able to "phagocytose" larger vesicles and even whole cells [72].

Present Concepts of Iron Overload in ALD and Ethanol-Mediated Dysregulation of Hepcidin

Both acute and chronic alcohol exposure have been shown to suppress hepatic hepcidin expression in rodents [73]. As will be discussed later, these early reports of acute alcohol exposure models in rodents are in contrast to human data [1]. In mice, acute exposure to ethanol for 24 h rapidly suppresses hepcidin [74]. Figure 57.4b shows confirmative data of these reports in an acute binge model in mice for 24 hours from our laboratory. We still saw suppressed hepcidin level in a chronic ethanol model after 4 weeks. Only after 4 months, hepcidin was induced as compared to controls (not shown). In these acute ethanol models in mice, it has been further shown that ethanol downregulates hepcidin promotor activity and the DNA binding activity of CCAAT/enhancer-binding protein alpha (C/EBP alpha) but not C/EBP beta in mice [54] leading to downregulation of hepcidin gene transcription thereby increasing duodenal iron transport. Recently, it has been shown that alcohol exerted different effects on TGF-β-mediated SMAD2 activation and BMP-mediated SMAD1 and SMAD5 activation [75]. Other data suggest the simultaneous inhibition of BMP-mediated SMAD activation and stimulation of TGF-β-mediated SMAD activation by alcohol in the involvement of hepcidin suppression by alcohol *in vivo*. However, doubt has been shed on publications showing suppression of hepcidin by oxidative stress [76], as these conditions were later shown to non-specifically suppress the transcription machinery while physiological low hydrogen peroxide levels even increased hepcidin [51, 77].

As already mentioned above, in our large cohort of heavy drinkers, we could not confirm suppression of hepcidin. Figure 57.4c shows that serum hepcidin levels from 300 heavy drinkers is actually increased as compared to a non-drinking control cohort (for patient characteristics see Appendix Table B.1) [1]. Of note, mean hepcidin of non-drinkers were in the range of levels reported for normal population [78]. This is also the case if drinkers and non-drinkers were matched for age (Fig. 57.4d). Of note, inflammation and elevated cytokines cannot be the sole explanation for the upregulation of hepcidin as CRP or white bloods are only moderately induced, if at all. As will be later discussed many positive upstream regulators are not correlated in these patients. In conclusion, the observed short-term inhibition of hepcidin mRNA levels by acute and high alcohol exposure cannot be recapitulated at the serum level in heavy drinking humans. As will be discussed later, low level of

hemolysis during normal RBC turnover continuously stimulates hepcidin in the absence of virtual inflammation. Erythrophagocytosis can also be studied in vitro [1]. These data also show that hepcidin is induced in response to oxidized RBCs or heme at low concentrations (below 2% hematocrit). At higher concentrations, hepcidin expression will be suppressed.

Iron Markers and Mortality in Heavy Drinkers

New preliminary data of our ongoing long-term prospective mortality study in heavy drinkers show that hemolytic anemia is one of the most important confounders of long-term mortality. Details of the ongoing study are discussed in book Chap. 7 on mortality. Briefly, in the current interim analysis, information of survival status was obtained in 786 patients that had presented from 2007 to 2022 with a mean daily consumption of alcohol of 184 g/day. Mean observation time was 3.8 years and mean duration of heavy drinking was 14.0 years. During the observation time, 159 patients (20%) had passed away. More details are provided in the chapter on mortality and in the appendix (Table B.3). The cause of death could be clarified in 47%. In 34%, the death was liver-related. Of most interest within the context of this chapter, signs of anemia were associated with long-term mortality. Table 57.2 shows an extract of parameters that are correlated with mortality. Parameters of the blood compartment are marked in red, while iron-associated markers are marked in blue. Among the three major markers of anemia (hemoglobin, RBC counts, hematocrit), RBC count was best associated with an increased mortality, suggesting that not only the amount of hemoglobin production, but also the number of cells are important. For more details, the reader is referred to the book chapter on bone marrow toxicity in this book. Interestingly, markers of anemia were better correlated with death than known other prognostic markers such as albumin or INR.

Bilirubin is also highly associated with death, and it is also often forgotten that bilirubin is the major end product of heme degradation. Multivariate analysis confirmed that low RBC count is an independent predictor of death. Table 57.2 also suggests that the anemia is primarily due to hemolysis as levels of the hemolytic enzyme LDH, the iron marker ferritin and the end-product of heme production bilirubin were all positively and significantly associated with long-term death. Moreover, death also correlated highly with a large size of RBCs (MCV), typical hallmark of drinkers. To further confirm the nature of the anemia we measured in the serum of a representative sub-cohort the precursor of conjugated bilirubin, the unconjugated or indirect bilirubin and the soluble hemoglobin-haptoglobin scavenging receptor CD163. Both showed the highest correlation with death ($r \sim 0.25$) only being surpassed by RBC count and AP. Interestingly enough, although ferritin

Table 57.2 Univariate Spearman rho correlation analysis with mortality status in 786 heavy drinkers after a mean observation time 3.8 years. Detailed table is provided in Appendix (Table B.10)

Haptoglobin (g/L)	– 0.070	1.4E-01
CAP (dB/m)	0.060	1.9E-01
Hepatic steatosis (US) (0-3)	0.035	3.9E-01

Parameters are sorted in descending order according to the absolute value of the regression coefficient r. Parameters of the blood compartment are marked in red, while iron parameters are marked in blue. Note that mortality in heavy drinkers is significantly associated with signs of hemolytic anemia (see also Chap. 7)

levels were still significantly associated with mortality, hepatic iron deposition either assessed by histology, atomic spectroscopy or non-invasive means was not associated with mortality as reported earlier (not shown). Thus, in hour cohort of heavy drinkers, we cannot confirm a direct relation between hepatic iron overload and mortality. However, the enhanced RBC turnover highly suggests that it is related to hepatic iron overload.

Hepatocyte Iron and Serum Hepcidin Levels in Heavy Drinkers

To better understand the induction of hepcidin in heavy drinkers, we first studied associated parameters with histological iron deposition in hepatocytes, the primary source for hepcidin.

As shown in Table 57.3, hepatocyte iron load, as measured histologically by Prussian blue stain, is indeed slightly negatively correlated with RBC count (although not significantly). Table 57.3 also shows that iron content in hepatocytes is associated with iron load in macrophages, other markers of iron overload such as ferritin or liver iron as measured by atomic absorption spectroscopy (AAS, the gold standard). Most importantly, hepatocyte iron is highly positively correlated with both levels of serum hepcidin and hepcidin mRNA. In Table 57.4, finally, we analyzed serum hepcidin levels and its association with other parameters in subcohort of 304 heavy drinkers. Positively and significantly associated parameters are shown on the left, negatively correlated parameters on the right. As seen, serum hepcidin levels highly correlate with hepcidin mRNA but also with several absolute markers of iron content such as hemoglobin, histological iron in hepatocytes and macrophages or total hepatic iron as measured by AAS. No conclusive associations were seen with cytokines such as IL6, although considered one of the strong and positive upstream regulators of hepcidin through the STAT3 pathway. Signs of liver cirrhosis were clearly negatively associated with hepcidin whether diagnosed by ultrasound or histology. In this analysis, the erythrophagocytosis marker CD163 was also negatively associated with hepcidin, and no clear association was found with ERFE,

Table 57.3 Univariate Spearman Rho correlation of hepatocyte iron with different parameters

Spearman Rho correlation with histological iron stain in hepatocytes

Positive associations are shown on the left, negative correlations are shown on the right. Note that serum hepcidin is tightly associated with hepcidin mRNA and parameters of iron compartments such as ferritin, histological iron stains or hemoglobin. Parameters are sorted in descending order according to the absolute value of the regression coefficient r, since this allows better direct comparison. Hepcidin is negatively associated with erythropoiesis (reticulocyte count) and signs of fibrosis

considered an important negative bone marrow derived regulator of hepcidin. Taken together, the data confirm that parameters of high iron load are positively and highly correlated with hepcidin. These findings match the current understanding of hepcidin as iron sensor. If the organism is loaded with iron (high hemoglobin levels, high ferritin levels or other iron parameters) then a high hepcidin prevents further uptake of iron through the duodenal compartment. The robust negative association of hepcidin with signs of cirrhosis is more complicated and not simply due to suppression

of protein synthesis or transcription. As e.g. shown in the Table B.25 for alpha2-macroglobulin (a2-MG), the cirrhotic liver maintains protein synthesis capacities for specific pathways, in this case alpha macroglobulin is higher in those with anemia who have progressed more. Most likely, a2-MG compensates for decreased albumin availability to maintain oncotic pressure. Alternatively, it could be due important hemodynamic changes in cirrhotic patients with a switch of the major blood supply from portal vein to hepatic artery and, consequently, with a disruption of the normal BMP6-hepcidin axes.

Macrocytic Anemia and Ineffective Erythropoiesis in Heavy Drinkers

To get more insights into potential causes of the anemia, patients were grouped (Tables 57.5, 57.6) according to the size of RBCs **mean corpuscular volume (MCV)** in three groups (microcytic <80, normocytic 80–96 and macrocytic >96). Compared to a normal population, hemoglobin levels values were about 20% lower, although only 20% of all patients full-filled criteria of anemia (<12.5 g/dL). Macrocytic group represents one third (31.8%) and it showed the highest mortality. In this group, mortality was three times as compared to patients with normocytic RBCs (31.1 vs 11.6%). Expectedly, the group with microcytic anemia, classically representing iron-deficiency anemia, had the lowest iron level. Important **hematopoietic parameters** such as levels of folic acid, erythropoietin (EPO), vitamin B12 were usually all in the normal range. In the macrocytic group, however, levels of EPO were highest and in the upper normal range, while B12 levels slightly exceeded upper normal levels. Finally, as a direct group, reticulocyte count as a direct measure of hematopoietic activity was only increased in this group.

The macrocytic group also showed further **evidence of hemolysis**. CD163, indirect bilirubin and LDH was highest while in this group haptoglobin was lowest. Based on levels of CD163 and ferritin in Tables 57.5, 57.6, ca. 50% of all drinkers show an increased erythrophagocytosis. Thus, 65.6% of all women and 46.3% of all men have elevated ferritin levels. Altogether, in 52.7%, and elevated ferritin was seen, in most cases due to ineffective erythropoiesis and enhanced heme turnover. Notably, enhanced erythrophagocytosis is not only observed in the macrocytic group (59.6%) but also in the normocytic and microcytic group (32.5 and 38.5%). In addition, ferritin levels were highest in the macrocytic group. Consequently, this laboratory represents a typical configuration of **hemolytic anemia with enhanced, but ineffective erythropoiesis**. With today's ethical and practical limitation of performing isotope RBC labeling studies in drinkers, we also used a chemical pulse chase approach to estimate RBC removal based on the specific alcohol marker phosphatitdylethanol (PEth). RBC represent the major phospholipid pool in blood

Table 57.5 Hematopoietic and iron parameters in heavy drinkers grouped according to RBC size (MCV). Complete data are provided in Appendix Table B.29

P* comparison between high and normal MCV

Note, that 31.8% of all drinkers show macrocytosis. Almost 30% of them have clear signs of anemia, corresponding to hemolytic anemia in the light of elevated ferritin levels. Hemolytic anemia is not due to the lack of folic acid and vitamin B12. Potential other causes are related either directly to RBC toxicity or bone marrow toxicity. Lowest levels of hepcidin are seen in the macrocytic group

and PEth is specifically formed in the presence of ethanol catalyzed by erythrocyte phospholipase D. Indeed, PEth elimination was highest and increased by 24% in the macrocytic group [79]. This is further underlined in Fig. 57.5, were RBC count, ferritin and CD163 levels are depicted for all three MCV groups. Figure 57.6 finally shows reticulocyte count for all three MCV groups. The reticulocyte count is an accepted measure of direct erythropoietic activity. As shown in Fig. 57.6, ALD patients with macrocytosis show an elevated erythropoiesis. Considering the fact that these patients have decreased hemoglobin levels and other indicators for hemolysis, these data further clearly confirm that alcohol causes ineffective erythropoiesis. Consequently, the enhanced RBC turnover could be considered as novel and important reasons for hepatic iron overload.

P* comparison between high and normal MCV

Patients with signs of hemolytic anemia (high MCV, signs of hemolysis, decreased hemoglobin) have a three-time increased mortality. Hemolytic anemia is also tightly linked to liver damage. Although signs of hemolysis occur already prior to the onset of liver damage, progressing cirrhosis further deteriorates RBC turnover

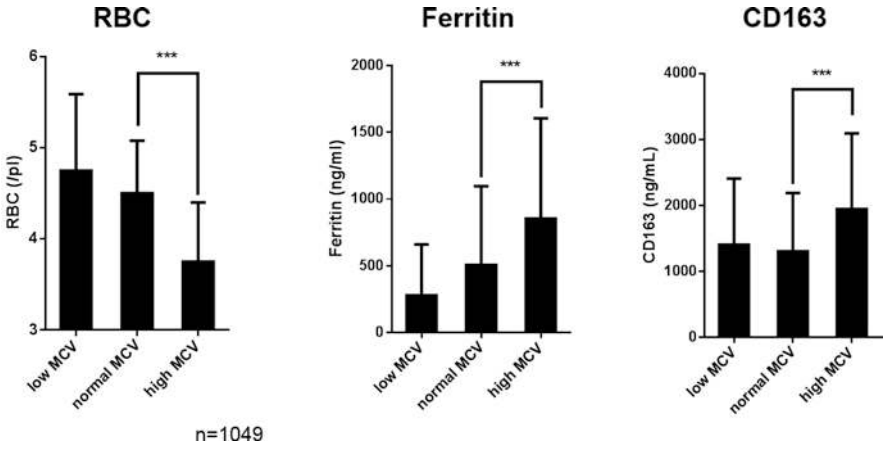

Fig. 57.5 Evidence for hemolytic anemia and elevated RBC turnover in heavy drinkers with enlarged RBC size (MCV). Patients with high MCV have a lower RBC count (anemia), elevated levels of the iron storage marker ferritin and the erythrophagocytosis marker CD163

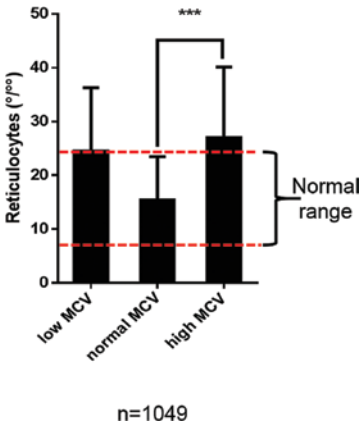

Fig. 57.6 Increased erythropoiesis (elevated reticulocyte count) in heavy drinkers with enlarged RBC size (MCV). Reticulocyte count is a direct measure of erythropoietic activity. Heavy drinkers with enlarged MCV show an enhanced erythropoiesis while patients with normal sized RBCs have normal RBC production. Note that patients with microcytic anemia (2.5%) also have increased erythropoiesis being in the upper normal range. These findings are strong indicators of an ineffective erythropoiesis in a large fraction (34%) of heavy drinkers

Is Hepcidin Involved in Iron Dysregulation in Drinkers?

As shown above, long-term heavy drinkers have upregulated hepcidin but not really elevated markers of inflammation nor a tight and conclusive association between hepcidin and markers of inflammation. To gain further insights into ethanol-mediated iron overload and the role of hepcidin, we now focused on the 52.7% patients with ineffective erythropoiesis and elevated ferritin levels has mentioned above. We divided this group into patients with normal hemoglobin and with anemia. In other words, the sub-group with normal hemoglobin seems to be able to efficiently recycle iron into de novo production of RBCs while the anemic groups fail to do so. Table 57.7 shows the data. Parameters are sorted according to the P values between both cohorts. Next to RBC count, parameters such as albumin, transferrin but also liver stiffness are among the most discriminative parameters. Direct parameters of hemolysis such as indirect bilirubin, transferrin saturation and CD163 are also significantly higher in the anemia cohort. The table underlines that, due to ineffective erythropoiesis, the anemia group seems to be overwhelmed with the recycling of damaged or fragile RBCs. It remains to be discussed whether albumin as bilirubin carrier and transferrin as iron carrier are suppressed due to liver toxicity or whether this is a specific adaptive response. There are more arguments for the latter. First, proteins such as alpha macroglobulin are increased in these patients. Second, serum iron is significantly decreased (111 vs 148 μg/dL) in the anemia group despite macrocytosis. This highly suggests that the bone marrow is overwhelmed with erythropoiesis under the toxic, alcohol-exposed environment. It also explains the elevated transferrin saturation which is not due to total iron increase in the serum compartment but rather reduced transferrin.

Table 57.7 Heavy drinkers with ineffective erythropoiesis and elevated ferritin (ca. 50% of all drinkers) are grouped according to anemia status. Note that suppression of important carrier proteins (albumin, transferrin) but also liver stiffness show the most significant differences between both groups. The anemia group also demonstrates higher levels of hemolysis as shown by CD163, LDH and indirect bilirubin

T-Test was performed, and parameters are sorted according to P values in ascending order. Note that suppression of important carrier proteins (albumin, transferrin) but also liver stiffness shown the most significant differences between both groups. The anemia group also shows higher levels of hemolysis as shown by CD163, LDH and indirect bilirubin

To better understand the underlying signaling of hepcidin, we further studied several important hormones such as EPO, but also BMP6, ERFE and cytokines, all involved in hepcidin regulation. The results are shown in Table 57.8, but the data remain largely inconclusive and it seems that not a single factor controls hepcidin expression. Hepcidin is slightly lower in the anemia group but BMP6, an important upregulator, is suppressed, and ERFE, and important negative regulator, is also suppressed. Moreover, IL6, also a strong upregulator of hepcidin, is also suppressed while IL8 is slightly increased. Of

Several categories are shown, and parameters are sorted according to P values in ascending order within the category. Note that hepcidin is slightly lower in the anemia group that has higher intracellular iron levels. Also note that erythropoiesis boosts after alcohol detoxification (reticulocyte count 2)

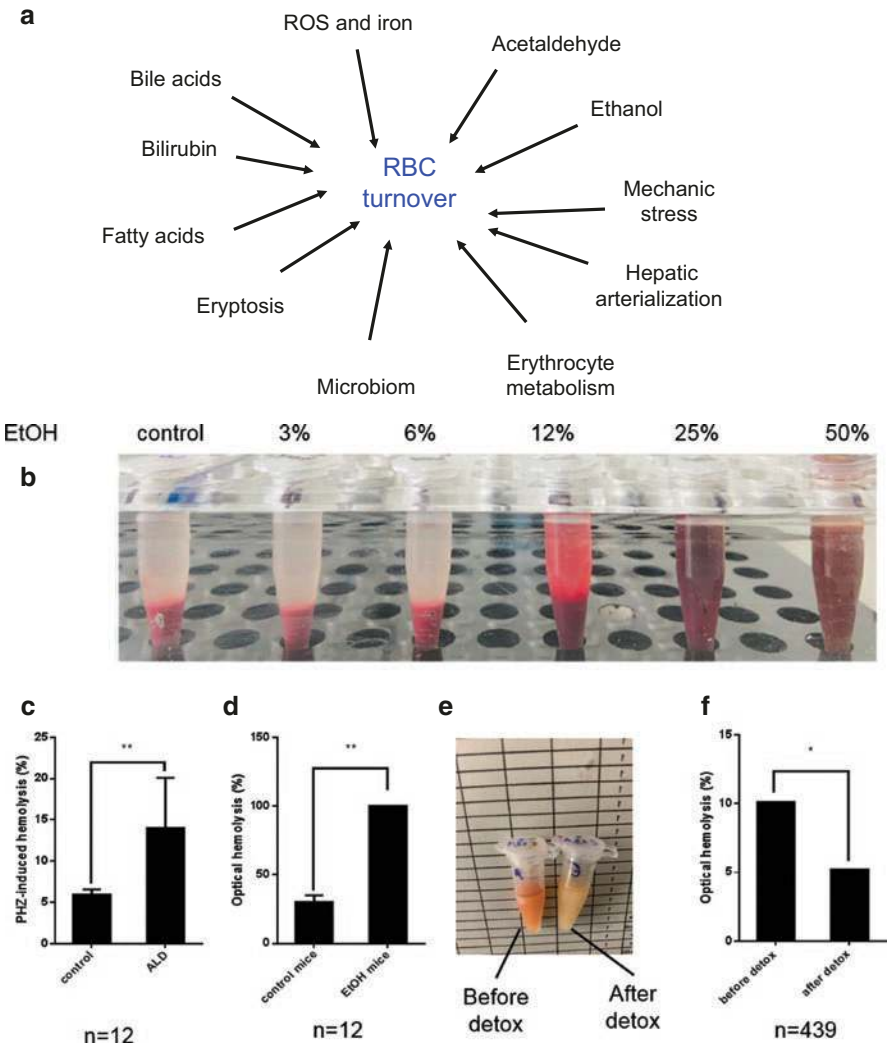
note, erythropoiesis boosts after 1 week of alcohol detoxification as shown by doubling of reticulocytes. Consistently, histological iron is higher both in macrophages and hepatocytes. Although rather complex, these findings allow the conclusion that, due to ineffective erythropoiesis and enhanced RBC turnover, both macrophages and hepatocytes are loaded with iron. In response, specific carrier proteins are downregulated rather than in a non-specific manner, to prevent toxic iron overload.

Potential Mechanisms of Hemolytic Anemia in Heavy Drinkers

It is known for a long time that alcohol consumption can result in structural and metabolic abnormalities of the erythrocyte membrane leading to hemolytic anemia varying from very mild to severe [80]. Reasons for hemolytic anemia are disorders altered erythrocyte cytoskeleton proteins, an increase of lipid fluidity by oxidative stress [81] and reduced phosphate levels (hypophosphatemia) [82]. In drinkers, an abnormal structure of erythrocyte surface can cause dysfunctional and heteromorphic echinocytes, such as stomatocytes or spur cells [80]. These spur cells with an irreversible rigid membrane will be prematurely removed by spleen macrophages [83, 84]. Spur-cell associated hemolysis is observed in ca. 3% of chronic heavy drinkers ultimately leading to progressive fatal anemia [82]. However, these changes have been not associated with mortality so far besides the novel mortality data presented in Table 57.2.

Several studies and experiments were performed to learn more about hemolysis in our cohort of heavy drinkers. Figure 57.7a demonstrates that ethanol can directly lyse fresh human RBCs as compared to e.g. hypoosmotic or mechanic shear stress conditions [57]. This is due to the amphiphilic properties of ethanol (see Fig. A.2) as we strictly controlled osmolality in these experiments. Although the concentrations of 10% are quite high, they could be readily achieved during binge drinking of high percentage beverages, at least in some blood compartments. Moreover, it has been recently shown that ethanol itself or enhanced levels of bile acids and conjugated bilirubin are able to induce eryptosis or prime RBCs for erythrophagocytosis [1, 85, 86]. Besides these direct hemolytic erythrophagocytosis-priming effects of

Fig. 57.7 RBC turnover and various signs of hemolysis in human RBCs of heavy drinkers. (**a**) RBC turnover is complex and affected by multiple factors. (**b**) Direct exposure of human RBCs with ethanol (EtOH) for 24 h. Note, that hemolysis or modification only occurs at quite high levels of ethanol (ca. 10%) which, however, may be achieved during binge drinking in some compartments using high percentage liquors or wine. (**c**) RBCs of heavy drinkers are more fragile in response to hemolytic stress by phenyl hydrazine or mechanically during blood taking. RBCs from both heavy drinkers and healthy volunteers (each cohort n = 6) were in silico treated with the hemolytic agent phenyl hydrazine (PHZ) for 60 minutes and hemolysis was measured by absorption spectroscopy in the supernatant. Hemolysis rate of ALD patients was significantly higher than in healthy controls. It indicates that RBCs seem to be generally more fragile in drinkers. (**d**) Presence of optical hemolysis in serum samples of ethanol-treated mice. Six mice were treated for 4 weeks with ethanol (see above). (**e**) Example of optical signs of hemolysis in a serum sample from a heavy drinker before and 1 week after alcohol detoxification. (**f**) Significantly lower optical hemolysis in sera after alcohol withdrawal in a large study on optical signs of hemolysis in serum samples before and after alcohol detoxification. Statistical analysis of frozen serum samples form n = 439 heavy drinkers prior and 1 week after alcohol detoxification from the Heidelberg heavy drinker cohort collected between 2007 and 2022. It is assumed that, in this large cohort of patient sample, mean mechanic stress to RBCs was similar both prior and after alcohol withdrawal. The data suggest that 1 week of alcohol detoxification already improves ethanol-mediated RBC fragility



ethanol, it can be also demonstrated that blood from heavy drinkers is less resistant to either direct chemical or mechanic hemolytic stress. Figure 57.7b shows a significant increase of ex vivo phenyl hydrazine (PHZ)-induced hemolysis in RBC preparations from heavy drinkers and controls. Hemolysis was directly measured photometrically after 60 min incubation with PHZ. These results are especially convincing since the test measures the overall fragility of RBCs towards a standard stress situation but does not detect the specific cause of hemolysis (membrane rupture, reduced antioxidative defense, hypophosphatemia etc.).

We also studied in our cohort of heavy drinkers another phenomenon of hemolysis. If RBCs from heavy drinkers or ethanol-treated animals should be more vulnerable to mechanic stress, routine blood taking should also causes more hemolysis as compared to healthy controls. This is shown in Fig. 57.7d which demonstrates the presence of optical macroscopic hemolysis in serum samples of ethanol-treated mice Fig. 57.7e in serum samples before and 1 week after alcohol detoxification in n = 439 heavy drinkers prior and 1 week after alcohol detoxification. It is assumed that, in this large cohort of patient sample, mean mechanic stress to RBCs was similar both prior and after alcohol withdrawal. The data suggest that 1 week of alcohol detoxification already improves ethanol-mediated RBC fragility.

We could also show that 4 weeks of chronic ethanol exposure significantly upregulates CD163 in mouse livers (Fig. 57.8a, b). The importance of the hemochromatosis gene HFE is underlined in Fig. 57.8c. Here, almost no hepcidin upregulation is observed a mouse model of hemolysis (PHZ). In other words, heme recycling seems to require an adequate hepcidin response that controls the iron release both from macrophages and hepatocytes through the iron exporter ferroportin. Figure 57.9 finally shows that normal human RBCs (Fig. 57.9a) develop spur-like phenotypes under conditions of oxidative stress (Fig. 57.9b, copper sulfate treatment) and area readily ingested by macrophages (Fig. 57.9c, human THP1 macrophage). They are also ingested by hepatocytes (Fig. 57.9d), a process called efferocytosis and not studied very well. We have been able to show RBC efferocytosis both in human cancer-derived hepatocytes but also in primary mouse hepatocytes. It remains unclear how

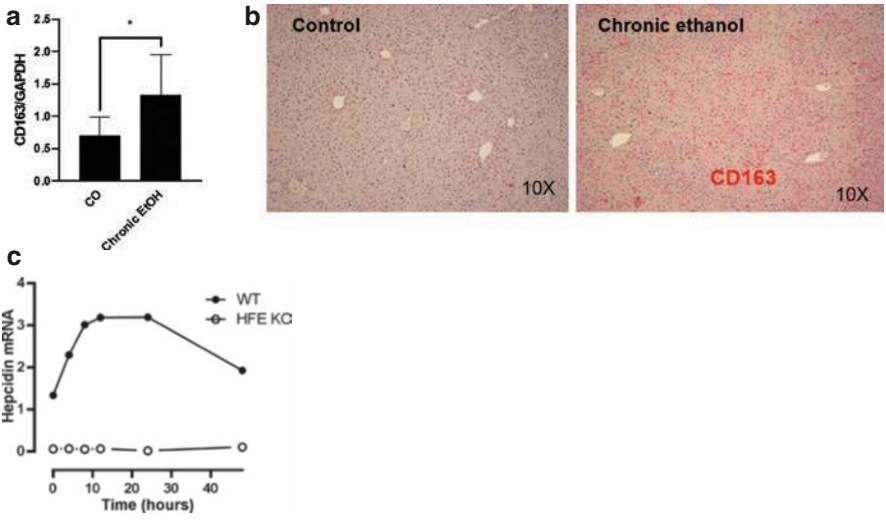


Fig. 57.8 Induction of the hepatic hemoglobin-haptoglobin scavenger CD163 in a chronic alcohol exposure model. (**a**) CD163 Western blot in mouse liver after 4 weeks of chronic alcohol feeding (n = 7). (**b**) Representative example of a CD163 immunostaining (red, Vectastain) and HE background stain. Note that CD163 is expressed in the liver (Kupffer cells) underlining the importance of hepatic erythrophagocytosis next to spleen erythrophagocytosis. (**c**) In wild type mice, mild hemolysis by phenyl hydrazine induces hepcidin mRNA which is completely blunted in the absence of HFE (HFE KO mice)

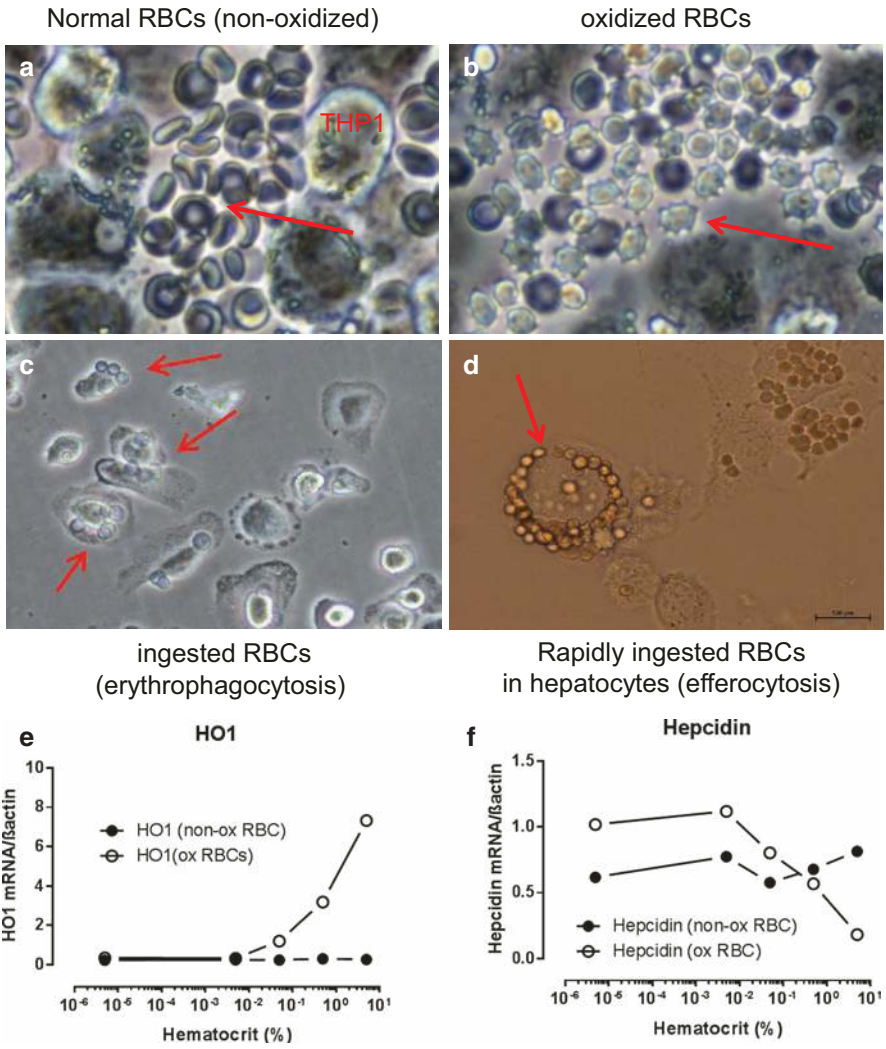

Fig. 57.9 Erythrophagocytosis in vitro of oxidized human erythrocytes. (**a**) Control RBCs (red arrow) and co-cultured human THP1 macrophages. (**b**) Morphological changes (spur cells, red arrow) of RBCs in the presence of copper sulfate-induced oxidative stress after 120 minutes (**c**) Erythrophagocytosis of oxidized human erythrocytes (red arrow, oxidized by copper sulfate) by THP-1 cells. (**d**) **Efferocytosis** of oxidized RBCs by hepatocytes. Huh7 cells were exposed for 60 min to oxidized human RBCs. RBCs are also rapidly ingested by hepatocytes which is demonstrated by aligning around the cell nucleus. Ingestion can also be seen in primary hepatocytes, followed by a strong HO1 response (not shown). Efferocytosis has been less studied in liver science. (**e**) Induction of HO-1 mRNA and (**f**) hepcidin mRNA in THP1 macrophages with increasing amounts of oxidized (white circles) and non-oxidized (black circles) RBCs. THP1 cells were exposed to oxidized RBCs (shown as %hematocrit). No HO1 induction is seen with non-oxidized control RBCs. Note that hepcidin mRNA is suppressed at high hemolysis rates

RBCs are directly taken up through the fenestrated endothelium in liver sinusoids. Finally, Fig. 57.9e, f demonstrates the expression of both hepcidin and HO1 during in vitro erythrophagocytosis with oxidized human RBCs using the macrophage cell line THP1. The figures demonstrate that only oxidized RBCs induced phagocytosis and HO1. It also demonstrates, the hepcidin is induced only at lower heme levels but suppressed and higher concentrations. The underlying mechanisms that are independent of bone marrow factors such as ERFE have been recently discussed [1, 48, 49]. It should be finally mentioned that alcohol directly interferes with the RBC production in the bone marrow and the hematopoietic stem cells. These mechanisms are more discussed in the chapter about ethanol-mediated bone marrow toxicity.

Clinical Implications of Ethanol-Induced Hemolysis for Hepatic Iron Overload

The prospective mortality analysis in heavy drinkers identifies hemolytic anemia as major prognostic factor (see Fig. 57.10). This is also implications for hepatic iron overload, long being recognized as typical feature in ALD. Since ca. 1% of the blood (ca. 40 mL, 20 mg iron) are recycled every day though the spleen-liver axis, this system becomes highly vulnerable to liver insults, since the heme degradation products needs to be eliminated by hepatocytes. Since the iron-carrier capacity of transferrin only allows to carry 2–3 mg undergoing receptor-mediated endocytosis and exocytosis, an enormous microtubule activity is required. This is

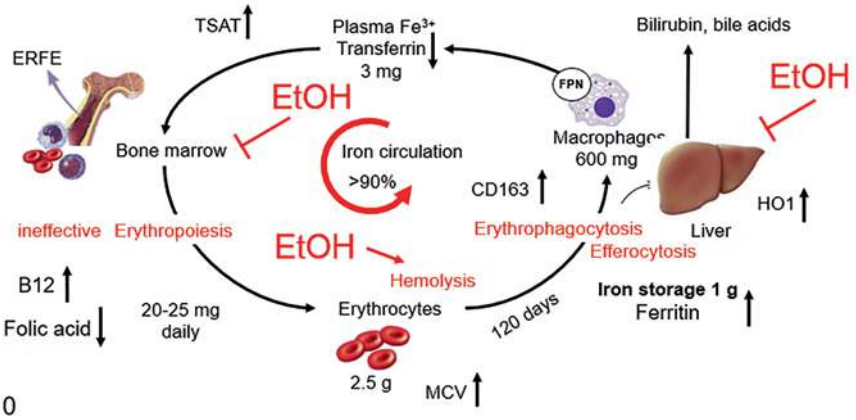

Fig. 57.10 Summarizing scheme of hematological and iron changes in heavy drinkers. Generally, RBC turnover is enhanced. Ethanol interferes with RBC turnover at three major sides: it blocks hematopoiesis, primes RBCs for erythrophagocytosis and interferes with hepatic iron handling. Major consequences are elevated ferritin and MCV, suppressed transferrin and low RBC count. Hemolytic anemia is one of the major factors associated with long-term mortality in heavy drinkers

also relevant for bilirubin transport which requires albumin binding and endocytic uptake within hepatocytes. Our clinical data show that ca. 50% of all heavy drinkers show some sign of ineffective erythropoiesis, meaning enhanced RBC turnover and heme release. In those patients were the hepatocyte is further impaired by ethanol, the enhanced bilirubin and iron recycling will cause an additional insult. As shown in Table 57.9, hemolysis as measured by CD163 levels is highest associated with hepatocellular bile acid production. Although a direct link between hemolysis and bile acid production has not been described and many explanations may account for this observation, it is quite intriguing that enhanced RBC turnover may not only be associated with release of bilirubin but also modulated bile formation, as RBCs are the major source of cholesterol and phospholipids in blood which are both also released and synthesized by hepatocytes, next to bile acids.

The link to RBCs has also shed new light on the hepcidin studies by us and others. Both, in vitro and in vivo, mild, physiological hemolysis causes a non-inflammatory hepcidin upregulation. Under conditions of severe hemolysis such as thalassemia, hepcidin is paradoxically inhibited. This has been intensively discussed in [1]. In our believe, the total understanding of iron homeostasis in heavy drinkers requires the cellular, organ and systemic considerations. Thus, the in Fig. 57.1 described lower iron levels in cirrhotics are very likely caused by an uncoupling of the spleen-liver axis under conditions of portal hypertension, where most of the

Positively associated markers are linked to hemolysis (indirect bilirubin, AST), erythropoiesis and liver damage while negatively associated markers are hemoglobin or important carrier proteins that are all synthesized in the liver. Suppression may be rather due to an adaptive response than toxicity since not all liver-synthesized proteins are suppressed (e.g. macroglobulin)

portal blood will bypass the liver and only has access to hepatocytes through multiple, by far less efficient systemic cycles through the hepatic artery. Consequently, the iron-carrying transferrin and bilirubin-carrying albumin will have less access to hepatocytes. Ultimately, since RBC fragility seems to be the major causes of iron disturbances, future therapeutic measures should be more target at the complex interplay of iron homeostasis but at stabilization of RBCs and, potentially, the bone marrow. As will be discussed in the chapter about ethanol-mediated bone marrow toxicity, alcohol detoxification at least transiently, deteriorates in some patients RBC fragility and hemolysis. The causes for this are not directly alcohol related and require further studies.

Conclusions

About half of all heavy drinkers show pathological hepatic iron overload. We here demonstrate that enhanced RBC turnover is strongly associated with mortality in heavy drinkers and seems to be a key mechanism responsible for the long-observed iron accumulation in alcohol drinkers (Fig. 57.10) (see also Chap. 7 on mortality in heavy drinkers). In line with this, ca. 50% show an enhanced erythrophagocytosis and ineffective erythropoiesis as evidenced by increased CD163 elevation and ferritin in the serum. In general, and in contrast to former acute ethanol exposure models in mice, heavy drinkers have elevated hepcidin levels. Our preliminary data both in humans and animals indicate that hepcidin is primarily upregulated due to continued physiological heme turnover. This regulatory loop is disrupted by HFE mutation, cirrhosis development or severe hemolysis. There are also first indications that ethanol blocks erythropoiesis (see also Chap. 58 on bone marrow toxicity). Taken together, RBC recycling provides a first comprehensive but complex rational for hepatic iron overload in patients with ALD. The data also provide new insights into our understanding of alcoholic hepatitis.

Chapter 58
Ethanol-Mediated Bone Marrow Toxicity and Impaired Erythropoiesis: Implications for Alcohol-Related Liver Disease

Sebastian Mueller and Marina Scheller

Abstract Alcohol-related liver disease (ALD) has been long associated with changes of red blood cells (RBC) such as macrocytosis with an elevated mean corpuscular volume (MCV). However, their implications for prognosis and disease progression have been poorly studied and understood. First preliminary data from the Heidelberg prospective study on long-term mortality in heavy drinkers has identified macrocytic hemolytic anemia as important confounder of survival in drinkers. This suggests an important role of bone marrow toxicity and connects hematopoiesis to the development of liver disease. The enhanced RBC turnover is not primarily due to vitamin or hormone deficiency but rather to enhanced RBC degradation and bone marrow injury, eventually resulting in so-called ineffective erythropoiesis. Preliminary studies in mice show that chronic alcohol exposure for 4 weeks drastically suppresses the stem cell niche while, in a compensatory manner, erythroblast maturation is increased. Of note, in humans, alcohol withdrawal initially deteriorates ineffective erythropoiesis, worsens anemia, and increases MCV. This either suggests that chronic ethanol-mediated damage to the stem cell compartment needs further repair or that additional conditions such as toxic iron overload additionally contribute to bone marrow damage. These observations have important clinical implications. There are first indications that the novel findings are not only relevant for ALD but also the rare but often fatal alcoholic hepatitis. The observations are also related to Zieve syndrome, a rare but severe form of hemolysis during heavy alcohol consumption.

Introduction to ALD

Alcohol-related liver disease (ALD) is the most frequent cause of severe liver disease in Europe. Based on the WHO database, more than 40% of the liver deaths are attributed to alcohol [1]. The number of performed liver transplantations for patients with ALD-related cirrhosis has increased over the past two decades, both in Europe and in the USA [2, 3]. Despite the high burden of ALD, it is regrettable that most patients with ALD are diagnosed in a stage of decompensation. As shown in Figs. B.7 and B.8, ALD includes a wide spectrum of lesions ranging from steatosis to steatohepatitis, progressive liver fibrosis, cirrhosis and its complications [1]. Although steatosis occurs in >90% of heavy drinkers (see e.g. Table B.9, it is estimated that only 10–20% will develop cirrhosis [4]. Genetic and non-genetic factors also modify both individual susceptibility and the clinical course of ALD [5], however, the underlying mechanisms are not completely understood. Most animal studies have been performed in rodents with chronic alcohol intake (e.g. Tsukamoto-French model or Lieber-DiCarli diet). However, these models induce only moderate liver disease and severe fibrosis, while liver damage usually develops after an additional insult by another toxic agent. Few studies have been performed so far in livers from patients with ALD. These translational studies are needed to develop novel targeted therapies for these patients [5].

ALD has been long associated with changes of red blood cells (RBC) such as macrocytosis with an elevated mean corpuscular volume (MCV). However, their implications for prognosis and disease progression have been poorly studied and understood. First preliminary data from the Heidelberg prospective study on long-term mortality in heavy drinkers has identified macrocytic hemolytic anemia as important confounder of survival in drinkers (see also Chap. 7). This suggests an important role of bone marrow toxicity and connects hematopoiesis to the development of liver disease. The enhanced RBC turnover is not primarily due to vitamin or hormone deficiency but rather to enhanced RBC degradation and bone marrow injury, eventually resulting in so-called **ineffective erythropoiesis**. We here discuss first preliminary data in a mice model of chronic alcohol exposure for 4 weeks demonstrating a drastic suppression of the stem cell niche while, in a compensatory manner, erythroblast maturation is increased. Of note, in humans, alcohol withdrawal initially deteriorates ineffective erythropoiesis, worsens anemia, and increases MCV. This either suggests that chronic ethanol-mediated damage to the stem cell compartment needs further repair or that additional conditions such as toxic iron overload additionally contribute to bone marrow damage. The observations have important clinical implications. There are first indications that the novel findings do not only have implications for ALD but also the rare but often fatal

alcoholic hepatitis (see also Chaps. 64–68). Whether the **Zieve syndrome**, a rare but severe form of hemolysis during heavy alcohol consumption, is caused by bone alcohol-mediated marrow damage remains an open question [6].

Production and Recycling of Red Blood Cells

In the last decades, an enormous progress has been made to better comprehend the molecular mechanisms of iron regulation and homeostasis at the systemic and the cellular level [7, 8] (see also Chap. 57). The human body contains ca. 5 g of iron, of which ca. 2.5 g is used in oxygen-carrying hemoglobin of red blood cells (RBC) (Fig. 58.1) corresponding to 0.5 mg iron per ml of blood. Another 2.0 g is used in liver, bone marrow and macrophages, mostly in the iron-storage protein ferritin and iron-containing proteins such as cytochromes [9]. The liver serves as interim iron storage organ and can store up to 1 g. Circa 0.4 g are devoted to cellular proteins and enzymes in other cells. Iron is typically stored (ferritin, transferrin, enzymes) in the ferric state (Fe^{3+}) but crosses membranes though transporters in the highly reactive reduced, ferrous state (Fe^{2+}). Iron circulates bound to transferrin to be released to all organs/tissues through transferrin receptor 1. The transferrin bound ferric iron is relatively small only representing 2 mg. Most iron is recycled by macrophages, which phagocytize senescent RBCs, a procedure termed **erythrophagocytosis**. Most of RBC recycling occurs mainly in the spleen and liver through the

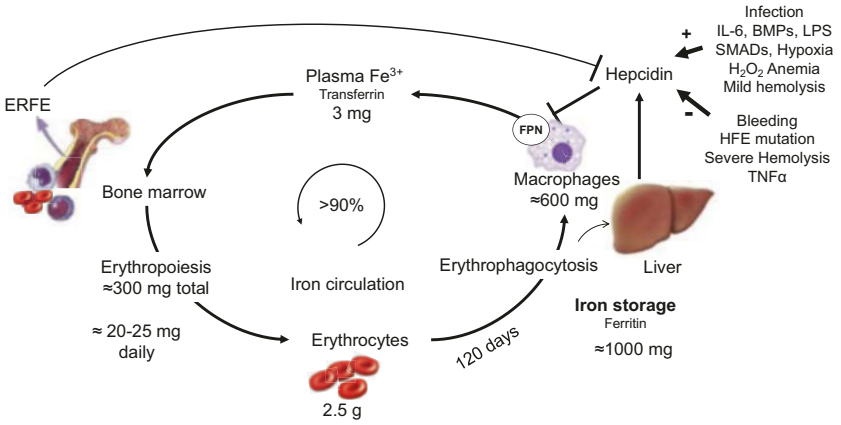

Fig. 58.1 System iron homeostasis and utilization in the human body. Dietary iron is absorbed in the duodenum and binds to transferrin. Iron is then delivered to the bone marrow for erythropoiesis the major utilization pathway. Senescent RBCs are phagocytosed by macrophages (erythrophagocytosis) and ca. 90% of iron is recycled for heme synthesis. Excess iron is stored in ferritin in the liver. Bone marrow-derived ERFE (erythroferrone) is an important repressor of hepcidin. Also note that mild hemolysis (physiological RBC turnover) stimulates hepcidin while severe hemolysis causes massive suppression

reticuloendothelial system. Macrophages can also directly recycle iron for new RBC production in the bone marrow [10].

The daily uptake of dietary iron by duodenal enterocytes compensates for net loss or iron and is relatively small with 1–2 mg [7]. Interestingly, in contrast to general believe, according to earlier observations, iron is not only lost through cell desquamation and blood loss but also through the bile and urinary tract [11]. As shown in Fig. 58.1, altogether about 90% of iron is recycled from senescent RBCs that typically have a mean survival of 120 days [10]. In other words, and considering that an average individual has 5 L total blood (2.5 g iron), ca. 40 mL blood are recycled every day which equals ca. 20–25 mg iron. Likewise, these 25 mg of iron is required for *de novo* erythropoiesis in the bone marrow [12].

During erythrophagocytosis, iron is recovered from the degradation of hemoglobin and heme by hydrolytic enzymes in the phagocytic vesicles. Iron is further released from heme in the endoplasmic reticulum by heme oxygenase-1 (HO-1) and then again redistributed to tissues via serum transferrin (see Fig. 58.1) [12]. More information about HO1, its upstream regulation and potential intracellular interactions are shown in Figs. A.73, A.74, and A.75. Besides the spleen, liver macrophages (Kupffer cells) are also an important side of erythrophagocytosis. In addition, liver is also the only location for bilirubin glucuronidation and excretion through canaliculi and bile ducts (see Fig. A.60). Mechanic obstruction of canaliculi or small bile ducts or direct hepatocyte damage through e.g., alcoholic liver injury/ballooning will also cause accumulation of bile content including bilirubin and bile acids.

Control of Iron Homeostasis during Erythropoiesis

More details about iron homeostasis and ALD are provided in book Chap. 57 on iron and ALD. A complex interplay exists between the liver and blood system requiring a fine-tuned coordination of iron homeostasis. Cells of both the blood compartment and the liver participate in iron homeostasis through specific functions. For instance, erythroblasts are specialized in iron uptake, macrophages and hepatocytes in iron export and iron storage. May be not by chance, both hepatocytes and macrophages share the expression of important iron related proteins and signaling cascades such as HO-1, ferritin, ferroportin and secretion of hepcidin. There are important differences, however, how hepcidin is regulated in both cell types [13] and respond to oxygen-derived molecules [14]. Hepatocytes also release almost 10 times more hepcidin than macrophages [14].

Absence or blockage of erythropoiesis or bone marrow failure, e.g., under conditions of aplastic anemia, myelodysplastic syndrome etc., lead to accumulation of iron in the blood that saturate the buffering capacity of serum transferrin and result in non-transferrin-bound highly reactive forms of iron. The excess iron in all these cases is derived from senescent RBCs that mainly accumulate in liver macrophages and later hepatocytes as mentioned above (see Fig. 58.2). Studies in animal models

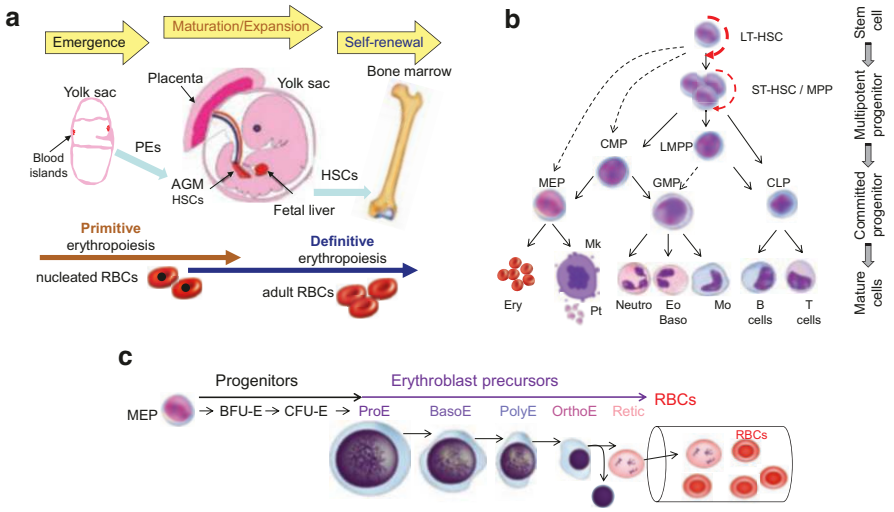

Fig. 58.2 Hierarchical organization of fetal and adult hematopoiesis. (**a**) There are three developmental stages of hematopoiesis in mammals. The first – the emergence of primitive erythroblasts (PE) in yolk sac blood islands, presence of nucleated erythrocytes, so called, primitive erythropoiesis. In the second – maturation and expansion of the HSC that emerges from the aorto-gonad mesonephros (AGM). Third – the self-renewal HSC migrates to fetal liver and to the adult BM, producing definitive erythroblasts. (**b**) Classical (solid line) and alternate (dotted) models of the adult haematopoietic hierarchy. In the classical model, the HSCs gives rise to either a CMP or CLP. The CMP then differentiates into either a GMP or MEP. These progenitors differentiate into mature cells of distinct lineages. Alternate pathways (dotted lines): HSCs were shown to differentiate directly into CMP, MEP and megakaryocytes. HSC can also differentiate into a lymphoid primed multipotent progenitor (LMPP) lacking any megakaryocyte erythroid potential. (**c**) Erythroid differentiation in the mouse: from MEPs to mature RBCs. *BFU-e* burst-forming unit, erythroid, *BM* bone marrow, *CFU-e* colony-forming unit, erythroid, *CLP* common lymphoid progenitor, *CMP* common myeloid progenitor, *GMP* granulocyte monocyte progenitor, *HSCs* hematopoietic stem cell, *MEP* megakaryocyte-erythroid progenitor, *MPP* multipotent progenitor, *RBC* red blood cell

[15, 16] and humans [17, 18] have shown that hepcidin expression is dependent on the degree of erythropoiesis, showing a dominance of the erythropoiesis over the storage regulator [19, 20]. Altogether, ineffective erythropoiesis strongly suppresses hepcidin, induces excess iron absorption finally leading to hepatic iron overload comparable to hereditary iron overload. The underlying mechanism, however, are still poorly understood.

Erythroferrone (ERFE) has been identified as important negative erythroid regulator of hepcidin and, in contrast to many other hepcidin stimuli (see Fig. 58.1) [21]. When the release of erythropoietin from the kidney stimulates the production of new RBCs, it also increases the synthesis of ERFE in bone marrow erythroblasts. Increased ERFE then suppresses hepcidin synthesis, thereby mobilizing cellular iron stores for use in heme and hemoglobin synthesis. Recent mechanistic studies have shown that ERFE suppresses hepcidin transcription by inhibiting bone

morphogenetic protein signaling in hepatocytes. In ineffective erythropoiesis, pathological overproduction of ERFE by an expanded population of erythroblasts suppresses hepcidin and causes iron overload, even in non-transfused patients. However, besides ERFE, we could recently demonstrate that excess of non-toxic iron, *in vitro* and in the absence of erythroid cells, is also able to suppress hepcidin expression [22].

Organization of Fetal and Adult Erythropoiesis

Hemoglobin-producing RBCs are the terminally differentiated end-product cells of a lineage-restricted erythroid progenitor which undergo differentiation and enormous expansion to cover the daily needs of $\sim 2 \times 10^{11}$ new erythrocytes [23]. There are large similarities between humans and mice, the latter often used for RBC development studies. Developmentally, there are two types of RBCs - embryonic and adult (Fig. 58.2a). In mice, the early embryonic erythroid cells arise in the yolk sac from the mesodermal cells. They are nucleated and short-lived cells [24]. This developmental stage known as primitive erythropoiesis, shows more immature, less differentiated erythroblasts or megaloblasts that are not pluripotent and self-renewing (Fig. 58.2a). The yolk sac blood islands contain primitive nucleated erythrocytes that disappear from the circulation very quickly during the embryonic-to-fetal transition period resulting in macrocytic and enucleated erythrocytes. Erythromyeloid progenitors (and subsequently hematopoietic stem cells, HSCs) from the aorta-gonad-mesonephros (AGM) region will migrate to the fetal liver to produce the first definitive erythrocytes (Fig. 58.2a). Similarly, in humans, definitive hematopoiesis from HSC and hematopoietic progenitors (HPCs) first in the AGM region, later in the fetal liver, until the 4th–fifth months of pregnancy. During embryonic and fetal development, hematopoiesis takes place in different organs: the yolk sac, the aorta–gonad mesonephros region, the fetal liver, the spleen, and bone marrow (Fig. 58.2a).

The hematopoietic function of the fetal liver is especially related to its erythroid function. Finally, HSCs from fetal liver migrate and colonize the bone marrow (BM) at birth, where they provide lifelong production of definitive RBCs. While the spleen, in addition to BM, remains an important additional erythropoietic organ in mice, the BM remains the **major place for steady-state adult erythropoiesis** in humans. Only under erythroid stress conditions, mainly as a compensatory mechanism under conditions of impaired BM function, spleen and liver of both mice and humans are used to expand the erythropoietic capacity [25]. This process is called extramedullary hematopoiesis (EMH).

Maturation from erythroid-committed precursors is called terminal erythropoiesis. It starts with HSCs in the adult BM (Fig. 58.2b, c). HSCs possess the unique ability to both self-renew and to generate multipotent (MPPs) and common myeloid progenitors (CMP) or common lymphoid progenitors (CLP) (Fig. 58.2b). The classical hierarchical relationship is, however, currently challenged by alternate differentiation pathways (Fig. 58.2b, dotted arrow) [26–28]. The committed granulocyte

monocyte progenitors (GMPs) differentiate into mature granulocytic and monocytic cells. Megakaryocyte erythroid progenitors (MEPs) further differentiate into erythroid precursor cells with distinct morphologies (Fig. 58.2c).

Burst forming unit-erythroid (BFU-E) cells are progenitors that possess colony-formation capacity in response to growth factors in methylcellulose culture *in vitro*. These multi-subunit colonies (or bursts) contain thousand hemoglobin-harboring cells and appear after 5–8 days (mouse) or 10–14 days (human) in culture. Later, more mature erythroid progenitors consisting of small colony- forming units-erythroid (CFU-E) colonies of 16–125 cells appear further after 2–3 days (mouse) or 5–8 days (human) of culture. Erythroblasts (EP) differentiate gradually reducing in cell and nuclear size, to proerythroblasts (ProE), basophilic erythroblasts (BasoE), polychromatophilic erythroblasts (PolyE), and orthochromatic erythroblasts (OrthoE) (Fig. 58.2c) [29, 30]. Specifically, one orthochromatic erythroblast undergoes an asymmetric division and divides into two cells, one containing the nucleus with a small cytoplasm, and one enucleated reticulocyte, which later matures into a red blood cell [30]. Normal and pathological erythropoiesis can be successfully analyzed using fluorescence-activated cell sorting (FACS) techniques based on changes in the expression of cell surface markers on mouse and human erythroid cells at different stages of erythropoiesis.

Alcohol-Related Toxicity on the Hematopoietic System

As shown in Table 58.1, alcohol can cause damage to hematopoietic cells both directly and indirectly [31–33]. The direct toxic targets of excessive alcohol include most of bone marrow cells, blood stem cells and precursors, mature erythrocytes, white blood cells, and platelets [31]. Impairment affects not only process of blood cells production but also changes bone marrow cell morphology. The most commonly observed effects of morphological changes are **large vacuoles** in erythroid and megakaryocytic lineages especially in early RBC precursor cells which usually emerge in the pronormoblasts within 7 days after heavy alcohol intake and disappear within 1–2 weeks after abstinence [34–37]. Culturing normal marrow cells in nutrient medium with alcohol can induce cytoplasmic vacuolization as well, and the proportion of cells developing vacuoles appears to correlate with the concentration of alcohol [37]. Of note, the hematologic alterations occur despite the concomitant administration of pharmacologic doses of folic acid [38]. To a lesser extent, vacuoles also develop in the granulocyte precursors of heavy drinkers.

The precise mechanisms underlying vacuole development in blood cell precursors is currently unknown but seems to be an indication for cell stress and reflects an adaptive response for cell survival, ultimately leading to different forms of cell death [39, 40], however, its role in survival versus apoptosis remains unclear. Moreover, alcohol induces oxidative stress, disrupts protein production in the ER, and inhibits ubiquitin-proteasome activity in cells [41–43]. These negative effects of alcohol on cell functions may potentially contribute to the formation of vacuoles.

Table 58.1 Reported effects of ethanol and its metabolites on erythropoiesis and RBCs

Molecules	Targets	Effects	Ref.
Ethanol	Intestine	Folate deficiency	Medici et al. [45]
Ethanol	Erythroid precursors	Vacuolization and cell death	Roselle et al. [36] Yeung et al. [37]
Ethanol	Erythroblasts	Iron deposit and ring sideroblasts, sideroblastic anemia	Pierce et al. [100] Lindenbaum et al. [98]
Ethanol	Erythrocytes	Elevated MCV, macrocytic anemia	Seppä et al. [94] Maruyama et al. [91]
Acetaldehyde	Hemoglobin	Forming adducts with hemoglobin A	Stevens et al. [106]
Acetaldehyde	DNA	Blocking DNA translesion	Yu et al. [72]
ROS	Erythrocytes	Disorder of erythrocyte cytoskeleton, stomatocytes and spur-cells	Morse et al. [107] Fukuda et al. [108] Koch et al. [109]
ROS	Erythroblasts	Disturbing the enucleation	Zhao et al. [110]
Fatty acid ethyl ester	Erythrocytes	Incorporating into the membrane and causing hemolysis	Tyulina et al. [111]

It is possible that vacuolization directly primes erythroid precursors to death, thereby contributing to macrocytic anemic of chronic drinkers combined with nutritional deficiency especially folate [44, 45]. Cytoplasmic vacuoles, however, can be also seen in several other clinical settings such as copper deficiency/zinc toxicity, antibiotic treatment, myelodysplastic syndrome (MDS), and acute myeloid leukemia (AML) [46–48]. Thus, blast vacuoles predict poor overall survival in AML patients undergoing induction chemotherapy [49]. Another consequence of alcohol cell toxicity is cell death via the apoptosis pathway. Although human and murine embryonic (ESCs), neural (NSCs) and mesenchymal stem cells (MSCs) are sensitive to the induction of apoptosis by alcohol administration, HSCs appear to be more resistant [50]

The other deleterious effect of alcohol abuse associates with myelosuppression, disruption of homeostasis of granulopoiesis and impaired functional activities of granulocytes [51–53]. This represents an underlying mechanism for defects in immune defenses in alcohol-dependent patients with severe bacterial infections, particularly pneumonia and septicemia reviewed in [50, 53, 54]. Analysis of alcoholic patients with severe neutropenia has shown that early granulocytic progenitors do not mature in bone marrow, and neutrophil stores are emptied faster than in healthy controls [31]

The cytotoxic effect of alcohol also affects the development of platelets. Although the abnormal alcohol-related cytotoxic effects on platelets development have been adequately described, a systematic review of the relationship between alcohol and thrombocytopenia is still lacking, and the postulated hypotheses are not adequately supported by research evidence [55].

Overall, chronic, and acute alcohol exposure affects multiple hematopoietic cell populations and their functions, indicating the crucial role of HSCs, which should be able to self-renew and restore the entire blood system under alcohol-related toxicity. Normally, HSCs reside in a quiescent state in specialized niches in the bone marrow, which represent an interdependent network of endothelial, osteolineage cells, pericytes, reticular (CAR) cells, MSCs, fat cells [56, 57]. Alcohol may impact key aspect of stem cell biology, namely maintenance of self-renewal and differentiation, indirectly fashion by altering function and maintenance of the cells in the bone marrow niche. These causes increase in osteocyte apoptosis and accumulation of lipid droplets within the osteocytes, which has been associated with the reduction of bone mass and decreased bone formation observed in alcoholics [58–60]. Such alcohol-induced adipogenic activity in the BM niches leads to osteopenia and pro-inflammatory environment and mobilization [61].

Ethanol-Derived Metabolites Potentially Involved in Bone Marrow Toxicity

Besides the direct influence of alcohol on bone marrow cells, the alcohol-derived metabolites such as acetaldehyde (AA) and reactive oxygen species (ROS) leads to enormous toxicity. The toxic effects of AA are caused by its ability to interact with proteins, peptides and other biomacromolecules in the cell to form harmful adducts [62, 63]. The formation of AA-induced adducts on the erythrocyte membrane is associated with ethanol-induced an abnormally large number of enlarged erythrocytes in the blood, called macrocytosis, and have been found both in blood and bone marrow of patients with ethanol-induced erythrocyte abnormalities [64].

Alcohol-induced ROS (see also Figs. A.35, A.67, A.68) modify erythrocyte membranes which leads to destabilization [65]. Normally, ROS decreases in erythroblasts in later stages when the cells are preparing for enucleation. However, in heavy drinkers, ROS accumulation of terminal erythropoiesis will interfere with the initiation of enucleation [66]. Furthermore, alcohol metabolism generates a variety of nitrogen oxygen species (NOS) radicals (see also Figs. A.35, A.67, A.68), which significantly alter erythrocyte membrane fluidity, membrane bound proteins, enzymes and transport mechanisms [65, 67].

Compared to alcohol effects per se, its metabolites, AA and ROS are mutagenic and carcinogenic due to induction of DNA damage [68, 69]. The obvious manifestations of AA-induced DNA damage are severe cytogenetic abnormalities, sister chromatid exchanges (SCEs), and chromosomal aberrations, including translocations and rearrangements [70, 71]. In particular, AA reacts with DNA to primarily form a dysfunctional adducts which ultimately and efficiently block DNA synthesis [72]. It also binds to proteins critical for DNA repair and DNA methylation, and to the antioxidant glutathione, causing both differentiation defects in stem cells as well as genomic damage that incites cellular aging and carcinogenesis [69, 73].

With regard to the hematopoietic system, it has been demonstrated that AA affects survival of HSCs but not their progenitors in the absence of aldehyde dehydrogenase (*Aldh2)* [74]. *At the same time,* AA and endogenous aldehydes in the absence of the protective role of the Fanconi anemia DNA repair pathway (*Fancd2*-loss) and *Aldh2* leads to engraftment defects and a severe depletion of the HSC pool and their progeny, including B cells and granulocyte-macrophage progenitors [70, 74]. Indeed, deficiency in aldehyde dehydrogenase 2 (ALDH2) expression and function in patients of East Asians (*ALDH2*2* genetic polymorphism) has been found to be associated with marrow failure, with both an increased risk of sporadic aplastic anemia and more rapid progression of Fanconi Anemia [75]. This points to important crosslinks between alcohol detoxification pathways and DNA repair mechanisms in triggering severe phenotypes of HSCs and their blood lineages. Furthermore, formaldehyde produced by the metabolism of methanol, which may be also present in alcoholic beverages at small amounts, exerts a genotoxic effect on HSCs [76]. In addition to AA, ROS also affects HSC function, induced hematopoietic aging linking elevated ROS levels and impaired DNA repair mechanisms [77] (Fig. 58.3). Taken together, alcohol derived AA acts as a genotoxic agent that can induce mutations in HSCs. Alcohol does not destroy healthy mature circulating cells, it gradually ruins HSCs and blood cells factory, resulting in bone marrow failure.

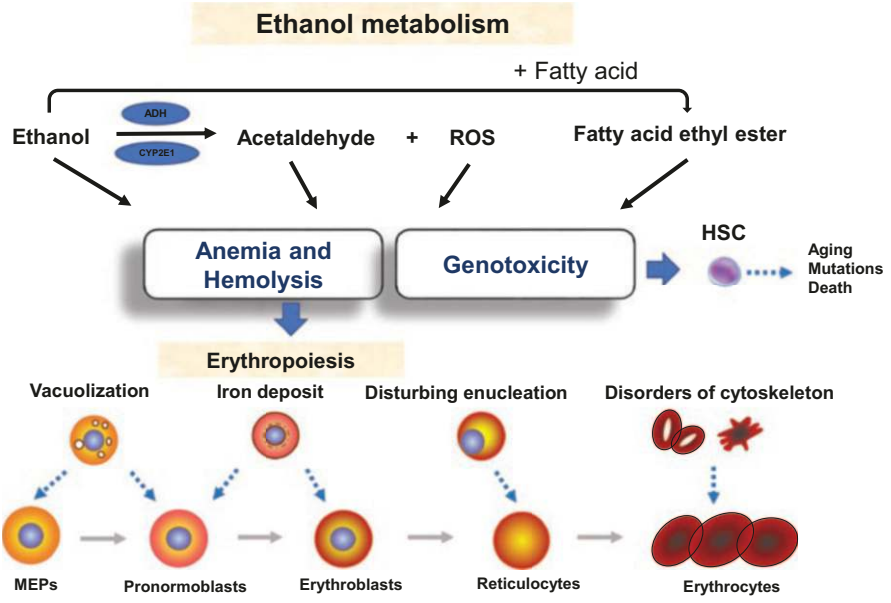

Fig. 58.3 Ethanol metabolism and bone marrow toxicity. Ethanol and its metabolites acetaldehyde, reactive oxygen species (ROS) and fatty acid ethyl ester interfere with erythropoiesis and cause damage to stem and precursor cells such as erythroblasts. This leads to vacuolization of MEPs and pronormoblasts, iron deposit in erythroblasts and malfunctional enucleation of reticulocytes

In steady state conditions, high and low oxygenated areas present in the BM microenvironment create conditions for a differential production of ROS in different niches. These niches contain undifferentiated HSCs with low levels of ROS and high self-renewal potential [78–80]. Conversely, ROS high areas contain more cycling, HSCs and progenitors that show bias toward myeloid differentiation, like aged mice *in vivo* [78]. Increased ethanol-induced ROS-stress may leads to reduced stem cell regenerative potential, excessive differentiation, resulting in stem cell "exhaustion", loss of ability to efficiently replenish progenitor pools that finally contribute to bone marrow failure. ROS seem well tolerated in "young" HSCs with highly proficient DNA repair, and thus have few long-term deleterious effects. However, "aged" HSCs, with less efficient repair become more sensitive to ROS levels, accumulate DNA damage [81] that lead to increased genome instability.

In summary, alcohol consumption causes impairment of structure, signaling, metabolism, proliferation, and differentiation of hematopoietic cells. HSCs and the upstream multipotent progenitors are more resistant to the negative effects exerted by ethanol and acetaldehyde in comparison to the myeloid and the downstream progenitor cells [82] which is thought to be related to aldehyde dehydrogenase (ALDH) activity [83–85]. Whether the Zieve syndrome, a rare but severe form of hemolysis during heavy alcohol consumption, is caused by alcohol-mediated bone marrow damage remains an open question [6].

Alcohol-Related Effects on Erythropoiesis

When ethanol was administered to human volunteers in doses equaling 46 to 66 per cent of caloric intake, and excellent protein and vitamin intake was maintained, vacuolization of bone-marrow pronormoblasts developed [38]. Their presence appeared to be dose-related. Vacuolation of promyelocytes was seen less consistently, and only with the larger doses. The hematologic alterations occurred despite the concomitant administration of pharmacologic doses of folic acid [38]. It directly damages erythroid precursors with vacuolization [33, 34, 37], thereby contributing to macrocytic anemic of chronic heavy drinkers combined with nutritional deficiency especially folate [44, 45]. Nucleated bone marrow cells metabolize ethanol [86] and the metabolites can also exert negative effects on erythropoiesis by disrupting and/or impairing the structural integrity, signaling regulation, metabolism, survival, proliferation, as well as differentiation of hematopoietic tissue [70, 87, 88].

Macrocytic Anemia and Sideroblastic Anemia in Heavy Drinkers

Excessive alcohol consumption is one of the most common causes of **macrocytosis (an elevated mean corpuscular volume of erythrocytes - MCV**) and non-megaloblastic macrocytic anemia [89, 90]. Alcohol detoxification can improve the

elevated MCV [91]. On the other side, it is also commonly observed that MCV can remain elevated for months despite abstaining from alcohol. Neutrophil hypersegmentation is a useful sign of folate depletion in patients [92, 93], whereas serum folate concentrations are not reliable. The Michigan Alcoholism Screening test and obtaining γ-glutamyl transferase (GGT) levels are most sensitive tests for detecting heavy drinkers and alcohol dependence with macrocytosis (see also Chap. 37), who may also exhibit other typical symptoms such as gynecomastia, caput medusae, and jaundice [94]. Significant folate depletion in alcoholism has been described as important reason for macrocytosis [95, 96]. The normal production and maturation of erythroid precursor cells require folic acid and other B vitamins [31]. Although ethanol itself has been considered as the main reason of folate deficiency in alcoholics [93], there are conflicting results and we and others have not seen a stringent association between an elevated MCV deficiency of folic acid and vitamin B12 (see also text to Table 58.3).

Sideroblastic anemia is characterized by the emergence of ring sideroblasts in bone marrow [97, 98]. In some patients with alcoholism, iron cannot be properly incorporated in hemoglobin. These pathological erythroblasts which have particular iron accumulation in perinuclear mitochondria are called ringed sideroblasts [99] and cannot further develop into functional erythrocytes. Acquired sideroblastic anemia is a common complication in heavy drinkers [100]. Furthermore, alcoholic sideroblastic anemia is often associated with **myelodysplastic syndrome** [101]. It has been shown that ring sideroblasts usually disappear within 1 week of abstinence [31].

Preliminary Lessons from the Prospective Survival Cohort of Heavy Drinkers in Heidelberg: Hemolytic Anemia as an Important Prognostic Marker

Mortality data are essential to identify important confounders of disease progression. So far, no prospective long-term data on survival are available for patients with ALD. In 2007, the Heidelberg Center for Alcohol Research started to prospectively enroll heavy drinkers. Most patients are presenting for alcohol detoxification allowing to also collect data after ca. 1 week of alcohol withdrawal. The study is still ongoing and covers now almost 15 years (see also Chap. 7). In an interim analysis, information of survival status was obtained in 786 patients that had presented from 2007 to 2022 with a mean daily consumption of alcohol of 184 g/day. Mean observation time was 3.8 years and mean duration of heavy drinking was 14.0 years. During the observation time, 159 patients (20%) had passed away. More details are provided in Chap. 7 on mortality. The cause of death could be clarified in 47%. In 34%, the death was liver-related. As shown in Table B.10, **signs**

of anemia were associated with long-term mortality. Among the three major markers of anemia (hemoglobin, RBC counts, hematocrit), a long RBC count was especially associated with an increased mortality. Interestingly, these markers were better than known other prognostic markers such as albumin, INR, or bilirubin. Multivariate analysis confirmed that low RBC count is an independent predictor of death.

Anemia in response to chronic alcohol exposure can have multiple causes ranging from iron deficiency due to blood loss up to inflammation. However, as discussed in the chapter on mortality, anemia rather shows typical characteristics of hemolytic anemia meaning that RBCs are destroyed faster than they can be made. Thus, levels of the hemolytic enzyme LDH, the iron marker ferritin and the end-product of heme production bilirubin were all positively and significantly associated with long-term death. Moreover, death also correlated highly with a large size of RBCs (MCV), the typical hallmark of drinkers. To further confirm the nature of the anemia we measured in serum of a representative subcohort the precursor of conjugated bilirubin, the unconjugated or indirect bilirubin and the soluble hemoglobin-haptoglobin scavenging receptor CD163. Both showed the highest correlation with death ($r \sim 0.25$) only being surpassed by RBC count and AP. In conclusion, long-term follow up in our prospective cohort of heavy drinkers identifies signs of **hemolytic anemia** as predominant predictor of death.

To get more insights into potential causes of the anemia, patients were grouped (Tables 58.2 and 58.3) according to the size of RBCs (MCV) in three groups (microcytic <80, normocytic 80–96 and macrocytic >96). Compared to a normal population, Hb values were about 20% lower, although only 20% of all patients full-filled criteria of anemia (<12.5 g/dL). The macrocytic group represents one third (31.8%) and it showed the highest mortality. In this group, mortality was three times as compared to patients with normocytic RBCs (31.1 vs 11.6%). Expectedly, the group with microcytic anemia, classically representing iron-deficiency anemia, had the lowest iron level. Important **hematopoietic parameters** such as levels of folic acid, EPO, B12 were usually all in the normal range. In the macrocytic group, however, levels of EPO were highest and in the upper normal range, while B12 levels slightly exceeded upper normal levels. Finally, reticulocyte count as a direct measure of hematopoietic activity was only increased in this group.

The macrocytic group also showed further **evidence of hemolysis**. CD163, indirect bilirubin and LDH was highest while in this group haptoglobin was lowest. Based on CD163 levels in in Table 58.2 and 58.3, 44% of all drinkers show erythrophagocytosis. Notably, enhanced erythrophagocytosis is not only observed in the macrocytic group (59.6%) but also in the normocytic and microcytic group (32.5 and 38.5%). In addition, ferritin levels were highest in the macrocytic group. Consequently, this laboratory represents a typical configuration of **hemolytic**

Table 58.2 Various parameters in heavy drinkers grouped according to RBC size (MCV)

Groups	Units	Normal	P*	high MCV	normal MCV	low MCV	All

P* comparison between high and normal MCV
Note, that drinkers with signs of hemolytic anemia (high MCV, signs of hemolysis, decreased hemoglobin) have a three-time increased mortality. Hemolytic anemia is also not due to the lack of folic acid and vitamin B12. Potential other causes are related either directly to RBC toxicity or bone marrow toxicity

anemia with enhanced, but ineffective erythropoiesis. Finally, we studied the effect of alcohol detoxification on RBC markers. As shown in Fig. 58.4, both anemia (RBC count and hemoglobin) and RBC size (MCV) further deteriorate despite increased reticulocytes/erythropoiesis after ethanol detoxification. This either suggests that chronic ethanol-mediated damage to the stem cell compartment needs further repair or that additional conditions such as toxic iron overload contribute to hemolysis. The observation has important clinical implications as alcohol withdrawal can have negative side effects and a sudden withdrawal from alcohol may put some patients at risk. Besides the molecular mechanisms of the further pronounced ineffective erythropoiesis after alcohol detoxification, it remains to be studied whether this phenomenon contributes to the rare but often fatal alcoholic hepatitis.

P* comparison between high and normal MCV

Hemolytic anemia is also tightly linked to liver damage, as shown by elevated transaminases, bilirubin and liver stiffness. Although sigs of hemolysis occur already prior to the onset of liver damage, progressing cirrhosis further deteriorates RBC turnover. CD163, the hemoglobin-haptoglobin scavenging receptor is also highest in the high MCV group

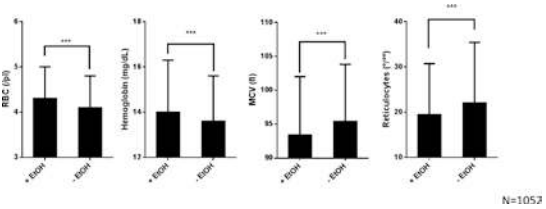

Fig. 58.4 Red blood cell parameters after alcohol detoxification. Note that both anemia (RBC count and hemoglobin) and RBC size (MCV) further deteriorate despite increased reticulocytes/erythropoiesis after ethanol detoxification. This either suggests that chronic ethanol-mediated damage to the stem cell compartment needs further repair or that additional conditions such as toxic iron overload play a role. The observation has important clinical implications as alcohol withdrawal can have some negative side effects. Besides the molecular mechanisms of the further pronounced ineffective erythropoiesis after alcohol detoxification, it remains to be studied whether this phenomenon contributes to the rare but often fatal alcoholic hepatitis

Alcohol-Related Effects on the Hematopoietic Stem and Progenitor Cells: Preliminary Data from an Ethanol Mouse Study *In Vivo*

Despite the considerable amount of research in this area, many questions remain unanswered of how alcohol-related stress impact the hematopoietic stem/progenitor cells function and their terminal differentiation. Due to its relevance, we are here sharing first preliminary findings of alcohol effects on hematopoietic system in a murine alcohol model. In this model, we focus on cellular aspects between alcohol consumption, iron overload and erythropoiesis. We explored two different established murine models of alcohol exposure. In the first [102], animals, C57BL/6N mice were fed 20% ethanol in water for 2–4 h in a dark cycle (DID-model). The other explored the classical isocaloric Lieber-DeCarli (LD) diet with alcohol (4.5 g/kg) [103]. Although, total body wight was not changed, ethanol tended to increase the liver/body weight ratio in both models (Fig. 58.5a), which was in difference to [104]. Four weeks after alcohol exposure, a significant increase of fat content as

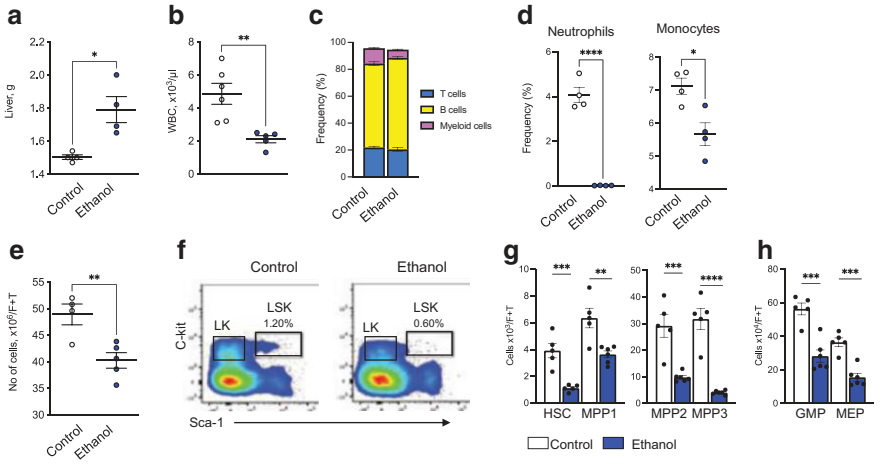

Fig. 58.5 Hematopoietic changes in a chronic murine ethanol model. A classical isocaloric Lieber-DeCarli diet with alcohol (4.5 g/kg) was applied for 4 weeks. (**a**) Elevation of liver weight and (**b**) Decrease of WBCs in peripheral blood (**c**) Frequency of the major differentiated cell lineages: B-, T- and myeloid cells in the peripheral blood of control and ethanol-treated mice (**d**) reduced frequency of the neutrophils and monocytes in the peripheral blood (**e**) Decreased total number of nucleated cells in the bone marrow as indication of toxic ethanol effects on stem und progenitor reservoir. (**f**) Representative FACS plot with gating strategy of stem and progenitor cells (LSK) from control versus ethanol-treated mice (**g**) Reduction number of HSCs and further undifferentiated MPPs. (**h**) Interestingly, ethanol-treated mice produced less of more committed myeloid GMPs and megakaryocytic-erythroid progenitors (MEPs). Abbreviations: *CLP* common lymphoid progenitors, *CMP* common myeloid progenitors, *GMP* granulocyte monocyte progenitors, *HSC* hematopoietic stem cell, *LSK* progenitor cells, *MEP* megakaryocyte erythroid progenitors, *MPP* multipotent stem cells, *Sca-1* stem cell antigen-1

assess by oil red O stain was observed but no signs of inflammation, iron changes or fibrosis (data not shown). On the other hand, level of blood AST were significantly increased after 4 weeks in the LD mice, confirming the development of liver injury in LD mice.

The hallmark of progressive alcoholic toxicity on the hematopoietic system in humans is anemia, neutropenia and thrombopenia. Four weeks post alcohol feeding, "chronic" mice showed a **remarkable decrease of WBCs** in peripheral blood (Fig. 58.5b). Multilineage contribution within WBCs showed reduction of frequency and number of myeloid cells, especially mature neutrophils and circulating monocytes, showing higher sensitivity to ethanol-related toxicity compared to B- and T-lymphoid lineages (Fig. 58.5c, d), confirming results by others [103].

The total number of nucleated cells also in the bone marrow was reduced showing toxic effect on stem und progenitors' reservoir (Fig. 58.5e). Determination of HSCs and progenitors in various developmental stage using phenotypic surface marker as described [105] showed reduction number of HSCs and further undifferentiated MPPs (Fig. 58.5f, g). Interestingly, LD and DID mice produced less of more committed myeloid GMPs and megakaryocytic-erythroid progenitors (MEPs) (Fig. 58.5h).

Thus, chronic ingestion of alcohol affected the early stem and progenitor compartment, especially the myelo-erythroid line. Ethanol-related effects were analyzed more precisely on differentiation stage of erythroid progenitors from proerythroblast till reticulocytes (Fig. 58.6a FACS and b picture, morphology of cells). Erythroid progenitors and their maturation can be monitored by the differential expression of CD44 and TER119 in mouse (Fig. 58.6a). Earlier megakaryocyte–erythroid progenitors (MEPs) lack TER119, but downstream erythroid progenitors, proerythroblast are $Ter119^{+}$ $CD44^{+}$ (Fig. 58.6a, b Fraction I). Accordingly, further differentiated stage may subdivide into downstream progenitor populations as II (basophilic erythroblasts), III (polychromatic erythroblasts), IV (orthochromatic erythroblasts) and V (reticulocytes) (Fig. 58.6a, b, plot of CD44 versus FSC (reflecting the cell size) of the TER119 positive cells). Our quantitative analysis revealed that alcohol drastically reduce number of all nucleated erythroblasts (I II III IV) (Fig. 58.6c). These findings demonstrate the decreased erythropoietic activity of bone marrow under stress conditions. Of note, within the nucleated erythroblast population, the ProE (I), Baso (II), Poly (III), and Ortho (IV) maintain the 1:2:4:8 ratio (Fig. 58.6d, left and e), confirming a normal progression of erythropoiesis in bone marrow. However, under chronic alcohol abuse, the ratio changed to 1:2:9:26 (Fig. 58.6d, right and e), showing intensive proliferation/mitotic division under alcohol-induced stress (shifting in the direction of enucleated erythrocytes). Surprisingly, proportion of enucleated erythrocytes/reticulocytes (V), measured in BM were slightly increased but number of mature RBCs in peripheral blood was unchanged (Fig. 58.6f, g).

In conclusion, these preliminary data in an *in vivo* ethanol mouse model show that chronic **alcohol exposure drastically decreases the number of phenotypically identified stem and early progenitors**. Our study also confirms the deleterious effects of chronic alcohol on early myeloid progenitors to mature circulating

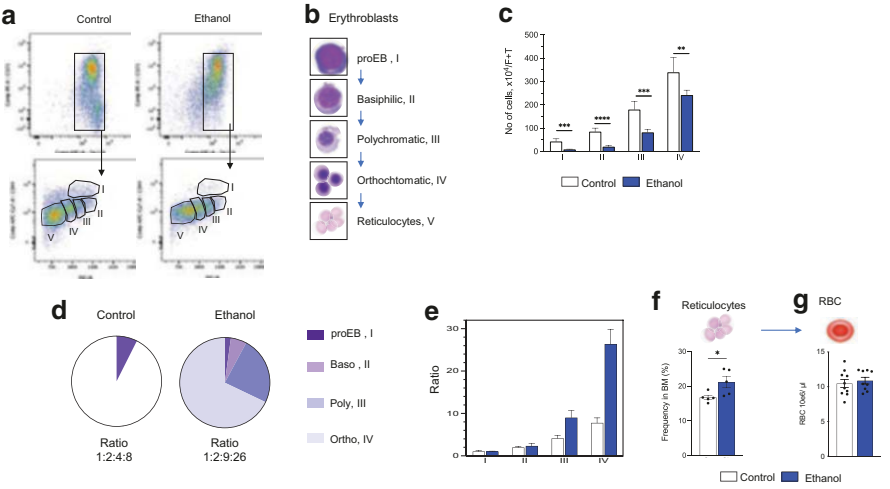

Fig. 58.6 Chronic ingestion of alcohol affects erythroid progenitor compartment. (**a**) Erythroblast differentiation stage of erythroid progenitors from proerythroblast till reticulocytes (stage I-V) can be analysed by FACS using expression of CD44 and TER119. (**b**) Morphology of maturation types I-V based on expression of CD44 and TER119 in mouse. MEPs downstream erythroid progenitors, proerythroblast (ProE, stage I) are $Ter119^{+}$ $CD44^{+}$. Further differentiated stage subdivide into downstream basophilic erythroblasts (Baso), II, polychromatic erythroblasts (Poly), III, orthochromatic erythroblasts (Ortho), IV and reticulocytes, V. (**c**) Quantitative analysis shows that alcohol drastically reduces number of all nucleated erythroblasts (I, II, III, IV). (**d** and **e**) Within the nucleated erythroblast population, the ProE (I), Baso (II), Poly (III), and Ortho (IV) maintain the 1:2:4:8 ratio (6**d**, left and **e**), confirming a normal progression of erythropoiesis in bone marrow. However, under chronic alcohol abuse, the ratio changed to 1:2:9:26 (**d**, right and **e**), showing intensive proliferation/mitotic division under alcohol-induced stress (shifting in the direction of enucleated erythrocytes). (**f** and **g**) Proportion of enucleated erythrocytes/reticulocytes (V), measured in BM were slightly increased but number of mature RBCs in peripheral blood was unchanged. Abbreviations: *CLP* common lymphoid progenitors, *CMP* common myeloid progenitors, *GMP* granulocyte monocyte progenitors, *HSC* hematopoietic stem cell, *LSK* progenitor cells, *MEP* megakaryocyte erythroid progenitors, *MPP*, multipotent stem cells, *Sca-1* stem cell antigen-1

granulocytes and monocytes. Erythroid cells were sensitive to alcohol exposure, developmental stages and maturation were disrupted, showing intensive proliferation in the late developmental stage from polychromatic to orthochromatic differentiation stage.

Conclusions

Enhanced RBC turnover seems to be a key mechanism responsible for the long-observed iron accumulation in alcohol drinkers. Although major ethanol-metabolites such as acetaldehyde and ethanol are able to cause hemolysis, quite

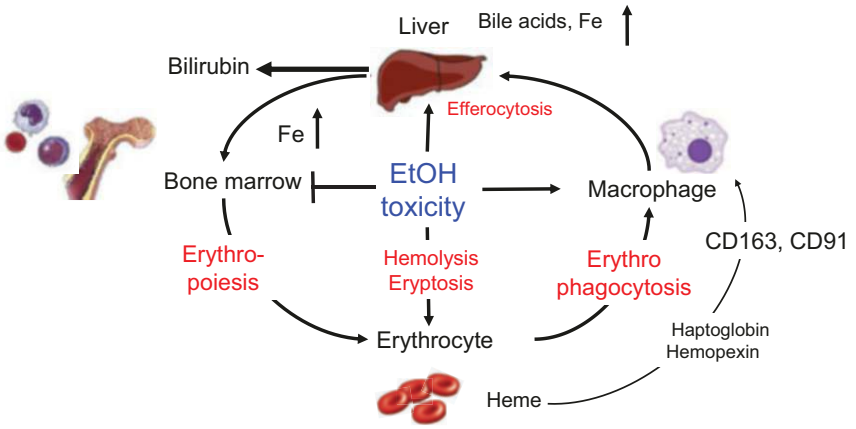

Fig. 58.7 Present model of potential interactions of ethanol with the red blood cell cycle. Ethanol increases RBC turnover by both enhancing degradation and erythropoiesis. Hepatocytes can also contribute to RBC recycling by direct efferocytosis, a process that is still poorly understood. Also note that folic acid levels decrease during ethanol-mediated ineffective erythropoiesis while B12 levels increase (see Table A2a)

high concentrations are necessary that may only be transiently reached e.g. in the portal vein (see also Chap. 57). However, many other causes of hemolysis are present in heavy drinkers and may be related to an altered RBC metabolism, a weakened erythrocyte antioxidant defense system by ethanol, priming for eryptosis, erythrophagocytosis or efferocytosis and, finally, at later stages of ALD, related to toxic effects of accumulating bile acids, bilirubin, hypalbuminemia and hypoosmolality. There are first indications that **bone marrow toxicity**, most likely at the **stem cell compartment**, contributes to this impaired RBC synthesis. It could also explain why MCV is elevated in ALD and considered a hallmark of chronic alcohol consumption for many decades. Of note, MCV remains elevated for several weeks despite complete alcohol withdrawal. Vitamin analysis by us and others also indicated that the seemingly first explanation, deficiency of either vitamin B12 or/and folic acid, are not the cause of MCV elevation in heavy drinkers. These observations also suggest that alcohol itself, so it may be the trigger for stem cell impairment, is not directly involved. One potential hypothesis could be the concept that iron accumulation itself could cause stem cell compartment toxicity as **iron overloaded erythroid precursor** cells have been observed in drinkers for a long time. Figure 58.7 schematically illustrates how alcohol may interact with the RBC life cycle. The observations are also related to Zieve syndrome, a rare, poorly understood but severe form of hemolysis during heavy alcohol consumption [6].

Chapter 59
The "Matrisome" and Alcohol-Related Liver Disease

Gavin E. Arteel

Abstract The progression of ALD represents a spectrum of disease stages ranging from simple steatosis, or fatty liver, to inflammation and necrosis (steatohepatitis), and ultimately, to fibrosis and cirrhosis. Unfortunately, severe ALD is usually first diagnosed when the patients show symptoms of severe liver dysfunction, where no therapies have been proven effective. Although the classic meaning of the ECM referred to only proteins directly involved in generating the ECM structure, such as collagens, proteoglycans and glycoproteins, the definition of the ECM is now broader and has been coined the 'matrisome'. The matrisome is a dynamic compartment that comprises a diverse range of players that work bi-directionally with hepatic cells to regulate overall homeostasis. However, when these responses are dysregulated, the changes to the ECM can be maladaptive. The most well-recognized example of ECM dyshomeostasis in the liver is that of hepatic fibrosis. Although end-stage collagenous scarring of an organ/tissue is often considered synonymous with ECM remodeling, this remodeling is actually a key factor in early stages of injury and restitution from injury and much more diverse than simple collagen accumulation. The purpose of this review is to explore the role (or potential role) of ECM dyshomeostasis across the earlier spectrum of pathology caused by alcohol consumption prior to fibrosis (i.e., steatosis, cell death and inflammation) and to discuss new approaches and opportunities of to discover and leverage this understanding to prevent and treat ALD.

Introduction

The Need for Better Strategies to Prevent and Treat Alcohol-Related Liver Disease

According to the National Survey on Drug Use and Health conducted in 2015, 86.4% of U.S. adults report consuming alcohol at some point in their lives [1], and the value is >50% Worldwide [2]. Alcohol (mis)use is reportedly the seventh leading risk factor for both death and disability-adjusted life years (DALYs) lost globally [3, 4]. A major burden of alcohol consumption and misuse is caused by alcohol-related liver disease (ALD). ALD impacts millions each year and is now the leading indication for liver transplantation in the US [5]. The incidence of ALD has been increasing across all ages and sociodemographics since 2008, with young adults (25–34) being the most rapidly growing group [6]. The latter point is alarming, as ALD is historically viewed as a disease that first manifests in middle age [7].

The progression of ALD is well-characterized and is actually a spectrum of liver diseases, that range from simple steatosis, or fatty liver, to inflammation and necrosis (steatohepatitis), and ultimately, to fibrosis and cirrhosis [8]. Moreover, alcohol-related hepatitis (AH) is an acute clinical syndrome that can occur at any time during the progression of ALD with a dismal survival rate [9, 10]. Although the prevalence of subclinical liver damage in heavy drinkers is nearly 100%, only a fraction of this at-risk population will later develop clinically relevant ALD [9]. Unfortunately, severe ALD is usually first diagnosed when the patients show symptoms of severe liver dysfunction (i.e., decompensation) very late in disease progression, where no therapies have been proven effective [10]. As a consequence, the overall prognosis of ALD has not improved in decades.

Over 65 years ago, there was a paradigm shift in the field of atherosclerosis, another pathogenic process characterized by lipid dysmetabolism, chronic inflammation and damage, and at the end-stage, by collagenous scarring. Specifically, atherosclerotic disease was no longer considered an unavoidable and untreatable condition of the elderly, but rather a chronic lifelong disease with identifiable and preventable risk factors that manifest at a young age [11]. This shift was driven by a landmark study in which Enos et al. [12] demonstrated that 77% of autopsied US soldiers killed in action during the Korean War already showed significant remodeling of their coronary arteries, indicative of early stage atherosclerosis. Moreover, a fraction of these young soldiers already had nearly complete vessel occlusion and were at high risk for clinically relevant cardiovascular disease later in life [13]. Research and therapy for atherosclerosis now focus on mechanism(s) of disease development prior to collagenous scarring of the plaque, as these targets more responsive to therapeutic intervention [14]. A major research goal in the alcohol-related liver disease field is to achieve a similar paradigm shift from treatment to prevention/intervention by better understanding the mechanism(s) of disease progression and risk. This understanding would in principle improve early detection, inform prevention efforts and identify novel protective “theragnostic” strategies.

The Hepatic Extracellular Matrix and the “Matrisome”

The hepatic extracellular matrix (ECM) is most accurately depicted as a dynamic compartment that comprises a diverse range of players that work bi-directionally with hepatic cells to regulate overall homeostasis. Although the classic meaning of the ECM referred to only proteins directly involved in generating the ECM structure, such as collagens, proteoglycans and glycoproteins, the definition of the ECM is now broader, and includes all components associated with this compartment, including ECM affiliated proteins (e.g., collagen-related proteins), ECM regulator/modifier proteins (e.g., lysyl oxidases and proteases) and secreted factors that bind to the ECM (e.g., TGFβ and other cytokines) [15]. This updated definition has been coined the ‘matrisome’ [16]. Although the canonical function of the ECM is structural, it is also a key storage unit for signaling molecules (e.g., growth factors and cytokines), as well as serving as a sensing mechanism for outside-in signaling and vice-versa [17, 18].

In solid organs, the ECM is separated into two distinct structural components: the interstitial matrix and the basement membrane [19]. Interstitial matrix proteins (e.g., fibrillar collagens, elastins and fibronectins) form networks that provide support to the overall superstructure that shapes and encapsulates the liver [20]. In most solid organs, the basement membrane is a thin, electron-dense sheet of mostly collagens that forms the foundation for epithelial and endothelial cells attachment and growth [18]. In contrast to other tissues, where the basement membrane is a true barrier between the epithelial/endothelial cells and the adjacent parenchymal cells, the basement layer in the liver is fenestrated and much more loosely organized [20]. Although it possesses similar ECM as more clearly-defined basement membranes [21], this region acts more as a structural and biochemical “sieve” that facilitates bidirectional exchange of proteins and xenobiotics between the sinusoidal blood and hepatocytes [18]. Although it is clear that liver does not have a *basal lamina*, whether or not the ECM found in the space of Disse should be considered a basement membrane is a subject of a histological, rather than functional, debate [19].

Balance and Imbalance of ECM Turnover in the Liver

The ECM responds dynamically to stress and changes. Under ideal conditions, these responses assist in maintaining organ homeostasis and help mediate appropriate responses to injury/stress. This coordinated dynamic response is most likely best illustrated by subcutaneous wound healing, in which the tightly regulated deposition and remodeling of the ECM not only mediates wound closure, but also restitution and repopulation of the wound with replacement cells [22]. However, when these responses are dysregulated, the changes to the ECM can be maladaptive [23]. For example, ‘aging’ of the ECM (i.e., increased crosslinking) is hypothesized to contribute to dysfunction in several organ systems, including the liver [24–27].

The most well-recognized example of ECM dyshomeostasis in the liver is that of hepatic fibrosis, which is the common end pathology of almost all chronic liver diseases [20]. Although end-stage collagenous scarring of an organ/tissue is often considered synonymous with ECM remodeling [28], this remodeling is actually a key factor in early stages of injury and restitution from injury and much more diverse than simple collagen accumulation [29]. The hepatic ECM also responds rapidly and dynamically to insult, even after acute injury. Indeed, we and others have shown dynamic transitional changes to the hepatic ECM that appear to be key to the normal response to acute injury and recovery, as well as setting the stage for chronic disease [18, 30]. Homeostasis in ECM is mediated by a balance in the production of ECM, as well as in the degradation of existing ECM by matrix metalloproteinases (MMPs) [31]. Even in cases where there is a net increase in ECM in liver (e.g. fibrosis) overall turnover is also increased [32].

The impact of the ECM and (to a certain extent, the matrisome) on hepatic fibrosis has been covered heavily in the literature [33, 34]. The purpose of this review is to explore the role (or potential role) of ECM dyshomeostasis across the earlier spectrum of pathology caused by alcohol consumption prior to fibrosis (i.e., steatosis, cell death and inflammation) and to discuss new approaches and opportunities of to discover and leverage this understanding to prevent and treat ALD.

Hepatic ECM Changes and Steatosis Caused by Alcohol

The liver plays a central role in lipid metabolism for the entire organism. There is intricate crosstalk between other organs involved in lipid metabolism and the liver that is controlled by a complex interplay of hormones, nuclear receptors, intracellular signaling pathways and transcription factors. Under homeostatic conditions, hepatic lipid flux maintains relatively low concentrations of lipid pools (e.g., free fatty acids, triglycerides and cholesterols). However, dysregulation of this flux can cause lipids to accumulate in hepatocytes and lead to steatosis.

The first and most common hepatic change caused by alcohol consumption is steatosis, or fatty liver [35]. The prevalence of steatosis is essentially 100% in those who regularly consume alcohol at pharmacodynamically-relevant concentrations [5]. Fat accumulation can be both macrovesicular (having one large fat droplet per hepatocyte and lateral displacement of the nucleus) or microvesicular (many small fat droplets per hepatocyte) [36]. Alcohol-induced steatosis is rapidly and readily reversible upon cessation of alcohol consumption. Steatosis can also be clinically ‘silent,’ and can exist in the absence of increases in any other index of liver damage (e.g., plasma transaminases) in individuals who chronically misuse alcohol. For these reasons, steatosis was originally viewed as an inert pathology in ALD (and in other fatty liver diseases). However, more recent studies have suggested that

blunting or preventing steatosis could help attenuate the progression of ALD; in fact, the degree of steatosis is an early predictor of overall disease severity [37]. Therefore, although other factors clearly mediate the overall risk of developing severe liver disease, steatosis may not be as inert a pathology as originally thought [35].

Alcohol directly and indirectly impacts numerous aspects of hepatic lipid flux that ultimately leads to lipid accumulation. The simplest example is that alcohol metabolism itself directly causes steatosis. Concentrations of alcohol can easily reach the mM range in the portal/hepatic circulation during alcohol consumption. In the process of metabolizing ethanol to acetate, two equivalents of reduced NADH are generated per equivalent of ethanol oxidized. This metabolism robustly increases the ratio of NADH:NAD^+ within the cell, which then favors inhibition of fatty acid β-oxidation in the liver (see also Chap. 50). Furthermore, ethanol metabolism also increases the rate of esterification of fatty acids [38]. The net effect is to favor TG and other lipid pool accumulation in the hepatocytes. However, the impact of alcohol exposure on lipid metabolism is far more complex than simple redox inhibition of β-oxidation (see [35] for review).

ECM/Matrisome and the Impact on Lipid Metabolism and Steatosis

The understanding of the role ECM/matrisome proteins in the induction of steatosis caused by alcohol is anecdotal and sparse at this time. It is known that models of ethanol-induced steatosis (e.g., chronic liquid diet feeding to rodents) is sufficient to cause robust increases in proteins associated with the matrisome in the liver [39]. It is also known that select ECM components (e.g., osteopontin, thrombospondin, fibrin(ogen) and periostin) appear to have a direct influence on lipid metabolism in experimental models of fatty liver diseases [40–43]. Moreover, signaling molecules that are stored in the matrisome and proteolytically released during remodeling/injury (e.g., hepatocyte growth factor) have a direct influence on hepatic lipid metabolism [44]. However, the functional impact and mechanisms by which ECM/matrisome components influence these changes is, at best, incompletely understood.

In contrast to the liver, the impact of ECM/matrisome on lipid metabolism in other organs/diseases is more clearly understood and can be used to leverage parallel assumptions fatty liver disease. For example, Baker et al. [45] determined that decellularized ECM from adipose tissue of diabetic patients was sufficient to drive a similar diabetic phenotype (i.e., decreased glucose update and lipolysis) in naïve adipocytes cultured *ex vivo*. Although the mechanisms by which ECM/matrisome alter metabolism are incompletely understood, these mechanisms fall generally into the categories of physical/mechanical effects and altered ligand/receptor interactions.

Physical/Mechanical Impacts of the ECM/Matrisome on Lipid/Glucose Metabolism

As mentioned above, the hepatic ECM/matrisome qualitatively and quantitatively responds rapidly to injury/stress. These changes can impact the elasticity of the ECM and organ [46], and injury directly increases ECM stiffness in organs [47–50]. The cell has several signaling mechanosensory pathways that drive phenotype changes in cellular function in response to the ECM changes. The best understood pathway involves the indirect linkages of the ECM to actin cytoskeleton via integrin receptors in focal adhesions on the surface of the cell [51]. However, actin-independent signaling via integrins have also recently been identified (e.g., via focal adhesion kinases) as well as integrin-independent pathways [52]. Interestingly, the latter (integrin-independent) pathway links ECM stiffness to key players hypothesized to be critical in alcohol-related steatosis and ALD (e.g., AMPK and SREBP-1 [53–55]).

Ligand/Receptor Interactions

The interaction between cells and the surrounding ECM can also impact downstream signaling cascades that mediate metabolic pathways [56]. This control can be at mediated via altering receptor affinity, or changes to downstream signaling cascades. Under basal conditions, receptors for these mediators are generally dispersed on the plasma membrane in lipid/lipoprotein-rich regions (i.e., lipid rafts); the relatively close proximity of receptor monomers facilitates ligand binding, receptor dimerization and subsequent downstream signaling [57]; ECM proteins contribute to this 2-dimensional organization on the plasma membrane [58]. Signal integration between ECM receptors and extracellular signaling factors also varies with interactions with the ECM stratum. This influence of ECM on signaling has best been described for cellular responses to growth factors, and is categorized as concomitant signaling, collaborative activation, direct activation, amplification and negative regulation [59, 60]. Injury impairs growth factor signaling, in part by altering the make-up of the ECM surrounding the cell [61]. Moreover, ECM interactions qualitatively and quantitatively influence the response of TLR and TNFα signaling [62].

In addition to fibrillar ECM, the matrisome contains components and mediators that may influence energy/lipid metabolism within the liver. For example, matrix metalloproteinases (MMPs) and related proteinases cleave a myriad of substrates that may impact cellular metabolism (e.g., lipoproteins and growth factors) that can directly or indirectly impact steatosis in the liver, and recent work suggest a direct metabolic effect of these proteases by targeting key complexes (e.g., mitochondria) involved in metabolism [63–65]. The ECM protein osteopontin has been shown to impact steatosis in both ALD and NAFLD [41]. Recent work has indicated that

thrombin activation and its canonical receptor, PAR-1 contribute to hepatic steatosis in experimental models of non-alcoholic fatty liver disease (NAFLD) [66, 67].

Taken together, there are at least anecdotal indications that ECM remodeling directly and indirectly impacts metabolism, and by extension steatosis. The magnitude, mechanisms and impact of these changes are generally incompletely understood in fatty liver diseases. This developing field that should more specifically be explored in more detail in the context of ALD.

Hepatic ECM Changes and the Regulation of Cell Viability

The accumulation of hepatic damage caused by alcohol is characterized by an increase in cell death. Interestingly, the magnitude of hepatocyte death appears to be out of balance with that of inflammation compared to non-steatotic liver injury. This observation has led to the understanding that hepatocytes and other noninflammatory hepatic cells appear to be sensitized to intercellular signals (e.g., cytokines) to favor downstream signaling pathways that lead to cell death [68–70]. In the past few decades, the binary concept of “cell alive/cell dead” has been demonstrated to woefully overly simplistic, with a myriad of processes that can mediate cell death of different phenotypes (e.g., apoptosis, necroptosis and pyroptosis) [71]. Alcohol exposure appears to increase the likelihood of almost all of these regulated cell death (RCD) pathways [72].

Work derived predominantly from the field of morphogenesis and development indicate that specific ECM proteins have key roles in cell viability and death [23, 73, 74]. Indeed, recent interest on the impact of ECM on hepatic cellular phenotype has increased dramatically, especially in the concept of ex vivo “liver-on-a-chip” platforms, as well as biomatrices for injury restitution [75, 76]. In toto, connection of the cells to basement membrane proteins (e.g., collagen III & IV, laminin and elastin) appear to be key for cells to maintain their normal viability and function [23]. Serum levels of several of fragments of these basement membrane proteins are elevated in ALD and other fatty liver diseases, and may represent increased turnover of these critical ECM compartments [77]. This effect can be mediated via ECM components acting directly as a ligands, or indirectly via altering the binding of other growth factors to their receptors.

In addition to serving as direct ligands that mediate and alter life/death signaling cascades, the ECM/matrisome serves as a reservoir of signaling molecules, including growth factors. The ECM sequesters and stores these molecules via charge affinities with glycosaminoglycans (GAG) [78]. Although this affinity is sufficiently strong to be metastable, ECM turnover activates and releases these mediators [79, 80]. Moreover, recent work indicates that several ECM peptide fragments are biologically active and can impact cellular viability and function (i.e., “matrikines”) [81]. The localized release of these mediators creates a gradient that acts as a ‘homing signal’ to the origin of the injury [80, 82]. In addition to storing/releasing growth

factor ligands, signal integration from ECM-binding receptors can alter growth factor signaling cascades, both positively and negatively [59, 61].

Integrins are heterodimeric proteins that are mainly responsible for facilitating interaction between the ECM and surrounding cells [83]. Integrins play a myriad of roles within the body that may directly or indirectly impact cell viability [84, 85]. Appropriate activation is critical for normal cellular survival, as well as for regulated cell death [74]. Dysregulated integrin signaling has been demonstrated to be involved in hepatic injury and disease progression in a wide variety of liver diseases [86, 87]. There are also several non-integrin receptors involved in signaling between the ECM and the cell. For example, CD44, a type I transmembrane glycoprotein with over 20 different isoforms, has been demonstrated to be involved in liver injury [88]. CD44 has also been implicated in the resolution of injury by facilitating the migration of hematopoietic stem cells to the injured liver [89].

Taken together, several of the effects of alcohol exposure on cell viability could, in principle, be mediated via changes to the ECM/matrisome and/or its partnered signaling pathways. What is lacking is an integrative analysis linking these potential interactions, as has been done extensively in other organ diseases. More research should also focus on this issue.

Role of the ECM/Matrisome in Hepatic Inflammation

As mentioned above, given the poor prognosis of treating late-stage liver disease, much of current research focuses on identifying at-risk individuals and preventing the progression of the disease during earlier phases, especially inflammation. Inflammation plays a central role in ALD and involves both the innate and adaptive immune responses [90, 91]. Inflammation in ALD is characterized by a chronic, low-grade inflammatory condition, in which innate immune cells are “primed”, and adaptive immune surveillance and tolerance is dysregulated [92–94]. It is this vicious cycle of cell damage/death and inflammation, when it overwhelms the repair/recover responses of the liver, which leads to the chronicity of ALD.

The role of the ECM in fibrotic liver injury has been heavily studied. This is not surprising, given that liver disease is often clinically asymptomatic until this later stage [95]. The ECM defines properties permissive and/or instructive to inflammation and changes to the ECM directly and indirectly alter this response. Although some areas of research have a deep understanding of the roles of the ECM in inflammation (e.g., subcutaneous wound healing), this is a developing field in the context of liver disease [22]. Work by this group and others have shown that the inflammatory response to hepatic damage involves several of the ECM proteins found in subcutaneous wound healing, such as fibrin, osteopontin, and fibronectin [96–99]. These histologically undetectable changes to the matrisome appear to resolve after acute injury [30, 39]; with chronic injury, the transitional matrisome is replaced by collagenous scarring in the liver, which is parallel to mechanisms associated with subcutaneous wound healing [22].

The involvement of the ECM/matrisome in inflammation has several mechanisms that overlap with those described previously for steatosis and cell death. For example, the ECM also serves as a source of ligands to inflammatory cells and can alter inflammatory cell phenotypes [100]. The matrisome also serves as a reservoir of cytokines and chemokines that are rapidly released to attract components of the inflammation/wound healing response [100]. Many of these reactions are also mediated by ECM receptors (see above) [84, 85, 101]. Specific matrikines released by degradation of the ECM can also be directly proinflammatory via interacting with specific ligand receptors and/or pattern recognition receptors [102–104]. Lastly, the clustering of integrins into focal adhesions that directly communicate with the cytoskeleton likely mediates the impact of ECM rigidity on the inflammatory response [105].

There are also functions mediated by ECM/matrisome that are unique to this portion of pathologic spectrum of ALD. For example, interaction between leukocytes and the ECM is critical for the process of leukocyte adhesion and transmigration to sites of inflammation/injury [56, 106]. Leukocyte surfaces contain ECM receptors/adhesion molecules that direct their migration through interaction with the ECM [107]. Regulation of these receptors is important for the rapid change between adhesive and nonadhesive states of immune cells [107]. The interaction between the ECM and cell infiltration is bidirectional; as leukocytes integrate structural and biochemical cues from the ECM, they in turn release matrix-degrading proteases [108] which alter the extracellular composition and allow for easier cell migration. Degradation of the ECM during inflammation can also expose self-antigens (e.g. the basement membrane ECM, collagen V) that can be used to promote infiltration of immune cells that are normally tolerant to the liver [109].

Inflammation and ECM remodeling can become a feed-forward cycle [100]. The ECM facilitates immune cell migration and differentiation, while immune cells trigger new ECM deposition and proteolytic remodeling. Proteases subsequently cleave ECM producing proinflammatory degradation products. These processes can be adaptive, but aberrant ECM and bioactive degradation products perpetuate inflammation in a maladaptive response, such as in chronic hepatic inflammation [110]. Given the key role of the ECM in mediating inflammation, it is not surprising that this compartment also plays key roles in the resolution of inflammation (i.e., catabasis; [111–113]).

Regulation of Regeneration by the ECM/Matrisome

The ability of the liver to regenerate after damage is a unique mechanism to recover from injury and protect against damage accumulation. Hepatic regeneration is a tightly organized process that is sensitive to perturbation. Indeed, the development of chronic liver diseases, including ALD, is almost universally present on the background of genetic/acquired impairment of regeneration and restitution from injury [114, 115]. The hepatic ECM plays a key role in liver regeneration. As discussed

above, it serves as a storage reservoir for preformed growth factors such as HGF. The storage capacity of these growth factors is so large that temporally controlled knockouts of HGF do not phenotype until this reservoir is depleted [116].

Hepatic regeneration can be organized into three phases: priming, proliferation and growth termination [117]. Hepatic regeneration requires a coordinated restructuring of the ECM/matrisome in all phases to facilitate de novo proliferation of surviving liver cells in response to injury [117]. This remodeling not only removes physical barriers to growth during the priming phase [118], but also breaks connections to ECM proteins that restrict proliferation under normal conditions (e.g., endostatin) [119]. Significant ECM synthesis and remodeling is also required to build the new infrastructure and superstructure on which the recently divided cells will populate during the growth termination phase [117]. Little is known about the influence of ethanol on ECM turnover that is critical for normal liver regeneration and this question should be the topic of future studies.

Senescence and aging of the liver have been extensively studies in the context of chronic liver diseases, including ALD. Aging is a not only a known risk factor for chronic liver disease, but the chronic cycle of injury and recovery leads to premature aging of organ [120]. As mentioned above, "aging" of the ECM is also a key factor in the loss organ elasticity associated with normal or premature senescence [24–27]. Some studies have suggested that there may be a direct link between ethanol-induced senescence and altered ECM/receptor signaling in chronic liver diseases and aging. For example, hepatic fibrosis is associated with a redistribution of laminin ECM away from the perisinusoidal space to the fibrous septa [121] and that this effect is associated with impaired growth factor (e.g., HGF) release [122]. The potential specific contribution of ethanol-altered ECM to premature aging of the liver and replicative senescence has not been yet investigated.

Summary and Future Prospects

Chronic liver diseases, including ALD, are usually clinically silent until very late stages, when the organ starts to decompensate. This is an especially important clinical need, as the potential reversibility of the disease decreases as disease severity progresses. There are various elastographic (e.g., transient elastography) and scoring (e.g., FIB-4) approaches that have good negative predictive values (NPV; i.e., low false negative rate), but do not have as strong positive predictive values (PPV; i.e., relatively high false positive rate) (e.g., [123]). The end result is that although these approaches are good at predicting who does not have active hepatic fibrosis, there are several false positives (i.e., high liver stiffness without active fibrosis) in the "at risk" group. Moreover, although these approaches are generally good at detecting hepatic fibrosis, they are less sensitive and specific for earlier stages of disease progression (e.g., inflammation) [124]. What is needed are more minimally-invasive approaches to detect disease progression accurately at earlier stages of development.

As mentioned above, *de-novo* synthesis of ECM proteins is a key factor during any stimulus of the wound healing response. Indeed, changes in biomarkers of collagen synthesis/deposition have been employed to serve as predictors of fibrosis severity. For example, the precursor of Type III collagen (PRO-C3) has been identified to have areas under the receiver operating characteristics curve (AUROC) values for predicting liver disease severity that are superior to imaging and/or scoring approaches; the improved AUROCs were largely driven by better PPVs compared to the imaging and scoring approaches [125, 126]. These approaches may also be favorable for ECM remodeling associated with earlier stages of ALD development.

Another possible source of new biomarkers is based on indices of ECM turnover. The degradation of ECM proteins is almost always induced simultaneously with upregulation of de novo synthesis during ECM remodeling. The accumulated signal of these peptide fragments of the ECM is part of the peptidome, and more specifically, the degradome [127–130]. The latter subset of the peptidome has generated key interest in some areas of human health as possible (surrogate) biomarkers for disease. Degradomic analysis of cancer metastasis, and by extension overall patient outcome, has garnished significant interest [131]. The rationale is that metastasis and tumor growth require significant remodeling of the normal and cancerous interstitial space, which can lead to alterations in the degradome profile in biological fluids. Similar approaches are beginning to be applied for liver diseases. For example, the peptidome has been shown to predict liver disease severity and outcome in HBV infection [126]. The study of the peptidome is a discipline related to proteomics, but with significant methodological and analytical differences [127, 132]. For example, as the original structure of the peptides is of interest, samples are not trypsin digested prior to mass spectrometry (MS) analysis, as is the case for bottom-up proteomic approaches. This difference originally limited peptide identification, as the available databases were based on trypsin-digested peptide fragments [128]. However, the development of peptidome-specific identification and analysis tools has addressed this concern [128, 129]. This approach could yield discovery of new biomarkers for earlier stages of ALD development.

This chapter summarized the roles (or potential roles) ECM plays in the progression of ALD, well before fibrotic scarring. What should become clear is that although the general understanding of the potential role of the ECM in all biochemical/cellular facets related to the initiation and progression of ALD, with the exception of the interaction between the ECM and inflammation, the specific role of the ECM in these processes is poorly established in the literature. A major goal of this review is to therefore highlight the key gaps in our understanding. This information can yield new mechanistic insight into improving the landscape of interventive strategies to treat and/or prevent the progression of ALD in the early stages of disease development, vis-à-vis atherosclerosis. However, to leverage this new understanding for interventive approaches in ALD, the early diagnosis of those truly at risk for severe ALD must be improved. Again, the ECM, and detection of its turnover, may be a fertile field to develop new and improved approaches in this area (Fig. 59.1).

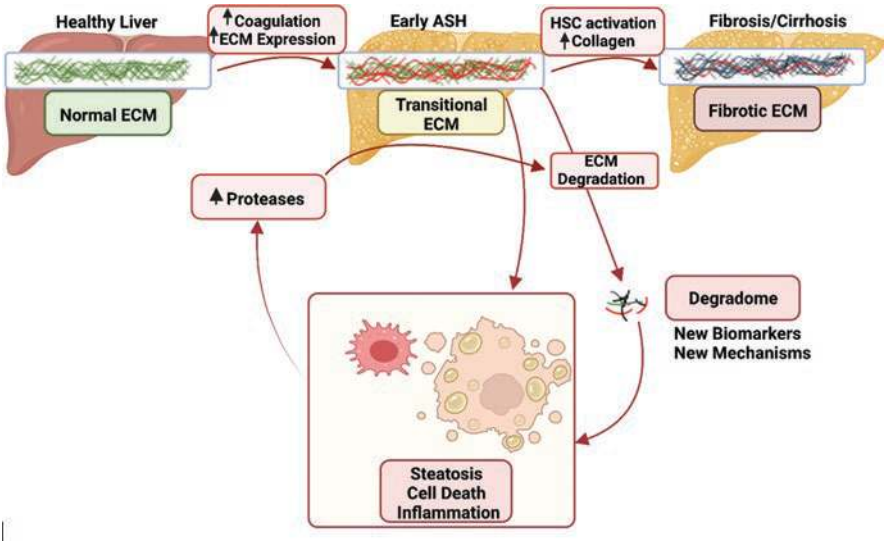

Fig. 59.1 Working hypothesis on the role of the ECM in the initiation and progression of alcohol-related liver disease (ALD). The progression of ALD is well-characterized and is actually a spectrum of liver diseases, that range from simple steatosis, or fatty liver, to inflammation and necrosis (steatohepatitis; "Early ASH"), and ultimately, to fibrosis and cirrhosis [8]. It is known that even early alcohol-induced liver injury causes formation of a transitional ECM. This transitional ECM may contribute to steatosis, cell death and inflammation. The transitional ECM often resolves after removal of the insult and may contribute to the recovery from that insult. With continued injury, the transitional matrix may progress to a fibrotic matrix, which can also resolve under some conditions. Even during ECM accumulation in response to acute/chronic injury, there is a net increase in turnover of the matrisome, yielding degraded ECM products ("degradome"). These degraded protein peptides may serve as biomarkers for disease development, as well as potentially driving disease progression

Chapter 60
MicroRNAs and Alcohol-Related Liver Disease

Kristina Perez, Jing Ma, Nazmul Huda, Zhihong Yang, and Suthat Liangpunsakul

Abstract MicroRNAs (miR) are small non-coding RNAs that bind to specific mRNA targets and promote their degradation or inhibit translation. In this book chapter, we reviewed the roles of multiple miRNAs, which are involved in the pathogenesis of alcohol-related liver disease (ALD). We also briefly discuss the roles of miRNAs as the mediators for inter-organ crosstalk and the development of ALD. We provided clues for the potential clinical applications of miRNAs as the prognostic markers and the future perspectives on the use of miRNA-based strategy for the treatment of patients with ALD.

Keywords miRNA · Pathogenesis · Alcohol-related liver disease

Introduction to Micro RNAs

MicroRNAs (MiRNAs) are evolutionarily conserved small single stranded non-coding RNA with around 18–24 nucleotides long [1]. While their size is relatively small, micro-RNAs are widely diverse and account for over millions of possible sequence combinations between their adenine, guanine, cytosine, and uridine base pairs [2]. Given this diversity, miRNA can be highly tissue and cell type specific, therefore adding to their importance in regulating intracellular pathways and in disease pathogenesis. The structure of miRNAs is dependent on the abundance of

adenine-uridine rich base pairings within their sequence [3]. Rich sequences harboring these pairs contribute to shorter half-lives of the miRNA [3]. MiRNA is first formed from the 60–70 nucleotide long RNA hairpin precursor [3]. In addition, RNA polymerase II are highly implicated in the synthesis of miRNA [4]. These clusters of miRNA precursors then undergo cleavage events that involve either dicer in the nucleus or drosha in the cytoplasm [5]. After generation, the exportin 5/RanGTP complex exports the pre-miRNA to mature in the cytoplasm. After maturation in the cytoplasm, the miRNA disperses in terms of their specificity and plays an important role in post-translation modifications.

MiRNAs play various roles in the post-transcriptional regulation of genes. Due to their small size, miRNAs require a minimum of 7 complimentary nucleotides to bind to their target and begin regulation [6]. MiRNAs bind to mRNAs by partial base pairing (partial complementarity) at the 3′-UTR (untranslated region); however, the interaction at the 5′- UTR, coding sequence or promoter region has also been reported [4, 7] The binding at the UTR target on the mRNA leads to translational inhibition [4]. In this review, we will focus on the reported roles of miRNAs in the pathogenesis of ALD.

Alcohol as Regulator of miRNA Biogenesis

The direct mechanisms between ethanol and microRNA dysfunction remain under investigation. However, recent studies provide growing evidence for the involvement of ethanol in the expression of mature miRNAs. One study showed that long-term alcohol use can impact miRNA profiles within mouse brains [8]. Prenatal ethanol exposure can also alter mature miRNA expression in fetal mouse brains [8]. Chronic alcohol induction illicits an upregulation of miRNA-155 in liver macrophages and miRNA-212 in the gut which contributes to disease progression through downregulation of gut tight junction proteins [9]. Mechanism studies revealed that ethanol may interfere with microRNA synthesis by altering activation of transcription factors (TF) and/or epigenetic modifications of DNA and DNA-associated histone complexes, including methylation (Me) and acetylation (Ac) [10]. Ethanol may reduce epigenetic DNA methylation, therefore leading to altered gene expression, including those that synthesize microRNAs [10].

MiRNAs as Mediators for Inter-Cellular Crosstalk in ALD Pathogenesis

While the studies of miRNAs in ALD pathogenesis focus on the role of miRNAs in regulating the target genes within each specific cell type, such as hepatocytes or Kupffer cells, miRNAs can be secreted into the extracellular space within

extracellular vesicles (EVs). Once secreted, miRNA-containing EVs can be uptaken by neighboring cells or enter the circulation to regulate the target genes in other tissues or organs. In the liver, parenchymal and non-parenchymal cells can release miRNA-containing EVs. Multiple miRNAs, such as miR-122 and miR-155, have been shown to be released from hepatocytes in ALD [11]. The pathogenesis of ALD involves the cross talk among multiple organs, which eventually leads to hepatic inflammation and metabolic alterations [12–14]. MiRNA-containing EVs likely are the key players in connecting the cross talk among several tissues, such as the gut, liver, adipose tissue, and brain, leading to the development of ALD.

Clinical Implications of miRNAs in Patients with ALD

Due to the myriad functions of miRNAs in ALD pathogenesis, circulating miRNAs have been extensively studied as potential biomarkers for patients with ALD. Circulating miRNAs are relatively stable and resistant to the degradation by RNases [15, 16]. Numerous studies have shown the superiority of several miRNAs as biomarkers for diagnosis and prognostic indicators for several liver diseases [17]. A recent study showed the use of miRNAs as prognostic markers for AH patients [18]. The following circulating serum miRNAs are found to be markedly reduced in such patients, miR-30b-5p, miR-20a-5p, miR-146a-5p, and miR-26b-5p [18]. Pathway analysis of the potential targets of these miRNAs revealed that the genes are related to DNA synthesis and cell-cycle progression pathways, including ribonucleotide reductase regulatory subunit M2 (RRM2), cyclin D1 (CCND1), cyclin D2 (CCND2), MYC proto-oncogene (MYC), and phorbol-12-myristate-13-acetate--induced protein 1 (PMAIP1) [18]. MiR-26b-5p and miR-30b-5p inhibit the 3′-UTR luciferase activity of RRM2 and CCND2, and miR-20a-5p reduces the 3′-UTR luciferase activity of CCND1 and CCND2 [18]. Among these miRNAs, the expression of serum miR-20a-5p, miR-146a-5p, and miR-26b-5p, are associated with mortality in AH patients [18].

Specific Micro RNAs in ALD

miRNA-21

MiR-21 is highly conserved and located on chromosome 17 [19]. It is one of the most abundant miRNAs and ubiquitously expressed in various tissues [20]. MiR-21 can be found in the cytosol, extracellular vesicle, and in multiple tissues such as liver, lung, kidney, and peripheral blood [21, 22]. Like other miRNAs, miR-21 regulates its mRNA targets by its interaction with the 3′ UTR binding leading to

post-transcriptional gene silencing. There are multiple gene targets for miR-21, illustrating its important role in regulating intracellular homeostasis [20]. MiR-21 controls cholesterol and triglyceride metabolism by targeting 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR) [23]. The level of hepatic miR-21 is significantly increased in animal models of mice fed with ethanol via intragastric ethanol feeding or Lieber Decarli ethanol feeding [24]. An induction of hepatic miR-21 after alcohol feeding is mediated by the IL-6/STAT3 axis and that the IL-6/STAT3 pathway mediates alcohol-induced liver injury by modulating apoptosis, cell proliferation, and cell survival [24]. The upregulation of miR-21 is also in parallel with the inflammatory responses in the livers [25]. Dysregulation of miR-21 expression has been implicated during hepatic stellate cell (HSCs) activation [26]. The miR-21 mediated hepatic inflammation is secondary to the Von Hippel-Lindau (VHL)/ NF-κB signaling pathway in hepatic stellate cells (HSCs) [25]. The lack of miR-21 *in vivo* suppresses the production of several pro-inflammatory cytokines, such as monocyte chemoattractant protein-1 (MCP-1), Interleukin (IL)-1β, and IL-6 in human HSCs during alcohol-induced liver injury [25]. MiR-21 is also involved in alcohol-induced liver injury through its effect on hepatic regeneration secondary to TGF-β/SMAD/SMURF signaling in activated HSCs. Inhibition of miR-21 activity followed by the stimulation of the TGF-β leads to the changes in the expression of components of the TGF-β signaling pathway [26].

miR-26a

MiR-26a is conserved across vertebrates, and has a differential effect on different types of cancer, either a tumor suppressor or a tumor promoter [27, 28]. MiR-26a also regulates IFN-β anti-inflammatory pathway, and hepatocyte proliferation [29, 30]. MiR-26a is dysregulated during the autophagic process; overexpression of miR-26a induces autophagic activity [31]. In an ethanol-induced acute liver injury mouse model, miR-26a down-regulated the expression of two mitogen-activated protein kinases (MAPK) inhibitors, dual specificity phosphatase 4 and 5 (DUSP4 and DUSP5) [31]. The inhibition of DUSP4 and DUSP5 by miR-26a lead to an activation of MAPK and Beclin-1, the autophagy mediator [31]. Taken together, miR-26a promoted autophagic activity by activating Beclin-1 and protects against alcohol-induced liver injury by an augmentation of lipid droplet degradation [31]. Additionally, long term ethanol binge had significantly decreased miR-26a expression in the hippocampus compared to control counterparts in rats during mid/peri puberty [32]. This downregulatory effect resulted in increased Brain Derived Neurotropic Factor (BDNF), however, this effect lasted immediately after binge and did not persist through late puberty [32].

miR-27a

The expression of miR-27a is significantly increased in the monocytes in the presence of alcohol in vitro [33]. The circulating extracellular vesicles (EVs) from plasma of alcoholic hepatitis patients showed a markedly increase miR-27a compared with healthy controls [34]. Alcohol-induced miR-27a plays an important role in the differentiation and M2 macrophage polarization of human monocytes [33]. Over-expression of miR-27a in monocytes enhances IL-10 secretion through the activation of ERK signaling pathway by inhibiting ERK inhibitor sprouty homolog 2 (sprouty2) in monocytes [33]. MiR-27a also modulates phagocytosis by targeting CD206 expression on monocytes [34].

miR-34a

The miR-34 family comprises of three members; miR-34a is transcribed from chromosome 1, and miR-34b and miR-34c are co-transcribed from chromosome 11 [35]. While mechanisms that address the role of miR34b/c in alcohol induced liver injury are sparse, research suggests that upregulation of miR34b/c may protect against liver fibrosis [36]. MiR-34a is an important regulator of tumor suppression. It regulates the expression of multiple target proteins involved in cellular differentiation, the cell cycle, and apoptosis [37]. MiR-34a is upregulated in neural crest cells exposed to ethanol treatment, affecting the inhibition of neural differentiation by targeting autophagy pathway [38]. Alcohol use disorder is also associated with the upregulation of this miRNA in the hippocampus [35]. The hepatic expression of miR-34a is markedly increased in patients with alcohol-related hepatitis and in ethanol-fed mice [37, 39]. In the liver, alcohol causes the loss of methylation on the miR-34a promoter, resulting in an increase in its expression in ethanol-fed mice, compared to that of controls [39]. The underlying mechanism of miR-34a-mediated alcohol induced liver injury is by the regulation of cellular remodeling and proliferation [39]. These effects are mediated through its target genes, *CASP2* (Caspase 2) and *SIRT1* (Sirtuin 1), two known regulator genes of apoptosis and tissue remodeling [39]. An increase in hepatic miR-34 expression is also associated with enhanced cellular senescence especially in hepatic stellate cells in ethanol-fed mice [40].

miR-122

MiR-122 is transcriptionally regulated by several transcription factors including hepatocyte nuclear factor (HNF)1α, HNF4α, HNF3β, and CCAAT/enhancer-binding protein (C/EBP)α [17, 41]. MiR-122 is considered a liver-specific miRNA,

and its expression is activated during embryogenesis and liver development [42]. MiR-122 target genes involve in cellular proliferation and differentiation [42]. One of the important targets is a transcriptional repressor of genes, *CUTL1,* which plays an important role in cell cycle progression [42]. MiR-122 suppresses liver fibrosis by targeting connective tissue growth factor (*CTGF*) gene [43]. It promotes hepatic lipogenesis via inhibiting the LKB1/AMPK pathway by targeting Sirt1 [44]. Chronic exposure of alcohol (0.5% v/v ethanol in aquarium water) increases the expression of hepatic miR-122 in the zebrafish in parallel with hepatic lipid accumulation [45]. The hepatic expression of miR-122 is decreased while hypoxia-inducible factor 1 alpha (HIF1α), the known miR-122 target is increased in ALD patients and in mice fed with ethanol containing diet [42]. The gain of miR-122 function ameliorates alcohol-induced liver injury by reducing several inflammatory cytokines, such as monocyte chemoattractant protein-1 (MCP-1) and IL-1β, and liver fibrosis [42]. Mechanistically, alcohol inhibits miR-122 transcription via alternate splicing of grainy head-like 2 (Grhl2) transcription factor [42].

miR-125b

MiR-125b mediates NF-κB-induced inflammatory response by targeting TNFα induced protein 3 (TNFAIP3) [46]. The upregulation of this miRNA by estrogens protects against hepatic steatosis by decreasing fatty acid uptake and triglyceride synthesis in non-alcoholic fatty liver model [47]. MiR-125b also has the anti-fibrotic property by regulating GLI family zinc finger 3 (Gli3) [48]. While miR-125b may implicate in the pathogenesis of non-alcoholic fatty liver disease and hepatic fibrosis, its role in ALD pathogenesis is not clear. It has been suggested that chronic alcohol treatment *in vitro* may not cause changes in miR-125b levels [49]. MiR-125b was reduced in hepatocytes of alcohol-fed mice, while miR-155 was upregulated [50]. MiR-125b protects against ethanol-induced apoptosis in neural crest cells and mouse embryos by targeting Bak 1 (BCL2 Antagonist/Killer 1) and PUMA (p53 upregulated modulator of apoptosis) [51].

miR-129

Downregulation of miR-129-5p improves alcohol-induced barrier dysfunction of Caco-2 human intestinal epithelial cells [52]. Downregulation of miR-129-5p by long non-coding RNA NEAT1 increases the expression of paternally expressed gene 3 (PEG3) and aggravates liver injury and fibrosis via NF-κB-induced hepatic stellate cell apoptosis [53]. An inhibition of NEAT1 leads to an increase in miR-129-5p, ameliorates lipid metabolism, and restrains inflammatory responses in ethanol-treated AML-12 cells. A similar observation is observed in ethanol-fed

mice when an inhibition of NEAT1 or an elevation of miR-129-5p promotes liver function and alleviates hepatocyte apoptosis and hepatic inflammation by targeting suppressor of cytokine signaling 2 (SOCS2) [54].

miR-155

The expression of miR-155 is relatively low in the normal liver [17]. However, its level is altered during liver injury [17]. MiR-155 is highly expressed in immune cells and regulates hepatic lipid metabolism, inflammation, and fibrosis [17, 55, 56]. In the *in vitro* experiments, chronic alcohol treatment of RAW 264.7 macrophages causes an increase in the expression of miR-155, and alcohol pretreatment augments lipopolysaccharides (LPS)-induced miR-155 expression [57]. An increase in the miR-155 expression after alcohol treatment is associated with an increased in TNFα production, though the stabilization of TNFα mRNA in macrophages [57]. Alcohol induced hepatic miR-155 expression at the transcriptional level via the toll-like receptor4 (TLR4) pathway [49]. Alcohol-induced miR-155 inhibits negative regulators of the TLR4 pathway leading to an increase in susceptibility of Kupffer cells in response to LPS [58]. MiR-155 mediates alcohol-induced steatosis by enhancing the proliferator-activated receptor response element (PPRE) and PPARα binding [49]. The deficiency of miR-155 attenuates alcohol-induced steatosis, hepatic macrophage and neutrophil infiltration, and hepatic oxidative stress [49].

miR-181b

MiR181b-3p is a potential negative regulator of TLR4 signaling in Kupffer cells from ethanol-fed rats [59]. Mechanistically, it regulates the expression of importin α5 and translocation of p65 subunit of NFκB in Kupffer cells [59]. The expression of miR-181b-5p is increased in ethanol-fed rat [60]. The loss of miR-181b-5p upregulates protein inhibitor of activated STAT 1 (PIAS1) to inhibit hepatic oxidative stress and inflammatory response by inhibition of protein arginine methyltransferase 1 (PRMT1) in ethanol-fed rats [60]. MiR-181b also mediates hepatic steatosis by targeting SIRT1 [61].

miR-182

The hepatic expression of miR-182 level is associated with disease severity and short-term mortality in patients with alcohol-related hepatitis [62]. An increase in the level of hepatic miR-182 in patients with AH is not consistently observed in

ethanol-fed animal model [62]. Its expression is comparable in animals treated with carbon tetrachloride (CCl_4) or ethanol alone [62]. The combination between CCl_4 and ethanol induces a slight, but significant increase, in its expression [62]. MiR-182 is mainly expressed in ductular reaction cells and hepatocytes. It promotes hepatocellular injury and hepatic inflammation by downregulation of predicted targets, solute carrier family 1 member 1 (SLC1A1) and cofilin1, and an upregulation of inflammatory and cell cycle genes such as C-C Motif Chemokine Ligand 20 (CCL20), C-X-C Motif Chemokine Ligand 1 (CXCL1), IL-8, and Cyclin D1 [62]. MiR-182 can also target forkhead box protein O1 (FOXO1) in mediating ALD pathogenesis [63].

miR-199

Liver sinusoidal endothelial cells (LSEC) derived from ethanol-fed rats exhibit a significant increase in endothelin-1 (ET-1), hypoxia-inducible factor-1α (HIF-1α), and inflammatory cytochemokines transcripts compared with control rat LSEC; the process involves the activation of NADPH oxidase [64]. As for the upstream, the activation of ET-1 by ethanol is secondary to the binding of hypoxia response element to its ET-1 promoter [64]. The inhibition of miR-199 by ethanol leads to an increase in HIF-1α and ET-1 expression [64].

miR-200

miR-200 is abundantly expressed in the liver and involved in cellular proliferation, hepatic fibrosis, and hepatocellular carcinoma [16, 65]. Hepatic expression of miR-200 is significantly increased in ethanol-treated AML-12 cells and ethanol-fed mice [66]. An induction of miR-200 leads to hepatocyte apoptosis and liver injury by targeting Zinc Finger E-Box Binding Homeobox 2 (ZEB2) [66].

miR-212

As previously mentioned, one of the key mechanisms of alcohol-induced liver injury is the impairment in gut permeability leading to bacterial translocation. Alcohol increased the expression of miR-212 in intestinal epithelial cells. Alcohol-induced miR-212 inhibits the expression of zonula occludens 1 (ZO-1), a major intestinal tight junction protein, leading to gut leakiness [67].

miR-214

One of the pathways associated with alcohol-induced oxidative stress is the glutathione pathway; the glutathione reductase (GSR) catalyzes glutathione disulfide (GSSG) into reduced glutathione [68, 69]. Cytochrome P450 oxidoreductase (POR), a flavin-containing electron donor for all microsomal cytochrome P450, acts as an antioxidant through association with heme oxygenase-1 (HO-1) [69, 70]. MiR-214 can bind to the 3'-UTR of GSR and POR genes and down-regulate their respective protein expression in both an *in vitro* model and ethanol-fed rats [69].

Ethanol-induced oxidative stress through the activation of miR-214, the process which may be regulated by long noncoding RNA UCA1 [69, 71].

miR-217

Ethanol up-regulates miR-217 in part through acetaldehyde during ethanol metabolism in AML-12 cells, ethanol-fed mice, and zebrafish model [45, 72]. MiR-217 promotes ethanol-mediated inhibition of SIRT1 and lipin-1α, a nucleocytoplasmic shuttling protein [72]. It also regulates genes associated with lipogenic enzymes or fatty acid oxidation [72]. In addition to the role of miR-217 in mediating alcohol-induced steatosis, ethanol also exacerbates LPS-mediated up-regulation of miR-217 and promotes the release of pro-inflammatory cytokines in RAW 264.7 macrophage cell line and primary Kupffer cells [73]. MiR-217 also plays an important role in the generation of TGF-β or reactive oxygen species (ROS) in macrophages [73]. MiR-217-mediated inflammatory responses are secondary to an activation of NF-κB and nuclear factor of activated T Cells 4 (NFATc4) [73].

miR-223

MiR-223 is highly expressed in neutrophils and is considered a neutrophil-specific miRNA. It plays an important role in attenuating neutrophil maturation and activation [74]. The expression of miR-223 in peripheral blood and hepatic neutrophils is markedly induced after chronic-plus-binge ethanol feeding in mice [75]. The induction of miR-223 by ethanol is through transcriptional regulation and not from the direct effect of ethanol or its metabolite [75]. *MiR-223*$^{-/-}$ mice are more susceptible to chronic-plus-binge-induced liver injury with an increase in hepatic neutrophil infiltration and ROS production in the liver and neutrophils [75]. The p47phox is predominately expressed in neutrophils and plays a key role in generating oxidative

burst [76]. Mechanistically, miR-223 down-regulates neutrophilic p47phox via the inhibition of IL-6 [75]. MiR-223 also plays an important role in mediating acute-on-chronic alcohol-induced liver injury in aging mice [77]. Neutrophilic Sirt1 and miR-223 expression are significantly reduced in age compared with young mice [77]. Deletion of the *Sirt1* gene in myeloid cells including neutrophils exacerbates chronic-plus-binge ethanol-induced liver injury and inflammation and down-regulates neutrophilic miR-223 expression [77]. SIRT1 promotes deacetylation of C/EBPα, a key transcription factor regulating miR-223 biogenesis, and increases the neutrophilic miR-223 expression [77].

miR-291b

Tollip is a negative regulator of the MyD88-dependent pathway of TLR2 and TLR4 signaling in Kupffer cells [78]. Chronic ethanol feeding increases the expression of miR-291b, which can target the 3′-'UTR on Tollip gene resulting in a decrease in the expression of Tollip [78]. This decreased expression of Tollip contributes to enhanced TNFα expression in response to activation of TLR2/TLR4 [78].

Let-7

The alteration of the let-7/Lin28 axis is associated with mesenchymal phenotypic changes and ALD progression [79]. A reduction of let-7, particularly let-7a and let-7b, is associated with HSC activation in ethanol-fed mice [79]. Let-7 (especially let-7b) is an endogenous ligand of TLR7; TLR7-let-7 pathway contributes to alcohol-induced hepatic inflammatory process in ethanol-fed mice and in patients with AH [80]. A brief summaries of selected miRNAs and their respective gene targets in mediating ALD are shown in Fig. 60.1 and Table 60.1.

Conclusions and Future Perspectives

To date, multiple miRNAs are reported to be involved in ALD pathogenesis. These miRNAs have multiple functions through their regulation of the target genes leading to the alterations in lipid metabolism, inflammation, and fibrosis. MiRNAs have the potential to serve as biomarkers in predicting outcomes of patients with ALD. They also are attractive targets for therapeutic strategies. Several miRNAs are being evaluated in pre-clinical studies in patients with liver diseases [84]. The understanding of basic molecular mechanism of specific miRNAs in ALD may pave the way in the development of novel miRNA-based therapeutics for patients with ALD.

Chapter 61
Intestinal Barrier and Pathogen-Associated Molecular Patterns (PAMPs) in the Development and Therapy of Alcohol-Related Liver Disease

Finn Jung, Annette Brandt, and Ina Bergheim

Abstract Alcohol consumption is still among the leading causes of liver damage world-wide. Molecular mechanisms of the development of alcohol-related liver diseases (ALD) are still not fully understood, however, several studies suggest an important role of alcohol-mediated changes in intestinal barrier function and the interaction with the liver (gut-liver-axis) seems to be critical for the development of ALD. This book chapter focuses on the present knowledge and understanding of the altered intestinal barrier function subsequently leading to an increased permeation of pathogen-associated molecular patterns (PAMP) followed by an activation of pattern recognition receptors like toll-like receptors (TLR) in the development of ALD.

Keywords ALD · Intestinal permeability · Toll-like receptors · Ethanol · Endotoxin · Tight junctions · PAMP

Abbreviations

ALD	Alcohol-related liver disease
ALDH	Aldehyde dehydrogenase
CD14	Cluster of differentiation 14
CYP2E1	Cytochrom P450 2E1
HIF	Hypoxia-inducible factors
IgA	Immunoglobulin A
iNOS	Inducible nitric oxide synthase
IRF3	Interferon regulatory factor 3
LBP	Lipopolysaccharide binding protein

https://doi.org/10.1007/978-3-031-32483-3_61

LPS	Lipopolysaccharide
M cells	Microfold cells
MAL	MyD88 adaptor-like
MAPK	Mitogen-activated protein kinase
MD2	Myeloid differentiation factor 2
MLC	Myosin light chain
MLCK	Myosin light chain kinase
MTP	Microsomal triglyceride transfer protein
MyD88	Myeloid differentiation primary response 88
NFκB	Nuclear factor kappa-light-chain-enhancer of activated B cells
PAI-1	Plasminogen activator inhibitor-1
PAMP	Pathogen-associated molecular patterns
PRR	Pattern recognition receptors
Reg3	Regenerating islet-derived protein 3
TIR	Toll-interleukin-1 receptor
TIRAP	Toll-interleukin 1 receptor domain containing adaptor protein
TLR	Toll-like receptor
TNF-R1	Tumor necrosis factor receptor 1
TNFα	Tumor necrosis factor α
TRAM	TRIF-related adaptor molecule
TRIF	TIR-domain-containing adapter-inducing interferon-β
ZO-1	Zonula occludens-1

Introduction

An interaction of the liver and the intestinal bacteria and/ or bacteria-derived compounds has been discussed for several decades. For instance, already in the 1950s, studies demonstrated that germ-free animals were protected from the development of liver necrosis [1]. Furthermore, the concomitant treatment with antibiotics like aureomycin protected animals with diet-induced steatohepatitis from the development of cirrhosis [2]. Results of these studies also suggested that absorbable antibiotics were markedly less efficient in delaying the development of cirrhosis when compared to non-absorbable once [3]. In line with these findings, case report documented development of steatohepatitis in a patient suffering from small bowel diverticulosis and altered bacterial composition in the small intestine [4]. In the second half of the last century, increasing evidence was found linking changes in the composition of the gut microbiota and the function of the gut barrier to liver health but also to the development of liver diseases of various etiologies. About 70% of the liver's blood inflow consists of venous blood derived from the intestine via the portal vein. In line with this, recent studies further indicate that the liver not only receives nutrients from the intestine but also substances derived from the intestinal microbiota that enter the bloodstream when the intestinal barrier is disrupted [5]. This book chapter focuses on the present knowledge and understanding of the interplay of intestinal barrier function, pathogen-associated molecular patterns (PAMPs) and the development of alcohol-related liver diseases (ALD).

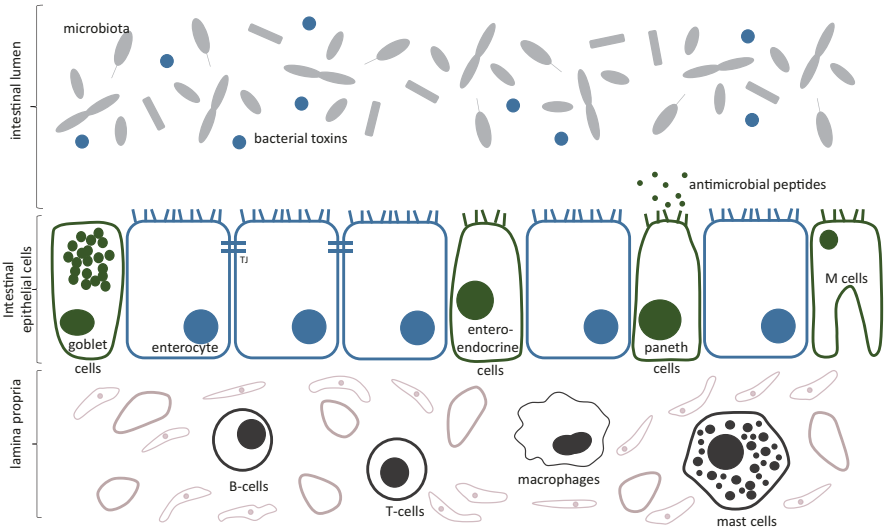

Fig. 61.1 Schematic overview of the intestinal barrier. The physical barrier consists of multiple different cells types including enterocytes, goblet cells, Paneth cells, microfold cells (M cells) and enteroendocrine cells, while the immunological barrier located in the lamina propria interacts with the intestinal barrier. Modified after [6–9]

Intestinal Barrier: Structure in Health

As depicted in Fig. 61.1 the intestinal barrier is composed of several interacting layers forming a complex structure. Apart from its function in nutrient digestion and absorption, the intestinal barrier also functions as physical barrier in the prevention of the entry of pathogens and PAMPs from intestinal lumen to circulation. For instance, an impaired barrier function or already minor changes in regulation of the interplay of the epithelial, microbial, biochemical, or immunological barrier already contribute to the development of liver disease such as ALD but also metabolic liver diseases (NAFLD) and even cognitive decline (for overview see [10–12]). In the following, we will describe key components of this complex structure thought to be critical in the development of alcohol-related impairment of intestinal barrier function with a specific focus on the epithelial layer.

Intestinal Epithelial Layer

Along with a stable microbiota the mucus layer can be considered as `first line defense´ against external injuries (for overview see [6, 13]). Herein, the microbiome not only contributes to the digestion of nutrients and production of vitamins but is also critical for shaping the immune system (for overview see [14, 15]). For instance,

studies in germ-free mice have shown that intestinal microbiota determines the number of peyer's patches, lymphoid follicles and in general, the number of immune cells, e.g., immunoglobulin A (IgA)-producing plasma cells or $CD8^+$ and $CD4^+$ T cells [16].

The core of the intestinal barrier is constituted of the epithelial cell layer composed of multiple different cell types, e.g., enterocytes, enteroendocrine cells, goblet cells, Paneth cells and microfold cells (M cells) (see also Fig. 61.1). All these cells which differentiate from pluripotent intestinal stem cells located in the crypts [17] contribute to the complex interplay of nutrient absorption, maintaining mucosal barrier function and secreting immunological mediators (for overview see [18–21]). Epithelial cells in the small intestine of humans typically have a turnover of ~3.5 days [22]. Through junctional complexes comprised of tight junctions on the luminal, apical side and adherence junction and desmosomes towards the basolateral side, intestinal epithelial cells are tightly connected (for overview see [23]). Studies indicate that tight junction proteins are key components in the control of paracellular transport in both the small and large intestines of the resulting semipermeable barrier (also see [21]). The permeation of ions and other substances is facilitated through this semipermeable barrier, whereas the translocation of noxious molecules like that of bacterial endotoxin is very limited in healthy subjects [13, 21, 23, 24]. Tight junctions which are composed of transmembrane proteins like claudins, occludin and junctional adhesion molecule have been shown to interact with peripheral membrane proteins such as the zonula occludens (ZO-1) (for overview see [24]). For the latter results of *in vitro* studies suggest that the protein connects with the cytoskeleton of the epithelial cell via F-Actin [25]. *In vitro* studies have also demonstrated an interplay of tight junctions and the actin-myosin cytoskeleton being critical in maintaining the paracellular barrier integrity [26] with myosin light chain kinase (MLCK) as key regulatory kinase [26] . Thus, activation of myosin light chain (MLC) by MLCK results in a restructuring of peri-junctional F-actin which in turn leads to a reorganization of occludin and ZO-1 and subsequently an increased permeability [27]. In addition, posttranslational phosphorylation of occludin seems to be critical for interconnecting tight junctions and, therefore, controlling the intestinal barrier function [28]. For example, it has been shown that, depending upon the phosphorylation site, tyrosine phosphorylation mitigates the interconnection of occludin-ZO-1 leading to a destabilization of tight junctions, whereas the phosphorylation of serine and threonine residues of occludin enhances the cohesion of tight junction proteins [29–31]. Also, results of more recent *in vivo* and *in vitro* studies suggest that a posttranslational nitration enhances the ubiquitin-dependent proteolytic degradation of tight junctions [32]. In contrast, studies in occludin knockout mice have shown that these animals display histological abnormalities in various tissues while tight junctions in intestinal tissue were found to be `normal´ in these mice [33]. This suggests that, in addition to tight junctions, other mechanisms may also be critical in regulating intestinal barrier function and compensate for loss of occludin. For instance, besides peptide hormones such as ghrelin, peptide YY, and cholecystokinin, glucagon-like peptide 1 secreted by

enteroendocrine cells in response to nutrient exposure (for overview see [34, 35]) and glucagon-like peptide-2 may also contribute to maintaining intestinal barrier function [36]. Further studies are needed to fully elucidate the complex interplay underlying the function of the intestinal barrier and, in particular, the function of the tight junction proteins therein.

Mucus and Immunological Barrier

Intestinal epithelial cells are covered by a thick mucus layer mainly synthesized by goblet cells and composed of glycosylated mucin proteins such as mucin-2 which is considered the main mucin in human intestine [6, 13, 37, 38]. Mucin-2 knockout mice have been shown to develop colitis and suffer from an impaired intestinal barrier function [39]. Furthermore, so called transmembrane mucins like mucin-1, -3, -4, -12, -13, 16 and -17 have been shown to carry out barrier and signaling functions (for overview see [38]). In addition, antimicrobial peptides secreted by Paneth cells are also important for maintaining the intestinal homeostasis [40]. Transgenic mice with a reduced number of Paneth cells have been reported to suffer from an increased penetration of commensal as well as pathogenic bacteria into the intestinal wall [41]. Secretion of antigen-specific IgA by B cells has also been shown to decrease intrusion of bacteria into the intestinal mucosa. Studies have also shown that dendritic cells which can be activated by epithelial M cells (located in follicle associated-lymphoid tissue as part of Peyer's patches) contribute to the antigen uptake from the intestinal lumen (for details please refer to [42, 43]). A loss of IgA has been shown to be associated with an impaired intestinal barrier function *in vivo* [44] and M cells may act as an entrance for pathogens (for overview see [43]).

Pattern Recognition Receptors Related Signaling Cascades

Alterations of the intestinal microbiota and a dysfunctional intestinal barrier can both result in an increased permeation of microbial compounds and even whole bacteria but also of viruses, fungi, parasites, and archea (for overview see [45]). In 1989, the concept of Pattern Recognition Receptors (PRR) recognizing pathogen-associated molecular patterns (PAMPs) was introduced with PAMPs subsequently activating both innate and adaptive immunity [46]. PRRs consist of a large variety of receptors including Toll-like receptors (TLRs), Nucleotide-binding oligomerization domain-like receptors, C-type lectin receptors and Retinoic acid-inducible gene I-like receptors [45]. In the following, TLRs will be in the focus since these are the main receptors that recognize intestinal bacteria and results of rodent and human studies suggest that the activation of TLRs, namely of TLR4, the most studied TLR, is critical in the onset and progression of ALD (for overview also see [47, 48]).

TLRs are not only expressed in innate immune cells like monocytes, macrophages and dendritic cells but also in non-immune cells such as epithelial cells and fibroblasts. Upon their cellular localization, the so far 10 TLRs described in humans can be distinguished in cell surface TLRs and intracellular TLRs. While TLR1, TLR2, TLR4, TLR5. TLR6 and TLR10 are localized in the cell surface, TLR3, TLR7, TLR8 and TLR9 are found intracellularly in the endosome [49] (for schematic overview see Fig. 61.2). However, recent studies also indicate that TLR3, TLR7 and TLR9 may occur at both sites, cell surface and intracellularly, and while this process is not yet fully understood it could contribute to endosomal TLR-mediated activation of immune response (for overview see [52]). TLRs located at the cell surface have been shown to predominantly recognize components of microbial membranes like lipids, lipoproteins, and proteins. TLR2 generally forms heterodimers either with TLR1 or TLR6. It has been shown to recognize a variety of PAMPs from Gram-positive bacteria such as lipoproteins, peptidoglycan, lipoteichoic acid but also lipoarabinomannan from mycobacteria zymosan from fungi, and tGPI-mucin from *Trypanosoma curzi* as well as hemagglutinin protein from measles virus [53]. For the recognition of some of the PAMPs by TLR2, a delivery through cluster of differentiation 14 (CD14) has been shown to be crucial [54]. Until recently, most studies suggested that TLR2 is mainly involved in mediating inflammatory

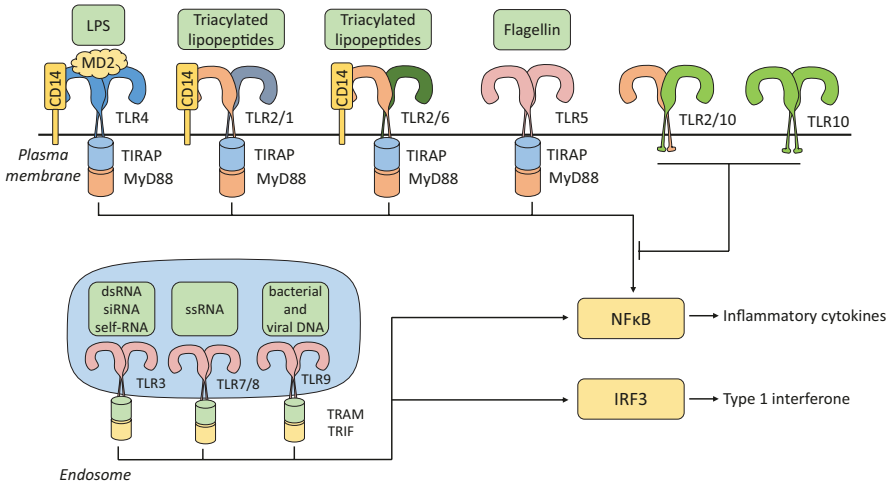

Fig. 61.2 Schematic overview of toll-like receptor signaling and their respective ligands. TLR1, −2, 4, −5, −6 and −10 are bound to the cell membrane and activated by the recognition of their respective ligands (TLR1/2/6: triacylated lipopeptides, TLR4: lipopolysaccharides, TLR5: Flagellin) whereas TLR10 exhibits anti-inflammatory properties by inhibiting MyD88-dependent signaling. TLR3, −7, −8 and −9 are endosome-bound and recognize bacterial and viral RNA and DNA fragments. Once activated by their respective ligands inflammatory cytokines like TNFα are released through the TIRAP/MyD88-dependend activation of NFκB or Type 1 interferon by IRF3. *IRF3* interferon regulatory factor 3, *MyD88* myeloid differentiation primary response 88, *NFκB* nuclear factor kappa-light-chain-enhancer of activated B cells, *TIRAP* toll-interleukin 1 receptor (TIR) domain containing adaptor protein, *TLR* toll-like receptor. Modified after [50, 51]

responses. However, results of more recent study suggest that TLR2, through the recognition of specific bacteria, may also modulate the intestinal barrier function and intestinal mucosal serotonin production [55, 56]. Further studies are needed to fully unravel the role of TLR2 in the latter.

Lipopolysaccharides (LPS) found in the outer-wall of Gram-negative bacteria have been identified to be recognized by TLR4 which forms a complex with myeloid differentiation factor 2 (MD2) (for overview see [57]). Somewhat similar to TLR2, LPS is also delivered to the TLR by CD14 [58]. Furthermore, results of several studies suggest that the lipopolysaccharide binding protein (LBP), a soluble plasma protein shown to bind LPS, is also involved in the delivery of LPS to the TLR4-MD2 complex [59]. However, there are also contradictory studies suggesting that LBP might not be involved in the recognition of LPS by the TLR4-MD2 complex [60]. TLR5 has been shown to be activated by flagellin [61]. While being a pseudogene in mice due to an insertion of a stop codon, in human, TLR10 being most homologous to TLR1 and TLR6 [62], has been suggested to interact with TLR2 in the sensing of triacylated lipopeptides and other agonists of TLR1 [62]. Also, more recent results suggest that TLR10 may exhibit anti-inflammatory properties (for overview see [63]). For instance, it can inhibit myeloid differentiation primary response 88 (MyD88) dependent and independent pathways [64]. The intracellularly located TLRs sense nucleic acids of bacteria and viruses but also self-nucleic acids in diseases like autoimmunity [65]. Specifically, TLR3 has been shown to recognize viral double stranded RNA (dsRNA), small interfering RNA, and self-RNA of damaged cells (for overview see [49, 66]) while TLR7 and 8 recognized single-stranded RNAs [66]. TLR9 has been shown to recognize bacterial and viral DNA being rich in unmethylated CpG-DNA motifs [66].

Upon sensing their respective ligands, TLRs differentially engage with members of the family of toll-interleukin-1 receptor (TIR) domain-containing adaptors such as MyD88, TIR domain-containing adapter-inducing interferon-β (TRIF), toll-interleukin 1 receptor domain containing adaptor protein/ MyD88 adaptor-like (TIRAP/MAL), or TRIF-related adaptor molecule (TRAM). Herein, MyD88 engages with all TLRs with the interaction leading to an activation of NFκB (nuclear factor kappa-light-chain-enhancer of activated B cells) and mitogen-activated protein kinases (MAPKs) and subsequently the induction of pro-inflammatory cytokines (for overview also see [45, 49]). TIRAP has been suggested to be a sorting adaptor recruiting MyD88 to TLR2 and TLR4 but has also been shown to be involved in signaling of TLR9 (for overview also see [45, 49]). The recruitment and activation of TRIF by TLR3 and TLR4 results in the activation of an alternative pathway that leads to the activation of interferon regulatory factor 3, NFκB and MAPKs resulting in an induction of type I interferon and proinflammatory cytokines. Herein, TRAM seems to be only recruited to TLR4 but not TLR3 linking TRIF and TLR4. Taken together, depending upon the adaptor protein employed, activation of TLR signaling can be divided in two main signaling pathways: the MyD88-dependent and the TRIF-dependent pathways (for overview also see [45, 49]).

Alcohol-Related Alterations of Intestinal Barrier Function and the Translocation of Bacterial (Endo) Toxins: Current Knowledge

In the following, some of the key findings regarding the interaction of alcohol with the intestinal barrier function and subsequently the translocation of bacteria and bacterial wall-compounds are summarized. Effects of alcohol on intestinal microbiota are summarized elsewhere in this book (book Chap. xxx) and are therefore only briefly touched in the following section.

PAMPs and TLRs in ALD

The groups of Christiane and Christian J. Bode but also Ronald G. Thurman and his team have reported already more than 30 years ago that in humans and rodents' alcohol-related liver disease is associated with elevated bacterial endotoxin levels in blood [67, 68]. It has also been shown that, in patients with ALD, bacterial endotoxin levels are positively correlated with intestinal permeability [69] and disease severity [70]. However, in the latter study, bacterial endotoxin levels were assessed in a mixed study population of patients with alcoholic and non-alcoholic cirrhosis. Results of several animal and human studies have by now confirmed these findings (for overview see [71]). Studies have also suggested that even the intake of one high-dose (> 20 g raw ethanol in one setting) is sufficient to increase bacterial endotoxin levels in peripheral blood in humans [67, 72]. In animals, even after one acute ingestion, this increase in bacterial endotoxin levels was found to be associated with the accumulation of fat in the liver [73]. In support of these data, we could recently show that not only liver parameters like activity of ALT and AST as well as γ-GT, liver stiffness and CAP are markedly reduced within 1 week of total abstinence in patients with alcohol-related liver disease but that this also goes along with a decrease of ligands of TLR2 and TLR4 in serum [74]. Furthermore, serum protein levels of zonulin and I-FABP were also almost similar to those found in healthy controls after 1 week of abstinence in these patients.

In the liver, gut derived bacterial endotoxin but also other PAMPs derived from Gram-positive bacteria and fungus as well as viruses, have been suggested to contribute to the development of ALD (for overview see [75]). Jun et al. even reported that the prevalence of cirrhosis was related to the presence of bacterial DNA in peripheral blood [76]. However, no details were provided in this study regarding etiology of cirrhosis. In line with this, it has been shown that besides TLR4 also other TLRs are induced in rodent liver upon chronic high intake of alcohol [77]. Furthermore, employing mice deficient of TLR4, TLR2 and TLR9, it has been shown that an activation of these TLRs not only plays a pivotal role in inflammatory processes associated with the development of ALD but also the hypermetabolic state e.g., increased hepatic oxygen uptake and accumulation of lipids after acute

and chronic alcohol exposure [78–80]. Indeed, in settings of acute and chronic alcohol intake, it was demonstrated that the activation of TLR4-dependent signaling cascades results in an induction of tumor necrosis factor α (TNFα) [81, 82], eventually impairing insulin signaling, inducing plasminogen activator inhibitor-1 (PAI-1) and subsequently hepatic growth factor/cMet-dependent signaling [83] (for schematic overview see Fig. 61.3). In further support of the hypothesis that an increased translocation of PAMPs and subsequent activation of Kupffer cells is critical for the development of ALD, treatment with both, non-resorbable antibiotics and Kupffer cell toxic Gadolinium(III)-chloride, has been shown to almost completely abolish hypermetabolic alterations after acute high alcohol ingestion in rodents [79].

In confirmation, various studies suggest that ethanol consumption is associated with an altered intestinal microbiota composition (for overview see [85] and Chap. X of this book). Studies have shown that the number of anaerobic and aerobic bacteria is significantly higher in jejunal juice of alcoholics than in controls. Herein, alcoholics were found to have a incidence of Gram-negative bacteria and endospore-forming bacterial correlating closely with the pH found in gastric juice [86]. Employing a hydrogen breath test, changes in microbiota composition in small intestine have been reported to be more prevalent in alcoholics than in controls [87]. Other studies showed that changes in microbiota composition in small-intestine is frequently associated with the presence of cirrhosis regardless of the cause of liver

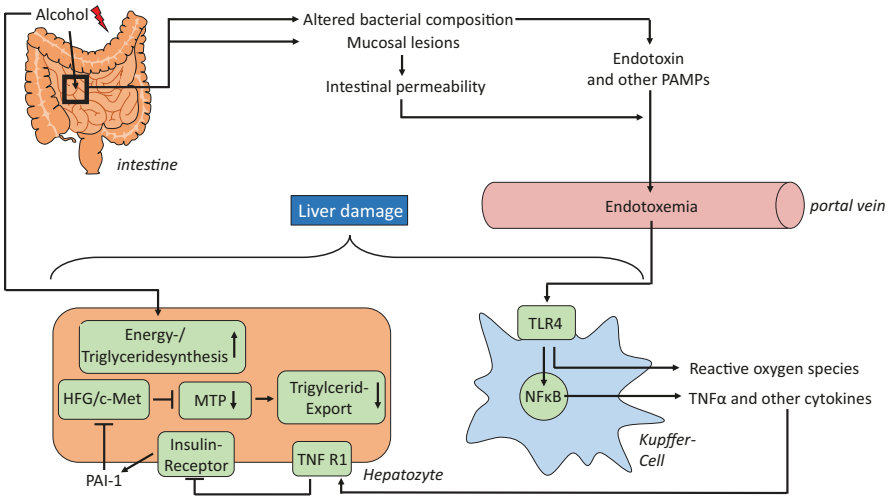

Fig. 61.3 Schematic overview of the role of gut-derived PAMPs in the development of alcohol-related liver disease. Through alcohol induced alterations of bacterial composition and intestinal permeability, gut derived PAMPs like endotoxin cross the intestinal barrier and are recognized by Kupffer cells in the liver. Reactive oxygen species and pro-inflammatory cytokines like TNFα are released and contribute to inflammatory processes and impairments of triglyceride export in the liver. *MTP* microsomal triglyceride transfer protein, *PAMP* pathogen-associated molecular patterns, *TNF-R1* tumor necrosis factor receptor 1, *TNF-α* tumor necrosis factor α. Modified after [84]

damage [88–92]. In a study assessing colonic bacterial composition in patients with alcohol dependence with and without liver disease, it was shown that altered colonic microbiota were correlated with higher blood endotoxin levels [93]. Finally, some studies suggest that patients with alcoholic cirrhosis may have a distinctly altered functional composition of the fecal microbiome e.g., a depletion of functional genes involved in nutrient metabolism including amino acids, lipid and nucleotide metabolism (for overview see [85]).

Effect of Acute and Chronic Alcohol Intake on Intestinal Mucosa

Both, chronic and acute high-dose-intake of ethanol have been reported to lead to losses of epithelial cells from the villi tips and even to hemorrhagic erosions in the lamina propria (for overview also see [94]. Furthermore, studies employing chronic feeding models in rodents have shown that mucus layer and expression of certain mucins like mucin 2 but also antimicrobial peptides like cathelicidin-related antimicrobial peptide, regenerating islet-derived protein 3β (Reg3β) and Reg3γ are altered in distal small intestine [95]. While some of the studies suggest that these alternations may not only be related to alcohol intake but also fatty acid composition of the diet [96, 97], a dysfunction of Paneth cells as major source of antimicrobial peptides [40] seems to be critical in the development of alcohol-related intestinal barrier dysfunction and subsequently ALD. For instance, it has been reported that overexpressing Reg3γ being inducible by Interleukin-22 [98] in intestinal epithelial cells restricts bacterial colonization of mucosal surface and subsequently translocation of bacteria and the development of ALD [95]. Furthermore, recently, it was reported that an oral supplementation of human beta defensin-2 can attenuate liver injury in mice and that this was associated with alterations of multiple bacterial genera in feces [99].

However, studies in Cytochrom P450 2E1 (CYP2E1) knockout mice fed ethanol also suggest that ethanol metabolism itself may be critical in the induction of alcohol-related intestinal barrier dysfunction. In these studies, serum endotoxin levels were markedly lower in knockout mice than in wild-type animals being also associated with lower inducible nitric oxide synthase (iNOS) induction and less mucosal damage [100]. Furthermore, it has also been reported that a disruption of ethanol metabolism through knocking out acetaldehyde dehydrogenase (ALDH) may enhance not only the development of ALD but also the disruptive effects of ethanol in intestinal barrier function [101]. Indeed, when being exposed chronically to ethanol ALDH (+/−) mice showed a greater permeability in large and small intestine along with a marked redistribution and disruption of tight and adherent junction proteins [101]. Somewhat in line with these results, studies in differentiated Caco-2 cells being a model of small intestinal epithelial cells suggest that expression of

tight junction proteins can also be diminished through direct effects of ethanol, e.g., ethanol metabolites and/ or metabolic alterations associated with the metabolism of ethanol e.g., the shift of NAD^+ $NADH^+H^+$ or the formation of nitric oxide [102, 103]. Specifically, studies employing cell lines have shown that, through NFκB-dependent signaling cascades, alcohol activates iNOS in enterocytes and that the resulting increase in nitric oxide and peroxynitrate can add to the ethanol-related disruption of intestinal barrier and loss of tight junctions [104, 105]. In line with these findings, it was also shown, that a concomitant treatment with iNOS inhibitors not only attenuated the development of ALD but also alcohol-induced intestinal barrier dysfunction and endotoxemia [106]. Other studies also suggest that intestinal barrier function is highly dependent on a `normal´ microcirculation of the underlying vasculature system [107]. Moreover, acute and chronic intake of alcohol is associated with impairment of the intestinal microcirculation [108] and a decreased expression of hypoxia-inducible factors (HIF) HIF1α and 2α seem to be involved [109, 110]. Taken together, these data suggest that alcohol, probably through its alcohol dehydrogenase- or CYP2E1-dependent metabolism, may also affect intestinal barrier function independently of its effects on intestinal microbiota composition.

Conclusion

Animal and human studies suggest that besides alterations of intestinal microbiota composition (for overview also see Chap. X of this book) impairments of intestinal barrier function and subsequently an increased permeation of PAMPs are critical in the development of ALD. Studies further suggest that abstinence is associated with a rather rapid change of intestinal microbiota composition and intestinal barrier function. So far, however, only a limited number of studies have addressed this question. Although the pharmacotherapeutic targeting of the intestinal barrier function and/or TLRs with pro- or prebiotics or drugs appears as an attractive molecular strategy to treat ALD in early stages, more experimental studies and clinical trials are needed.

Chapter 62
Microbiota and Alcohol-Related Liver Disease

Alina Popescu and Felix Bende

Abstract Alcohol-related liver disease (ALD) comprises different histopathological changes in patients with excessive alcohol intake ranging from alcohol-induced steatosis to alcoholic steatohepatitis, and liver cirrhosis. The presence of advanced fibrosis or cirrhosis in these patients is the main predictor of long-term survival. The gut microbiota plays an important role in the pathogenesis and progression of ALD, and its role within the progression to liver cirrhosis and hepatocellular carcinoma has been intensively studied. Several changes in ALD patients' microbiota were documented starting with an increased dysbiosis, an increased intestinal permeability, and an increased small-intestinal bacterial overgrowth. These considerable gut flora abnormalities present in ALD patients may affect their liver disease's natural course and may represent potential targets for intervention in the management of these patients. Despite an significant progress in this field of medical research, more data are needed to fully understand the implications of microbiota in the pathogenesis and progression of ALD. This chapter briefly describes and discusses some of the key observations.

Keywords Alcohol-related liver disease · Microbiota · Dysbiosis · Liver cirrhosis · Alcohol use disorders

Introduction

The human microflora, also known as "microbiota", includes multiple species of germs (bacteria, fungi, bacteriophages or viruses) that colonize the skin, the genitourinary system, the respiratory system and the digestive tract. The highest microbial

density is found in the intestine where it forms the intestinal microbiota. The gut microbiome includes about 1000 different species of bacteria, totaling a weight of about 1 kg [1]. The stomach and small intestine are less populated by bacteria, the vast majority of them colonizing the large bowel. At this level, there are normally over 10^{14} microorganisms [2]. The vast majority belongs to two groups, either gram-positive *Firmicutes* or gram-negative *Bacteroides* [1, 2]. However, there are other species, less abundant, but important for homeostasis, among which *Proteobacteria*, *Actinobacteria*, *Fusobacteria* and *Verrucomicrobia* should be mentioned [2]. The intestinal microbiome is characterized by a great diversity of germs. Important bacterial species are *Clostridium coccoides* (C. coccoides)-*Eubacterium rectale*, *Clostridium leptum* (C. leptum), *Bacteroides-Prevotella*, *Bifidobacterium* and *Atopobium* [3]. The intestinal microbiota is in symbiosis with the human body, it is accepted by it (it has "compatibility"), it has functions (defense, immunity, digestion and metabolism), it communicates with the intestinal epithelium and with other systems, including the central nervous system ("gut-brain interactions"), behavior similar to that of any organ. For these reasons, the microbiom is sometimes considered an "organ" often forgotten in medical practice [1]. The intestinal microbiome contains 100 times more genes, compared to the human genome [4]. It has multiple functions that are not yet fully understood.

First, it forms an external barrier ("barrier effect"), preventing pathogenic germs from colonizing the intestinal mucosa. Intestinal epithelial cells create a physical barrier between intraluminal microbes and the intestinal tissue. In addition, they produce a mucus layer and secrete antimicrobial proteins, such as secretory immunoglobulin A (Ig A), which limit the exposure of epithelial cells to microbial agents [5]. Clostridium difficile-associated colitis is an example of losing this barrier function [4]. Second, the microbiome has metabolic and energetic functions ("metabolic organ"), producing energy from undigested residues in the small intestine ("recovers residues"). Under the action of the bacterial flora, short-chain fatty acids are converted largely to butyric acid, with a beneficial role for colonocytes, as well as vitamin formation. Thus, vitamin K is mainly derived from intestinal microbiota) [5].

Third, the maturation and education of the intestinal immune system is unthinkable without the microbiome through continuous, direct and indirect stimulation, and the production of a chronic, physiological, mild inflammation ("low-grade physiological inflammation"), which constantly keeps the immune system on alert, maintaining a perfect symbiosis with the microbiota ("innate and adaptive immune responses"). The microbiota ensures homeostasis of the immune system, so that the body tolerates microorganisms. Dysregulation of the interaction between the host and the microbiota can lead to an inadequate or exaggerated inflammatory reaction, with increased mucosal permeability.

In healthy subjects, the microbiome aids at maintaining a balance between the immune tolerance of the host and the permanent stimuli coming from the existing flora and its metabolic products [4]. Microbial recognition using antigen-presenting cells (for example dendritic cells, DC) and epithelial cells, is achieved by identifying "microbial-associated molecular patterns" (MAMPs), using "toll-like"

receptors (TLR), capable of detecting a multitude of bacterial components, such as lipopolysaccharides (LPS), lipoproteins, CpG DNA, but also through "nucleotide-binding oligomerization domain (NOD)-like" (NLR) receptors, which recognize peptidoglycan molecules from the bacterial cell wall [6]. In healthy subjects, the pro-inflammatory pathways associated with TLRs and NLRs are suppressed by inhibitors, both of human nature and bacterial origin such as Cyclooxygenase-2 (COX-2) inhibitors, LPS, A20, peroxisome proliferator-activated receptor-γ (PPAR-γ), nuclear factor-κB (NF-κB) inhibitor IκB-α, interferon-α/β (IFN-α/β), interleukin-10 (IL-10), TGF-β, and eicosanoids] [7, 8]. On the other hand, the tolerance mechanisms of the commensal microbiota offer protection against the inappropriate inflammatory response, but also against the invasion of pathogenic flora [4]. So far, however, the mechanisms by which the commensal flora is tolerated by the host, at the expense of pathogenic germs, is not fully known [4].

Gut Microbiota Changes in Alcohol-Related Liver Disease

Alcoho-related liver disease (ALD) comprises different histopathological changes in patients with excessive alcohol intake ranging from alcohol-induced steatosis, to alcoholic steatohepatitis, which features hepatocytes necrosis, inflammation and potential evolution to fibrosis, and liver cirrhosis. ALD is the major cause of chronic liver diseases worldwide, accounting for approximately 27% of liver-related deaths [9]. While simple alcohol-induced steatosis is present in almost all heavy drinkers, it is estimated that ca. 10–20% of these subjects will eventually develop liver cirrhosis [10]. The presence of advanced fibrosis or cirrhosis in these patients is the main predictor of long-term survival [11]. The gut microbiota plays an important role in the pathogenesis and progression of ALD, and its role in the progression to liver cirrhosis and hepatocellular carcinoma has been intensively studied.

Thus, several changes in ALD patient's microbiota were documented starting with an increased *dysbiosis*, an *increased intestinal permeability*, and an *increased small-intestinal bacterial overgrowth* [12]. Alcohol-induced gut ***dysbiosis*** is an important feature of ALD that modulates disease progression [13]. Increased metabolism of ethanol in the gut promotes gut dysfunction (a decreased function of tight junction proteins and adhesion junction proteins) and small bowel bacterial overgrowth, generating a leaky gut. When the intestinal barrier is weakened due to dysfunctional tight junctions, microorganisms such as bacteria and fungi may translocate to the blood stream and reach the liver via the portal vein. These bacterial products interact with Toll-like receptors (TLRs) on the surface of the hepatic cells, which leads to inflammation, with the activation of the nuclear factor kappa-B pathway, which releases pro-inflammatory cytokines and chemokines, and the development of liver injury [14]. Chronic alcohol consumption also increases the production of its main toxic metabolite acetaldehyde, promoting mitochondrial dysfunction and oxidative stress perpetuating liver injury [13].

Gut-Liver Axis in Alcohol-Related Liver Disease

Around 15–20% of people with alcohol use disorders (AUDs) may develop ALD [15]. Progression of the disease can vary considerably and intestinal microbiota have been suggested to causes this variability in ALD risk [16–18]. ALD progression, however, may be influenced by coexisting depression and other psychiatric illnesses, as well as abnormalities in circadian rhythms. These factors could interact and skew the microbiological data as well as negatively affect intestinal permeability [19]. In a recent study that included 48 patients with AUDs with ALD (n = 19) and without ALD (n = 28), as well as 18 healthy control persons, the stool and mucosa-associated colonic microbiota were examined [17]. There was no difference between the groups with AUDs, although higher serum levels of endotoxin were observed in both AUD groups. In addition, patients with AUDs (with or without ALD) had significant overlaps in the general distribution of the microbiom. The relative abundance of the family Bacteroidaceae was found to be highest in the healthy control group and lowest in the AUD patients with ALD. However, colonic mucosa dysbiosis was not entirely linked with ALD in AUD patients.

Another study also found differences in the amounts of microbial metabolic products including short-chain fatty acids (SCFAs) and sulfides as well as a decline in antioxidant fatty acids in patients with AUD when compared to healthy control individuals [20]. In this study, however, ALD status was not characterized. Leclercq et al. Studied in 60 patients with AUD whether alcohol-mediated dysbiosis of the microbiome can be reversed [16]. Interestingly, only 40% showed dysbiosis were restored to levels of control persons after 3 weeks of complete alcohol abstinence. Ruminococcaceae abundance also increased during this time. Even after alcohol cessation, increased intestinal permeability was associated with higher levels of anxiety, despair, and alcohol craving.

It is also important to better understand how the gut-brain axis functions in individuals with AUDs and ALD. The interfaces between the liver, intestine, and brain are caused by inflammatory cytokines and direct neuronal connections that can be bidirectional, and these factors all significantly affect the prognosis as a whole. ALD is most severe in patients with endstage cirrhosis or alcoholic hepatitis. These patients not only have extremely poor clinical outcomes, a multifold increased risk of infections, complications due to protal hypertension and acute-on-chronic liver failure, but they also clearly show changes in the composition and function of their microbiota tightly associated with the presence of liver injury. Even in the absence of alcohol drinking, patients with alcohol-related cirrhosis show more gut dysbiosis and endotoxemia than non-alcoholics [21]. Gut microbiota profiles of patients with alcoholic cirrhosis with a cognitive impairment have more Enterobacteriaceae and less Lachnospiraceae and Ruminococcaceae [22].

Patients with cirrhosis who continue to drink alcohol have lower levels of native taxa and functional microbiota in their colonic and duodenal mucosa and feces [23]. These changes are accompanied by increased secondary bile acid synthesis and enterohepatic bile acid circulation [23]. A surge in secondary bile acids can

undermine the already weakened intestinal barrier, impair cell membrane integrity, and accelerate alcohol-related gut-liver axis damage [24]. Another study that analyzed the gut microbiota's composition and activity in cirrhotic and noncirrhotic patients revealed that cirrhosis patients had more oral-derived microbiota and Lactobacillaceae in their stool than the others [25]. These changes could be explained by the high prevalence of periodontitis, altered salivary microbiota, use of proton pump inhibitors, and low gastric acid in these patients [26, 27]. Earlier studies of gut microbiota in cirrhosis patients have also seen an increase in Lactobacillaceae, which was linked to the therapeutic use of lactulose [28].

In alcoholic hepatitis (AH), typically having already manifest cirrhosis, increased Enterobacteriaceae and Streptococcaceae groups have been associated with disease severity [29]. The same study observed a rise in secondary bile acids with progressing AH. Patients with AH exhibited the lowest relative abundance of commensal Akkermansia muciniphila [30]. An impaired immune response was found in another ALD study that compared circulating microorganisms in patients with AH, cirrhosis without AH, and healthy controls [31]. Fusobacteria abundance was higher in drinkers than in healthy controls, but lower in those with severe AH. Bacteroidetes showed the opposite distribution, with the highest relative abundance in healthy non-drinkers. In contrast, patients with severe AH exhibited the greatest endotoxemia. In summary, these data demonstrate that ALD patients have considerable abnormalities in their gut flora, which may affect their liver disease's natural course.

Gut-Brain Axis in Alcohol-Related Liver Disease

AUD effects on the brain range from acute intoxication to personality, behavioral changes to dementia. Hepatic encephalopathy and nutritional deficits can further deteriorate the brain reserve and function [32]. The gut-brain axis as a whole must be considered when evaluating the gut as a potential pathway by which brain function is altered in patients with AUDs [19]. In individuals with early AUD, a correlation between increased intestinal permeability and symptoms of depression, anxiety, and alcohol seeking has been identified [16]. Even after alcohol withdrawal, patients with high intestinal permeability remained depressed, and anxious. In primary mental illnesses such as depression and schizophrenia, the gut-brain axis can be affected also in the absence of alcohol misuse [33]. Systemic inflammatory mediators, ammonia, and endotoxemia exacerbate neuroinflammation in AUD as a result of dysbiosis. Patients with alcohol-related cirrhosis are more likely to experience persistent cognitive impairment than those with cirrhosis unrelated to alcoholism, which may have an impact on their ability to carry out everyday activities [22]. However, more research is required to better understand the interaction between gut and brain at the molecular level and to discriminate between "unspecific" toxic specifically mediated effects.

ALD Therapies Involving the Microbiome

ALD inpatients with probiotics (Bifidobacterium bifidum and Lactobacillus Plantarum 8PA3) for 5 days increased levels of potentially beneficial bacteria [34]. Along with these findings, liver enzymes alanine aminotransferase, aspartate aminotransferase, and -glutamyl transpeptidase improved. In a study by Han et al., 117 patients with AH from four centers were randomly assigned to a probiotic regimen comprising Bacillus subtilis and Enterococcus faecium or a placebo for 7 days [35]. Serial plating showed that probiotics reduce stool E. Coli, endotoxemia and liver-related enzymes, but not inflammatory cytokines. Fecal microbiota transplantation (FMT) has been explored for several years to restore or change the microbiome [36]. In a study on patients with steroid-resistant AH followed-up for 1 year, FMT patients had a higher overall survival rate (87.5 vs. 33.3%) as compared to non-FMT patients [37]. In another open-label trial, male AH patients were treated with FMT, nutrition, corticosteroids, or pentoxifylline. Compared to other interventions, FMT improved 90-day survival (75 vs. 38% for steroids, 29% for nutrition, and 30% for pentoxifylline) and gut microbiota composition and functionality [38].

Conclusions

In ALD, the development of liver injury is tightly connected to the gut flora. There is increasing evidence that specific alterations in the human gut microbiota may modulate liver disease progression. However, more large-scale, long-term and randomized clinical trials are required to confirm these initial observations.

S. Mueller, M. Heilig (eds.), *Alcohol and Alcohol-related Diseases*,
https://doi.org/10.1007/978-3-031-32483-3_63

Abstract Life expectancy in people living with HIV (PLWH) has increased due to effective antiretroviral therapy (ART). Consequently, they survive longer, which increases co-morbidities. Liver disease is one of the leading co-morbidities in PLWH representing 18% of non-AIDS mortality. In addition, the incidence of alcohol abuse is twice as high in PLWH as compared to the general population. Generally, ethanol metabolism has been shown to aggravate the HIV-mediated liver damage. It enhances the accumulation of HIV in hepatocytes, which further aggravates oxidative stress and lysosomal damage/dysfunction. When oxidative stress is high, hepatocytes undergo apoptosis with the release of apoptotic bodies (ABs), while low oxidative stress causes exosome release from these cells. Engulfment of either ABs or exosomes by liver macrophages induces liver inflammation, and internalization of these extracellular vesicles (EVs) by hepatic stellate cells (HSC) promotes fibrosis development. The proposed anti-fibrotic therapy in PLWH with alcohol-use disorders (AUD) includes antioxidants, nanoparticles to block activation of pro-fibrotic pathways in HSC, and Obeticholic Acid (OCA).

Keywords Hepatocytes · HIV · Ethanol · Acetaldehyde · Lysosomal damage · Apoptotic bodies · Exosomes · Hepatic stellate cells · Macrophages

Introduction

A special interest in HIV-associated liver damage is supported by the fact that 40 million people are living with HIV globally, with 1.2 million of them in the US. While life expectancy has increased due to effective antiretroviral therapy (ART), people living with HIV (PLWH) survive longer, which has increased the risk of co-morbidities. Liver disease is one of the leading co-morbidities representing 18% of non-AIDS mortality [1, 2]. In fact, the liver plays a major role in the clearance of circulating viral particles from the blood, as was shown for Simian Immunodeficiency Virus (SIV) [3]. Liver transaminases are frequently elevated in the sera of HIV-infected patients even in the absence of accompanying viral hepatitis [4]. HIV-1 infects hepatocytes, but this infection is either low or latent [5, 6]. There is an association between HIV RNA content and liver fibrosis [6]. Hepatocytes are found in the proximity of actively replicating HIV in Kupffer cells (KC), sinusoidal endothelial cells (LSEC), stellate cells (HSC), and $CD4^+$ T cells. While hepatocytes seem non-permissive and are not harmed by HIV mono-infection, their exposure to the virus triggered by HCV co-infection or other second hits may lead to increased cell death [4, 7, 8]. The major turnover of damaged hepatocytes is mediated by liver macrophages, which regulate hepatocyte damage and fibrotic replacement. Modern ART efficiently blocks active viral replication. Still, it does not eliminate latently infected cells with HIV DNA integrated into the host genome, thereby improving disease outcomes without halting disease progression [9] with increased age-dependent comorbidities, including liver diseases [10].

Why HIV-infection has such an impact on liver cells? Hepatocytes are generally exposed to high levels of HIV because the liver is scavenger of activated immune cells that replicate the virus. Highest levels of HIV are found in gut-associated lymphoid tissue, and in contrast to peripheral blood mononuclear cells, HIV persists in this tissue despite of ART [11] [12]. HIV is typically brought to liver with portal blood, infecting Kupffer cells [13] and accessing hepatocytes. Although long-term ART is claimed as a major reason for hepatotoxicity [14], hepatotoxic effects maybe observed even in the absence of ART to be attributed to damaging effects of HIV by itself, especially when HIV-infection is potentiated by second hits, like alcohol.

HIV-Infection in Hepatocytes: Effects of Ethanol Metabolism

The above reasons prompted us to study the combined effects of HIV and ethanol metabolites on the survival of HIV-infected hepatocytes. For this purpose, we used ethanol-metabolizing primary human hepatocytes (PHH) and Huh7.5-CYP2E1 (designated as RLW) cells, which efficiently oxidize ethanol by overexpressed CYP2E1 but lack of alcohol dehydrogenase (ADH), a major generator of acetaldehyde. PHH were exposed to 50 mM ethanol and RLW cells- to the acetaldehyde-generating system (AGS), which contains ethanol as a substrate, yeast ADH as a source of the enzyme, and NAD^+ as a co-factor. The aforementioned system mimics Ethanol metabolism in PHH and was successfully used in prior studies [15–17]. While hepatocytes were usually not considered HIV-permissive cells, surprisingly, we found that after pre-exposure of PHH to 50 mM ethanol for 24 h followed by HIV infection for 3 days, they express more HIV gag RNA and HIV gag protein, p24 than the cells infected without ethanol pre-exposure [18]. These effects were seen when HIV- and ethanol-induced hepatocyte death was prevented by co-treatment with pan-caspase inhibitor (PCI). In fact, under the specified conditions, cells undergo rapid apoptosis, as became evident from M30 and caspase 3 measurements. To clarify whether HIV gag RNA detected in hepatocytes is inside of cells or is just attached to cell membrane from outside, after pre-treatment of RLW cells with AGS followed by exposure to HIV, the membrane-associated binders were removed by low acid stripping [19]. Then HIV gag RNA was repeatedly measured by RT-PCR. However, no difference in the levels of HIVgag RNA expression was observed between these two protocols indicating that HIVgagRNA is not cell membrane-associated [18]. We next studied the HIV entry receptors on hepatocytes because these cells do not express canonic CD4 receptors. We assumed that HIV_{ADA} enters via CCR5 receptor (HIV-co-receptor). To prove it, we blocked CCR5 receptor on infected either with HIV alone or HIV combined with AGS liver cells by Maraviroc, a specific CCR5 receptor blocker. While AGS potently increased HIVgag RNA expression, this does not happen in the presence of Maraviroc, indicating that CCR5 may serve as a receptor for viral entry to hepatocytes. The blocking effects of Maraviroc have also been shown by others for HIV infection in hepatocytes with no ethanol metabolite exposure [6].

The entry via CCR5 receptor requires the trafficking of HIV via an endosomal compartment with low pH, to which HIV is highly sensitive [20]. Moreover, ethanol has been shown to increase the pH of the endosomal-lysosomal compartment [21], thereby allowing HIV to survive. This becomes evident from lysoSensor experiments, in which the combination of AGS and HIV changed pH in RLW cells to neutral, which became visible due to appearance of a blue staining in hepatocytes [22]. Thus, it is important to understand if an increase in HIVgag RNA and HIV proteins under ethanol treatment in hepatocytes is due to increased viral replication or due to the accumulation of these HIV particles in hepatocytes. To address this, we measured the effects of ethanol/AGS on HIV RNA, HIV DNA and integrated HIV DNA. These measurements were performed in hepatocytes protected from HIV-ethanol-triggered cell death by exposure to pan-caspase inhibitor as well as in the absence of this inhibitor. While exposure to pan-caspase inhibitor just increased HIV RNA expression in HIV-infected hepatocytes treated with ethanol, we were unable to quantify HIV DNA and integrated HIV DNA in these cells in the absence of pan-caspase inhibitor, which suggests that reverse transcription from HIV RNA to HIV DNA and HIV DNA integration are associated with hepatocyte apoptosis induction. In the literature, there are several very controversial reports on HIV DNA integration to hepatocyte genome in the absence of AGS: although some authors demonstrated HIV DNA integration and low levels of productive infection in hepatocytes, others do not support it [6, 23, 24]. We indeed observed that caspase 3 cleavage, as well as cleaved cytokeratin 18, were enhanced by co-exposure of PHH/RLW cells to Ethanol/r AGS and HIV in a MOI-increasing fashion, and this apoptosis was attenuated by azidothymidine (AZT), a reverse transcriptase inhibitor. This also indicates that the reverse transcription from HIV RNA to HIV DNA initiates the mechanism of cell death [18, 25]. Thus, we deal with abortive replication. Since the full HIV replication cycle in hepatocytes does not take place due to rapid apoptosis.

The kinetic studies on HIVgag RNA, p24 and cleaved caspase 3 in HIV-infected RLW cells either exposed or not to AGS indicated that AGS treatment stabilized HIV gag RNA and protein in hepatocytes, which, in turn, induced oxidative stress and consequent apoptosis [18, 25, 26].

Stabilization of HIV Proteins in Hepatocytes Exposed to Ethanol Metabolites Due to Lysosomal Dysfunction

We observed the accumulation of HIV proteins (namely, p24) in RLW cells exposed to lysosomal inhibitor, bafilomycin as well as to the combination of HIV and AGS [18]. This means that suppression of lysosome function by HIV infection and AGS treatment prevents HIV protein degradation by lysosome leading to protein

stabilization in the cells, which might induce oxidative stress. In fact, cell exposure to AGS decreased cathepsins B and L (lysosomal enzymes) activities in HIV-infected hepatocytes [27]. The same treatments caused co-localization of lysosomal protein, LAMP1 with Gal3, thereby indicating lysosomal leakage. As known, the leakage of cathepsins and their co-localization to organelles damage these organelles and induce apoptosis [28]. In HIV-infected hepatocytes, leaked cathepsin B co-localized with mitochondrial outer membrane protein, TOM 20, and this becomes even more visible after exposure of RLW cells to AGS [27]. Furthermore, caspase 3 cleavage in HIV^+ AGS-treated RLW cells was reversed in the presence of caspase 9 inhibitor, suggesting that co-localization of cathepsin B with mitochondria may, in turn, induce mitochondrial leakage with the release of cytochrome C to activate intrinsic apoptosis. Another reason for apoptosis induction is related to enhanced expression of the lysosomal protein, DRAM1, which is co-localized with BAX and has p53 as its downstream target [29, 30]. This overexpression is observed when HIV-infected hepatocytes are treated with AGS [27]. Induction of apoptosis, as well as the reduction in cathepsin activities in HIV-infected hepatocytes exposed to ethanol metabolites can be reversed by N-acetyl cysteine (NAC) and thus, is related to oxidative stress. While the pathogenic importance of lysosomal leakage has already been shown for steatohepatitis of both alcoholic and non-alcoholic origins [31–33], previously, this has never been implemented into mitochondrion-dependent pathologic mechanism of HIV-ethanol metabolism -triggered hepatotoxicity.

Damaged lysosomes can be easily removed and replaced if lysosomal biogenesis is not impaired. However, it has been shown that the activation of lysosomal genes is significantly reduced in RLW cells infected with HIV and exposed to AGS [27]. The reason for that is an impaired translocation of a master regulator of lysosomal biogenesis, transcription factor EB (TFEB), from the cytosol to the nucleus to activate lysosomal genes. It appears that, in HIV-infected hepatocytes, acetaldehyde induces acetylation of tubulin, thereby contributing to impaired TFEB trafficking via microtubules [27]. This mechanism is not unique for TFEB and has been demonstrated for trafficking of other transduction factors in alcohol-exposed hepatocytes [34, 35]. In addition, our study [27] revealed that in HIV^+ hepatocytes, AGS increases the levels of ZKSCAN3, a repressor of lysosomal gene transcription, which prevents activation of lysosomal biogenesis. These *in vitro* findings were supported by *in vivo* studies on liver-humanized mice injected with HIV and pair-fed either control or ethanol liquid diets. In fact, ethanol suppresses LAMP1 expression and cathepsin activities in these mice, which was accompanied by activation of oxidative stress as evident from the increased TBARS (malondialdehyde) activity in liver tissue. The findings summarized here are presented on Fig. 63.1. More details have been described in [27]. In addition, we could not exclude that HIV + ethanol induced oxidative stress damages lysosomes and cell death not only in the liver but in other organs, such as the pancreas, thereby promoting metabolic changes and dysregulation [36].

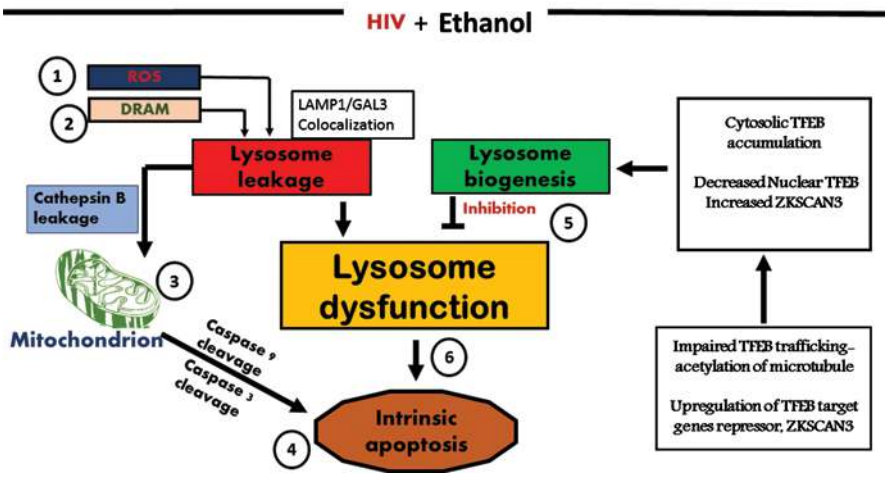

Fig. 63.1 Role of lysosomal rupture/dysfunction in HIV-and ethanol metabolism -induced apoptosis (1) Combined treatment with HIV and AGS triggers ROS and acetaldehyde release, which mediates lysosome leakage; (2) HIV/ethanol metabolism triggers the release of DRAM1, which also induces lysosome leakage; (3) Cathepsin B leaked out from damaged lysosome and diffused into the mitochondrion to initiate the intrinsic apoptotic pathway; (4) Caspases 9 and 3 become cleaved, leading to hepatocyte apoptosis; (5) Alcohol metabolites inhibit lysosome biogenesis factor TFEB, hence impairing the compensation of damaged lysosomes; (6) Both lysosome damage and impaired lysosome biogenesis lead to HIV–ethanol-metabolism-induced lysosome dysfunction, which triggers apoptosis

Exposure of HIV-Infected Hepatocytes to Ethanol Promotes the Release of Extracellular Vesicles (EVs)

Extracellular vesicles (EVs) are small membrane-bound vesicles, which contain proteins, lipids, and nuclear acids as a part of their cargo. These vesicles are subdivided into three groups: exosomes, micro-vesicles, and apoptotic bodies. Inside cell cytoplasm, the intraluminal vesicles are formed by components of the endosomal-sorting-complex-required-for-transport (ESCRT) machinery, lipids, and tetraspanins (e.g., CD63, CD81, etc.). When the multivesicular bodies (MVB) dock and fuse with the plasma membrane, the intraluminal vesicles are released as exosomes [37]. The mechanisms by which MVB sort either to the plasma membrane or to lysosome are unclear. It is possible that the suppression of lysosome function, which is observed in HIV-infected hepatocytes exposed to ethanol metabolites, may cause not only cell death [27], but also promotes exosome release from activated alive cells [22]. In fact, the outcome depends on the levels of oxidative stress induced by both hits, HIV and ethanol: if oxidative stress is low and cells can manage it, they try to compensate for it by releasing exosomes carrying excessively expressed harmful proteins not degraded properly by lysosome; however, if oxidative stress is high, this can lead to apoptotic cell death and release of apoptotic bodies (AB) [38].

Indeed, in pro-apoptotic conditions in the absence of pan-caspase inhibitor, where hepatocytes were under prolongated exposure to HIV and AGS, exosome release was diminished [22].

Many sαtudies are focused on the roles of liver-derived EVs in the induction of inflammation and fibrosis because of cell-to-cell EV-mediated crosstalk between parenchymal and non-parenchymal liver cells in the settings of exposure to ethanol [38–41]. MicroRNAs as a part of EV cargo can also be used as the biomarkers of Alcohol-Associated Liver Disease (ALD) [42]. However, so far, the information on liver EVs and their cargo released from cells exposed to HIV and alcohol is very limited. In our hands, AB formation may contribute to liver fibrosis progression in alcohol-abusing PLWH, and the characterization of the cargo of AB derived from HIV-and AGS-exposed hepatocytes demonstrated an increased content of HIVgag RNA, p24, Nef, and TAT proteins as well as oxidative modification of proteins with malondialdehyde (MDA) [43]. Furthermore, internalization of these AB by HSC suppresses innate immunity (activation of Interferon-stimulated anti-viral genes by IFNα), but triggers IL-6-induced activation of JAK-STAT3 pathway, which is survival for HSC [43]. As shown, AB engulfed by macrophages induce inflammasome activation, while engulfment by HSC causes pro-fibrotic activation [18]. Interestingly, a similar situation was observed in HCV infection [44], indicating that from this standpoint, there is no difference in disease outcomes when AB internalized by non-parenchymal cells were generated from hepatocytes either replicating or just accumulating the viruses. The pro-fibrotic effects of AB were hepatocyte-specific because we observed an activation of pro-fibrotic markers in HSC when AB were prepared from HIV-infected hepatocytes, but not HIV-infected immune cells [18]. Currently, we cannot explain why engulfment of only hepatocyte AB promotes pro-fibrotic activation in HSC; however, we anticipate that HIV proteins combined with so far non-identified hepatocyte-specific markers may serve as a driving force of this process. In non-HIV/alcohol studies, AB were also claimed as the trigger or fibrosis development [45], but HIV component in these AB significantly enhanced pro-fibrotic HSC activation [18]. Importantly, along with large EVs (AB), exosomes derived from HIV-infected hepatocytes exposed to ethanol metabolites also up-regulate pro-fibrotic activation of HSC [46].

Those proteins, which are not degraded by lysosomes, may be secreted with exosomes. Partially, it is related to posttranslational modification of subjected to degradation HIV proteins named ISGylation, which is interferon (IFN)-inducible [47]. ISGylated HIV proteins are prone to lysosomal cleavage, but ethanol by suppressing IFN type 1 signaling, interferes with protein ISGylation, thereby promoting their stabilization and release with exosomes [48]. It has also been shown that lysosome inhibition with various chemicals, such as bafilomycin A1 increases EV secretion [49]. In fact, we observed exosome secretion in HIV- and ethanol-exposed hepatocytes, which was corroborated by bafilomycin treatment [22]. Here, in primary human hepatocytes (PHH), EV secretion was induced by each ethanol and HIV; however, the combined treatment provided the strongest effect. These *in vitro* results were supported by *in vivo* data. To this end, using pan-exosome isolation kit, EVs from plasma of FRG-KO liver-humanized mice were quantified by

Nano-tracking analysis (NTA), and the highest levels of hepatocyte-specific EVs were in mice fed ethanol diet and injected with HIV (HIV injection has been used since human hepatocytes only abortively replicate HIV) [22]. In these studies, oxidative stress served as EVs trigger since exosome secretion was attenuated by NAC co-treatment. Also, there was a direct association between increasing lipid peroxidation marker, TBARS (MDA) in liver tissue and liver EVs release. Furthermore, the results of next generation sequencing (NGS) from the same study predicted that hepatocytes exposed to HIV and ethanol activated stress-regulated genes and provided lysosome dysfunction in HIV and ethanol-treated PHH, potentially increasing exosome release from these cells [22]. In addition, in-silico data revealed that PHH exposed to ethanol-HIV enhanced upstream regulators targeting genes associated with oxidative stress, lysosomal dysfunction and exosome secretion. Specifically, we observed the increased expression of genes associated with alcoholic hepatitis (CRP, ICAM1, FMO5, CD109, CHI3L1, ERRFI1, HAO2, MT1M, KLF9, RHOB, PER1, TSC22D3) and HIV-1 gene (gag, pol, vpr, nef, and env). PHH-EVs were characterized by Transmission Electron Microscopy, NTA (NanoSight), and western blot, confirming their cup shape, size around 100 nm consistent with exosomes, and the enrichment of ALIX and TSG101 throughout the tested samples, respectively. In addition, the expressions of hsa-miR16–2; hsa-miR-27a, hsa-miR-501 and hsa-miR-99A miRNAs were significantly altered in PHH-EVs in ethanol and HIV group from their controls. The network analysis revealed the targets of miRNAs which were associated with of HIV1 (ATP5G3, ABCC4, SLCO5A1, AFG3L2, OTUD3, SFXN4 and ERP27) and liver disease (PTER, PAMR, MAPKAPK3 and PEX5L) progression [50].

Circulating macrophages infiltrate liver during organ injury and replenish the resident macrophage population, Kupffer cells (KC) [51]. As shown, ethanol increases HIV-1 replication in macrophages by causing DNA damage, CYP2E1 elevation and decreased expression of antioxidants [52]. The polarization into M1 cells results in a decreased expression of HIV DNA. Thus, while M1 phenotype marker, TNFα is an activator of HIV replication, some studies indicated its protective role in HIV infection by stimulating the production of RANTES and decreasing CCR5 expression in macrophages [53]. A recent study demonstrated that miR-99a expression is negatively correlated with inflammation by targeting TNFα, showing that overexpression of miR-99a prevented M1 phenotype activation and promoted a phenotype switching to M2 [54]. Alcohol-HIV treatment of PHH caused upregulation of four EV-miRNAs (miR-99a, miR-16, miR-122 and miR-17HG) and downregulated ten miRNAs [38]. KEGG pathway analysis demonstrated that metabolic pathways, such as the MAPK signaling pathway, ubiquitin-mediated proteolysis, the insulin signaling pathway etc., were significantly upregulated by miRNAs in hepatocytes from the HIV^+ alcohol group compared to either alcohol or HIV-only groups. Mapping of miRNA target genes on KEGG disease database identified pathways associated with liver disease i.e., alcohol-related disorders, insulin resistance, fatty liver, fibrosis, and inflammation in HIV^+ ethanol and HIV- treated

groups. The internalization of hepatocyte-exosome by macrophages induced anti-inflammatory TGFß and ARG1, as well as downregulated expression of pro-inflammatory IL-1ß, IL-6, and TNFα markers in the latter cells.

Treatment Approaches for Prevention of HIV-Ethanol-Induced Liver Fibrosis Development

Treatment of alcohol abusing PLWH with modern and less hepatotoxic ART will be important to limit the supply of HIV coming to the liver and hepatocytes. However, HIV does not replicate in hepatocytes, and in combination with ethanol, HIV proteins are stabilized in hepatocytes to induce oxidative stress. While intensive apoptosis is initiated by exposure of hepatocytes to HIV and Ethanol metabolites, it will not be beneficial to treat alcohol abusing PLWH with anti-apoptotic drugs because the prevention of apoptosis in HIV-infected hepatocytes may potentially induce HIV DNA integration to the hepatocyte genome. In fact, the prevention of HIV and AGS- induced apoptotic hepatocyte death by exposure to pan-caspase inhibitor caused accumulation of cells with integrated HIV DNA [18]. Thus, a major treatment strategy should be directed to prevent oxidative stress. In prior studies, when HIV-Ethanol-exposed hepatocytes were treated with antioxidants, such as NAC, we observed the reduction in lysosomal damage and restoration of cathepsin activities, which are supposed to reverse stabilization of HIV proteins in liver cells, thereby suppressing intrinsic apoptosis in hepatocytes [27]. Usually, the bioavailability of NAC in vivo is limited, but many other potent antioxidants can be used in a complex with ART therapy in alcohol abusing PLWH. One of the optional antioxidants shown efficiency in alcohol-induced liver injury is a pro-methylating agent, betaine [55].

The major strategy for prevention of liver fibrosis development in PLWH with alcohol use disorders (AUD) is to block the activation of HSC, the regulators of fibrosis progression. We found that Obeticholic Acid (OCA) reduces HIV markers expression in hepatocytes and thus, attenuates HIV-AGS-induced hepatocyte death, thereby, reversing pro-fibrotic activation in HSC (based on Col1A1 and TGFβ mRNA levels) [56]. The treatment with OCA also restores proteasome and lysosome functions by scavenging ROS and suppressing oxidative stress in hepatocytes [56]. Many other approaches to block HSC pro-fibrotic changes by nanoparticle delivery [57] are under investigation for PLWH with AUD.

In conclusion, ethanol metabolism significantly potentiates toxic events in HIV-exposed hepatocytes. It promotes liver inflammation/fibrosis progression due to hepatic parenchymal-non-parenchymal (macrophages, HSC) cell communications via HIV protein-containing EVs, ABs and exosomes. Schematically, it is illustrated by Fig. 63.2.

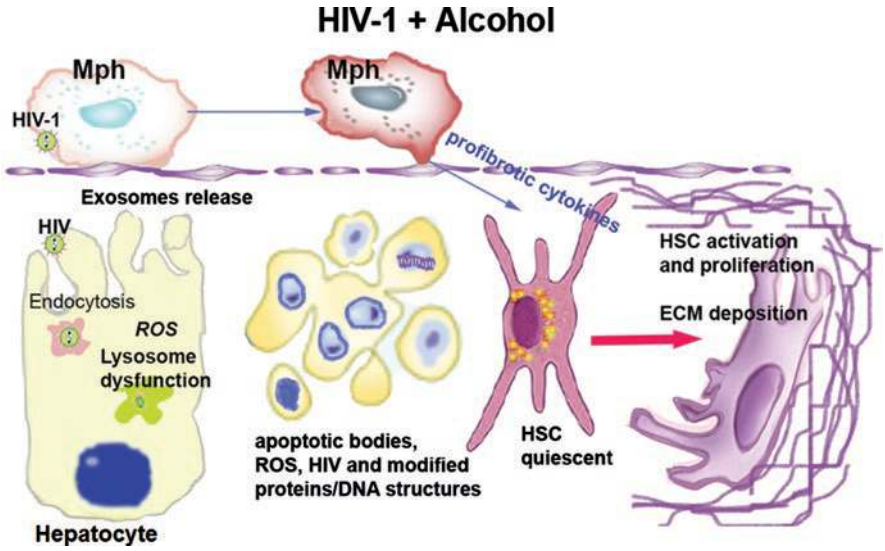

Fig. 63.2 Scheme of EV-mediated crosstalk between parenchymal and non-parenchymal liver cells in the settings of HIV and alcohol exposure

Part X
Severe Alcoholic Hepatitis

Chapter 64
Pathophysiology of Alcoholic Hepatitis: Emerging Role of Enhanced Red Blood Cell Turnover

Sebastian Mueller

Abstract This chapter introduces to the book section on alcoholic hepatitis (AH) and the emerging role of hemolytic anemia and enhanced red blood cell (RBC) turnover. AH is a rare but prognostically one of the most severe complications in heavy drinkers, with a 90 day mortality almost reaching 50%. Present diagnostic and therapeutic options are very limited and the molecular mechanisms are poorly understood. Only a minor fraction of patients benefits from steroids with regard to short-term but not long-term mortality. Based on novel prospective mortality data in heavy drinkers, ineffective erythropoiesis and macrocytosis anemia are identified as important, so far unrecognized confounder of liver damage and mortality. Preliminary data also indicate that these mechanisms contribute to AH. Of note, alcohol detoxification initially deteriorates blood parameters suggesting that additional, non-alcohol related factors also contribute to RBC changes. The novel insights link AH and liver damage to the blood and bone marrow compartment. It is hope that these first data will stimulate the search for novel targeted therapies. It will especially be interesting to further dissect the close interaction of RBC turnover and liver and the role of iron in various forms of hepatocyte cell death such as apoptosis, pyroptosis and ferroptosis.

Introduction to Severe Alcoholic Hepatitis and Current Challenges

Alcoholic hepatitis (AH) sometimes also described as severe alcoholic hepatitis (sAH) is considered one of the prognostically most severe complications in heavy drinkers, with a 90 day mortality almost reaching 50%. Figure 64.1 shows an overall scheme of the natural cause of ALD, its complications such as AH, cirrhosis, HCC but also highlights the role of non-ALD related-death in heavy drinkers. Despite continued discussions, AH originates in this figure solely from cirrhosis, according to the evidence provided below. As mentioned in part I of the book, ca 200 pathological entities are associated with alcohol consumption. Although it seems that the liver is the major target organ of alcohol, important other organ systems include the heart, bone marrow, immune system, red blood cells and brain. It should be appreciated more that these organ systems interact not only in the stage of liver cirrhosis, but much earlier.

Although AH is rather rare among drinkers (ca. 2%), the natural course is often tragic as patients are not really addicted to alcohol, and they typically have even stopped drinking for several days or weeks prior to admission to the hospital. However, they eventually face rather limited therapeutic options and, due to organ shortage and societal considerations, will not have access to liver transplantation in the following 6 months.

For these reasons, an especial scientific interest has been generated for the last five decades in order to better understand the underlying pathology and to develop targeted therapies. Unfortunately, with a good portion of honest self-reflection, we must admit that improvements have been very limited. Moreover, confusion and debates continue even among experts about definition, diagnostic measures and

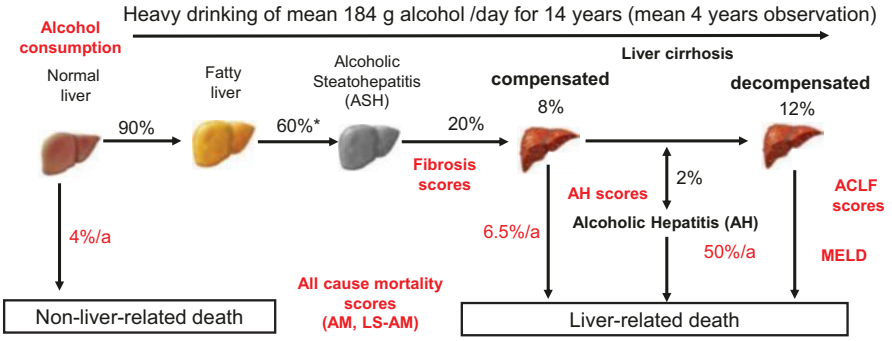

Fig. 64.1 Progression of liver diseases from the Heidelberg cohort of heavy drinkers (n = 1078). Score for several endpoints are given in red. Note that AH and decompensated liver cirrhosis show similar per annum mortality. Percentage numbers are related to 100% of initial drinking cohort. See also Tables B.1 and B.2 and Chap. 7 on mortality in Part I. Signs of inflammation* are seen in 78% in the liver biopsy cohort, and in 42–62% using biochemical markers in necrosis/inflammation/damage

therapeutic algorithms. Discussions also continue about the strict discrimination of AH from "conventional histological alcoholic steatohepatitis" which affects e.g. almost 80% in the Heidelberg cohort of heavy drinkers (see also Table B.9). In fact, in liver biopsy specimen, the pathologist cannot discriminate between simple alcohol-related liver disease, alcoholic hepatitis (AH), acute on chronic liver failure (ACLF) or non-alcohol-related liver disease (NAFLD).

In such a situation, it may be advisable to rather stop for a minute to ask what potential and fundamental confounders have been missed or overlooked? For this reason, this book contains one part just devoted to alcoholic hepatitis and closely related topics such as ACLF in order to cross-read and collect the state of the art to renew and inspire discussions for future directions. Topics of the following chapters include diagnosis, therapy, relation to ACLF and role of biopsy. This introductory chapter is, in addition to several comments in the general chapter on the pathophysiology of ALD, a brief discussion of potential missing links and introduces the novel and emerging role of the red blood cell (RBC) turnover in heavy drinkers with all its consequences.

What Are Major Unresolved Problems in Understanding AH?

1. Despite many randomized studies and metanalyses, only **steroids** remain an option for a small fraction of patients with AH, having only a very limited, short-term benefit. Thus, the last larger trial (STOPAH) only found a benefit for 28-day mortality for steroids (14% vs 17% mortality as compared to placebo) but no differences after 90 days or 1 year [1].
2. Despite numerous original articles and reviews on the role of intestinal translocation of bacteria, the role of pathogen-associated molecular patterns (PAMPs) and their role in liver inflammation, it remains difficult to comprehend **why then antibiotics are not effective in AH**. With a sobered view, it can only mean that bacteria are just playing a bystander role and increasingly contribute to systemic inflammation and organ failure in the final stages. This is also somehow reflected in the definition and terminology of ACLF that highlights the important role of these features in all endstage liver diseases (see also Chap. 67). There is no controversy that in these clinical stages, bacteria find ideal conditions for growth.
3. On the other side, it is a typical clinical finding, that both AH patients but also patients with decompensated liver cirrhosis with ongoing and proven viral or bacterial infections typically do not show pronounced clinical signs of infection such as fever or parameters of inflammation. While this can be explained by an "exhaustion" of the immune system, additional, potentially **more relevant mechanisms specific to alcohol and AH may have been overlooked**.
4. As mentioned above, the **striking similarity in liver histology between AH, ACLF, ALD and NAFLD** is unsatisfying and it is strongly asking for a novel rational to plausibly explain why all these clinically different entities result in the same histological picture.

5. Although normally not directly related to AH, there are many laboratory features of ALD patients that have been quietly and generally accepted. Consequently, they are not discussed anymore although still poorly understood. This includes the typical "liver parameters" such as levels of AST, ALT but also AP, GGT and even bilirubin. The latter is often seen as sign of a liver damage while it is less frequently appreciated that bilirubin is primarily derived from heme degradation. As is discussed in the Chap. 41 on AST, **AST seems to be mainly derived from RBCs** and not hepatocytes. It also remains unclear why a typical ALD-associated parameter such as GGT is only elevated in some patients and the role of AP is also poorly understood. Moreover, although known for many decades, the reason why heavy drinkers show an **elevated RBC size (MCV)** has been not really addressed so far.

Present Understanding of AH

Precent concepts to understand AH within ALD are nicely described in Chap. 67 by R. Jalan, but also some other chapters on ALD in part IX in this book. Accordingly, a systemic inflammatory state is regarded as important driver for AH [2, 3]. Proteases, oxidative molecules, cytotoxic cytokines, prostaglandins, and leukotrienes, among other mediators, are consequently released by activated immune cells, leading to further worsening of the tissue damage [4]. Two main components have been observed to drive this intense systemic inflammation in ACLF, PAMPs and damage-associated molecular patterns (DAMPs) [3] (see also Chaps. 61 and 62). PAMPs represent molecular structures that are expressed by different pathogens and microbial agents. In contrast, DAMPs are circulating intracellular molecules following death or damage of the host cells, albeit without infection as a triggering agent. PAMPs and DAMPs bind to specific Pattern Recognition Receptors (PRRs) such as Toll like Receptors (TLR) located on peripheral innate immune cells [5]. Receptor binding activates down-stream signaling pathways that ultimately lead to the increased transcription and release of inflammatory cytokines with induction of severe systemic inflammation [6].

Emerging Role of RBC Turnover in ALD

One plausible explanation for the many frustrating attempts to shed more light into the pathophysiology of AH is very likely due to the endstage situation. There is good agreement among experts that AH requires several years to develop during heavy drinking. The sometimes emotionally discussed questions whether AH only develops in cirrhotics may distract from the fact that AH requires at least a fibrosis stage higher than F2. In fact, in our Heidelberg cohort of heavy drinkers, we have never seen any AH in patients with normal liver stiffness.

One major recent inspiration has come from the analysis of the **first 15-year lasting prospective mortality study in heavy drinkers** (see Chap. 7). Importantly, the study design tried to be as unbiased as possible recruiting patients that presented to the hospital for alcohol detoxification and not patients with organ-specific clinical symptoms such as jaundice.

Besides routine laboratory parameters and abdominal ultrasound, liver stiffness was measured initially in all patients. The study newly **identifies hemolytic anemia as important driver of all-cause mortality** while also ruling out typically associated confounders such as deficiency of vitamin B12 and folic acid. As is discussed in more detail in the Chaps. 57 and 58 on iron and bone marrow changes in drinkers, alcohol causes an environment of enhanced RBC degradation but also, in a compensatory manner, enhanced erythropoiesis. While this is compensated for many years it eventually leads to anemia in a significant portion of heavy drinkers and at least in half of them to 20% reduction of the hemoglobin mass. The degradation is sometimes not directly obvious as LDH, haptoglobin or indirect bilirubin are still in the normal range.

Is Heme Degradation Causing Transformation to an Erythrophagocytosis Macrophage M2?

However, when specifically studying markers of heme-turnover or erythrophagocytosis such as CD163, RBC turnover starts from the very beginning of drinking in more than 50% of drinkers (see also Chap. 37). On the other side, once cirrhosis has been established, hemolysis increases further. It will eventually lead to so-called ineffective erythropoiesis that further aggravates hemolysis through release of bilirubin and/or bile acid accumulation. It should also be noted that the mechanisms of RBC turnover are quite diverse ranging from simple RBC erythrophagocytosis triggered by membrane oxidation/apoptotic changes up to complete hemolysis with release of hemoglobin or even free heme, a known and important DAMP [7]. Figure 64.2 provides an overview of some of the **important RBC recycling pathways**. It should be also mentioned that RBC degradation can activate TLR4 through toxic heme but is normally and rather safely recycled by direct receptor mediated erythrophagocytosis (CD163 and CD91). This process is still not completely understood nor the fact that also hepatocytes are able to uptake intact RBCs, a process termed **efferocytosis**. Some more details are discussed and presented in Chap. 57 on iron and ALD. Even in the case of uncontrolled RBC lysis (hemolysis), liver-produced scavenging proteins such as haptoglobin or hemopexin are rapidly secreted to bind either hemoglobin or heme and to internalize and further degrade them through the receptors CD163 and CD91.

As is further discussed in Chap. 58 on bone marrow and alcohol, RBC turnover is not only caused by degradation. Alcohol seems to directly effect erythropoiesis in the bone marrow causing most likely imperfect production of fragile RBCs. Thus,

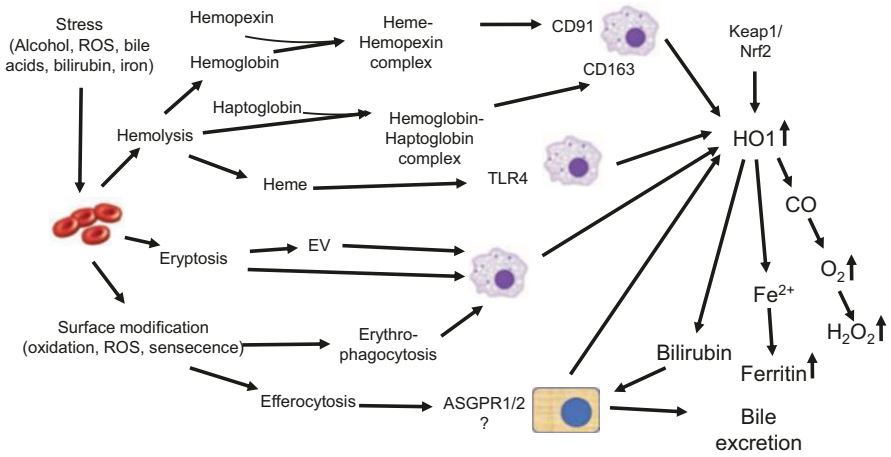

Fig. 64.2 Pathways of red blood cell turnover triggered by alcohol or related conditions. *EV* extracellular vesicle

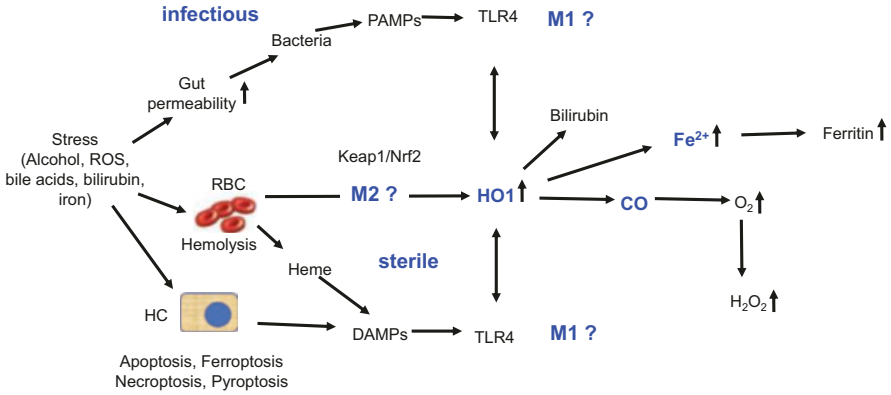

Fig. 64.3 Difference between alcohol-triggered RBC-turnover and TLR4 activation by DAMPs, PAMPs and bacteria. About 40 mL whole blood are daily recycled by macrophages and the liver, far exceeding the load of bacteria. Moreover, this physiological process has unique properties including the release of iron and carbon monoxide (CO). It remains to be studied whether heme turnover allows a better discrimination between the long established M1 and M2 macrophage state

elevated MCV is a result of ineffective erythropoiesis and hemolysis. More studies are needed to explore the molecular effects of alcohol on the hematopoietic stem cell niche. Importantly, abstaining from alcohol normalizes RBC count and MCV, but normalization requires longer than e.g. the normalization of liver parameters (see also Chap. 57 on iron and ALD).

Finally, Fig. 64.3 shows the difference between alcohol-triggered RBC-turnover and TLR4 activation by DAMPs, PAMPs and bacteria. About 40 mL whole blood are daily recycled by macrophages and the liver, far exceeding the load of bacteria. Moreover, this physiological process has unique properties including the release of iron and carbon monoxide (CO) which has important effects on macrophage and hepatocytes metabolism. As is highlighted in Fig. A.76, carbon monoxide is an efficient heme binding molecule that may interact with important heme enzymes such as CYP p450 system, catalase, mitochondrial cytochromes of the respiratory chain. This all should result in an increase of cellular oxygen levels that can now serve other enzymes such as oxidases (NOX1, NOX4, DUOX) allowing for fascinating but complex molecular interactions at the cellular, sub-cellular and interorgan level. In the case of peroxisomal catalase, carbon monoxide should directly lead to peroxide elevation. It remains to be studied whether heme turnover allows a better discrimination between the long established M1 and M2 macrophage state. More specific and mechanistic studies are urgently needed.

Interaction of Heme Degradation, Release of Iron and Hypoxia Signaling

The release of iron is also noteworthy since it will interfere with the hypoxia signaling pathways including HIF1 alpha. HIF1 is targeted for degradation by prolyl hydroxylases (namely PHD2) that contain soluble iron in their reactive center. Iron elevation will increase PDH2 activity (see also Figs. A.70, A.71, A.72), downregulate HIF1 and eventually stop many energy and metabolic pathways. It is often overlooked that the HIF1-PHD2 loop always results in HIF1 degradation and rather loop disrupting signals are important to control HIF1 than oxygen itself [8] (see also Fig. A.72). Alpha-Ketoglutarate is another important substrate of PHD2 linking it to the Krebs cycle and, hence, to alcohol metabolism or transaminase reactions (see Figs. A.43, A.44, A.48, A.70, A.71, A.72).

In conclusion, based on recent prospective mortality data, enhanced RBC turnover is a so far underrecognized important feature in heavy drinkers that drives liver damage and mortality. Consideration of RBCs and hemolysis is able to explain several key features in patients with ALD, including elevated AST levels (see chapter on AST), typical iron changes in patients with ALD, and, finally, development of macrocytic anemia with elevated MCV. More studies are required to better understand the interplay between RBC recycling and liver damage. Preliminary data suggest that hepatocyte damage is closely related to enhanced heme turnover, and hepatocyte death resembles a recently introduced type of death called ferroptosis [9–12].

Preliminary Evidence for Enhanced RBC Turnover and its Association with AH

First preliminary data indicate that AH is indeed associated with enhanced RBC turnover. In this first approach, we analyzed all 25 cases (1.9%) with proven AH (see Tables B.21, B.22) from our Heidelberg cohort of heavy drinkers (n = 1063) and performed Spearman Rho correlation of AH status. Data are shown in Table 64.1. Here, clearly, markers of hemolysis or enhanced RBC turnover such as CD163 are significantly associated with AH but also deficiency in folic acid and lipidomics parameters and genotypes. We next also compared these 25 AH cases with a cohort of 30 cases with alcoholic cirrhosis matched for histological fibrosis. Only 7/25 (28%) of AH cases had a liver biopsy, 2 with F3 fibrosis and 5 with F4 cirrhosis. All patients in the cirrhosis group had histologically proven liver cirrhosis F4. Consequently, fibrosis score was slightly higher in the cirrhosis cohort (see Table 64.2). According to Table 64.2 which shows parameters that are different between these two cohorts, leukocyte count but also signs of hemolysis were higher. In addition, liver stiffness was also significantly higher but both parameters were in the cirrhotic range (69 v 52 kPa). These first data suggest to us that development of AH is associated with enhanced RBC turnover as described above. As is discussed in more detail in Chap. 57 on iron and ALD, **MCV and anemia deteriorate after alcohol detoxification**. This means that the sudden stop of alcohol consumption interferes with the complex blood-bone marrow-liver axis in a way that, at least transiently, ineffective erythropoiesis worsens. These insights provide a first idea to better target the problem in patients in AH since they usually voluntarily abstained from alcohol prior to hospital admission and this may aggravate, at least in some patients, complications. It further means that not alcohol alone, but additional confounders are responsible. One potential explanation could be that the sudden removal of the toxic blockage of ethanol on physiological processes such as apoptosis [13] or cell regeneration or division (see also Chap. 49 on the pathophysiology of ALD) could both **unchain regeneration in the bone marrow and liver**, potentially in an iron overloaded toxic environment, that causes production of fragile RBC and, unintentionally, aggravates ineffective erythropoiesis (see also Chap. 58).

Table 64.2 Comparison between AH and alcoholic cirrhosis matched for histological fibrosis

25 patients with AH were histologically matched with 30 patients with alcoholic liver cirrhosis. Only 7/25 (28%) had a liver biopsy, 2 with F3 fibrosis and 5 with F4 cirrhosis. All patients in the cirrhosis group had histologically proven liver cirrhosis F4. Note that AH score was higher in the AH group, Leukocyte count and signs of hemolysis.

Table 64.3 Correlation of ferroptosis marker ACSL4 (Long-chain-fatty-acid—CoA ligase 4) with various clinical and laboratory markers from a heavy drinking cohort

Parameter	Category	ACSL4/β-actin		
		r	p	N

Alcohol consumption (g/day)	Alcohol	−0.442	5.8E-02	19
Maddrey	Score	0.433	6.4E-02	19
Ballooning (0–2)	Histology	0.428	5.3E-02	21

ACSL4 mRNA was assessed in liver biopsies from heavy drinkers using Western blotting and subsequent densitometry. Parameters were first sorted according to P value and then, in descending order, according to the absolute correlation coefficient (Spearman Rho correlation). Numbers of samples are indicated in the far-right column. ACSL4 converts free long-chain fatty acids into fatty acyl-CoA esters, preferentially arachidonate. Note that this ferroptosis markers is highly correlated with markers of hemolysis or iron (CD163, liver iron, haptoglobin, ERFE), liver damage (Mallory hyaline, lobular inflammation) and directly with the Maddrey score. Maximum 21 samples were available for analysis. P is given in bold if smaller than 0.05

In this context, it is highly interesting that ACSL4, which is Long-chain-fatty-acid-CoA ligase 4 and involved in **ferroptosis**, is also highly associated with hemolysis in the Heidelberg cohort of heavy drinkers (preliminary data in Table 64.3 and Table B.39). ACSL4 converts free long-chain fatty acids into fatty acyl-CoA esters, and thereby plays a key role in lipid biosynthesis and fatty acid degradation. This isozyme preferentially utilizes arachidonate as substrate. Lipidomics data combined with ACSL4 data on ferroptosis are still very limited but suggest a positive association with AH. More data are needed on this topic.

Future Directions

Enhanced RBC turnover could be one of the long thought important and less well appreciated pathomechanisms involved in ALD and AH. Since the amount of protein turnover by macrophages during physiological erythrophagocytosis is by far much higher as compared to PAMP- and DAMP-mediated macrophage uptake, heme degradation in the release of iron and carbon monoxide must play an important role. The accumulating iron in liver of ALD patients is most likely derived from RBC recycling. It remains to be studied how hepatocytes actually get access to this

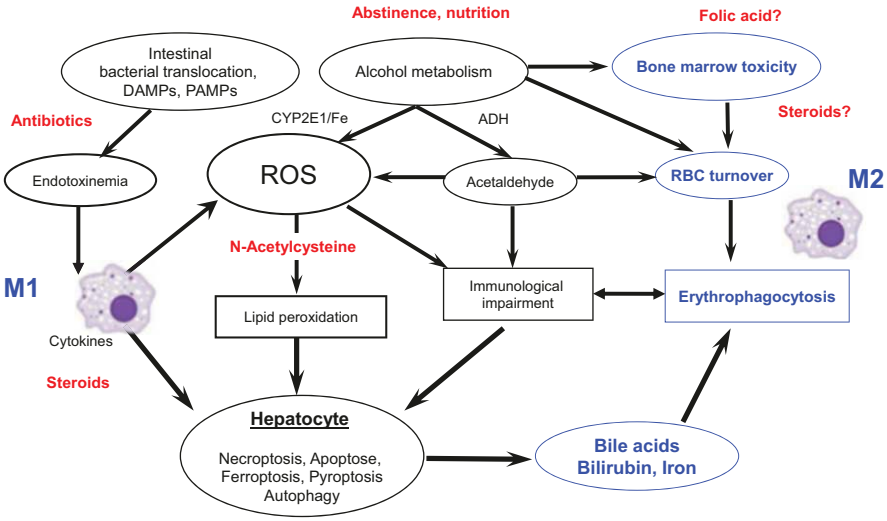

Fig. 64.4 Emerging role of enhanced RBC turnover and hemolysis and the conventional concept of AH pathophysiology. Established pathomechanisms are given in black with corresponding therapeutic measures in red. RBC turnover is highlighted in blue. There are indications that the inflammatory macrophage (M1) results from the signaling events on the right while heme turnover may generate M2-like macrophages with an important role of HO1

iron. Obviously, it is not only transferred through transferrin since hepatocytes can directly uptake erythrocytes and transferrin is typically downregulated in these patients. However, it remains completely unknown how they get access to RBCs and which chemokines and chemotactic factors are involved. As has been already discussed in the pathophysiology Chap. 49 of ALD, direct efferocytosis of RBCs by hepatocytes could also explain the release of bilirubin in these cells. It also needs to be studied why hemolysis is highly associated with hepatocyte synthesis of bile acids (see Table B.24) and how the lipids from the RBC membrane (phospholipids, triglycerides and cholesterol) are processed by hepatocytes and whether this contributes to steatosis or even the ballooning and foamy degeneration, described in more detail in Chap. 38 on histology by C. Lackner. In this context, it is also quite exciting to see, that heme degradation by HO1 occurs in the ER where also P450 CYPs are located, heme enzymes, that should be blocked by HO1-mediated release of carbon monoxide. Consequently, heme degradation could block ethanol oxidation by CYPs and interfere with the metabolism of lipids and steroids performed by CYPs. Hence, a new molecular link between steroid metabolism and the therapeutic action of steroids in AH could exist (Fig. 64.4).

Chapter 65
Diagnosis and Staging of Disease-Severity in Symptomatic Alcoholic Hepatitis

Christophe Moreno and Delphine Degré

Abstract Alcoholic hepatitis should be suspected in patients with a recent onset of jaundice and with excessive chronic alcohol consumption. Diagnosis is based on clinical presentation and typical laboratory findings (AST/ALT ratio > 1.5, AST > 50 UI/L, AST and ALT <400 IU/L, total serum bilirubin >5 mg/dL). A liver biopsy is useful to confirm the diagnosis and exclude other diagnosis, but is not routinely performed in clinical practice in many centers. Different prognosis tools aiming to estimate the risk of short-time mortality and to determine whether the patients should be treated with a specific therapy, have been developed. The most used in clinical practice are the Maddrey discriminant function and the model for end-stage liver disease.

Keywords Alcoholic hepatitis · Jaundice · Liver biopsy · Prognosis · Maddrey discriminant function · MELD score

Introduction

Excessive alcohol consumption is one of the leading causes of liver disease worldwide (see also part I of this book). According to the World Health Organization's (WHO) 2014 report, harmful alcohol use causes approximately 3.3 million deaths per year, corresponding to among 6% of all death [1]. Alcohol-related liver disease (ALD) presents a broad spectrum of disorders including steatosis, alcoholic hepatitis (AH), cirrhosis and development of hepatocellular carcinoma. AH is one of the most severe manifestation of ALD associated in severe forms with high morbidity and mortality [2]. The incidence of AH has been difficult to estimate and varies

worldwide. In United States, admissions for AH were found to have increased to 0.83% of all admissions in 2010 [3]. In Denmark, the incidence of AH for the period 1999–2008 rose from 37 to 46 per million persons per year in men and 24 to 34 per million persons per year in women [4]. However, estimating the burden of AH is difficult since the incidence assessment is based on diagnostic coding [5].

Definition of Symptomatic Alcoholic Hepatitis

AH is a clinical syndrome characterized by recent onset of jaundice in patients with excessive chronic alcohol consumption. Some patients have ceased drinking alcohol but a period of less than 60 days of abstinence before the onset of jaundice is generally observed [6]. Jaundice is often associated with other symptoms such as fever, malaise, malnutrition or other signs of liver decompensation (i.e. ascites, encephalopathy or bleeding).

Diagnosis of Symptomatic Alcoholic Hepatitis

Diagnosis of AH is based on clinical presentation and typical laboratory findings, and imaging should exclude biliary obstruction. Blood analysis of AH patients typically shows hyperbilirubinemia (> 5 mg/dL), AST > 50 IU/L with an AST/ALT ratio typically greater than 1.5. The AST and ALT levels usually do not exceed 400 U/L distinguishing AH from other diseases such as ischemic hepatitis or drug induced liver injury. In severe forms, a prolonged prothrombin time, hypoalbuminemia and decreased platelet count are frequently observed [2]. When AH is suspected based on clinical and laboratory analysis, a liver biopsy can be useful to confirm the diagnosis. Typical histological findings are described in more detail in chap. xxx of this book. They show steatohepatitis including steatosis, hepatocyte ballooning, an inflammatory infiltrate with neutrophils, bilirubinostasis and fibrosis with a typical chicken-wire pattern [7]. However, liver biopsy is not routinely performed in many centers. The main restrictions to perform liver biopsy in routine clinical practice are routine access to transjugular liver biopsy (indicated in the presence of ascites, coagulation disorders and low platelet count), potential risks, the cost of the procedure and the absence of well-validated grading systems. Recently, National Institute on Alcohol Abuse and Alcoholism (NIAAA) Alcoholic Hepatitis Consortia recommendations have defined AH patients for inclusion in clinical studies as follows: definite AH defined as clinically diagnosed and biopsy proven, probable AH defined as clinically diagnosed but not biopsy-proven; and possible AH as clinically diagnosed but not biopsy-proven with potential confounding factors [6]. Confounding factors include possible ischemic hepatitis (e.g., severe upper gastrointestinal bleeding, hypotension, or cocaine use within 7 days), possible drug-induced liver injury, uncertain alcohol use assessment, atypical laboratory tests

(e.g., AST < 50 IU/L or >400 IU/L, AST/ALT ratio < 1.5), and blood markers of auto-immunity. Based on these definition, which still need to be validated, a liver biopsy is mandatory in possible AH but not absolutely mandatory in cases of probable AH. In clinical practice, we routinely performed a transjugular liver biopsy in suspected severe AH, because of long term experience, easy access to the procedure, and absence of significant complications. However, in centers without easy access or without experience in this procedure, applying the NIAAA criteria is an acceptable alternative and should probably be applied in many centers. The challenge in clinical practice is to identify cases without the typical clinical or laboratory features of AH and the potential confounders, in order to avoid to expose patients without AH to corticosteroids or other specific therapies.

Noninvasive tests for AH diagnosis are sorely needed. Cytokeratins have emerged as serum biomarkers of hepatocyte damage. Circulating fragments of cytokeratin-18 (CK-18), and the main constituent of Mallory-Denk bodies, termed M65 and M30 are of particular interest in AH. A recent study reported higher levels of total and microvesicle-bound M65 and M30 in the circulation of patients with biopsy-proven AH [8]. Although promising, these biomarkers need further investigation before recommending their routine use.

Assessment of Symptomatic AH Severity

Several laboratory-based prognostic models are available for assessing severity and prognosis of AH (see Table 65.1). The aims of these scores are first to estimate the probability of short-term mortality and second to determine whether a specific therapy is indicated (i.e. corticosteroids). The Maddrey discriminant function (mDF) which uses bilirubin and prothrombin time, is frequently used for predicting the

Table 65.1 Variables included in the different prognostic scores for assessing severity in alcoholic hepatitis

Scores	Bilirubin	PT/ INR	Creatinine	Age	Albumin	Urea	WCC	ΔBilirubin	Cut-off
mDF	+	+							Severe >32
MELD	+	+	+						Severe ≥21
GAHS	+	+		+		+	+		Severe ≥9
ABIC	+	+	+	+					Low risk ≤6.71 Severe >9
Lille score	+	+	+	+	+			+	<0.45 >0.56

The Lille score with change of bilirubin after 1 week identifies those who benefit from continued steroid treatment

ABIC age-bilirubin-international normalized ratio-creatinine, *GAHS* glasgow alcoholic hepatitis score, *INR* international normalized ratio, *mDF* maddrey discriminant function, *MELD* model for end-stage liver disease, *PT* prothrombin time, *WCC* white cell count.

severity of AH and for assessing the need for corticosteroid (CS) therapy [9, 10]. The limitations of this score include its use of prothrombin time expressed in seconds, which is not standardized between clinical laboratories and the absence of renal function assessment, as acute kidney injury is a strong predictor of mortality in AH [11]. A cut-off value above 32 identified patients with severe AH in whom CS are usually initiated. In the absence of treatment, 1-month mortality of patients with severe AH was 50% in early studies but decreased to approximately 20% in more recent studies [12]. Patients with non-severe AH defined as mDF < 32 have less than 10% risk of 1-month mortality. However, recent reports have shown rather low 1- and 5-year survival rates of 80% and 50%, respectively, for patients with symptomatic non-severe AH who were admitted with liver decompensation [13]. The term "non-severe alcoholic hepatitis" seems therefore inappropriate for patients with symptomatic AH and mDF < 32. This study also showed that non-commitment to a strict alcohol abstinence is associated with a worse outcome in this AH population.

The model for end-stage liver disease (MELD) score, which includes bilirubin, international normalized ratio (INR) and creatinine levels, is also useful for predicting 30- and 90-day mortality in patients with AH. Patients with a MELD score ≥ 21 have a 90-day mortality of 20% [14], and is generally accepted as a cut-off for indicating CS.

The Glasgow alcoholic hepatitis score (GAHS) and the Age, serum Bilirubin, INR, and serum Creatinine (ABIC) score are other scores used to predict short-term mortality in patients with AH [15–17]. The variables included in the scoring systems for AH and the cut-offs used to determine the severity of the disease are shown in Table 65.1. Although the mDF remains the most commonly used score in clinical studies and in many centres, the MELD, GAHS and ABIC scores appear to have a slightly better efficacy for predicting short-term mortality in patients with severe AH and are used according to the local practice of each centre [18].

More recently, baseline neutrophil-to-lymphocyte ratio (NLR) has been suggested as a parameter that may help to stratified risk and likelihood of CS response in patients with AH. Patients with low (<5) and high (>8) NLR values do not appear to benefit from CS treatment. In the modified GAHS (mGAHS) NLR has been incorporated in place of the white cell count to improve the discriminatory power of the score [19]. However, validation studies are needed before NLR can be recommended for routine clinical practice.

Some histological features are also associated with severity and mortality in AH. Specifically, degree of fibrosis, neutrophil infiltration, type of bilirubinostasis and the presence of megamitochondria have been found to be independently associated with 90-day mortality and are included in the Alcoholic hepatitis Score (AHHS). This score identifies patients with low (0–3 points), moderate (4–5 points) and high (6–9 points) risk of death within 90 days (3%, 19%, and 51%, respectively) [20]. Limitation of this score is the requirement of liver biopsy and significant interobserver variability among pathologists [21].

The gene-signature plus MELD (gs-MELD) combines the baseline liver expression patterns of 123 genes with the MELD score to discriminate patients with poor

and good 90-day survival. Patients with a gs-MELD score greater than 2.66 were considered to have a poor prognosis [22]. However, the need for liver biopsy limits its clinical application. Recently, a plasma protein-based surrogate of the gene signature was developed and combined with the MELD score. The high-risk plasma-signature (ps)-MELD score was associated significantly with death or liver transplantation within 90 days [23].

The presence of acute kidney injury, infection or systemic inflammatory response syndrome (SIRS) are associated with mortality in patients with severe AH [11, 24, 25]. Acute-on-chronic liver failure (ACLF) defined as an acute deterioration of liver function combined with single or multiple organ failure is frequent during the course of severe AH and is associated with high mortality. In clinical practice, it is important to understand that ACLF is not a specific disease but rather a clinical syndrome caused by different precipitating factors (alcoholic hepatitis and infection are the most frequent causes of ACLF in Western countries). In the setting of AH, the main interest of ACLF is its prognostic value. Indeed, the ACLF scoring system, was recently studied as a strong predictor of short-term mortality in AH patients. The 28-day cumulative incidence of death in patients with and without ACLF were 54% and 10.4%, respectively (30.8%, 58.3% and 72.4% for ACLF-1, ACLF-2 and ACLF-3 respectively) [26].

Prognostic factors of long-term outcome in AH patients have been less well studied. Abstinence seems to be the most important predictive factor for long-term survival in patients with AH [13, 27, 28]. Improvement in long-term survival after AH should thus include secondary prevention strategies to promote complete alcohol abstinence.

New biomarkers, such as serum transferrin or circulating hepatocyte-derived.

extracellular vesicles seem to be promising biomarkers for prediction of mortality in AH patients but validation studies are needed before recommending their routine use [29, 30].

In conclusion, alcoholic hepatitis should be suspected in every patient with recent onset of jaundice and excessive alcohol consumption. Diagnosis is based on clinical presentation, typical laboratory findings, exclusion of biliary obstruction and can be confirmed by liver biopsy. Maddrey Discriminant function and MELD score are the most frequently used scores in clinical practice and in clinical trials. A mDF > 32 and/or MELD ≥21 identifie patients at high risk of death in the short term and are used to indicate specific therapy.

Chapter 66
Management of Severe Forms of Alcoholic Hepatitis

Alexandre Louvet

Abstract Severe alcoholic hepatitis (AH) is one of the most fatal liver complications of chronic alcohol use and occurs predominantly on a background of alcohol-related cirrhosis. Severity is defined by Maddrey's and/or MELD scores. Medical treatment is based on a 28-day course of prednisolone at 40 mg/day and therapeutic response is evaluated at day 7 using the Lille score, which integrates baseline biological features and evolution in bilirubin after 7 days of steroids. Infection is a frequent event which requires a systematic screening at admission in all patients (urine and blood culture, ascitic fluid examination, chest X-ray). In case of response to treatment (Lille<0.45), prednisolone is continued for a total of 28 days. Conversely, non-responders take no benefit of steroids and treatment is stopped at day 7. Survival of non-responders is poor at 6 months (approx. 30–40%) and no medical option has been proven efficient in improving outcome. Liver transplantation can be offered to a minority of patients, experiencing their first liver decompensation, and carefully selected in a multidisciplinary approach. Several new molecules are being tested either alone or in combination with steroids and progress in the management of these patients is expected soon.

Introduction

Alcoholic hepatitis (AH) is one of the most severe manifestations of alcohol-related liver disease (ALD) (see also book Chaps. 64 and 65). It is typically a clinical diagnosis in patients with sudden onset of jaundice, previous periods of heavy drinking. Often, patients present to the hospital with sustained jaundice despite several days

https://doi.org/10.1007/978-3-031-32483-3_66

or weeks of abstinence [1–3]. Histology shows typical signs of ALD (described in detail in book Chap. 38). Elementary features comprise cell damage with changes in hepatocyte (ballooning), cytoplasm eosinophilic condensations (Mallory-Denk bodies) and inflammatory infiltrate mostly with neutrophils [3]. The clinical severe form of AH should be discriminated between the more often observed histological steatohepatitis. Terminology is still somewhat confusing, and the international debate continues to better describe the various clinical and histological entities.

It is also important to underline that these histological features are not specific for an alcohol etiology, especially because ballooning and Mallory-Denk bodies can also be found in patients with metabolic fatty liver (see also chapter on histology 38). Conversely, infiltrates with neutrophils are less frequently observed in patients with metabolic syndrome without excessive alcohol consumption. Of note, the precise definition of AH on liver biopsy needs international consensus because the number of elementary lesions required for a definite diagnosis has not been fully validated by a panel of experts. More specifically, there is no consensus as to whether the three histological lesions mentioned above must be present or whether two are sufficient. Given that such histological lesions occur in patients with excessive drinking for several years, it is not surprising that, besides inflammation, other alcohol-related liver abnormalities are also present, such as steatosis (triglyceride accumulation in the cytoplasm secondary to heavy and recent alcohol consumption) and/or a certain degree of fibrosis, which is often closely associated with the duration of heavy alcohol consumption.

Besides the clinical features, AH diagnosis is confirmed on liver biopsy, which implies that such alcohol-related inflammation can cover several clinical entities. While some patients have no symptoms except those related to excessive alcohol consumption, the severe form of AH is often accompanied by clinical signs of liver decompensation (jaundice, ascites and/or encephalopathy). The definition of disease severity (i.e. severe alcoholic hepatitis) is based on biological scores (see below). When liver biopsy is performed (mostly using the transjugular route given that coagulation disorders and ascites are often present in severe alcoholic hepatitis), cirrhosis is common: more than 90% of patients with severe AH included in randomized controlled trial with liver biopsy required have histological cirrhosis [4].

In patients with a background of alcohol-related cirrhosis, AH can be difficult to discriminate from other causes of decompensation. Over the last years, a new entity **termed acute-on-chronic liver failure** (ACLF) has been described. This wording encompasses a spectrum of different clinical diseases and is defined by the number of organ failures [5]. ACLF is not a specific disease but rather a clinical syndrome caused by different precipitating factors (infection, AH, drug-induced liver injury, viral hepatitis, etc.). given that most patients with ACLF present with jaundice, it can be difficult to differentiate AH from other causes of liver decompensation. Liver biopsy is certainly useful in this setting. However, if biopsy is not available, a careful analysis of clinical and biological profile of patients can help. Typically, patients with AH have a moderate elevation of transaminases, a recent onset of jaundice, no fever, etc. (see Chap. 65). The fact that jaundice precedes all other signs of ACLF

(renal fever, sepsis, etc.) argues for AH as the precipitating event, the other entities being more consequences of AH than causes of liver dysfunction.

Clinically, severe AH is suspected in case of a recent onset of jaundice in a heavy drinking patient [1–3]. Given that several factors apart from AH can cause jaundice in patients with excessive alcohol drinking, liver biopsy is considered the gold standard for disease confirmation [1–3]. Differential diagnoses include hemolysis, infection, drug-induced liver injury, acute viral hepatitis (especially caused by hepatitis E virus), red cell transfusion (which can cause jaundice, especially in patients with cirrhosis), etc. However, liver biopsy may be difficult to make, mostly in non-tertiary centers and in some countries in which access to this technique is uneasy. Routine biochemistry shows moderately elevated transaminases, elevated GGT (closely related to time from last drinking), altered coagulation parameters and high bilirubin, predominantly conjugated [3, 6]. In addition, a certain degree of acute kidney injury is often seen. As mentioned below and in the chapter dedicated to diagnosis and prognosis (see book Chap. 65), several biological scores can be used to define severe AH and most of them use liver function as key elements for calculation. If liver biopsy is not available, a careful analysis of events by a trained practitioner can help to rule out other diagnoses (see above). In cases of clinical uncertainty, liver biopsy is very useful.

Medical Treatment of AH: Steroids and the Lille Model

Several pharmacological options have been tested to treat severe AH, although most of them have failed in showing a clinical benefit. Nowadays, there is a consensus to restrict pharmacological treatment to patients with severe AH, mostly defined by a Maddrey's discriminant function equal or greater to 32. Both the European Association for the Study of the Liver (EASL) and the American association for the Study of Liver Diseases (AASLD) support this recommendation in their guidelines [1, 2]. The reason for not treating patients with a less severe disease (i.e. those with a Maddrey's discriminant function lower than 32 is the lack of an effective and specific treatment perspective. Conversely, in patients with Maddrey's discriminant function greater than 32, a 28-day of prednisolone improves short-term survival which has been supported by several randomized controlled trials and meta-analyses [7–11]. Thus, corticosteroid treatment significantly decreased risk of death within 28 days compared with controls (hazard ratio [HR] 0.64 [7]. Prednisolone is mostly given orally at a dose of 40 mg daily for 4 weeks, regardless of patient weight or body mass index. Other treatments have failed in improving survival at 1 month, for example pentoxifylline [4, 7, 11] or antioxidants drugs [7, 12, 13].

Although prednisolone remains the only medical therapy option to treat severe AH, it is not an ideal drug. Indeed, some patients will do not improve their liver function upon treatment and their risk of death is very high, related to persistent liver decompensation and injury. An early identification of these patients unlikely to take benefit from corticosteroids is a major challenge to clinicians in order to stop

treatment and consider other therapeutic options. Since patients with severe AH have hepatic decompensation, persistent liver impairment is strongly associated with outcome and most patients at risk of dying will succumb from a lack of improvement in liver function [14–17]. Thus, not surprisingly, response to treatment is mostly defined by a decrease in bilirubin after some days of challenge with prednisolone. This early change in bilirubin level (ECBL) is defined by the presence of absence of a decrease of total bilirubin within the first 7 days of prednisolone therapy [17]. The absence of a bilirubin decrease (i.e. absence of ECBL) is strongly associated with death and the risk of dying within 6 months following treatment initiation is higher than 60%. Although this criterion is simple and easy to apply in clinical practice, it lacks sensitivity since some patients, despite an ECBL, will not show a bilirubin decrease upon treatment sufficiently strong enough to minimize the risk of liver events and of death. Based on mortality and treatment response data, consequently, the Lille model has been developed which integrates several prognostic markers including the magnitude of change (either decrease or increase) in bilirubin after a challenge of 7 days by prednisolone [16]. Other prognostic parameters of the Lille score include age, presence of a renal insufficiency, albumin, total bilirubin and prothrombin time at baseline (i.e. at the beginning of prednisolone). Once combined, the final Lille model ranges from 0 to 1, the lower score being associated with the best prognosis. The 0.45 cut-off classifies patients into responders (Lille <0.45) who have an acceptable survival rate at 6 months (>80%) and non-responders (Lille ≥0.45) who have a very high risk of mortality at 6 months (>60–70%). In non-responders, most deaths are related to liver dysfunction and occur generally within the first 2 months [16]. Outcome can also be predicted by the combination of the Lille model at day 7 with the MELD score at baseline [18]. This approach can help to calculate survival at 2 and 6 months and adapt therapeutic management. Such prediction of survival is especially useful when liver transplantation is considered (see below).

In order to refine prediction of survival, a definition of treatment into three groups can be proposed according to two other cut-offs (0.16 and 0.56). Patients with a Lille score at 7 days <0.16 are called complete responders and their risk of dying is minimal while partial responders (0.16 < Lille<0.56) have an intermediate survival [9]. The subgroup of patients with a null response (Lille ≥ 0.56) have a poor prognosis at short term, and prednisolone should be stopped after 7 days in them. Indeed, patients who have been randomized in clinical trials testing steroids vs. placebo have not shown any survival benefit in patients with Lille ≥0.56 treated with prednisolone as compared to controls who did not receive steroids [9]. Both EASL and AASLD recommend stopping prednisolone after 7 days if the Lille score is equal or greater to 0.56 [1, 2]. It has also been suggested that the Lille score can be calculated after 4 days of prednisolone by using the same cut-offs [19] but this has not been largely confirmed by independent studies. While prednisolone has to be stopped in non-responders, patients who have a therapeutic response, either complete or partial, continue treatment for a total of 1 month and can be discharged. After 1 month of treatment, steroids can be stopped without tapering [1, 2]. While prednisolone

improves survival rate at 1 month as compared to placebo, the survival benefit disappears at 3 and 6 months and trials and meta-analyses do not show a survival benefit over placebo at these time points [7]. Thus, evaluation of new therapeutic options is required.

Non-steroid Medical Treatment of AH

Given that corticosteroids are associated with a significant number of treatment failures, some strategies have tried to combine other drugs to prednisolone. Unfortunately, no combined therapy has been able to increase short-term survival. It must be borne in mind that patients treated with placebo have nowadays a better survival as compared to studies performed in the 70s and 80s. This is related at least in part to a better management of sepsis and of renal failure. Pentoxifylline was thought to decrease the incidence of hepatorenal syndrome [20] but this did not result in a better survival when combined to prednisolone [4]. Intensive enteral nutrition and antioxidants yielded similar disappointing results [21]. N-acetylcysteine was tested for 5 days in an intravenous protocol similar to that used for acetaminophen poisoning, but this did not reach statistical significance, although a trend toward a better survival was observed in the study for patients treated with the combined therapy with prednisolone [13]. Several other medical options have been tested recently. A corticosteroid-free combination of an IL-1β inhibitor, called anakinra, pentoxifylline and zinc has failed in improving survival [22]. An FGF-22 agonist, called F-652, has shown promising results in an open-label phase 2 trial in terms of safety [23] but its clinical benefit must be confirmed in larger trials. At present, only prednisolone is recommended to treat severe AH.

Management of Infectious Complications in AH

Due to the severe liver dysfunction in AH patients, the risk of systemic infections is very high [24]. Prospective studies have shown that 25–30% of patients admitted with severe AH have infections, either patent or identified by a systematic screening [25, 26]. This risk of infection is not due to steroid treatment but can be observed before steroid initiation. Common sites of infection are lung, blood, ascites and urine. This high risk of infection which can be observed without any clinical symptoms is a strong argument to systematically and extensively screen patients with suspected AH at admission for infections. Screening should include chest X-ray, urine and blood cultures and ascites fluid examination. Lung infections are of particular interest because they are associated with a high short-term mortality and a lower probability to receive steroids [26]. Risk factors for pneumonia include a history of smoking, male gender and encephalopathy. In case of suspicion of lung

infection, chest CT-scan can be recommended because it can help diagnose infection [26]. If infection improves after initiation of antibiotics, patients can safely be treated subsequently with prednisolone and their prognosis is similar to that observed in patients admitted without infection [25].

Management of Alcohol Abstinence

Abstinence from alcohol is required as in other forms of decompensated alcohol-related cirrhosis. There is also a general consensus to recommend complete abstinence [2]. However, alcohol recurrence is observed in about 30% of patients [14, 27]. While survival at short term (less than 6 months) is not influenced by alcohol recurrence, it clearly impacts survival at medium and long term. Not surprisingly, alcohol relapse is seen more often in the most heavy drinkers because alcohol dependence is more prevalent in patients with the highest daily alcohol consumption [14]. Thus, addiction management is crucial in patients with severe AH and should be based on a multidisciplinary approach, in close collaboration between hepatologists and addiction specialists. Despite the absence of specific studies in the field of AH, we recommend that addiction management be started as soon as possible, preferably during hospital stay. It must however be emphasized that the use of medications to treat alcohol use disorder in patients with decompensated liver disease should be further studied. Indeed, only baclofen at low doses (less than 30 mg/day) has shown an efficacy in a randomized controlled trial in patients with decompensated cirrhosis [28] with an acceptable safety profile. At higher doses, a cohort study has suggested baclofen might be used in patients with cirrhosis [29], however high doses were not frequently used in this cohort and the absence of a control arm somewhat limits the conclusions of this work. Of note, while baclofen is used in France [30], it is not approved in many countries, especially in the USA (no approval was received from the FDA). Other medications such as acamprosate, naltrexone and disulfiram must not or should not be used in patients with decompensated cirrhosis [30]. Recently, a panel of French experts has elaborated in their guidelines the body of evidence surrounding the efficacy and safety use of medications to treat alcohol use disorder [30].

Liver Transplantation for Patients with Severe Alcoholic Hepatitis

Alcohol-related liver disease has become the first indication for liver transplantation in Western countries [2]. Most patients are transplanted for decompensated cirrhosis and/or for hepatocellular carcinoma. For patients with alcohol-related cirrhosis (without AH), liver transplantation is normally only offered after an significant

period of abstinence [31]. This recommendation is based on the fact that alcohol cessation generally improves liver function [32], especially in the first 3 months. Of note, however, improvement after abstinence is mostly seen in patients with mild liver dysfunction [33] while an important proportion of patients with a more profound liver failure will continue to worsen despite alcohol cessation [33].

On the other hand, because of organ shortage, liver transplantation cannot be offered to all patients with decompensated cirrhosis and some selection rules must be applied. From an addiction point of view, it seems relevant to propose liver transplantation to candidates with the lowest probability of alcohol recurrence after liver transplantation. Indeed, while return to alcohol drinking does not affect graft and patient survival in the first 5 years following liver transplantation [34], long-term outcome of patients is drastically affected by alcohol recurrence after 5 years [35]. Unfortunately, selection of transplant candidates is still challenging, since we lack strong predictors of alcohol relapse after liver transplantation and despite the identification of important predictors of continued drinking such as lack of family support, young age, other addictions, poor compliance, mental disorders, relatives drinking excessively [36, 37].

Not surprisingly, one of the most often used tools to select "good" candidates (i.e. patients with the lowest probability of alcohol recurrence after liver transplantation) for transplantation is the length of sobriety. It has been shown by several studies that a longer period of abstinence before liver transplantation was associated with a lower probability of alcohol relapse and the "6-month rule" has been established in order to select a patient for transplantation [38, 39]. Although the 6-month rule is a simple tool, it cannot be regarded as optimal. For instance, the 6-month rule leads to excluding patients who have a good addiction profile but who have stopped alcohol for a shorter period of time. This can be quantified by the prognostic capacity of the 6-month rule to predict alcohol consumption after liver transplantation. Indeed, several studies have shown that patients who were abstinent for at least 6 months before transplantation had a lower probability of drinking alcohol after transplantation [38, 40]. This suggests that the 6-month rule has a good specificity to identify patients less likely to return to alcohol drinking. However, the sensitivity is poor (less than 60%), and many candidates are turned down but would be abstinent after liver transplantation despite a period of sobriety before entering the waiting list of less than 6 months [38, 40].

With respect to AH, liver transplantation is a special challenge since patients are, by definition, not abstinent, or only short-term abstinent at their admission to the hospital. Given that medical treatment fails in improving survival in about 40% of patients (overall survival of patients with severe AH is around 60% and response to treatment is only observed in 60% of cases), a very significant proportion of patients are at risk of death in the weeks/months following their admission for severe AH. In addition, as pointed out earlier, in non-responders to corticosteroids (see above), no alternative treatment has been established so far. The lack of pharmacological option to treat these non-responders has led the French consensus on liver transplantation in 2005 to propose the evaluation of an early access to liver transplantation in a subgroup of carefully selected patients [31].

Based on the French consensus, French and Belgian teams have tested the access of an early liver transplantation in patients identified as non-responders to medical therapy [41]. Although the selection process was not protocol-based, patients had to experience their first episode of decompensation of alcohol-related liver disease (any decompensation, not only AH) and a consensus of the transplantation team was required. This consensus was reached after a discussion with the patient and his/her relatives about the absence of severe coexisting psychiatric disorders and an agreement by patients to adhere to lifelong total alcohol abstinence. Not surprisingly, the presence of close supportive family members was also an important parameter of patient selection. In this pilot study, 26 patients with severe AH not responding to medical treatment were transplanted and survival at 6 months and 2 years was much better than that of not-transplanted controls [41]. An acceptable low proportion of patients developed evidence of alcohol recurrence after liver transplantation (3 patients relapsed during the follow-up) and this important step has led other teams to evaluate this accelerated access to transplantation for severe AH.

Given the notion that early access to liver transplantation raises some important ethical issues [42], this procedure must be validated and endorsed by regulatory agencies. The American consortium ACCELERATE has gathered data from several centers in the USA and have reported good survival after early liver transplantation for AH [43]. The risk of alcohol relapse in this cohort can be estimated at around 15–20%. More recently, the same authors performed a modeling study which demonstrates that early liver transplantation provides the most important survival benefit over a delayed procedure [44]. No prospective controlled studies had been performed until the publication of the French and Belgian study QuickTrans [45] which has compared early liver transplantation for AH not responding to medical therapy to transplantation for alcohol-related cirrhosis, with a primary endpoint on 2-year alcohol consumption. Controls were included following the 6-month rule while patients with severe AH were selected using a dedicated algorithm based on a large evaluation which included a consensus meeting gathering members of the hepatology, surgery and addiction teams after several interviews of the patient and the family members. This trial has concluded that alcohol recurrence in patients treated with early transplantation was not non-inferior to standard liver transplantation with 6 months of abstinence. Alcohol consumption was recorded using the TLFB agenda [46, 47] and any evidence for alcohol recurrence was seen in 33.8% of patients early transplanted for AH and in 24.7% of patients transplanted for alcohol-related cirrhosis. This difference was not significant, but patients who had been early transplanted for AH had a higher rate of heavy alcohol consumption after transplantation than patients with alcohol-related cirrhosis. In the two groups, survival at 2 years was very high, close to 90% without differences between the two arms.

Despite encouraging results regarding survival, more data are required to understand the drivers of alcohol recurrence after liver transplantation. Some factors such as a young age [43] or the history of alcohol consumption (legal issues, attempts of prior rehabilitation, illicit drug use, etc.) [48] have been identified but they must be

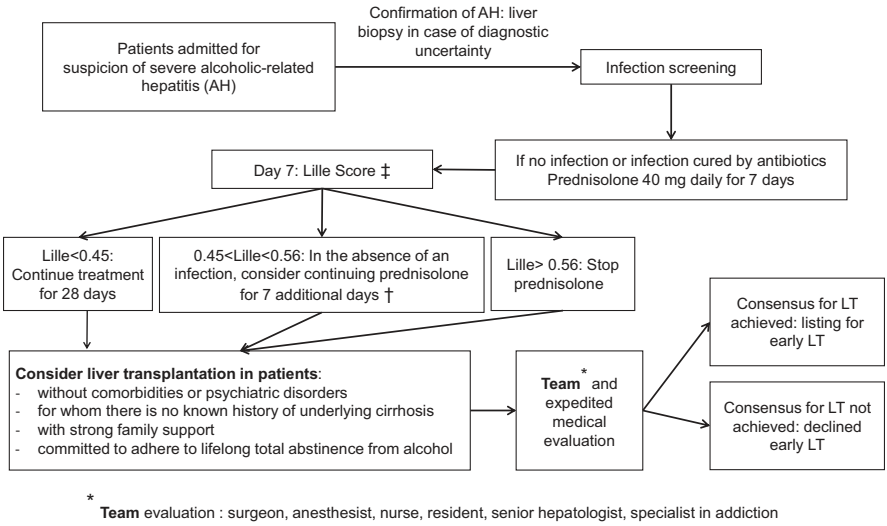

Fig. 66.1 Algorithm for management of patients with severe alcoholic hepatitis. †There is no consensus in patients with 0.45 < Lille<0.56 to continue or stop prednisolone. In patients with no sign of infection, we propose to consider a further challenge by steroids for 7 additional days, but this is not evidence-based and this is only an expert opinion. ‡Lille score formula: Exp(−R)/[1 + Exp(−R)], where R = [3.19–0.101 × age (in years) +0.147 × albumin (in g/L) +0.0165 × evolution in bilirubin (in μmol/L) −0.206 × renal insufficiency −0.0065 × bilirubin (in μmol/L) −0.0096 × prothrombin time (in seconds)]

validated at a large level (see also Book Part III). At present, there are some important discrepancies between countries in terms of policies towards early transplantation for AH [49]. Conversely, although some reluctance from the general public was expected but a recent study has shown that most people were in fact neutral toward or in favor of this procedure [50]. Further addiction data are also required to adapt addiction management after transplantation. An algorithm of medical management of patients with severe AH including LT is given in Fig. 66.1.

Conclusion

Severe AH is a life-threatening condition which requires specific management by a dedicated team. While medical treatment is still based on corticosteroids, new pharmacological agents are currently tested. In case of non-response to medical treatment, no drug has been proven efficient and early liver transplantation can be proposed in a subgroup of patients selected using a multidisciplinary approach. It is hoped that a better understanding of the underlying molecular mechanisms of AH will help to develop novel targeted therapies and optimize the management of AH (for more details see also Chap. 64).

Chapter 67
Mechanisms of Recovery from and Strategies for Survival of Severe Alcoholic Hepatitis and ACLF

Ahmed Y. E. Ibrahim and Rajiv Jalan

Abstract Acute on Chronic Liver Failure (ACLF) is a syndrome characterised by rapid deterioration of liver function, multiple organ failure and high short term mortality rate. Several precipitating factors can be implicated in the development of ACLF. The most common triggering factors encountered in the western countries are bacterial infections and alcoholic hepatitis. Severe alcoholic hepatitis (SAH) is by far the most devastating and life-threatening form of alcohol-related liver diseases (ALD). ACLF can be identified at any point during course of SAH, either at the first presentation or during follow up. Although different trigger-specific pathophysiological mechanisms are involved in the development of ACLF, the clinical outcomes in SAH induced ACLF is comparable to other precipitating factors. This chapter focuses on the interactive relationship between SAH and ACLF and provides insights on potential mechanisms of survival from these two clinical syndromes.

Introduction

Acute on chronic liver failure (ACLF) is a syndrome that occurs in patients with acute decompensation (AD) of liver cirrhosis, characterised by multiorgan dysfunction and high risk of short-term mortality [1]. The findings of the CANONIC study have paved the way for the European Association for the Study of the Liver–Chronic Liver Failure (EASL-CLIF) consortium to provide a clear definition of ACLF. This definition is based on the results of prospective evaluation of 1343 patients hospitalized with AD [2]. Organ failures are identified using EASL-CLIF Consortium criteria which forms the basis of the diagnosis of ACLF [3] (Table 67.1). Although, differing views regarding the diagnostic criteria have been proposed by the Asian Pacific Association for the Study of the Liver (APASL) and The North American Consortium for the Study of End-Stage Liver Disease (NACSELD) groups, the definition proposed by the EASL-CLIF Consortium and criteria have been best validated [4]. The mortality rate of ACLF patients is about 30% to 50% and is closely related to the number and severity of organ failure/dysfunction. Without liver transplantation, the 28-day mortality rate among patients with ACLF grade 1, grade 2 and grade 3 was estimated to be 23%, 31% and 74% respectively compared to 1.9% in patients with decompensated cirrhosis but without ACLF [5] (Table 67.2). The global prevalence of ACLF among hospitalized patients is estimated to be 35% in a systematic review and metanalysis which included 43,206 patients with ACLF and 140,835 patients without ACLF [6].

Alcoholic hepatitis (AH) is a clinical syndrome of jaundice and liver failure that generally occurs after years of heavy alcohol consumption (mean intake, approximately 100 g per day) [7]. For more details see also book Chaps. 65 and 66 on diagnosis and treatment of AH in this book part. The typical age at presentation is 40–60 years [8]. The severity of this syndrome can markedly influence the clinical

Table 67.1 Clinical criteria for the diagnosis of ACLF

Organ/system	Subscore = 1	Subscore = 2	Subscore = 3
Liver	Bilirubin <6 mg/dL	Bilirubin ≥6 mg/dL and < 12 mg/dL	Bilirubin ≥12 mg/dL
Kidney	Creatinine <1.5 mg/dL Creatinine 1.5–1.9 mg/dL	Creatinine ≥2 mg/dL and < 3.5 mg/dL	Creatinine ≥3.5 mg/dL or renal replacement
Brain (west-haven grade for HE)	Grade 0	Grade 1-2	Grade 3–4
Coagulation	INR <2.0	INR 2.0–2.4	INR ≥2.5
Circulatory	MAP ≥70 mm Hg	MAP <70 mm hg	Vasopressor requirement
Respiratory	$PaO_2/FiO_2 > 300$ $SpO_2/FiO_2 > 357$	PaO_2/FiO_2 201–300 SpO_2/FiO_2 215–357	$PaO_2/FiO_2 \leq 200$

outcome. Presenting with a Maddrey's Discriminant Function (mDF) ≥32 [9], it is the most life-threatening form of alcohol-related liver diseases (ALD), a clinical entity defined as severe alcoholic hepatitis (SAH) [10]. The occurrence of ACLF is frequent during SAH. ACLF can be identified at the time of first presentation with AH but can also develop during the course of medical management of this disorder [11]. From the outline above, the rates of survival at 28-days and 3 months, is related to the severity of ACLF at presentation.

This review will briefly describe the main pathophysiological factors and organ immunopathology known to be associated with AH-related ACLF and explore how these are restored in relation to recovery of organ function either spontaneously or with liver transplantation.

Pathophysiological Basis of AH-Related ACLF and its Evolution during Recovery

This section describes the underlying pathophysiologic mechanism associated with ACLF and explores whether targeting the underlying mechanisms can lead to the recovery from ACLF. Although not all the data described here are from AH-associated ACLF, most can be validated even in this group.

Systemic Inflammation

The accumulating understanding of the pathophysiological basis of ACLF indicates that a systemic inflammatory state is the main driver of widespread tissue damage and organ dysfunction, a state that is overexpressed in AH-related ACLF [12, 13]. The term "immunopathology" refers to the immune-mediated tissue damage that

can be caused by effectors of systemic inflammation such as cytokines and chemokines. Proteases, oxidative molecules, cytotoxic cytokines, prostaglandins (PGs), and leukotrienes (LTs), among other mediators, are consequently released by activated immune cells, leading to further worsening of the tissue damage [14].

Two main components have been observed to drive this intense systemic inflammation in ACLF, pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs) [13]. PAMPs represent molecular structures that are expressed by different pathogens and microbial agents. In contrast, DAMPs are circulating intracellular molecules following death or damage of the host cells, albeit without infection as a trigging agent. PAMPs and DAMPs bind to specific Pattern Recognition Receptors (PRRs) such as Toll like Receptors (TLR) located on peripheral innate immune cells [15]. Receptor binding activates down-stream signalling pathways, leading to the increased transcription and release of inflammatory cytokines with induction of severe systemic inflammation [16].

Taking the alcohol model into account, AH-related ACLF can exhibit both sterile and non-sterile pathways of systemic inflammation. Chronic alcohol consumption can lead to disturbance of the gut microenvironment in the form of intestinal barrier disruption, dysbiosis and impaired release of antimicrobial peptides [17–19]. The defective gut barrier permits translocation of bacterial PAMPs, particularly lipopolysaccharide (LPS) which could then reach the liver where they are recognized by TLRs expressed in hepatic Kupffer cells (see also Chap. 61). The end result is induction of inflammation with over production of proinflammatory chemokines and cytokines such as IL-8 and TNF-α [8, 20]. LPS-induced TNF-α may cause hepatocyte necrosis [8] resulting in the release of DAMPs that further aggravates the already existing inflammation. ACLF is characterised by a cytokine storm where there are markedly increased pro-inflammatory (TNF, IL-6, IL-8) and anti-inflammatory (IL-10, IL-1RA) cytokines, soluble markers of macrophage activation (sCD163 and mannose receptor) [21], C-reactive protein, and white blood cells in the plasma of ACLF patients [2]. The importance of systemic inflammation is highlighted by the temporal clinical correlates with the severity of systemic inflammation observed. Patients who showed clinical improvement of their disease had decreasing levels of these markers compared to increasing levels among those who were deteriorating [13].

The next important question is whether targeting the intense systemic inflammation at various levels would influence the outcome of ACLF syndrome. To answer this question, ACLF-simulating rodent models were used to study the therapeutic benefits of TAK-242, a molecule known to have inhibitory effects on TLR4 activation, a key component in driving systemic inflammation. This study showed that inhibiting TLR4 signalling with TAK-242 ameliorated organ injury and systemic inflammation [22]. One of the key PAMPs that plays a pivotal role in ACLF development is LPS. Targeting LPS with recombinant alkaline phosphatase in rat model of bile duct ligation with LPS co-administration has shown significant reduction in TLR4 expression with improvement of the systemic inflammation and organ recovery [23]. Blocking DAMPs signalling is another method of modulating the systemic inflammation (see later).

These findings suggest that there are three key characteristics in the relationship between systemic inflammation and ACLF. First, the development of ACLF is associated with intense systemic inflammation. Second, this relationship seems to be dynamic rather than static, with improvement in systemic inflammation being parallel to clinical improvement in ACLF and vice versa. Finally, the course and prognosis of the illness can be improved by using agents that target certain inflammatory checkpoints.

Immune Deficiency

In addition to the intense systemic inflammation in ACLF, the syndrome is also associated, paradoxically, with immune deficiency at both humoral and cell mediated levels [24, 25]. Three main factors are implicated in the dysfunctional innate immune response in patients with liver cirrhosis; reduced production of acute phase proteins, defective complement system and hypoalbuminemia, all of which are features of hepatocellular insufficiency [26, 27]. In ACLF, the situation is even worse with impaired gut barrier and, circulatory and endothelial dysfunction adding more to the already existing defect [14].

The immune status in ACLF patients is not exclusively restricted to one phenotype, rather it exhibits a spectrum fluctuating from immunosuppressed, immunomodulated, tolerogenic to hyperinflammatory prototypes. The fact that this cohort of patients are living with nearly constant hyperinflammatory state with over production of inflammatory mediators (e.g., galectin-3, IL-6, TNFα, IL-10) [13, 28] and lipid mediators (e.g., PGE2), which can lead to restraining of the innate immune response and giving the steering wheel to immunomodulatory cells with subsequent immunosuppression [29, 30] indicates that the two states can coexist within the same patient at the same time.

Therapeutic interventions targeting gut dysbiosis may provide a clue to induce recovery of the immune paralysis in ACLF. In experimental models as well as human studies, intestinal cleansing with non-absorbable antimicrobials was associated with restoration of dendritic cell function and TNF-α production [31]. This approach is currently being investigated in patients with decompensated cirrhosis to evaluate safety and efficacy of using rifaximin and simvastatin in prevention of ACLF development (LIVERHOPE project, EU H2020). Yaq-001 is an oral non-absorbable synthetic carbon compound which showed promising results in animal studies investigating its effects on the gut microbiome. This study also demonstrated that the use of Yaq-001 was associated with positive impacts on monocyte function [32].

The high energy demanding systemic inflammatory state in ACLF is not met by equivalent energy production, due to mitochondrial dysfunction with subsequent metabolic switch to the cytosol [33]. This metabolic switch is associated with implications on glutamine, which is known to be involved in maintaining immune system

health. In vitro inhibition of glutamine synthesis was associated with recovery of dysfunctional monocytes in ACLF [34].

Disturbed phagocytic and bactericidal functions of monocytes was found to be correlated with higher expression of MERTK pathway in ACLF patients. The ex vivo function of the monocytes was restored by pharmacological inhibition of MERTK with UNC56915 (Calbiochem/Millipore, UK) [28]. Similar defects were identified in the bactericidal properties of neutrophils from ACLF patients. These defects were attributed to impaired N-formylmethionine-leucyl-phenylalanine-induced myeloperoxidase release due to defective AKT (protein kinase B)–p38 MAPK (mitogen-activated protein kinase) pathway signalling. Ex vivo activation of the TLR7/TLR8 pathway using the agonist CL097, could overcome these defects, and induce recovery of the neutrophilic functions [35].

The idea of simulating the immune paralysis using serum from ACLF patients, and the in vitro restoration of cell function utilising immunological targeted techniques raise the possibility that cell reprogramming-induced immunodeficiency may be reversible and point to novel therapeutic targets [36].

Portal Hypertension

Reduced activity of hepatic endothelial nitric oxide synthase (eNOS) eventually leads to increased hepatic vascular resistance [37]. This phenomenon is exaggerated in ACLF, since systemic inflammation can induce endogenous eNOS regulatory proteins, such as NOSTRIN, caveolin-1, and asymmetric dimethylarginine (ADMA) [38–40]. The resulting increase in hepatic vascular resistance promotes rise in the portal pressure with decreased hepatic blood flow in patients with ACLF compared to those with alcohol related stable or decompensated cirrhosis without ACLF [41]. Additionally, reducing systemic inflammation by blocking TNFα with infliximab in AH patients resulted in significant reduction in portal pressure [42]. The PREDICT study provided evidence that portal hypertension is important in the pathogenesis of ACLF [43]. However, it is unclear at present whether the increased portal pressure observed in ACLF is a cause or a consequence.

Metabolic Dysfunction

Significant alterations in the main metabolic pathways as evidenced by accumulating levels of certain blood metabolites in the course of systemic inflammation in ACLF patients provide further understanding of the role of metabolic dysfunction in general and mitochondrial dysfunction in particular in the pathogenesis of ACLF syndrome, and their contribution to the development of organ failures [33].

Defective urea cycle enzymes with significant portosystemic shunting can lead to increased plasma levels of ammonia in patients with liver cirrhosis [44]. In

addition to neurotoxicity, hyperammonaemia has been found to be involved in immune dysfunction, activation of hepatic stellate cells proliferation and sarcopenia [45, 46]. In patients with AH, increased blood ammonia at admission was an independent predictor of in-hospital mortality rates [47]. Lowering blood ammonia levels has been shown to improve survival in ACLF patients regardless the presence of HE [48], indicating that ammonia level is not only correlated with organ failure, but also with ACLF prognosis.

Organ Immunopathology

Liver

It has been shown that circulating markers of hepatocyte death are markedly elevated in AD and continue to rise as ACLF progresses. Even though apoptosis occurs in ACLF, several studies demonstrated that other non-apoptotic forms of cell death that are known to be more immunogenic, predominate [22, 23, 49]. It was therefore not surprising that targeting apoptosis in patients with ACLF was not successful [50]. The inflammasome, which cleaves and activates gasdermin proteins, is responsible for the activation of the caspase family of proteins during cell pyroptosis, a type of immunogenic programmed cell death [51]. This pathway has been shown to be activated both in patients as well as models of ACLF [52]. Strategies inhibiting this pathway using limonin or disulfiram in experimental models promoted liver recovery and cell death reduction [53, 54]. The other non-apoptotic, immunogenic pathway that is observed in ACLF is necroptosis. Plasma levels of RIPK3, a marker of necroptosis was elevated in ACLF and could be used to identify patients transitioning from “no ACLF” to “ACLF”. Inhibition of RIPK1 activity in a rodent model of ACLF prevented hepatocyte death [55]. These findings provide multiple levels of evidence not only about mechanisms of liver injury in ACLF, but also about the potential therapeutic targets that may improve recovery and survival in these patients.

Kidneys

Renal dysfunction in the context of ACLF seems to be complex whereas pre-renal causes or hepatorenal syndrome may be implicated in some cases, acute tubular necrosis is the predominant underlying pathology in others [56, 57]. The presence of renal dysfunction in ACLF was correlated with higher levels of systemic inflammatory markers rather than plasma renin concentrations, a marker for systemic circulatory disturbance, suggesting two important concepts; firstly the deleterious effects of systemic inflammation on the kidneys is mediated predominantly by non-hemodynamic mechanisms [58], and secondly renal dysfunction in ACLF patients is more likely to be organic rather than functional disorder. Renal histology in ACLF

patients showed significant tubular cell death, which was associated with increased renal expression of TLR4 in humans [59], and RIPK1 and RIPK3 in animal models. Targeting RIPK1 was protective against renal tubular cell death, [55]. These observations help to explain the higher likelihood of non-response to terlipressin and albumin and potential irreversibility of kidney injury [60] if the acute tubular necrosis does not recover in weeks.

Brain

Although data from human studies are lacking, it has become clear that the pathogenesis of hepatic encephalopathy is complex, and although hyperammonemia and systemic inflammation are the key underlying mechanisms, neuroinflammation and neuronal cell death are important features specially in ACLF [61, 62]. Additionally, in about 5% patients with ACLF, severe cerebral oedema, indistinguishable from that seen in acute liver failure can be found [63]. Recovery from ACLF either spontaneously or with liver transplantation leads to resolution of brain dysfunction but complete reversibility is questionable [64–67].

Reduction in ammonia concentration and severity of inflammation are key metrics defining recovery. Drugs targeting ammonia such as ornithine phenylacetate and L-ornithine L-aspartate have been shown to result in faster resolution of hepatic encephalopathy, which correlates with the reduction in ammonia levels [68–70]. In those with refractory hyperammonaemia, veno venous hemofiltration as a method of removing ammonia [71] should be considered to enhance recovery.

Circulation

Systemic vasodilatation with reduction of systemic vascular resistance and mean arterial pressure (MAP), are frequently encountered in ACLF patients [41]. Cardiac dysfunction is manifested by inability to increase cardiac output despite fluid resuscitation and the attendant vasodilation. Sepsis, in addition to sterile inflammation together impact on endothelial function to produce systemic hypotension [72]. Although the mainstay of therapy are vasoconstrictors using noradrenaline and fluid expansion with albumin, removal of circulating inflammatory molecules with plasma exchange or other liver support devices such as molecular adsorbents recirculating system reduces inotrope requirements and improves blood pressure [73–76]. This argues for better understanding of mechanisms underlying hypotension to allow recovery. The mechanism underlying cardiac dysfunction is not clear and there are no available strategies to enhance cardiac contractility. It is uncertain if cardiac dysfunction persists or recovers completely with recovery from ACLF.

Respiration

The inflammatory sequelae of ACLF and/or lung infections contribute to respiratory failure in the ACLF population. Proinflammatory cytokines and nitric oxide hyperproduction could participate in the high incidence of acute respiratory distress syndrome (ARDS) observed in ACLF [77]. Alterations of consciousness due to hepatic encephalopathy increase the risk of aspiration pneumonia. Tense ascites reduces basal lung expansion [78]. Ventilation with low tidal volume strategy seems to be the best approach to manage ARDS related respiratory failure in ACLF [79]. Even with the best practice, ACLF patients with respiratory failure requiring mechanical ventilation still have considerable 1-year mortality rate (89%) [80].

The one-year post transplant survival in patients with ACLF grade 3 who did not require mechanical ventilation before liver transplantation is 85.4% compared to 75.3% among those who required it, suggesting that the need for mechanical ventilation at time of liver transplantation can significantly influence the outcomes after liver transplantation [81]. Whether ACLF itself contributes to respiratory failure or it is a consequence of critical illness is unknown and whether it recovers fully with resolution of ACLF requires more studies.

Coagulation

Coagulation status in patients with liver disease is governed by a balance between procoagulant and anticoagulant pathways, a balance that is lost in ACLF. The predominance of one pathway over the other depends on many factors and superimposed conditions [82]. As sepsis and systemic inflammation are often closely associated with the syndrome, thrombocytopenia due to consumption and disseminated intravascular coagulation are features of the syndrome [83, 84]. Whether endothelial dysfunction and release of tissue factor to drive this is the mechanism remains to be determined. A shift of the coagulation profile towards greater risk of bleeding is manifest particularly when the patients are placed on extracorporeal systems or undergo invasive procedures. [83, 85, 86].

Assessment of the coagulation status in patients with liver diseases using the standard laboratory tests (PT, APTT, INR, and bleeding time), has some limitations in terms of accurate measurement of the potential risk of bleeding [87], which may have implications on clinical decision making in critical situations. Therefore, incorporating viscoelastic tests into clinical practice can minimize the unnecessary transfusion of coagulation factors and other blood products based on the accurate data obtained [88]. In general terms, the severity of coagulopathy tends to improve with treatment of sepsis [89] and resolution of ACLF but coagulation disturbance consequent on synthetic failure of the liver remains.

Considerations in the Management of AH-Related ACLF Allowing Recovery

General Outline

The current approach to the management of AH-related ACLF is primarily based on identifying the underlying disease, precipitating factor (severe AH in our case), type and severity of organ dysfunction/failure and treat accordingly. The patients should be managed in an enhanced care area, a high dependency unit or an ICU, dependent on their requirement for organ support [90]. The general organ support strategies will not be described here except to highlight the importance of early, aggressive monitoring for infection and rapid treatment using broad spectrum antibiotics according to pre-defined local practice [91, 92].

Specific Strategies

Steroids

The current guidance for management of SAH recommends prednisolone as a first line treatment [93]. This guidance mainly relies on the results of meta-analyses investigating the value of steroids as a rescue therapy in this life-threatening condition [94, 95]. A large randomized controlled study (STOPAH) concluded that irrespective of using corticosteroids, the 90-day mortality for patients with SAH was about 30% [96], suggesting that there was no added survival benefit from using steroids in this cohort of patients. Whether corticosteroids improve the short-term survival of patients with SAH complicated by ACLF is unclear [97]; current data suggest a lower rate of response in patients with ACLF grade 2 and 3 (42 and 8%, respectively) [96, 98]. On the other hand, the risk of infection increases markedly with increasing severity of ACLF leading many to consider ACLF a contraindication to steroids [99].

Granulocyte Colony Stimulating Factor (G-CSF)

G-CSF is produced mainly by monocytes, macrophages, endothelial cells, fibroblasts, astrocytes, and several immune cells in response to injury or infection [100]. Impaired liver regenerative capacity is the main driver for the use of G-CSF in patients with SAH [101]. The therapeutic effects of G-CSF have been examined in several small single centre studies, some of which have shown overwhelming beneficial effects [102]. However, in a large, multicentre, carefully monitored clinical trial, G-CSF failed to confirm these previous data suggesting that G-CSF should not be used for the treatment of ACLF outside clinical trials [103].

Extracorporeal Liver Support (ELS)

The result of the systemic inflammation and immune dysfunction in patients with ACLF is accumulation of toxins and cytokines, which drive organ dysfunction/failure. If these toxins and cytokines can be removed via a liver support system, this may theoretically aid in replacing or complementing the work of a failing liver [104]. This idea to some extent, is similar to the concept of ECMO or renal dialysis, where the ultimate goal is to prolong the patient survival [105]. Based on this mechanism, there are two types of ELS systems available, artificial system (MARS, Prometheus, SPAD and HepaWash) and bioartificial system (HepatAssist and ELAD) [74, 106, 107]. The findings from studies on the artificial systems have shown promising results, where MARS was associated with improved outcomes in patients with grade 3 and 4HE, better short-term transplant free survival and improved biochemical parameters. In patients with MELD score > 30, Prometheus system has been proven to significantly improve the survival at both 28 and 90 days [108]. However, neither the artificial nor the bioartificial devices have been shown to improve overall survival of patients with ACLF, therefore further studies are needed prior to implementation in current clinical practice [109].

Albumin

Albumin use in spontaneous bacterial peritonitis, HRS and large volume paracentesis, has been associated with reduction of hypovolemia related complications and mortality [110]. Besides, albumin is well known to have other non-oncotic features such as homeostatic, antioxidant, immunomodulatory and endothelial stabilizing and toxic binding capabilities [111]. These unique features of albumin have made its use in ACLF become an interesting research area. However, clear data about the dosage, duration and frequency of administration are still lacking in patients outside of these conditions [112].

INFECIR-2 study provides novel insights into the effect of administration of human albumin on systemic inflammation in patients with decompensated cirrhosis [113], but the ATTIRE study did not improve clinical outcomes when albumin was used to treat acutely decompensated cirrhosis [114]. The ANSWER study, in which the aim was to prevent acute decompensation using long-term albumin administration, survival benefits were observed [115]. The MACHT study on the other hand, in which long term albumin was trialled, was negative for survival [116]. However, both studies provided useful data on the dose and frequency of albumin administration to attenuate systemic inflammation and improve cardiocirculatory dysfunction. The PRECIOSA study, which is currently running, is powered to determine the actual role of long-term albumin therapy [117]. However, implementation of this approach in real-world settings will be challenging given the cost and utilization of clinical services [112].

Liver Transplantation

If multiorgan supportive efforts fail to achieve clinical and biochemical improvement, liver transplantation would represent the last solution available for patients with ACLF. The overall 5-year survival rate after liver transplantation ranges between 74 and 90% [118]. The main challenge is the pre-transplant disease severity where multiple organ failure and bacterial infections usually supervene, leading to high mortality rate within the waiting list reaching about 50% [119].

The rate of delisting or mortality within 28 days of listing is about 44% in patients with ACLF grade 3. These findings should raise many questions about the best time to transplant those severely ill patients. Early liver transplantation within 30 days in this cohort, is associated with significant improvement in overall survival compared to the standard supportive care. The decision of when to transplant these sick patients is governed by many factors. However, the most important equation here is to weigh the benefit of waiting for good quality grafts against the risk of mortality while waiting for too much [81].

Looking further into the long-term outcomes of this intervention, analysis of the United Network for Organ Sharing (UNOS) registry for liver transplantation from 2004 to 2017 revealed that post-transplant 5-year survival was lowest among patients with ACLF grade 3 (67.7%) compared with the other patient groups (75%-79%, $P < 0.001$). However, the majority of deaths amongst ACLF grade 3 patients occurred during the first year post-transplant and then became comparable with other groups for the following 4 years [120]. These findings suggest that patients with ACLF grade 3 continue to have high mortality until 1 year post transplantation [120]. In the ELITA/EF-CLIF collaborative study, it was estimated that 1-year post-transplant survival rate in ACLF patients was about 80%, reflecting the importance of liver transplantation as a rescue therapy in this cohort of patients with high short term mortality rate. Poor prognostic factors that could be identified in this large international multicentre study included serum lactate >4 mmol/L, need for renal replacement therapy at time of liver transplantation and MDRO infections while on the waiting list [121].

Although the most widely accepted practice for liver transplantation in ALD follows an alcohol abstinence interval strategy, early liver transplantation in SAH has been proved to improve the clinical outcomes and survival [122, 123]. In ideal world, a decision to transplant a patient with SAH should be preceded by clear determination of unsatisfactory spontaneous recovery probabilities to avoid the unnecessary risks associated with LT. In a single-centre retrospective study, younger age, lower index INR, and lower peak MELD scores were found to be associated with higher likelihood of spontaneous recovery from SAH [124]. However, relying on MELD score may underestimate the risk of mortality in severely ill ACLF patients with multiple extrahepatic organ failure [125, 126]. On the other hand, identification of the risk of mortality based on ACLF grade, can provide a prognostication tool in patients with SAH [98], which can aid in better prioritisation in the setting of organ allocation.

Future Perspectives

The concept of ACLF as a distinct clinical entity has been validated world-wide with emerging clarity on the diagnostic and prognostic criteria for this syndrome. Alcoholic hepatitis is the most important cause of ACLF in the western world. With this clinical characterisation of the syndrome has emerged a deeper understanding of the pathobiology, which has led to the recognition of several therapeutic targets. The importance of the gut in shaping the immune dysfunction of cirrhosis and knowledge about the intestinal microbiome led to studies targeting the gut using Yaq-001, fecal microbiota transplantation and bacteriophages [32, 127–129]. The role of cell transplantation is maturing, and clinical trials of mesenchymal and hepatic progenitor cells are underway [130, 131]. The failure of the MARS and ELAD devices and the better understanding of the pathophysiology has led to the development of novel liver support devices such as DIALIVE and Cytosorb, which have shown promise in early studies [132, 133]. Finally, liver transplantation, a treatment approach for the sickest patients shows huge promise but there are many unanswered questions. These are being addressed in the CHANCE study (NCT04613921), which is a global multicentre international study.

In conclusion, when patients with SAH fulfil ACLF criteria, their prognosis is determined by organ failures, and it is likely that the novel therapeutic approaches targeting multiple domains in ACLF will also be effective on SAH patients with ACLF.

Conflict of Interest Rajiv Jalan is the inventor of OPA, which has been patented by UCL and licensed to Mallinckrodt Pharma. He is also the founder of Yaqrit Discovery, a spin out company from University College London, Hepyx Limited and Cyberliver. He had research collaborations with Yaqrit Discovery. The other author has no conflicts of interest to declare.

Financial Declarations This study had no specific source of funding.

Chapter 68
The Role of Liver Biopsy and Hepatic Venous Pressure Gradient in the Prognosis of Acute Alcoholic Hepatitis

Andreea Bumbu and Bogdan Procopet

Abstract The use of liver biopsy in diagnosing alcoholic hepatitis has been controversial. Usually is used via the transjugular approach due to frequent ascites and coagulation abnormalities. Due to low availability and the risk of complications, the real-life applicability is questionable. However, apart from the diagnostic certainty, the histology feature has prognostic relevance. The main counterargument against liver biopsy would probably be that treatment decision relies on laboratory findings demonstrating disease severity. Finally, the most considerable responsibility is the correct diagnosis and avoiding unnecessary corticosteroid treatment in patients without alcoholic hepatitis. Using only clinical criteria is challenging, especially because patients with severe alcoholic hepatitis associate bacterial infection and both conditions may precipitate acute-on-chronic liver failure. Recently, the proposal to classify the condition as definitive, probable or possible alcoholic hepatitis could standardize the clinical practice for diagnosis. Apart from biopsy, portal hypertension is essential in developing complications. The standard method for portal hypertension diagnosis is hepatic venous pressure gradient, which was extensively validated as a prognostic marker in liver disease. In alcoholic hepatitis, there is a single study that demonstrates the prognosis relevance in patients with alcoholic hepatitis. In these patients, an HVPG higher than 22 is associated with increased mortality.

Keywords Transjugular liver biopsy · Prognosis · Advanced liver disease · HVPG · Diagnostic accuracy

Liver Biopsy: The Debate Is Still Open

The role of liver biopsy in diagnosing and managing alcoholic hepatitis (AH) has been controversial throughout the years. The main counterargument to its routine use as a precise diagnostic tool is its low availability of the transjugular approach, performed mainly in tertiary centers [1]. Therefore, even though the guidelines for clinical practice recommend it as the golden standard for the definitive diagnostic of AH, the real-life applicability is questionable. The later EASL guideline softened the indication for the cases of diagnostic uncertainty or if the disease staging must be precise, as in clinical trials (grade A1) [2]. However, the diagnostic certainty based only on clinical and paraclinical criteria is illusory because the clinical picture of decompensated alcoholic liver cirrhosis and severe alcoholic hepatitis are perfectly superposable and sometimes associated.

Transjugular liver biopsy is usually the preferred route because, frequently, these patients manifest severe ascites and prolonged conventional coagulation tests. Although it is well tolerated, it remains an invasive procedure, and periprocedural complications can occur. However, significant complications that include intraperitoneal bleeding through capsular perforation, cardiac arrhythmias, perforation of the hepatic artery, pseudoaneurysm, or haemobilia are rare, accounting for 0.5–0.8% of the cases. The most frequent minor complications are bleeding at the puncture site or abdominal pain [3, 4]. Recent reports are consistent with previous publications. Thus, a recent study on 1321 TJLBs showed an overall major and minor complication rate of 1% and 9.5%, respectively. There was no difference in the incidence of minor and major complications between different subgroups of patients classified according to varying ranges of platelets and INR [5]. This follows the new evidence that conventional coagulation tests do not correctly reflect the hemostasis of patients with advanced liver diseases [6].

The suspicion of AH diagnosis is based on clinical criteria, which involve the recent onset of jaundice in a patient with a recent history of alcohol heavy abuse, combined with the laboratory findings. The most typical laboratory features are hyperbilirubinemia, increased transaminases with the dominance of AST more than twice the level of ALT, but usually not higher than 300 UI/L, and neutrophilia [2]. Over the years, the severity of the condition was assessed based on a different combination of variables related directly to liver function. The oldest severity score, the Maddrey discriminant function (DF) based on bilirubin and prothrombin time, is still recommended to select patients that could benefit from corticosteroids [7]. Newer scores, such as Model for End-stage Liver Disease (MELD) [8], Glasgow Alcoholic Hepatitis Score (GAHS) [9], or the Age, serum Bilirubin, INR, and Creatinine (ABIC) score [10], proved to be superior to DF by adding variables associated with short term prognosis [11]. Once the patients were under corticosteroid treatment Lille model, based on the early dynamic of the bilirubin after 7 days of treatment, prevents continuation of the treatment in patients without response [12, 13].

The certainty of the diagnosis is given by liver biopsy. The histological diagnosis is based on steatohepatitis, which typically includes microvesicular steatosis, hepatocyte ballooning, and polymorphonuclear neutrophils (PMN) infiltrate [2]. The histology features proved to have prognostic relevance, either in the short term, as the type of bilirubinostasis, presence of megamitochondria or neutrophils infiltration [14, 15], or in the long term, as the stage of fibrosis [16]. At the moment, two histology scores have been developed, the Alcoholic Hepatitis Histologic Score (AHHS) [14] and the Study of Alcohol-related LiVer disease in Europe (SALVE) histology system [15], and both seem to have prognostic relevance.

In this context, it would be relatively simple to follow an algorithm starting from the clinical suspicion of severe alcoholic hepatitis, confirming the diagnosis by liver biopsy and, according to the histology findings, to step further to the treatment. However, this algorithm is rather exceptional, being applied in expert research centers or the context of clinical trials. There is an ongoing debate about whether the biopsy is essential in managing severe AH. Maybe the most justifying and straightforward argument against liver biopsy is that the diagnosis and the severity are suspected based on laboratory findings. Moreover, the decision for the corticosteroid treatment and the assessment of the treatment's response is based mainly on the bilirubin levels. Thus, the liver biopsy would not influence the treatment decision despite the prognostic relevance of some histology features. The discussion is still open because the performances of the clinical criteria for an accurate diagnosis are not perfect. Differentiating between severe AH and decompensated cirrhosis seems impossible, and 25–30% of the clinically suspected patients have an alternative diagnosis on liver biopsy [17, 18]. The proportion of patients that may receive corticosteroid treatment without AH is unacceptable, especially knowing that corticosteroid treatment is associated with an increased risk of bacterial infections [19]. Moreover, 25–45% of patients with decompensated cirrhosis present with bacterial infections at admission [20, 21]. In the studies reporting insufficient accuracy, the clinical diagnostic criteria were not the most appropriate. In the study of Mookerjee et al., the clinical suspicion of AH was based on the SIRS criteria, and the overall accuracy was only 54%, with only 50% of the patients with SIRS criteria having AH and 40% of the patients without SIRS criteria having AH on liver biopsy [18]. It is not surprising that in the same study, the authors found that in patients with SIRS criteria but without AH, canalicular cholestasis was associated with bacterial infections and, consequently, with a worse prognosis. It is well known that both AH and bacterial infection trigger systemic inflammation and may precipitate acute-on-chronic liver failure (ACLF); therefore, SIRS criteria are an inappropriate diagnostic tool. An editorial to the Mookerjee et al. paper suggested that when applying clinical criteria, increasing the bilirubin threshold from 50 to 80 μmol/L will increase accuracy from 70–80 to 96% for AH diagnosis [22]. The rationale is that hyperbilirubinemia is the main feature that differentiates the AH from decompensated cirrhosis. In fact, higher bilirubin thresholds were used in trials where a biopsy was not a prerequisite for entry to the trial, as in the most recent large randomized trial (STOPAH trial) [23]. In this trial, 1103 patients were randomized to receive either prednisolone or pentoxifylline. While pentoxifylline did not improve

survival, prednisolone was associated with a reduction in 28-day mortality that did not reach significance and no improvement in outcomes at 90 days or 1 year. This is the most extensive negative trial that increased the doubts about the efficiency of the corticosteroid treatment, but is this enough to ban this treatment in severe AH? One of the significant drawbacks in all the studies dedicated to AH, including RCTs, is the heterogeneity of the included populations [24], and the STOPAH trial makes no exception. When reviewing the data, an essential hint regarding the population selection is to look closely at the placebo arms, which should reflect the natural history of the disease. Let's compare the populations in the STOPAH trial with the patients included in the individual data meta-analysis of Mathurin et al. [25]. They are pretty similar in terms of mean bilirubin or DF, even a little more severe in the STOPAH trial [62.6 ± 27.2 vs. 48.5 (45.5–51.3)]. However, the 28-day mortality rate in the placebo arms is 17% in the STOPAH trial vs. 38% in Mathurin's study. This means the failure of the STOPAH trial to correctly identify the patients with severe AH, despite the use of clinical criteria with a higher bilirubin threshold. There is no obvious explanation for this difference, and the improvement in healthcare over the years, including the management of malnutrition, is not enough. At least in part, a possible explanation would be the inclusion of patients without AH in the absence of liver biopsy. In our view, these results advocate for the mandatory use of liver biopsy in therapeutical trials, despite the risk of reducing the number of patients potentially included.

An excellent solution to overcome the risk of heterogeneity regarding the population to be included is the standardization proposed by The National Institute on Alcohol Abuse and Alcoholism (NIAAA)-funded Alcoholic Hepatitis Consortia as **Definite AH** (clinically diagnosed and biopsy-proven), **Probable AH** (clinically diagnosed AH without confounding factors) and **Possible AH** (clinically diagnosed but with potential confounding factors) [26] (see also Appendix Figs. A.9 and A.10).

The following clinical criteria proposed by NIAAA to diagnose alcoholic hepatitis (AH) in clinical trials, as outlined in reference [26]:

- Jaundice that has developed within the previous 8 weeks.
- Consumption of more than 40 g of alcohol per day for women or 60 g of alcohol per day for men, for at least 6 months, with less than 60 days of abstinence prior to the onset of jaundice.
- Aspartate aminotransferase (AST) levels greater than 50 IU/L, a ratio of AST to alanine aminotransferase (ALT) greater than 1.5, and both AST and ALT values below 400 IU/L.
- Total serum bilirubin levels greater than 3.0 mg/dL.
- In patients with confounding factors, confirmation of the diagnosis with a liver biopsy may be necessary.

Interobserver variability is a relatively constant counterargument against liver biopsy in diagnosing liver diseases. The data is limited regarding the diagnosis and assessment of the AH's histological severity. There is only a fair level of agreement

between the pathologists regarding the inclusion in different AHHS [14] for prognostic stratification of AH categories [27]. The lowest agreement was reported for identifying megamitochondria, while the highest was in fibrosis and steatosis. The standardization of the histological diagnosis using validated staging and grading scores should be helpful in clinical practice. It should also overcome the heterogeneity of the diagnosis criteria in clinical studies. Recently, the Study of Alcohol-related LiVer disease in Europe (SALVE) consortium proposed a new grading and staging system for AH that standardize the pathological report [15]. This new system seems reproducible and prognostically relevant for the histological assessment of disease activity and fibrosis in ALD.

In recent years, many non-invasive tools, especially liver and spleen elastography, have been validated for staging liver disease, diagnosing clinically significant portal hypertension, and assessing these patients' prognoses [28]. Because liver fibrosis, intrahepatic inflammation [29], and alcohol consumption increase liver elastography [30], using elastography to diagnose AH was not helpful. Moreover, due to ascites for the vibration-controlled transient elastography (VCTE), the feasibility is lower than other elastography methods [31]. The lack of non-invasive methods also represents an argument for using liver biopsy in the scenario of AH.

Patients without clinical criteria of severity (a discriminant function <32) and who would not need corticosteroid treatment but with histology of AH represent a particular subgroup of patients. A high proportion of them has a histology score of severe AH [32]. While the short-term mortality is very low (around 5%) compared to those with DF > 32, the long-term mortality is considerable, 20 and 50% at one and 5 years, respectively. Interestingly, the severity of the histology score does not predict survival. Still, in patients with an AHHS of 0–3, the 5 years mortality was 30%, while in those with AHHS >3, the mortality was around 50%. The factors independently associated with long-term survival were the presence of encephalopathy at baseline and long-term abstinence. There is a need for more data on this subgroup of patients and whether they should receive treatment, but what is certain is that they cannot be identified without biopsy.

Finally, besides the drawbacks and disadvantages of using biopsy in AH, there are certain benefits. Table 68.1 lists the main advantages and disadvantages of using liver biopsy in AH. It should be recommended in patients with possible AH with any atypical features or concurrent factors. To prevent confounding factors and

Table 68.1 The arguments and counterarguments for using liver biopsy in alcoholic hepatitis

The use of liver biopsy in alcoholic hepatitis	
Advantages	Disadvantages
Certainty of diagnosis	The transjugular approach is not widely available
Prognostic relevance	Percutaneous rarely possible
Concomitant HVPG measurement	Invasive
Lack of non-invasive methods	Risk of complications
	Do not contribute to treatment decision

heterogeneity, liver biopsy should be required in clinical trials. Moreover, serial biopsy in abstinence could give hints about disease regression and regeneration, which could represent a therapeutic target.

Hepatic Venous Portal Gradient: A Superstar in Liver Diseases but Still a Cinderella for Alcoholic Hepatitis

Hepatic venous portal gradient (HVPG) is the best method to diagnose portal hypertension (PHT). Over the years was extensively validated against hard clinical endpoints and is now considered a robust surrogate marker for the prognosis [33]. Any factor influencing the HVPG would be reflected in a change in prognosis, making the changes in HVPG a reliable end-point therapeutic trial [34]. An HVPG less than 5 mm Hg is considered normal, while a value between 5 and 10 mm Hg is considered mild PHT. HVPG over 10 mm Hg represents clinically significant portal hypertension (CSPH), which is associated with the risk of decompensation [35]. HVPG measurement can be performed easily together with TJLB without increasing the risk of complications.

Until now, only one study investigated the role of HVPG in patients with AH [36]. In this study, 60 patients with AH were compared with 66 patients with advanced alcoholic and viral cirrhosis listed for transplantation. Patients with AH had significantly higher HVPG values than cirrhosis, and an HVPG value higher than 22 mm Hg was associated with increased mortality among AH patients. A straightforward explanation for higher HVPG is AH could be the intrahepatic inflammation that characterizes the hepatitis process. However, there is no correlation between the degree of inflammation, fatty change, or occurrence of Mallory bodies [36]. These findings were also confirmed by Altamirano et al. They found no differences in HVPG measurements between patients with a definitive AHHS $\geq$5 points and a definitive AHHS <5 points (19.0 ± 6 mm Hg vs. 19.7 ± 6 mm Hg, respectively) [14].

Let's go back to the pathogenesis of the PHT. The main factors that increase the portal pressure are the amount of fibrosis (the mechanical compound) and the increase in intrahepatic vascular resistance (the dynamic compound) [37]. There is evidence that the thickness of fibrous septa is well correlated with HVPG [38–40]. Therefore, probably the new grading and staging proposed by the SALVE consortium [15], which classifies the cirrhosis stage according to the Laennec classification, could bring hints about the mechanism of very high HVPG in patients with AH. On the other hand, the dynamic compound should not be ignored in this context. AH is characterized by marked bacterial translocation and liver cell necrosis that will increase the systemic inflammation through the PAMPs and DAMPs pathway, in particular through TLR4 signaling, which will further activate hepatic stellate cells and will aggravate the endothelial dysfunction and finally will lead to an increase intrahepatic vascular resistance [41]. This hypothesis is of great interest

because intrahepatic vascular resistance may represent a therapeutic target in patients with AH.

Although there is limited data, it seems that HVPG correlates well with the prognosis of patients with AH. Further studies are needed to evaluate the mechanism of portal hypertension in these patients and whether it could be a therapeutic target. HVPG may be easily obtained during TJLB, thus, offering the possibility of having two standard methods for the diagnosis and the prognosis of patients.

Alcohol-Related Damage of Other Organs

Chapter 69
Skeletal Muscle and Adipose Tissue: Targets or Relays for Interorgan Axis in Alcohol-Induced Tissue Injury?

Liz Simon, Brianna L. Bourgeois, Jonquil M. Poret, and Patricia E. Molina

Abstract At-risk alcohol use is an independent risk factor for liver disease and type 2 diabetes and synergizes with an obesogenic environment additively increasing the risk of cardiometabolic disease. At the core of metabolic dysregulation is alcohol-induced cellular injury of the liver, pancreas, skeletal muscle (SKM), and adipose tissue (AT). This chapter focuses on the contribution of SKM and AT to alcohol-mediated metabolic dysregulation. SKM and AT are targets of alcohol-mediated dysregulation of glucose, protein, and lipid metabolism; aberrant extracellular matrix remodeling; bioenergetic adaptations; and impaired differentiation of muscle and adipose derived progenitors. Based on emerging evidence of interorgan communication as an important mechanism underlying alcohol-associated tissue injury, SKM and AT as relays are discussed. Secretion of soluble factors and extracellular vesicles are proposed as critical mediators of inter-organ communication contributing to metabolic dyshomeostasis associated with at-risk alcohol use. We provide insight into areas of research gaps that warrant systematic studies on how alcohol-mediated changes in mediators, particularly extracellular vesicles, and their bioactive cargo, mechanistically contribute to cardiometabolic disease. Research integrating these complex metabolic networks is imperative to elucidate their role and potential as targets for interventions to reduce comorbidities and improve quality of life among people with at-risk alcohol use.

Introduction

At-risk alcohol use is a major global risk factor for preventable morbidity and mortality, significantly contributing to health care burden and economic costs [1]. More details about epidemiology are provided in part I of this book. People with at-risk alcohol use are at increased risk for psychiatric comorbidities, liver disease, and cardiometabolic disease. Moreover, clinical [2–4] and preclinical studies [5–7] demonstrate that at-risk alcohol use promotes metabolic dysregulation and is an independent risk factor for development of type 2 diabetes [8, 9] through yet unknown mechanisms.

Compelling evidence indicates that at-risk alcohol use leads to tissue injury. However, patterns of alcohol consumption, types, and amount of alcohol consumed complicate the classification of at-risk alcohol use [10]. While studies suggest a J-shaped curved in the relationship between the amount of alcohol consumed and risk for metabolic dysregulation [11, 12], any protective effects of moderate drinking are eliminated when adjusting for physical activity and health status [13]. Thus, while the beneficial impact of low to moderate alcohol consumption on metabolism is debatable, at-risk alcohol use, including binge drinking negatively impact metabolic homeostasis [10, 14, 15].

The mechanisms involved in alcohol associated metabolic dysregulation are likely due to alcohol metabolism and the resulting cellular alterations [10, 16, 17]. Acetaldehyde and acetate; metabolites generated during ethanol metabolism [10] can produce tissue injury by activating immune responses, and protein and histone acetylation that dysregulate gene and protein expression [18]. The altered NAD^+ to NADH ratio resulting from alcohol metabolism also adversely affects numerous cellular metabolic processes [16, 17]. Similarly, reactive oxygen species (ROS) generated by alternative alcohol metabolic pathways damage DNA and proteins and deplete antioxidant capacity in tissues. Reduction of cellular S-adenosylmethionine (SAM) levels resulting from increased oxidative stress contributes to epigenomic modifications like DNA hypomethylation [19]. More details are also provided in book Chap. 55.

These alcohol-mediated cellular and metabolic effects have been well characterized in alcohol-related liver injury [10]. However, increasing evidence suggests that metabolic tissues such as the pancreas, skeletal muscle (SKM), adipose tissue (AT) are also significantly impacted by at-risk alcohol use. The SKM and AT play key roles in the multidirectional network of metabolically active organs involved in maintaining metabolic homeostasis. This has led to novel explanatory models invoking inter-organ communication and interplay as contributing mechanisms of alcohol-induced pathology. This chapter will discuss how the SKM, and AT are targets of alcohol-induced tissue injury and emerging evidence suggesting a role for these tissues as relays of interorgan communication contributing to metabolic dysregulation (Fig. 69.1).

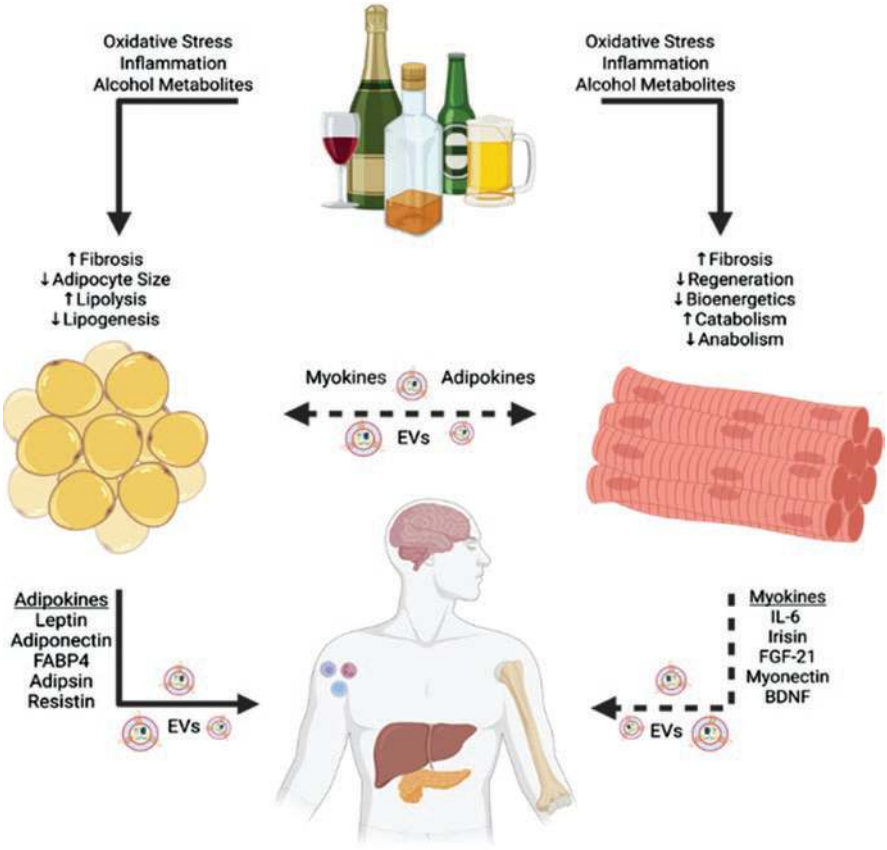

Fig. 69.1 Skeletal muscle and adipose tissue function as targets of alcohol-mediated tissue injury. Alcohol and alcohol metabolites, alcohol-induced oxidative stress, and inflammation, promote a profibrotic milieu and dysregulate metabolic capacity in both the tissues. Skeletal muscle and adipose tissue act as relays of interorgan communication by the release of extracellular vesicles, and myokines and adipokines, respectively. Evidence suggests alcohol-mediated changes in adipokines. However, whether alcohol alters skeletal muscle myokine levels or extracellular vesicle number or cargo from both the tissues is not known

Skeletal Muscle Is a Target of Alcohol-Induced Tissue Injury

At-risk alcohol use decreases functional SKM mass defined as loss of muscle mass or function (i.e. alcohol-induced myopathy). Clinically, alcohol-induced myopathy can be acute or chronic. Acute alcohol-induced myopathy occurs when an alcohol binge leads to myonecrosis, or the breakdown of muscle tissue. Muscle fiber contents can be released into circulation to cause rhabdomyolysis [20]. Rhabdomyolysis

results from increased intracellular calcium through membrane damage or impaired energy production and the increase in intracellular calcium leads to destructive cellular processes [21, 22]. Acute alcohol-induced myopathy can present with acute pain, swelling, and tenderness of the affected muscle and elevated circulating creatine kinase and myoglobin levels. In severe cases, acute kidney failure can occur [20].

Chronic alcohol-induced myopathy is more common than acute alcohol-induced myopathy and presents with progressive muscle weakness. Clinical and preclinical studies have demonstrated that chronic at-risk alcohol use leads to a reduction in functional muscle mass. Alcohol-fed mice have reduced gastrocnemius mass to total body mass ratio, and patients with alcohol-induced cirrhosis have reduced total muscle area as measured by computed tomography [23]. In athletes, alcohol consumption negatively impacts SKM recovery after strenuous exercise, and dose-dependently diminished muscle strength in men [24]. In a preclinical model of simian immunodeficiency virus (SIV)-infection, chronic binge alcohol (CBA) reduced thigh muscle area at end stage infection [25]. These reductions in SKM mass with at-risk alcohol use can be due to an imbalance in catabolic and anabolic signaling, increases in fibrosis, or impaired regenerative capacity, as described in the next section (Table 69.1).

Alcohol-Associated Dysregulation of SKM Anabolic and Catabolic Signaling

SKM is a highly adaptable organ that balances anabolic and catabolic signaling based on environmental cues such as growth factors, energy status, or mechanical strain. It plays a major metabolic role and is responsible for about 85% of insulin-mediated glucose utilization [53].

SKM mass is determined by the balance between protein synthesis and breakdown. Protein synthesis is driven by the mammalian target of rapamycin (mTOR) complex 1 (mTORC1) signaling pathway, activated by insulin and insulin-like growth factor 1 (IGF-1) [54]. Activation of mTORC1 initiates S6 kinase 1 (S6K1) phosphorylation resulting in activation of ribosomal protein S6 and inactivation of eukaryotic initiation factor 4E-binding protein (4E-BP1). Both activation of S6K1 and inactivation of 4E-BP1 increase translational machinery allowing protein synthesis. Preclinical models show that chronic alcohol decreased the phosphorylation of mTOR and 4E-BP1 contributing to decreased protein synthesis [29]. Acute alcohol also attenuated refeeding-induced increases in protein synthesis and S6K1 phosphorylation [26]. Thus, both acute and chronic alcohol impair the activation of protein synthesis. Negative regulators of the mTORC1 pathway include AMP-activated protein kinase (AMPK) and Regulated in Development and DNA damage responses (REDD1 & REDD2). AMPK is activated by energy stress while REDD1 & REDD2 are activated by hypoxia, ROS, and glucocorticoid excess. While acute

Table 69.1 Summary of alcohol effects on skeletal muscle and adipose tissue

Summary of Alcohol's Effects on Skeletal Muscle	Refs #	Summary of Alcohol's Effects on Adipose Tissue	Refs #
Alcohol decreases anabolic signaling		*Alcohol decreases lipogenesis*	
• Chronic alcohol decreases phosphorylation of mTOR and 4E-BP1	[26]	• Chronic alcohol decreases PPARy expression	[27], [28]
• Acute alcohol attenuates refeeding-induced increase in S6K1 phosphorylation	[29]	• *In vitro* alcohol decreases ACC phosphorylation	[30]
• Acute and *in vitro* alcohol increase REDD1 and AMPK gene expression	[31]	• Alcohol decreases ACLY enzyme expression in VAT	[28]
		• *In vitro* alcohol decreases AMPK activity	[30]
Alcohol increases catabolic signaling		*Alcohol increases lipolysis*	
• Acute and chronic alcohol increase atrogin-1 expression	[32], [25]	• Chronic alcohol inhibits insulin anti-lipolytic effects	[27], [33]
• *In vitro* alcohol increases proteolysis through autophagy	[23]	• Chronic alcohol increases activation, expression, and activity of HSL	[27], [34], [35]
		• Chronic alcohol increases ATGL expression	[27], [28], [34]
Alcohol dysregulates ECM remodeling		*Alcohol dysregulates ECM remodeling*	
• Chronic alcohol increases hydroxyproline content	[36], [37]	• Chronic alcohol increases VAT collagen content in SIV infection	[38]
• Alcohol increases the expression of proinflammatory mediators	[39], [40, 41]		
• Chronic alcohol increases MMPs	[42]		
Alcohol decreases regeneration		*Alcohol increases inflammation*	
• Chronic alcohol increases *Tnfa* and decreases muscle fiber area in mice after injury	[41]	• Alcohol promotes macrophage polarization to M1 pro-inflammatory phenotype	[43], [44]
• Chronic alcohol decreases myogenic gene expression	[40], [45]	• Alcohol metabolism by CYP2E1 increases the expression of pro-inflammatory cytokines	[46], [47], [43]
• Chronic alcohol in non-human primates decreases myoblast differentiation	[45]		
Alcohol alters bioenergetic function		*Alcohol dysregulates adipokine profile*	
• *In vitro* alcohol decreases glycolytic function	[48]	• Chronic alcohol decreases VAT and SAT adiponectin	[33], [49]
• Chronic alcohol increases mitochondrial size	[50]		
• Chronic alcohol decreases mitochondrial gene expression and myoblast mitochondrial respiration in SIV-infection	[51], [52]		

and *in vitro* alcohol appear to increase REDD1 mRNA expression [31] and AMPK activation, respectively, chronic alcohol does not have the same effects. Thus, while impairment in various proteins in the mTOR signaling pathway appears to contribute to alcohol-induced decrease in protein synthesis, REDD1 and AMPK are unlikely mediators of alcohol-induced decreases in protein synthesis [55],

Loss of muscle mass may result from increased protein breakdown mediated by the ubiquitin proteosome pathways (UPP) and autophagy. Proteins destined for degradation are tagged with ubiquitin through action of E1 ubiquitin activating enzymes, E2 ubiquitin conjugating enzymes, and E3 ubiquitin ligases. Acute alcohol increased expression of two ubiquitin ligases, atrogin-1, and muscle ring finger 1 (MuRF1), in a rodent model but this was not associated with increased proteolysis [32]. In SIV infection, CBA increased atrogin-1 expression, dysregulated proteins in the UPP pathway, and increased proteasome activity [25]. Autophagy is activated during cellular stress to remove misfolded proteins or damaged organelles. Ethanol decreased murine myotube cell size and increased proteolysis, which was attenuated with an autophagy inhibitor but not a proteosome inhibitor suggesting that the increase in proteolysis was mediated by autophagy [23]. Overall, alcohol reduces SKM protein synthesis and increases autophagy, leading to a decrease in functional mass.

Alcohol Modulation of SKM Extracellular Matrix (ECM) Remodeling

The ECM contains capillaries and nerves, and surrounds SKM cells, or muscle fibers. The ECM provides a scaffold for SKM regeneration, and its structural integrity is maintained by fibroblasts that produce collagen. Abnormal increases in fibroblast activity or dysregulated ECM turnover can lead to aberrant SKM ECM remodeling, which is another contributor to reduced functional SKM mass.

Chronic alcohol administration in rats increased SKM collagen and hydroxyproline expression [36]. Similarly, CBA increased SKM collagen content as indicated by picrosirius red staining and hydroxyproline content in SIV-infection [37]. Alcohol-associated increases in SKM fibrosis are thought to be mediated by growth factor and cytokine expression and signaling, leading to an increase in fibroblast proliferation and activation. The release of profibrotic mediators such as transforming growth factor β (Tgfb1) from proinflammatory cells can increase SKM fibrosis [56]. In a transgenic HIV-1 rat model, chronic alcohol decreased SKM fiber area and increased myostatin and *Tgfb* gene expression [39]. Similarly, alcohol feeding during recovery from hind limb immobilization increased *Tgfb* and tumor necrosis factor α (*Tnfa*) expression [40] and increased collagen expression (unpublished data) (Fig. 69.2). Additionally, chronic alcohol increased SKM matrix metalloproteinases (MMPs), which can lead to pathologic remodeling of the ECM [42].

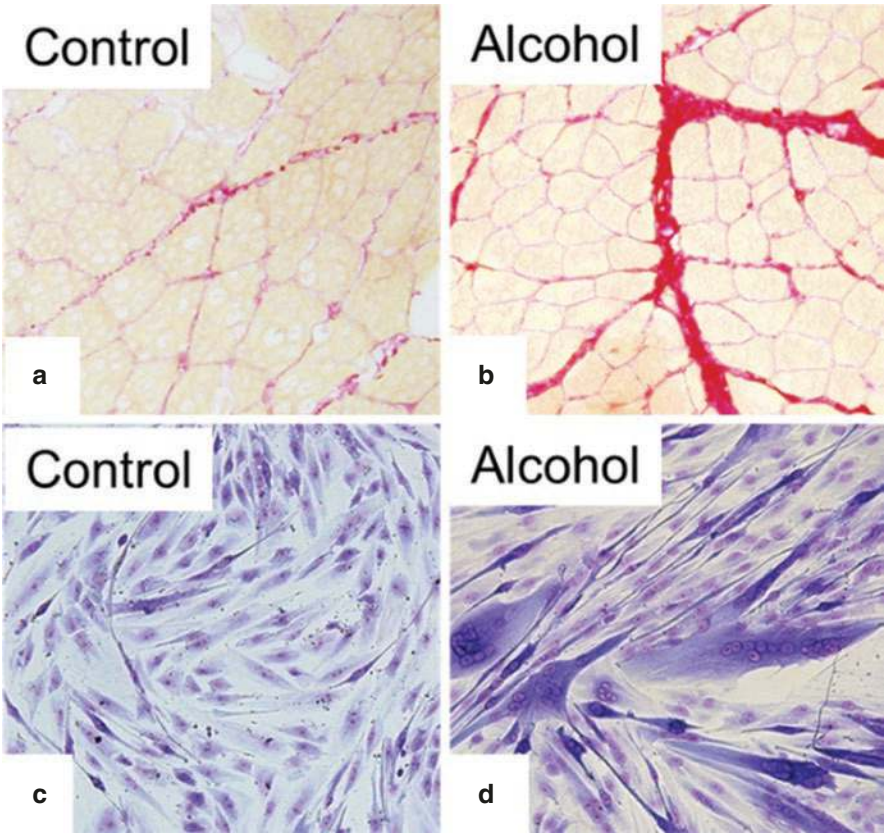

Fig. 69.2 Collagen content in skeletal muscle. Representative images of picrosirius red staining of quadriceps muscle in (**a**) Control (**b**) chronic alcohol fed rats. Representative images of Jenner-Giemsa staining of ex vivo differentiation of myoblasts isolated from (**c**) control (**d**) chronic in vivo alcohol administered nonhuman primates

Alcohol-Associated Decrease in SKM Regenerative Capacity

SKM has an exceptional regenerative capacity allowing it to replace loss or damaged tissue. SKM loss can occur with prolonged periods of disuse or damage that can occur routinely through exercise, or in the case of trauma or surgery. About 2–5% of nuclei in adult SKM are from satellite cells (SCs). SCs are quiescent stem cells that when activated can proliferate and differentiate in response to muscle injury. Impaired SKM regenerative capacity can also contribute to alcohol-associated loss of SKM functional mass. SCs express Pax7 and Myogenic factor 5 (Myf5) until activated to myoblasts, which express Myod and myogenin. Myoblasts are myogenic progenitor cells that can fuse with each other or damaged muscle fibers to regenerate the muscle tissue. Typically, muscle injury results in the recruitment of neutrophils followed by proinflammatory macrophages that secrete TNF-α,

interleukin 1β (IL-1β), and interferon γ (IFN-γ). This acute proinflammatory environment activates SCs and increases myoblast proliferation. Two to four days after injury, anti-inflammatory macrophages are recruited that secrete IL-4 and IL-10, which promote myoblast differentiation [57]. However, a chronic inflammatory state or increased oxidative stress can interfere with this physiologic process. While acute alcohol has anti-inflammatory effects, chronic alcohol exposure promotes a proinflammatory environment [58, 59] that can interfere with appropriate SKM regeneration [41]. These effects of alcohol on regeneration are evident in preclinical models where alcohol-fed mice have increased *Tnf*α 2 days after injury and fail to recover muscle fiber cross sectional area 2 weeks after injury [41]. Additionally, alcohol-fed rats have reduced expression of *Myod* 3 days after hind-limb immobilization [40] suggesting impairments in SC activation. Similar effects are reported in nonhuman primate models where CBA decreased myogenic gene expression and myoblast differentiation [45] (Fig. 69.2). Taken together, these data support a contribution of impairments in SKM regenerative capacity to reductions in functional SKM mass that accompany at-risk alcohol use.

Alcohol Decreases SKM Function

SKM must generate enough adenosine triphosphate (ATP) to meet energy demands. ATP in SKM is generated through creatine phosphate, glycolysis, and oxidative phosphorylation. The ability of SKM to uptake glucose from the blood is not only necessary for the generation of ATP but important in maintaining whole-body glucose homeostasis. Thus, any impairments in SKM glucose utilization have the potential to significantly affect SKM bioenergetics and functional homeostasis. Preclinical models suggest that alcohol impairs insulin-mediated glucose uptake likely through a decrease in GLUT4 translocation [60]. Furthermore, *in vitro* ethanol (50 mM) reduced glycolytic function while increasing oxygen consumption rate in primary rhesus macaque myoblasts suggesting a shift from glycolysis to oxidative phosphorylation and this was associated with decreased myoblast differentiation potential [48]. Whereas, ethanol (100 mM) decreased basal, ATP-linked, maximal respiration, and spare respiratory capacity [61, 62]. Chronic alcohol negatively impacts mitochondrial dynamics, and SKM mitochondria are larger in alcohol-induced muscle injury [2, 3, 50]. In people living with HIV, proton leak is higher in myoblasts from those with high Alcohol Use Disorders Identification Test (AUDIT) scores [63]. Additionally, CBA dysregulated mitochondrial gene expression and decreased myoblast mitochondrial respiration in SIV infection [51, 52]. Together, these reports strongly suggest a significant role for altered bioenergetics and mitochondrial dysregulation in alcohol-associated loss of functional SKM mass. Despite associations between alcohol use, myoblast bioenergetics, myoblast differentiation, and dysglycemia, the exact mechanisms for the decrease in functional SKM mass seen with alcohol-induced myopathy and its contribution to metabolic dysregulation are yet to elucidated.

Adipose Tissue Is a Target of Alcohol-Induced Tissue Injury

Adipose tissue (AT); together with SKM, the liver, and the pancreas, plays a vital role in regulating whole-body energy and glucose homeostasis. AT can be classified as brown, beige or white. Brown adipose tissue has high levels of mitochondria and is involved in energy expenditure. Beige adipose tissue is a mix of white and brown adipose tissue and is also involved in heat generation and energy expenditure but to a lesser extent than brown adipose tissue [64, 65]. White adipose tissue (WAT), considered an endocrine organ releases biologically active adipokines and cytokines and contribute to maintaining whole body energy homeostasis [66]. WAT tissue is classified based on anatomical location as either visceral AT or subcutaneous AT.

In rodents, chronic alcohol consumption decreased overall AT mass and adipocyte size [27]. In humans, chronic at-risk alcohol consumption is associated with decreased total adiposity [67] but increased visceral adiposity [68]. The elevated waist-to-hip ratio resulting from increased visceral adiposity is associated with worse metabolic clinical outcomes [69]. The alterations in AT mass and distribution associated with at-risk alcohol consumption are thought to result from alterations in lipid metabolism, impaired adipose ECM remodeling, adipose tissue inflammatory milieu, and/or impaired adipose tissue secretory phenotype (i.e., adipokines) as discussed in the next section.

Alcohol Dysregulates AT Metabolic Function

AT is central to lipid homeostasis and has a modest contribution (about 10%) to insulin-stimulated whole body glucose uptake/storage [70, 71]. AT mass is maintained by a balance between lipogenic and lipolytic pathways that predominate during the fed and fasted states, respectively. Alcohol directly and indirectly alters the balance of lipogenesis and lipolysis, dysregulating lipid homeostasis (Fig. 69.3, Table 69.1).

Accretion of AT mass involves lipogenesis from dietary triglyceride (TG) uptake and *de novo* lipogenesis from acetyl-coenzyme A (acetyl-CoA). In addition, glucose can be metabolized to glycerol 3-phosphate and participate in the synthesis of TGs. Alcohol regulates several components of the lipogenic pathway. Alcohol decreases AT expression of peroxisome proliferator- activated receptor gamma (PPARγ or PPARG), one of the most potent lipogenic stimulators [27, 28, 72]. Activation and binding of PPARG and CCAAT-enhancer-binding protein alpha (CEBPA) is central to the activation of adipogenesis. Chronic alcohol decreased CEBPA expression in rodent visceral AT, but not in subcutaneous AT or in 3T3-L1 cells [28]. Lipoprotein lipase (LPL) enables adipocyte lipoprotein uptake and hydrolysis to two free fatty acid (FA) molecules and one monoacylglycerol. Reports on the effects of alcohol on LPL expression and activity are incongruent, with some showing increased [73, 74],

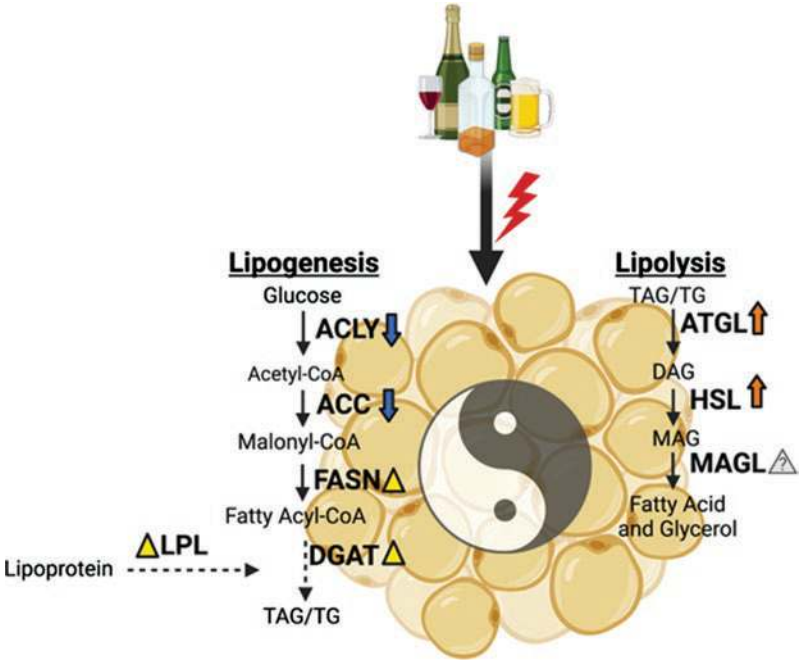

Fig. 69.3 Alcohol alters the balance of lipogenesis and lipolysis in adipose tissue. Alcohol decreases lipogenic enzymes, ATP-citrate lyase (ACLY) and Acetyl coA carboxylase (ACC). Alcohol is shown to increase, decrease or not affect fatty acid synthase (FASN), diacylglycerol acyl transferase (DGAT), and lipoprotein lipase (LPL) expression (Δ). Alcohol increases lipolytic enzymes, adipose tissue triglyceride lipase (ATGL), and hormone sensitive lipase (HSL) expression. These alcohol-mediated dysregulation of lipid homeostasis contributes to alcohol-related liver disease

decreased [75], or unchanged [76, 77] patterns. These differences may be attributable to dose and route of alcohol administration, experimental model, or tissue type.

A major hormonal regulator of AT homeostasis is insulin. Insulin stimulates FA and glucose uptake into adipocytes. Glucose participates in the lipogenic pathway via downstream oxidation to acetyl CoA or glycerol-3-phosphate. Several of the enzymes responsible for glucose conversion to a fatty acid substrate are modulated by alcohol. Before glucose is converted to fatty acyl-CoA (FA-CoA), it must undergo glycolysis to pyruvate and conversion to acetyl-CoA by ATP-citrate lyase (ACLY), which is decreased by alcohol in visceral AT but not in subcutaneous AT or in primary adipocytes [28]. The conversion of acetyl-CoA to malonyl-CoA is catalyzed by acetyl-CoA carboxylase (ACC), the rate-limiting enzyme of lipogenesis. *In vivo* alcohol decreased ACC stimulatory phosphorylation at Ser79 [30, 75]. Additionally, activity of AMPK, which is responsible for ACC phosphorylation, is also decreased with chronic alcohol [30, 78]. Activation of AT AMPK can also inhibit both basal and stimulated lipolysis, thus this alcohol-mediated decrease in AMPK activity may also lead to increased lipolysis. The conversion of

malonyl-CoA to FA-CoA in preparation for assembly of a TG molecule is catalyzed by fatty acid synthase (FASN). There is conflicting evidence of alcohol's effect on AT FASN expression or activity, including decreased FASN in visceral, but not in subcutaneous AT [28, 72]. Finally, after the conjugation of FA-CoA molecules to a monoacylglycerol (MAG) or glycerol-3-phosphate molecule, diacylglycerol acyl transferase (DGAT) catalyzes the addition of the last FA-CoA to form the full TG molecule. DGAT expression is either unchanged or decreased by chronic alcohol in visceral AT of mice [79]. Overall, most reported studies suggest alcohol decreases several lipogenic regulatory enzymes. These effects appear to be alcohol dose- and route-dependent, depot-specific, and model-specific.

Lipolysis occurs during times of starvation or extreme energy demands and AT mobilizes TG stores to release glycerol and FA for hepatic glucose production and SKM fatty acid oxidation, respectively. Chronic alcohol stimulates AT lipolysis and there is an associated increase in FA release [33, 80]. Circulating levels of FA may not directly reflect increased release from AT, because of lipid deposition in the liver, a likely mechanism involved in the pathogenesis of liver steatosis [27]. Beta-adrenergic receptor stimulation by sympathetic nervous system activation is a potent activator of lipolysis, while insulin inhibits the lipolytic pathway. Early studies provided evidence that epinephrine-stimulated lipolysis in rodent visceral AT was not affected by alcohol [81]. Additionally, studies provided evidence that alcohol diminished the inhibitory actions of insulin [82]. These data provided the foundation for later studies that revealed that alcohol's ability to increase lipolysis was principally attributable to insulin inhibitory effects [33, 83]. As with lipogenesis, there are also several regulatory checkpoints in the lipolysis pathway that are affected by alcohol. Activation of the beta-adrenergic receptors mediate an increase in intracellular cyclic adenosine monophosphate (cAMP) and chronic alcohol increased AT cAMP levels [77, 84, 85]. Activation of PKA by cAMP phosphorylates proteins involved in lipolysis, including perilipin and hormone sensitive lipase (HSL). Once phosphorylated, perilipin undergoes a conformation change allowing for lipid droplet hydrolysis by HSL. Additionally, PKA phosphorylates HSL at the Ser660 to increase its activity and remove fatty acids from TG to form a MAG molecule. Chronic alcohol increased phosphorylation, activity, or mRNA expression of HSL [27, 34, 35] and increased adipose tissue triglyceride lipase (ATGL), the principal rate-limiting enzyme in lipolysis, which catalyzes the removal of the first fatty acid forming DAG [27, 28, 34]. Insulin suppresses lipolysis by two main mechanisms: (1) phosphodiesterase-3B (PDE3B) activation and (2) protein phosphatase 1 (PP1) activation. Insulin decreases PKA activity by increasing PDE3B activity, a downstream mediator of the insulin signaling cascade. Activation of PP1 leads to the dephosphorylation of HSL and inhibition of lipolysis. Chronic alcohol does not affect PDE3B mRNA or protein expression in rodent visceral AT or visceral adipocytes [33]. However, chronic alcohol decreased PP1 phosphorylation in rodent visceral AT, while upregulating phosphatase and tension homologue (PTEN) and suppressor of cytokine signaling 3 (SOCS3) expression, major negative

regulators of insulin signaling [27]. Collectively, these data strongly suggest that inhibition of insulin signaling is a key mechanism underlying alcohol-induced adipose tissue lipolysis.

Alcohol Dysregulates AT ECM Remodeling

The AT ECM is composed of a complex network of fibrillar and non-fibrillar fibers that provide structural support and aids in differentiation, migration, and survival for normal tissue homeostasis. ECM fibers in the AT are not produced by one specific cell type but rather a combination of adipocytes and stromal cells, such as immune and progenitor cells [86]. Collagen is the most abundant AT ECM fiber and provides structural support for cellular functions [87]. Despite evidence indicating that ECM is an essential factor in maintaining tissue homeostasis and development of pathology (i.e., fibrosis), little is known about AT ECM physiology and pathophysiology. In the SIV-infected macaque model, CBA increased collagen content in omental AT, a visceral AT depot [38] (Fig. 69.4). To date, this is only study that has investigated alcohol's effects on AT ECM content. However, evidence from studies in other disease models indicate that AT fibrosis is a common pathophysiological response to tissue injury. For example, clinical studies show increased omental AT fibrosis in obese subjects compared to other adipose depots and compared to lean subjects [88–91]. Similarly, HIV and SIV increased AT collagen deposition and impaired ADSC differentiation in humans and cynomolgus macaques [92].

Alcohol Increases AT Inflammation

The alcohol metabolizing enzyme CYP2E1, is expressed in both visceral and subcutaneous AT [28, 93] and its expression is increased by alcohol [46, 94]. CYP2E1 mediated increased oxidative stress and increased endotoxins induce the expression of proinflammatory cytokines such as TNF-α, IL-6, and monocyte chemoattractant protein-1 (MCP-1), which directly contribute to the alcohol-induced inflammatory milieu in AT [43, 44, 46, 47]. CYP2E1 knockout mice show attenuated alcohol-induced increase in adipose pro-inflammatory cytokine expression, suggesting a role for the CYP2E1 axis in mediating adipose inflammation with alcohol [46]. Additionally, CBA in TLR4 knockout mice attenuated alcohol-mediated accumulation of proinflammatory AT macrophages [95]. In humans, AT inflammatory cytokine production is correlated with acute alcohol-related hepatitis [43]. Alcohol also induces a reversible shift in AT macrophage towards a M1 pro-inflammatory phenotype. One week of alcohol withdrawal alleviated macrophage infiltration in subcutaneous AT and transitioned AT macrophages toward a M2 anti-inflammatory phenotype [44]. In the SIV-infected macaque model, CBA increased immune cell infiltration in omental AT [38] (Fig. 69.4). Additionally, a role for lymphatic vessel hyperpermeability was revealed as a likely mediator of alcohol-induced

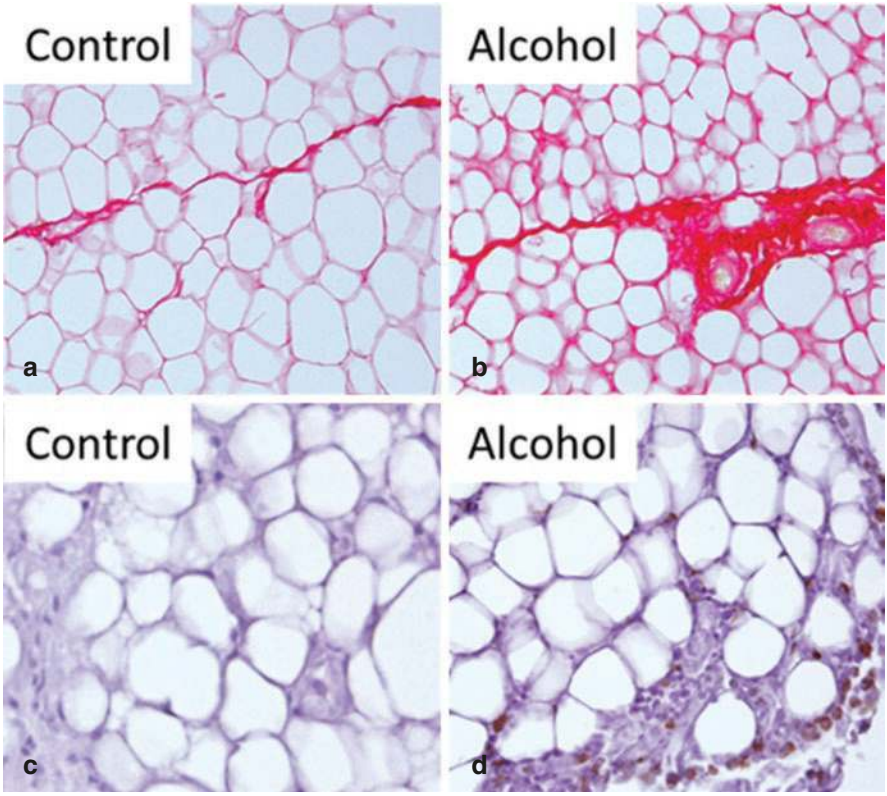

Fig. 69.4 Collagen content and immune cell infiltration in omental adipose tissue. Representative images of picrosirius red staining in (**a**) Control (**b**) chronic binge alcohol administered non-human primates. Representative images of HAM56 (macrophage) staining in (**c**) control (**d**) chronic binge alcohol administered non-human primates

inflammation in perilymphatic and mesenteric adipose tissue [96]. The effects of alcohol on AT hormonal, inflammatory, oxidative stress, and ECM environment significantly impact on AT homeostasis. The increasing reports of secreted factors as mediators of interorgan communication, strongly suggest this may play a role in multi organ alcohol induced tissue injury.

Skeletal Muscle and Adipose Tissue as Relays of Alcohol-Induced Tissue Injury

The maintenance of whole-body energy homeostasis relies on effective inter-organ communication. In the early 1900s, hormones were first identified as chemical messengers that allowed for communication between tissues, and more recently other mechanisms of intercellular communication such as cytokines and extracellular vesicles (EVs) have been recognized. Cytokines include growth factors,

interleukins, and interferons that are mostly secreted by immune cells. Adipocytes and muscle fibers also secrete cytokines (i.e., adipokines and myokines, respectively) into the extracellular space and impact neighboring and distal target cells. The importance of interorgan communication is highlighted in physiologic conditions of fasting, feeding, thermogenesis, and exercise [97] and likely contributes significantly to alcohol-related pathologies.

EVs are membrane bound nanoparticles that transport proteins, lipids, mRNA, and non-coding RNAs from the originating cell to a target cell are involved in intercellular communication. Their protective membrane prevents nucleases and proteases from degrading the bioactive cargo making them an effective vehicle for delivery. Three types of EVs have been identified: apoptotic bodies, microvesicles, and exosomes. These subtypes are difficult to distinguish experimentally so the term EV is preferred. Apoptotic bodies are released from cells undergoing apoptosis. Microvesicles directly bud from the cell membrane, a process which is initiated by translocation of phosphatidylserine to the outer leaflet of the cell [98]. Exosome biogenesis on the other hand, starts with the formation of an endosome. Intraluminal vesicles are formed through the invaginations of the endosome. These invaginations are created through either endosomal sorting complex required for transport (ESCRT)-dependent or ESCRT-independent mechanisms. The ESCRT-dependent pathway requires several ESCRT complex proteins including tumor susceptibility gene 101 (TSG101) and Alix that are often found associated with exosomes [99]. In the ESCRT-independent pathway, sphingomyelinase catalyzes the formation of ceramide from sphingomyelin to initiate the inward budding of the endosome. Once intraluminal vesicles are formed, the endosome is called a multivesicular body. Rab27a/b proteins along with actin, annexins, and tubulin transport the multivesicular body and allow for fusion to the cell membrane [98]. Once fusion occurs, the intraluminal vesicles are released into the extracellular space as exosomes.

Many of the studies on alcohol-mediated dysregulation in intercellular communication are in the context of liver disease. For example, the increased secretion of TNF-α from immune cells with at-risk alcohol use contributes to hepatocyte injury [100]. Additionally, patients with alcohol-related hepatitis have increased circulating EVs [101], and EVs from alcohol-treated hepatocytes can sensitize monocytes and contribute to alcohol-mediated liver damage [102]. Despite compelling evidence that SKM and AT secrete cytokines and tissue specific factors that are implicated in interorgan communication, there is a gap in the literature on how alcohol modulates these factors and thus affect metabolic regulation. Here we briefly discuss the existing literature on SKM and AT as relays of interorgan communication and how alcohol regulates these factors.

Mechanisms of SKM Communication

Myokines can directly act on a wide range of tissues including metabolic tissues such as AT, the liver, and pancreas. IL-6; the first myokine discovered, is released during exercise [103], increases lipolysis in AT, increases hepatic glucose

production, and stimulates pancreatic β-cell proliferation [104]. Two other myokines; irisin and fibroblast growth factor 21 (FGF-21), are secreted by SKM and contribute to the browning of white adipocytes and induction of thermogenesis [105]. Myonectin is another myokine released in response to glucose and fat intake and increases free fatty acid uptake into AT by increasing expression of fatty acid transporter proteins [106]. In addition to having direct metabolic effects on distant organs, myokines modulate immune cell function and the anti-inflammatory effects of exercise are at least partially mediated by increased IL-6, that has been shown to reduce TNFα secretion from endotoxin-stimulated monocytes *in vitro* [104].

SKM-derived EVs; positive for the membrane marker α-sarcoglycan [107], account for approximately 5% of circulating EVs [108]. Exercise transiently promotes the release of EVs into circulation [107, 109] and miRNAs in myotube-derived EVs silence genes in target myoblasts and promote myoblast differentiation [110]. Additionally, satellite cell EVs downregulate MMP-9 expression in myotubes [111] and Wnt-inducible signaling pathway protein 1 (Wisp1) expression in fibroadipogenic progenitor cells [112] during mechanical overload allowing for an ECM environment suitable for muscle hypertrophy. In addition, SKM EVs containing miRNA-1 can target AT and suppress transcription factor AP-2, a repressor of adrenergic receptor β3 expression, thereby affecting lipolytic gene expression [113]. Additionally, SKM-derived EVs from high palmitate diet fed mice affect pancreatic β-cell development *in vitro* [114]. While numerous studies suggest that SKM-derived EVs can be taken up by other metabolic cell types, most of this work is limited to *in vitro* studies. SKM EVs are believed to be mostly taken up by the liver and spleen and can also be found in the pancreas and other tissues [114].

Alcohol's effect on SKM communication mechanisms is not well characterized. Circulating levels of myokines such as IL-15 and TNF-α are higher in people with alcohol use disorder (AUD) [115, 116]; however, it is unclear if muscle is the main source of these cytokines. Additionally, brain-derived neurotrophic factor (BDNF), which is increased in muscle following exercise, is reduced in circulation in people with AUD and correlates with muscle strength [117]. And while we know SKM cells release EVs, how acute or chronic alcohol modulates EV release, and their paracrine or endocrine function is not known.

Mechanisms of AT Communication

Alcohol's produces marked alterations in adipokine levels. Adiponectin, a well-known insulin-sensitizing and anti-inflammatory adipokine [118] also has protective effects on pancreatic β-cell proliferation, apoptosis, and insulin secretion. Most preclinical studies show that chronic alcohol decreased circulating adiponectin levels [49, 119, 120]. Decreased adiponectin protein and mRNA in visceral AT [49, 119] and subcutaneous AT [33] can lead to deleterious effects on SKM and impair hepatic lipid metabolism [121]. Reports from clinical studies are incongruent. Some clinical studies report increased adiponectin levels with alcohol consumption [122–124], while others have shown a dose dependent decrease [125]. Leptin, another

important adipokine is secreted in direct proportion to AT mass and regulates several processes including food intake, energy expenditure, lipolysis, lipogenesis, and insulin sensitivity [126, 127]. Leptin protein levels in rodent visceral AT are reported to be increased [128] or unchanged [129] with chronic alcohol administration. Similar discordant effects of alcohol are reported for circulating leptin levels, with studies reporting decreased [130], increased [131] or unchanged [128] circulating concentrations in animal models and humans. Thus, the effects of alcohol on leptin are inconsistent and may be related more to changes in fat mass than direct effects of alcohol on leptin synthesis. The impact of chronic alcohol on resistin levels has not been extensively investigated. One study has shown chronic alcohol feeding in rats increased serum resistin and visceral AT resistin mRNA levels [132]. Another study showed higher resistin levels among alcohol-related liver disease patients compared to healthy controls [133]. Much remains to be characterized with respect to the effects of at-risk alcohol use on adipokine release. However, it is unlikely that alterations in adipokine release may be solely responsible for distant organ pathophysiology resulting from at-risk alcohol use.

An alternative mechanism through which adipose-secreted mediators impact on distant tissue pathophysiology is through the release of EVs [134, 135] containing bioactive cargo including adiponectin, perilipin A, FABP4 and miRNAs, proteins and mRNA [136]. Adipocyte-derived EVs mediate paracrine communication between adipocytes and macrophages inducing M1 pro-inflammatory macrophage polarization through a miR-155 mediated mechanism in high fat diet fed mice [137]. Adipocyte-derived EVs also modulate metabolic regulation through their effects on SKM, liver, and the brain. EVs derived from AT macrophages of obese mice showed a direct effect to impair insulin signaling in hepatocytes and myocytes, possibly through miR-29a, which targets PPARG [138]. Similarly, the effects of adipocyte-derived EV miR-27a to induce insulin resistance in SKM are also attributed to its suppression of PPARG [139]. EV miR-130b target muscle cells and reduce the expression of its target gene, PPARγ coactivator 1α (PGC1α), which plays a key role in lipid oxidation and mitochondrial function [140]. Adipose derived EV mir-155 also affects pancreatic β-cell proliferation and insulin secretion [141]. Alcohol-fed mice have an adipocyte EV profile that differs from control mice [142], though the functional effect of these EVs has not been studied. Alcohol-mediated AT lipolysis and TG release can be reverse transported to the liver [27] demonstrating a role in adipose-liver crosstalk in alcohol-induced liver disease. Studies are warranted to fully understand the alcohol-mediated direct effects on adipokine profile and function, changes in EV bioactive cargo and function and its contribution to metabolic homeostasis.

Concluding Remarks

This chapter has largely focused on the contribution of skeletal muscle and adipose tissue to alcohol-mediated metabolic dysregulation; however, additional mechanisms significantly contribute to alcohol's damaging effects including that of the pancreas and liver. SKM and AT are targets of alcohol-induced cellular injury that contribute to dysregulation of metabolic processes (glucose homeostasis, protein balance and lipid metabolism), increased aberrant extracellular matrix remodeling, bioenergetic adaptations, and impaired differentiation ability of muscle and adipose derived progenitors. The diet composition, nutrient availability, gut microbiome, and its metabolites, all add layers of complexity to alcohol-induced end organ injury and metabolic dyshomeostasis. We now know that SKM and AT function as relays through the secretion of soluble factors and EVs. We speculate that these mechanisms of interorgan communication are disrupted with at-risk alcohol use contributing to alcohol-associated pathologies. Understanding the mechanisms of release and targeted uptake of EVs, the naturally occurring vehicles carrying multiple types of mediators warrant special attention and extensive investigation. There is a gap in the literature on how alcohol modulates SKM and AT EV biology, despite compelling evidence of EVs from both these tissues playing critical roles in metabolic homeostasis. Integrating multiorgan multiomics to identify mediators of interorgan communication and modulation by alcohol will provide insight of target cells, transporters, receptors, and signaling pathways that are differentially regulated, and can potentially provide therapeutic targets for alcohol-related metabolic dysregulation. Alcohol-mediated cellular injury of metabolically active tissues potentially synergizes with the obesogenic environment including diet, and sedentary lifestyle behaviors significantly increasing the risk of cardiometabolic and liver disease. Thus, research integrating these complex networks of factors are imperative to reduce health care burden and improve quality of life among people with at-risk alcohol use.

Chapter 70
Alcoholic Cardiomyopathy: Pathogenic Aspects

Joaquim Fernández-Solà

Abstract In susceptible individuals, chronic ethanol consumption may cause progressive myocardial damage leading to alcoholic cardiomyopathy (ACM). This progressive effect of ethanol on the myocardium is dose-dependent, worsens with binge-drinking and is modulated by gender, race and some genetic polymorphisms (acetetaldehyde dehydrogenase 2, angiotensin-converting enzyme). Ethanol has synergistic myocardial damaging effects with other drugs (tobacco, cocaine) and other comorbid diseases (arterial hypertension, cirrhosis, malnutrition, vitamin deficiencies or ionic disturbances). At the molecular level, ethanol may damage several myocyte structures including membrane phospholipid composition, ionic receptors and channels, disturbs intracellular [Ca^{2+}] transients and damage sarcomere structural proteins disturbing excitation coupling and contractile function. The main histological lesions in ACM include myocyte apoptosis and necrosis causing myocytolysis and cell loss, which repair mechanisms compensate for by inducing myocyte hypertrophy and interstitial fibrosis. This limited remodeling process is regulated by cardiomyokines and growth factors (myostatin, IGF-1, FGF21, Metrnl). The final process of ACM is the result of ethanol dosage and individual predisposition and the prognosis depends on the degree of persistence in ethanol intake and the equilibrium between damage *vs* repair mechanisms. New strategies to minimize ethanol-related cardiac damage, avoid pathological myocyte hypertrophy and interstitial fibrosis and improve myocyte regeneration are addressed.

Introduction

Alcoholic Cardiomyopathy—ACM—*(2020 ICD-10-CM Diagnosis Code I42.6)* is the disease manifestation of long-standing and additive deletereous efects of ethanol- ethanol- (also referred to as "alcohol" in this chapter) on the heart myocites in susceptible subjects [1–6]. In fact, this disease originates from the sum of repeated acute ethanol binge-drinking effects in addition to the persistence of chronic long-standing direct and indirect effects of ethanol and its metabolites on the myocardial tissue [7, 8]. Genetic, racial and gender factors as well as other comorbidities [9–12] and polytoxic misuse, spetially tobacco and cocaine [13, 14], can influence the course and intensity of ACM [6, 8].

In the case of the heart, the potential beneficial effects of low-dose alcohol on coronary artery disease and mortality coexist with the detrimental effects on the myocardium induced by the dose-dependent damaging effect of ethanol intake [15]. In view of the coexistence of other ethanol-related diseases (liver cirrhosiscirrhosis, dementia, arterial hypertension) with ACM, it would be recommendable to avoid any degree of alcohol consumption [16]. In addition, low-dose ethanol may increase the risk of cancer, neurological brain damage, and alcohol addiction [16–18], and therefore, even low-dose consumption should be discouraged in the general population. Accordingly, the only safe ethanol dose for the cardiovascular system is zero [6, 19], making it necessary to establish a balance in relation to alcohol counseling [15, 20].

At present, ACM should not be considered an isolated or independent disease, but rather as a part of systemic damage induced by ethanol misuse in a specific subject [8, 17]. In this sense, the presence of other alcohol-related comorbidities (i.e. liver cirrhosiscirrhosis, malnutrition or skeletal myopathy) is frequent and influences the presence and worsens the course of ACM [14, 21, 22]. In fact, the myocardium is one of the most susceptible targets of long-standing effects of ethanol and is involved in most of comorbidities produced by alcohol consumption.

Thus, ACM is more prevalent in alcohol misusers with other alcohol-related diseases such as liver cirrhosis than in those without [9, 22].

Recently, a new perspective in ACM has appeared due to the description of novel pathogenic mechanisms [8, 15, 23, 24]. It has been clear that ethanol not only damage myocytes but also is able to impair their repair mechanism, disturbing some local and also systemic cardiomyokines (CMK) and growth factors [25]. This produces a lower rate of myocyte repair mechanisms and diminishes adaptative mechanisms. In addition, it has recently been reported that alcohol consumption also alters the myocyte regenerative process, causing an additive and synergic damage [26, 27].

This review describes and discusses the global effects that ethanol exerts on the heart myocytes, and specifically, the so-called ACM, in relation to the description of new pathogenic data. More clinical data on ethanol and heart failure are provided in Chap. 71.

Historical Perspective of Alcoholic cardiomyopathy

Alcohol has been consumed as different beverages by almost all civilizations in human history. Therefore, the toxic deleterious effects of alcohol misuse on the heart have been recognized since ancient times [28]. In fact, in Greece, in the IVth century B.C, Hippocrates observed and described the development of "hidropressy", the equivalent of congestive heart failure in individuals with chronic high alcohol consumption. In these individuals, Hippocrates recommended complete avoidance of alcohol consumption, establishing the first documented treatment on ACM. After this early clinical observation, no other references appeared related to ACM until the nineteenth century. To the contrary, alcohol was usually recommended as a heart tonic beverage. At this time, detailed clinical descriptions in Germany and England reported the development of progressive congestive heart failure in beer drinkers. Otto von Bollinger described the "Munich beer heart" with fibrosis, hypertrophy, and fatty degeneration in postmortem cardiac tissue of alcoholics who consumed more than 400 liters of beer per year [29]. Curiously, in this period, it was suspected that this noxious effect was not related to alcohol itself but rather to beer contaminants as arsenic or beer additives, especially cobalt which was used as anti-foam agent. Similarly other etiological causes of ACM were proposed, with the hypothesis of vitamin deficiencies, especially thiamine in the context of occidental beriberi [30], selenium deficit, ionic (Na^+, K^+, P^{4+}, Mg^{++}) disturbances or nutritional deficiencies [31]. Until the second part of the twentieth century there was no scientific evidence of a clear and direct relationship between alcohol consumption and myocardial damage, leading to ACM in a dose-dependent manner related to the lifetime dose of ethanol consumed [32, 33]. In fact, it has been determined that the minimal cumulative dose of pure ethanol necessary to achieve ACM is 10 kg ethanol/kg body weight, but usually ranges from 20 to 30 kg ethanol/kg body weight.

More recently, specific groups of major susceptibility have been described, spatially in relation to race, ethnicity, gender, metabolic polymorphisms and genetically-mediated variants and the co-existence of other collateral factors for the development of ACM [12, 14, 34]. The consumption of other toxic substances such as tobacco or

cocaine in addition to alcohol has additional deleterious effects in ACM [35, 36]. ACM is not considered as an isolated disease, but is rather part of ethanol-related systemic damage and a consequence of the global biological response [9, 17, 37]. Similarly, the progressive pathogenic mechanisms of ACM have been described at a structural, biochemical and molecular level, improving our pathomechanistic understanding [8, 27]. Looking towards the future, new strategies to prevent and treat or minimize this disease are currently evolving [25, 38].

Epidemiology of Alcoholic cardiomyopathy

Alcohol is the sixth most relevant factor of global burden of disease and responsible for 5.3% of all deaths [39]. The global alcohol-attributable fraction (AAF) of cardiovascular (CV) death based on alcohol exposure measures (AAFs) is estimated 6.9% (95% CI: 5.4–8.4%). Alcohol is responsible of 21–36% of all cause of idiopathic dilated cardiomyopathy (CMP) [40]. In active alcohol consumers, the prevalence of clinical ACM ranges from of 0.25% in men to 0.43% in women (global mean 0.34%). Considering 10% of global population with excessive alcohol intake, the global number of subjects with ACM worldwide in 2020 was 2,650,000. These numbers would double if subclinical ACM were taken into account [41]. In clinical settings evaluating high-dose chronic alcohol consumers, the prevalence of subclinical left ventricular (LV) diastolic dysfunction is 33% [42] while that of systolic dysfunction usually with overt LV heart failure 13% [32].

The global mortality attributable for ACM per year is 41,400 subjects/year (range 16,200–27,900, 95% CI). The population-weighted mean crude ACM mortality rate was estimated at 8.4 deaths per 1,000,000 (95% CI: 7.4–9.3). The number of daily adjusted life years (DAYLYs) attributable to ACM in 2016 was 897,000 (corresponding to 9.7% of all alcohol attributable DAYLYs in CV disease). In a chronologic overview, comparing civil registries with 2015 data and the Global Burden of Disease 2020 study, a 3.71-fold increase in ACM mortality was observed, although there may be some gap in this estimation. The increase in ACM is related to the absolute rate of global alcohol consumption and not to changes in the disease itself [41].

Despite the clear epidemiological evidence demonstrating that ethanol consumption is not safe and increases health risk, consumption policies are not sufficiently effective [16, 43]. The need to establish more effective control of ethanol consumption is discussed elsewhere in this book [41, 44].

Natural History of Alcoholic cardiomyopathy

Due to the relevant genetic, gender and ethnic predisposition, the course of ACM is different according to each individual and medical care should be individualized [11, 45, 46]. ACM may develop though consumption of any type of alcohol

beverage such as beer, wine or spirits and has a linear dose-dependent relationship with the total lifetime dose of ethanol (TLDE) consumed by an individual [32, 47]. In global terms, the natural history of ACM begins with an asymptomatic phase in people from 35 to 55 years of age, predominantly in men [2]. Diastolic dysfunction is detected by echocardiography or magnetic resonance spectroscopy in one third of alcohol consumers with a TLDE >10 kg ethanol/kg body weight [42]. If the TLDE progresses, systolic dysfunction appears and is clinically relevant when the left ventricular ejection fraction (LVEF) is <50% [2, 5, 15]. During this period, around 20% of women and 25% of men with excessive alcohol consumption develop exertion dyspnea and orthopnea, leading to episodes of LV failure [48]. The clinical characteristics of LV failure in ACM are similar to other causes of LV heart failure such as idiopathic dilated CMP [49]. Signs of right ventricular or congestive heart failure with lower limb oedema or anasarca appear later in the course of the disease [5, 50, 51]. In addition, a diversity of arrhythmias may develop, atrial fibrillation being the most frequent [52] and ventricular tachycardia the most dangerous [50]. Arrhythmias are first related to episodes of binge drinking in the scenario of the holiday heart syndrome and also in end-stage disease causing sudden death [1, 53, 54]. In this stage, cardiac thrombi may appear as a rare but ominous finding [55]. More detailed characteristics of heart failure in ACM are discussed in book Chap. xxx of this book.

In alcohol misusers with ACM the most important prognostic factor is the maintenance of active ethanol consumption [56–58]. In patients with persistent alcohol intake >60 g/day, the reduction in the LVEF is maintained, leading to episodes of heart failure and arrhythmias, and frequent sudden death [51, 53, 59]. In contrast, in most patients with ACM who are able to achieve abstinence, the LVEF improves and returns to normal values (LVEF >50%) in half of the cases. Similarly, with complete abstinence, early LV diastolic dysfunction reverses within 6 months [60]. In individuals who are unable to achieve complete abstinence and maintain controlled drinking with a daily ethanol intake <60 g/day, the LVEF may improve, albeit to a lesser degree than individuals with complete abstinence. Therefore, while alcohol abstinence is the best goal, the LVEF can improve with controlled drinking (<60 g/day) in subjects unable to achieve abstinence [20, 57, 61]. Episodes of binge-drinking, defined as the consumption of four or more alcoholic beverages in women and five or more drinking in men in a period about 2 h [62], have been demonstrated to worsen the clinical course of ACM [63]. During binge drinking, alcohol blood levels reach 0.08 g or higher. QRS duration, systolic blood pressure, and New York Heart Association classification at admission provide independent prognostic information in patients with ACM [58].

Moderate alcohol drinking, considered as the consumption of 10–40 g /day in women (1–3 standard drinks) and 20–60 g/day (1.5–4 standard drinks) in men, is usually not considered cardiotoxic unless it is consumed over a large period of time, usually more than 10 years [2, 15, 64]. In fact, moderate alcohol consumption in healthy individuals has been related to lower risk of development of heart failure [2, 65]. However, it should be avoided in presence of other causes of cardiac disease (i.e. hypertensive, or valve disease), other systemic-related effects of ethanol or in the presence of alcohol use disorder or dependence [6, 66].

Other factors Influencing Alcoholic Cardiomyopathy

In addition to the direct effects of ethanol that can explain around 60% of the global effects in ACM [48], other factors may have a relevant influence on the development of ACM.

Gender

The absorption, distribution and metabolism of alcohol are clearly different in women compared to men [67–69], resulting in higher ethanol blood levels at the same ingested dose of ethanol and inducing a major propensity to myocardial damage). Functional proteomic analysis reveals sex-dependent differences in structural and energy-producing myocardial proteins in rat model of alcoholic cardiomyopathy [70]. In the follow-up of progressive ethanol intake, the decrease in LVEF over time is 30% steeper in women than in men [48]. This indicates that with the TLDE consumed, the prevalence of ACM in women is higher than in men [48, 68]. In has been described that women with heart failure due to ACM consume a significantly lower TLDE tan men [71], which would explain the greater susceptibility of women to the myocardial toxic effects of ethanol compared to men [48]. In ACM, there are also sex differences in certain co-occurring conditions among men and women. Women with ACM experienced more anxiety and depression tan men [72]. Pregnancy is a period were alcohol consumption should be discouraged because the high prevalence of fetal alcohol syndrome that may also involve heart diseases [73].

Ethnicity

Although ACM has been described in all races and ethnicities, racial predisposition to ACM is more prevalent in Asian and black people than in Caucasians [45, 74]. Acetaldehyde dehydrogenase 2 (ALDH2) gene mutations that increase the risk of developing ACM are present in around 50% of East Asians, with 40% being homozygous. This represents around 8% of the global world population with increased ACM risk [75, 76].

Genetic Polymorphisms

The involvement of dilated CMP-related genes has also been reported in ACM [11, 12]. ACE (angiotensin converting enzyme) gene polymorphism also influence ACM development. Alcoholic consumers with the ACE "*DD"* genotype presented a 16-fold excess risk of developing alcoholic CMP compared to the other *"ID* "or "*II*

“variants [77]. Carriers of the truncate variant of titin, a structural protein related to ventricle distensibility, are more susceptible to ACM development and are also associated with a worse LVEF [78]. Enzymatic polymorphisms in ALDH2 have been described to modulate the incidence and course of ACM [69, 75]. These individuals have ineffective acetaldehyde detoxification mechanisms and present with the clinical phenotype of Asian-alcohol facial flushing and tachycardia after alcohol consumption (see also book chapter within this book xxxx). They should completely avoid alcohol consumption because of the influence of ALDH2 polymorphism variants in mitochondrial ALDH2 alcohol metabolism during which toxic acetaldehyde is oxidized [76].

Malnutrition

The presence of protein or caloric malnutrition, vitamin deficiencies, especially thiamine deficiency causing beriberi heart disease [30] and ionic disturbances (Na^+,K^+,Ca^{2+}, Mg^{2+}) may interfere with and aggravate the course of ACM [6, 79]. Therefore, this should be avoided in order to improve ACM symptoms and prognosis. Correction of these deficiencies may help to stabilize the course of ACM and avoid acute heart failure or episodes of arrhythmia [6, 80].

Other Drugs

Co-abuse of alcohol with tobacco and cocaine increases global myocardial damage and the intensity of ACM and accelerates disease progression (13 ,35, 36,81, 82). In fact, two third of ACM patients are active smokers. Tobacco may act at the same targets as ethanol such as mitochondrial oxidative stress and apoptosis [13, 35, 36, 81, 82]. In the context of persistent polytoxic drug consumption, the global effect in ACM is clearly detrimental.

Other Systemic Effects of Ethanol

The presence of alcohol-related cirrhosis, malnutrition, chronic pancreatitis, peripheral neuropathy, skeletal myopathy, dementia of arterial hypertension can negatively influence the course of ACM [17, 22, 37, 66, 79]. This is due to the global and synergistic effect that ethanol exerts on the development of ACM e.g. water retention in cases of liver cirrhosis [6, 9]. Obesity is unusual in ACM (<5% of cases) and has no relevant synergistic effect on ACM. In contrast to alcohol-related liver damage, alcohol-dependent iron overload in the myocardium has not been shown to be relevant in ACM.

Ethanol Induction of Functional and Structural Myocardial Damage

Both in clinical and experimental studies, ethanol has been demonstrated to induce an immediate negative and dose-dependent effect on myocyte contractility [83, 84]. Over longer periods of time, ethanol also not only decreases contractility of myocytes but also increases excitability causing arrhythmias [24, 27, 34, 64, 85]. Episodes of binge-drinking are especially damaging in the course of the disease [62, 63]. The pattern of alcohol consumption is also more relevant than the type of alcohol consumed [7, 86]. Both the sum of acute, repeated intake and the duration of chronic abuse are likely to contribute to disease progression [1, 15].

Since ACM usually appears in middle-aged adults in the third to the fifth decades of life, it is assumed that a minimum period of time (>10 years) is necessary for the clinical development of this disease [1, 2]. Similarly, a minimum cumulative dose of ethanol is necessary to develop ACM [32]. Combining both factors, the minimum TLDE per kg of body weight necessary to develop of ACM is 7 kg ethanol/kg for women and 10 kg ethanol /kg for men. However, patients with overt ACM have usually consumed more than 25 kg ethanol/kg over a period longer than 25 years [15].

The first functional signs of ACM in these patients is the echographic detection of LV diastolic dysfunction in asymptomatic alcohol consumers [42]. This is evident by the presentation of echographic parameters of a mitral valve filling pattern (E/A ratio, the deceleration time of the E wave, the early and late velocities of the mitral annulus measured by tissue Doppler, the left auricular volume, the pattern of pulmonary vein flow, and the duration of reversed flow into the pulmonary veins during atrial contraction) [87]. Diastolic dysfunction usually precedes detection of systolic dysfunction. LV diastolic dysfunction may appear at TLDE as low as 5 kg/ethanol/kg of body weight [15]. Mirijello et al. [60] described altered E/e' ratio as characterization of early-ACM before the occurrence of other relevant echocardiographic alterations.

Among individuals who continue ethanol consumption, on third may develop LV systolic dysfunction, usually detected by echocardiography with a reduction in the LVEF lower than 50%. At this time episodes of LV heart failure may appear within a clinical spectrum similar to idiopathic dilated CMP [2, 5, 88].

At the histological level, this subclinical period may be accompanied by myocyte hypertrophy and oxidative LV damage and pro-apoptotic activation mechanisms. Myofibre size variability and disarray is one of the most relevant initial features of ACM [21, 89] (Fig. 70.1). As the disease progresses, focal necrosis of myocytes appears with increased oxidative damage and the development of nuclear apoptotic phenomena. This causes progressive myocytolysis and final myocyte loss that may involve more than 30% of the global myocardium [21, 90].

Advanced cases of ACM have evident variability of fibre-size with some presenting massive hypertrophy [91], as well as active myocyte necrosis and fibrosis that starts at the subendocardial level and progressively appears in the myocardial

interstitium. In advanced cases, fibrosis may occupy more that 30% of the histological myocyte fraction [21, 92, 93] (Fig. 70.2).

In early stages of ACM, the deleterious effects of ethanol causing acute LV depression are reversible within hours or few days in subjects able to completely suppress ethanol intake [94, 95]. This acute reversibility is not present in advanced stages.

End-stage LV failure is defined as a LVEF <20%. The clinical situation is repetitive episodes of congestive heart failure, with oedema and anasarca [2, 50]. Arrhythmias are also frequent in this period, being atrial fibrillation the most frequent and ventricular extrasystole and tachycardia the most dangerous [52, 85]. At a histological level, diffuse fibrosis appears, substituting the death myocytes, which may be macroscopically evident with cardiac enlargement and focal scars together. In this phase, heart transplantation is the only effective measure, but is limited to subjects who achieve complete alcohol abstinence [96]. In long-term follow-up studies in ACM, mortality is related to progression of heart failure and the development of malignant arrhythmias [1, 85]. In this period, mortality is high (>10% patient/year) in the group of subjects withe persistent high-dose ethanol consumption >60 g ethanol/day.

In the course of ACM it is also important to determine the coexistence of other heart risk factors such as malnutrition, vitamin deficiencies, tobacco or cocaine consumption, and the presence of uncontroled diabetes mellitus, arterial hypertension and hypercholesterolemia that can further impair the course of ACM [6].

Pathophysiological Mechanisms in Alcoholic Cardiomyopathy

Ethanol and its metabolites, especially acetaldehyde and its protein adducts, produce a diversity of toxic effects on heart myocytes, most of which act in synergistic manner [8, 24, 34, 64, 97]. Figure 70.3 shows 14 different multiple-site ethanol targets in cardiac myocyte. These targets include modification of membrane composition and structure [98], disruption of ion channels and receptors [35, 83], interference in second messenger cell receptors [35, 99, 100], disruption of protein synthesis and composition [101], cytoskeletal structure and inter-cellular connections [100, 102], a reduction in cell energy mechanisms (mitochondria, carbohydrates) and the induction of pro-oxidative effects [7, 103]. All these processes disrupt myocyte excitation/contraction (E/C) coupling mechanisms and induce myocyte autophagy leading to progression to apoptosis and structural and functional cardiac myocyte damage with final cell loss [93, 104–106].

In experimental models of acute ethanol exposure, this damaging effect of ethanol is dose-dependent and reversible within minutes in the absence of ethanol [83, 107]. The direct effect of ethanol consumption on the myocardium accounts for 60% of the global risk to develop ACM. This is a long-standing and dose-dependent cumulative effect [32, 48]. These cummulative effects usually appear in subjects with a long-life consumption greater than 7 kg of ethanol per kg of body weight in men and 5 kg of ethanol per kg of body weight in women [15, 48]. The combination of the direct and indirect ethanol effects with other toxins, especially with tobacco and cocaine, or other additional risk factors (ethnicity, gender, ALDH2 or ACE gene polymorphisms) render ACM highly diverse [6, 10].

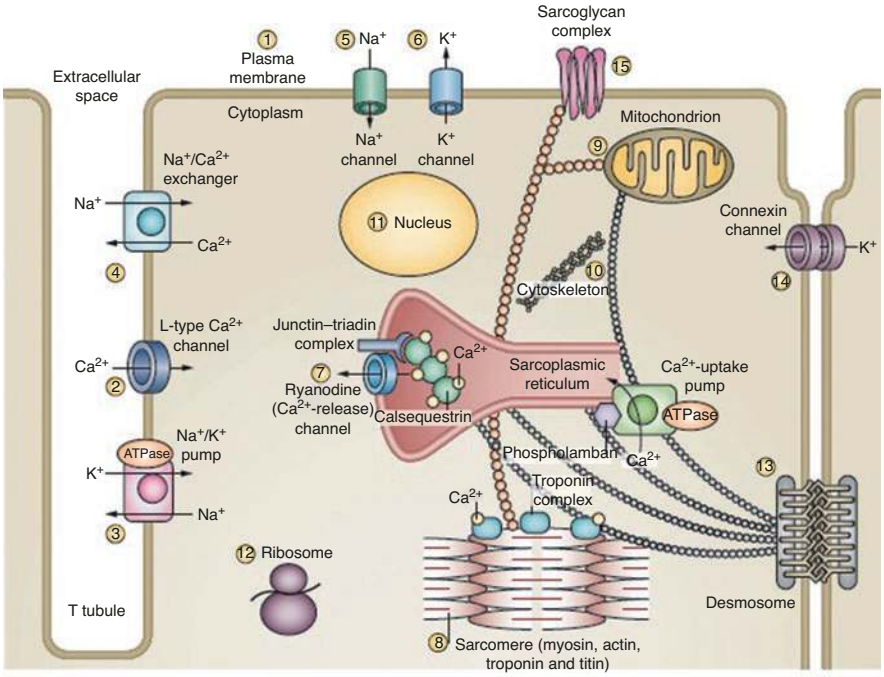

Fig. 70.3 Effects of ethanol on cardiomyocyte structure and organelles. Cardiac myocytes are excitable cells with complex signaling and contractile structures, and are highly sensitive to the toxic effects of alcohol on: (1) plasma membrane composition and permeability, signaling, and activation of apoptosis; (2) L-type Ca2 + −channel activity; (3) Na+/K+ ATPase channel activity; (4) Na+/Ca2+ exchanger activity; (5) Na + channel currents; (6) K+ channel currents; (7) ryanodine (Ca^{2+}- release) channel activity; (8) sarcomere Ca2+ sensitivity, excitation–contraction coupling, myofibrillary structure and protein expression; (9) several aspects of mitochondrial function, including respiratory complex activities; (10) cytoskeletal structure; (11) nuclear regulation of transcription; (12) ribosomal protein synthesis; (13) desmosomal contacts; (14) connexin channel communication; (15) sarcoglycan complex interactions. Permission obtained from Nature Publishing Group © Knollmann, B. C., Roden, D. M. A genetic framework for improving arrhythmia therapy. Nature. 2008;45:929–936

The coexistence of other cardiac risk factors in ACM such as arterial hypertension, and coronary or valve disease, is frequent, inducing an additional factor for increasing final myocyte damage [66]. The synchronic and multiple effects of ethanol on myocyte structure, energy production, oxidative stress, E/C coupling mechanisms, inflammatory response, and genetic control can explain the multiple-target synergistic effects of this substance [8, 14, 15, 34]. The combination of factors leading to cardiac damage demonstrates the need for personalized evaluation of the noxious effects of alcohol consumption and the development of ACM in each individual [14, 108].

Alcohol Damaging Effects on Myocytes (Table 70.1)

The Role of Acetaldehyde in Alcoholic Cardiomyopathy

Acetaldehyde is and active metabolite of ethanol oxidation, able itself to cause relevant cardiac toxicity and damage [109–111]. Lower quantities of this metabolite are produced in the heart compared as to the liver while systemic acetaldehyde production seems not to reach toxic heart concentrations [112]. At an experimental level, acetaldehyde directly impairs cardiac contractile function [113, 114], disrupts cardiac excitation-contraction coupling and promotes lipid peroxidation and oxidative damage [34]. Due to the evident direct cardiotoxic effect of both of these molecules [114], it is questionable whether cardiac damage is due to ethanol itself or to the effects of acetaldehyde [97, 111]. Elevated cardiac acetaldehyde exposure via alcohol dehydrogenase may exacerbate alcohol-induced myocardial dysfunction, hypertrophy, insulin resistance and endoplasmic reticulum stress [75, 115]. Acetaldehyde also activates a local myocardial renin angiotensin aldosterone

Table 70.1 Mechanisms of alcohol-induced heart damage

Mechanisms	Effectors
Interference with cell signaling and calcium transients	MAPK, TGF-β, PKC, PPARγ, MMPs, NF-κβ, PAI-1
Decrease in excitation-contraction coupling mechanisms	Intracellular $[ca]^{2+}$ transients, L-type Ca^{2+} channel
Induction of oxidative damage	ROS, SOD, acetaldehyde
Pro-inflammatory effect	IL-2, TNF-α, NF-κβ
Induction of apoptosis	FAS, TNF-α, TGF-β, Bax-Bcl-2, caspases 3,6
Induction of fibrosis	TLR-4, TGF-β
Protein-adduct formation	Protein-ethanol-adducts
	Malondialdehyde-DNA adducts
Disruption in protein synthesis	Decrease in ribosomal protein synthesis, actin, myosin, troponin, titin
Increased glycogen deposition	Glycogen synthase kinase-3β, PARP
Renin-angiotensin-aldosterone activation	Renin, angiotensin, aldosterone, p38 MAPK/Smad
Interference in hormone-growth factors	Myostatin, ghrelin, leptin, IGF-1
Interference in regulatory cardiomyokines	FGF21
Decrease in myocyte regeneration	Myostatin, IGF-1
Impairment of extracellular matrix turnover	Cytoskeletal structure, connexin channel, desmosome contacts
Imbalance between cardiac lesions/repair mechanisms	Cell apoptosis and necrosis increased myocardial fibrosis decreased myocyte regeneration

system [111]. In fact, both molecules are able to increase myocyte oxidative and metabolic damage, decrease structural protein synthesis and heart contractility, leading to myocate autophagy [34, 105, 114]. Another pathogenic effect of acetaldehyde is its interaction with proteins, generating protein-adducts that are highly reactive and may induce additional inflammatory and immunologic heart damage, including DNA damage [116]. With its multiple actions, acetaldehyde can influence the pathogenesis of ACM in addition to the direct effect of ethanol [34, 112, 116].

[Ca^{2+}] Transients, Sarcoplasmic Reticulum Activation and Sarcomere Contractile Damage

The most relevant function of cardiac myocyte is heart contraction. As an excitable cell, this myocyte contraction is mediated by (E/C) coupling mechanisms, regulated by transmembrane electrically-induced Ca^{2+}transients, followed by activation of the ryanodine L-Type Ca^{2+} receptors, with final activation of the sarcomere actin/myosin coupling that produces myocyte contraction [83, 84, 107, 117]. Ethanol may damage these myocyte contractile mechanisms in a dose-dependent manner at different levels [15, 24]. This first transmembrane transient step is modified by the effect of ethanol on the membrane composition bilayer, that modifies its composition, permeability, signaling and activation mechanisms producing a disruption of transmembrane electrically-induced Ca^{2+} transients [107]. This involves plasma membrane L-type Ca^{2+} channel activity, Na^+/K^+ ATPase channel activity, Na^+/Ca^{2+} exchanger activity, Na^+ channel currents and K^+ channel currents [98] (Fig. 70.3).

The second step is at the sarcoplasmic reticulum level, at which ethanol specifically alters the ryanodine L-type Ca^{2+} receptor (RyR), producing a dose-dependent down regulation of sarcolemmal Ca^{2+} release and sarcomere Ca^{2+} sensitivity [34, 99, 104]. There is induction of sarcoplasmic reticulum Ca^{2+} leakage by CaMKII-mediated pathways downstream from reactive oxygen species (ROS) [24, 103]. Finally, the sarcomere E/C coupling contractile mechanism is also affected [118]. Chronic ethanol consumption down-regulates myofilament Ca^{2+} sensitivity [34, 104] and depressed structural and non-structural heart protein synthesis and degradation [118, 119]. This effect, if persistent, induces sarcomere structural damage expressed as sarcomere Z-line distortion and disruption of sarcomere contractille pattern with focal myofibre dissolution, causing myocytolysis, cell vacuolization and fiber disarray [34, 103, 118]. Titin is a sarcomere complex protein early affected by ethanol exposition, and a reduction in this protein leads to impairment in sarcomere relaxation and LV distensibility [120–122]. As a consequence of this progressive damage, first subclinical and later clinically evident diastolic dysfunction develops [42, 60]. This is followed by damage of contractile sarcomere proteins such as myosin, actin and troponin, causing progressive functional depression of myocyte contractility, inducing progression to systolic dysfunction and overt heart failure [50, 106, 120].

In addition, this transient intracellular [Ca^{2+}] disturbance also involve other intracellular [Ca^{2+}]$^{-}$ dependent organelles, as in the case of mitochondria or ribosomes [123–125]. Myocyte adaptative responses to ethanol-mediated toxicity leads to an up-regulation of myocardial L-type [Ca^{2+}] channel receptors, the activity of which is decreased in the presence of ACM [99, 117].

Mitochondrial Oxidative Damage and Energy Disturbance

The myocardium maintains the persistent sarcomere contractions requiring a high energy supply. Therefore, it has been supposed that alcohol could exert his damaging effect on the mitochondrial energy supply system by disruption of oxidative control mechanisms and ROS production [10, 103, 125]. At an ultrastructural level, the mitochondria of chronic alcohol consumers show typical structural changes, having the appearance of being swollen, the presence of megamitochondria and distortion of inner cristae [106, 126, 127]. At the functional level, ethanol decreases the activity of Complexes I, II and IV of the mitochondrial respiratory chain and alters the myocyte oxidative pattern [10, 109, 110], leading to subsequent glycogen deposition and cytoplasmic lipid droplet accumulation. Dysfunction on the transition pore in the inner membrane is also a key point in the mitochondrial effects of ACM [123]. Ethanol may also induce a mitochondrial-dependent apoptosis pathway with Bax and caspase activation [123, 128].

Inflammation

The myocardium is sensitive to the inflammatory effects of ethanol and the persistence of systemic inflammation increases cardiovascular risk [129]. At low doses (<20 g per day), ethanol has anti-inflammatory effects but at high doses (>60 g/day) it has a pro-inflammatory effect [17, 27]. It has been hypothesized that the cardiovascular effects of ethanol are mediated, at least in part, by inflammatory mechanisms [17, 27, 129, 130].

Ethanol may induce diverse pro-inflammatory effects increasing the levels of C-reactive protein, interleukins, pro-inflammatory cytokines, tumor necrosis factor, decreasing serum concentrations of fibrinogen and IL-5 and changing the levels of inflammasomes [131]. Specifically, microRNAs related to inflammation increase after beer consumption and decreased after non-alcoholic beer consumption [132].

As a consequence of this inflammatory process, increased oxidative stress develops with nicotinamide adenine dinucleotide phosphate oxidase activation, and lipid peroxidation, with glutathione and superoxide dismutase depletion. This may cause an increase of endothelial nitric oxide synthase expression, as well as endothelial and myocyte dysfunction [27, 131–133].

Cardiac Hypertrophy and Remodeling

When myocardium undergoes is challenged by toxins such as ethanol, a global remodelling adaptation process is induced, making the myocytes relatively resistant to the toxic effects of ethanol [134–136]. To minimize or repair the toxic effects of ethanol, heart myocytes develop functional and structural compensatory mechanisms [4, 34, 134]. Structural myocyte hypertrophy appears in the early stages of ACM to avoid contractile myocyte depression [2, 106]. If the toxic effects of ethanol persist, the sarcomere contractile system and myofibrillary composition is altered and myocitolysis progressively develops, causing heart ventricle wall hypertrophy and compensatory ventricle dilatation. This induces a dose-dependent decrease of cardiac output, inversely related to the TLDE consumed by the patient [19, 137]. Cardiac hypertrophy increases cardiomyocyte size and mass, induces cardiac remodeling and it is a key factor in the transition from a normal to a pathologic heart [15, 91].

Myocyte Apoptosis and Autophagy

The development of cardiomyopathy of diverse origin is usually accompanied by active myocyte apoptosis, a situation that induces progressive myocyte loss and myocardial functional and structural damage [134, 138]. This is also the case of chronic high-dose ethanol consumption in both clinical [128] and experimental settings [101]. The presence of apoptosis may be assessed by TUNEL staining and immunohistochemistry and caspase activity [128].

Ethanol can induce myocyte apoptosis by different mechanisms [139, 140]. One mechanism is direct damage and permeabilization of the mitochondrial membrane transition pore by physiological calcium oscillations. This produces the release of pro-apoptotic factors (cytochrome c) from the mitochondrial inter-membrane space to the cytosol [7, 123]. Another mechanism is independent of the mitochondrial pathway [139] and occurs by an extrinsic pathway, which involves cell surface death receptors [126, 141]. It has also been described that a specific microRNA, miR-378a-5p, is involved in the stimulation of cardiomyocyte apoptosis through ALDH2 gene suppression [105, 142].

In parallel to this ethanol- dependent induced apoptosis, ethanol also has additional effects in inhibiting anti-apoptotic molecules such as BCL-2 [118, 128, 139]. Several growth factors [101] and CMK [24, 71] might regulate this ethanol –induced myocyte apoptosis. Although the percentage of apoptotic myocytes is relatively low in ACM, the combined effect of a persistent decrease of myocyte proliferation results in absolute cell loss and decreased cardiac contractility [95].

In addition to apoptosis and necrosis, autophagy has recently been described as a possible relevant mechanism in ACM [101, 105, 138, 143]. Autophagy is a physiological mechanism that is responsible for the removal of cell debris and

defective organelles. This process is essential to the maintenance of cardiac homeostasis in both physiological and pathological conditions. At present, few data are available in relation to the involvement of autophagy and the pathogenesis of ACM [8, 23].

Cardiac Fibrosis and End-Stage ACM

When the heart is submitted to persistent myocyte apoptosis or necrosis by chronic ethanol consumption, the myocardium attempts to activate repair and regenerative tissue damage mechanisms [4, 144]. However, the regenerative capacity of cardiac myocytes is low leading to ineffective repair mechanism [90, 140]. In addition to direct myocyte damage, chronic ethanol intake also significantly decreases the myocyte regeneration capacity and increases the myocardial fibrogenic process [2, 15, 92]. Some CMKs such as FGF21 may regulate this process of alcohol-induced cardiac fibrosis [124, 145]. Ethanol treatment directly promotes cardiac fibroblast activation by stimulating transforming growth factor (TGF)-β release from fibroblasts. Inhibition of the action of TGF-β decreases the fibrogenic effect induced by ethanol treatment [146]. This results in the progressive development of subendocardial and interstitial fibrosis that is more evident in advanced stages of ACM in which fibrotic tissue may replace more than 30% of the myocyte ventricular fraction [21, 106]. This fibrotic myocardial process reduces heart elasticity and contractile capacity [42, 50, 64].

In the setting of end-stage ACM, progression of ethanol-induced myocardial damage and blockage of the heart's plastic and repair mechanisms limit myocardial remodeling that is apparently ineffective in this chronic longstanding scenario [50, 90, 136]. This situation usually appears after more than 20 years of high- ethanol consumption, when the total lifetime cumulative doses of ethanol exceeds of 20 kg ethanol/kg body weight [2, 15] and at which time the myocardium has been submitted to major structural damage. The histological pattern of diffuse myocyte necrosis with significant myocyte loss is compensated by fibre and nuclei hypertrophy of the remaining myocytes. This myocyte loss is replaced by subendocardial and interstitial fibrosis, which is functionally less effective [21, 106]. In this scenario, individuals present an LVEF <15% and have developed frequent episodes of congestive heart failure and ventricular arrhythmias leading to possible sudden death [52, 53, 85]. At the time of advanced myocardial damage, these subjects normally also develop other systemic ethanol-related diseases [6]. Thus, liver cirrhosis, digestive tract and neurological lesions and psychiatric disorders are usually present. Indeed, this systemic involvement contributes to worsening the prognosis of the patient [37]. In this end-stage scenario, the mortality is higher than 30% per year, mainly in subjects who continue with ethanol consumption [2, 88, 147].

The Effects of Alcohol on Myocyte Repair Mechanisms

Repair mechanism are crucial to maintain a normal cardiac function over time [50, 136, 141]. Ethanol not only damages myocyte structure and function, causing apoptosis and myocyte loss, but also decreases and alters the myocyte repair mechanisms at different levels [26, 50, 90]. In this setting, alcohol consumption impairs cardiac adaptation and remodeling mechanisms and causes additional heart damage [6, 24].

Thus, the structural damage of sarcolemmal E/C proteins is difficult to be repaired in the presence of ACM due to the inhibition that ethanol produces in myocyte structural protein synthesis at the ribosome level [103, 118]. Hypertrophy of the myocytes may be a compensatory phenomenon in early stages but has a limited effect in advanced stages [106]. The myocyte regenerative capacity, that is usually low, is clearly decreased in the presence of ACM [26, 148]. These factors limit the plasticity and myocardial remodeling mechanisms, resulting in progressive myocardial damage, especially if alcohol consumption persists [57, 134].

The Role of Cardiomyokines and Growth factors in ACM

Cardiomyokines (CMK) are autocrine and paracrine proteins with systemic and local protective effect and play a relevant role in intercellular connectivity within the myocardium [124, 149, 150]. At present, more than 60 CMK are described, 30 of which are biologically relevant**.** CMK act as metabolic regulators in lipid and carbohydrate metabolism, having a relevant role in the control of obesity, diabetes mellitus, exercise tolerance and energy expenditure. They coordinate the interorgan cross-talk and they are also involved in the modulation of heart remodeling and have a regulating role in the alcohol-induced heart damage [124].

Recently, a new CMK (FGF21, Metrnl) and several growth factors (myostatin, IGF-1, leptin, ghrelin, miRNA, and rho-associated protein kinase- ROCK- inhibitors) have been described as being able to regulate cardiac plasticity and decrease cardiac damage, and improving cardiac repair mechanisms, respectively [26, 124, 145]. Their effect may explain different adaptative mechanisms in ACM and may be of potential therapeutic use [151].

With respect to **myocyte hypertrophy**, FGF-21 and Metrnl have a protective role against excessive cardiac hypertrophy [124, 145, 152]. Myostatin, a member of the TGF-β family, is a potent inhibitor of muscle and heart growth and mediator on alcohol-induced myocyte hypertrophy [26]. It controls cell cycle progression, arresting G1 phase and inhibiting myoblast proliferation and terminal differentiation. Myostatin has antihypertrophic effects and its disruption causes increased myocyte mass with hypertrophy and hyperplasia and increased satellite cell stimulation and myocyte regeneration. Ethanol up-regulates heart myostatin expression

[119]. In human myocytes, the expression of myostatin is higher in alcohol consumers with CMP compared to those without CMP or to non-alcoholic controls. This increase in myostatin expression in alcoholic CMP is significantly higher compared to other causes of CMP, as hypertensive CMP [26].

Myocte proliferation, evaluated with the Ki-67 proliferation index, increases in different causes of CMP (alcohol, arterial hypertension or idiopathic) compared to those groups without CMP, with ACM showing a lower increase in this proliferation response. This explains an antiproliferative effect of ethanol on cardiac myocyte regeneration [26, 153]. Ethanol increases the activity of myostatin [26] and decreases IGF-1 myocardial expression, leading to inhibition of myocyte proliferation [145]. Metrnl has a pro-proliferative effect [152] and alpha-lipoic acid has a robust anti-hypertrophic and anti-remodeling effect that is mediated by the inhibition of C/EBPβ [25].

With regard to **heart fibrosis**, ethanol consumption down-regulates IGF-1 activity, increasing heart fibrosis [145]. As a protective effect, FGF-21, IGF-1, Metrnl and TGF-β antagonists have antifibrogenic effect in ACM [25, 93, 146]. Pharmacological inhibition of soluble epoxide hydrolase ameliorates chronic ethanol-induced cardiac fibrosis by restoring autophagic flux [154]. The potential use of CMK to control ethanol-induced damage in ACM aims to control oxidative disruption, myocyte hypertrophy, interstitial fibrosis and persistent apoptosis and increase myocyte regeneration. However, these new strategies have not yet demonstrated their real effectiveness in clinical trials, require further evaluation, and are not still approved for clinical use [6, 153].

The final cardiac status in ACM will be the consequence of an equilibrium between the intensity of damaging effects and the possibility of defense, plasticity, regeneration, and adaptation in each individual [23, 134, 150]. Thus, ACM is the result of dosage effect and individual predisposition to myocyte damage and the capacity of heart repair mechanisms [46, 134]. In the future, gene testing will be most likely performed in order to predict and individualize the degree of alcohol-induced cardiac damage [2, 11, 12].

Complementary strategies to decrease alcohol-induced systemic subclinical organ damage, avoid other cardiovascular risk factors [17, 37, 44], and improve nutritional health with the Mediterranean diet and vitamin or ion deficiencies supplementation may improve prognosis in ACM [25, 80].

In summary, total lifetime alcohol consumption produces progressive cardiac myocyte damage and loss through apoptosis but also partially inhibits myocyte proliferation by means of cardiomyokine and growth factor regulation. The final result supposes an imbalance in myocyte homeostasis, with a net decrease in total ventricular myocyte mass and progressive ventricular dysfunction as well as structural damage leading to end-stage cardiac failure.

Future Trends in Alcoholic Cardiomyopathy

Since the prevalence of alcohol consumption is not decreasing in Europe, especially among teenagers and young people [155], the prevalence of ACM is not expected to diminish in the near future [156]. In fact, the total alcohol consumption per capita (15+ years) is expected to increase until 2025 in half of the regions of the World Health Organization [41]. Therefore, according to the global alcohol consumption rates in Europe, ACM cases are expected to rise in the next years due to the direct dose–dependent effects of alcohol consumption on ACM [15].

Taking into account the expected increase in the number of cases of ethanol-induced ACM in the future, preventive strategies are needed to minimize the damaging effects on health and these should be personalized with a multidisciplinary approach combining control of alcohol-induced systemic damage, as well as antiinflammatory, antioxidant, antifibrotic and antiapoptotic preventive measures [24, 25, 44, 108]. Nonetheless, treatment of alcohol-use disorders to achieve abstinence is among the main goals on managing ACM [16, 61]. Strategies to control alcohol consumption would be useful to minimize the global burden of disease by ACM [61].

On the other hand, alcohol consumers able to diminish ethanol ingestion to a controlled drinking situation (ethanol consumption<60 g/day), will develop less myocardial damage compared to those consuming higher ethanol doses [57, 157]. In addition, the use of CMK in subjects not able to achieve abstinence may potentially reduce ongoing myocyte damage and improve cardiac remodelling [25]. Improvement in myocyte protein synthesis and reduction in degradation may be modulated by Valsartan, an angiotensin receptor antagonist that inhibited the RhoA-ROCK2-MYL pathway in rat model of ACM, and contribute to improving heart function [25, 158].

Gene therapies, targeting a defective gene or transcript, or ameliorating a genetic insufficiency are currently under study and may modulate downstream faulty protein products affected in CMPs [12, 24, 38]. Thus, miRNAs have a role in the regulation of oxidative-stress induced apoptosis, and selected mRNAs have regulatory effects on target gene expression with potential therapeuthic use in the control of heart apoptosis and damage [159]. Different variants of stem-cell therapy have been studied in an attempt to improve myocyte regeneration, albeit with limited success to date [160–162]. Heart transplantation is the final step in patients with end-stage ACM [96], but alcohol abstinence is a necessary requirement and only a minority (<15%) of ACM patients undergo heart transplantation [50].

Chapter 71
Ethanol and Heart Failure: A Clinical Perspective

Adina Ionac

Abstract Ethanol consumption is the primary cause of alcoholic cardiomyopathy, known to affect only a fraction of drinkers. So far, it remains difficult to define a border between healthy and unhealthy alcohol ingestion either for risk of development of cardiac pathology or for worsening of pre-existing heart failure. The negative effects of ethanol on cardiac structures and function determines the decrease of systolic and diastolic left and right ventricular function and the clinical onset of heart failure. Diagnosis is primarily based on multimodality imaging and echocardiography. Ethanol has also an important role in arrhythmic complications, the most frequent and important being atrial fibrillation. However, it can also trigger life-threating arrhythmias or sudden cardiac death, especially in heavy drinkers or in binge drinkers. There is also evidence for other cardiac diseases influenced by alcohol such as coronary artery disease or systemic hypertension. On the other hand, controversies continue till today whether alcohol, in small quantities, has a cardioprotective or deleterious effect as improved lipid and glucose metabolism, anti-inflammatory effect, beneficial effect on endothelial function and lowered platelet aggregation have been reported.

Keywords Ethanol toxicity · Heart failure · Cardiovascular disease · Alcoholic cardiomyopathy · Multimodality cardiac imaging

Introduction

The cardiovascular system and the heart are probably the secondly most affected system by ethanol toxicity, after the gastrointestinal/ liver system [1, 2]. Cardiovascular disease is the leading cause of mortality in Europe (47%) and one of the main causes of death worldwide (31%) [3, 4]. It seems that in moderate

consumers there is a mild cardiovascular risk, while heavy consumers have a high risk for cardiovascular disease. Exact borders are still difficult to delineate. For more details on epidemiology and alcoholic cardiomyopathy (ACM), the reader is referred to the respective chapters in part I and this part of the book and Chap. 70.

Defining the Concepts

Moderate consumers are those people who drink 3–9 drinks/week, corresponding to less than 20-gram pure alcohol per day [3]. It seems that a moderate amount of ethanol ingestion is beneficial or associated with a low risk for cardiovascular disease [3, 5]. Heavy consumers are those people who drink more than 9–10 drinks/week [3]. They have a high risk for cardiovascular disease, such as: systemic hypertension (SHT), angina pectoris, arrhythmias, even life-threating arrhythmias, and sudden cardiac death (SCD), systolic and diastolic left ventricular (LV) and sometimes associated with right ventricular (RV) dysfunction and, finally, global heart failure (HF). Even rather moderate amounts of ethanol ingestion can affect the function of the heart, most frequently being directly toxic for the myocardium, causing toxic dilated cardiomyopathy (DCM) [1–3] with its complications, most of them arrhythmias, including life threatening ones, and sudden cardiac death [6]. Generally, small doses of ethanol ingestion do not cause cardiac disturbances, but can be dangerous in some groups of population, such as children, adolescents, or women.

Mechanisms of Ethanol Cardiac Toxic Effects

Ethanol causes myocardial damage through multiple mechanisms and affects both the systolic and/or diastolic left ventricular function. The mechanisms that may cause myocardial damage are discussed in more detail in Chap. xxx of this part of the book. Briefly, they include:

- Direct toxic ethanol effects on the myocardium
- Ethanol toxic effect through its metabolites (acetaldehyde and ROS)
- Deficiencies of vitamins, minerals, or electrolytes (magnesium, potassium), which sometimes occur in heavy drinkers and may affect myocardium function
- Other toxic substances which sometimes contaminate alcoholic beverages may damage myocardium (cobalt, arsenic).

Direct toxic effects of the ethanol on myocardium cells are well documented: the alteration of sarcolemma membrane function (which leads to the decrease of calcium in the sarcolemma reticulum, and the inhibition of the sarcolemma adenosine triphosphate-dependent Na/K pump) and an altered mitochondrial function (through the decrease of mitochondrial respiratory rate). These processes determine myofibrillar degeneration and progressive fibrosis [3].

Moreover, they increase extracellular protein synthesis, accumulation of collagen in the extracellular matrix and progressively lead to the extracellular fibrosis [3]. Finally, these modifications will determine the alteration of ventricular systolic and diastolic function, in other words, the clinic syndrome of heart failure will develop. Ethanol also impairs the coupling of the excitation/contraction system. It can favour the development of atherosclerotic plaques and vascular disease such as coronary, carotid or peripheric artery disease [3]. Ethanol consumption must be stopped once cardiac ethanol-related diseases are diagnosed [7, 8]. In most cases, the symptoms are ameliorated although the disease will never completely disappear.

Alcoholic Cardiomyopathy: Definition and Diagnosis Evaluation

The association between alcohol consumption and HF remains controversial: **alcoholic cardiomyopathy** (ACM) may appear in cases of heavy alcohol consumption, while moderate alcohol intake may be associated with a lower risk of HF [8]. Limited data are available regarding the period of alcohol consumption. Most authors agree that more than 10 years are required for developing ACM while the amount of alcohol consumption is still under debate. As compared to alcohol-related liver disease, there are also gender differences in alcohol consumption: women develop ACM and HF at smaller amounts of alcohol consumption than men, and also after a shorter period. The most prevalent form of ethanol-induced heart damage is Alcoholic Cardiomyopathy. It was first described in heavy drinkers and already gained first clinical recognition by Hippocrates [9]. Ethanol induces toxic cellular effects followed by repair mechanisms, cardiac remodelling, and progressive systolic and diastolic LV dysfunction. ACM depends on dosage and individual predisposition, while management and prognosis will focus on abstinence or at least on controlled drinking [9, 10]. As mentioned above, the risk of ACM is higher in women than in men (for any given lifetime amount of alcohol) [9].

The definition of **Cardiomyopathy** was established many years ago in European and American Societies of Cardiology position papers and has remained almost unchanged until now: Accordingly, cardiomyopathy is "*a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes that frequently are genetic*" [11]. Despite many classifications, all authors agree strongly to "Dilated Cardiomyopathy" (DCM) which is defined by the dilation and decreased systolic function of the left ventricle and/or the right ventricle [11, 12]. The genetic or acquired causes are multiple and there is a permanent debate for a new classification according to the aetiology. The toxic effects of alcohol on the myocardium are recognized as one cause of DCM.

ACM typically presents with exertional dyspnoea, orthopnoea and paroxysmal nocturnal dyspnoea, palpitations, and fatigue. Although decreased systolic function has been long thought as major reason for HF, it is been learnt that an impaired diastolic function occurs in one third of heavy drinkers with otherwise normal systolic function. In many patients, however, systolic and diastolic dysfunction coexist. The specific diagnosis is challenging, and multimodality imaging (MMI) is the best solution. There are many studies, guidelines and position papers, which review the current knowledge on MMI diagnosis in ACM and they can also be applied to ACM-HF studies [13–19].

Accordingly, ACM is considered a non-ischemic dilated cardiomyopathy. Among the available imaging modalities, **transthoracic echocardiography** (TTE) is the method of choice for these patients. The assessment of ventricular function is essential and TTE is the first line for the assessment of LV and RV systolic and diastolic functions. The assessment of systolic function should include conventional data. For LV global systolic function, the established parameters are ejection fraction (EF), shortening fraction and stroke volume. The EF is defined as the percentage ratio between stroke volume and LV end-diastolic volume with a normal value higher than 55%. Despite the many limitations of EF, its use is strongly recommended since most doctors with easily understand its significance and implications, regardless of their training and medical background. The European Association of Cardiovascular Imaging (EACVI) and the American Society of Echocardiography (ASE) recommend the EF evaluation in two-dimensional (2D) echocardiography by the modified Simpson's method of discs and not in M mode echocardiography [20]. Calculation of EF by M mode echocardiography was originally based on the, clearly wrong, assumption that LV is a cube. Calculation of EF by the modified Simpson's formula consider the LV is an ellipsoid and LV size is calculated based on several LV sections. Although closely meeting reality, the best evaluation of EF is obtained by three-dimensional (3D) echocardiography using full-volume acquisition. However, even using 3D-EF evaluation, there may be situations with normal EF despite clinical signs of heart failure. This can be due to a particular LV architecture: the disposition of the myocardial fibrils in two layers with an oblique arrangement. Consequently, the global contraction is the sum of all radial, longitudinal and circumferential contractions. Studies have shown that the longitudinal contraction is first reduced while the radial and circumferential contraction increase in a compensatory fashion a global contraction remaining normal.

The **EF** is a parameter which should describe the global contraction and myocardial movement does not necessarily mean contraction. The term "deformation" should be better used for such cases. The movement of a myocardium point has velocity in systole and diastole. Strain is a dimensionless parameter which describes the percentual change of a myocardial segment length. By convention, it has a negative value in systole (the myocardium is thickening) and a positive value in diastole (the myocardium is lengthening). The strain will describe better the LV systolic function because it can evaluate separately the longitudinal, radial and circumferential contraction or the global contraction taking into account all three. The strain rate is defined as the rate at which the myocardium deformation ocurs [21–24].

Strain parameters can by evaluated by Tissue Doppler Imaging (TDI) and 2D and 3D speckle tracking echocardiography (STE). TDI can measure the velocities of myocardial movement and can calculate the strain and the strain rate based on the differences in two points of myocardial movement velocities. A major limitation is the fact that it is a Doppler-derived method and, consequently, it is angle dependent. This is also the reason why it measures the longitudinal velocities, respectively the longitudinal strain and strain rate [23]. For longitudinal LV systolic function evaluation, the pulsatile TDI measures the systolic velocity (S′) and for LV diastolic function, it measures the diastolic velocities (E′ in early diastole, in the same time with transmitral E wave; A′ in late diastole, in the same time with transmitral A wave).

Speckle tracking echocardiography is a method which is based on registration of acoustic points (named speckles) movement during the cardiac cycle. In contrast to Doppler-derived methods, it is not angle-dependent [23, 24]. The longitudinal systolic LV function is described by global longitudinal strain (GLS), which has been shown to have a superior sensitivity for LV systolic function evaluation, and a superior prognosis for HF as compared to the classical parameter LVEF [25]. The normal value is 20 ± 2% [20].

The diagnostic criteria for DCM rely on the identification of a LVEF <45% and/or a fractional shortening <25%, in association with a LV end-diastolic dimension >112% predicted value corrected for age and body surface area. However, because of the limitations of LVEF, a correct evaluation of LV systolic function must be extended to more other parameters derived from TDI, 2D and 3D speckle tracking and 3D echocardiography (Table 71.1) [22]. Systolic (S′) velocity measured by TDI, and global longitudinal strain (GLS) evaluated by 2D speckle tracking are robust parameters for evaluation of LV systolic dysfunction [21–24].

According to the American Society of Echocardiography [26–28] and the European Association of Cardiovascular Imaging [29], the assessment of diastolic function should include a multiparametric evaluation. In the patients with low EF, transmitral diastolic flow pattern is usually enough to identify the presence and the

Table 71.1 Parameters of left ventricular function

Echocardiographic technique	Parameters
Conventional TTE (2D, doppler)	Ejection fraction Fractional shortening Stroke volume Myocardial kinetics
Tissue doppler	Velocity (S′ wave) Strain Strain rate

3D TTE	Ejection fraction Myocardial kinetics

2D two-dimensional, *3D* three dimensional, *TTE* transthoracic echocardiography

type of diastolic dysfunction [28, 29]. However, it should be verified by other parameters. Moreover, if the E/A ratio is ≤08 and E wave velocity > 50 cm/s or E/A ratio is between 0.8 and 2, it is mandatory to use other parameters for diastolic function evaluation [28]. The most important parameters are the values of early diastolic wave (E′) of mitral annulus movement measured by TDI, the E/E′ ratio, the left atrium volume index and tricuspid regurgitation velocity. The normal values are given in Table 71.2 while Fig. 71.1 shows an example of an evaluation of LV diastolic function in a patient with toxic dilatative cardiomyopathy and diastolic LV dysfunction. There are recommendations for other parameters as well such as: transmitral flow parameters (E wave, E/A ratio, E wave deceleration time and isovolumic relaxation time), the difference between transmitral A wave duration and pulmonary vein A wave duration, etc. (Table 71.2) [26–30].

The **right ventricular systolic function** should also be evaluated in patients suspected with ACM, and a low RV function is a predictor of high mortality [29]. The quantification of RV function is challenging due to its complex 3D shape [20, 31]. The most useful parameters are fractional area change (FAC) (normal value >35%), tricuspid annular systolic excursion (TAPSE) (normal value >17 mm), systolic (S′) velocity measured by TDI (normal value >9.5 cm/s), RV longitudinal strain measured by STE and EF measured by 3D echocardiography. In Fig. 71.2 there is an example of an evaluation of RV systolic function in a patient with toxic dilatative cardiomyopathy. Because all of these parameters have some limitations, a multiparametric evaluation of RV function is recommended [20, 31–33]. These parameters do not only have a diagnostic value, but are also prognostic. The RV longitudinal strain measured by STE seems to be the most valuable one, because it is angle independent and recent studies have shown its very good prognosis value [34–37].

Transthoracic echocardiography is considered the imaging modality of choice for mitral regurgitation severity and progression, which appears frequently secondary to mitral annulus dilation [38]. The evaluation must be also multiparametric and

Table 71.2 Parameters for left ventricular diastolic function [28, 29]

Echocardiographic parameter	Normal values
Transmitral E velocity	<50 cm/s
Transmitral E/A ratio	0.8–2
Septal annular E′ velocity (TDI)	>7 cm/s
Lateral annular E′ velocity (TDI)	>10 cm/s
LV E/ E′ (average of medial and lateral E′) ratio	<14
Left atrium volume index	≤34 mL/m^2
Transmitral A wave duration - pulmonary vein A wave duration	>30 ms
Tricuspid regurgitation velocity	≤2.8 m/s
Transmitral E wave deceleration time	160–240 ms
Isovolumic relaxation time	60–90 ms

TDI tissue doppler imaging

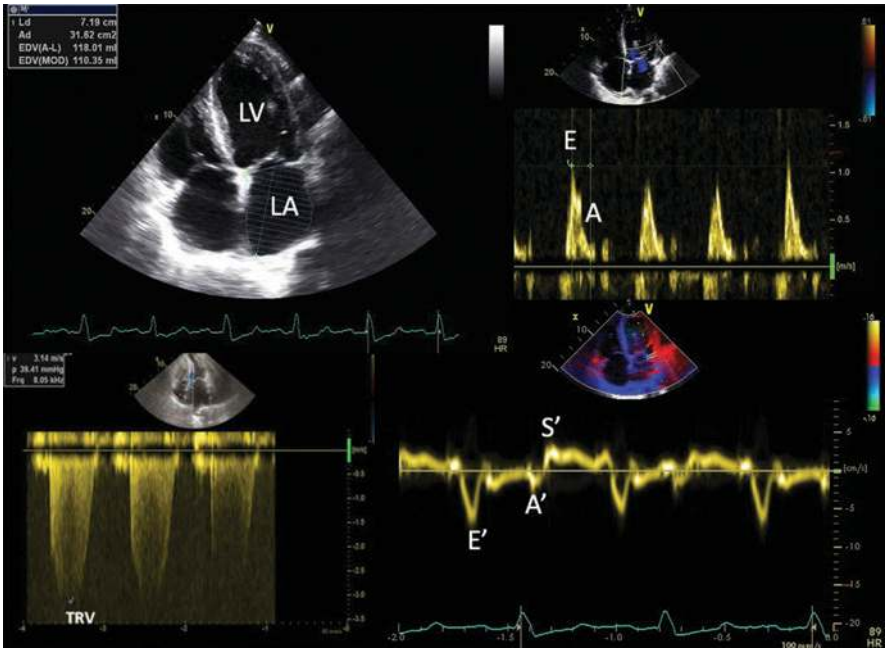

Fig. 71.1 Transthoracic echocardiographic evaluation of LV diastolic function in a patient with toxic dilatative cardiomyopathy. *LV* left ventricle, *LA* left atrium, *TRV* tricuspid regurgitation

integrative. The severity evaluation is the same as for the primary mitral regurgitation, but it must take into account that the stroke volume is generally lower due to the systolic dysfunction, so the values for severe mitral regurgitation parameters are lower. Generally, a regurgitant orifice ≥40 mm^2 and a regurgitant volume >60 mL/beat will define a severe mitral regurgitation [38]. In ACM, the severe mitral regurgitation can be described by lower values: a regurgitant orifice ≥30 mm^2 and a regurgitant volume <60 mL/beat, or ≥45 mL/beat if flow conditions are very low [38].

Transthoracic echocardiography is useful as well for estimating the presence and the extent of mechanical desynchrony in the failing heart, and therefore it can serve as an aid to patient selection for cardiac resynchronization therapy [38]. **Cardiac magnetic resonance imaging** (CMR) may help in the assessment of LV dimensions and function whenever image quality is suboptimal with echo. Global longitudinal strain determine by CMR is a better parameter for risk stratification in DCM, than EF, but there is not a cut-off value yet and the technique is not routinely recommended [39]. Assessment of RV size and function should be evaluated by CMR as well. CMR has also the unique ability to non-invasively characterize the morphology and structure of the myocardium, making it an excellent diagnostic tool to differentiate the aetiologies of DCM. It can also detect myocardial perfusion defects. For an optimum treatment, it is very important to differentiate between ischemic and non-ischemic aetiology and, here, CMR is the best tool [39]. The technique uses late gadolinium enhancement (LGE). It can describe the places of scars, fibrosis or inflammation. In patients with ischemic DCM, the LGE (which describes fibrosis) appears subendocardial or transmural, according to the extension of myocardial infarcts. In contrast, in patients with non-ischemic cardiomyopathy, the LGE is located in the middle of the myocardium, has a patchy distribution, or there is no LGE [40].

In the past, it was assumed that fibrosis dies not appear in ACM, however, this has changed recently. The presence and pattern of distribution of LGE in ACM and idiopathic non-ischemic DCM showed a different LGE localization, mostly septal in ACM and lateral in idiopathic non-ischemic DCM, with different prognostic impact [40–42]. Importantly, presence of fibrosis is an independent prognostic factor for both DCM and ACM, and for risk evaluation of cardiac arrhythmias and sudden cardiac death. Here, the native T1 mapping is a valuable technique for ventricular arrhythmia risk evaluation in these patients and it is used for intracardiac defibrillators implantation indications [43]. Extracellular volume CMR evaluation has been reported to also have a good prognostic value for major cardiovascular events and heart failure decompensation [44, 45].

It is possible to use nuclear imaging and **computer tomography** (CT) imaging to complete the MMI diagnosis in ACM, but they rarely provide more data, so they are not routinely used. Cardiac CT is useful to exclude coronary artery disease. In conclusion, MMI evaluation in ACM is very important to introduce the optimum treatment and follow-up it, but it is also very important to appreciate the risk for cardiovascular events, for complications and to establish the prognosis. The best markers for prognosis in ACM are:

- LV EF $\leq$ 35%
- RV EF < 45%
- Abnormal GLS (determined by TTE and CMR)
- Advanced diastolic LV ± RV dysfunction
- Significant mitral regurgitation (secondary; the organic cause must be excluded)
- Presence, extension and pattern of LGE
- High T1 and extracellular volume values (by CMR) [41].

HF and Alcohol Consumption

With regard to the association between HF and alcohol consumption, most available data have been published for alcohol intake in patients with known HF. Several studies have suggested that moderate drinking in patients with known heart failure do not cause acute deterioration of cardiac function. In patients with ischemic left ventricular dysfunction, light to moderate drinking was even associated with decreased all-cause mortality [46]. However, other studies clearly suggest that ACM heart failure treatment requires complete abstaining form alcohol [1, 9, 47]. It remains unclear so far, whether abstaining from alcohol in patients with severe HF and ACM will reverse disease progression. There are published data, however, that patients with LV systolic dysfunction and moderate alcohol consumption have a lower mortality risk as compared with abstainers [48]. Other studies concluded that both reduction of alcohol intake or complete abstinence had similar effects on LV systolic function (LVEF) [49, 50].

Currently, the debate continues whether patients with HF should be advised to abstain from alcohol drinking. Regarding the genetic predisposition for ACM, very few studies have explored genetic association and ACM. There is a report showing an association between alcohol dehydrogenase gene polymorphisms, alcohol consumption and myocardial infarction risk, but no studies have shown directly association with heart failure or ACM [47].

Association of Ethanol and Artery Disease

There are multiple mechanisms and factors that may explain how low alcohol intake protects against coronary artery disease. It is known that ethanol improves lipid and glucose metabolisms. For instance, low ethanol consumption increases HDL cholesterol and apolipoprotein A1 and lowers LDL cholesterol and C-reactive protein blood level. Ethanol has also been shown to improve insulin sensitivity by increasing adiponectin. Seemingly paradox as compared to liver effects, it also modulates inflammatory processes by decreasing the level of C reactive protein, interleukin 6, PAI–1 and fibrinogen. All these mechanisms lead to a decreased atherosclerotic risk and an improved endothelial function. Other favourable effects are the activation of the fibrinolytic system and lowering of the platelet aggregation. Taken together, all these effects will reduce the risk for clot formation [3, 47].

Beneficial effects have also been attributed to wine for a long time, via improved endothelial function, reduced inflammation, and through the action of antioxidants [50]. Non-alcoholic substances in wine such as flavonoids and resveratrol may also play an important protective role. Another study, published in 2018, suggested that wine consumption increases coronary artery plaque calcification which could stabilize the atherosclerotic plaque reduce the risk of myocardial infarction [51]. It should be noted, however, that the seemingly beneficial effects of alcohol by various

studies on the development of coronary artery disease have been obtained under conditions of low alcohol consumption [50].

Controversies exist on whether alcohol has a direct cardioprotective effect on the ischemic myocardium. According to some studies, heavy drinkers have a high risk for coronary artery disease. However, this could be the cumulation of various confounders such as systemic arterial hypertension, hypertriglyceridemia and other cardiovascular risk factors such as smoking. On the other side, in low alcohol level drinkers, a decreased risk for myocardial infarction has been repeatedly shown, also called "French paradox" [50]. Mukamal and collaborators studied alcohol habits in people free of major illness and with low cardiovascular risk. They found that mild to moderate alcohol consumption was associated with a low risk for myocardial infarction [50]. The beneficial effects low alcohol consumption seem also to vary between countries, depend on other habits and are often traced back to non-alcoholic ingredients such as antioxidants as mentioned above. At present, it is generally accepted, that the dose of alcohol intake but not the type (wine, beer, spirits) are important for the risk of cardiovascular events.

Association of Ethanol and Systemic Arterial Hypertension

Ethanol is a poor risk factor for systemic arterial hypertension and the underlying mechanisms are poorly understood. Several mechanisms are discussed such as an increased sympathetic activity, stimulation of the renin- angiotensin-aldosterone system, increased intracellular calcium level, increased vascular reactivity, release of vasoconstrictors or inhibition of nitric oxide production from the endothelial bed. It has been also suggested that ethanol increases the level of catecholamines, renin, cortisol and aldosterone which all may contribute to elevated blood pressure [47, 52]. On the other side, it has been established that development and maintenance of high blood pressure by alcohol is dose-related while completely abstaining from alcohol normalize pressure values [52, 53]. In the Framingham study, an increase of 7 mm Hg in mean arterial pressure has been observed in heavy alcohol drinkers [54]. However, rendering it more complex, other publications have shown that moderate alcohol consumption lowers blood pressure values [55, 56].

Association of Ethanol and Arrhythmias

Arrhythmic complications can always appear in HF and ethanol consumption is associated with a variety of atrial and ventricular arrhythmias, from ectopic beats up to ventricular life-threating arrhythmias. The most common ethanol-induced arrhythmia is by far the atrial fibrillation and a linear relationship between atrial fibrillation risk and the dose of alcohol has been described [54]. Ethanol can be

arrhythmogenic via several mechanisms which are described in more detail in the book Chap. xxx [47]. Briefly, these mechanisms include:

- Alcohol consumption in the presence of other predisposing factors such as cigarette smoking, electrolyte disturbances
- Increased diuresis with accompanied disturbances of electrolytes
- Myocardial fibrosis
- Ventricular hypertrophy
- Ventricular dilation
- Decreased heart variability
- Autonomic dysfunction

Many episodes of arrhythmia and frequent atrial fibrillation occur after binge drinking, usually at weekends or on holidays [57]. Regarding sudden cardiac death (SCD), an U-shaped relationship between the dose of alcohol intake and the risk this severe complication has been described [58–61]. An increased all-cause mortality has been observed at consumption levels higher than 30 g/day [58, 60]. Doll and collaborators [60] published in 1994 a study which followed-up 12,000 males for up to 13 years and looked at all-cause mortality and alcohol drinking. They reported that people who consumed less than 29 g/day pure alcohol had a lower all-cause mortality than people who consumed more than 30 g/day pure alcohol, but also lower mortality than people who consumed no alcohol. So, "too little or too much alcohol intake was associated with a higher risk of death than moderate intake of alcohol" [58]. A metaanalysis which included more than 84 studies showed a low risk for coronary artery disease, ventricular life threating arrhythmias and sudden cardiac death in people with low-to-moderate alcohol consumption (less than 60 g/day) [61]. Interestingly, alcohol's beneficial effects on SCD were independent of its source [58–60].

Conclusions

At a high dose (more than 60 g/day for men and 40 g/day for women) and chronic consumption (more than 10 years), alcohol increases the risk for atherosclerosis and the risk of coronary, cerebral, and peripheral vascular complications. At these levels, it also increases blood pressure values, causes progressive myocardial fibrosis and development of alcoholic dilative cardiomyopathy with subsequent atrial fibrillation (the most frequent complication) up to ventricular life threating arrhythmias and sudden cardiac death. In contrast, low doses of alcohol consumption have a dual effect on the cardiovascular system. They are beneficial against coronary artery disease but can cause tissue damage at moderate to high doses. Therefore, many authors consider that the only safe ethanol dose for the cardiovascular system are zero ethanol levels. Prospective, randomized trials remain to be initiated to exactly determine whether one drink per day (or perhaps one drink every other day) reduces mortality and major cardiovascular events.

Chapter 72
Wernicke-Korsakoff Syndrome

Alain Dervaux, Lisa Blecha, and Amine Benyamina

Abstract Wernicke-Korsakoff syndrome is a complication of thiamine (vitamin B1) deficiency, common in patients with alcohol use disorders. Up to 80% of patients with Wernicke's encephalopathy are undiagnosed and, thus remain untreated. This syndrome is classically described as a clinical triad consisting of confusion, ocular dysfunction (notably nystagmus and ophthalmoparesis) and ataxia. However, a minority of patients (16%) with Wernicke's encephalopathy present with the complete triad. According to the European Federation of Neurological Societies, the clinical diagnosis of Wernicke's encephalopathy in patients with alcohol use disorder requires two of the following signs: (1) dietary deficiencies, (2) ocular symptoms, (3) cerebellar dysfunction and (4) either an altered mental state or mild memory impairment. Wernicke encephalopathy is readily reversible if treated with adequate doses of parenteral thiamine, preferably within the first 48–72 h of the onset of symptoms. The overall safety of intravenous thiamine is very good.

When untreated, Wernicke's encephalopathy can lead to coma or death, or progress to Korsakoff syndrome. Korsakoff syndrome is chronic and may be irreversible. It is characterized by cognitive and behavioral symptoms, including anterograde and retrograde memory impairments, executive dysfunction, confabulation, apathy, affective and social-cognitive impairments. Cognitive rehabilitation, including memory compensation techniques, as well as long-term thiamine supplementation, are currently recognized in the treatment of Korsakoff syndrome.

Keywords Alcohol · Alcohol use disorder · Wernicke-Korsakoff syndrome · Wernicke's encephalopathy · Korsakoff syndrome · Memory · Thiamine · Thiamine deficiency · Vitamin B1

Introduction

Wernicke-Korsakoff syndrome includes two different syndromes, Wernicke encephalopathy and Korsakoff syndrome. First described by Wernicke in 1881, it is characterized by a triad of eye movement disturbances, ataxia, and mental confusion [1]. Wernicke encephalopathy is acute and often reversible whereas Korsakoff syndrome is chronic and potentially irreversible. Postmortem histological analyses have provided evidence that Wernicke's encephalopathy occurs in about 1% of the general population (between 0.4 and 2.8%) and in 12.5–35.0% of patients with alcohol use disorder [1–3].

Thiamine (Vitamin B1) Deficiency

Wernicke's encephalopathy and Korsakoff syndrome are caused by thiamine deficiency resulting from malnutrition. Over 90% of Wernicke's encephalopathy is reported in patients with alcohol use disorders. Wernicke's encephalopathy may also occur in patients with nutritional deficiencies resulting from hyperemesis gravidarum, intestinal obstruction, bariatric surgery, cancer chemotherapy, hemodialysis or malignancies [1, 4].

Thiamine is one of 12 water-soluble vitamins. It plays a significant role in the maintenance of the nervous system [5]. Thiamine pyrophosphate, the biologically active form of thiamine, plays a key role in glucose metabolism and energy production [6]. Thiamine pyrophosphokinase is responsible for phosphorylating thiamine to its active co-enzyme form. This step requires magnesium as a cofactor, which may often be depleted in patients with alcohol use disorders [7].

The human body is incapable of synthesizing thiamine and, thus, the vitamin needs to be supplied by food intake [7]. A healthy person requires between 1 and 2 mg of dietary thiamine daily [3]. Human stores of thiamine are limited to 30–50 mg [2]. Inadequate intake, inadequate activation and/or decreased

absorption may result in thiamine depletion within 2.5–6 weeks [2, 3]. Wernicke's encephalopathy symptoms begin to appear when thiamine levels drop below 20% of optimal levels [2].

Alcohol consumption decreases thiamine intake, gastrointestinal absorption, and hepatic storage while it increases cellular utilization [3, 8]. Alcohol damages the mucosa of the gut, thus reducing intestinal thiamine uptake. Thiamine absorption can further be depleted by diarrhea or vomiting which are common in patients with alcohol use disorder [7]. Cumulatively, alcohol dependence leads to thiamine deficiency via the reduction of intake and uptake, as well as increased utilization [7].

Due to its comparatively increased energy requirements, the brain represents the primary site that is damaged by thiamine deficiency [3]. However, over time, deficiency can cause nerve damage, leading to alcoholic neuropathy, as well as immune dysfunction. Thiamine deficiency can also affect the cardiovascular systems resulting in high-output cardiac insufficiency, known as wet beriberi.

Wernicke Encephalopathy

Clinical Characteristics

Wernicke's encephalopathy is a medical emergency, most commonly seen in patients with alcohol use disorders. The diagnosis of Wernicke's encephalopathy is primarily clinical but also histopathological [9].

The classic triad of clinical manifestations of Wernicke's encephalopathy includes delirium, ophthalmoplegia (nystagmus and ophthalmoparesis) and ataxia [5]. In reality, the complete triad is present in only 8–17% of cases [4, 6, 10, 11]. The absence of the stereotypical presentation reinforces the misconception that Wernicke's encephalopathy is rare [4]. Most patients only present with delirium. Cerebellar symptoms are the most frequent followed by oculomotor dysfunction [6]. In the absence of large, prospective data, the precise prevalence of symptoms/signs of Wernicke's encephalopathy cannot be determined [4]. When left untreated, Wernicke's encephalopathy evolves to coma, and even death, or progresses to Korsakoff syndrome in approximately 80% of patients [4].

Delirium

Wernicke's encephalopathy is consistently characterized by altered mental status consisting of acute confusional state with often reversible clinical features [4]. Cognitive changes range from apathy and mild neurocognitive symptoms to severe symptoms, disorientation, indifference, inattentiveness, increased loss of consciousness, that may rarely evolve towards a comatose state [4].

Gait Ataxia

Gait ataxia includes a range of symptoms from mild gait abnormalities to a complete inability to stand [4]. In the Dingwall et al. study [10], ataxia was diagnosed based on the presence of one or more of the following symptoms: abnormal gait, upper or lower limb dysmetria or abnormal Romberg's test. Lesions to the anterior and superior vermis of the cerebellum are a primary cause of ataxia and dysarthria of the limbs. However, Chandrakumar et al. [6] stressed that vestibular paralysis and polyneuropathy also contribute to ataxic gait.

Ocular Dysfunction

Horizontal nystagmus is the most common oculomotor symptom in Wernicke's syndrome. While complete ophthalmoplegia is rarely observed, it is a pathognomonic symptom [12]. Thus, it has been suggested that the term "ocular" should replace ophthalmoplegia in the clinical triad [4]. Other ocular findings include: sixth nerve palsy, lateral rectus palsy, lateral gaze palsy, conjugate gaze palsy, internuclear ophthalmoplegia, sluggish reactions to light, ptosis, retinal hemorrhage, papilledema, anisocoria or miosis. Dingwall et al. [10] diagnosed the presence of oculomotor abnormalities when one or more of the following were present: nystagmus, abnormal range of eye movement or diplopia. Bilateral visual disturbances frequently occur together rather than alone [6].

Neuropathology

Chandrakumar et al. [6] have emphasized that the symptoms in patients with Wernicke's encephalopathy are a direct outcome of the neuropathological lesions in specific areas of the brain. These lesions follow a symmetric distribution among structures that surround the third and fourth ventricles and the aqueduct [4]. The most commonly affected structures are the mammillary bodies, in up to 80% of cases. Most patients have bilateral histopathological lesions in the dorsomedial thalamus which have been associated with reported memory loss in Wernicke's encephalopathy.

The ocular deficits are due to brainstem lesions affecting pons and the midbrain. However, with thiamine administration, the condition improves, as there is no significant damage to the nerve cells [6]. The ataxic gait is due to the lesions of the superior vermis of cerebellum. Vestibular apparatus damage in these patients further worsens the abnormalities with gait and stance [6]. Abnormal vital signs, characterized by respiratory distress, hypothermia, and hypotension, are due to brainstem lesions (vestibular and inferior olivary nucleus) [6].

Comorbidities of Wernicke Encephalopathy

Liver Diseases Comorbidities

Caine et al. [13] found significant overlap in clinical signs between hepatic encephalopathy and Wernicke's encephalopathy in patients with severe liver disease and alcohol use disorder. In a Spanish multicentric study, Novo-Veleiro et al. [14] found that 37% of patients diagnosed with Wernicke's encephalopathy and alcohol use disorders (n = 434) also had alcohol-related liver disease (ALD). In patients with ALD (n = 272) versus those without, a relationship was found between mortality and the presence of anemia, low level of consciousness and previous diagnosis of cancer. The presence of liver disease was also associated with less chance of full recovery: 27 patients with (17.8%) versus 71 (27.8%) without ALD (p = 0.03) [14].

Neurologic Comorbidities

Marchiafava–Bignami disease, pontine or extrapontine myelinolysis, acute pellagra encephalopathy (B3 depletion), traumatic brain damage, as well as head injury should be diagnosed prior to simply attributing cognitive dysfunction to ethanol neurotoxicity [1].

Psychiatric Comorbidities

Guirguis et al. [2] found that 1.85% of psychiatric inpatients (n = 486) had clinical signs of Wernicke's encephalopathy and 7% were at high risk for developing the disorder. However, Lin et al. [15] found that the frequency of Caine-positive Wernicke-Korsakoff syndrome was 12% among psychiatric inpatients, but only half used alcohol. Patients treated with high-dose thiamine showed clinically significant neurocognitive improvement. Few cases of schizophrenia-related Wernicke's encephalopathy have been published in the literature [16]. Depression represents an additional risk factor for malnourishment [17].

Caine's Criteria

Caine et al. [13] proposed operational criteria for the diagnosis of Wernicke's encephalopathy. These criteria require two of the following four signs: (1) dietary deficiencies, (2) oculomotor abnormalities, (3) cerebellar dysfunction, and (4) either an altered mental state or mild memory impairment [13].

1. Dietary deficiencies include undernutrition (body mass index <2 SD below normal), history of grossly impaired dietary intake or abnormal thiamine status [1].
2. Oculomotor abnormalities include ophthalmoplegia, nystagmus, or gaze palsy [1].
3. Cerebellar dysfunction includes unsteadiness or ataxia, abnormal past pointing or dysdiadokokinesia [1].
4. Altered mental state includes disorientation in two of three fields: confusion, coma, or abnormal digit span memorization. Mild memory impairment include failure to remember two or more words in the 4-item memory test or impairment on more elaborate neuropsychological tests of memory function [1].

The criteria were designed to differentiate Wernicke's encephalopathy from other cognitive disorders, including hepatic encephalopathy, in patients with alcohol use disorders [13]. Using the proposed criteria, sensitivity for the diagnosis of Wernicke's encephalopathy was improved to 100% versus 31% with the classic triad [13]. Differential diagnosis of Wernicke's encephalopathy either alone or with amnesia (Wernicke-Korsakoff syndrome) or hepatic encephalopathy improved from 22 to 85% using these criteria [13]. Patients who met one criterion in the presence of alcohol use disorders, medical morbidity or psychiatric disorders were considered to have a high risk for Wernicke's encephalopathy [2]. Nonspecific signs and symptoms of malnutrition may include but are not limited to any of the following: reported loss of appetite, living alone or homelessness, weight loss, nausea and/or vomiting [1, 2].

Caine's et al. diagnostic criteria have shown high sensitivity (94%) and specificity (99%), thus several authors (e.g. [1, 2]), as well as the European Federation of Neurological Societies (EFNS) [11] strongly recommend using them for diagnosing Wernicke's encephalopathy in both alcohol-dependent and non-alcohol-dependent patients. Ritz et al. [18] found that 16% of patients with alcohol use disorders "without complications", presented two Caine criteria and half of them presented one criterion.

It is noteworthy that clinical presentation can differ greatly in individuals with Wernicke's encephalopathy [3]. Above all, it remains a clinical diagnosis. Diagnostic testing (whether imaging or laboratory) should not delay thiamine administration in individuals suspected of having Wernicke's encephalopathy [3, 4]. Treatment for Wernicke's encephalopathy is frequently administered prior to diagnostic confirmation [3]. Many authors consider reversal of clinical signs upon treatment with thiamine to be the best argument in favor of an antemortem diagnosis of Wernicke's encephalopathy. Chandrakumar et al. [6] suggested that patient improvement following thiamine therapy was considered a good diagnostic strategy.

Neuroimaging Characteristics

Numerous magnetic resonance imaging (MRI) studies have typically shown symmetrical signal intensity alterations of the mammillary bodies, thalamus, fornices, midbrain and periaqueductal-periventricular grey matter area [11, 19, 20]. Finding

these alterations on MRI strongly supports a clinical diagnosis of Wernicke's encephalopathy [2]. These signal changes are seldomly seen in the chronic stages of Korsakoff's syndrome. While MRI imaging is not recommended in the diagnosis of Wernicke's encephalopathy, it could be used to rule out other, alternative diagnoses [6]. For instance, lesions to the corpus callosum on MRI should raise suspicion of Marchiafava-Bignami disease [4].

About 60% of patients present typical lesions on MRI scans [3, 4]. MRI has a 53% sensitivity and a 93% specificity in detecting Wernicke's encephalopathy [3]. Wernicke's encephalopathy is by far the most frequent cause of lesions to the mammillary bodies in humans [9]. Mammillary body atrophy is frequently observed in MRI scans within a week of encephalopathy onset [6]. Similarly to clinical signs, damage to brain areas observed in these scans varies widely from person to person [3]. Computed tomography is not a reliable test for Wernicke's encephalopathy [4]. Diagnostic imaging should not delay thiamine administration in individuals suspected of having Wernicke's encephalopathy [3, 4].

Thiamine Blood Dosage

Thiamine levels can be measured using high-performance liquid chromatography [4]. However, Wernicke's encephalopathy cannot be diagnosed solely on the basis of thiamine concentration, as there is not a specific threshold below which all individuals develop the disease [6]. Blood dosage is neither sensitive nor specific for diagnosing active disease [4]. Since the majority of the blood's thiamine is contained in red blood cells, a less common but more accurate method involves detecting monophosphorylated and dephosphorylated thiamine in these cells [4]. Direct measurement of thiamine pyrophosphate or thiamine via high performance liquid chromatography has been shown to be more precise and robust [3]. However, these tests are not available in most clinical laboratories and treatment must not be delayed to obtain these results [3].

Wernicke Encephalopathy: Challenges and Pitfalls

Up to 80% of all cases of Wernicke's encephalopathy are undiagnosed and therefore go untreated [9, 10, 28]. This is due to variable clinical presentations, symptom overlap with other neurological conditions, a lack of sensitive laboratory tests and a low incidence of oculomotor symptoms [10, 11, 13]. Altered mental state, the most common symptom of Wernicke's encephalopathy, may be confused for inebriation, withdrawal delirium, hepatic encephalopathy or a number of other neurological conditions [8]. Early signs and symptoms of Wernicke's encephalopathy are vague and nonspecific. Patients report nausea, vomiting, weight loss and sometimes memory loss [2]. In addition, administering glucose prior to thiamine can cause or exacerbate Wernicke's encephalopathy.

Many conditions encountered in patients with alcohol use disorders can mimic Wernicke's encephalopathy. The most frequent include acute alcohol intoxication, acute alcohol withdrawal syndrome or delirium tremens, hepatic encephalopathy, and head injuries. Exclusion of these comorbid pathologies may prove difficult in everyday clinical practice [1, 12]. There are symptom overlaps with other alcohol induced disorders such as acute hypoglycemia, alcohol-induced seizures, subdural or intracranial bleeds induced by head injury, or when alcohol-induced seizures result in head injury and/or cerebral hypoxia [12].

Kopelman [12] stressed that multiple factors can underlie the etiology of alcohol-related brain lesions such as recurrent head injury and its complications, recurrent seizures and cerebral hypoxia, recurrent hypoglycaemia, and chronic hepatic toxicity/cirrhosis. Both smoking and substance misuse are commonly associated with alcohol misuse and can cause or exacerbate brain pathology. Other medical conditions may mimic Wernicke's encephalopathy including stroke, drug overdose, particularly nonmedicinal use of prescription medications, benzodiazepine withdrawal, anticholinergic induced delirium, other encephalopathies, hyperammonemia from valproic acid, central nervous system infections, CO intoxications, electrolyte disturbances (sodium, calcium, magnesium, phosphate), endocrine disturbances (thyroid, parathyroid, pancreas, pituitary, adrenal), seizures, especially nonconvulsive status epilepticus, psychiatric conditions, cardiac, kidney, and liver failures [4].

In psychiatric patients, Wernicke's encephalopathy can mimic major depressive disorder with psychotic or catatonic features, psychotic disorders, or dementia [2]. Clinicians, especially those working in the emergency setting, need to be aware of the clinical variability of Wernicke's encephalopathy because most patients initially present to the emergency department and the disorder remains underdiagnosed [4].

Treatment of Wernicke's Encephalopathy

Early recognition of Wernicke's encephalopathy is vital, as rapid treatment can restore cognitive and ocular function. Indeed, thiamine is relatively inexpensive and safe; rapid administration has been reported to prevent progression of Wernicke's encephalopathy to irreversible deficits of Korsakoff syndrome [4, 5, 21]. Mortality was drastically reduced with acute administration of thiamine [10]. Unfortunately, the living conditions and socioeconomic status of patients with alcohol use disorders may be responsible for extended treatment delays [1].

Thiamine Treatment

Primary treatment includes timely administration of thiamine. When treated effectively, within hours after encephalopathy development, a full recovery is likely to occur. Even after a delayed initiation of treatment for a few days, a complete

recovery is still possible following thiamine replacement [1, 5]. The response to thiamine administration on ocular findings is quite predictable and constant. Failure of recovery should alert the physician to consider alternative diagnoses [4].

There is no consensus on the effective dose of thiamine, route of administration, daily dose frequency, or the duration of the treatment [4]. The traditional recommendation is a parenteral thiamine dosage greater than or equal to 100 mg/day [22]. Oral administration of thiamine is normally insufficient to treat Wernicke's encephalopathy since patients require a higher daily dosage of thiamine [22]. For instance, Thomson et al. [23] suggested regimens include high-dose thiamine (≥500 mg) prescribed intravenously three times a day, for 2–3 days initially with additional doses based on clinical response.

Smith et al. [5] conducted a review to determine the optimal thiamine dosage in alcohol-induced Wernicke's encephalopathy. Six publications including 138 patients were evaluated. Clinical diagnostic criteria varied significantly between publications. Doses ranged from 100 to 1500 mg intravenous thiamine and up to 300 mg IM thiamine. All patients who received thiamine experienced symptom improvement [5]. Ambrose et al. [24] conducted a trial using five thiamine dosing regimens ranging from 5 to 200 mg IM administered daily. Patients who received the highest doses experienced the most rapid resolution of symptoms and demonstrated higher mental acuity. Patients with hepatic encephalopathy may have an additional risk of Wernicke's encephalopathy and should be treated with parenteral thiamine [13]. Later case studies have shown that 100–250 mg doses of parenteral thiamine did not prevent death and that Korsakoff's psychosis developed in 56–84% of patients upon later follow-up [19].

High-dose parenteral administration also facilitates passive diffusion of thiamine across the blood-brain barrier [4]. Parenteral thiamine is capable of rapidly correcting depleted stores, thus achieving therapeutic plasma levels that assist in reversing neurological symptoms [5]. Some observations have reported the development of symptoms in patients taking high doses of oral thiamine [6]. In terms of parenteral administration, the intravenous route is preferred over intramuscular. Pharmacokinetic studies have documented that the plasma half-life of thiamine is only 96 minutes. Thus, administering thiamine two to three times daily might achieve better bioavailability than a single dose [4].

These recommendations are not based on controlled trials [4]. A Cochrane review by Day et al. [25] identified only two double-blind, randomized, controlled trials (RCT) on thiamine administration in Wernicke's encephalopathy of adequate quality. The review concluded that there was insufficient data from the available clinical studies to recommend an optimal therapeutic regimen that clinicians could use for treatment or prophylaxis in patients with alcohol dependence [6]. Recently, Dingwall et al. [10] conducted two double-blind, parallel group, randomized controlled trials to determine optimal thiamine dose required in asymptomatic but "at-risk" alcohol misuse patients (history of heavy alcohol use in the past 3 months with nutritional risk but without neurological symptoms), and in symptomatic alcohol misuse patients with Wernicke's encephalopathy (two or more clinical signs of oculomotor abnormalities, ataxia, confusion, or nutritional risk). There was no clear

benefit of high dose thiamine over intermediate or lower doses, over the time intervals examined in the treatment and prevention of cognitive and neurological abnormalities related to Wernicke's encephalopathy [10]. The authors concluded that if replicated in other randomized trials, such a finding may change clinical recommendations [10].

A literature review reported that it was reasonable to consider a minimum of 72 h of treatment with a high dose as likely to achieve complete resolution of symptoms [5]. If patients continue drinking alcohol, prophylactic thiamine supplementation should be administered indefinitely.

Parenteral thiamine is underutilized in patients with alcohol use disorders and risk factors for Wernicke's encephalopathy. Education is needed to enhance thiamine prescription and evaluation of risk factors for Wernicke's encephalopathy in this population.

Hypomagnesemia is also common in alcohol-dependent patients and can contribute to the development of Wernicke's encephalopathy, as thiamine requires magnesium as a cofactor [2]. In the presence of hypomagnesemia, patients with suspected Wernicke's encephalopathy may be unresponsive to parenteral thiamine. Thus, those who are at potential risk should have their magnesium level checked and be supplemented via oral or parenteral administration [2, 4, 22].

Prophylaxis

Substitution of parenteral thiamine in individuals with suspected Wernicke's encephalopathy is a well-established treatment regimen, but available guidelines are widely variable [1]. The use of thiamine as prophylaxis is widespread internationally. Many hospitals use thiamine administration prophylactically for patients with alcohol use disorders [3]. When a suspected case of Wernicke's encephalopathy is administered glucose, it is recommended that thiamine infusion be given before or conjointly with glucose load to prevent the exacerbation of symptoms [4, 6]. Sinha et al. [4] suggested that oral administration of thiamine 100 mg, three times daily may be reserved for prophylactic treatment of patients with low clinical suspicion. This is based on standard clinical practice since insufficient evidence exists in the literature to support this recommendation**.** Placebo-controlled thiamine substitution trials in treating suspected Wernicke's encephalopathy are needed, but would be unethical by modern standards [8].

Standardized National Guidelines

Pruckner et al. [8] conducted a review of 14 treatment guidelines for patients with alcohol use disorders in order to identify recommendations for the use of thiamine, including the recommendations of the American Psychiatric Association, the

American Society of Addiction Medicine (ASAM), the Österreichische Gesellschaft für Neuropsychopharmakologie und Biologische Psychiatrie (ÖGPB), the British Association for Psychopharmacology (BAP), the French Alcohol Society, the Italian Society on Alcohol, the National Institute for Health and Care Excellence (NICE), the Substance Abuse and Mental Health Services Administration (SAMHSA), the Deutsche Gesellschaft für Psychiatrie und Psychotherapie, Psychosomatik und Nervenheilkunde (DGPPN), the German Guidelines for Austria, Germany and Switzerland, the World Federation Federation of Societies of Biological Psychiatry (WFSBP), the Mental Health Gap Action Programme (WHO mhGAP) Guidelines of the World Health Organization, and the Australian Government Department of Health and Ageing (AGDHA). Pruckner et al. [8] concluded that although specific modalities and indications varied considerably, high-dose treatment with parenteral thiamine in several daily doses should be considered a state-of-the-art procedure.

The most detailed recommendations were those of the BAP and the AGDHA. The BAP "Guidelines for the Pharmacological Management of Substance Abuse" recommended oral thiamine administration of (>300 mg/day) in healthy uncomplicated heavy drinkers during withdrawal. For patients at high risk for developing Wernicke's encephalopathy, thiamine should be administered IV or IM for 3–5 days or until no further improvement can be seen [22]. If Wernicke's encephalopathy is suspected or established, the treatment regimen should be >500 mg of thiamine IV or IM three times a day for 3–5 days, followed by 250 mg thiamine administered parenterally once daily for another 3–5 days minimum [22].

Little information on thiamine treatment was provided in APA, ASAM, ÖGPB (2013), French Alcohol Society, NICE, SAMHSA, and WHOmhGAP.

Safety Profile of Thiamine

Thiamine is very well tolerated regardless of administration route or dosage [4]. Adverse reactions to thiamine are rare. Thomson et al. [26] reviewed the previously released data on adverse reactions to parenteral thiamine in the treatment of Wernicke's encephalopathy. They retrieved 10 anaphylactic reactions from 5,431,235–6,651,947 patient-days of treatment. They concluded that the risk-benefit ratio for administration is favorable given the potential severity of brain damage in Wernicke-Korsakoff syndrome. Pruritus and local irritation may occur [6].

Korsakoff Syndrome

Korsakoff described the syndrome between 1887 and 1891. According to Arts et al. [1], Korsakoff syndrome is a residual syndrome in patients who suffered from Wernicke encephalopathy but did not receive immediate and adequate treatment with thiamine replacement therapy.

Clinical Characteristics

Korsakoff syndrome is characterized by memory impairments, in particular of episodic memory, disordered cognition, executive dysfunction, confabulation, disorientation, apathy, flattened affect, lack of illness insight, in the context of alcohol abuse and malnutrition. These symptoms are chronic and may be irreversible [3]. Cognitive impairments may have a significant impact on a patient's daily life, and memory impairments can heavily impact their sense of self and identity.

As a core characteristic for Korsakoff syndrome, memory impairments primarily relate to declarative memory. Within this domain, both episodic memory – explicitly remembered, personally experienced events specific to time and place - and semantic (fact-related) memory are affected [1]. In each subdomains, there are significant deficits in anterograde and retrograde memory. Patients are unable to acquire new information [27]. Overall intelligence, attention, immediate memory and implicit or procedural memory generally remain intact [28]. Segobin and Pitel [29] highlighted the central role of neuronal loss within the thalamus, especially the anterior thalamic nuclei, in amnesia associated with alcohol use disorders and Korsakoff syndrome.

Korsakoff syndrome is also characterized by behavioral and affective impairments [1].

Among these, apathy is a characteristic and fundamental symptom, blunted or detached affect, irritability, emotional over-reaction, and confabulation [1, 28]. Confabulation refers to the emergence of memories of experiences and events that are incorrect in place and time, or never took place [30, 31]. Patients may fabricate stories in the setting of clear consciousness. Confabulations can be spontaneous or provoked. Rensen et al. [31] validated the Nijmegen-Venray Confabulation List (NVCL), an observation scale for quantifying both spontaneous and provoked confabulations in patients with Korsakoff syndrome. The NVCL includes four factors: provoked confabulations, spontaneous confabulations, severity of spontaneous confabulations, and distorted sense of reality [31].

Clear diagnostic criteria for Korsakoff syndrome are lacking; it is often used interchangeably with alcohol-related dementia (ARD) [9, 28]. Arts et al. [1] suggested certain specific clinical criteria for Korsakoff syndrome including: (1) minimal severity of memory dysfunction, expressed in evidence-based cutoff scores for memory tests (such as the California Verbal Learning Test or the Rivermead Behavioral Memory Test); (2) in vivo evidence for Wernicke's encephalopathy pathology, either clinical (e.g., the operational criteria by Caine et al.), neuroradiological (i.e., MRI), or lab reports (very low serum thiamine) and (3) a set of exclusion criteria [1].

Neuroimaging

Current neuroimaging literature regarding Korsakoff syndrome clearly showed lesions to the thalamus, mammillary bodies and hippocampus [12, 20, 29]. In a population of patients with alcohol use disorders, comparing those with or without

Korsakoff syndrome, Segobin and Pitel [29] showed significantly greater bilateral grey matter loss in the thalami and mammillary bodies within the group of patients with Korsakoff syndrome. The fornix and the cingulum, both of which have direct connections to the thalamus and hippocampus, have been observed to have increased white matter bundles. Thus, impaired microstructural integrity seems to be more severe in Korsakoff syndrome [20, 29].

Treatment of Korsakoff Syndrome

Several authors argued that Korsakoff patients can improve through weeks, months, or years if adequately treated with thiamine, and if they abstain from alcohol use [1, 10, 12]. To date, no effective pharmacological treatment for Korsakoff syndrome, except thiamine, is available.

The treatment of Korsakoff syndrome is based on cognitive rehabilitation, including memory compensation techniques, and interventions based on errorless learning [1]. Memory compensation techniques such as using agendas, memory cards, smartphones and smartwatches are promising. Six studies on the use of traditional and digital assistive technologies provided evidence that these memory compensation techniques may be helpful in Korsakoff syndrome, improving autonomy in everyday life [20, 30–33]. Arts et al. [1] suggested that these techniques are helpful if (1) the formulated goals are restricted (2) sufficient time is available to guide the patient, and (3) the use of these technologies is holistically embedded or combined with elaborated learning techniques including memory compensation techniques and interventions based on errorless learning. Patients with Korsakoff syndrome and somatic or psychiatric comorbid conditions should receive integrated care based on accurate multidimensional and multidisciplinary diagnosis in which nurses play a prominent role.

Conclusions

Wernicke-Korsakoff syndrome is a complication of thiamine (vitamin B1) deficiency that requires urgent diagnosis and treatment to prevent serious and life-threatening complications. Recommended diagnosis is clinical, requiring two of the following: (1) dietary deficiency, (2) ocular symptoms, (3) cerebellar dysfunction and (4) either an altered mental state or mild memory impairment. Parenteral thiamine is a safe and effective treatment. Wernicke encephalopathy is readily reversible if treated within the first 48–72 h of symptom onset.

Untreated Wernicke's encephalopathy may lead to coma, or more rarely, death. It may also lead to Korsakoff syndrome which is chronic and may be irreversible. Characterized by anterograde and retrograde memory impairments, executive dysfunction, confabulation, apathy, affective and social-cognitive impairments, it is a highly debilitating syndrome. Cognitive rehabilitation, including memory

compensation techniques, as well as long-term thiamine supplementation, are currently recognized in the treatment of Korsakoff syndrome.

Conflicts of Interests AD received honoraria for lectures from Camurus, Indivior, and Lundbeck and have received travel support from Janssen and Otsuka; he has no conflicts of interests within the scope of this chapter.

Part XII
Alcohol and Cancer

Chapter 73
Mechanisms of Alcohol-Mediated Cancer

Sebastian Mueller

Abstract Cancers of the upper digestive tract, including oral cavity, pharynx, larynx, esophagus squamous cell carcinoma), liver, colorectum, and female breast were causally related to alcohol consumption. This chapter introduces to the book part on cancer and alcohol consumption. According to a recent report from the International Agency for Research on Cancer (IARC), 4.1% of all new cases of cancer, are attributable to alcohol consumption. They could have been avoided if there had been no alcohol use. Mechanisms of cancer development during alcohol exposure are also briefly discussed. Of note, not ethanol itself but its mandatory oxidation to acetaldehyde causes carcinogenesis, in association with multiple other pathways that lead to the generation of reactive oxygen species (ROS) and accumulation of iron. Together, these metabolites are genotoxic, impair DNA repair, cause cell injury, enhanced cell regeneration and, hence, provide conditions for genomic instability, an optimal environment for cancer formation. In addition, a combination of immunosuppression and reduced tumor clearance through elimination pathways such as apoptosis further contribute to carcinogenesis. At the systemic level, enhanced red blood cell (RBC) turnover in combination with liver and bone marrow injury provide an additional novel loop that specifically challenges the immune system and provides enhanced toxic iron trafficking.

https://doi.org/10.1007/978-3-031-32483-3_73

Introduction

Alcohol is responsible for up to 200 different diseases [1]. As is discussed in the subsequent Chaps. 74 and 75 by Pietro Ferrari and colleagues and Akira Yokoyama, the consumption of alcohol is one of the top-10 risk factors contributing to the worldwide burden of disease. Cancers of the upper aero digestive tract (UADT), including oral cavity, pharynx, larynx, esophagus and squamous cell carcinoma, as well as liver, colorectum, and female breast were causally related to the consumption of alcoholic beverages. The incidence of hepatocellular carcinoma (HCC) among patients with alcoholic cirrhosis ranges range from 7–16% [2] within 5 years to as much as 29% after 10 years. According to a recent report from the International Agency for Research on Cancer (IARC), 4.1% of all new cases of cancer, are attributable to alcohol consumption. They could have been avoided if there had been no alcohol use. Mechanisms of cancer development during alcohol exposure are also briefly discussed. Of note, not ethanol itself but its mandatory oxidation to acetaldehyde causes carcinogenesis, in association with multiple other pathways that lead to the generation of reactive oxygen species (ROS) and accumulation of iron. Together, these metabolites are genotoxic, impair DNA repair, cause cell injury, enhanced cell regeneration and, hence, provide conditions for genomic instability, an optimal environment for cancer formation. In addition, a combination of immunosuppression and reduced tumor clearance through elimination pathways such as apoptosis further contribute to carcinogenesis. At the systemic level, enhanced red blood cell (RBC) turnover in combination with liver and bone marrow injury provide an additional novel loop that specifically challenges the immune system and provides enhanced toxic iron trafficking.

Potential Mechanisms of Alcohol-Mediated Carcinogenesis

As shown in Fig. 73.1 not ethanol itself but its oxidation leads to formation of highly cancerogenic acetaldehyde and, through multiple pathways to the generation of ROS and accumulation of iron. Of note, cells cannot escape from ethanol metabolism and there are no negative feedback loops. Alcoholic beverages are group 1 carcinogens (known to be carcinogenic to humans) per classification by the IARC [3]. Thus, alcohol should be considered a procarcinogen that is converted to the primary carcinogenic metabolite, acetaldehyde. Individuals with the *ALDH2*2* (which encodes aldehyde dehydrogenase) loss- of-function mutation have an increased risk of esophageal cancer, which serves to convincingly link acetaldehyde to cancer [4, 5]. Acetaldehyde is electrophilic and, as mentioned previously, forms an adduct with DNA and interstrand crosslinks [6, 7]. Alcohol consumption also causes a gradual accumulation of cellular iron, mostly in the liver. Iron itself is considered a cancerogenic molecule, leading to highly reactive hydroxyl radicals through the Fenton chemistry [8]. As is also shown in Fig. 73.1, these toxic

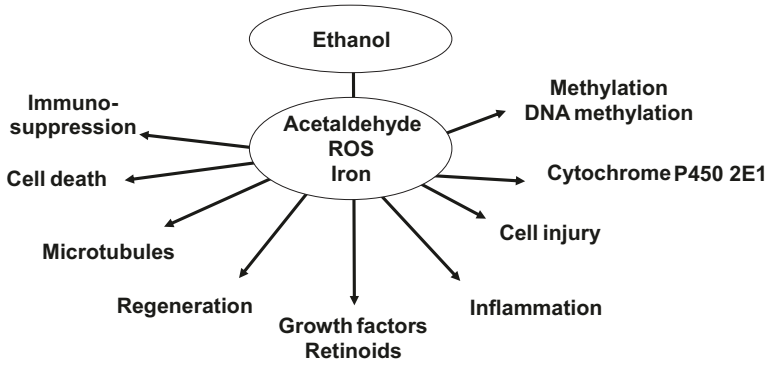

Fig. 73.1 Mechanisms of alcohol-mediated hepatocarcinogenesis

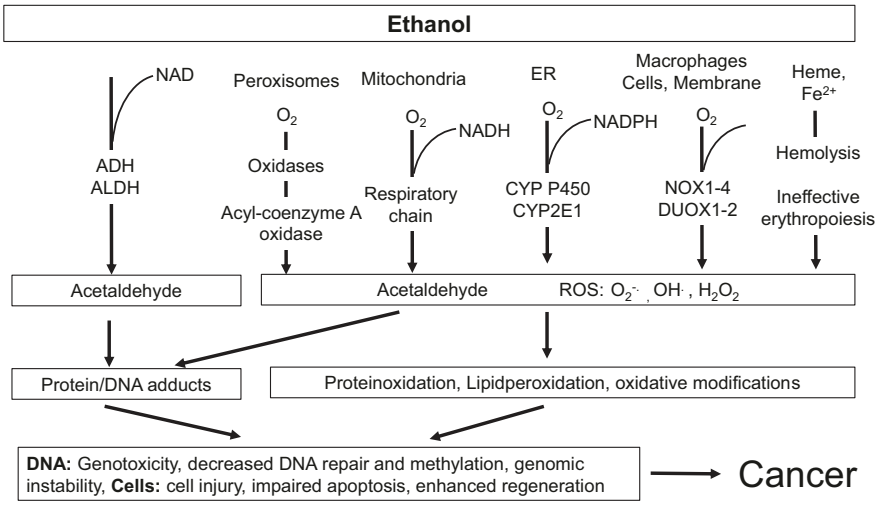

Fig. 73.2 Mechanisms of biochemical activation of oxygen to ROS in various organelles and the formation of the carcinogen call I acetaldehyde

metabolites can interfere with important physiological cellular functions known to be critical for cancer development.

Figure 73.2 shows at the cellular level how ethanol not only drives acetaldehyde formation but the formation of ROS through various oxygen-consuming pathways in mitochondria, peroxisomes, membrane-bound oxidases such as NADPH-dependent oxidases (NOXs) and, of course, the endoplasmic reticulum-localized cytochrome p450 system, namely the subtype CYP2E1. Together, these metabolites are genotoxic, impair DNA repair, cause cell injury, enhanced cell regeneration and, hence, provide conditions for genomic instability, an optimal environment for cancer formation. In addition, a combination of immunosuppression and reduced tumor clearance through elimination pathways such as apoptosis further contribute to

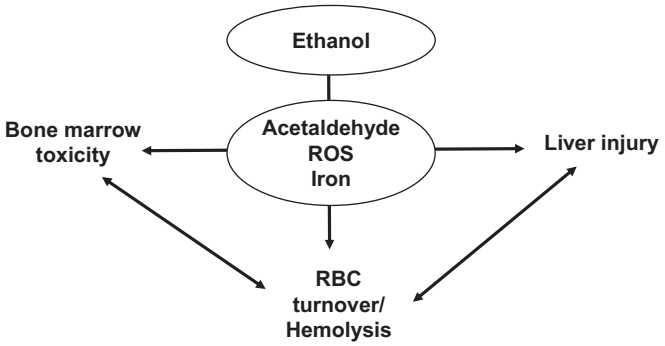

Fig. 73.3 Recent identification of a novel vicious loop between bone marrow, liver and blood. Ethanol impairs both RBCs and bone marrow leading to an enhanced RBC turnover and iron trafficking. The liver plays an important role in this cycle as the sole excretion organ of heme-degradation end products such as bilirubin, an intermediary storage of iron and the synthesis and release of important carrier proteins such as albumin, transferrin or haptoglobin

carcinogenesis. As is shown in Fig. 73.3, at the systemic level, enhanced RBC turnover in combination with liver and bone marrow injury provide an additional novel loop that specifically affects the immune system and provides enhanced iron trafficking. These findings are rather new and are described in more detail in the Chaps. 57 and 58 on iron and ALD and ethanol and bone marrow toxicity.

Carcinogenesis by Acetaldehyde

There are several biological mechanisms by which alcohol, as ethanol, induces cancer [9]. Once consumed, alcohol is metabolized to **acetaldehyde** by the enzymes alcohol dehydrogenase (ADH), cytochrome P-450 2E1 (CYP2E1) and bacterial catalase [10].

Acetaldehyde is electrophilic and highly reactive towards DNA and can bind directly to DNA to form DNA adducts which can block DNA synthesis and repair, induce point mutations, double-strand breaks, sister chromatid exchanges and structural changes to chromosomes [11, 12]. Another property of acetaldehyde is that it can also bind to proteins causing structural and functional changes to enzymes involved in DNA repair and DNA methylation. DNA methylation is often disrupted by both ethanol and acetaldehyde due to their ability to inhibit S-adenosyl-L-methionine synthesis and the DNA repair enzyme O6-methylguanine DNA methyltransferase (DNMT) activity as well as their ability to dysregulate one-carbon metabolism which has a downstream effect on DNA methylation [10, 13, 14]. Epigenetic changes induced by chronic heavy alcohol consumption can lead to chromosomal instability [15]. Hypomethylation of promoters for oncogenes (for

example, *SERPINB5* and *IGF2*) causes their aberrant activation and loss of imprinting (loss of the normal expression pattern), whereas hypermethylation of promoters of genes involved in cellular differentiation or DNA repair (for example, *MLH1* and *MGMT*) promotes transformation.

DNA mutations can result if DNA repair is insufficient, particularly for homologous recombination repair [7]. As mentioned above, ROS generated by CYP2E1 generates aldehydic lipid metabolites such as 4-HNE and MDA. The presence of MDA increases acetaldehyde adduct formation by ~10–30-fold, synergizing the formation of a highly reactive, hybrid MDA–acetaldehyde adduct [16]. These aldehydes modify proteins (generating neoantigens) and DNA (causing mutations) while depleting reduced glutathione, amplifying oxidant stress and cytotoxicity. Induced CYP2E1 also converts other procarcinogens to active carcinogens, including nitrosamines [17].

While acetaldehyde has many carcinogenic and genotoxic properties, it is not the final product of ethanol metabolism: non-toxic acetate is formed when aldehyde dehydrogenases (ALDH) oxidize acetaldehyde. The main ALDHs involved in acetaldehyde oxidation consist of ALDH1A1, ALDH2, and ALDH1B1, and ALDH2 is responsible for most of this processing in the liver [18]. The common polymorphism *ALDH2**2*, present among 28–45% of East-Asian populations, dramatically reduces ALDH2's ability to metabolize acetaldehyde and carriers have a substantially increased risk of UADT cancer when consuming alcohol [19].

Although gastric bacteria do not contribute much to overall alcohol metabolism, they are also capable of producing acetaldehyde from alcohol. Gastric acetaldehyde is thought to contribute to gastric mucosal damage and the pathogenesis of UADT cancer [20]. σ-ADH is also able to detoxify the dietary carcinogen nitrobenzaldehyde [21]. It has been shown that Japanese who lack this enzyme exhibit an increased risk for stomach cancer. In the colon, ADH isozymes may also activate dimethylhydrazine – a well-known colon carcinogen.

Generation of acetaldehyde also leads to damage of the microtubular system [22–24] with an altered secretion of proteins [25, 26], a decrease of the important antioxidant glutathione and an inhibition of the nuclear repair systems with an enhancement of carcinogenesis [27]. Although detailed studies on carcinogenesis are lacking these interactions are very likely to modulate the process of carcinogenesis.

Formation of Reactive Oxygen Species

Ethanol-mediated carcinogenesis can also result from the induction of oxidative stress by the increased activity of CYP2E1 which produces high quantities of **reactive oxygen species** (ROS) when oxidizing ethanol to acetaldehyde [28, 29]. Classical ROS are formed during the reduction of oxygen and may be released

during uncoupling of enzymatic reactions. The reduction cascade and the following ROS are shown in Appendix Figs. A.67 and A.68. Being highly reactive, ROS (especially superoxide anion and hydroxyl radicals) can induce lipid peroxidation resulting in the formation of aldehydes which can bind to DNA forming highly mutagenic etheno-DNA adducts [30, 31]. ROS can also induce metastasis and angiogenesis by interfering with signaling pathways to upregulate vascular endothelial growth factor and monocyte chemotactic protein 1 [32]. In addition to CYP2E1 activity, ROS can also be produced as a result of inflammation in the tumor microenvironment where monocytes and macrophages produce pro-inflammatory cytokines, such as tumor necrosis factor α and interleukins [32, 33], activating further ROS-generating enzymes [31]. ROS may also trigger the production of profibrotic cytokines and collagen in liver cells leading to liver cirrhosis which is another well-recognized intermediary step towards hepatocellular carcinoma development [34]. Up to 50% of ROS may be produced by the ER-localized p450 system, especially CYP2E1.

Major consequences are production of above mentioned ROS including hydroxylethyl radicals [11]. ROS results in lipid peroxidation with lipid peroxidation products such as 4-hydroxynonenal or malondialdehyde. 4-Hydroxynonenal binds to DNA, forming highly carcinogenic exocyclic etheno–DNA adducts [35]. Interaction of the microsomal ethanol metabolism with the metabolism of various drugs, leading to decreased drug blood levels and increased drug toxicity [36, 37]. Interaction of CYP2E1 ethanol metabolism with the metabolism of various xenobiotics and carcinogens, leading to increased toxicity and carcinogenesis [38]. Interaction of CYP2E1 ethanol metabolism with the metabolism of retinol and retinoic acid, leading to vitamin deficiency and increased toxicity, including enhanced carcinogenesis [11, 39].

Growth Factors

Another pathway through which alcohol is involved in carcinogenesis is through interference with **retinoid metabolism** and the oxidation of vitamin A to retinoic acid [11]. Retinoids are necessary for normal cell growth, cell differentiation, and apoptosis [32]. Alcohol also interferes with estrogen pathways by increasing estrone and estradiol levels and enhancing the activity of estrogen receptors which might be important in breast carcinogenesis [40]. Heavy use of alcohol has also been linked with increased circulating levels of estrone and estradiol as well as dehydroepiandrosterone sulphate which is subsequently metabolized to estrogen [41]. As is already discussed in Chap. 49 on the pathophysiology of alcohol, in general, ethanol blocks growth factors such as HGF1, IGF or EGF. The molecular reasons are still poorly understood. However, if physiological signals such as anemia or hepatocytes loss stimulate cell division, **DNA replication will be performed in a toxic environment despite regeneration blocking signals**.

Immune Dysfunction and Tumor Clearance

Alcohol reduces the normal function of the immune system by disrupting the production of **necessary proteins to target and destroy potentially cancerous cells** [33]. It has also been hypothesized that alcohol can activate natural killer T cells leading to liver injury and apoptosis of hepatocytes [33]. As is discussed in the chapter on iron and alcohol and bone marrow (Chaps. 57 and 58), the enhanced erythrophagocytosis may further "overcharge" the immune system and increase toxic iron trafficking.

Inflammation

Furthermore, chronic alcohol use can cause microbial dysbiosis and bacterial overgrowth in the intestine leading to "gut leakiness"; in this case, the intestinal lumen becomes so permeable that bacterial products including lipopolysaccharides and peptidoglycan move into the blood and reach the liver resulting in a state of chronic inflammation [10, 33, 42]. In the oral cavity, bacterial catalase metabolizes ethanol to acetaldehyde, but these bacteria have limited capacity to metabolize acetaldehyde to acetate, thus leaving the oral epithelia exposed to acetaldehyde and its carcinogenic properties for longer [11, 43]. There is further hypothesis that alcohol consumption might activate the pathways of other carcinogenic agents such as some pro-carcinogens in tobacco smoke and industrial chemicals (see UADT above) [11]. It is also postulated that ethanol might increase the absorption and penetration of these carcinogens in the mucosa of the UADT, [11, 44] where it has been reported that tobacco smoking and alcohol consumption have a synergistic effect on the risk of cancer [45, 46].

Alcohol-induced hepatic inflammation and the oxidative stress associated with such inflammation causes hepatocellular DNA damage and contributes to tumor initiation. Tumor-associated M2-polarized macrophages support tumor promotion, in part by activating hepatic stellate cells (HSCs). Ectopic expression of TLR4 in hepatocytes and its activation by LPS induces HCC [47] via generation of TLR4 and homeobox protein Nanog- dependent liver tumor-initiating stem-cell-like cells (TICs) [48]. In addition to promoting fibrosis, activated HSCs also promote HCC formation via production of matrix or soluble factors that support tumor cell survival and growth [49]. Activated HSCs also promote TIC-mediated liver tumorigenesis and liver tumor formation induced by a hepatotoxin, diethyl nitrosamine, and promoted by alcohol [50]. The two major drivers of alcohol-associated tumor initiation, CYP2E1 in hepatocytes [35, 51], and LPS from gut dysbiosis [52], also activate HSCs and promote tumor development. The role of the senescence- associated secretory phenotype of HSCs may be important in HCC promotion, as shown in obesity- associated HCC [53]. Alcohol- promoted hepatocarcinogenesis is associated with activation of the canonical WNT–β- catenin pathway [54], which may

allow β- catenin-dependent tumor growth and stimulate *CYP2E1* transcription [55]. Finally, alcohol consumption promotes HCC development via immunosuppression, with decreased numbers of antitumor $CD8^+$ cells [56], and by loss of miR-122, which upregulates HIF1α, a tumor- promoting transcription factor [57]. In summary, alcohol and its metabolite acetaldehyde are implicated in several interlinked pathways to carcinogenesis and thus demonstrate the complexity of alcohol-mediated carcinogenesis.

Genetic Associations and Liver Cancer

More recently, novel genes have been discovered that drive liver carcinogenesis independent of the cirrhosis status. More details are provided in the Chap. 52 by H. Innes and F. Stickel on the genetics of ALD. Briefly, In HCC tumors, the most frequently mutated genes are *TERT*, *CTNNB1* and *TP53* [58]. In their recent GWAS of ALD HCC, Buch et al. identified a new germline variant in *TERT* (rs2242652) [59] showing that both hereditary and somatic mutations in HCC driver genes are associated with hepatocarcinogenesis. Also, in the first French GWAS on HCC, it was reported that the lead variant (rs708113) was associated with somatic mutations in *CTNNB1* in HCC tumour cells [60]. It is hoped that these GWAS approaches will help to identify novel target genes and help to better understand the mechanisms that drive liver cancer during alcohol consumption.

Chapter 74
Alcohol and Cancer: The Epidemiological Evidence

Pietro Ferrari, Harriet Rumgay, Elisabete Weiderpass, and Isabelle Soerjomataram

Abstract The consumption of alcohol is one of the top-10 risks contributing to the worldwide burden of disease. In 2012, the Monograph program at the International Agency for Research on Cancer (IARC) reviewed the epidemiological evidence on the possible association between alcoholic beverage consumption and cancer risk at 27 anatomical sites, and reported that **cancers of the upper digestive tract** (**UADT**: oral cavity, pharynx, larynx, esophagus squamous cell carcinoma), liver, colorectum, and female breast were causally related to the consumption of alcoholic beverages. In this chapter we review and summarize the most recent scientific evidence on the link between alcohol intake and cancer risk, including cancer sites with a non-established relationship with alcohol. Several candidate mechanisms of alcohol carcinogenesis are presented. An estimate of the global impact of alcohol on cancer burden is provided, using the population attributable fractions, according to a recent IARC study. Some 741,000 new cancer cases, equal to 4.1% of all new cases of cancer, globally in 2020 were estimated to be attributable to alcohol consumption and could have been avoided if there had been no alcohol use. Last, the future perspectives and challenges of the research on alcohol and cancer were comprehensively discussed.

possible association between alcoholic beverage consumption and cancer risk at 27 anatomical sites, and reported that **cancers of the upper digestive tract** (**UADT**: oral cavity, pharynx, larynx, esophagus squamous cell carcinoma), liver, colorectum, and female breast were causally related to the consumption of alcoholic beverages [2, 3]. In parallel, the Continuous Update Project of the World Cancer Research Fund (WCRF)/American Institute for Cancer Research (AICR) concluded that there was convincing evidence that consumption of alcoholic beverages increased the risk of site-specific cancers mentioned above [4]. The WCRF/AICR also indicated that alcohol could be associated with stomach cancer, and reported suggestive evidence of a link with pancreatic, lung and skin cancers.

In 2016, alcohol consumption caused an estimated 3.0 million deaths from all causes worldwide, representing 5.3% of all deaths [5]. Cancer contributes a large proportion of the health burden caused by alcohol consumption. In 2016, alcohol caused an estimated 376,200 cancer deaths, representing 4.2% (95% uncertainty interval: 3.6–4.9%) of all cancer deaths, and an age standardized rate (ASR) of 4.8 deaths (95% confidence interval, CI: 4.2–5.7) per 100,000 people, as reported in Table 74.1 [6]. The proportion of alcohol-attributable cancers is thus defined by the proportion of cancers that would not have occurred if there had been no alcohol use. In parallel, a recent study conducted at IARC highlighted that globally, 741,300 new cancer cases in 2020 were attributable to alcohol consumption, the 4.1% of the total [7].

While alcohol intake is a risk factor for UADT, colorectum, liver, and female breast cancers, its impact on other cancers remains controversial. A comprehensive meta-analysis investigated the association between alcohol intake and 23 cancer

Table 74.1 Alcohol-attributable cancer deaths in 2016, by sex and cancer site

ICD-10 International Statistical Classification of Diseases and Related Health Problems, 10th revision.

types through the examination of 572 studies and 486,538 cancer cases [8]. Results suggested that alcohol was positively related to the risk of other cancers, including pancreas and prostate cancers and melanoma. The relationship between alcohol and cancer is complex and characterized by different potential biological mechanisms. Several challenging aspects of alcohol intake, including drinking patterns, binge drinking, the existence of specific susceptibility exposure windows and the type of alcoholic beverages, may play a role on alcohol carcinogenicity and are far from being elucidated.

A recent comprehensive study by the Global Burden of Diseases (GBD) group evaluated the health risks associated with moderate alcohol consumption region, age, sex, and time [9]. Using updated systematic reviews, burden-weighted dose–response relative risk curves across 22 health outcomes, including cancer, were built to estimate the levels of alcohol consumption that minimise health loss through the theoretical minimum risk exposure level (TMREL) and non-drinker equivalence (NDE), the consumption level at which the health risk is equivalent to that of a non-drinker. The study confirmed that the level of alcohol consumption that minimises health loss varies significantly across populations and age groups and remains zero or very close to zero for several population groups, particularly young adults. Given these findings, the GBD group recommended a modification of existing policy guidelines to focus on emphasising differential optimal consumption levels by age, rather than the current practice of recommending different consumption levels by sex.

Colorectal Cancer

Colorectal cancer is the second most diagnosed cancer and impacted 1.9 million people in 2020 [10]. Alcohol intake has been consistently associated with ***colorectal cancer*** (CRC) risk [2, 11]. A comprehensive meta-analysis posterior to the Volume 100E of the IARC Monograph Program [3] was carried out by scientists of the WCRF/AICR Continuous Update Project (CUP) [12]. The study summarized the evidence on the link between alcohol intake and CRC based on data from 16 prospective studies reported in PubMed until May 2015. Each increase of 10 g/day of alcohol intake, as ethanol in alcoholic beverages, equivalent to a standard drink of wine (about 100 ml), beer (about 275 mL) or spirits (about 30 mL) was positively associated with CRC risk, with relative risk estimates (RR) equal to 1.07 (95% CI: 1.05, 1.09). Similar RR estimates were reported for colon cancer (1.07, 95% CI: 1.05, 1.09, based on 14 studies) and rectal cancer (1.08, 95% CI: 1.07, 1.10, based on 11 studies). Stratified analysis by sex showed positive associations in men and borderline significant relationships between alcohol intake and CRC risk in women. For colon and rectal cancer, alcohol intake was associated with a significant increase in women and men. Among five studies [13–16] with data on distal and proximal colon cancer, two observed a significant association with distal colon cancer: the Melbourne Cohort Study [16] and the European Prospective Investigation into

Cancer and Nutrition (EPIC) study [17]. Two studies in women observed a significant association with proximal cancer, the Iowa Women's Health Study (IWHS) [13] and the Netherlands Cohort Study (NLCS) [15].

Few studies have examined the association between CRC and other metrics of alcohol exposure, including average alcohol intake during the lifetime or during early adulthood, age at starting, duration. The limited evidence suggests that there is no strong association with duration of drinking in years or age at started drinking [17–19]. Associations with CRC risk were similar for baseline and lifetime alcohol intakes [17, 20]. The association of consumption of alcoholic beverages and CRC did not seem to differ by beverage type [13, 17, 20, 21]. No interaction was observed between alcohol drinking and smoking with respect to CRC risk [17]. Few studies have examined whether the association of alcohol with cancer of the colorectum varies by folate status; the European Prospective Investigation into Cancer and Nutrition (EPIC) found some evidence that the risk for colorectal cancer associated with alcohol intake was stronger in individuals with a low folate intake, but the interaction term was of marginal statistical significance [17], and two other studies found no evidence that the association of alcohol intake with risk differed according to intake of folate, or intake of related nutrients such as vitamin B6, vitamin B12 or methionine [22, 23].

Recent research also focused on early onset CRC, whose incidence has increased recently widely. A systematic literature review and meta-analysis of studies was conducted to examine demographic and lifestyle factors for early onset CRC, defined as CRC occurring before age 50 [24]. Based on two recent studies [25, 26] eligible for the review, alcohol intake was strongly associated to CRC risk, with RR estimates equal to 1.71 (95% CI: 1.62, 1.80), comparing high drinkers versus non-drinkers.

Breast Cancer

Breast cancer (BC) affects more than two million women each year around the world [27]. Although many risk factors for BC are not modifiable, understanding the role of the factors that can be altered, including alcohol intake, is critical. The IARC Monographs in 2010 [3] and 2012 [11] concluded that the occurrence of cancer of the ***female breast*** was causally associated with the intake of alcoholic beverages. This conclusion was based on data from more than 110 epidemiological studies, together with a pooled analysis of 53 studies on more than 58,000 women with BC, with a RR estimate equal to 1.07 (95% CI: 1.05, 1.09) for each 10 g/day of alcohol intake [28]. The Million Women Study in the United Kingdom, with over 28,000 incident cancers, is the largest single study to estimate the BC risk at low to moderate levels of alcohol consumption. A 10 g/day increase of alcohol intake was linearly associated with BC risk, with RR estimate equal to 1.12 (95%CI: 1.09, 1.14) [29]. Interestingly, variation over time was taken into account in the study by

repeating the alcohol intake assessments approximately 3 years after recruitment. Within the EPIC study, an evaluation that included over 11,000 incident BC cases, alcohol intake was significantly related to BC risk [30]. For each 10 g/day increase in alcohol intake the hazard ratio (HR) increased by 4.2% (95% CI: 2.7–5.8%). Taking 0.1–5 g/day as reference, alcohol intake between 5 and 15 g/day was related to a 5.9% increase in BC risk (95% CI: 1–11%). Significant increasing trends were also observed between alcohol intake and hormonal receptor status BC, notably in ER+/PR+, ER−/PR−, HER2− and ER-/PR−HER2− tumors. Associations were marginally stronger among women who started drinking prior to first full-time pregnancy.

A recent large meta-analysis of epidemiological studies until December 2018 provided a dose-response estimation between different aspects of alcohol intake and BC risk [31]. Dose-response analysis modeled the relationships between drinking type and BC risk. Sources of heterogeneity were explored, and sensitivity analyses were conducted to test the robustness of findings. In total, 22 cohort studies and 45,350 BC cases were included. Current drinkers for ER+ had an increased risk compared with never drinkers. In dose-response analysis, there was a statistically significant linear trend with BC risk increasing gradually by total alcohol and wine dose: for each 10 g per day of alcohol, RR estimates were 1.10 (95%CI: 1.08, 1.13) for total alcohol and 1.08 (95% CI: 1.04, 1.14) for wine intake. For postmenopausal women, the risk increased by 11.1% (RR = 1.11, 95% CI: 1.09, 1.13) with every 10 g of total alcohol per day.

Overall, there is consistent evidence that the risk for BC does not vary significantly by menopausal status [23, 30, 32–35] or beverage type [29, 35–38]. Noteworthily, while some evidence suggested that associations did not vary by folate intake [35, 37, 39], within the EPIC study the risk of BC per 10 g/day of alcohol intake was 1.06 (95% CI: 1.03, 1.08) for women with low intake of dietary fiber (<18.5 g/day), while among women with dietary fiber greater than 24.2 g/day the risk of BC was 1.02 (95% CI: 0.99, 1.05), with a statistically significant interaction (p-value for testing the homogeneity of associations was equal to 0.01) [40]. This modulating effect was stronger for dietary fiber from vegetables. These results suggested that dietary fiber intake may modulate the positive association of alcohol intake and BC.

Overall, evidence is strongest for North America and Europe, where more studies have been conducted, but other regions also show consistent associations [41]. Additional studies focusing on beverage type, the participant's age at the time of consumption provided less consistent findings. A better understanding of the roles of drinking pattern, by separating out drinking intensity and frequency, is needed. More studies of alcohol consumption and BC subtypes would help increase insights into this relationship. A clearer understanding of the effects of exposures in early life, including *in utero* exposure, is warranted. Examination of how other BC risk factors (e.g., physical activity, body mass index, smoking, reproductive history) interact with alcohol consumption in relation to BC incidence and prognosis is needed.

Liver and UADT Cancers

Alcohol intake has been consistently associated to ***liver cancer*** [3, 4], based on several case-control and cohort studies. The finding was also confirmed by a large meta-analysis of 36 studies and 8800 liver cancer cases [8]. The most recent IARC Monograph assessed a link for alcohol intake for both hepatocellular carcinoma and cholangiocarcinoma [3]. As cholangiocarcinoma is a rare cancer, the etiological link with alcohol was largely examined in case-control studies rather than in prospective cohorts. Chronic infection with hepatitis viruses B and C are the major causes of cancer of the liver, yet associations between alcohol and liver cancer were observed among individuals infected with hepatitis viruses and among uninfected individuals.

Quantification of the relationship between alcohol and cancer is challenging since cirrhosis and other liver disorders that often anticipate cancer onset tend to lead to a decrease or a cessation of consumption of alcoholic beverages many years before the occurrence of cancer of the liver (reverse causation). It has been estimated that at least 75% of ***UADT cancers*** (upper aerodigestive tract including cancers of the oral cavity, pharynx, larynx and esophagus) were attributable to a combination of cigarette smoking and alcohol drinking [42]. An open research question is if the only role of alcohol is through its synergistic association with tobacco or whether alcohol also has an independent effect in never-smokers. It was observed that alcohol acts as a solvent that enhances the penetration of carcinogenic compounds into the mucosa, thus facilitating the uptake of environmental carcinogens, especially from tobacco smoke [43]. The results of a pooled analysis of 15 case-control studies suggested that, in the absence of tobacco use, the association between alcohol consumption and risk of head and neck cancer was weak, and apparent only at high doses, mainly confined to pharyngeal and laryngeal cancers [44, 45].

Cancer Sites with a Suggestive Link with Alcohol

The link between alcohol use and the risk of cancer of several other sites is far from being established. It has been observed that alcohol use might be positively associated with risk of pancreatic cancer [46], stomach cancer [8], prostate cancer [8], and melanoma [47]. On the other hand, evidence is suggestive of a protective role of alcohol use in relation to the risk of cancer of the kidney [48] and thyroid [8], and Hodgkin [49] (HL) and Non-Hodgkin [50, 51] (NHL) lymphomas. The mechanisms for the inverse associations observed are unclear.

Prostate cancer is the most diagnosed cancer among men worldwide, with incidence rates displaying large variability between areas. The exact nature of the association between alcohol intake and prostate cancer risk remains unclear despite the large number of research studies [52]. Prostate cancer is a heterogenous disease and

risk factors may differ. In two recent studies [53, 54] that reported significant positive associations between alcohol use and the risk of prostate cancer [53, 54], associations were more apparent for lifetime alcohol use compared to alcohol use at recruitment.

Pancreatic cancer is characterized by the difficulty in detecting it at early stages and lack of effective treatments, leading to high fatality rates, necessitating the need to identify modifiable risk and preventive factors for this cancer. A large meta-analysis of 14 cohort and 15 case-control studies provided evidence for an increased risk of pancreatic cancer only for heavy alcohol drinking [55]. In a more recent study, it was estimated that heavy use of alcohol increased the risk of pancreatic cancer by 19% compared with nondrinkers or occasional drinkers, with homogenous associations across studies [8]. These findings of an association observed primarily for heavy alcohol use were also confirmed in several large pooling studies [46, 56–59], and in a recent EPIC study [59].

A role for alcohol use in the etiology of ***stomach cancer*** is plausible but the epidemiological evidence remains equivocal [8, 60]. Most evidence from prospective studies is based on consumption data that refer to the time of study recruitment, that is, alcohol intake at baseline, which might not be representative of participants' long-term consumption during earlier age periods, particularly for heavy drinkers who had reduced alcohol consumption. Within recent pooling study of EPIC and the Melbourne Collaborative Cohort Study (MCCS) including 1225 incident stomach cancers (78% noncardia), a weak association was observed between baseline alcohol intake and noncardia stomach cancer, but none for cardia cancer, nor using lifetime alcohol intake [61].

Evidence for a relationship between alcohol consumption and skin ***melanoma*** risk is inconsistent and findings from prospective investigations are so far very limited [29, 62, 63]. A recent meta-analysis [47] of 14 case-control and 2 cohort studies reported an increased risk of melanoma for increasing levels of alcohol intake, but the authors warned for caution in interpretation of their findings because of residual confounding by sun exposure, as alcohol increases sunburn severity, a major risk factor for melanoma. A recent study from the EPIC cohort reported that baseline alcohol intake was positively associated with risk of melanoma, and with of basal-cell and squamous-cell skin cancers [64].

The results on the relationship between alcohol consumption and risk of ***bladder cancer*** are controversial [8]. A recent meta-analysis of nine prospective studies a lack of association between alcohol intake and the risk of bladder cancer in the entire population. However, one alcoholic drink increments each day could elevate the risk of bladder cancer by 9% (RR = 1.09; 95%CI: 1.01–1.17), and an association was found for male drinkers [65].

Recent epidemiologic evidence reported that moderate alcohol consumption was inversely associated with the risk of ***kidney cancer***. This was observed in two comprehensive meta-analysis [8, 65], in a recent EPIC study on baseline and lifetime alcohol use [66], and in a systematic review of the literature about modifiable risk factors for kidney cancer [67]. The mechanism for the inverse association between alcohol consumption and renal cancer risk is not well understood. Moderate alcohol

consumption is associated with a lower risk for type-II diabetes and could be related to increased insulin sensitivity. Alcohol use would prevent insulin resistance and then indirectly renal cancer.

An inverse association of alcohol with both **Hodgkin lymphoma** ***(HL)*** [49] and **Non-Hodgkin lymphoma** ***(NHL)*** [51] has been reported in meta-analyses. The mechanisms accounting for a possible alcohol-induced decrease in the risk of lymphomas remain largely unknown but may in part be mediated by immune-related mechanisms, given that lymphomas appear to arise in a milieu characterized by immune activation or inflammation, and are believed to result from errors in cellular processes associated with normal lymphocyte maturation and differentiation [68]. If immune hyperactivation increases lymphoma risk and modest alcohol intake suppresses immune activation, this could plausibly explain reported modest inverse associations of alcohol with lymphoma [69, 70]. It has also been suggested that the inverse relationship observed could be partially attributable to reverse causation, whereby early symptoms of lymphomas may cause cancer cases to either quit or reduce their alcohol drinking [71].

The evidence for an association between alcohol use and ***thyroid cancer***, although mildly suggestive of an inverse relationship, is very sparse [8]. A recent evaluation based on 556 (90% women) thyroid cancer cases in the EPIC study provided some support to the hypothesis that moderate baseline and lifetime alcohol consumption may be associated with a lower risk of differentiated thyroid carcinoma [72].

Potential Mechanisms

There are several biological mechanisms by which alcohol, as ethanol, induces cancer [73]. Once consumed, alcohol is metabolized to acetaldehyde by the enzymes alcohol dehydrogenase (ADH), cytochrome P-450 2E1 (CYP2E1) and bacterial catalase [74]. Acetaldehyde is highly reactive towards DNA and can bind directly to DNA to form DNA adducts which can block DNA synthesis and repair, induce point mutations, double-strand breaks, sister chromatid exchanges and structural changes to chromosomes [43, 75]. Another property of acetaldehyde is that it can also bind to proteins causing structural and functional changes to enzymes involved in DNA repair and DNA methylation. DNA methylation is often disrupted by both ethanol and acetaldehyde due to their ability to inhibit S-adenosyl-L-methionine synthesis and DNA methyltransferase (DNMT) activity as well as their ability to dysregulate one-carbon metabolism which has a downstream effect on DNA methylation [74, 76].

While acetaldehyde has many carcinogenic and genotoxic properties, it is not the final product of ethanol metabolism: non-toxic acetate is formed when acetaldehyde dehydrogenases (ALDH) oxidize acetaldehyde. The main ALDHs involved in acetaldehyde oxidation consist of ALDH1A1, ALDH2, and ALDH1B1, and ALDH2 is

responsible for most of this processing in the liver [77]. The common polymorphism *ALDH2*2*, present among 28–45% of East-Asian populations, dramatically reduces ALDH2's ability to metabolize acetaldehyde and carriers have a substantially increased risk of UADT cancer when consuming alcohol [78].

Ethanol-mediated carcinogenesis can also result from the induction of oxidative stress by the increased activity of CYP2E1 which produces high quantities of reactive oxygen species (ROS) when oxidizing ethanol to acetaldehyde [79, 80]. Being highly reactive, ROS can induce lipid peroxidation resulting in the formation of aldehydes which can bind to DNA forming highly mutagenic etheno-DNA adducts [81, 82]. ROS can also induce metastasis and angiogenesis by interfering with signaling pathways to upregulate vascular endothelial growth factor and monocyte chemotactic protein 1 [83]. In addition to CYP2E1 activity, ROS can also be produced as a result of inflammation in the tumor microenvironment where monocytes and macrophages produce pro-inflammatory cytokines, such as tumor necrosis factor α and interleukins [83, 84], activating further ROS-generating enzymes [82]. ROS may also trigger the production of pro-fibrotic cytokines and collagen in liver cells leading to liver cirrhosis which is another well-recognized intermediary step towards hepatocellular carcinoma development [85].

Another pathway through which alcohol is involved in carcinogenesis is through interference with retinoid metabolism and the oxidation of vitamin A to retinoic acid [43], but retinoids are necessary for normal cell growth, cell differentiation, and apoptosis [83]. Alcohol might also interfere with estrogen pathways by increasing estrone and estradiol levels and enhancing the activity of estrogen receptors which might be important in breast carcinogenesis [86]. Heavy use of alcohol has also been linked with increased circulating levels of estrone and estradiol as well as dehydroepiandrosterone sulphate which is subsequently metabolized to estrogen [87].

Alcohol might reduce the normal function of the immune system by disrupting the production of necessary proteins to target and destroy potentially cancerous cells [84]. It has also been hypothesized that alcohol can activate natural killer T cells leading to liver injury and apoptosis of hepatocytes [84]. Furthermore, chronic alcohol use can cause microbial dysbiosis and bacterial overgrowth in the intestine leading to "gut leakiness"; in this case, the intestinal lumen becomes so permeable that bacterial products including lipopolysaccharides and peptidoglycan move into the blood and reach the liver resulting in a state of chronic inflammation [74, 84, 88]. In the oral cavity, bacterial catalase metabolizes ethanol to acetaldehyde, but these bacteria have limited capacity to metabolize acetaldehyde to acetate, thus leaving the oral epithelia exposed to acetaldehyde and its carcinogenic properties for longer [43, 89]. There is further hypothesis that alcohol consumption might activate the pathways of other carcinogenic agents such as some pro-carcinogens in tobacco smoke and industrial chemicals (see UADT above) [43]. It is also postulated that ethanol might increase the absorption and penetration of these carcinogens in the mucosa of the UADT [43, 90], where it has been reported that tobacco smoking and alcohol consumption have a synergistic effect on the risk of cancer [91, 92].

In summary, alcohol and its metabolite acetaldehyde are implicated in several interlinked pathways to carcinogenesis and thus demonstrate the complexity of alcohol-mediated carcinogenesis.

Global Impact of Alcohol on Cancer Burden

The impact of alcohol on cancer burden can be estimated using population attributable fractions (PAFs), which compare the current cancer burden to the expected burden if there had been no alcohol use. According to a study conducted at IARC which used the IARC Monograph and WCRF classifications of cancer risk factors to determine which cancer sites could have potentially alcohol-attributable cases, 741,300, or 4.1%, of all new cases of cancer globally in 2020 were attributable to alcohol consumption [7]. Men accounted for more than three-quarters (76.7%) of this total, with 568,700 alcohol-attributable cancer cases among men in 2020 and the remaining 172,600 alcohol-attributable cancer cases among women. As for the contributing cancer sites, the cancer sites with the highest PAFs attributable to alcohol at the global level were cancers of the esophagus (31.6%), pharynx (22.0%), and oral cavity (20.2%), although there were considerable differences by sex; for example, 39.2% of esophageal cancer cases among men were attributable to alcohol, versus 14.3% among women. But when considering the total burden by number of cases, the cancer sites that contributed the most alcohol-attributable cases were cancers of the esophagus (189,700 cases), liver (154,700 cases), and breast (98,300 cases, female only). Together, these results confirmed the higher burden of alcohol-attributable cancers among men, yet with breast cancer among the top three contributing cancer sites, this highlights that even though alcohol-attributable cancer is a predominantly male disease, in settings where the incidence of breast cancer among women is high, this female disease is placed among the top causes of alcohol-attributable cancers and causes a major burden of alcohol-attributable cancer. For example, in the United Kingdom, breast cancer contributed the most cases of cancer attributable to alcohol and represented nearly a quarter (24.2%) of total alcohol-attributable cases among both men and women.

The study conducted at IARC also presented the alcohol-attributable cancer burden according to three levels of alcohol intake: moderate (<20 g per day), risky (20–60 g per day), and heavy alcohol consumption (>60 g per day), which roughly corresponded to one or two alcoholic drinks per day (moderate), two to six alcoholic drinks per day (risky), and more than six alcoholic drinks per day (heavy). From this analysis, moderate drinking contributed 103,100 (13.9%) cases of alcohol-attributable cancer, risky drinking contributed 291,800 (39.4%) cases, and heavy drinking contributed 346,400 cases (46.7%). Moderate and risky drinking had a larger impact among women (32.3% and 50.3% of alcohol-attributable cancers among women, respectively) compared with men (8.3%, 36.1%, respectively).

The IARC study also presented PAFs for regions and countries of the world which uncovered further disparities (Fig. 74.1). The highest PAFs of cancer cases

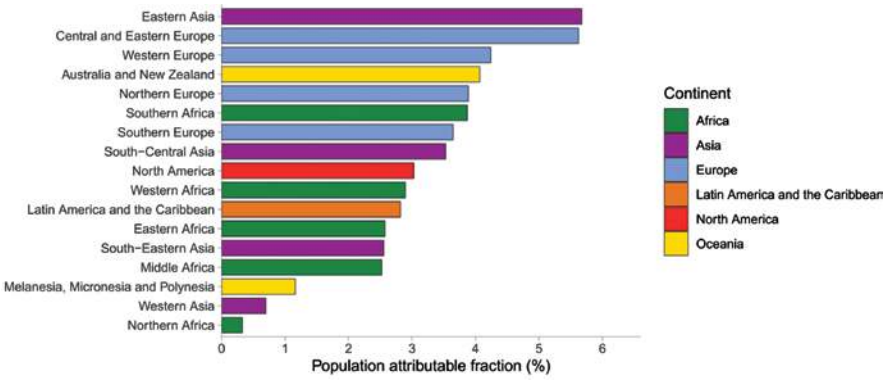

Fig. 74.1 Proportion of cancer cases in 2020 attributable to alcohol consumption, by world region. Chart created using results from Rumgay et al. [7]

attributable to alcohol were observed in eastern Asia and central and eastern Europe (5.7% and 5.6% of all cancer cases, respectively). These regions also held the countries with the highest PAF for alcohol-attributable cancers, namely Mongolia (9.8%), Moldova (7.9%), Romania (6.8%), Belarus (6.5%), and China (6.2%). The world regions with the lowest PAFs were northern Africa (0.3%) and western Asia (0.7%), which also included the countries with the lowest PAFs, namely Kuwait, Libya, and Saudi Arabia (all 0.1% of cancer cases attributable to alcohol). When exploring regional PAFs by sex, the patterns among men were of the same magnitude of the average for both sexes combined. Yet, differences were found for the patterns for women with the largest PAFs in central and eastern Europe (3.4%), Australia and New Zealand (3.3%), and western Europe (3.2%).

Future Perspectives

The assessment of the relationship with cancer sites that do not have an established link with alcohol intake presents several analytical challenges. First, any association with alcohol intake, if true, is likely to be weak or moderate. Thus, the statistical power to detect an association in a single study is likely very low. Second, cancer is a very heterogeneous disease, and some of the specific anatomical sites mentioned above are less common cancer sides, in particular pancreatic cancer, NHL in women and thyroid cancer in men. Accurate investigations on the role of alcohol on risk of less common cancers, as well the investigations of the alcohol and cancer relationship among specific subgroup of the study populations, e.g., among never smokers, requires the collection of information from a sizeable study population with a sufficiently large number of cancer cases.

For this purpose, this is likely achievable through international consortia to jointly analyze existing data from ongoing large prospective epidemiological

investigations. Third, most epidemiological investigations that evaluated the role of alcohol on risk of cancer focused primarily on total alcohol intake collected at baseline through self-reported dietary (or lifestyle) questionnaires. Several studies showed that exposure to alcohol in different life periods could be relevant for disease development [17, 93–96]. Recent studies have complemented analyses of baseline alcohol use with evaluations of alcohol use at different ages during participants' early and mid-adulthood, typically, at 20, 30, 40 and 50 years of age, a variable customarily referred to as 'lifetime alcohol intake' [17, 96]. Although more comprehensive, this approach still ignores potential within-person changes in alcohol intake during adulthood. To date, a few studies have evaluated the effect of changing alcohol intake during adulthood with respect to cancer risk using retrospective and/or prospective assessments in large epidemiological investigations [97, 98]. Fourth, drinking patterns may play a role in the carcinogenesis related to alcohol intake, and binge drinking has received increasing attention in cancer research [99]. Large amounts of alcohol consumed in a limited amount of time may trigger cancer risks that are more harmful than if the same alcohol quantities were consumed over a longer time span [87, 99]. Fifth, self-reported alcohol intake is, like other dietary factors, prone to exposure measurement errors, and more specifically underreporting [100]. Alcohol is a (culturally) sensitive exposure, rendering it susceptible to underreporting across self-reported assessments. However, the extent and distribution of measurement errors are unknown [101], and it is likely that observed associations between alcohol use and disease risk are biased. Objective assessments not relying on the capacity of study participants to recall their past exposure to alcohol would be useful [102]. Biomarkers of habitual alcohol use, including light-to-moderate drinking, would be necessary to more accurately assess alcohol exposure in epidemiological studies and to improve risk estimates for diseases including cancer where modest associations may exist. Throughout the present chapter, we presented an overview of the relationship between cancer and overall alcohol intake, without providing extensive details on the cancer site-specific risks associated with different types of alcoholic beverages (wine, beer, or spirits), although several studies attempted this type of examination [12, 17].

Conclusion

The carcinogenicity of alcohol drinking has been established and well documented over four decades [103], and in most recent assessment it has been linked to at least seven cancer sites, contributing to at least 740,000 new cancer cases annually worldwide. While studies have reported on causal relations of alcoholic beverages, drinking patterns and alcoholic types, questions regarding its associations to various cancer types such as stomach, bladder, prostate and pancreatic cancer, as well as inverse relations to HL, NHL, thyroid and kidney cancers remain. Mechanistic studies have gone a long way confirming the multiple, complex, pathways from alcohol drinking to carcinogenesis, yet a better understanding as to how other risk factors

such as smoking may modify the risk can prove extremely useful to design cancer prevention programs.

In this respect, it is noteworthy to mention the Pooling Project on Alcohol and Cancer (PPAC), an international collaborative project led by scientists at IARC (PI: Dr. Pietro Ferrari) and at the T'Chan Harvard School of Public Health (PI: Dr. Stephanie Smith-Warner), which aims at investigating the relationships between alcohol intake and risk with cancers of the prostate, pancreas, kidney, thyroid, and non-Hodgkin lymphoma, for which the evidence is still inconsistent or sparse. The PPAC will also focus on UADT cancer among non-smokers. The project gathered data from over 30 cohorts in Nort America, Europe, Asia and Australia, and was funded by the US National Institute of Alcohol Abuse and Alcoholism (NI-AAA). In addition, future research on alcohol might leverage available biomarker and -omics data to identify molecular correlates of alcohol drinking that may inform on mechanisms. Tools for causal inference create promising opportunities to quantify potential mediating role of sets of molecular data using individual features but also the concept of signatures, quantities that greatly summarize overwhelming amount of biological information into scores [104]. For this to happen, we will need flexible models for data sharing and resources for capacity building.

While alcohol consumption has decreased in countries where its prevalence was traditionally high, 2.34 billion adults worldwide consumed alcohol regularly in 2016. Studies that have examined public understanding of alcohol drinking and its consequences on health on cancer are lacking [41], but have showed low overall awareness e.g., in a study of women attending a breast screening clinic in the United Kingdom, only 19% were aware that alcohol consumption is a BC risk factor [105, 106]. The World Health Organization has therefore called for global commitments to reducing alcohol drinking in 2010 and renewed this call updating evidence-based actions through its best buys a set of most effective interventions including pricing policy through taxes on alcoholic beverages, bans or restrictions on advertising, restricting availability of retailed alcohol [107]. These interventions require modest investments from countries, yet they are expected to have a large impact on health including on reduction of cancer burden [108], and bring nations closer to better health for all.

Chapter 75
Alcohol-Related Cancers of the Esophagus, Head and Neck, and Stomach in East Asians

Akira Yokoyama

Abstract Esophageal squamous cell carcinoma (SCC) in East Asians is characterized by field cancerization in the upper aerodigestive tract (UAT: esophagus and head and neck region) and stomach. In addition to alcohol consumption, smoking, and a low intake of fruit and vegetables, the combination of slow-metabolizing alcohol dehydrogenase-1B (ADH1B) and inactive aldehyde dehydrogenase-2 (ALDH2) with long and high exposure to ethanol and acetaldehyde increases the risk of SCC in the UAT. The combination of alcohol consumption and ALDH2 deficiency also increases the cancer risk in the stomach. Screening evaluations using chromoendoscopy or image-enhanced endoscopy and questionnaires that include alcohol flushing and drinking behaviors can provide predictors of both primary and secondary SCC of the UAT, and abstinence or a reduction in alcohol consumption has been reported to prevent second cancers in high-risk patients after UAT cancer treatment.

Keywords Alcohol · Alcohol dehydrogenase · Acetaldehyde · Aldehyde dehydrogenase · Esophageal cancer · Head and neck cancer · Stomach cancer

Introduction

The most common esophageal cancers in East Asians are squamous cell carcinomas (SCCs), which are strongly influenced by alcohol consumption and smoking and are characterized by multiple cancerization in the esophagus, head and neck, and stomach. The risk factors for esophageal SCC are clear, and treatment based on a risk assessment is useful for cancer prevention. Risk factors for secondary SCCs of the esophagus and head and neck (upper aerodigestive tract [UAT]) and the preventive effect of abstinence from alcohol have also been discussed.

Carcinogenic Mechanism of SCC in the UAT

Synergistic Effects of Direct Alcoholic Beverage Exposure and Smoking

Alcohol beverages include acetaldehyde (AA), and many strong alcoholic beverages are strong AA beverages. The UAT is directly exposed to ethanol and AA. In Japan, there are reports of a higher SCC risk in the UAT from the consumption of strong beverages such as shochu (20%–25% v/v) and whiskey [1, 2]. While blood AA levels after drinking are on the order of 1–10 μM, beer contains an average of 100–200 μM, sake and wine 700 μM, and shochu and whiskey 1000 μM [3, 4], although there are large differences depending on the manufacturer, with some brands of shochu containing several μM only. Cigarette smoke also contains AA, and roughly 400 μM of AA is detected in saliva during smoking [5]. Ethanol is a solvent that allows tobacco smoke to penetrate the mucosa. The risks of esophageal SCC from drinking and smoking are synergistic, with odds ratios (ORs) reported to be 30–50 times higher in heavy drinking smokers [6, 7].

Ethanol Metabolism in Saliva and UAT Mucosa (Fig. 75.1)

The concentration of ethanol in saliva and blood is almost the same. Oral bacteria produce AA from ethanol, and salivary AA concentrations exceed 50–100 μM and are even higher in ALDH2-deficient individuals [8–11]. Although poor oral hygiene

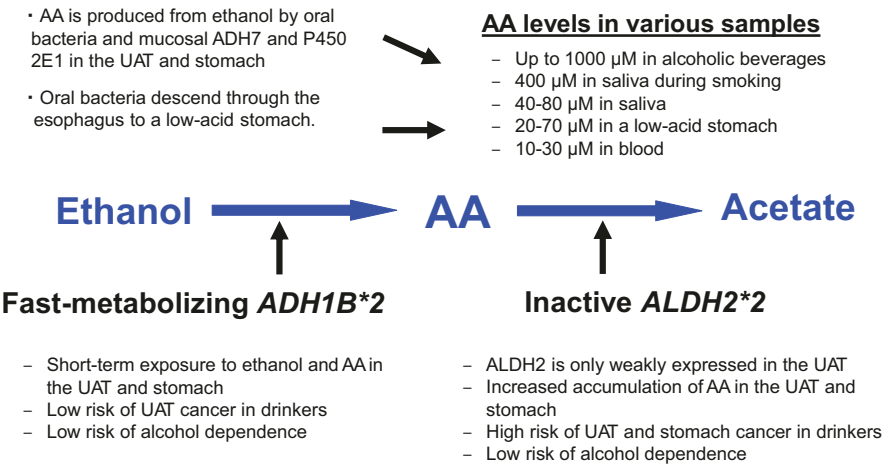

Fig. 75.1 Ethanol and acetaldehyde (AA) exposure and accumulation in the upper aerodigestive tract (UAT) and stomach and role of *alcohol dehydrogenase-1B*2* (*ADH1B*2*; rs1229984) and *aldehyde dehydrogenase-2*2* (*ALDH2*2*; rs671)

and dental care is a risk factor for UAT cancer [12], the quantity of bacteria in saliva is correlated with the ability to produce AA [8, 13]. In alcohol-dependent patients, the quantity of bacteria in saliva immediately before hospitalization is high; after hospitalization, the quantity of bacteria decreases with improvements in lifestyle, including teeth brushing, and the AA production capacity of saliva decreases accordingly [13].

Alcohol dehydrogenase-7 (ADH7), which has a relatively high Km value and is not found in the liver, is strongly expressed in the UAT, while aldehyde dehydrogenase-2 (ALDH2), which is strongly expressed throughout most of the body, is only slightly expressed in the UAT [14, 15]. Therefore, AA produced locally in the UAT mucosa tends to accumulate to high concentrations.

Genetic Polymorphisms of ALDH2 (rs671)

Ethanol is mainly metabolized in the liver, where it is converted to AA by ADHs and the microsomal ethanol oxidizing system (MEOS) and to acetate by ALDHs. ALDH2, which has a low Km value, plays a major role in AA metabolism. The Asian gene polymorphism of *ALDH2* is homozygous inactive (**2/*2* or *A/A*) in less than 10% of Japanese individuals, while a heterozygous inactive status (**1/*2* or *G/A*) is seen in about 40% and an active status (**1/*1* or *G/G*) is seen in more than 50%. The ALDH2 homozygous inactive form shows zero activity, and the heterozygous inactive form has a theoretical activity of 16% and a measured activity of 17% in liver tissue [16].

Many ALDH2-deficient individuals are flushers who experience facial flushing after drinking one glass (≈180 mL) of 5% beer, a typical Japanese beer glass, and they can develop hangovers after relatively small amounts of alcohol consumption [17]. Most homozygous ALDH2-deficient individuals are nondrinkers or occasional drinkers, but some heterozygous individuals are less prone to develop or lack alcohol flushing, and some can drink because they have developed tolerance, and more than 15% of alcohol-dependent individuals have an inactive heterozygous ALDH2 status [18]. The ALDH2-deficient genotype originated among the Han Chinese and spread to East and South Asia about 2000–3000 years ago. In Japan, the number of ALDH2-deficient individuals is relatively low in the southern and northern areas (e.g., less than 40%), while it is high in the central areas (e.g., around 50%), reflecting the history of immigration from the continent and racial mixing [19]. Thus, regional differences should be considered in ALDH2-related studies in Asians.

ALDH2 heterozygous deficiency increases the risk of UAT cancer arising from alcohol consumption. In Japan, 60%–70% of esophageal SCC patients are ALDH2 deficient [2, 20–25]. In a meta-analysis of 31 Asian studies of esophageal cancer, the OR for the heterozygous inactive form of ALDH2 per se was 6.50 (95% confidence interval, 5.34–7.92) among heavy drinkers and 3.79 (3.04–4.72) among light/moderate drinkers [26]. In a meta-analysis of 13 Asian studies of head and neck cancer, the OR for the inactive ALDH2 was 2.30 (1.11–4.77) among heavy drinkers

and 1.47 (1.16–1.86) among light/moderate drinkers [27]. Japanese [28] and Chinese [29] cohort studies in general populations have demonstrated that the ALDH2 genotype improves predictions of the development of cancer in the UAT. The risk of carcinogenesis arising from a heterozygous ALDH2 status is higher in Japan and Taiwan than in mainland China [30].

Genetic Polymorphisms of ADH1B (rs1229984)

Class I ADH in the liver consists of 1A, 1B, and 1C isozymes and is a major player in ethanol metabolism, with a low Km value and a high enzyme content. In non-Asian ethnic groups, more than 90% have the slow-metabolizing form of ADH1B (*ADH1B*1/*1* or *G/G*), while more than 90% of Asians have fast-metabolizing forms (**1/*2, *2/*2* or *G/A*, *A/A*) [31, 32]. In heavy drinkers with slow-metabolizing ADH1B, ethanol remains at a high concentration until the next day of drinking [11, 13, 33, 34]. Furthermore, some *ADH1B*1/*1* patients may start to drink again the next day when residual ethanol is still present in their system from their previous drink. The slow metabolizing form of ADH1B is a strong risk factor for alcohol dependence. Roughly 30% of patients with alcohol dependence in Japan have this form, and younger patients are more likely to have this form [18, 35]. In addition to heavy drinking, slow metabolizers of ADH1B are more likely to develop UAT cancer at the same dose. When higher levels of ethanol linger in alcohol-dependent *ADH1B*1/*1* carriers, the UAT is exposed to saliva containing higher levels of AA produced by oral microbes for longer periods of time [8, 13], especially in alcohol-dependent *ALDH2*1/*2* carriers [11]. In a meta-analysis of Asian esophageal cancer, the OR for the slow metabolizing form of ADH1B per se was 4.82 (3.50–6.64) among heavy drinkers, 2.01 (1.23–3.28) among moderate drinkers, and 1.67 (1.19–2.35) among other drinkers [36]. In a follow-up study of alcohol-dependent patients who were cancer-free at an initial endoscopic screening, 20% of patients had developed UAT cancer at 10 years, and the hazard ratio (HR) for UAT cancer was 11.55 (5.73–23.3) and 2.02 (1.02–4.02) for the heterozygous inactive ALDH2 type and the slow-metabolizing ADH1B type, respectively [37].

In heavy drinkers with slow-metabolizing ADH1B, UAT is exposed to high concentrations of ethanol for a longer time, resulting in longer exposure to AA that is locally produced by bacteria [11, 13, 33, 34]. The WHO's International Agency for Research on Cancer (IARC) concluded that alcoholic beverages, ethanol in alcoholic beverages, and AA associated with drinking are carcinogenic to humans (Group 1 carcinogen) [38]. There has been growing evidence that the effect of the *ALDH2* genotype is much stronger than that of the *ADH1B* genotype in esophageal SCC [2, 22, 23] and somewhat stronger in hypopharyngeal SCC [39–41], while the effects of the *ADH1B* genotype are equivalent to or somewhat stronger than that of ALDH2 in head and neck cancer overall [25, 39, 40, 42, 43].

Combination of Heterozygous Inactive ALDH2 Genotype and Slow-Metabolizing ADH1B Genotype

A large genome-wide association study (GWAS) in Japan reported the above genotype combination to account for 1.9% and 14.1%, respectively, in controls and esophageal SCC cases [22], and another large Japanese GWAS, 2.6% and 17.0%, respectively [23]. Many individuals with this genotype combination tend not to report alcohol flushing responses, partly because the initial AA production is slow due to the slow-metabolizing ADH1B, but the peak blood AA levels are high due to the heterozygous inactive ALDH2 [35, 44, 45]. This combination increases the OR of esophageal SCC by 29–56-fold [2, 22, 23]. When the genotype combination was combined with other risk factors, one Japanese GWAS showed a 189-fold (95–377) increase in the esophageal SCC risk for smokers who consumed more than 96.5 g of ethanol per week [22], while another Japanese GWAS showed a 357-fold (105–1210) increase in the esophageal SCC risk for alcohol consumption plus smoking [23], compared with a combination of low-risk factors. A Taiwanese case-control study of esophageal SCC also showed an OR of 382 (47–3085) for the genotype combination carriers who drink more than 30 g ethanol per day, compared with nondrinkers [46]. A low-cost *ADH1B*/*ALDH2* genetic analysis service is now available using mucosal smears; this service is expected to be used widely as well as clinically.

Genetic Damage by Acetaldehyde

In ALDH2 heterozygous drinkers, AA-DNA adducts [47, 48], sister chromatid exchanges [49] and micronucleus formation [50] occur more frequently than in ALDH2 active drinkers. Ethanol administration to *Aldh2*-knockout mice caused the formation of AA-DNA adducts in esophageal tissue [51], and in a 10% ethanol free drinking experiment, adducts in the esophageal tissues of *Aldh2*-deficient mice were markedly elevated for 1–3 days; the elevation persisted for 2 weeks and then quickly disappeared upon the discontinuation of ethanol administration [52]. *Aldh2* and *Fancd2* (a DNA repair pathway) double knockout mice showed chromosomal rearrangement from DNA double-strand breaks, and this damage also occurred in hematopoietic stem cells, further destabilizing the genome in the absence of p53 function [53].

Other ADH/ALDH Gene Polymorphisms

In a large scale GWAS in Europe, slow metabolizers of *ADH1B* (rs1229984) and *ADH1C* (rs1693482) and polymorphisms of unknown function in *ADH7* and *ALDH2* were associated with the UAT cancer risk [54]. The *ADH1B* variant has

consistently displayed pleiotropic UAT-cancer associations in GWASs with a European ancestry [55]. In Japan, a linkage disequilibrium exists between the slow metabolizing forms of ADH1B and ADH1C. The slow metabolizing form of ADH1C alone is a risk factor for esophageal and head and neck cancers, but the association disappears when corrected for the slow metabolizing form of ADH1B, reflecting the influence of the concomitant slow metabolizing form of ADH1B [2, 40]. In Japan, multiple polymorphisms of the *ADH4* and *ADH7* genes were also reported to be associated with UAT cancer, but the functions of the polymorphisms are unknown [56].

Induction of P450 2E1 by Alcohol Consumption

P450 2E1 in MEOS also oxidizes ethanol to AA, and habitual drinking increases the amount of enzyme [57]. This enzyme induction occurs not only in the liver, but also in the epithelium of the UAT, where P450 2E1 produces ROS and lipid peroxides as well as 4-hydroxynonenal and malondialdehyde, which form DNA adducts. In human esophageal biopsies, an increase in AA-DNA adducts was correlated with P450 2E1 induction [58]. P450 2E1 also activates carcinogenic precursors such as N-nitrosamines. P450 2E1 is induced in the esophagus of drinkers, promoting AA production and the activation of carcinogens.

Clinical Assessment for Cancer Risk in the UAT and Stomach

Endoscopic Screening of High-Risk Group

Since the burden arising from gastric cancer has been large among Asians, endoscopy has been commonly used in clinical practice and for cancer screening. In 2016, the Japanese government decided to introduce endoscopic screening for gastric cancer as a national program [59]. Endoscopic screening for gastric cancer also provides an opportunity for the early detection of asymptomatic esophageal and head and neck cancer. When the high-risk group for esophageal SCC was defined as men over 55 years old, heavy drinkers, and heavy smokers, esophageal SCC was diagnosed as a mainly superficial carcinoma in 0.4–0.7% of the high-risk group using Lugol chromoendoscopy with esophageal iodine staining screening [60]. We performed an initial screening of 2115 alcohol-dependent male patients (≥40 years) with no history of cancer in the UAT between 2004 and 2010 using Lugol chromoendoscopy with esophageal iodine staining [61]. Biopsy specimens of distinct iodine-unstained lesions in the esophagus showed low-grade intraepithelial neoplasia (LGIN) in 155 patients (7.3%), high-grade intraepithelial neoplasia (HGIN) including epithelial SCC in 57 patients (2.7%), and invasive SCC in 35 patients

(1.7%). However, the lesions were missed during the first passages of the endoscope before iodine staining in 97.4% of the subjects with LGIN, 77.2% of the subjects with HGIN, and 14.3% of the subjects with invasive SCC. A meta-analysis of 12 studies has shown that narrow-band imaging (NBI) and iodine staining can diagnose high-grade dysplasia and SCC in the esophagus with equal sensitivity in high-risk groups [62]. However, most of the studies were conducted in patients who had already been diagnosed as having UAT cancer. To evaluate whether image-enhanced endoscopy, such as NBI or Lugol chromoendoscopy, is more appropriate for esophageal cancer screening in high-risk groups, an evaluation of general screening in non-cancer-bearing high-risk groups is awaited.

Field Cancerization of UAT

In Japan, patients with esophageal SCC frequently have simultaneous and metachronous multiple cancers in the esophagus, the head and neck region, and the stomach [63]. Iodine staining examinations in 788 cases of head and neck SCC showed that esophageal SCC was diagnosed in 11.8% of the cases [64]. NBI examinations in 667 cases of esophageal SCC showed that head and neck SCC was diagnosed in 6.7%, and hypopharyngeal SCC was diagnosed in 5.4% [65].

Whether ALDH2 heterozygotes become heavy drinkers is influenced by social and cultural changes and associated peer pressure, and the number of ALDH2-deficient heavy drinkers is still progressively increasing. The frequency of the heterozygous form of ALDH2 deficiency in Japanese alcohol-dependent patients was 2.5% in 1972, increasing to 8.0% in 1986, 13.0% in 1993 [66], and up to 17.1% in 2013–2018 [67]. *ALDH2* genotyping of 8808 alcohol-dependent men from 1996–2019 has identified 4 inactive ALDH2 homozygotes since 2013 [68]. This change coincides with a dramatic increase in the proportion of multiple organ cancers among esophageal cancer patients in Japan over the years [63]. ALDH2 heterozygous deficiency is a risk factor for field cancerization of the UAT: 78%–95% of esophageal SCC Japanese patients with multiple SCCs in the UAT were ALDH2 deficient, and the ORs for multiple SCCs were 5.3–16.2 for ALDH2 deficiency [69, 70], while the HRs for second cancers were 2.25–3.97 [24, 25]. Simultaneous head and neck SCC occurred in 11% of alcohol-dependent Japanese males with esophageal SCC, and even in those without simultaneous head and neck SCC at an initial screening, head and neck SCC occurred in 39% at 5 years [71]. Multiple concurrent intraesophageal SCC lesions were also seen in 31% at an initial screening, and the ORs for heterozygous ALDH2 deficiency were 3.68 (1.17–11.57) for 2 SCC lesions and 4.73 (1.15–19.47) for three or more SCC lesions, compared with a solitary SCC lesion. Multiple esophageal SCCs and ALDH2 heterozygous deficiency resulted in HRs for the metachronous development of secondary SCCs of 3.09 (1.41–6.78) and 3.38 (1.45–7.85), respectively, in the esophagus after endoscopic treatment and 3.25 (1.41–7.47) and 4.27 (1.42–12.9), respectively, in the head and neck region [71]. In addition to inactive ALDH2, the slow-metabolizing ADH1B also increased the risk

of multiple UAT cancer in Japanese follow-up studies of esophageal SCC patients after mucosal resection [24, 25] and Taiwanese case-control studies of esophageal cancer patients [72] and head and neck cancer patients [73], but not in Japanese alcohol-dependent esophageal SCC patients [71]. In addition to cancer multiplicity, several studies have suggested that the presence of inactive ALDH2 is a biomarker associated with a poor prognosis in Asians with UAT cancer [74–76].

Iodine-Unstained Lesions (Lugol-Voiding Lesions [LVLs]) in the Esophagus (Fig. 75.2)

Morita et al. examined surgical esophageal SCC tissues and found that an increasing number of intraesophageal SCC lesions was associated with an increasing number of concurrent dysplasia lesions [77]. Shimizu et al. found that the cumulative incidence of metachronous SCC in the esophagus [78] and the head and neck region [79] after the endoscopic resection of superficial esophageal SCC was much higher in the group with numerous iodine-unstained lesions than in the group without such lesions. Muto et al. called iodine-unstained lesions LVLs and found that multiple LVLs (Fig. 75.2c) were a strong risk factor for multiple SCC in the UAT; furthermore, multiple LVLs were associated with alcohol consumption, smoking, and ALDH2 heterozygous deficiency [80, 81]. In the follow-up screening of Japanese alcohol-dependent patients, the 6-year cumulative incidences of the development of esophageal SCC and head and neck SCC were 31% and 20%, respectively, in cancer-free patients with biopsy-proven esophageal dysplasia from distinct LVLs ≥5 mm (Fig. 75.2b); 56% and 35%, respectively, in esophageal-SCC patients after endoscopic mucosectomy; and 4 and 4% in cancer-free patients without distinct LVLs ≥5 mm [82]. Thus, multiple LVLs and large dysplastic LVLs are strong predictors of field cancerization in the UAT.

In a prospective Japan esophageal cohort study (JEC study) of 331 cases with endoscopically resected esophageal SCC from 16 hospitals, subjects with esophageal LVLs visualized using Lugol chromoendoscopy were graded at the time of enrollment according to the maximum number of LVLs (i.e., A = no lesions; B = 1–9 lesions; C = ≥10 lesions in at least one endoscopic field of view) [83]. The 5-year cumulative incidence of secondary SCC in the UAT was particularly high in group C. For grades A, B, and C, the incidences of secondary SCC were 6.0%, 17.8%, and 47.1% for the esophagus and 0%, 4.3%, and 13.3% for the head and neck region, respectively [52]. A case-control study was conducted for the 331 patients in the JEC study and 1022 historical controls for whom information on drinking, smoking, eating habits, and alcohol flushing had been obtained using the same questionnaire [52]. Carcinogenic risk factors were alcohol consumption and the frequent drinking of strong alcoholic beverages, alcohol flushing, smoking, hot food, and the inadequate intake of green and yellow vegetables and fruit. The ORs for esophageal SCC with grade A, B, and C LVLs were 3.57, 45.2, and 241, respectively, for moderate

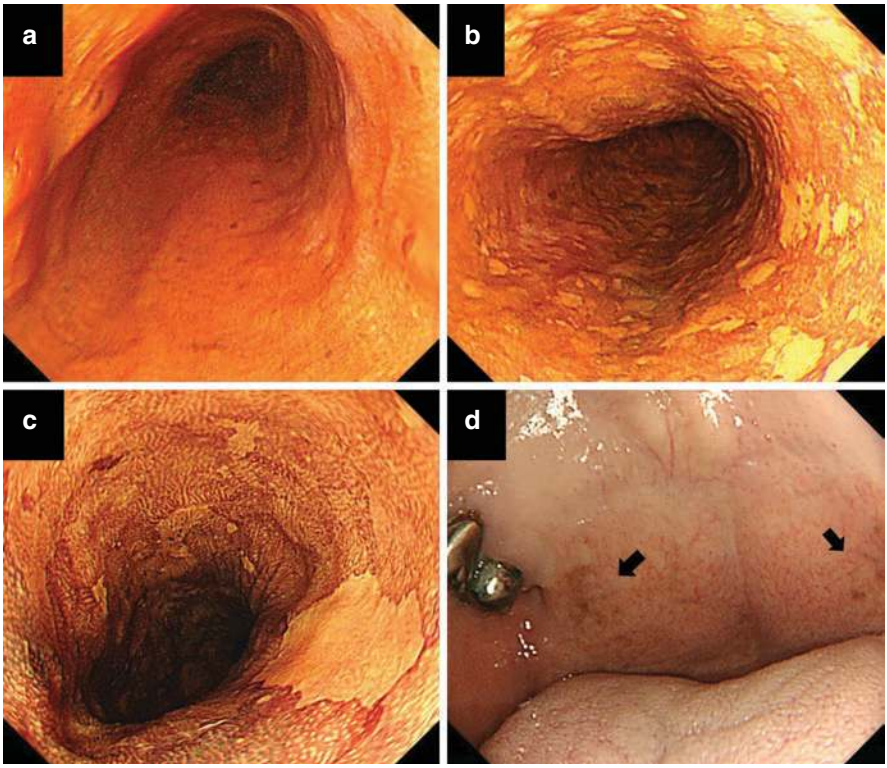

Fig. 75.2 Endoscopic screening for cancerogenic lesions in the upper digestive tract. (**a**) No Lugol voiding lesions (LVLs) in the esophagus. (**b**) The LVL ≥5 mm was diagnosed as mild dysplasia. (**c**) "Multiple LVLs" are present when 10 or more LVLs of any size are observed in at least one endoscopic field of view. (**d**) The endoscopic view of soft palatal melanosis shows multiple flat and pigmented (greenish-black) areas

drinkers (198–395 g ethanol/week) with current/former flushing but were only 1.17, 3.88, and 19.1, respectively, for moderate drinkers with never flushing, indicating that moderate drinking in flushers causes more aggressive esophageal SCC in terms of secondary cancer. A prospective follow-up study after the treatment of head and neck SCC in Taiwan also showed that the presence of multiple LVLs was a strong predictor of metachronous esophageal squamous neoplasia [84]. The presence of multiple LVLs was associated with ALDH2 deficiency in drinkers but was a predictor of second cancer in a manner that was independent from both ALDH2 deficiency and alcohol flushing [24, 52, 80, 81, 83, 85]. Multiple and large LVLs were associated with both heterozygous inactive ALDH2 and slow-metabolizing ADH1B in heavy drinkers [61], and abnormalities of P53 protein [86], TP53 gene mutations [83] and a shortened telomere length [87] were highly prevalent in the esophageal tissues with multiple and large LVLs.

Simple Flushing Questionnaire Method

When Japanese subjects were asked about current facial flushing after drinking alcohol without specifying the alcohol dose, half of those with active ALDH2 reported that they were sometimes or always flushers because they experienced facial flushing after drinking a substantial amount of alcohol [88]. When they were asked about current facial flushing after drinking a glass of beer, some ALDH2-deficient heavy drinkers answered "No" because they did not experience flushing due to AA tolerance, even though they were former flushers. So, "flushing" as determined using these two questionnaires was not useful for predicting ALDH2 deficiency or assessing UAT cancer risk [89, 90].

In the simple flushing questionnaire [44], the questionnaire asked (a) "Do you have a tendency to flush in the face immediately after drinking a glass of beer?" and (b) "Did you have a tendency to flush in the face immediately after drinking a glass of beer during the first 1–2 years after you started drinking?" A "glass" means about 180 mL, which is the volume of the most common size of Japanese beer glass. If either of these questions are answered affirmatively, the drinker is considered to be a flusher (current or former flusher), and ALDH2 deficiency can be determined with a sensitivity and specificity of about 90% in Japan [44, 91–93]. The sensitivity and specificity have been reported to be 79%–95% and 77%–82%, respectively, in Korea [94] and 89% and 81%, respectively, in Taiwan [95]. Drinking habits also affect the sensitivity of this method, with a reduced sensitivity seen for habitual drinkers, alcohol-dependent patients, and UAT cancer patients [44, 45, 95]. The risk of UAT cancer is significantly increased in drinkers with flushing [37, 39, 40, 44, 45, 52, 71, 83, 91, 92, 95–99]. The HR for second cancer of the UAT in 285 Japanese with head and neck cancers was 2.63 (1.25–5.52) in flushers identified using this method [97] and 1.70 (1.02–2.82) for second cancer of the esophagus in flushers of the JEC study [83]. Japanese people have a habit of toasting with a glass of beer of about 180 mL, so this question can be easily answered. If a smaller volume is used, the sensitivity decreases; if a larger volume is used, the specificity decreases. An esophageal examination of 815 cases of head and neck SCC in Taiwan showed that 15% had neoplasia, 47% of which were high-grade dysplasia or SCC, and the OR among the flushing drinkers was 8.6–9.6 [98]. In a cohort study in China, males who drank alcohol weekly were asked whether they had a flushing response "immediately after the first sip" [99]. Probably because this amount was too small, the sensitivity of discriminating ALDH2 deficiency was low at 57%, with a specificity of 88%. However, flushers had a drinking-adjusted HR of 1.45 (1.05–2.01) for esophageal cancer, compared with non-flushers, while the HR was 3.31 (1.94–5.67) for heterozygous ALDH2 deficiency. Although the discrimination of ALDH2 deficiency based on flushing is useful as a carcinogenesis risk assessment, highly accurate discrimination methods appropriate for populations with different drinking cultures are needed.

Health Risk Appraisal (HRA) Model for SCC in the UAT

Figure 75.3 shows the HRA model for SCC in the UAT based on a Japanese case-control study [100]. The results of the simple flushing questionnaire are combined with drinking, smoking, and dietary habits, and a score of 11 or more is considered to be a very high risk for SCC in the UAT. Fifty-eight percent of Japanese men in their 50s and 60s with esophageal SCC who completed the questionnaire [100] and 46% of men in their 60s and 70s with esophageal cancer who were enrolled in the JEC study [101] scored 11 or higher. In general, 5%–11% of middle-aged and older men scored 11 points or more [100, 102, 103]. A Lugol chromoendoscopic follow-up study of Japanese men showed that the detection rate of SCC in the UAT was 3.48 (1.28–7.58) per 100 person-years in subjects with 11 points or more, while it was 0.13 (0.02–0.46) in those with 10 points or less, resulting in a relative risk of 26.6 (51.5–134) for the high-risk group [102]. In a general endoscopic screening using iodine staining, the frequency of esophageal SCC among subjects with 11 points or more was 4.3%, which was six times higher than that in the group with less than 11 points (0.7%) [103]. The HRA model was also useful in assessing the risk of second cancer of the esophagus; when male patients in the JEC study were divided into those with an HRA score of 12 or more and those with an HRA score

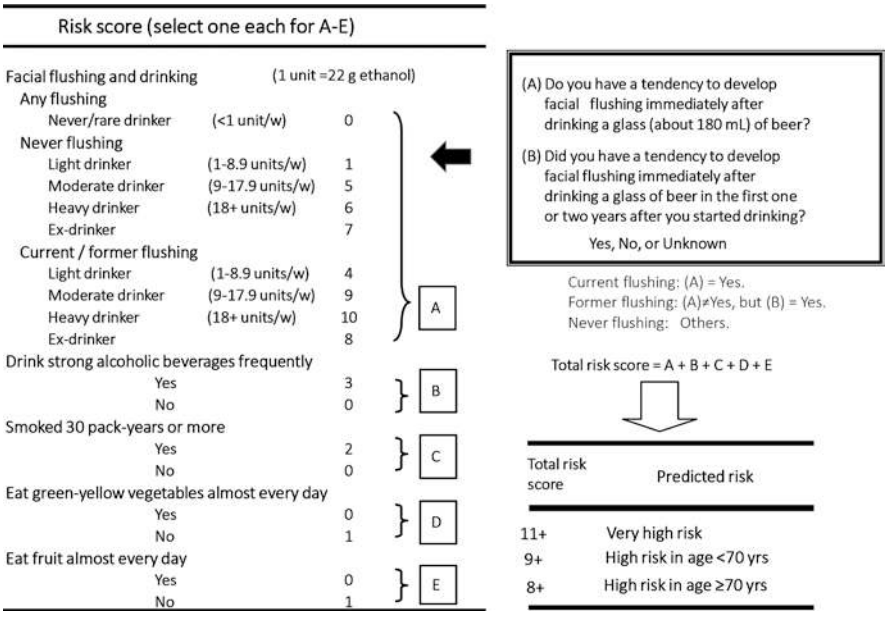

Fig. 75.3 Simple flushing questionnaire used to identify inactive ALDH2 and a health risk appraisal model for SCC in the UAT

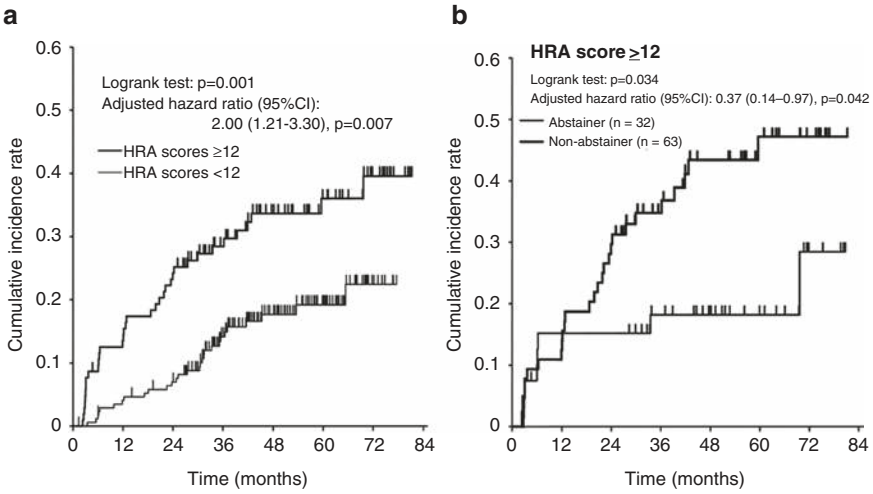

Fig. 75.4 Cumulative incidences of metachronous esophageal SCC after endoscopic mucosectomy of superficial esophageal SCC according to HRA score (**a**) and drinking status in the high-HRA-score drinker group (**b**). Hazard ratio was adjusted for age and LVL grades. PLoS One 2017; 12: e0175182. https://doi.org/10.1371/journal.pone.0175182

of less than 12, the detection rates for second esophageal SCC were 9.8 (6.8–13.7) and 4.5 (3.0–6.5) per 100 person-years, respectively, with a 2.00-fold (1.21–3.30) HR for those with an HRA score of 12 or more (Fig. 75.4a) [101].

Alcohol Use Disorders Identification Test (AUDIT) in UAT Cancer Patients

The AUDIT is a screening test developed by WHO to identify "suspected alcohol dependence" and "hazardous drinking" for early intervention and the prevention of alcohol problems [104]. The cutoff values are uniquely set according to the situation in each country. In Japan, an AUDIT score of 8 or higher is considered "hazardous drinking," while an AUDIT score of 15 or higher is considered "suspicious of alcohol dependence"; in the general adult male population, 26% have an AUDIT score of 8 or higher and about 5% have an AUDIT score of 15 or higher [105]. However, 62.1% of the esophageal SCC patients had an AUDIT score of 8 or higher and 25.4% had an AUDIT score of 15 or higher at the time of enrollment in the JEC study [105]. The AUDIT score was positively associated with the grade of multiple LVLs. In the grade C group, 37.7% had an AUDIT score of 15 or higher. Furthermore, the HR for the development of second cancer in the head and neck region was 6.98 (1.31–37.1) in the group with an AUDIT score of 15 or more, "suspected alcohol

dependence", compared with the group with a score of 0–7, and the HR was 3.19 (1.19–8.54) in the grade C group, compared with the grade A group. Secondary cancers of the head and neck after esophageal cancer treatment are markedly more frequent among Japanese alcohol-dependent patients than esophageal cancer patients in general [71], and the "suspected alcohol-dependency" group in the AUDIT may be indicative of this feature. A comprehensive assessment using AUDIT for the detection of alcohol problems is desirable once alcohol-related cancer, not just esophageal cancer, is diagnosed.

Melanosis, Macrocytosis, Macrocytic Anemia, Leukopenia

Melanosis of the soft palate, pharynx, and esophagus looks like a small greenish-black stain (Fig. 75.2d). This overexpression of melanin is highly comorbid with UAT neoplasia [106–108]. Melanosis is particularly common in heavy drinkers with ALDH2 heterozygous deficiency and increases with smoking and aging. Soft palate melanosis can be observed with a penlight and is a high-risk finding that is instantly apparent upon endoscopic insertion.

The mean corpuscular volume (MCV) of red blood cells increases with heavy drinking, but in alcohol-dependent individuals with ALDH2 heterozygous deficiency, the MCV is particularly large and is associated with macrocytic anemia [109, 110] (see also Chaps. 37, 57 and 58). The combination of heterozygous inactive ALDH2 and fast-metabolizing ADH1B causes a particularly pronounced macrocytic anemia [110]. Alcohol-dependent patients with this genotype combination had the highest levels of AA-DNA adducts in leukocytes [48] and the highest blood AA/ethanol ratio [33]. While the precise mechanisms of red cell enlargement are not fully known, high AA exposure is probably a major cause of this finding. Increased MCV and macrocytic anemia are also associated with smoking, aging, folic acid deficiency, and emaciation in alcohol-dependent patients. The ORs for SCC detection in the esophagus [109] and the head and neck region [39] were 3.68 (1.96–6.93) and 2.71 (1.42–5.16), respectively, in Japanese alcohol-dependent men with an MCV ≥106 fl, compared with those with an MCV <106 fl. In alcohol-dependent patients with an MCV ≥106 fl, SCC in the UAT occurred in more than 20% of patients at 5 years, with a HR of 2.91 (1.63–5.21) [37]. Furthermore, the OR of UAT neoplasia increased to 1.49, 3.14, 4.80, and 7.80 for each additional one of the four risk factors of 55 years of age or older, flusher, MCV ≥106 fl, and soft palate melanosis [107].

The association between leukocytopenia and alcohol dependence has long been known, and monocytes, granulocytes, and lymphocytes are all decreased in patients with inactive heterozygous ALDH2; when inactive ALDH2 is combined with the fast-metabolizing forms of ADH1B, the reductions in the monocyte and granulocyte counts are particularly prominent [111]. This phenomenon can also be explained by high AA exposure in the blood of alcohol-dependent patients with this ALDH2/

ADH1B combination [33, 48]. This change is considerably reversed after 4 weeks of abstinence from alcohol [112]. Recent studies have shown that in non-abstinent alcohol-dependent patients, not only the number of monocytes is reduced, but also the ability to produce LPS-stimulated inflammatory cytokines is suppressed in this genotype combination, with a partial recovery observed after sobriety [113]. Similar findings were observed using ethanol feeding in *Aldh2*2* transgenic mice [113]. About 60% of men with esophageal SCC in Japan have this genotype combination [2, 22, 23], and anemia and a decreased immune response can interfere with cancer treatment; abstinence from alcohol before treatment should be considered from the viewpoint of bone marrow recovery. The immune deficiency caused by high AA exposure may be another possible cause of alcohol-related carcinogenesis.

Esophageal SCC in Female Asian Drinkers

A case-control study in Japanese women showed a markedly high risk of esophageal SCC in women with the inactive heterozygous *ALDH2*1/*2* genotype who were heavy drinkers [91]; this result was comparable to the results of a male study conducted simultaneously [2]. A Japanese GWAS also showed similar ORs for esophageal SCC for the *ADH1B*1/*1* genotype and the *ALDH2*1/*2* genotype between men and women [22]. Meta-analyses of Asian case-control studies showed that female drinkers with the *ALDH2*1/*2* genotype had an increased risk of esophageal SCC [26, 30]. The drinking culture in Japan is much more restrictive for women than for men, and the male-to-female ratio for alcohol-dependence is approximately 10:1 according to the latest nationwide survey [114]. The age-adjusted mortality rate for esophageal cancer per 100,000 Japanese men in 2019 was estimated to be 7.1, whereas that for Japanese women was 1.2 [115]. However, alcohol-dependent women and men share several common risk factors of esophageal neoplasia and multiple LVLs, but with considerably different magnitudes. These factors include the slow-metabolizing *ADH1B*1/*1* genotype, the inactive heterozygous *ALDH2*1/*2* genotype, a low BMI, and a large MCV [96].

Gastric Cancer and Alcohol

In a pooled analysis of 20 studies, drinking more than 48 g/day increased the risk of gastric cancer by 26%, and drinking more than 72 g/day increased the risk by 48% [116]. In 2018, the World Cancer Research Fund International concluded that a greater consumption of alcoholic drinks was probably a cause of stomach cancer. This was based on evidence obtained from individuals with intakes of greater than

45 grams per day [117]. Gastric cancer has been frequently detected in esophageal SCC patients in Japan [63, 64, 67, 118, 119]. One reason is the very high incidence of *H. pylori*-associated atrophic gastritis in Japan. In a study by the Aichi Cancer Center (1375 cases, 2050 controls), the OR of gastric cancer increased with increasing alcohol consumption only in ALDH2-deficient individuals, compared with non-drinkers with active ALDH2, reaching 3.57 (2.04–6.27) at 230 g/week or more, suggesting the direct involvement of AA [120]. In addition to *H. pylori*-associated atrophic gastritis, ALDH2 heterozygous deficiency, MCV enlargement, and concurrent UAT cancer were risk factors for gastric cancer diagnosed by screening in Japanese alcohol-dependent men, suggesting the involvement of ethanol and AA in gastric carcinogenesis [121]. The first meta-analysis of 7 Asian studies showed that ALDH2 deficiency increased the OR of gastric cancer (1.42 [1.21–1.67]) in drinkers, but not in non-drinkers [122]. Another meta-analysis that included 3251 cases and 4943 controls showed that ALDH2 deficiency increased the risk of gastric cancer in moderate to heavy drinkers (OR = 1.85 [1.52–2.25]) more than in non−/mild drinkers (OR = 1.19 [1.05–1.36]) [123]. A genomic-scale trans-ethnic analysis of gastric cancers (319 Asians and 212 non-Asians) also showed one distinct gastric cancer subclass with a clear alcohol-associated mutation signature and strong Asian specificity, almost all of which were attributable to alcohol intake behavior, smoking habit, and inactive ALDH2 [124].

In a meta-analysis of seven studies, the presence of atrophic gastritis was associated with an esophageal SCC OR of 1.94 (1.48–2.55) [125]. *H. pylori*-associated atrophic gastritis was at more advanced stages in Japanese alcohol-dependent men with esophageal SCC than in those without esophageal SCC [119]. In a follow-up study of Japanese alcohol-dependent men after treatment for esophageal SCC, the frequency of metachronous gastric cancer was 15% at 5 years [119]. This result is comparable to the high rate of metachronous gastric cancer after endoscopic treatment for gastric cancer in the Japanese general population.

In heavy drinkers, smoking, a salt preference, and a low intake of fruit and vegetables are also likely to coexist, which is a common risk for esophageal SCC, atrophic gastritis, and gastric cancer. On the other hand, the progression of atrophic gastritis may increase the risk of esophageal SCC. A major component of the esophageal microbiota is oral *Streptococcus* species [126]. It has been experimentally shown that oral bacteria descend and multiply in a low-acid stomach environment, producing AA from ethanol and increasing the concentration of AA in gastric juice [127]. Asian studies have demonstrated positive associations between excessive drinking and gastroesophageal reflux disease or short segmental Barrett's esophagus [128, 129]. Antiseptic acid reflux alters the esophageal microbiota in high-acid subjects without gastric atrophy [127]. The frequent occurrence of gastric cancer in esophageal SCC patients might be partly attributable to the low-acid stomach environment and the subsequent alterations of microbiota and AA exposure in the esophagus and stomach.

Detection Rates of Esophageal SCC and Gastric Cancer Have Decreased in Japanese Alcohol-Dependent Men in Parallel with the Decreasing Rate of Infection with *H. Pylori*

The author has been conducting esophageal iodine staining screening for men with alcohol dependence since 1993. We performed an initial screening of 7582 patients (40–79 years old) with no history of cancer until 2018 and diagnosed head and neck SCC in 1.1%, esophageal SCC in 3.5%, and gastric cancer in 1.1%; at 5-year intervals over a 26-year period, esophageal SCC was diagnosed at rates of 3.7, 3.9, 4.3, 3.0, and 2.1%; thus, the rate of esophageal SCC detection has decreased over the last 10 years [67]. Furthermore, the detection of not only SCC, but also of large LVLs and multiple LVLs in the esophagus has decreased over the past decade [130]. As a result of the decrease in *H. pylori* infection, the rates of gastric cancer also decreased during the above-mentioned periods to 1.5%, 1.4%, 1.3%, 0.3%, and 0.7%, respectively [67]. The combined effect of a decrease in *H. pylori*-associated gastric atrophy, which is associated with the risk of esophageal SCC, a decrease in smoking, an improved nutritional status in terms of BMI, and a change in preferences for alcoholic beverage types may be responsible for the decrease in esophageal SCC and LVLs. However, even after adjusting for these confounding factors, the cause of the decrease in esophageal squamous neoplasia has not been determined and will continue to be a subject of future research [67, 130]. This outcome might be linked to global trends showing a decreasing incidence of male esophageal SCC during recent decades [131].

Effects of Abstinence or Drinking Moderation on SCC in the UAT

Inactive ALDH2 has two opposing effects on the digestive tract: direct carcinogenic effects in response to drinking, and indirect protective effects arising from less or no drinking because of aversive alcohol flushing responses [132]. In a Japanese male case-control study, the OR of esophageal SCC among ALDH2 heterozygotes who drank less than 198 g ethanol per week was 6.8, compared with non-drinkers, but the OR was 65.3 for those who drank 198–396 g ethanol per week. It was estimated that 53% of male esophageal SCC cases would not have occurred if ALDH2-heterozygous moderate drinkers had not drunk or drunk less than 198 g per week from the beginning [92]. Another Japanese case-control study estimated that 12% of heterozygous drinkers who drink more than 46 g ethanol on each occasion and on 5 days a week or more are likely to have esophageal SCC by the age of 64 years and 20% by the age of 79 years, while among those who drank less, only 5% are expected

to have esophageal SCC by the age of 79 years [133]. Although many studies have shown that there is no safe level of alcohol consumption for alcohol-related cancer [38, 134, 135], a steep increase in the risk of esophageal SCC occurs in ALDH2-deficient individuals with a daily alcohol consumption of around 30 g or more.

In a meta-analysis of nine studies of esophageal cancer, the risk decreased significantly early in abstinence and disappeared at 16.5 years [136]. In a meta-analysis of 4 studies of laryngeal cancer and 8 studies of pharyngeal cancer, 5 years of drinking cessation was associated with a reduction of around 15% in the alcohol-related elevated risk, but a long time period was required to eliminate the elevated alcohol-related risk of laryngeal (36 years) and pharyngeal cancers (39 years) completely [137].

In the JEC study, after a median of 80.7 months of prospective follow-up, abstinence from alcohol after enrollment was associated with an HR of 0.47 (0.26–0.85) for secondary esophageal SCC, compared with continued alcohol consumption [52]. Moreover, the preventive effects of abstinence on the secondary esophageal SCC were more pronounced in the high-risk groups, with an HR of 0.30 (0.13–0.67) for abstinence (vs. continued drinking) in the group with grade C LVLs [52]. In a subanalysis of men in the JEC study, abstinence from alcohol reduced the HR for the secondary esophageal SCC by 63% in the group with an HRA score of 12 or more (Fig. 75.4b) [101]. In a Hokkaido University study of 158 patients with endoscopically resected esophageal SCCs followed for a median of 80 months, the HR increased by 2.25-to-4.39-fold for the ALDH2 heterozygous deficient group for a second, third and fourth SCC of the UAT [25]. Drinking cessation or reducing alcohol consumption to less than 198 g ethanol per week significantly reduced the HRs to 0.35 (0.20–0.63) and 0.22 (0.07–0.56), respectively, for a second and third SCC [25]. In a retrospective multicenter study of 198 patients with head and neck SCC (mainly hypopharyngeal) who were treated with transoral surgery, the HRs for a second and third SCC of the head and neck region were significantly reduced to 0.54 (80.31–0.92) and 0.19 (0.03–0.65), respectively, when those who drank at least 198 g ethanol per week abstained from alcohol or reduced their alcohol intake to less than 198 g ethanol per week after treatment [138]. Quitting or reducing alcohol to less than about 30 g per day may significantly reduce the risk of esophageal and head and neck SCCs, including second SCCs.

Conclusion

Knowledge of alcohol-related cancers in the UAT and stomach has been accumulating, but it still remains challenge to translate this knowledge into prevention and clinical practice.

Part XIII
Center Experiences for the Interdisciplinary Management of Alcohol Use Disorders

Chapter 76
Model for Secondary Health Care Alcohol Services: Optimising the Response to Alcohol Use Disorders in Acute Hospitals

Omar Elshaarawy, Lynn Owens, Edward Britton, and Paul Richardson

Abstract Optimising the care of patients attending acute hospitals with an alcohol use disorder requires health organizations to deliver (a) consistent and accurate screening processes, (b) develop locally appropriate integrated care packages, and (c) identify co-existing physical and psychological comorbidities. It has been shown that Alcohol Care Teams (ACT) are best placed to respond to this challenge, affording the opportunity to develop a highly skilled workforce with specific emphasis on development of skills and competence that support and enable delivery of a wide range of clinical pathways. In this chapter, we will explore the core service components of an Alcohol Care Team and the potential pathways required to optimize care and improve clinical outcomes.

Keywords Alcohol care team · Alcohol use disorder · Patient pathways Screening · Pharmacotherapy

Introduction

Optimising the care of patients attending acute hospitals with an alcohol use disorder (AUD) requires health organizations to deliver (a) consistent and accurate screening processes, (b) develop locally appropriate integrated care packages, and (c) identify co-existing physical and psychological comorbidities. It has been shown that Alcohol Care Teams (ACT) are best placed to respond to this challenge,

affording the opportunity to develop a highly skilled workforce with specific emphasis on development of skills and competence that support and enable delivery of a wide range of clinical pathways. In this chapter, we will explore the core service components of an Alcohol Care Team and the potential pathways required to optimize care and improve clinical outcomes.

Background, Burden and Magnitude of the Problem

More than 60 medical conditions have been linked to alcohol consumption, including circulatory and digestive diseases, liver disease, a variety of malignancies, and depression. In England, there were 337,113 hospital admissions with an alcohol-related diagnosis as the primary diagnosis between 2016 and 2017 [1, 2]. Heavy drinkers are at a higher risk of developing alcohol-related chronic diseases. Importantly, this burden is set to rise as the incidence of alcohol-related disease is increasing year on year across all age groups. Worryingly, there is an increasing incidence in younger age groups. The burden of alcohol-related disease to acute care accounts for 78% of the total estimated £3.5 billion per year cost of alcohol to the NHS [3].

Data indicate that around 5% of inpatients in acute hospitals are alcohol dependent compared to 1.4% in the general population. The average length of stay for alcohol related admissions is 5.69 days compared to 2.25 days for non-alcohol admissions for the same diagnosis. Alcohol-related attendances comprise 12–15% of accident and emergency (A&E) visits. There were 12,600 emergency admissions for alcohol-related liver disease (ALD) alone in 2016–2017 in Royal Liverpool University Hospital [4]. 12% of patients admitted with an alcohol-specific disease are re-admitted to the hospital within 30 days of discharge [4, 5].

To satisfy the requirements of these vulnerable group with alcohol use disorder, effective models of care and clinical pathways are required and they need to be implemented in all hospitals by a highly trained workforce. This model of care we are presenting in this chapter has been explicitly identified milestone toward achieving the second aim of the alcohol harm reduction strategy by NHS England [4, 6]. This has targeted early identification and treatment of adults with AUD in either acute or secondary care setting.

Aims of the Optimal Alcohol Care Team

ACTs are teams in acute hospitals that provide specialist support services to patients with a suspected or established AUD [7]. They aim to:

- Improve identification of AUD as a contributing factor in hospital attendance
- Reduce avoidable alcohol-related hospital admissions

- Reduce rates of re-admission
- Reduce the length of stay for inpatients
- Improve the management of acute alcohol withdrawal (AAW)
- Provide timely and meaningful psychosocial interventions
- Facilitate integrated alcohol related care between secondary, primary and community care providers
- Provide evidence-based treatments to support recovery (pharmacotherapy and psychological treatments)
- Support the wider workforce on AUDs identification and management
- Improve data collection and opportunities for audit and clinical research

Core Service Components of the Alcohol Care Team

A multi-faceted ACT should be able to provide packages of care that include [7, 8]:

- Case identification/alcohol identification and delivery of brief advice (IBA)
- Comprehensive alcohol assessment
- Specialist nursing and medical care planning
- Management of medically-assisted alcohol withdrawal (MAW)
- Provision of psychosocial interventions
- Planning safe discharge, including referral to community services
- Clinical leadership by a senior clinician with dedicated time for the team
- Provision of hospital wide education and training in relation to alcohol

Roles of the Alcohol Care Team

Emergency Department (ED) Presentations

The ACT will use well validated screening tools to assess patients presenting to the ED to accurately identify the presence of an AUD and stratify the severity. Patients in acute withdrawal will undergo a comprehensive assessment to ensure that the most appropriate and safe care can be planned. This may require admission or an ambulatory care plan to monitor and manage mild alcohol withdrawal symptoms. Patients presenting with other alcohol-related complications will be assessed by the ACT, who will contribute to their care plan [9].

This is where you need to discuss screening for co-morbidities using liver elastography such as Fibroscan to screen for liver fibrosis, MoCA (Montreal Cognitive Assessment), etc. and appropriate referral to specialist clinicians.

Patients who present to A&E will be assessed to determine the appropriate pathway according to the risk of AUD. Screening using a validated tool as AUDIT-C which is a brief version of AUDIT (see also App. Fig. A20) is usually more feasible

to use in screening. Assessment determines the nature and extent of alcohol abuse, a person's level of need, and necessary interventions. Assessment depth and detail vary by purpose and expected outcome. This is best achieved by acquiring a full history of alcohol intake, which can be limited due to underreporting. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) suggests a single-question screening that asks, "How many times in the last year have you drunk 5 or more drinks in a day (for men) or 4 or more drinks in a day (for women)?" [10]. If one or more episodes are reported, additional questioning with the Alcohol Use Disorders Identification Test (AUDIT) is advised. This comprises 10 questions about drinking habits, dependent symptoms, and any alcohol-related concerns. The AUDIT has been demonstrated to detect harmful alcohol consumption in individuals with a score of eight or higher, or moderate or severe AUD in patients with a score of 15 or higher. According to the scoring, patients are classified according to risk of AUD into "no risk", "moderate risk" or "high risk" [9, 10]. Most patients who will present to A&E with alcohol related medical issues will require at least a brief intervention as moderate risk group or will even require alcohol detox either ambulatory or as in patient as high risk group (see Fig. 76.1).

Inpatients

Inpatients with an AUD admitted for any condition will undergo a comprehensive assessment by the ACT. Based on the assessment outcome, the ACT will contribute to the overall care plan with alcohol specific treatments. This will include plans for ongoing care post hospital discharge. The initial care plan could be used to focus on a patient's engagement in the treatment system, ensure their immediate needs are met, build a therapeutic relationship with patients, and establish adequate interim support if they are waiting for other specialist treatments (see Fig. 76.1) [11].

The ACT usually assesses the patient to see if there are underlying problems triggering alcohol use disorder and would do comprehensive assessment. Comprehensive assessment is for problem drinkers with complex needs who may need structured treatment. The assessment aims to determine the patient's alcohol and other substance misuse problems and co-existing health, social functioning, offending, and legal issues which might require risk assessment. The goal of risk assessment is to determine whether the individual has or has had in the past certain experiences or displayed certain behaviours that could lead to harm to themselves or others [12]. The main areas of risk that must be assessed are as follows:

- Risks associated with alcohol use or other substance use (such as physical damage, alcohol poisoning)
- Risk of self-harm or suicide
- Risk of harm to others (including risks of harm to children and other domestic violence, harm to treatment staff and risks of driving while intoxicated

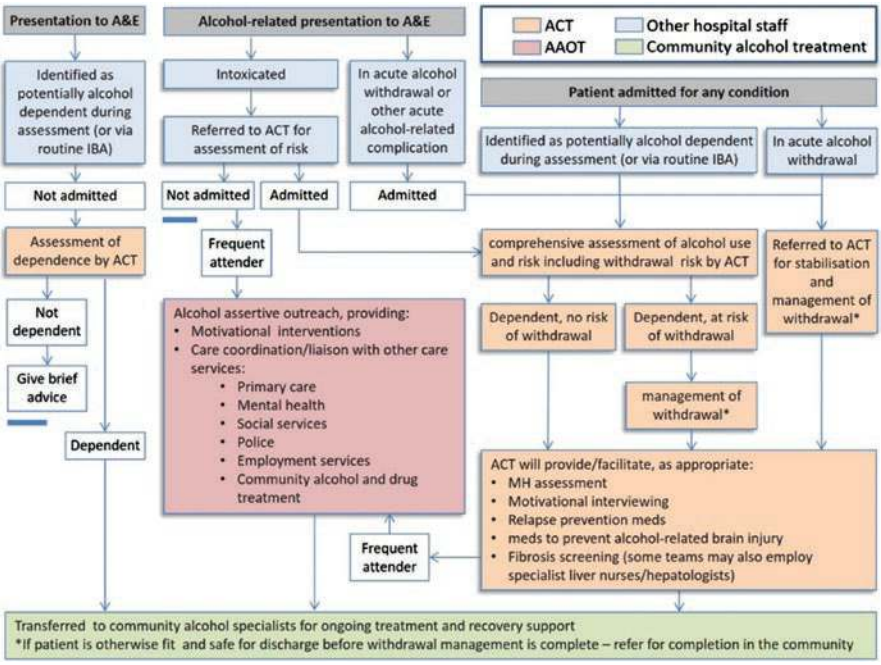

Fig. 76.1 Role of Alcohol Care Teams in the pathway for alcohol dependent patients. Adopted from NHS England Long term Plan https://www.longtermplan.nhs.uk) [11]. *AAOT* alcohol assertive outreach treatment; *ACT* alcohol care teams

- Risk of harm from others (including being a victim of domestic abuse)
- Risk of self-neglect.

Risk management plans must be developed and implemented once risks have been identified in order to mitigate immediate risk. Risk assessment, like comprehensive assessment, is an ongoing process that must be integrated into care planning. Local protocols should be followed if ACT is concerned about the risk of significant harm, social services should be involved in the risk assessment process [11].

According to the outcomes of the assessment process, referring patients to specialist mental health assessment could be a necessary step to initiate psychosocial interventions to support engagement with community alcohol treatment and to identify and mange co-existent metal heath diagnosis. All alcohol-dependent patients will be referred to specialist alcohol support in the community for continuation of alcohol treatment on discharge. When patients are medically fit for discharge before their alcohol detoxification is complete, the ACT will advise on the appropriateness of completion of detoxification in the community on a case by case basis, based on comprehensive assessment (see Fig. 76.1) [11, 12]. An alcohol care plan may include a medication regimen to support management of symptoms of AAW and /or a medication to support sustained abstinence or consumption reduction, and should be in accordance with national guidelines (NICE CG100).

Management of Patient with AUD

The ACT aims toward providing access to pharmacotherapy and screening for end organ damage such as alcohol associated cognitive impairment and liver fibrosis.

Access to Pharmacotherapy

The main outpatient task of the ACT is providing access to pharmacotherapy promoting abstinence. Pharmacological therapies are most effective when used in conjunction with psychosocial therapies as part of a comprehensive care plan. Pharmacotherapy includes medications to promote abstinence or prevent relapse, including sensitising agents [13].

ACT follow up patients in telephone and face to face clinics after prescribing medications to promote abstinence such as acamprosate and baclofen. Nurse led phone clinics by the ACT provide the required support for patients on pharmacotherapy regarding management of side effects, mild withdrawal symptoms, checking blood tests for patients after being on ambulatory detoxification or being discharged from hospital [13, 14].

Screening for End Organ Damage

Detection of Chronic Liver Disease

Only 35% of patients with high-risk alcohol consumption develop steatohepatitis and alcoholic hepatitis (AH), and 10–20% develop cirrhosis, indicating the existence of associated risk factors [10]. Women have been found to be more at risk for ALD, with higher risk related with daily alcohol use of 20–40 g compared to 60–80 g for males [15]. Finally, various concurrent liver illnesses, notably nonalcoholic fatty liver disease, hepatitis C, and hemochromatosis, can exacerbate ALD and encourage the rapid development of severe fibrosis and cirrhosis.

Transient elastography has been well established to assess the degree of fibrosis without dedicated ultrasound knowledge. Transient elastography has a sensitivity of 86% and a specificity of 95% for diagnosing advanced fibrosis or cirrhosis using a threshold value of 15 kilopascals in patients with hazardous alcohol use [10]. However, it is critical to screen for active alcohol consumption prior to undergoing these tests, as liver stiffness can improve after 2 weeks of abstinence [16]. Furthermore, the fibrosis detection threshold may need to be changed based on AST and bilirubin levels, as elevations signal hepatic inflammation and may exaggerate the degree of fibrosis present. In UK, Commissioning for Quality and Innovation

(CQUIN) promotes fibrosis assessment for all patients presenting with AUD [10]. More details are provided in the respective chapter on liver elastography in this book.

Detection of Alcohol-Related Cognitive Impairment

Studies show that about 35% of patients with AUD suffer from some form of Alcohol-related cognitive impairment (ARBI). Many patients present with multiple types of symptoms of ARBI, and about 25% also show evidence of other brain trauma. This can render an accurate diagnosis quite difficult. Many of these conditions are treatable. For example, about 75% of people with Wernicke-Korsakoff syndrome recover to some degree after appropriate treatment (see also chapter on Wernicke-Korsakoff syndrome in this book). Therefore, an early diagnosis is important [15, 17].

ACT flags patients with alcohol-related cognitive impairment and request professional mental and cognitive capacity assessment usually through Montreal Cognitive Assessment test (MoCA). Clinicians usually perform full neurological examination and exclude any neurological abnormality via proper brain imaging. Risk factors for ARBI include history of heavy drinking (5+ years of 35+ units per week), poor nutrition, particularly thiamine deficiency and history of withdrawal/poorly controlled alcohol detoxification [18]. Alcohol-related liver disease has been identified as a risk factor of ARBI as well as low socio-economic status. ACT is not clinically involved with the alcohol-related cognitive impairment clinical pathway, they just screen and flag patients with risk.

Patients with alcohol-related cognitive impairment may present with one of the following: Confusion, confabulations, slurring of speech, personality changes, poor impulse control, memory deficits, difficulties in decision-making, executive function difficulties, unsteady gait and problems with walking and other movement.

Confounding factors include the following: Coexisting physical and/or mental health conditions, hard to assess cognitive impairment whilst intoxicated, clinical lack of knowledge of conditions, misdiagnosis as dementia, shame and stigma affecting help-seeking behaviours of carers, reluctance of patients to seek help, belief that nothing can be done [17, 18].

Training and Competencies for ACT

The changing nature and aspects of medical care require nurses to ensure that they have the appropriate skills and knowledge to practice. Champs Public Health collaborative in collaboration with Chairs of the Cheshire and Merseyside ‘Reduction of Harm from Alcohol’ Programme launched PROACT Competencies Framework: **PRO**gram for **A**lcohol **C**are **T**eams Competencies which is a competency

framework and development plan for nurses working in an ACT [19]. In the detailed framework, each competency was discussed in detail and how to gather information and evidence to support the competencies as outlined. Each individual nurse is expected to develop an action plan that is specific to their own learning needs and style, with support of learning aids. Some examples of learning aids which can be useful within this process are the following: R.

1. Reflective diaries
2. Attending clinical ward rounds
3. Critical incident analysis
4. Profiling of populations
5. Caseload/individual case analysis
6. Shadowing of other disciplines
7. Clinical supervision/group supervision
8. Peer review
9. Mandatory training
10. Critiquing research articles
11. Dissemination of findings.

Assessment of competencies should be undertaken by an appropriate assessor, which could be a senior medical consultant and pharmacist. Some skills can be measured using the objective structured clinical examination (OSCE) style tick lists [19]. Competencies highlighted by the framework to be achieved before assessment include the following [19]:

1. The nurse/patient relationship - communicating with families and multidisciplinary teams (mdt).
2. Equality and diversity
3. Alcohol screening and detection of alcohol use disorders
4. Assessment and management of the alcohol dependent patient and alcohol withdrawal syndrome
5. Brief interventions
6. Non-medical prescribing
7. Detection and management of Wernicke's encephalopathy and alcohol related brain injury (cognitive impairment)
8. Detection and management of alcohol related liver disease
9. Detection and management of dual diagnosis patients
10. Leadership
11. Service development

The aim of this framework is to define and describe the knowledge and skills which ACTs need in order to deliver quality services. It will support the nurse candidate in identifying their learning needs and plan the candidate development. Matching learning to domains within the Knowledge and Skills Framework (KSF), they can identify the knowledge, skills, learning and development that they need to do their job well. This approach can also support a fair and consistent approach to Personal Development Planning and Review (PDP&R) [19].

Evaluating Effectiveness of Care Pathways

At the Royal Liverpool University Hospital, for many years, we have routinely collected data on all referrals to our ACT. The data is based on standard operating procedures and include:

1. Patient experience and perceptions
2. Alcohol screening
3. Psychosocial interventions
4. Screening to detect co-morbid disease (Liver, Brain)
5. Provision of ambulatory care and prescribing for alcohol withdrawal management
6. Prescribing in relapse prevention
7. Provision of bespoke care at end of life

Over time, bespoke databases have been designed to enable service evaluation and map patient outcomes. Within this routine data set, unique patient outcome measures can be matched to alcohol phenotype and co-morbidities. This provides confidence for wider implementation of any recommendations that emerge from our findings. It also has potential to benefit clinical practice, and subsequently and most importantly provide improvements in access to and quality of alcohol care for patients in general hospitals [20]. After establishing these databases, we are currently starting analytics to drive the services toward a better patient care which includes the implementation of alcohol care pathways using routinely collected data and evaluation of staff, patient experience and perceptions.

Chapter 77
An Interdisciplinary Approach to Alcohol Use Disorders: What Hepatologists Can Do in a Resource-Limited Setting

Andreea Fodor, Andra Nicoara, Madalina Taru, Vlad Taru, Andreea Bumbu, and Horia Stefanescu

Abstract The prevalence of alcohol use disorders and alcohol-related liver disease is high in Romania, due to multiple socioeconomic, demographic, and cultural factors. Their management is also precarious, mainly because there is a lack of understanding towards addiction issues and an increased level of stigma. The hepatologist is often in the middle of this landscape, as many of the alcoholics seek medical care when liver disease is overt, or advanced, or having a complication. Consequently, the liver specialist is subjected to a considerable burden, which he/she copes with by creating a multidisciplinary team, by getting involved in research and development projects, or by education and training. The AddictHelp Project describes a local hepatologist driven initiative towards the establishment of a multidisciplinary team, and also towards providing education and raising awareness.

Background

Alcohol misuse remains worldwide the only addiction to a psychoactive agent that is not actively regulated by a control body [1]. It represents, together with tobacco smoking and high salt/sugar food, the main driver of increasing incidence of non-communicable diseases [2]. Although the so-called "social drinking" is not considered harmful, recent data demonstrates the opposite [3], especially among young and middle-aged populations (15–49 years), where it represents the main cause of mortality (approximatively 12% among men, and 4% among women). Not only that alcohol represents a risk factor for 23 diseases, its misuse is responsible for a significant number of domestic and social violence incidents and also for a decreased workforce productivity.

Alcohol-related liver diseases (ALD) represent a particular facet of alcohol use disorders (AUD), because alcohol is associated (at least in the western world) with an increasing risk of liver cirrhosis and hepatocellular carcinoma, conditions that are diagnosed in up to 75% of cases in a late or advanced stage. About 1.25 million individuals die annually because of a liver disease, representing 2.3% of total deaths (>50% higher than 30 years ago) [4]. More details on the epidemiology of AUD and ALD are discussed in part I of this book.

The Romanian Case: A Resource Limited Country in the Western World

Romania has significantly changed and improved in the last 30 years since the end of the communist dictatorship and the Cold War in terms of economic growth and quality of life (GDP/capita PPP increased from ~11,000 USD in 1992 to >35,000 USD in 2021, as World Bank data suggest). Romania became full member in NATO (2004) and EU (2007), which established its way towards development and recovering the disparities from the Western countries. However, there are specific challenges that characterize and impact the country's transition.

Demographics and Socioeconomics

The majority of communist industrial and agricultural plants and factories closed due to their unsustainable business model, leaving a huge number of persons unemployed and many small towns without any perspective. As a consequence, more than 3.5 million individuals left Romania. Nowadays (2017), the unemployment rate in Romania is 6.8%, at a population of 19.815.000 [5]. Almost half of this

population still lives in rural areas [6], which is an important issue, because the disparities between rural and urban areas increased, leading to a situation where 46.6% of rural workforce is either unemployed, or working in subsistence agriculture [7]. This situation leads to a paradox: although the national unemployment rate is lower than the EU average (9.4%), the relative poverty rate is double (19.8%) [5].

It is not a surprise that under these circumstances, the alcohol intake in Romania is high and continues to grow, both in terms of volume of pure alcohol (11.7 L/capita—higher than the EU average—8.7 L/capita, ranking ninth among the EU countries) and in episodes of heavy drinking (first for males and second overall), as recent (2019) report on the prevalence of heavy episodic drinking in European countries, at least once a month among alcohol drinkers shows [8]. Apart from thus, there is a significant problem of illicit and domestic alcohol production, which continues to be high and is virtually not accessible to objective quantitation.

The amount of alcohol intake is important because since it is directly related to ALD prevalence and progression. Thus, it has been demonstrated that most patients with advanced liver disease due to alcohol are abusive drinkers (>120 units/week for men and >80 units/week for women) [9] [10]. Apart from the quantity, the drinking pattern (moderate vs binge; constant vs. occasional), the type of beverage (beer, wine, or spirit) and their quality influence the progression of ALD. For instance, it has been shown that, in countries with low GDP, the high prevalence of advanced liver diseases and increased mortality is associated with the intake of low-quality spirits [11].

Healthcare System

The healthcare system in Romania is shifting from being inpatient oriented to community and primary care, but still bears unsolved problems:

- Low health care expenditure: lowest in EU, both in EUR/capita (814), or as GDP share (4.9%, as compared with the EU average of 9,9%);
- Shortage of medical staff, affecting both doctors (2.8/1000 population vs. 3.5/1000 in EU) and nurses (6.4/1000 population vs. 8.4/1000 in EU), ranking among the three most affected countries in EU. This is a consequence of a major brain drain affecting healthcare professionals in the 2000s, especially after 2007 as a response to EU accession and lowering wages due to the economic crisis;
- Underdeveloped and outdated infrastructure, especially in rural areas [5].

All these factors led to an increased number of amendable or avoidable deaths, the highest in the EU [5]. This is also mirrored by the number of liver diseases in Romania being the country with the highest prevalence of chronic liver diseases (~1200/100000), but also the country with the highest mortality due to cirrhosis and liver cancer (40/100000) [12].

Cultural Issues

Despite its progress, Romania remains a traditional society, being less inclusive and tolerant. Therefore, stigmatization is frequent, especially in poorly educated communities. Education is an important factor in this regard, since the functional illiteracy is the second worst in EU (reaching 42%), despite the high rate of adult literacy (~99%) [13]. A systematic review investigating stigma in various mental illnesses, found that AUD patients are less frequently regarded as mentally ill, but ranked highest for every aspect of stigma: blame, dangerousness, social rejection, negative emotions, and they are at particular risk for structural discrimination [14]. This creates the premises for another Romanian paradox: a high AUD stigma in a country with an increased alcohol misuse. Not surprisingly, in the Romanian Code of Occupations there is no equivalent for the "drug and alcohol addiction counsellor" (ESCO 2635.1.2).

The Role of the (Romanian) Hepatologist

All these socioeconomic and cultural factors, together with a precarious healthcare system render healthcare professionals working in liver clinics the first who get in direct touch with AUD patients, when they seek medical assistance e.g. because of gastrointestinal bleeding, decompensated liver cirrhosis, episodes of alcoholic hepatitis (AH) or acute on chronic liver failure (ACLF). Therefore, the skills and knowledge, used by the hepatologist in everyday practice, shifted from clinical—specific to each spectrum of ALD (see Table 77.1) to more complex ones, needed to diagnose and quantify alcohol misuse and addiction and to stratify risk of chronic liver disease (CLD) (see Table 77.2). Table 77.3 shows how to characterize alcohol misuse according to DSM-V.

Whatever the clinical situation is in a resource limited settings,, the hepatologist faces all the socio-economic, demographic and cultural issues mentioned before. All this translates into poorer care and bad outcomes for patients, and burnout for caregivers. All in one, an increased burden on the medical staff that deals with ALD is observed, as depicted in Fig. 77.1. However, the hepatologist "under siege" has several solutions in hand to overcome the situation: education, research, development and coagulation around him/her of all the other actors involved in delivering better care for ALD patients.

Table 77.1 Traditional assessment of patients with ALD by the hepatologist

Spectrum of ALD	Clinical signs and symptoms[a] [15]	Diagnostic tests	Therapeutic measures
Alcohol abuse	Alcoholic halena Stellate angiomas on the chest and face; palmar erythema, leukonychia, ecchymosis, Dupuytren's contracture, bilateral parotid gland hypertrophy, rhinophyma; overweight/obesity	Increased AST and ALT; AST/ALT >1; increased GGT [16] [17]	Refer to psychologist/psychiatrist
Alcoholic steatosis		Abdominal ultrasound LSM (+ CAP) by liver elastography	Silymarin Phospholipids
Alcoholic cirrhosis	Jaundice, minimal/overt hepatic encephalopathy Weight loss-due to muscle atrophy or weight gain-due to ascites and oedema	MELD & CPT scores Ultrasound & CT scan (HCC screening) EGDS—variceal screening	NSBB, diuretics Rifaximin, lactulose EBL
Alcoholic hepatitis (AH)	Jaundice, fever, nausea, ascites, SIRS/infection	Maddrey, ABIC, GAHS & MELD scores Lille model ± liver biopsy (neutrophil infiltration, Mallory-Denk bodies, ballooning, cholestasis, steatosis	Prednisolone, ACC, antibiotics, nutrition, ICU admission, vasoactive drugs, mechanical ventilation, dialysis; early liver transplantation or palliative care
Decompensated liver disease	Liver, kidney, and other organ failures	SOFA score	

Abbreviations: *ABIC* age-bilirubin-INR-creatinine score, *ACC* acetyl cysteine, *CAP* continuous attenuation parameter, *CPT* child-pugh-turcotte, *EBL* endoscopic band ligation, *GAHS* glasgow alcoholic hepatitis score, *ICU* intensive care unit, *LSM* liver stiffness measurement, *MELD* model for end-stage liver disease, *NSBB* non selective beta blockers, *VCTE* vibration controlled transient elastography;

[a]At any time, alcohol withdrawal syndrome (which is a psychiatric disorder caused by the cessation of a heavy, prolonged alcohol consumption) may occur, and it could involve: autonomic hyperactivity, tremor, insomnia, nausea, hallucinations, psychomotor agitation, anxiety and seizures. It is not necessarily associated with distress or impairment [18]

Table 77.2 Integrative multidisciplinary assessment of patients with ALD, typically performed by the hepatologist

	Assessment of liver involvement		Assessment of alcohol misuse		
Patient category	Method	Intervention	Type	Methods	Comments/intervention
AUD	Screening of fibrosis (serum test)—most frequently used: Fib4 score		Biomarkers [15]	**CDT** (serum) **EtG** (urine, hair) **PEth** (serum) (cutoff value: 20 ng/ml)	Low sensitivity and specificity False + Limited availability High sensitivity and NPV
ALD	Assess risk for compensated advanced chronic liver disease (LSM by VCTE) or CSPH (add platelets count) [19] (Adjust LSM values according to ALT/AST [20]) Use ultrasound and/CT to screen for HCC Address frailty and sarcopenia by nutritional assessment	Start NSBB if LSM >25, or LSM > 20& PLT <150.000 Monitor annually Biannual Adjust diet; promote exercise Treat complications if they occur	Psychologic	**AUDIT** [21]—most used; 10 q; screening; evaluates: 1. Alcohol intake, 2. Potential dependence 3. Experience of alcohol-related harm **CAGE** [22]—4q; more inaccurate **ASQ** [23]—15 y/n q; can be self-administered; proved to be a reliable predictor for various subjectively perceived effects of alcohol use.	Brief intervention (BI) according to AUDIT score [24]: **0–3**: Positive health message; **4–9**: BI aimed to reduce use (advise) **10–13**: BI aimed to reduce or abstain + appoint follow-up visit; **14+**: BI aimed to accept referral for full assessment and therapy Educational booklet Information about support groups (alcoholics anonymous) Pharmacologic treatment of WS Pharmacologic prevention of relapse [15] (*baclofen—the only compound studied in the setting of ALD!*) [25]
Decompensated ALD	See table 1 for AH and ACLF				

All patients should be characterized for alcohol misuse according to DSM-V* as shown in Table 77.3

Abbreviations: *ASQ* alcohol sensitivity questionnaire, *AUDIT* alcohol use disorders identification test, *CAGE* cut down, annoyed, guilty, eye-opener test, *CDT* carbohydrate deficient transferrin, *EtG* ethyl glucuronide, *NPV* negative predictive value, *PEth* phosphatidylethanol, *Q* question, *se* sensitivity, *Sp* specificity, *Y/N* yes/no

Table 77.3 Characterization of alcohol misuse according to DSM-V

1. Alcohol is often taken in larger amounts or over a longer period than was intended.
2. There is a persistent desire or unsuccessful efforts to cut down or control alcohol use.
3. A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects.
4. Craving or strong desire, or urge to use alcohol.
5. Recurring alcohol use resulting in a failure to fulfil major role obligations at work, school or home.
6. Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol.
7. Important social, occupational, or recreational activities are given up/reduced because of alcohol use.
8. Recurrent alcohol use in situations in which it is physically hazardous.
9. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.
10. Tolerance, as defined by either of the following:
    a. Need for markedly increased amounts of alcohol to achieve intoxication or desired effect;
    b. Markedly diminished effect with continued use of the same amount of alcohol.
11. Withdrawal or taking alcohol to relieve withdrawal.

For AUD to be present, at least 2 of the 11 depicted criteria have to be met in the span of 12 months If the criteria are met for AUD, the severity can then be ascertained as follows: (i) Mild: between 2–3 symptoms in the past year; (ii) Moderate: between 4–5 symptoms in the past year; (iii) Severe: 6 symptoms or more in the past year [18]

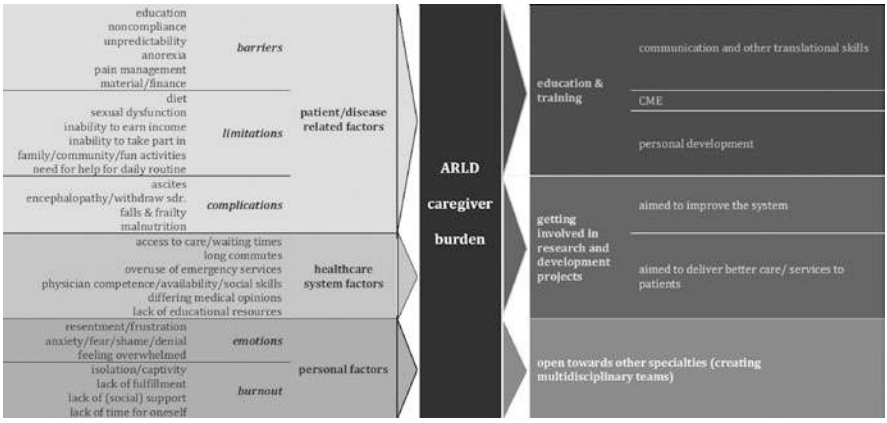

Fig. 77.1 Factors that increase the burden/burnout of caregivers involved in alcohol related chronic liver disease (ARLD) and generate change in practice and care (adapted from [26])

The AddictHelp Project: A Possible Solution for Many Problems

The AddictHelp Project is implemented by Liver Research Club in close partnership with Regional Institute of Gastroenterology and Hepatology from Cluj-Napoca, Romania and is financed through the Active Citizens Fund (an EEA Grants Program). The projects aim at increasing the social inclusion and mobilization of alcohol users by:

(i) Increasing the access to medical and psychological services;
(ii) Educating healthcare professionals and social workers towards increasing compliance to and reducing stigma of alcoholics;
(iii) Increasing awareness of general population regarding these issues.

These objectives are being implemented by:

1. Creating the first outpatient clinic (offering both medical assessment and psychological counselling) for individuals with alcohol misuse;
2. Creating an online educational platform;
3. Generating a set of guidelines, resources, and good practices for the management of addiction

The AddictHelp Outpatient Clinic

The center offers integrated care, both psychological and medical and offers a personalized advice (from educational resources, brief intervention to linkage to care—either medical, or support groups), as shown in Fig. 77.2a. The protocol used to assess every client combines the AUDIT questionnaire with simple non-invasive tests (Fib4, liver elastography such as Fibroscan and abdominal ultrasound), as detailed in Fig. 77.2b. The implementation of the project was superimposed over the COVID-19 pandemic. Of course, this led to certain delays e.g. the launch of the outpatient clinic had to be delayed. On the other hand, this situation offered the opportunity to develop an internet-based resource that offers (i) an educational resource—the AddictHelp Guide (available https://addicthelp.ro/cursuri/), and also (ii) a self-evaluation tool, consisting of the AUDIT questionnaire—to assess the individual alcohol misuse, and the Medical Condition Regard Scale (MCRS)—to evaluate the stigma towards alcoholics.

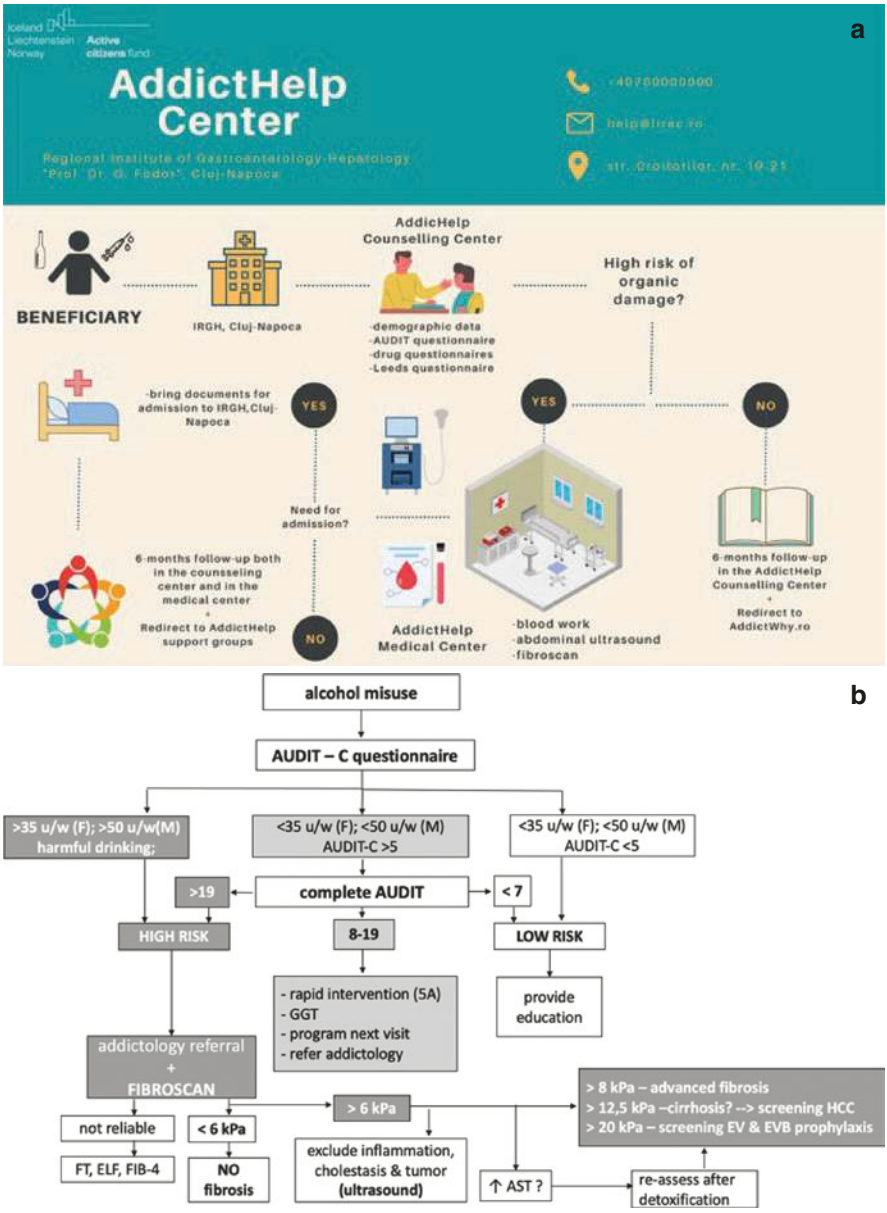

Fig. 77.2 The functional diagram of the AddictHelp outpatient clinic. (**a**) General view of the patient's flow. (**b**) Detailed examination protocol combining addiction assessment and clinical (focused on liver disease) evaluation

Conclusion

The alcohol consumption in Romania is high, because of socioeconomic, demographic, and cultural factors. This is also generating an important number of liver diseases and deaths. On the other hand, the management of alcohol misuse and ALD is precarious, mainly because there is a lack of understanding towards addiction issues and an increased level of stigma. The hepatologist is often in the middle of this landscape, as many of the alcoholics seek medical care when liver disease is overt, or advanced, or having a complication. Consequently, the liver specialist is subjected to a considerable burden, which he/she copes with by creating a multidisciplinary team, by getting involved in research and development projects, or by education and training. All these solutions are viable, as they are aimed to improve the care (medical and psychological) addressed to patients with alcohol addiction. Apart from these local initiatives, comprehensive Governmental measures are needed, especially targeted towards community care, education, and prevention.

Appendix A: Figures/Biochemical Schemes and a Clinical Case

Sebastian Mueller

Abstract This appendix of the book "Alcohol and Alcohol-Related Diseases" is aimed to provide the reader with easy accessible general data on ethanol and alcohol-related diseases. Data encompass basic knowledge about physics, chemistry and biochemistry of ethanol, general data on addiction, epidemiology and natural course of alcohol-related diseases. A major body consists of important biochemical pathways that are relevant for ethanol metabolism. In addition, important histology scores are listed for the diagnosis of alcohol-related liver disease (ALD), alcoholic hepatitis, general prognosis scores, diagnostic work-ups using liver elastography and mortality data. This appendix also provides various images from light microscopy and electron microscopy of liver samples from ALD patients. Finally, a clinical cases is presented with questions/answers to actively recapitulate and apply the knowledge obtained from the book.

Fig. A.3 Alcoholic beverages and corresponding ethanol and energy content. *Liter of alcoholic beverage required to cover the daily caloric need of a standard person estimated with 2500 kcal/day or 10,000 kJ/day. Note that caloric needs strongly depends on age, gender, weight, and physical activity. Also note that only ethanol is considered but not other energy carriers

Epidemiology of Alcohol Consumption

See Figs. A.4, A.5, and A.6.

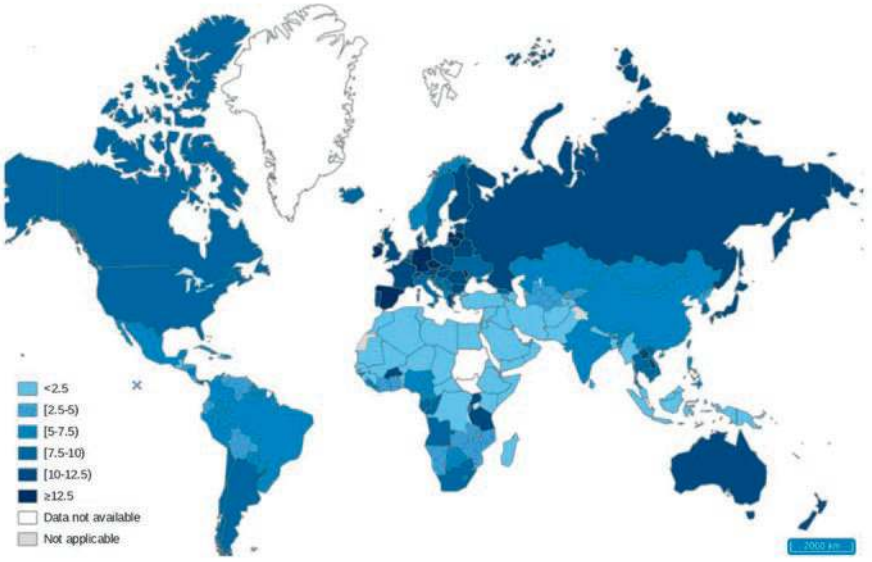

Fig. A.4 Adult per capita consumption of alcohol in litres ethanol for 2019. (Source: World Health Organization, World Health Statistics 2022, see also chapter on Epidemiology by J. Rehm/Part I)

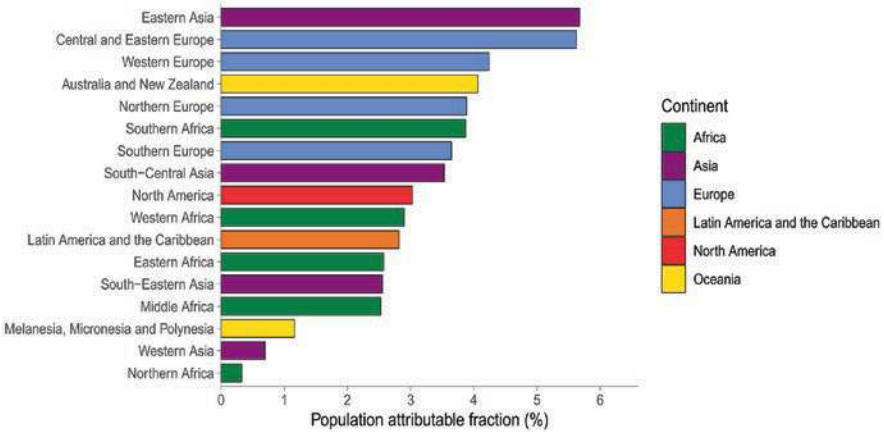

Fig. A.5 Proportion of cancer cases in 2020 attributable to alcohol consumption, by world region. (Chart created using results from *Rumgay H et al. Lancet Oncol. 2021;22(8):1071–80*. See also chapter on Alcohol and Cancer: The Epidemiological Evidence by P. Ferrari)

Alcohol-related disease	Number of death	Percentage
Cirrhosis of the liver	588,100	19.8%
Road injury	370,800	12.5%
Tuberculosis	236,300	8.0%
Haemorrhagic stroke	287,000	9.7%
Ischaemic heart disease	250,800	8.5%
Self-harm	147,000	5.0%
Alcohol use disorders	145,600	4.9%
Liver cancer	101,400	3.4%
Lower respiratory infections	95,200	3.2%
Colon and rectum cancers	92,600	3.1%
Interpersonal violence	86,800	2.9%
Oesophagus cancer	82,900	2.8%
All alcohol-attributable deaths	2,967,800	100.0%

Fig. A.6 Number of alcohol-attributable deaths by single cause of death categories with globally more than 80,000 alcohol-attributable deaths in 2016. (See also chapter on Epidemiology of Alcohol and Opioids by J. Rehm. Compilation based on Shield K et al. The Lancet Public Health. 2020;5(1):e51–e61)

Natural Course of Alcohol-Related Liver Disease (ALD)

See Figs. A.7 and A.8.

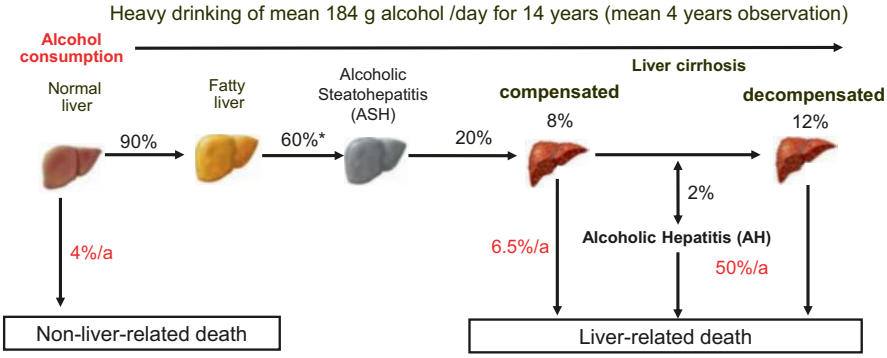

Fig. A.7 Progression of liver disease from the Heidelberg cohort of heavy drinkers ($n = 1078$). Percentage number are related to 100% of initial drinking cohort. See also Tables B.1–B.9 and Chap. 7 on Mortality in Part I. Signs of inflammation are seen in 78% in the liver biopsy cohort, and in 42–62% using biochemical markers in necrosis/inflammation/damage

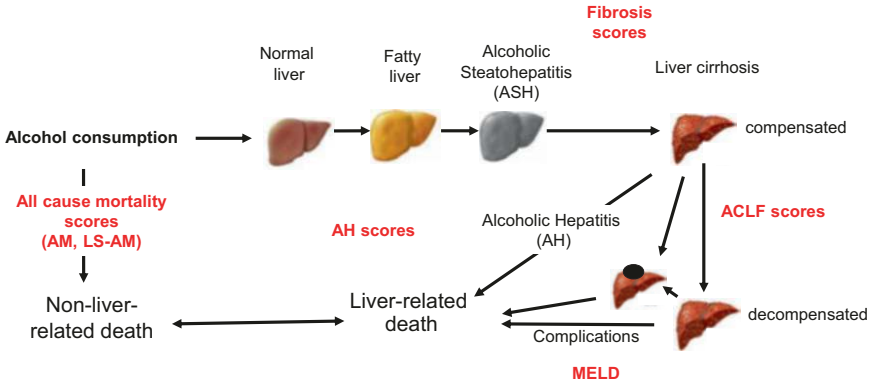

Fig. A.8 Natural course of alcohol consumption, endpoints and various scores. See also following figures for more information about scores. *ACLF* acute on chronic liver failure, *AH* alcoholic hepatitis, *AM* alcohol mortality score, *LS-AM* liver stiffness alcohol mortality score. See also Mortality Chap. 7

Scores for ALD, ACLF and AH

See Figs. A.9, A.10, A.11, A.12, A.13, A.14, A.15, A.16, A.17, A.18, A.19, A.20, A.21.

Fig. A.9 Different scoring systems related to alcohol-related liver diseases and their parameters. Different scores aim at predicting different endpoints such as fibrosis stage, mortality by fibrosis, mortality by alcoholic hepatitis, or all-cause mortality. Parameters are sorted in descending order depending on their used frequency in the various scores

a **Diagnosis of alcoholic hepatitis (AH)**

- Clinical diagnosis!
- Previous heavy alcohol consumption
- Elevated AST/GOT und ALT/GPT (< 400 U/L)
- AST/ALT>1.5
- Bilirubin > 3 mg/dL
- (Elevated INR/PT)
- (Elevated leukocytes (Neutrophiles))
- In case of comorbidities consider liver biopsy

b

Definite AH	Probable AH	Possible AH
clinically diagnosed		
biopsy-proven	without confounding factors	with potential confounding factors

Fig. A.10 Clinical definition and diagnosis of alcoholic hepatitis (AH). (**a**) Clinical and laboratory criteria for AH. (**b**) Criteria for diagnosis of AH in clinical trials used by the NIAAA. (See also Chaps. 64, 65, 66 and 67. See also Louvet A et al. *Liver Int*. 2022;42(6):1330–1343; Singal et al., Journal of Hepatology 2018, vol. 69: 534–543 and Crabb DW et al. Gastroenterology. 2016;150:785–790)

Fig. A.11 Clinical scores for the prognosis of alcoholic hepatitis. AUROCs for survival prediction, parameters and patient numbers are given (modified from Mueller S et al. World J Gastroenterol. 2014;20(40):14626–14641. References: (1) Maddrey WC et al. Gastroenterology. 1978;75(2):193–9. (2) Dunn W et al. Hepatology. 2005;41(2):353–8. (3) Forrest EH et al. Gut. 2005;54(8):1174–9. (4) Louvet A et al. Hepatology. 2007;45(6):1348–54. (5) Dominguez M et al., Rincon D, Abraldes JG, Miquel R, Colmenero J, Bellot P, et al. A new scoring system for prognostic stratification of patients with alcoholic hepatitis. Am J Gastroenterol. 2008;103(11):2747–56). *ABIC* age, serum bilirubin, INR, and serum creatinine score, *GAHS* Glasgow alcoholic hepatitis score, *MDF* Maddrey's discrimination function, *MELD* model for end-stage liver disease

a Original of MDF formula with PT by Maddrey et al. Gastroenterology 75,193:1978

MDF = 4.6 x (PT Patient – PT control) + Bilirubin (mg/dL)

b Example of MDF: DF > 32 = 1-month mortality 50 %

c Estimated MDF using INR (not PT):

MDF = ca. 46 x (INR -1) + Bilirubin (mg/dL)

d Example with estimated INR formula:

INR=1.5 und Bili=24 mg/dL → MDF= 47 → 1-month mortality >50 %

Fig. A.12 Maddrey's discrimination function (MDF) to calculate short-term mortality in patients with alcoholic hepatitis (**a**). (**b**) Severe disease ≥32 with 1-month mortality of 50%. (**c**) and (**d**) Provide an estimated alternative (**c**) and an example (**d**) using the widely available INR, since standardized PT values are not available in many laboratories

Author	Forrest et al (1), 2005	Mookerjee et al (2), 2011	Altamirano et al (3), 2013
Score	GAHS	ASH Grade	ASH score

GUT. 2013;62(3):452–60). *ASH* alcoholic steatohepatitis, *GAHS* Glasgow alcoholic hepatitis score

Chevallier (SSS) Score		**Points**
A. Central lobular vein (CLV)		
1. Normal vein or absence of vein		0
2. Moderately thickened (stellate aspect of vein wall)		1
3. Markedly thickened (annular aspect of vein wall with numerous fibrous intercellular extensions)		2
B. Portal tract (PT)	***C. Perisinusoidal space (PS)***	
1. Normal	1. Normal	0
2. Enlarged without septa	2. Localized fibrosis	1
3. Enlarged with septa	3. Diffuse fibrosis	2
4. Cirrhosis		3
D. Number of septa (NS)	***E. Width of Septa (WS)***	
1. Absence	1. Thin and or incomplete	0
2. $\leq$ 6 septa /10 mm	2. Thick and loose connective matrix	1
3. > 6 septa / 10 mm	3. Very thick and dense connective matrix	2
4. Nodular organization	4. >2/3 of biopsy area	3
Score expression : SSS = CLV + PS + PT + 2(WS x NS)		

Fig. A.14 Chevallier semiquantitative scoring system (SSS) for liver fibrosis. (See also Chevallier M et al. Hepatology. 1994;20(2):349–355)

NASH Clinical Research Network Scoring System Definitions			
A. Steatosis grade	***B. Location (predominant)***	***C. Lobular inflammation***	**Points**
1. < 5%	1. Zone 3	1. No foci	0
2. 5%-33%	2. Zone 1	2. < 2 foci per 200 x field	1
3. > 33%-66%	3. Azonal	3. 2-4 foci per 200 x field	2
4. > 66%	4. Panacinar	4. > 4 foci per 200 x field	3
D. Micro vesicular steatosis	**E. Micro-granulomas**	**F. Large lipogranuloma**	
1. Absent	1. Absent	1. Absent	0
2. Present	2. Present	2. Present	1
G. Fibrosis stages			
1. None			0
2. Perisinusoidal or periportal			1
3. Mild, zone 3, perisinusoidal			1A
4. Moderate, zone 3, perisinusoidal			1B
5. Portal/periportal			1C
6. Perisinusoidal and portal/periportal			2
7. Bridging fibrosis			3
8. Cirrhosis			4
H. Portal inflammation	***I. Pigmented macrophages***	***J. Mega mitochondria***	
1. None to minimal	1. None to rare	1. None to rare	0
2. More than minimal	2. Many	2. Many	1
K. Ballooning	***L. Glycogenated nuclei***	***M. Acidophil bodies***	
1. None	1. None to rare	1. None to rare	0
2. Few ballooned cells	2. Many	2. Many	1
3. Many cells / Prominent ballooning			2

Fig. A.15 Histological NASH clinical research network score. *NASH* – non-alcoholic steatohepatitis. This score is also frequently used for ALD studies. (Kleiner DE et al. Hepatology. 2005;41(6):1313–21)

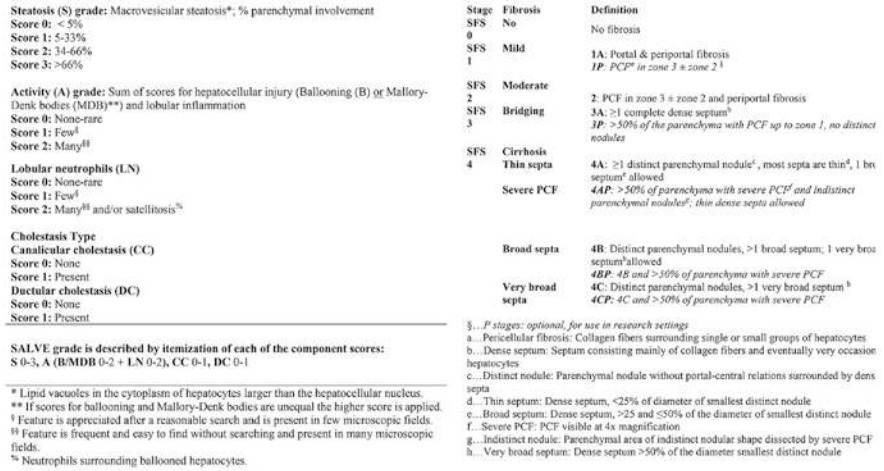

Fig. A.16 Histological SALVE grading for ALD. (See also Lackner C et al. J Hepatol 2021; 75:810–819)

Organ/System	Subscore = 1	Subscore = 2	Subscore = 3
Liver	Bilirubin < 6 mg/dl	Bilirubin ≥6 mg/dl and < 12 mg/dl	Bilirubin ≥12 mg/dl
Kidney	Creatinine < 1.5 mg/dl Creatinine 1.5–1.9 mg/dl	Creatinine ≥2 mg/dl and < 3.5 mg/dl	Creatinine ≥3.5 mg/dl or renal replacement
Brain (West-Haven grade for HE)	Grade 0	Grade 1-2	Grade 3–4
Coagulation	INR <2.0	INR 2.0–2.4	INR ≥2.5
Circulatory	MAP ≥70 mm Hg	MAP < 70 mm Hg	Vasopressor requirement
Respiratory	PaO2/FIO2 >300 SpO2/FIO2 >357	PaO2/FIO2 201–300 SpO2/FIO2 215–357	PaO2/FIO2 ≤200

Fig. A.17 Clinical criteria for the diagnosis of acute-on-chronic liver failure (ACLF) (adapted from Jalan, R. et al. J. Hep. 2014. 61(5): p. 1038–1047). *FiO_2* fraction of inspired oxygen, *INR* international normalized ratio, *MAP* mean arterial pressure, *PaO_2* partial pressure of arterial oxygen, *SpO_2* oxygen saturation as measured by pulse oximetry

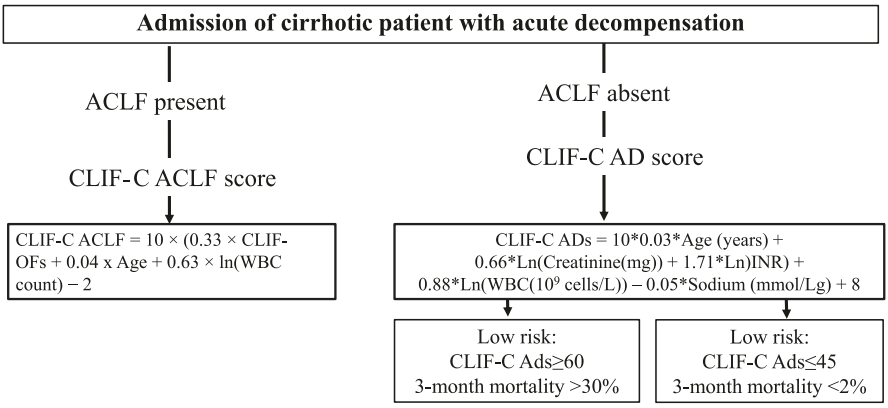

Fig. A.18 Proposed algorithm for the use of EASL-CLIF Consortium predictive scores for ACLF and non-ACLF patients (adapted from Jalan R et al. *J Hepatol*. 2015;62(4):831–840. See also chapter by R. Jalan). *AD* acute ecompensation, *ACLF* acute-on-chronic liver failure, *EASL-CLIF* The European Association for the Study of the Liver–Chronic Liver Failure

Patient group	Prevalence over 1287 patients (%)	28-day Mortality (%)	Assigned grade
Absence of organ failure	68.3	4.4	Absence of ACLF
Single non-Kidney organ failure without KD or BD	9.9	6.3	
Single KF	6.7	18.6	ACLF-1
Single non-Kidney organ failure with KD or BD	4.2	27.8	ACLF-1
Two organ failures	7.5	32	ACLF-2
Three organ failures	1.9	68	ACLF-3
Four to six organ failures	1.4	88.9	ACLF-3

Fig. A.19 Mortality of ACLF patients according to its severity (adapted from Moreau, R., et al., Gastroenterology, 2013. 144 (7): p. 1426–1437. e9). *ACLF* acute-on-chronic liver failure, *BD* brain dysfunction, *KD* kidney dysfunction, *KF* kidney failure. See also chapter on ACLF by R. Jalan

	Score	0	1	2	3	4
Central nervous system	**Glasgow coma scale**	15	13–1	10–12	6–9	< 6
Cardiovascular system	**Mean arterial pressure OR administration of vasopressors required**	MAP ≥ 70 mmHg	MAP < 70 mmHg	dopamine≤ 5 µg/kg/min or dobutamine (any dose)	dopamine > 5 µg/kg/min OR epinephrine ≤ 0.1 µg/kg/min OR norepinephrine ≤0.1µg/kg/min	dopamine > 15 µg/kg/min OR epinephrine > 0.1 µg/kg/min OR norepinephrine >0.1µg/kg/min
Respiratory system	**PaO2/FiO2 [mmHg (kPa)]**	≥ 400 (53.3)	< 400 (53.3)	< 300 (40)	< 200 (26.7) and mechanically ventilated including CPAP	< 100 (13.3) and mechanically ventilated including CPAP
Coagulation	**Platelets×103/µl**	≥ 150	< 150	< 100	< 50	< 20
Liver	**Bilirubin (mg/dl) [µmol/L]**	< 1.2 [< 20]	1.2–1.9 [20-32]	2.0–5.9 [33-101]	6.0–11.9 [102-204]	> 12.0 [> 204]
Renal function	**Creatinine (mg/dl) [µmol/L] (or urine output)**	< 1.2 [< 110]	1.2–1.9 [110-170]	2.0–3.4 [171-299]	3.5–4.9 [300-440] (or < 500 ml/day)	> 5.0 [> 440] (or < 200 ml/day)

Fig. A.20 The sequential organ failure assessment score (SOFA score) for liver failure. It is typically used to track a person's status during the stay in an intensive care unit (ICU) to determine the extent of a person's organ function or rate of failure (adapted from Weng C-H, et al. (2012) PLoS ONE 7(12): e51743). *CPAP* continuous positive airway pressure, *MAP* mean arterial pressure

New definition of Acute Kidney Injury – AKIN score
serum creatinine increase of ≥ 0.3 mg/dL in 48 h or > 50% of reference serum creatinine or sustainable in the last 7 days

AKIN stages	Criteria	3-months survival
AKI 1A	Increase of serum creatinine >0.3 mg/dL (26.4 µmol/L) or more than 1.5 times of reference serum creatinine	70%
AKI 1A	Serum creatinine < 1.5 mg/dL (132.6 µmol/L)	82%
AKI 1B	Serum creatinine ≥ 1.5 mg/dL (132.6 µmol/L)	55%
AKI2	Increase more than 2-3 times than reference serum creatinine	42%
AKI3	Increase >3 times from reference serum creatinine or Serum creatinine ≥ 4 mg/dL (353.6 µmol/L) or Renal replacement therapy	31%

Fig. A.21 Diagnosis criteria for acute kidney injury (AKI) also applied to hepato-renal syndrome in ALD patients. Substages of AKI are based on serum creatinine. AKIN is also used assess hepatorenal syndrome (HRS). See also chapter by A. Trifan on "Hepato-Renal Syndrome in Patients with Alcohol-Related Liver Disease". *AKIN* acute kidney injury network

Alcohol Dependence and Brain Research

See Figs. A.22, A.23, A.24, A.25, A.26, A.27, A.28, and A.29.

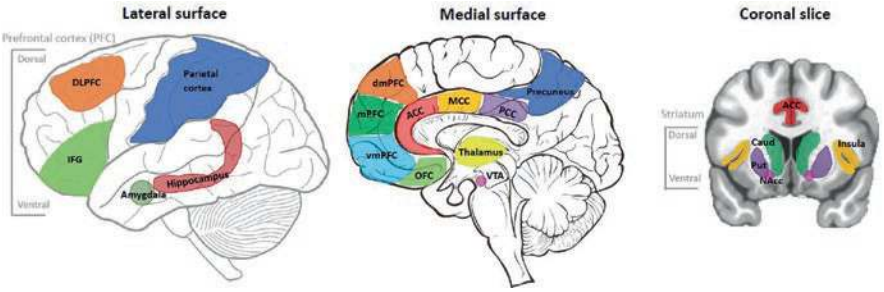

Fig. A.22 Brain areas referenced in this book. *DLPFC* dorsolateral PFC, *IFG* inferior frontal gyrus, *dmPFC* dorsomedial PFC, *mPFC* medial PFC, *vmPFC* ventromedial PFC, *OFC* orbitofrontal cortex, *ACC* anterior cingulate cortex, *MCC* middle cingulate cortex, *PCC* posterior cingulate cortex. Note that the amygdala and hippocampus are located in the medial temporal lobe but are depicted on the lateral surface image. On the coronal slice, the striatum comprises the caudate (Caud), putamen (Put), and nucleus accumbens (NAcc). For details see Chap. 26 by J. Schacht entitled "Structural and Functional Imaging of Alcohol's Effects on the Brain"

Questions	0	1	2	3	4
1. How often do you have a drink containing alcohol?	Never	Monthly or less	2 to 4 times a month	2 to 3 times a week	4 or more times a week
2. How many drinks containing alcohol do you have on a typical day when you are drinking?	1 or 2	3 or 4	5 or 6	7 to 9	10 or more
3. How often do you have 5 or more drinks on one occasion?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
4. How often during the last year you found that you were not able to stop drinking once you had started?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
5. How often during the last year have you failed to do what was normally expected of you because of drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
7. how often during the last year have you had a feeling of guilt or remorse after drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
8. How often during the last year have you been unable to remember what happened the night before because of your drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
9. Have you or someone else been injured because of your drinking?	No		Yes, but not in the last year		Yes, during the last year
10. Has a relative, friend, doctor or other health care worker been concerned about your drinking or suggested you cut down?	No		Yes, but not in the last year		Yes, during the last year

Fig. A.23 AUDIT questionnaire to identify patients with alcohol use disorder. To score the AUDIT questionnaire, sum the scores for each of the 10 questions. A total ≥ 8 for men up to age 60, or ≥ 4 for women, adolescents, or men over age 60 is considered a positive screening test. *AUDIT* alcohol use disorders identification test

Medication (daily dose) *	Site of action	FDA Approval	Efficacy	Common side effects
Medications approved for treatment of AUD				
Disulfiram (125-500 mg)	Inhibition of alcohol metabolism (acetaldehyde dehydrogenase enzyme)	AUD	Tachycardia, headache, nausea, and vomiting after alcohol consumption. Medium effect in open-label trials, no effect in blind designs.	disulfiram-alcohol interaction
Acamprosate calcium (666 mg TID)	Putative antagonism of NMDA receptors	AUD	Improves probability of maintaining abstinence. Reduces the number of drinking days.	diarrhea
Naltrexone (50 mg)	Antagonism of μ-, κ-, and δ-opioid receptors	AUD Opioid use disorder (OUD)	Reduces craving, number of heavy drinking days, risk of return to drinking, risk of binge drinking, and improves quality of life.	nausea, headache, dizziness, and sleep problems
Naltrexone LAI (380 mg / 4 week) i.m.	Antagonism of μ-, κ-, and δ-opioid receptors	AUD OUD	Reduces number of drinking days and number of heavy drinking days. Compared to oral naltrexone, time to relapse is longer.	injection site related inflammation, infection
Nalmefene (18 mg)	Antagonism of μ- and δ-opioid receptors; partial agonism of κ-opioid receptor	Reversal of opioid overdose. Approved for AUD in Europe	Reduces number of heavy drinking days and total alcohol consumption.	nausea, vomiting, fatigue, insomnia, and dizziness

Fig. A.24 Approved, effective and promising new medication for AUD. See also Chap. 16. *Oral administration, unless otherwise specified

Medication (daily dose) *	Site of action	FDA Approval	Efficacy		Common side effects
Additional effective medications based on clinical trials					
Topiramate (100–300 mg)	Antagonizes glutamatergic AMPA and kainate receptors, and facilitates GABA activity; blocks L-type calcium channels, reduces voltage-dependent sodium channel activity, inhibits carbonic anhydrase	Adjunct for partial and tonic-clonic seizures and migraines. Topiramate ER in combination with phentermine for weight management in obesity	Reduces craving, percentage of heavy drinking days and drinks per drinking days.	paresthesia, taste abnormalities, anorexia, difficulties with concentration	
Gabapentin (600–1800 mg)	Blocks voltage-gated calcium channels and enhances permeability of voltage-gated potassium channels. Indirectly modulates GABA receptors.	Adjunct for partial seizure and postherpetic neuralgia	Reduces the number of drinks and percentage of heavy drinking days, especially in patients with history of alcohol withdrawal symptoms.	dizziness, somnolence	
Gabapentin enacarbil extended-release (GE-XR) (1200 mg)	Blocks voltage-gated calcium channels and enhances permeability of voltage-gated potassium channels. Indirectly modulates GABA receptors.	Restless leg syndrome and postherpetic neuralgia	Reduces the number of drinks and drinks per heavy drinking days in patient subgroup with higher baseline heavy-drinking days per week, impulsivity, and lower levels of anxiety, depression, and mood disturbances.	fatigue, dizziness, somnolence	
Baclofen (30-80 mg)	Agonism of $GABA_B$ receptors	Muscle spasticity	Improves probability of maintaining abstinence; decreases craving. More effective in patients with alcohol-associated liver disease.	sedation, drowsiness, dizziness, headache	
Varenicline (2 mg)	Partial agonism of α4β2 nicotinic acetylcholine receptors	Smoking cessation	Decreases craving in smokers and non-smokers. Reduces mean number of drinks in smokers. Better response in less-severe AUD, depressive symptoms, males.	nausea, abnormal dreams, constipation	
Ondansetron (8 μg/kg)	Antagonism of 5-HT3 serotonin receptor	Nausea and vomiting	Reduces amount and frequency of drinking in early-onset AUD.	headache, constipation	
Prazosin / Doxazosin (16 mg)	Antagonism of α1 receptors	Hypertension and benign prostatic hyperplasia	Reduces number of heavy drinking days and drinks per week. Better response in patients with higher blood pressure and positive AUD family history.	drowsiness, dizziness, fatigue	

Fig. A.25 Approved, effective and promising new medication for AUD (continued). See also Chap. 16. *Oral administration, unless otherwise specified

Medication (daily dose) *	Site of action	FDA Approval	Efficacy	Common side effects
Promising new medications				
Zonisamide (500 mg)	Blocks voltage-sensitive sodium channels and T-type calcium channels, enhances synaptic inhibition by facilitating GABAergic, dopaminergic, and serotonergic transmission. Indirectly attenuates glutamatergic transmission.	Adjunct treatment for epilepsy	Reduces number of heavy drinking days, drinks per week, and alcohol craving	Drowsiness, difficulties with concentration, decreased appetite, abdominal pain
Aripiprazole (15-30 mg)	Partial agonism of D2 dopaminergic and 5HT1A serotonergic receptors, antagonism of 5HT2A receptors	Schizophrenia, bipolar disorder	Reduces number of drinks per drinking days. Better response in patients with higher impulsivity. Genetic polymorphisms of dopamine transporter (DAT), dopamine receptor and catechol-O-methyltransferase (COMT) genes moderate the effects.	insomnia, anxiety, restlessness, and disturbances in attention
Mifepristone (600 mg)	Antagonism of glucocorticoid receptors	Pregnancy termination	Reduces alcohol craving.	nausea, vomiting, diarrhea
N-acetylcysteine (2400 mg)	Antioxidant, affecting glutamatergic neurotransmission	Antioxidant (over the counter)	Decreases alcohol drinking in cannabis dependent patients.	dry mouth, nausea, vomiting, diarrhea
Oxytocin (24 IU) intranasal	Agonism of oxytocin receptors	Labor induction, termination of pregnancy (not the intranasal form)	Reduces alcohol cue-elicited brain activity, craving and symptoms of alcohol withdrawal.	runny nose, nasal discomfort, headache
Promising new compounds				
ABT-436 (800 mg)	Antagonism of V1b vasopressin receptors	Not approved	Increases percentage of abstinent days.	diarrhea, anxiety, and nausea
LY 2940094 (40 mg)	Antagonism of nociceptin (NOP) receptors	Not approved	Decreases percentage of heavy drinking days and increases percentage of abstinent days.	insomnia, anxiety, vomiting
LY2196044 (250 mg)	Antagonism of μ, κ, and δ-opioid receptors	Not approved	Increases percentage of abstinent days per month and decreases mean number of drinks per day. Better response in patients with dopamine receptor type 4 (DRD4) gene polymorphism.	diarrhea, nausea, abdominal pain, and flatulence
Samidorphan (1-10 mg)	Antagonism of μ-opioid receptor, mixed agonism-antagonism of κ, and δ-opioid receptors	Not approved	Reduces craving and average daily alcohol consumption.	nausea, vomiting, somnolence, dry mouth, dizziness
Ibudilast (100 mg)	Inhibits phosphodiesterase-4 (PDE4) and -10 (PDE10), and macrophage migration inhibitory factor (MMIF). Reduces neuroinflammation and supports neurotrophin expression	Not approved	Reduces craving, percentage of heavy drinking days and alcohol-cue elicited activation in brain. Better response in patients with depressive symptoms.	headache, nausea
Ifenprodil (60 mg)	Inhibits G protein-activated inwardly rectifying potassium (GIRK) channel	Not approved	Reduces frequency of alcohol drinking and presence of heavy drinking.	nausea, dry mouth, dizziness, headache

Fig. A.26 Approved, effective and promising new medication for AUD (continued). See also Chap. 16. *Oral administration, unless otherwise specified

Alcohol Dependence	Harmful Pattern of Use of Alcohol
A disorder of regulation of substance use arising from repeated or continuous use of substance. The characteristic feature is a strong internal drive to use substance, which is manifested by impaired ability to control use, increasing priority given to use over other activities and persistence of use despite harm or negative consequences The diagnosis requires two or more of the following three central features to be evident over a period of at least 12 months, but the diagnosis may be made if alcohol use is continuous for at least 1 month. 1. Impaired control over alcohol use – in terms of the onset, level, circumstances or termination of use, often but not necessarily accompanied by a subjective sensation of urge or craving to use alcohol. 2. Alcohol use becomes an increasing priority in life – takes precedence over other interests or enjoyments, daily activities, responsibilities, or health or personal care. Alcohol use takes an increasingly central role in the person's life and relegates other areas of life to the periphery; continues despite the occurrence of problems. 3. Physiological features (indicative of neuroadaptation to the alcohol) as manifested By; (i) tolerance, (ii) withdrawal symptoms following cessation or reduction in use of that substance or (iii) repeated use of the substance (or pharmacologically similar substance) to prevent or alleviate withdrawal symptoms. Withdrawal symptoms must be characteristic for the withdrawal syndrome for alcohol and must not simply reflect a hangover effect.	A pattern of alcohol use that has caused damage to a per-son's physical or mental health or has resulted in behaviour leading to harm to the health of others The pattern of alcohol use is evident over a period of at least 12 months if substance use is episodic or at least 1 month if use is continuous. Harm to health of the individual occurs due to one or more of the following: 1. Behaviour related to intoxication 2. Direct or secondary toxic effects on body organs and systems 3. A harmful route of administration. Harm to health of others includes any form of physical harm, including trauma, or mental disorder that is directly attributable to behaviour related to alcohol intoxication on the part of the person to whom the diagnosis of Harmful Pattern of Use of Alcohol applies.

Fig. A.28 Alcohol dependence and harmful pattern of use of alcohol as described by ICD-11. For more details see also Chap. 12

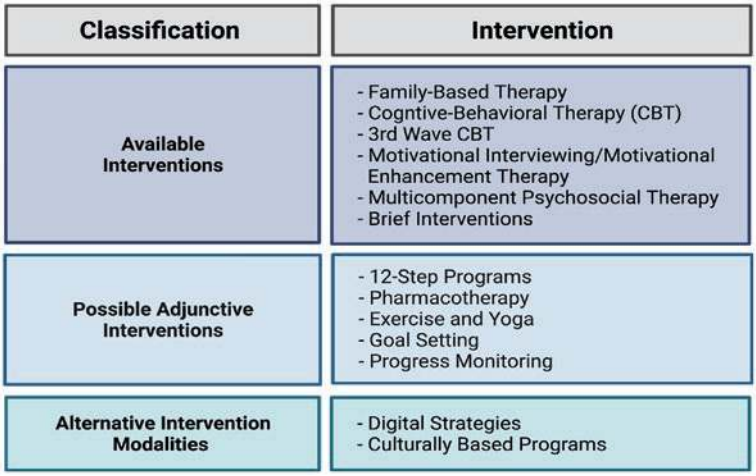

Fig. A.29 Overview of adolescent AUD treatments covered in this chapter. Interventions range from available, possible adjunctive, and alternative modalities. For more details see Chap. 18

Macro- and Microscopic Images of Alcohol-related Liver Disease (ALD)

See Figs. A.30, A.31, A.32, A.33, A.34, A.35, and A.36.

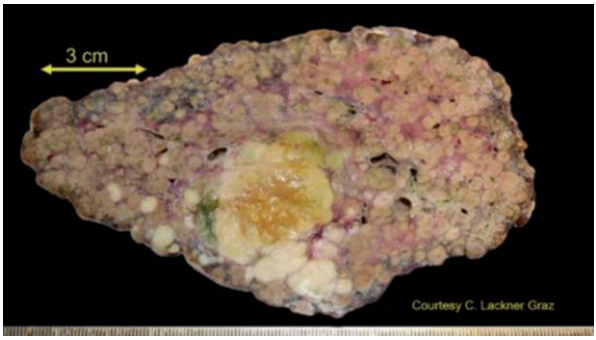

Fig. A.30 Liver explant from a male heavy drinker (53 years) with alcohol-related liver cirrhosis. (Courtesy C. Lackner Graz)

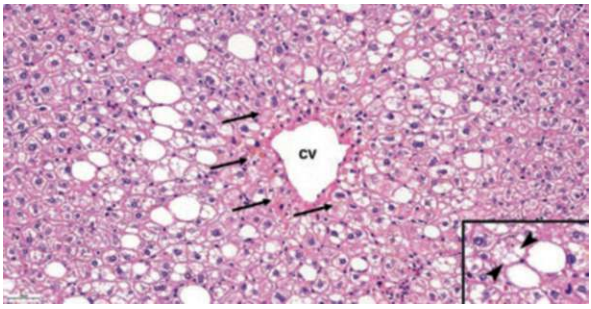

Fig. A.31 Alcohol-related macrovesicular steatosis: hepatocytes in intermediate and central portions of the hepatic lobules contain large lipid vesicles taking up most of the hepatocellular cytoplasm and dislocating the nucleus to the periphery of the cell (inset). The large macrovesicles may result from confluence of several smaller ones (marked by arrow head in inset). Also note that bilirubin-stain seems to appear in the pericentral hepatocytes in cytoplasm (arrows). It needs to be resolved whether this is related to the hemolytic anemia seen in heavy drinkers that also drives mortality. See also Chaps. 38, 57 and 58 on Histology, Iron, and Bone Marrow Toxicity. Image: H&E; *CV* central vein. (Courtesy of C. Lackner, Graz. See also chapter by C. Lackner on "Histology and ALD")

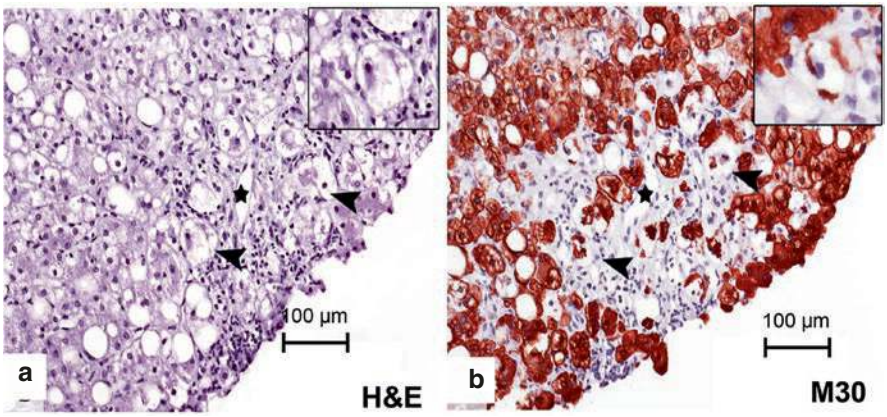

Fig. A.32 Morphological and immunohistochemical features of steatohepatitis and M30 expression in a case of alcoholic steatohepatitis (**a**, **b**). Note that serum M30 levels correlate excellently with the hepatic expression of M30 in liver stains. M30 allows to diagnose liver apoptosis in the serum and is more sensitive than transaminases. (**a**) Centrilobular area (asterisks marks central vein) with ballooned hepatocytes (enlargement shown in inset) and hepatocytes with fatty change are surrounded by inflammatory infiltrates (H&E, 200×). (**b**) Consecutive section of centrilobular area shown in (**a**) (asterisks marks central vein). The ballooned hepatocytes show loss of cytoplasmic staining while Mallory Denk bodies are decorated with antibodies against keratin (K)8 and 18 (enlargement shown in inset). Regular sized hepatocytes and hepatocytes with fatty change retain a K8/18 (M30) positive cytoplasm (200×). Serum level of M30 in this patient was 4753.0 U/L. (Modified from Mueller S et al. *Hepatology*. 2017;66(1):96–107)

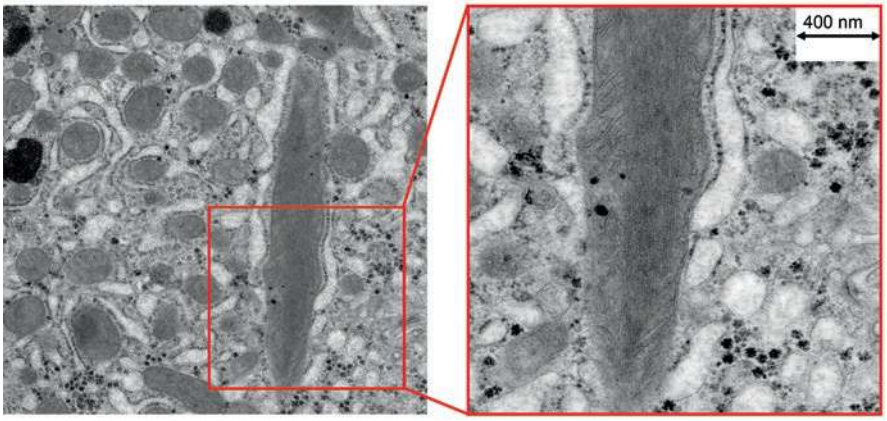

Fig. A.33 Electron micrograph of a liver specimen from a patients with alcoholic hepatitis (female, 53 years). Mitochondrial inclusions show para-crystalline ("parking lot") inclusions that are classically seen with electron transport chain defects. In light microscopy, this mitochondrion would resemble a megamitochondrium

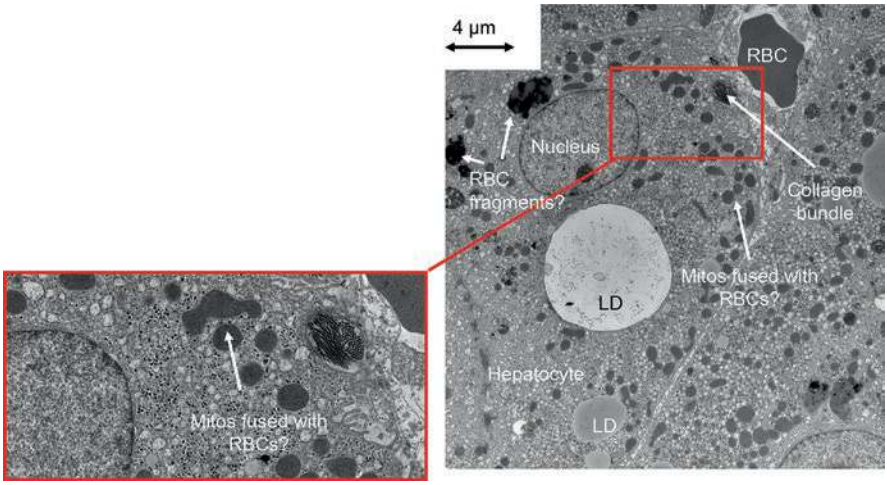

Fig. A.34 Electron micrograph of a liver specimen from a patients with alcoholic hepatitis. In the lower magnification on the right, an RBC is seen in the liver sinus (top right). It remains to be studied why the small mitochondria structures resemble RBC texture. It could well be that RBCs are efferocytosed and fuse with mitochondria. More studies are needed (see also Electron micrographs Figs. A.33, A.35, and A.36) and Chap. 57 on Iron and ALD

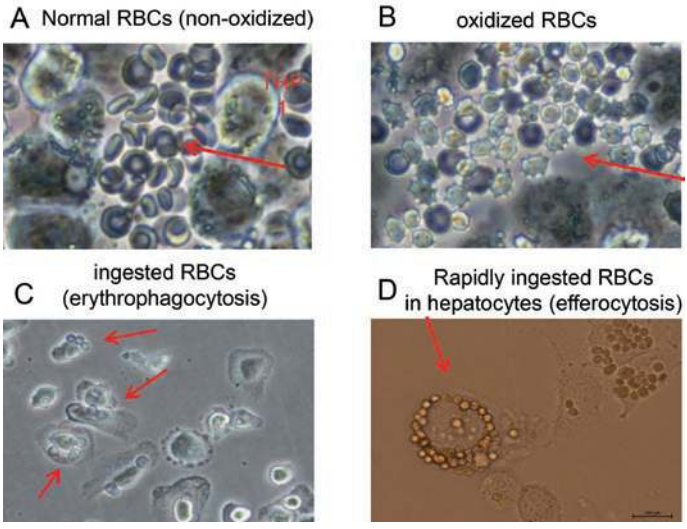

Fig. A.35 Phagocytosis and efferocytosis of red blood cells (RBC) by human macrophages (THP1) and hepatocytes (Huh7). Mortality, clinical and biochemical data suggest that hepatocytes contribute to RBC turnover. More studies are needed to better understand potential RBC uptake and digestion (see also Electron micrographs Figs. A.33, A.34, and A.36) and Chap. 57 on Iron and ALD. (**a**) Control RBCs (red arrow) and co-cultured human THP1 macrophages. (**b**) Morphological changes (spur cells, red arrow) of RBCs in the presence of copper sulfate-induced oxidative stress after 120 min. (**c**) Erythrophagocytosis of oxidized human erythrocytes (red arrow, oxidized by copper sulfate) by THP-1 cells. (**d**) Efferocytosis of oxidized RBCs by hepatocytes. Huh7 cells were exposed for 60 min to oxidized human RBCs. RBCs are also rapidly ingested by hepatocytes which is demonstrated by aligning around the cell nucleus (see also Zheng, C. et al, 2023, Front. Imm. in press)

Fig. A.36 Electron micrograph of a rat liver specimen exposed to mild hemolysis using the glucose oxidase (GOX) system (for details see also Rost D et al. *J Hepatol*. 2007;46(3):482–491). Note a phagocytosed RBC in a macrophage in the middle. In remains to be studied whether the RBCs on the left are RBCs and fragments efferrocytosed by a hepatocyte. *GOX* glucose oxidase, *Mi* mitochondria, *RBC* red blood cell

Biochemical Pathways Relevant for Ethanol Metabolism

See Figs. A.37, A.38, A.39, A.40, A.41, A.42, A.43, A.44, A.45, A.46, A.47, A.48, A.49, A.50, A.51, and A.52.

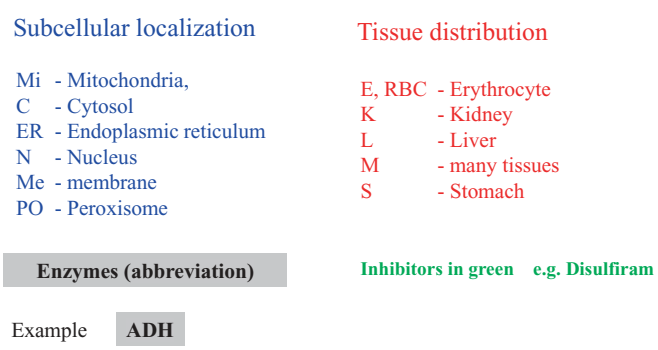

Fig. A.37 Abbreviations and colours used for the biochemical pathways and enzyme reactions (Figs. A.38–A.76)

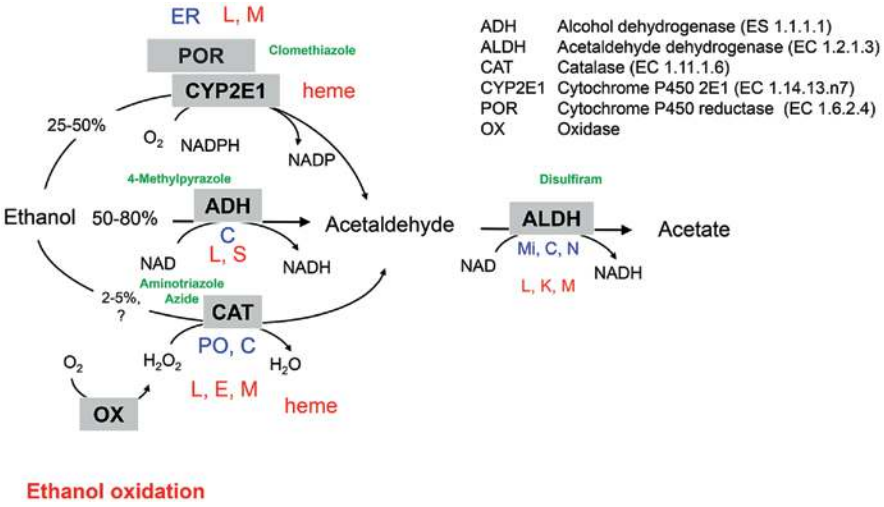

Fig. A.38 Major enzymatic ethanol oxidation pathways. ADH and ALDH convert ethanol to acetic acid by transforming NAD to NADH. This causes an important shift of the redox potential and is responsible for many biochemical consequences including enhanced lipogenesis. Also note that CYPs require NADPH. They directly use oxygen which can lead to ROS formation through uncoupling. The proximity to carbon monoxide releasing HO1 in the endoplasmic reticulum has less well studied but suggests a potential inhibitory interaction between CYPs and HO1. See also Chap. 57. For abbreviations: see previous page

Gene[a]	Class	Alias[a]/Isoforms	Synonyms[b]	Subunit encoded[c]	K_M (mM)	V_{max} $(min)^{-1}$	Subc.[d]	Tissue[e]	Comments
ADH1A	I	aclohol dehydrogenase 1A (class I), alpha polypeptide	ADH1	α-ADH, ADH1	4	30	C	S, L	Metabolizes a wide variety of substrates, including ethanol, retinol, other aliphatic alcohols, hydroxysteroids, and lipid peroxidation products. major role in ethanol catabolism.
ADH1B	I	aclohol dehydrogenase 1B (class I), beta polypeptide	ADH2	β-ADH, ADH2			C	S, L	Single nucleotide polymorphism rs1229984, that changes arginine to histidine at residue 48. The 'typical' variant of this has been referred to as ADH2(1) or ADH2*1 while the 'atypical' has been referred to as, e.g., ADH2(2), ADH2*2, ADH1B*48His. This SNP is associated with the risk for alcohol dependence, alcohol use disorders and alcohol consumption, with the atypical genotype having reduced risk of alcoholism.
		ADH1B*1; ADH1B1[Arg48/Arg370]	AHD2*1	β1-ADH, ADH2*1	0,0013	5,2	C		Metabolizes ethanol at the slowest rate among the 3 isoforms. It is the most common isoform globally except in much of East Asia, and it is the form to which others are compared. (Edenberg 2018)
		ADH1B*2; ADH1B[His48/Arg370]	ADH2*2	β2-ADH, ADH2*2	1,8	190	C		Differs from ADH1B*1 only due to rs1229984. In vitro, ADH1B*2 oxidizes ethanol much faster than ADH1B*1. High frequency in China and Japan. Protective. (Edenberg 2018)
		ADH1B*3; ADH1B[Arg48/Cys370]	ADH2*3	β3-ADH, ADH2*3	61	140	C		Differs from ADH1B*1 only due to rs2066702. The turnover number for ADH1B*3 is more than 60-fold that of ADH1B*1 in vitro. Almost only found in individuals of african origin (Edenberg 2018)
ADH1C	I	Alcohol dehydrogenase 1C (class I), gamma polypeptide	ADH3	γ-ADH, ADH3			C	S, L	Class I alcohol dehydrogenase, consisting of several homo- and heterodimers of alpha, beta, and gamma subunits, exhibit high activity for ethanol oxidation and play a major role in ethanol catabolism. Association of ADH1C with alcohol dependence is less robust than that of ADH1B (Edenberg 2018)
		ADH1C*1; ADH1C[Arg272/Ile350]	ADH1C*1	γ1-ADH, ADH1C*1	0,1	32	C		Encoded at position 350 by rs698.
		ADH1C*2; ADH1C[Gln272/Val350]	ADH1C*2	γ2-ADH, ADH1C*2	0,14	20	C		Encoded at position 272 by rs1693482
ADH4	II	Alcohol dehydrogenase 4 (class II), pi polypeptide	class II ADH, ADH2	π-ADH, ADH4	11	9	C	S, L	Metabolize a wide variety of substrates, including ethanol, retinol, other aliphatic alcohols, hydroxysteroids, and lipid peroxidation products. high activity for oxidation of long-chain aliphatic alcohols and aromatic alcohols and is less sensitive to pyrazole.
ADH5	III	Alcohol dehydrogenase 5 (class III), chi poypoptide	class III ADH ADH 3	χ-ADH, ADH5	>1000	100	C	S, L	Glutathione-dependent formaldehyde dehydrogenase, has virtually no activity for ethanol oxidation, but exhibits high activity for oxidation of long-chain primary alcohols and for oxidation of S-hydroxymethyl-glutathione, important for the elimination of formaldehyde
ADH6[d]	V	Alcohol dehydrogenase 6 (class V)	class V ADH, ADH5	-	-	-	?	L	Metabolizes a wide variety of substrates, including ethanol, retinol, other aliphatic alcohols, hydroxysteroids, and lipid peroxidation products but may have a distinct physiologic function
ADH7	IV	Alcohol dehydrogenase 7 (class IV), mu or sigma polypeptide	class IV ADH, ADH4	μ-ADH, σ-ADH, ADH7	30	1800	C	S, L	Metabolizes a wide variety of substrates, including ethanol, retinol, other aliphatic alcohols, hydroxysteroids, and lipid peroxidation products. inefficient in ethanol oxidation, but highly active as a retinol dehydrogenase

[a] HUGO Gene Nomenclature Committee.
[b] Position in precursor protein; aa487 in the mature protein
[c] Protein subunits have traditionally been named with Greek symbols, but can also be named based upon the gene encoding them; genes are in italics, proteins in roman font.
[d] Subcellular localization: C - cytosol
[e] tissue localization: L - liver, S - Stomach

Fig. A.39 Alcohol dehydrogenases. (Modified from Edenberg HJ et al. ACER. 2018;42(12):2281–97; Marchitti SA et al. Expert Opinion on Drug Metabolism & Toxicology. 2008;4(6):697–720)

Gene[a]	Chromos. location	Synonyms[b]	K_M (µM)	V_{max} $(min)^{-1}$	preferred substrate	Subc.[c]	Tissue[d]	Comments
ALDH1A1	9q21.12	ALDH1; ALDH-E1; ALDH11; RALDH1; ALDC	180	380	Retinal, Acetaldehyde	C	L, D, K, T, B, Lu, RBC, lens	Belongs to corneal crystallins.
ALDH1A2	15q21.3	RALDH2			Retinal	C	U, T	Catalyzes the synthesis of retinoic acid (RA) from retinaldehyde.
ALDH1A3	15q26.3				Retinal	C	T, U, prostate, bladder, skeletal muscle	
ALDH1B1	9p13.1	ALDH5; ALDHX	55	655	Acetaldehyde	M	L, K	May protect the cornea from UV-light.
ALDH1L1	3q21.3	10-formyltetrahydrofolate dehydrogenase			10-Formyltetra-hydrofolate	C	L, K	Catalyzes the conversion of 10-formyltetrahydrofolate to tetrahydrofolate, formate oxidation in vivo. Deficiencies result in methanol poisoning.
ALDH1L2	12q23.3	10-formyltetrahydrofolate dehydrogenase			10-Formyltetra-hydrofolate	M	Pancreas, salivary gland	Converts 10-formyltetrahydrofolate to tetrahydrofolate.
ALDH2	12q24.12	ALDHI; ALDH-E2; ALDM	-	-	Acetaldehyde, 4-hydroxy-2-nonenal (a-HNE), Malondialdehyde (MDA)	M	Fat, L	Major encyme in ethanol metabolism.
ALDH2 Isoform		ALDH2*1; ALDH2[Glu504][b]	0,2	280				Most common isoform.
ALDH2 Isoform		ALDH2*2; ALDH2[Lys504][b] variant rs671		in-active				Present in more than 50% of East Asians, makes ALDH2 inactive.
ALDH3A1	17p11.2				Aromatic and aliphatic aldehydes	C, N	Cornea, Esophagus, stomach, skin	Conversion of aldehydes from lipid peroxidation to their corresponding carboxylic acids in mammalian cornea and saliva e.g. 4-Hydroxynonenal (4HNE).
ALDH3A2	17p11.2	Fatty aldehyde dehydrogenase (or Long-chain-aldehyde dehydrogenase)			Fatty aldehydes, Hexaldehyde	Mic, Per, ER	L, Skin, adrenal glands	Associated with Sjögren-Larsson-Syndrome.
ALDH3B1	11q13.2				Octaldehyde, Benzaldehyde and others	C, PM	L, K, Lu, bone marrow	
ALDH3B2	11q13.2				Medium-chain to long-chain aldehyde	LD	Skin, esophagus

Fig. A.41 Acetaldehyde dehydrogenases. (Modified from Edenberg HJ et al. ACER. 2018;42(12):2281–97; Marchitti SA et al. Expert Opinion on Drug Metabolism & Toxicology. 2008;4(6):697–720; Jackson B et al. Human genomics. 2011;5(4):283–303)

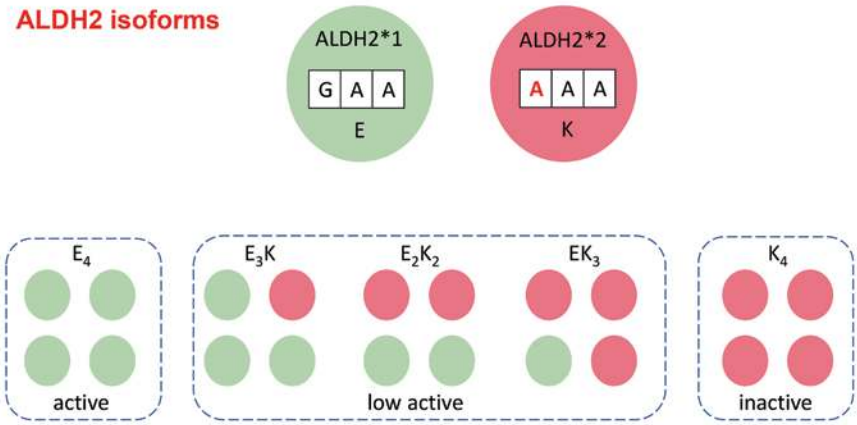

Fig. A.42 Acetaldehyde dehydrogenases 2 (ALDH2) is composed as a tetramer. In East Asians, due to the inactive ALDH2*2 isoform, various enzyme variants are formed with reduced activity. (Adapted from Gao J, et al., Int J Mol Sci 2022;23)

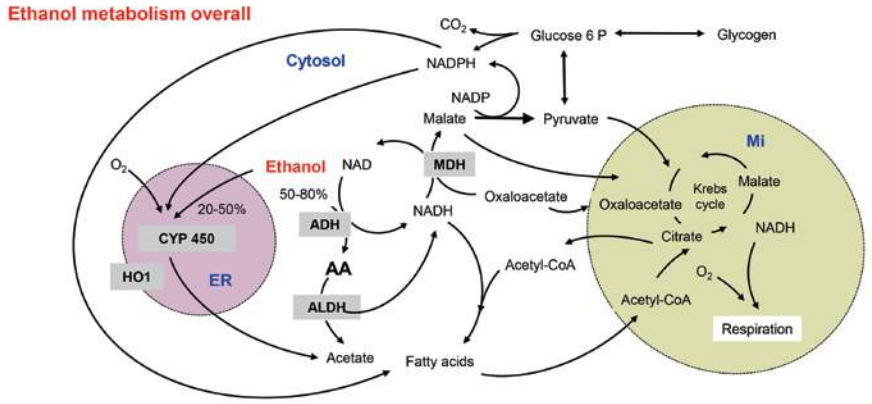

Fig. A.43 Simplified scheme of ethanol metabolism in hepatocytes. Due to abundance of NADH, mitochondria are overloaded with hydrogen donors which contribute to mitochondrial damage. *AA* acedaldehyde, *ADH* alcohol dehydrogenase, *ALDH* acetaldydedehydrogenase, *CYP450* cytochromes p4502E1, *HO1* hemo oxygenase 1, *MDH* malate dehydrogenase

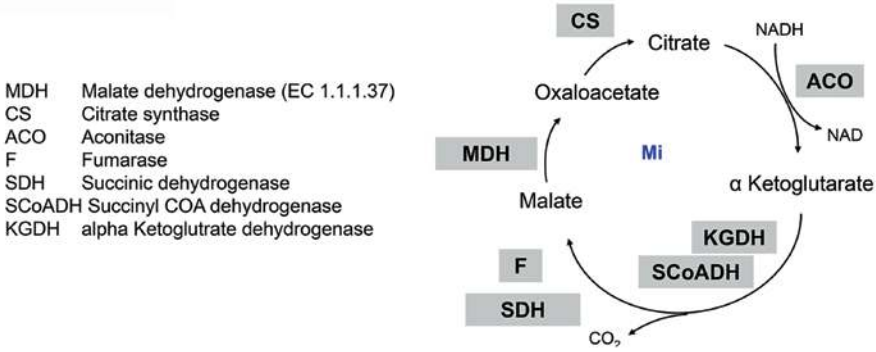

Fig. A.44 The citric acid cycle. (Krebs cycle or tricarboxylic acid cycle) is a series of chemical reactions to release stored energy through the oxidation of acetyl-CoA derived from carbohydrates, fats, and proteins. The Krebs cycle is used in respirating organisms to generate energy, either anaerobically or aerobically. In ethanol metabolism, all potential substrates such as oxaloacetate, pyruvate and acetyl Co A as well as NADH are abundant which determines the balance of reversible enzyme reactions

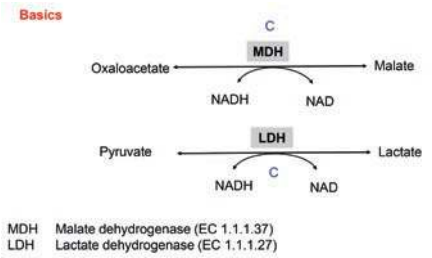

Fig. A.45 Important dehydrogenases. Through the Malate Aspartate Shuttle, cytosolic NADH can be transferred to the mitochondrial compartment

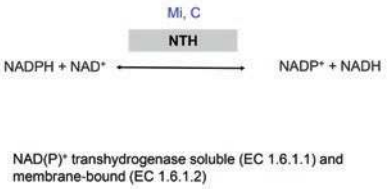

Fig. A.46 NAD(P)$^+$ transhydrogenase

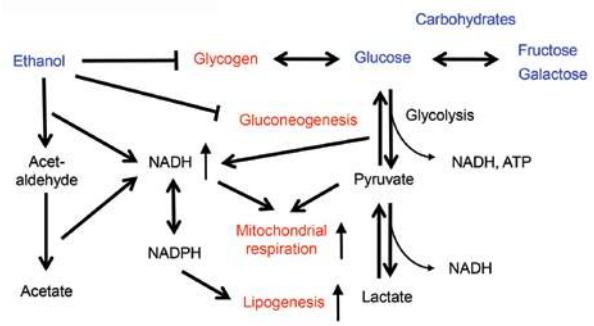

Fig. A.47 Carbohydrate and ethanol metabolism. Some similarities may explain why ethanol, obesity and diabetes mellitus all cause a similar hepatic steatohepatitis whether alcohol-associated or non-alcoholic. Both glycolysis and ethanol oxidation lead to formation of NADH which drives mitochondrial respiration and lipogenesis and may be the joint key feature in causing mitochondrial and organ damage. In difference to carbohydrates, however, ethanol oxidation ultimately blocks gluconeogenesis causing rapid glycogen depletion. Hence, glucose, which is essential for brain, red blood cells or muscles, becomes limiting. Sugars and ethanol also share the fate of having almost no evolutionary evolved negative feedback loops except by elimination through lipogenesis or oxidation. Not by chance, vital energy metabolism is also closely related to dependence (alcohol and food dependence)

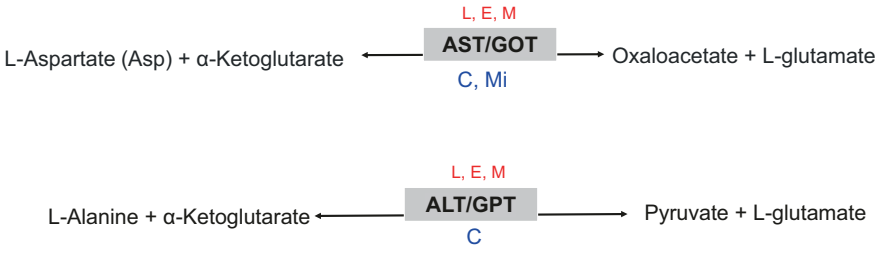
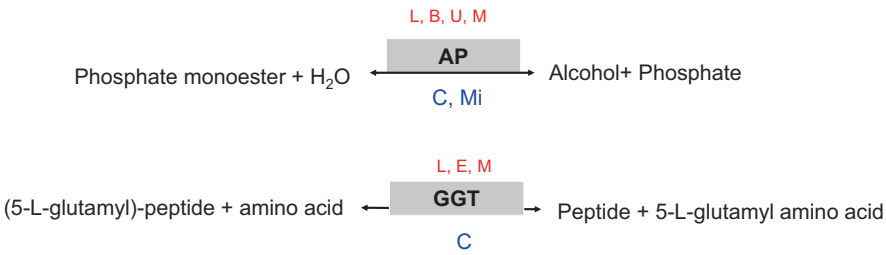


AST =GOT	Aspartate aminotransferase/Glutamic oxaloacetic transaminase (EC 2.6.1.1)
ALT=GPT	Alanine aminotransferase/Glutamic-pyruvic transaminase (EC 2.6.1.2)

Fig. A.48 Transaminases



AP	Alkaline phosphatase (EC 3.1.3.1)
GGT	Gamma-glutamyltransferase/ γ-glutamyltransferase, gamma-glutamyl transpeptidase (EC 2.3.2.2)

Fig. A.49 AP and GGT

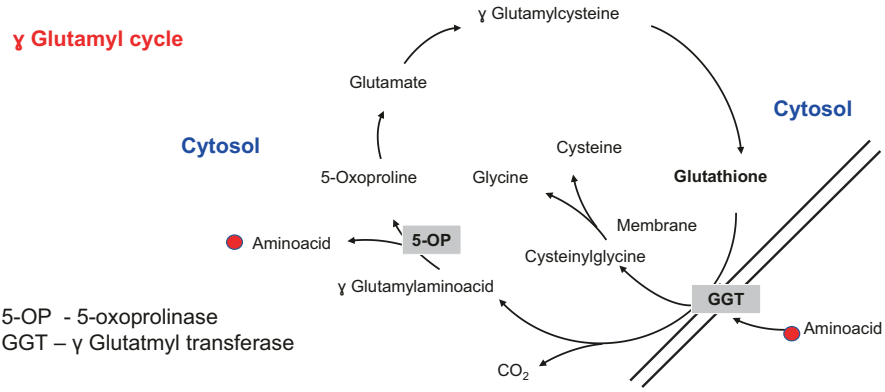


Fig. A.50 γ Glutamyl cycle. The metabolism of glutathione (GSH) is closely connected to Meister's γ-glutamyl cycle, in which a pivotal role is played by membrane GGT. GGT participates in the salvage pathway of extracellular GSH by catalyzing its hydrolysis to amino acid components of cysteine, which is used for intracellular GSH biosynthesis. Consequently, the importance of the γ-glutamyl cycle lies in recovering and delivering cysteine. In most biological systems, glutathione serves as the γ-glutamyl donor. GGT is strongly induced in many heavy drinkers. It is highly expressed in cholangiocytes and supports intracellular GSH synthesis with substrates from bile

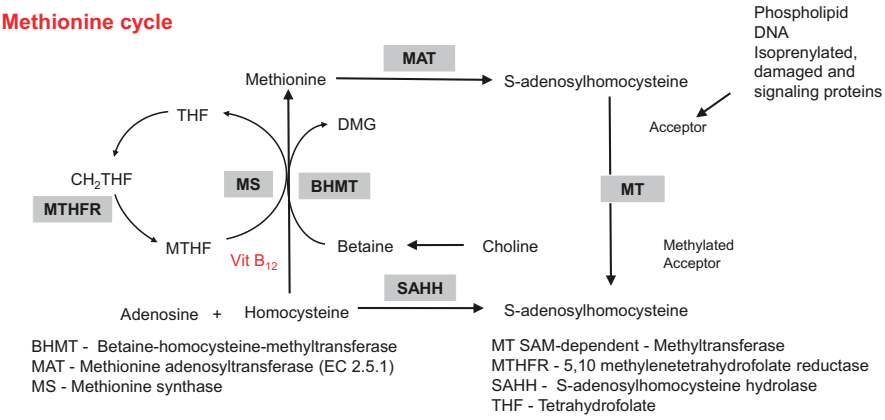

Fig. A.51 Methionine adenosyltransferase (MAT) is a methyl donor for transmethylation. It is also the propylamino donor in polyamine biosynthesis and the rate rate-limiting step of the methionine cycle. As a methyl donor MAT allows DNA methylation. It is also involved in gene transcription, cell proliferation, and production of secondary metabolites. More details are provided in the Chap. 55

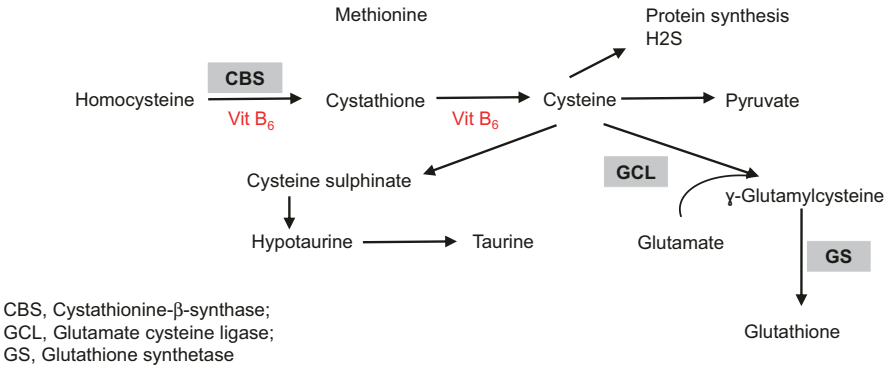

Fig. A.52 The transsulfuration pathway. The transsulfuration pathway is a metabolic pathway involving the interconversion of cysteine and homocysteine through the intermediate cystathionine. All transsulfuration enzymes require vitamin B6 in its active form (pyridoxal phosphate) which is critically limited in heavy drinkers

Pathways of Inflammation and Lipid Signaling

See Figs. A.53, A.54, A.55, A.56, and A.57.

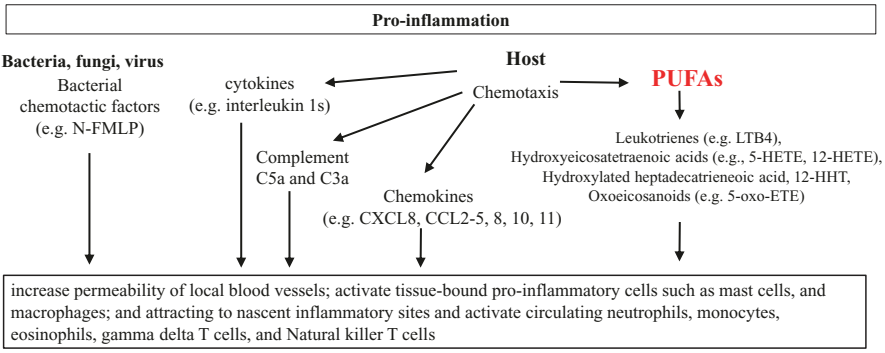

Fig. A.53 Pro-inflammatory molecules/pathways that are involved in ethanol-mediated metabolism. Especially with PUFA involvement, ethanol-metabolism is directly biochemically interacting with these signaling pathways. Important ethanol-metabolizing enzymes such as cytochromes p450 are also involved in SPM synthesis. *PUFA* poly unsaturated fatty acids, *SPM* specialized pro-resolving mediators. (See also Serhan CN et al. BBRC 118 (3): 943–9)

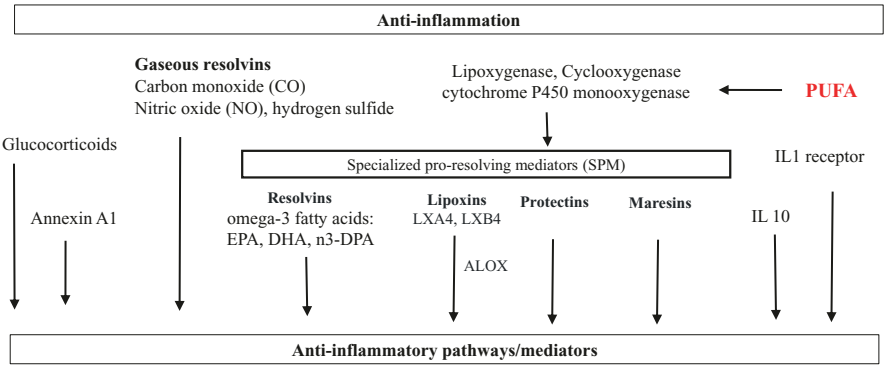

Fig. A.54 Anti-inflammatory molecules/pathways that are involved in ethanol-mediated metabolism. The specialized pro-resolving mediators (SPM) are only recently gaining attention. SPMs can modulate leukocyte migration and function, alter cytokine/chemokine release, modify autophagy, among other immune-related activities. As shown in Tables B.10–B.20 and following, preliminary data indicate that SPMs play an important role (lipidomics). Moreover, important ethanol-metabolizing enzymes such as cytochromes p450 are also involved in SPM synthesis

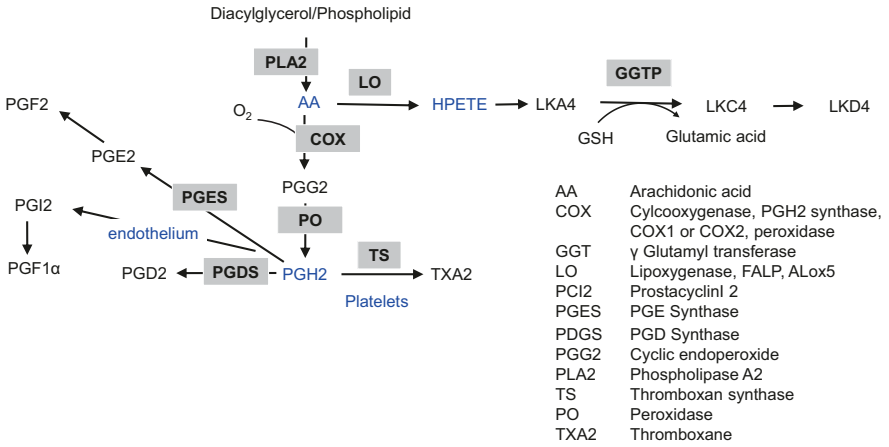

Fig. A.55 Arachidonic acid related synthesis of prostaglandins. Important cellular and systemic mediators are generated that can both have anti- or pro-inflammatory functions. Ethanol strongly interferes with this metabolism since P450 cytochromes are also involved in the synthesis. PGI2, for instance is a prostaglandin member of the eicosanoid family of lipid molecules that inhibits platelet activation and is also an effective vasodilator

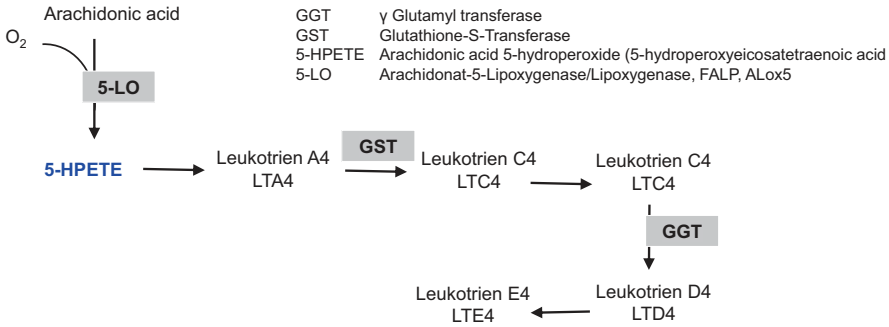

Fig. A.56 Leukotriene metabolism. Leukotrienes are a family of eicosanoid inflammatory mediators produced in leukocytes by the oxidation of arachidonic acid and the essential fatty acid eicosapentaenoic acid (EPA) by the enzyme arachidonate 5-lipoxygenase. Leukotrienes use lipid signaling to convey information to either the cell producing them (autocrine signaling) or neighboring cells (paracrine signaling) in order to regulate immune responses. The production of leukotrienes is usually accompanied by the production of histamine and prostaglandins, which also act as inflammatory mediators. One of their roles (specifically, leukotriene D4) is to trigger contractions in the smooth muscles. Their overproduction is a major cause of inflammation. Ethanol strongly interferes with lipid metabolism but more studies are needed to better understand its molecular interactions

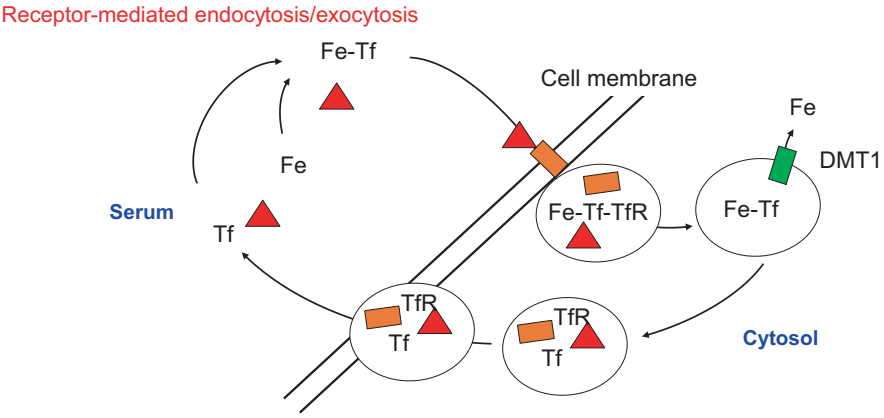

Fig. A.57 Example of receptor-mediated endocytosis: iron uptake by transferrin-bound iron through the Transferrin-transferrin receptor 1 (TfR1). Receptor-mediated endocytosis plays and important role in the liver and ALD and are both not fully understood well. Iron is typically transported in the serum bound to transferrin, bound to transferrin receptor 1 (TfR1) and internalized in vesicles. Iron is released insight through acidification and pumped into the cytosol through metal transporter DMT1. Other examples include uptake of Apo Lipoproteins, Haptoglobin and Albumin, the latter has been shown to transcytose through endothelial cells within 15 s. Alcohol seems to block endocytosis. It remains to be studied whether this is merely due to toxic modifications or is an adaptive response. *DMT1* dimetal transporter 1, *Tf* transferrin

Types of Cell Death and Hepatic Excretion

See Figs. A.58, A.59, and A.60.

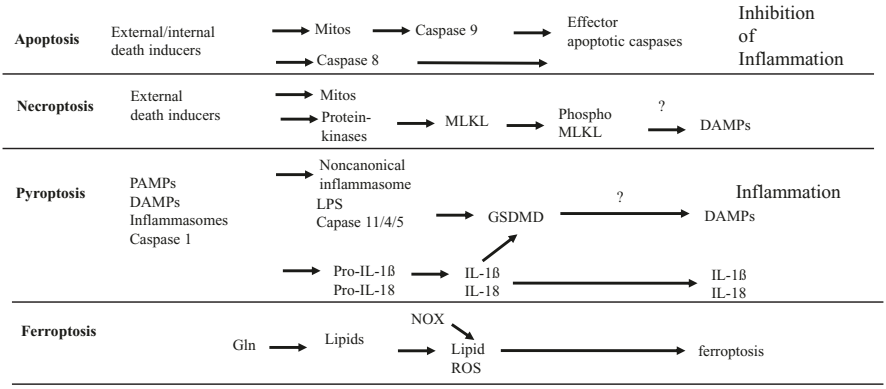

Fig. A.58 Cell death pathways with important pathways are shown for apoptosis, necroptosis, pyroptosis and ferroptosis. Pathways are not yet fully understood. As discussed in Chap. 64 on AH, first preliminary data suggest that ferroptosis is playing an important role in ALD, most likely related to RBC degradation and turnover. *MLKL* mixed lineage kinase domain-like; *GSDMD* Gasdermin-D, for other abbreviations see front matter

Phases of excretion of organic compounds and bile acids

Phase 0 Uptake (NTCP, OATPs, OATs, OCT1)

Phase I (Cytochrome P450 3A1)
hydrophobic potentially toxic secondary bile salts (lithocholate and deoxycholate), and other lipid soluble organic anions like bilirubin are hydroxylated

Phase II (Uridine glucuronyl transferase and sulfatase)
metabolism to form water soluble glucuronide and sulfate conjugates. These important metabolic processes enable these compounds to be more readily

Phase III (MRP2, 3, and 4) export pumps.
Unconjugated bile salts are processed in peroxisomes where they are conjugated with taurine or glycine through the action of the enzyme, bile acid acyl co-A transferase. See reference (160) for details of the role of peroxisomes in bile salt metabolism. For a detailed account of the enzymes, regulation, and genetics of bile acid synthesis, see reference (473).

Fig. A.59 The hepatic clearance of bile salts and other organic solutes is determined by four phases. Expression of these key genes is regulated by nuclear receptors such as the retinoid X receptor (RXR), fetal transcription factor (FTF), and hepatocyte nuclear factor 1 (HNF-1). Enhanced turnover of red blood cells could be an important physiological stimulus, in contrast to xenobiotics, for these phases, and drastically be enhanced during ethanol metabolism. See also Chaps. 49 and 57

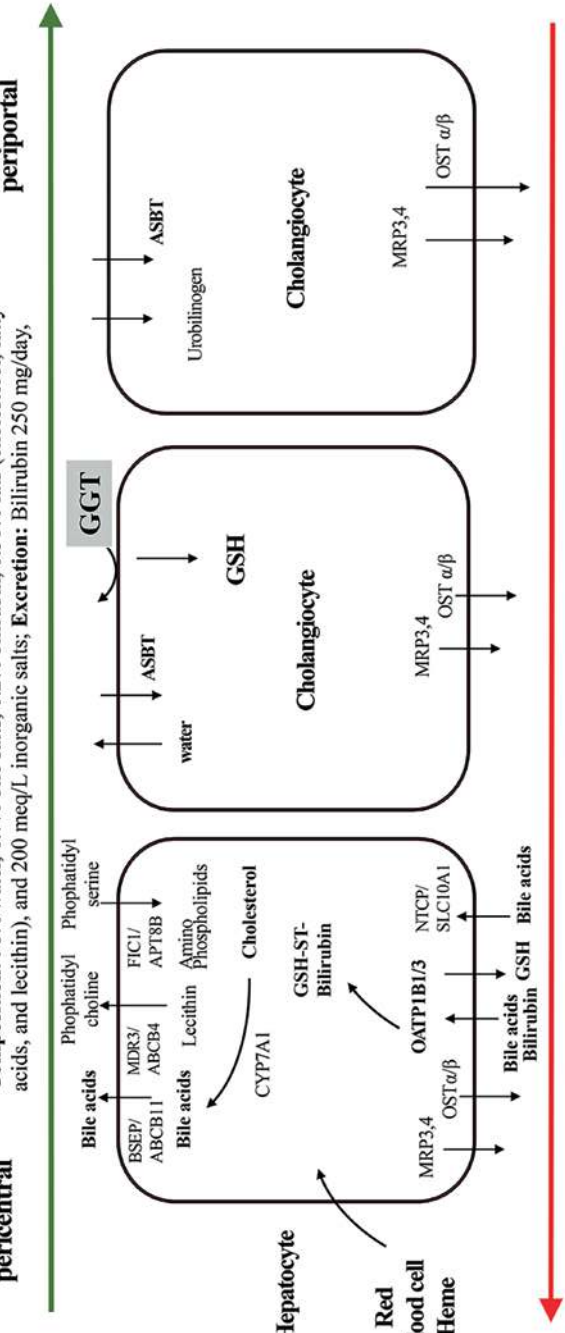

Fig. A.60 Bile acid production. In phase 0, bile acids and other organic products are transported through the basolateral membrane of the hepatocyte. Phase I and II take place in the cytoplasm through activation and metabolization of different CYPs. In phase III the bile acids are secreted into the biliary canalicus by the transmembrane transporters. *ASBT* apical sodium dependent bile acid transporter (SLC10A2), *ABCG5/8* ATP-binding cassette sub-family G member 5/8, *BSEP* bile salt export pump, *BRCP* breast cancer resistance protein, *CYP7A1* cytochrome P450 family 7 subfamily A member 1, *GGT* glutamyltransferase, *GSH* glutathione, *MRPs* multidrug resistance-associated proteins, *MDRs* multidrug resistance glycoproteins, *FIC1* familial intrahepatic cholestasis 1, *NTCP* Na+-taurocholate cotransporting polypeptide, *OATPs* organic anion transporting polypeptides, *OST α/β* organic solute transporter. (Further reading: Boyer JL. Compr Physiol. 2013;3(3):1035–1078 and Boyer JL et al. J Hepatol. 2021;75(1):190–201)

Reactive Oxygen Species, CYP2E1 and Redox Regulation

See Figs. A.61, A.62, A.63, A.64, A.65, A.66, A.67, A.68, A.69, A.70, A.71, and A.72.

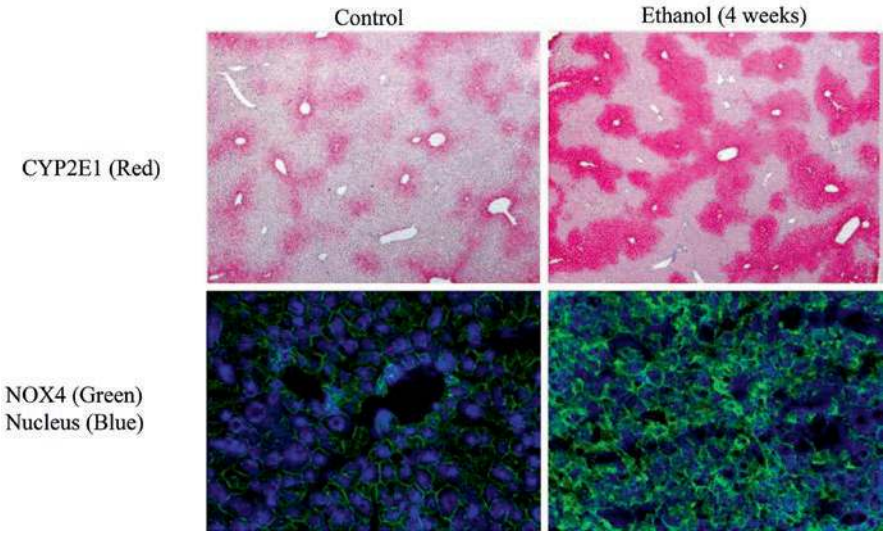

Fig. A.61 Typical hepatic, pericentral expression of CYP2E1 in mice that is strongly induced after 4 weeks of ethanol exposure (drinking model, 14%). In contrast, NADPH dependent oxidase 4 (NOX4) shows a membrane expression pattern with no zonal preference. According to Fig. A.76, CYP2E1 could be expressed to compensate for lower oxygen levels in the pericentral region while HO1-released carbon monoxide increases oxygen availability evenly in the cells to induce NOX4. (C. Chen and S. Mueller, Heidelberg)

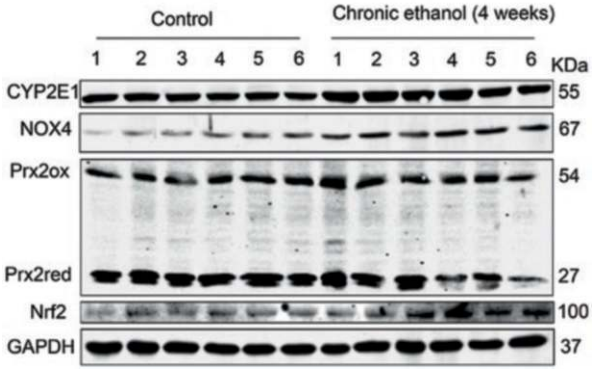

Fig. A.62 Expression of redox-related proteins in mice exposed to ethanol for 4 weeks in drinking water (15%). As can be seen in this Western blot, without further densitometry, CYPE1 is induced and reduced peroxiredoxin 2 decreases. The transcription factor Nrf2 is also upregulated (also see Fig. A.75). (unpublished data from C. Chen and S. Mueller, Heidelberg)

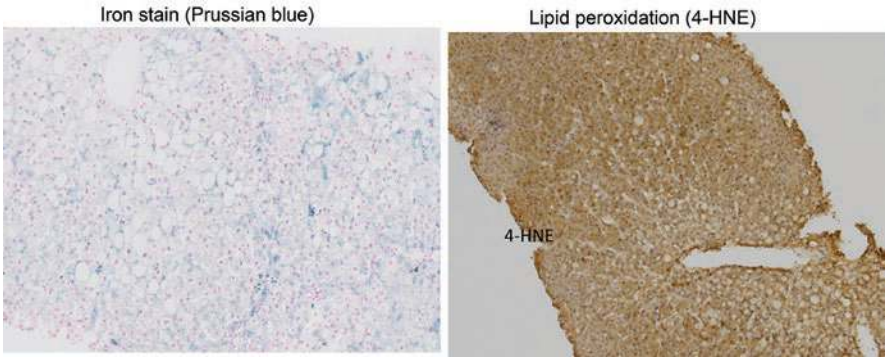

Fig. A.63 Prussian blue stain for iron (left) and immunostaining for the lipid peroxidation products 4-hydroxynonenal (right) in a human liver biopsy from a heavy drinker. Chronic alcohol consumption leads to hepatic iron accumulation and lipid peroxidation (see also Chap. 57). As shown in both images, no zonation is observed and both iron and lipid peroxidation are evenly distributed in patients with ALD. (unpublished from S. Mueller, Heidelberg)

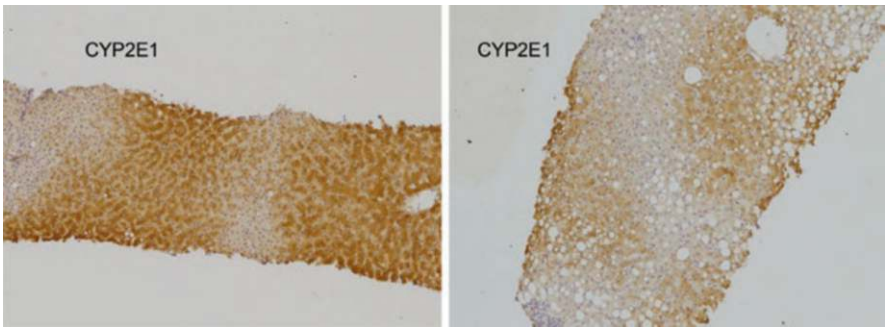

Fig. A.64 Typical zonal expression pattern of CYP2E1 in two human liver samples from heavy drinkers. Note that CYP2E1 is predominantly expressed in the pericentral region most likely due to reduced oxygen levels in the pericentral region (8% vs 16% oxygen). Since CYP2E1 is an oxygen-consuming enzyme, increased expression could allow for same turnover rates despite lower oxygen levels. (unpublished, S. Mueller, Heidelberg)

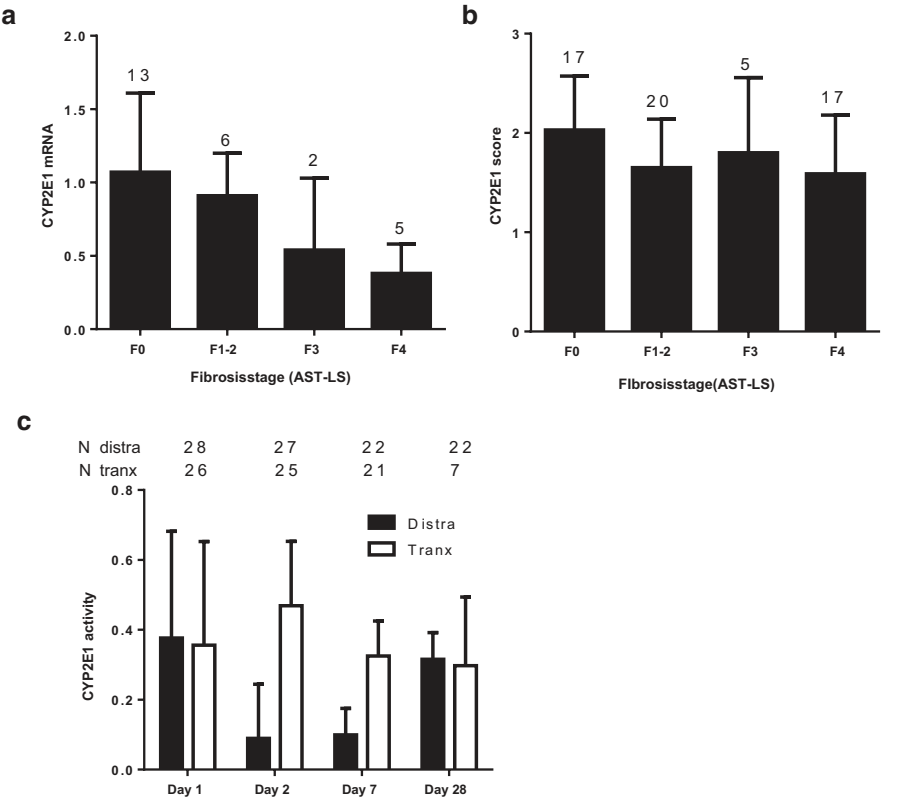

Fig. A.65 CYP2E1 mRNA, protein and activity in heavy drinkers. (**a**) Both CYP2E1 mRNA and (**b**) protein expression decrease with higher fibrosis stages. The most likely explanation is the fact that, with advanced liver fibrosis, the liver is increasingly supplied through the hepatic artery. As a consequence, nutritional ethanol uptake will not directly reach the liver through the portal vein but it will first distributed systemically. (**c**) Efficient inhibition of CYP2E1 in vivo activity by the CYP2E1 inhibitor chlormethiazole (black bars) in heavy drinkers after 5 days of treatment during alcohol detoxication therapy. No inhibition is seen in patients treated with the benzodiazepine chlorazepate (white bars). Of note, after 28 days of abstinence, CYP2E1 activity is only marginally reduced. This raises the question whether CYP2E1 is induced only by alcohol or whether additional factors such as enhanced red blood cell (RBC) turnover contribute to it. CYP2E1 activity was measured using the chlorzoxazone method. (From Lucas D et al. in: Johnson EF, Waterman MR, eds. Methods in Enzymology. Vol. 272: Academic Press; 1996:115–123. Modified from Hohmann N et al. *Gut*. 2022;71(4):842–844)

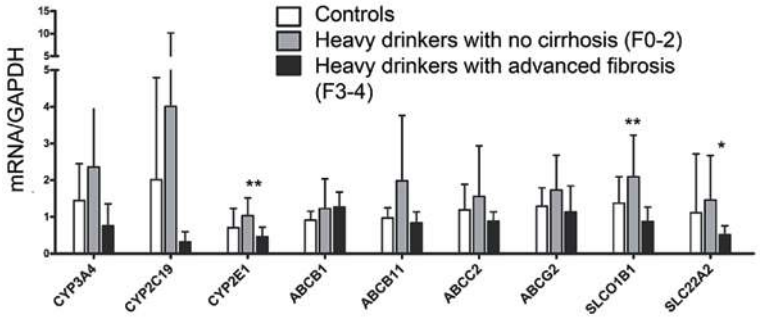

Fig. A.66 Differences in expression levels of CYPS and bile transporters between controls (white bars, $n = 5$), heavy drinkers with no/moderate increased liver stiffness (LS) (<8.0 kPa; gray bars, $n = 18$), and heavy drinkers with increased LS and F3/4 fibrosis (>8.0 kPa; black bars, $n = 8$). Depicted are mean ± SD. Statistical significance was evaluated using unpaired, two-sided Student's *t*-test for comparison of all groups with each other within the particular gene. See also Theile D et al. Alcohol Clin Exp Res 2013;37 Suppl 1:E17–22

ROS/RNS	Antioxidative defense systems	
	Enzymatic defenses	Non-enzymatic defenses
Superoxide anion (O_2·-) Hydrogen peroxide (H_2O_2)	SODs (against O_2·-) GSH (against H_2O_2)	Vitamin A/C/E Ubiquinone
Hydroxyl radical (.OH)	Glutathione peroxidases (GPx 1-8)	Uric acid
Peroxyl radical (ROO·)	Catalase (CAT)	
Nitrix oxide (NO)	Peroxiredoxins	
Nitrogen dioxide (NO_2·)	Heme oxygenases (HO)	
Peroxynitrite (ONOO)	Thioredoxin (Trx) system	
	Ferritin	
	Ceruloplasmin	

Fig. A.67 Reactive oxygen species (ROS), reactive nitrogen species (RNS) and important cellular antioxidative defense systems. ROS and RNS are heavily involved in the pathology of ethanol

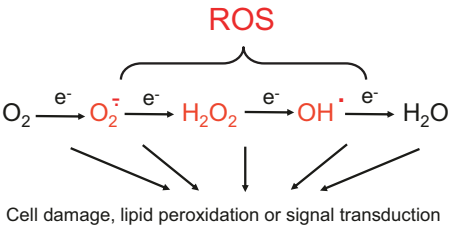

Fig. A.68 Reduction cascade of oxygen leading to so-called reactive oxygen species (ROS). Superoxide, hydrogen peroxide and hydroxyl radicals are considered the classical ROS. Note, by physico-chemical definition (at least one unpaired spin of outer orbital electron/valence electron), however, hydrogen peroxide is not a radical, while oxygen is a bi-radical

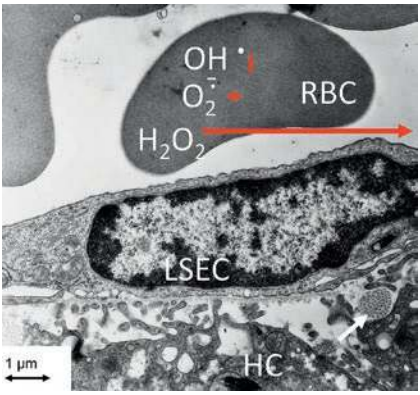

Fig. A.69 Mean diffusion distance of reactive oxygen species (ROS). Due to reactivity and diffusion, ROS have different mean diffusion distances (red arrows). Especially H_2O_2 has the lowest reactivity with a half-time of milliseconds. It thus can cross membranes and, participate in intercellular and interorganelle communication. Electron micrograph 7500×. *RBC* red blood cell, *LSEC* liver sinusoidal endothelial cell, *HC* hepatocytes, *white arrow* collagen bundle in the Disse space. (Further reading: Radi, R. Biochemistry115 (23) 5839–5848). Electron micrograph from Mueller, S. unpublished

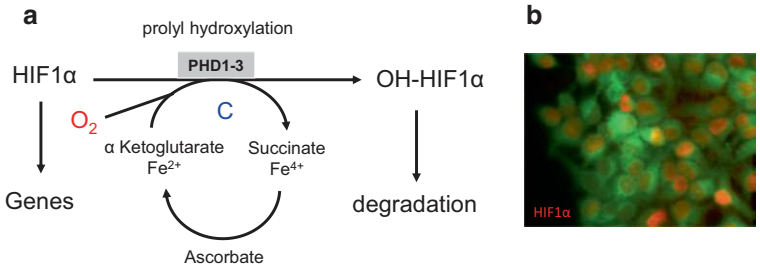

Fig. A.70 Relation of hypoxia signaling with energy and iron metabolism. (**a**) Through ethanol metabolism, oxygen is consumed potentially leading to hypoxia. Hypoxia inducible factor 1 alpha (HIF1α) is an important transcription factor induced in response to hypoxia that controls more than 5% of the genome, including many metabolic and energy pathways. Mechanistically, HIF1α is marked by prolyl hydroxylases (PHD1–3) mark HIF1α for degradation under normoxia. As demonstrated, the reaction is also linked to iron and energy metabolism (modified from Jaakkola *et al.*, *Science* 2001; R. K. Bruick, S. L. McKnight, *Science* 2001). (**b**) Nuclear and heterogenous HIF1α expression is shown in cultured hepatocytes after enzymatic induction of hypoxia. The hypoxia dye pimonidazole is used as counterstain (green) (modified from Millonig G et al. FRBM 2009;46(2):182–191)

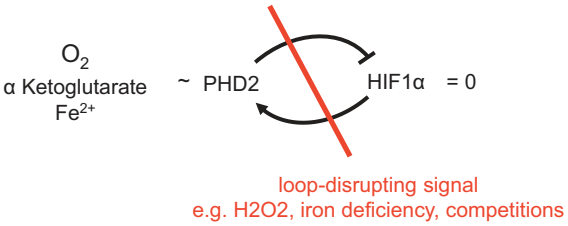

Fig. A.71 HIF1α causes its own downregulation by inducing its target gene PHD2. Consequently, hypoxia only causes a transient upregulation of HIF1α while loop disruption signals such as iron chelators, hydrogen peroxide or metabolic changes affect or compete with α-ketoglutarate or succinate and will strongly affect HIF1α expression. HIF1α should thus be better called a **metabolic control**. (Modified from Millonig G et al. FRBM 2009;46(2):182–191)

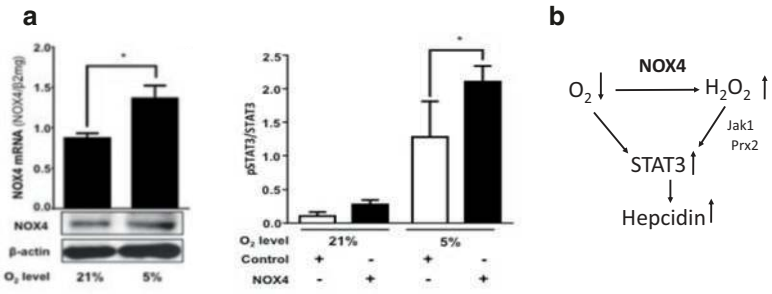

Fig. A.72 Redox regulation of the systemic iron masterswitch hepcidin by an oxidase (NOX4). Note that ethanol induces hepatic NOX4 in mice (see Fig. A.61 and A.62). NOX4 uses oxygen (hypoxia) to produce H_2O_2. Since both hypoxia and H_2O_2 are able to induce hepcidin, NOX4 could be an important upstream regulator of hepcidin in alcohol-related liver disease. (**a**) In vitro, hypoxia also increases NOX4 mRNA and protein levels in Huh7 cells and overexpression of NOX4 increases expression of the redoxsensitive iron hormone hepcidin and enhances hypoxia-mediated hepcidin induction. (**b**) These data point to an important role of oxidases such as NOX4 for the regulation of iron homeostasis. (Further reading: Silva I et al. Redox Biol. 2018;16:1–10. Millonig G et al. J Biol Chem. 2012;287(44):37472–37482. To independently control oxygen and peroxide levels in cell culture, enzymatic systems such as the GOX/CAT system can be explored (see also Mueller S et al. Adv Med Sci. 2009:1–15). NOX4- NADPH-dependent oxidase 4

Pathways of Heme Degradation and Signaling (HO1, Nrf2)

See Figs. A.73, A.74, and A.75.

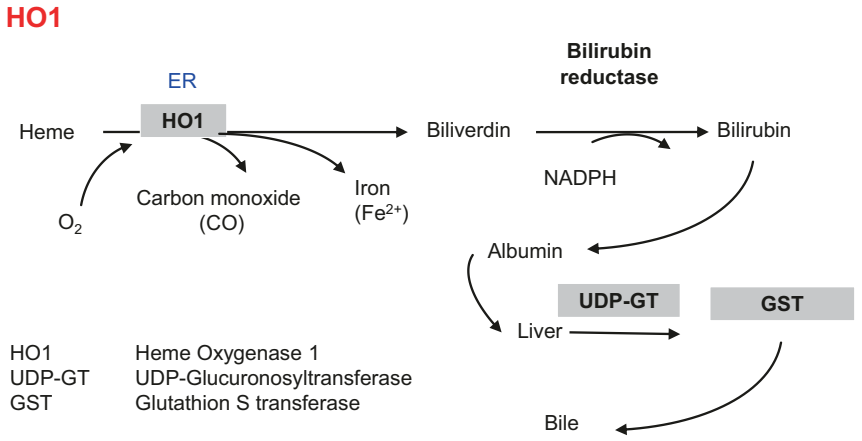

Fig. A.73 Heme degradation by heme oxygenase 1

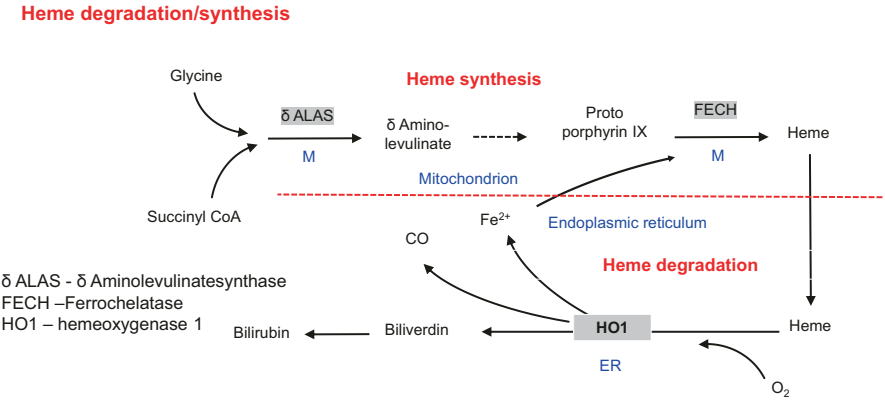

Fig. A.74 Heme degradation versus synthesis. Note that both pathways are placed in different compartments (Endoplasmic reticulum versus mitochondria). Cellular iron and heme trafficking is not yet fully understood. Iron-rich, originally bacteria-derived mitochondria could play an important role in the aquisition of efferocytosed red blood cells (see also Figs. A.33–A.36)

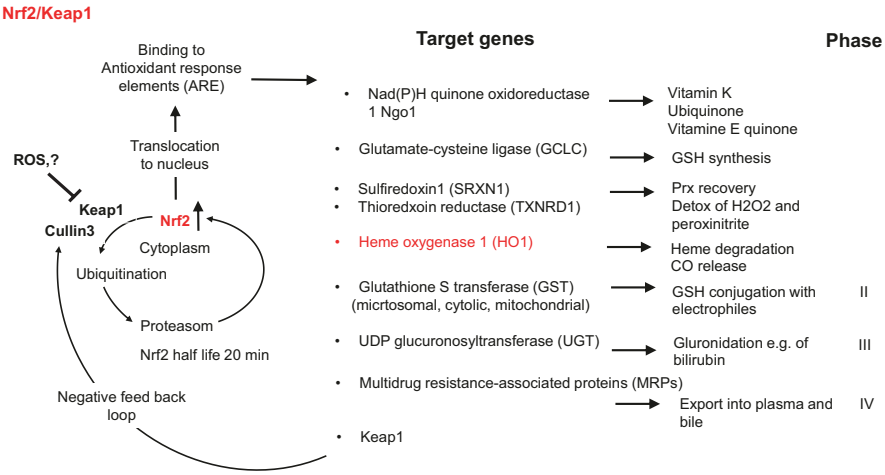

Fig. A.75 Nuclear factor erythroid 2-related factor 2 (Nrf2) signaling. Nrf2 is a transcription factor that regulates the expression of antioxidant proteins by binding to antioxidant response elements (AREs) in the promoter regions of genes encoding cytoprotective proteins. Nrf2 is redox-sensitive and also induces the expression of heme oxygenase 1. In ALD, during hemolysis and enhanced red blood cell (RBC) turnover, it could play an important role in cellular signaling. See also Fig. A.63

Diagnosis of ALD: Laboratory and Liver Elastography

See Figs. A.76, A.77, A.78, A.79, A.80, A.81, A.82, A.83, A.84, and A.85.

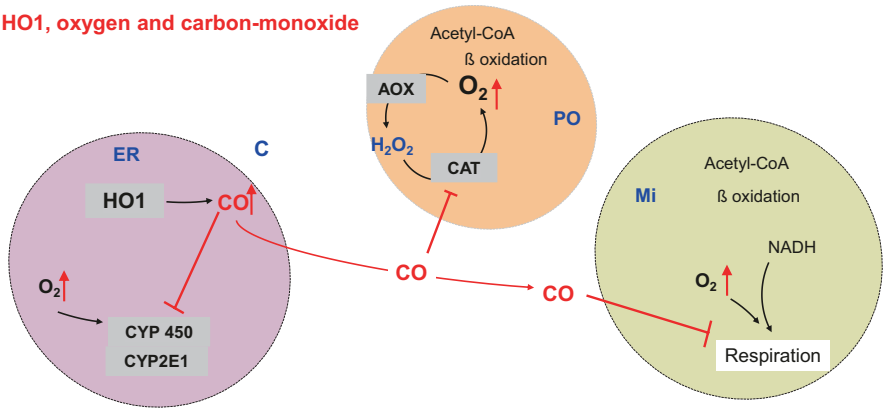

Fig. A.76 Potential intra- and inter-organelle role of the gaseous resolving carbon monoxide (CO) in ethanol-metabolism. Enhanced hemolysis in ALD causes CO-release through HO1 which could directly block CYP2E1 in the ER. It could also block mitochondrial respiration and peroxisomal catalase. In summary, CO-release would ultimately decrease oxygen consumption, e.g. as adaptive response to hypoxia

Duration of alcohol consumption	Amount of alcohol consumption	
	> 1g/d	> 40-60g/d
< 1 day	serum, urine: EtOH,EtG, EtS	Serum and urine: EtOH, EtG, EtS PEth in whole blood and dried blood spots (LC-MS/MS)
> 1 day	serum, urine: EtOH,EtG, EtS	Serum and urine: EtOH, EtG, EtS PEth in whole blood and dried blood spots (LC-MS/MS)
> 14 days	serum, urine: EtOH,EtG, EtS	Serum and urine: EtOH, EtG, EtS PEth in whole blood and dried blood spots (LC-MS/MS)
Weeks to months	serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS PEth in whole blood and dried blood spots (LC-MS/MS), EtG and FAEE in hair

Abbreviations: EtOH,Ethanol; EtG, Ethyl glucuronide; EtS, Ethyl sulfate; PEth, Phosphatidylethanol; FAEE, Fatty-acid ethyl esters

Fig. A.77 Clinically relevant options for the determination of direct biomarkers, concerning the amount and duration of alcohol intake. (For more details see also Chap. 13. Modified according to Thon N et al. Fortschr Neurol Psychiatr 81:493–502)

Biomarkers	Amount of alcohol consumption	Cut-off values
EtG in hair	Abstinence and low intake (< 10g alcohol /day)	< 7 pg/mg
	Social consumption (20-40g/d)	7 – 30 pg/mg
	Excessive drinking (>60g/d)	> 30 pg/mg
FAEE in hair	Repeated alcohol intake	≥ 200 pg/mg
	Excessive intake	≥ 500 pg/mg
EtG in urine	Total abstinence	0.1mg/L
	- unintentional intake - recent alcohol use - longer back-dated alcohol intake in larger amounts	0.1mg/L – 0.5 mg/L
	unintentional intake unlikely, but possible, active alcohol intake probable	0.5-1 mg/L
EtS in urine	Total abstinence	0.05mg/L
PEth	>40g/d, more than 2 weeks alcohol intake at least once with 1 detectable	HPLC: 0.22µM, LC/MS-MS: 20/30ng/ml

Abbreviations: EtOH,Ethanol; EtG, Ethyl glucuronide; EtS, Ethyl sulfate; PEth, Phosphatidylethanol; FAEE, Fatty-acid ethyl esters

Fig. A.78 Clinically relevant options for the determination of direct biomarkers, concerning the amount and duration of alcohol intake. (For more details see also Chap. 13. Modified according to Thon N et al. Fortschr Neurol Psychiatr 81:493–502)

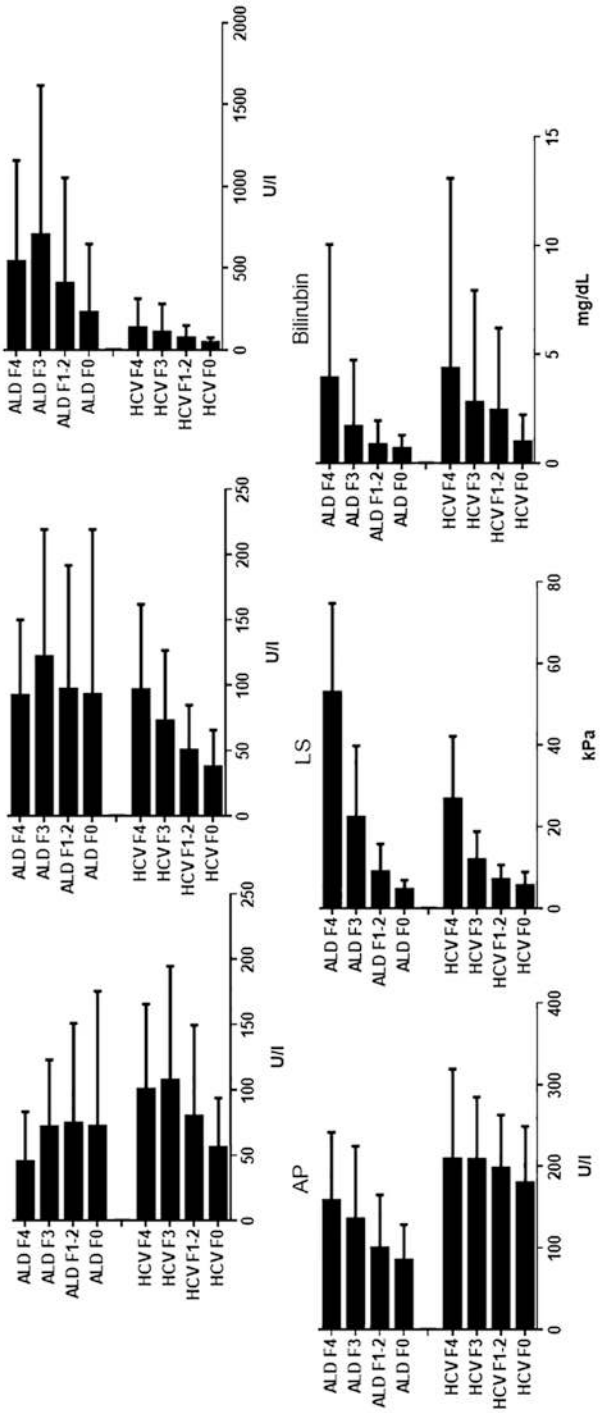

Fig. A.79 Comparison of important liver parameters between alcohol-related liver disease (ALD, lobular liver disease) and HCV (hepatitis C infection, portal disease) according to biopsy-proven fibrosis stage F0–F4. GGT is higher throughout all fibrosis stages in ALD. While AST is almost constant in ALD, it increases with fibrosis stage in HCV. In contrast, AP is generally higher in HCV and constant, while it increases with fibrosis stage in ALD. As is discussed in Chap. 7 and 41 on AST and Mortality, in ALD, AST is mostly derived from red blood cells. In addition, AP is an important prognostic parameter in ALD. Finally, as discussed in Chap. 42 on Elastography and Fig. A.81, liver stiffness (LS) values are generally higher in ALD as compared to HCV

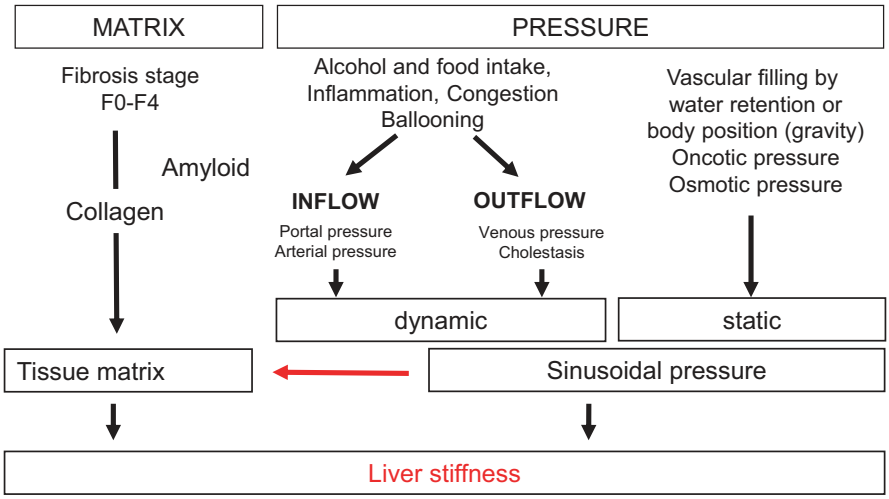

Fig. A.80 Established confounders of liver stiffness. Irrespective of fibrosis (left), many important and pressure-related confounders cause liver stiffness elevation through an increased sinusoidal pressure. Thus, in normal livers, liver stiffness reflects the sinusoidal pressure. According to the **sinusoidal pressure hypothesis**, this pressure drives fibrosis (red arrow and responsible e.g. for the typical macroscopic changes in the cirrhotic liver). (Modified from Mueller S. World J Gastroenterol. 2016;22(48):10482–10501). See also Chaps. 42 and 49, and Fig. A.92

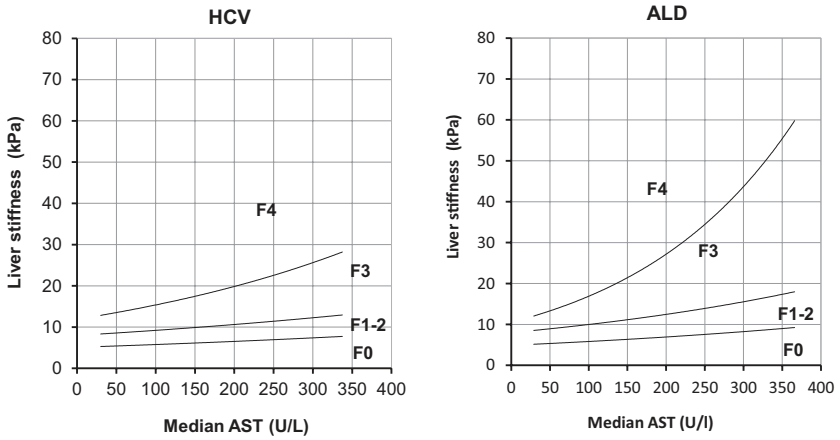

Fig. A.81 AST-adapted cut-off values for alcohol-related liver disease (ALD) and hepatitis C virus infection (HCV). Note that identical AST levels cause higher LS elevation in ALD as compared to HCV. These graphs allow for instant fibrosis stage reading based on liver stiffness measurements and laboratory markers. A more precise assessment of fibrosis stage requires treatment interventions to remove the inflammatory component such as alcohol detoxification or antiviral therapy. (Modified from Mueller S et al. *Liver Int*. 2015;35(12):2514–2521). See also Chap. 42

Fibrosis stage	Cut-off for Liver Stiffness (kPa) in HCV	Cut-off for Liver Stiffness (kPa) in ALD
F0 vs F1-2	≥ 5.1 x exp (0.0018 x AST)	≥ 4.9 x exp (0.0022 x AST)
F1-2 vs F3	≥ 9.0 x exp (0.0023 x AST)	≥ 8.1 x exp (0.0046 x AST)
F3 vs F4	≥ 11.9 x exp (0.0035 x AST)	≥ 10.5 x exp (0.0069 x AST)

Fig. A.82 Calculation of AST-adapted cut-off values for alcohol-related liver disease (ALD) and chronic hepatitis C virus infection (HCV). These formulas are useful to calculate fibrosis stages based on transient elastography data and AST levels. (Modified from Mueller S et al. *Liver Int*. 2015;35(12):2514–2521)

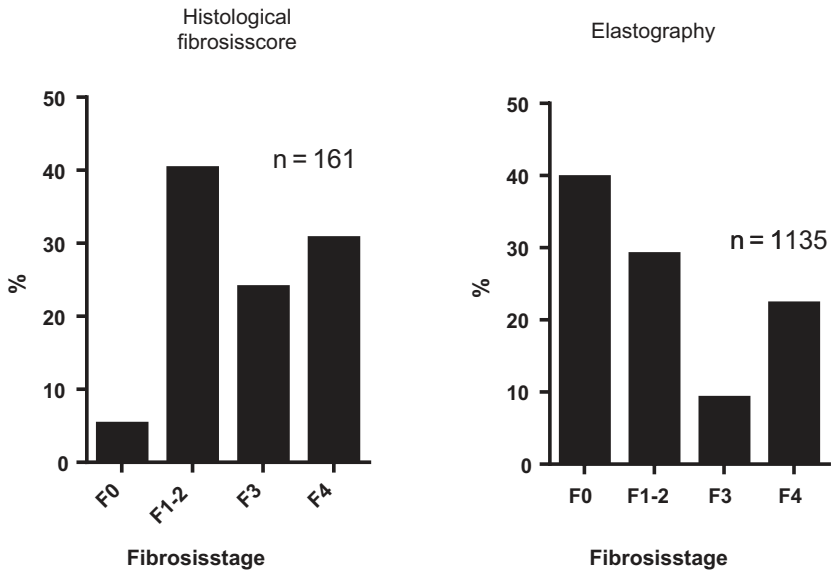

Fig. A.83 Fibrosis distribution of heavy drinkers based on liver biopsy (left) and transient elastography (right). Note that the non-invasively characterized cohort contains 10 times more patients with normal livers as patients with a healthy liver are not frequently biopsied. AST-adapted cut-off values were used (see Figs. A.81 and A.82) for instant fibrosis stage reading (Mueller S et al. *Liver Int*. 2015;35(12):2514–2521). Another important conclusion from these data is, that biopsy-proven study cohorts tend to have higher fibrosis stages. This may negatively impact upon search strategies for disease mechanisms, as "non-diseased" patients are also required for such strategies

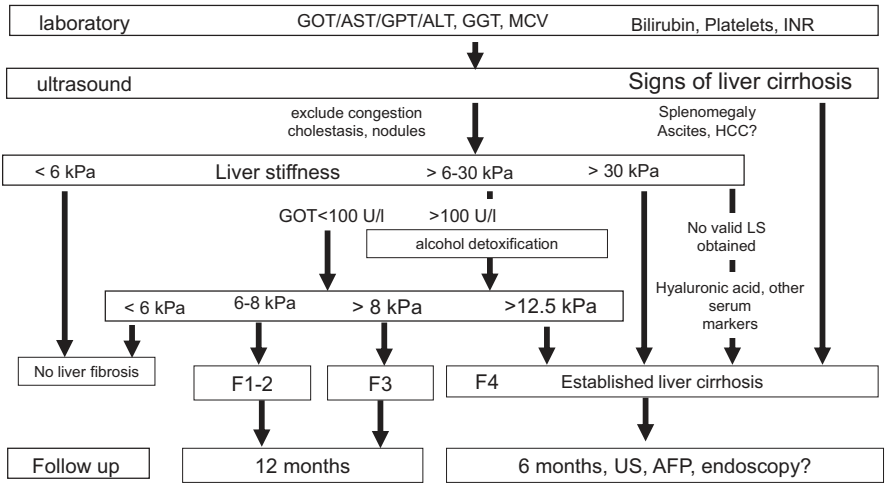

Fig. A.84 Example of a diagnostic flow chart for the diagnosis of alcohol-related liver disease using liver stiffness measurements. (Modified from Mueller S et al. *World J Gastroenterol*. 2014;20(40):14626–14641). See also Chaps. 40 and 42

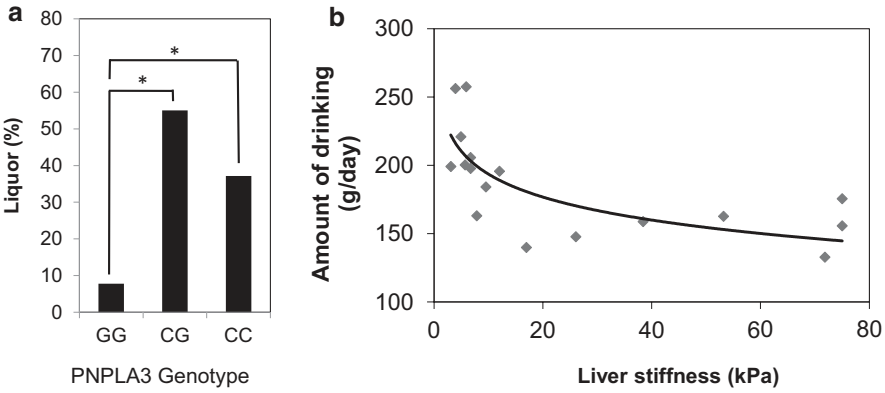

Fig. A.85 Effect of liver gene variants or fibrosis stage on daily drinking behavior in heavy drinkers. (**a**) Homozygote carriers of the GG genotype of adiponutrin/PNPLA3 drink significantly less high-percentage spirits (n = 503, unpublished). (**b**) The amount of consumed alcohol decreases with increasing liver stiffness (n = 1041, not published) (Mueller S et al. *Suchtmedizin*. 2018;20(1):1–9). Data are from the Heidelberg cohort of heavy drinkers (see also Tables B.1–B.30)

Kaplan-Meier Survival Curves of Various Parameters in Drinkers

See Figs. A.86, A.87, A.88, A.89, and A.90.

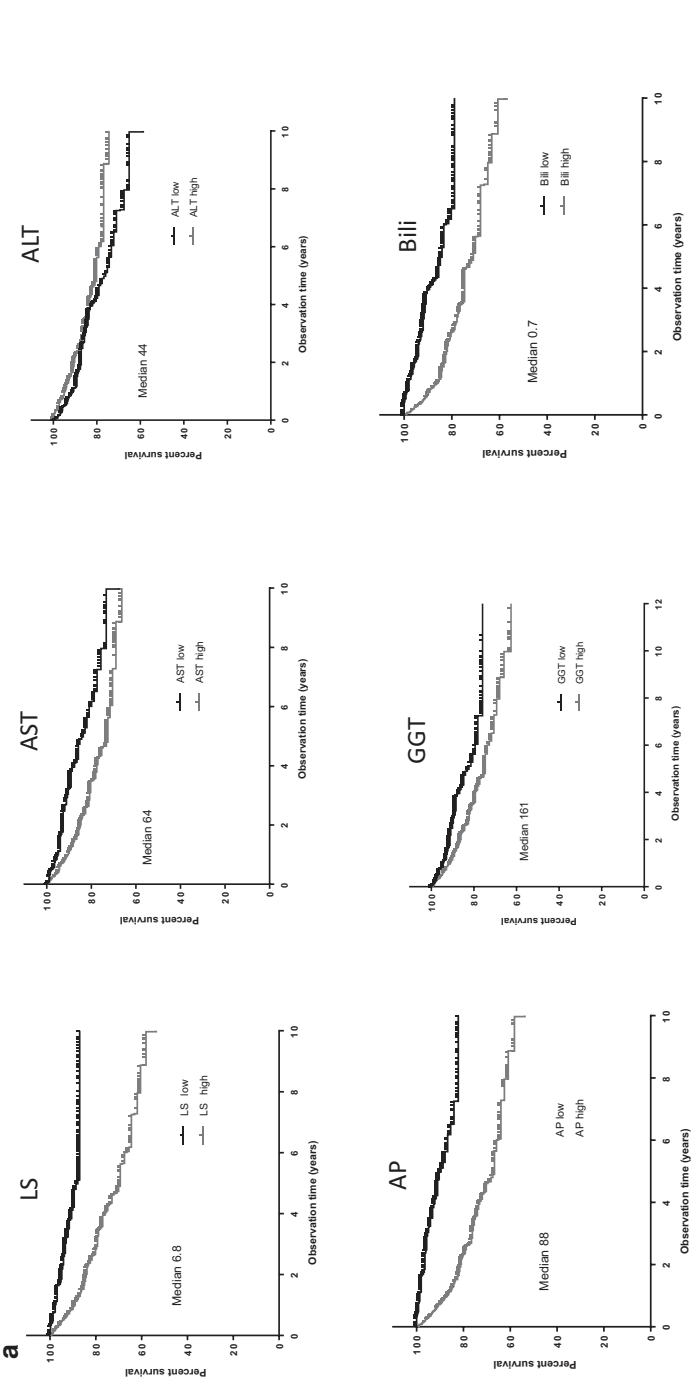

Fig. A.86 Routine laboratory parameters and Kaplan Meier survival curves. Kaplan Meier curves are shown for upper and lower median of various routine parameters. Please also see chapter on Mortality in Part I. Note that RBC count, AP and liver stiffness have the highest prognostic value for long-term survival

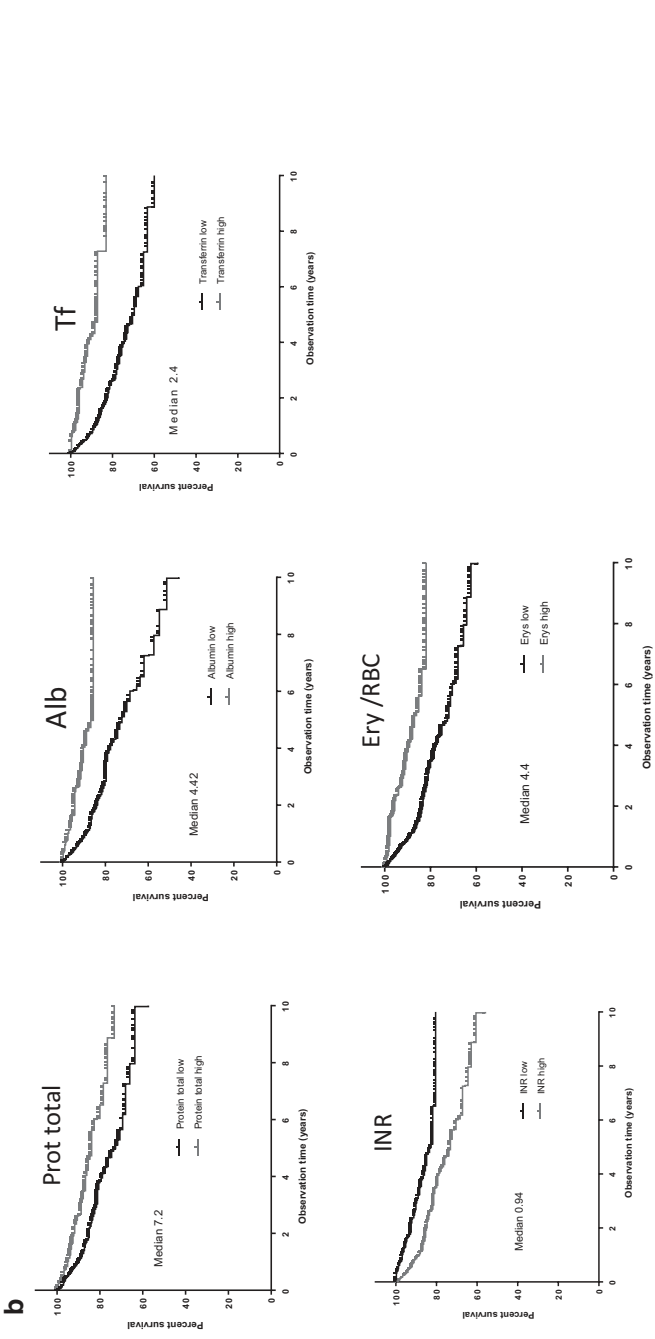

Fig. A.87 (continued) **Routine laboratory parameters and Kaplan Meier survival curves.** Kaplan Meier curves are shown for upper and lower median of various routine parameters. Please also see Chap. 7 on Mortality in Part I. Note that RBC count, AP and liver stiffness have the highest prognostic value for long-term survival

AM score (alcohol mortality score without LS):

AM Score = 0.03*Age + 0.0027 *AP + 0.053 *Bili + -0.549 *Erys -0.003 * Platelets - 0.0034 * Cholesterol;

AM-LS score (alcohol mortality score with LS)

AM-LS score =0.0593 * Bili+-0.5385 * Erys+0.0028 * AP+0.0074 * LS+0.0316 * Age

Logarithmized AM-LS score:

AM-LS LN score: = 17.1 * LN(Age) + 7.8 * LN(AP) + -18.9 * LN(Erys) + 2.1 * LN(LS)-79.15
(for conventient calculation multiplied by 10 and subtracted by 79.15)

Fig. A.88 Developed alcohol mortality scores for predicting of mid and long-term survival in alcohol consumers. See also Chap. 7 on Mortality in Part I

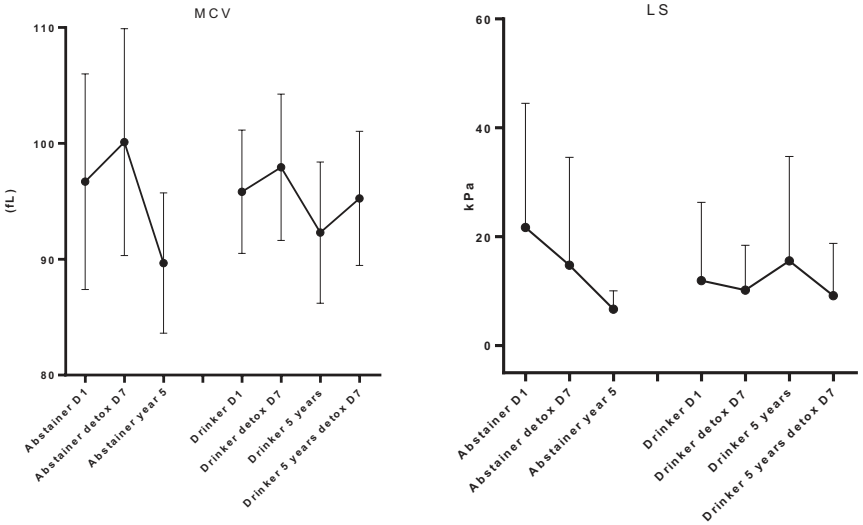

Fig. A.89 Effect of 5 years abstaining from alcohol versus continued drinking in heavy drinkers on various parameters. Data are shown for initial admission (D1), 7 days after alcohol detoxification (D7) and 5 years later. For continued drinkers, an additional time point 7 days after detox can be shown. In every figure, abstainers are shown on the left, drinkers on the right. Mean corpuscular volume (MCV) always increased during alcohol detoxification but normalized after long-term abstinence. Note that consequent abstainers have significantly higher initial liver stiffness in contrast to continued drinkers. After 5 years of abstaining from alcohol, liver stiffness was lower as compared to continued drinkers

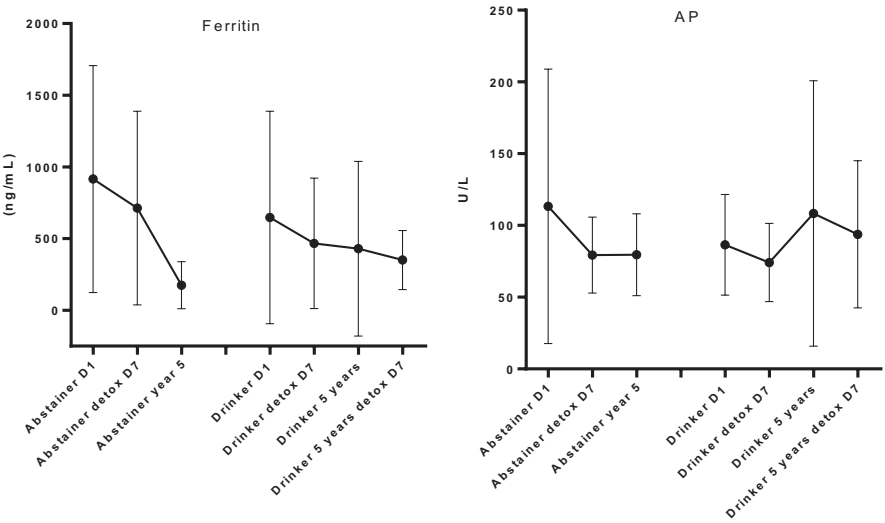

Fig. A.90 Effect of 5 years abstaining from alcohol versus continued drinking in heavy drinkers on various parameters. Data are shown for initial admission (D1), 7 days after alcohol detoxification (D7) and 5 years later. For continued drinkers, an additional time point 7 days after detox can be shown. In every figure, abstainers are shown on the left, drinkers on the right. Ferritin always decreases during alcohol detoxification but was finally higher in drinkers. In contrast, prognostically relevant AP increased during long-term drinking. Note that consequent abstainers have significantly higher initial liver stiffness in contrast to continued drinkers (see also Fig. A.89)

Pathological, Mechanical and Hemodynamical Aspects of Cirrhosis

See Figs. A.91, A.92, A.93, and A.94.

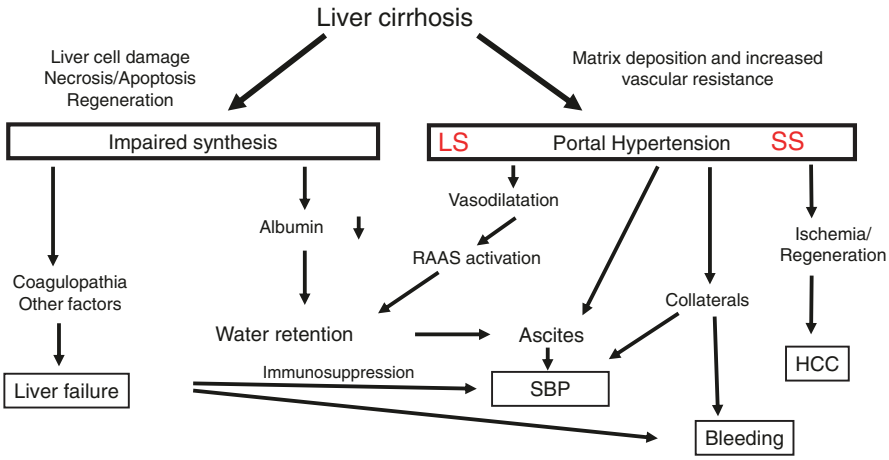

Fig. A.91 Clinical significance of synthesis impairment and portal hypertension in cirrhotics. Both factors are independently and individually occurring in cirrhotic patients and determine the individual risk of severe complications (framed). While liver synthesis is easily assessed by lab tests (e.g. INR, albumin), elastographic techniques are the methods of choice to identify patients with portal hypertension through measurement of liver stiffness (LS) and spleen stiffness (SS)

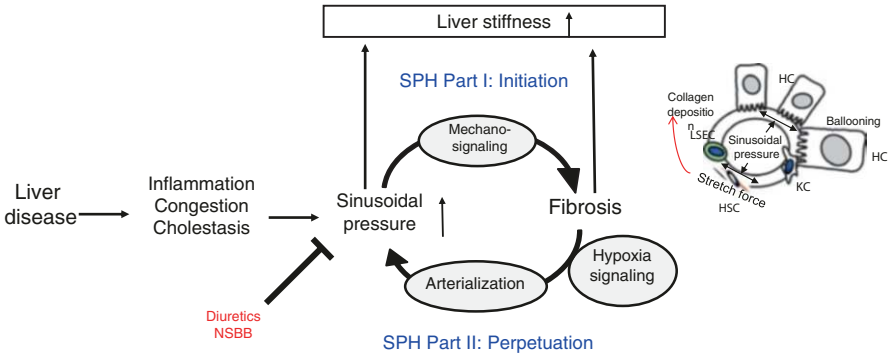

Fig. A.92 Sinusoidal pressure hypothesis (SPH) at the whole organ level and therapeutic target sides (red). Sinusoidal pressure (SP) is the driving force of matrix deposition. Irrespective of the etiology, all liver pathologies (shown in the left) increase the SP that initiates matrix deposition via specific inter- and intracellular biomechanic signaling pathways (SPH Part I, Initiation). LS should be regarded as the combined read-out of elevated pressure and fibrosis. Both SP elevation and matrix deposition increase vascular resistance that ultimately lead to elevated hepatic arterial flow and finally complete arterial blood supply of the liver (without portal blood supply). Depending on dosage (>12 mmHg) and time (>4 weeks), this vicious cycle will ultimately cause a complete arterialization of the liver leading to irreversible cirrhosis by exposing the low pressure organ liver to permanent high pressure (SPH Part II, Perpetuation). According to SPH, non-selective beta blockers (NSBB) and diuretics are not only symptomatic therapies but interrupt the vicious cycle of pressure-driven fibrosis progression. The right panel demonstrates how elevated sinusoidal pressure causes stretching of perisinusoidal aligned cells to induce mechano-signaling. (Modified from Mueller S. World J Gastroenterol. 2016;22(48):10482–10501)

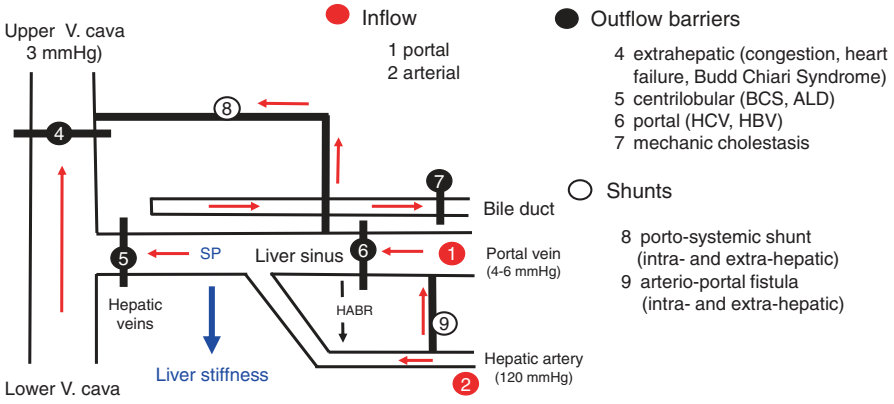

Fig. A.93 Hemodynamics of the low-pressure organ liver in the context of systemic circulation. Cirrhosis causes an increased vascular resistance, collateral formation and increased hepatic arterial flow to maintain hepatic perfusion. Elevated hepatic arterial flow can be observed already before the onset of fibrosis. It eventually leads to a complete arterialization of the cirrhotic liver, sometimes even with hepatofugal flow through the portal vein (modified from Mueller S. World J Gastroenterol. 2016;22(48):10482–10501). *HABR* hepatic arterial buffer response

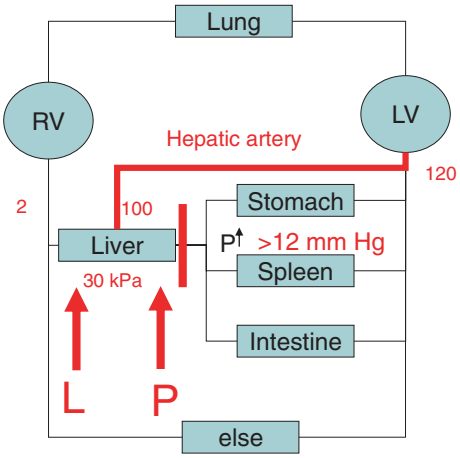

Fig. A.94 Systemic circulation in a patient with liver cirrhosis. Note that portal pressure is increased and the hepatic artery takes over the majority of hepatic blood supply. This not only increases the cardial work (heartwork) but seems also to increase shear stress on red blood cells (RBC), potentially one reason for pericentral RBC uptake by macrophages/hepatocytes but also for the elevation of transaminases such as AST (see also Chaps. 7, 41 and 57). Depending on the location of the liver inflammation (portal versus pericentral,) the sinusoidal pressure is first elevated in the indicated areas (arrow P = portal and L = lobular) (see also Elshaarawy O et al. JHEP Reports. 2019;1(2):99–106). As a consequence, in portal disease, spleen stiffness increases earlier, while in lobular disease (e.g. ALD), liver stiffness is higher. The ratio of both (SS/LS) can help to dissect the location of liver disease. Complete arterialization also determines the irreversibility of the liver disease. (See also Mueller S. Does pressure cause liver cirrhosis? The sinusoidal pressure hypothesis. World J Gastroenterol. 2016;22(48):10482–10501)

Clinical Case with Questions (Mild Alcoholic Hepatitis)

See Figs. A.95, A.96, A.97, A.98, A.99, A.100, A.101, A.102, A.103, A.104, A.105, A.106, A.107, A.108, A.109, A.110, A.111, A.112, A.113, and A.114.

Fig. A.95 Elshaarawy, O./ Mueller, S. Clinical case presented in Grand Round at EASL Vienna 2019

(1) Clinical case - Personal history

- 51 year old female patient
- Presenting again for alcohol withdrawal after relapse
- Ca. 180 g alcohol per day, mostly white wine
- 15 years of heavy drinking
- Obesity with a BMI of 34.6 kg/m^2
- Diabetes mellitus II for 10 years
- Otherwise, almost no symptoms at admission and no history of any chronic illness

Fig. A.96 Physical examination: see also Chap. 37

(2) Physical examination

- Fully conscious and oriented with a tinge of jaundice
- Normal blood pressure
- Tachycardia
- Hepatosplenomegaly
- No detectable abnormalities in cardiac, respiratory or nervous system examination

(3) Laboratory investigations at admission

Blood count

- Hemoglobin 11.8 g/dL
- MCV 110 /fL
- RBC 3.1 /pL
- WBC 6.1 /nL
- Platelets 134 /nL

Liver function tests

- Total bilirubin 5.9 mg/dL
- AST 233 U/L
- ALT 91 U/L
- AP 410 U/L
- gGT 3359 U/L
- INR 0.84

Other parameters

- Serum Ferritin 2420 ng/mL
- All markers for HCV, HBV and AIH were negative
- B12 and folic acid were normal

Fig. A.97 Laboratory examinations: see also Chaps. 37, 39, 40 and 41. Elshaarawy, O./ Mueller, S. Presented in Grand Round at EASL Vienna 2019

(4) Imaging

Abdominal ultrasound

- Hepatomegaly 19 cm
- Hepatic steatosis grade III
- Splenomegaly 13.5 cm
- No ascites

Fibroscan

- XL probe
- Liver stiffness 55.1 kPa
- IQR 21.6 kPa

- CAP 247 dB/M
- IQR 37 dB/M
- S2

Fig. A.98 Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019

(5) Question 1: Does the patient have cirrhosis with respect to elastography?

1- Yes

2- No

Fig. A.99 For elastography, see also Chap. 42. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019

(6) Manifest liver cirrhosis according to inflammation-adapted cut-off values of elastography.

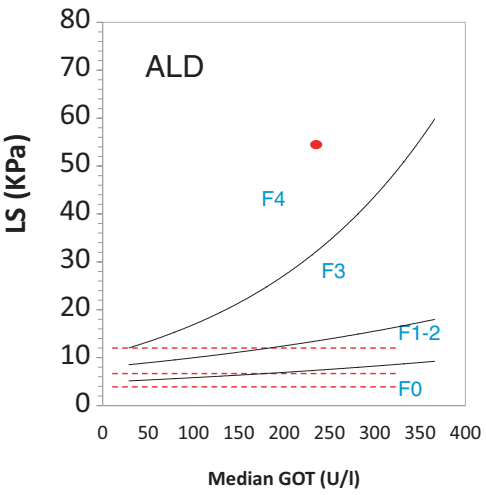

Fig. A.100 Elastography: see also Chap. 42. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. For more details see Chaps. 37, 38, 39, 40, 41 and 42 on the Diagnosis of ALD in part VII of this book. (Adapted from Mueller et al., 2015, Liver International; 35:2514–2521)

Fig. A.101 Prognostic score. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. For more details about AH and ACLF scores also see Figs. A.9–A.21 and respective Chaps. 64, 65, 66, 67 and 68 in part X

(7) Prognostic scores: day of admission

- Maddrey score 16
  (PT - Control PT – Total bilirubin)
- Glasgow AH score 6
  (Age, BUN, WBCs, PT, PT lab normal, Bilirubin)
- CLIF-C OF score 8 (grade 0)
  (Bilirubin, Creatinine, INR, Encephalopathy, MAP, SPO2)
- CLIF-C AD score 38
  (Age, Creatinine, WBCs, INR, Na)

(8) Queston2: What is your preliminary diagnosis?

1- Acute on chronic liver failure (ACLF)

2- Alcoholic hepatitis (AH)

Fig. A.102 Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. Answer: Mild AH. See also Figs. A.7–A.21 and Chap. 67 on AH and ACLF

(9) Question 3: Would you do a liver biopsy?

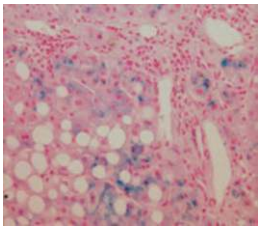
1- Yes
2- No

Fig. A.103 Liver biopsy. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. Answer: Not mandatory. See also Figs. A.7–A.21 and Chaps. 38, 64, 67 and 68 on the pros and concs for performing a liver biopsy in these patients

Fig. A.104 Liver histology in ALD. See also Chap. 38. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. For iron markers, see also Chap. 57 and Fig. B.7. ALD patients do have iron overload, low transferrin and elevated ferritin levels

(10) Liver biopsy

- Severe steatohepatitis
- Concomitant hepatocellular siderosis
- In addition to portal, peri-cellular, perisinusoidal and septal fibrosis
- Findings consistent with alcoholic hepatitis



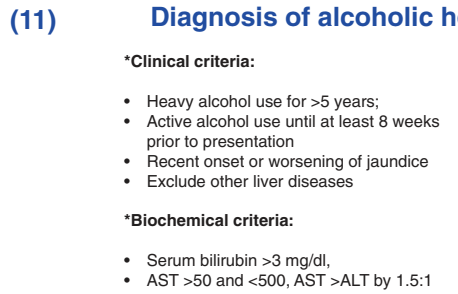


Fig. A.105 Alcoholic hepatitis. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna. See also Figs. A.7–A.21 and Chaps. 64, 65, 66, 67 and 68 on AH

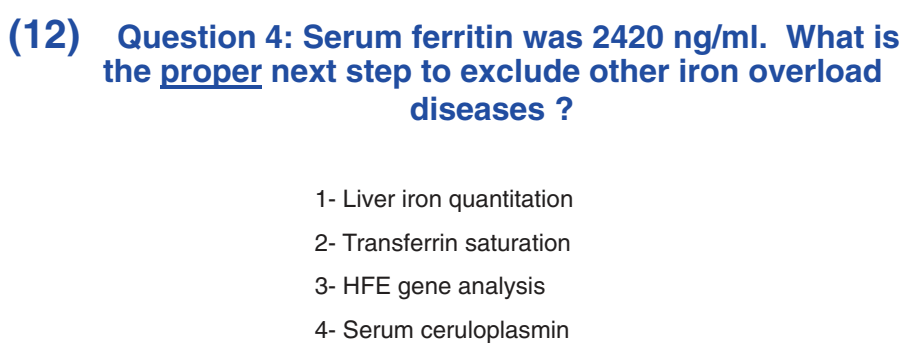

Fig. A.106 Iron parameters in patients with ALD. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. See also Chaps. 37 and 57

Fig. A.107 Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. (For more details see Table B.7 and Chap. 57. (see also Mueller, S., Seitz, H. K., and Rausch, V. (2014) *World J Gastroenterol* 20, 14626–14641, Makker, J et al., Case Rep Gastroenterol 2015;9:7–14)

(14) After 1 week of alcohol withdrawal

Score	Admission	1 week
Maddrey	16	24
Glasgow AH	6	8

- Thiamin substitution
- Detox with chlormethiazole, tapering scheme
- Serum bilirubin started to increase from 5.9 to 17.7 mg/dl in the first week while INR was within normal range.
- LS increased to 75 kPa.

Fig. A.108 Treatment of ALD: see also Chaps. 22, 48, 66, and 67. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. (EASL CPG ALD. J Hepatol 2018;69:154–81)

(15) Question5: How would you manage the case?

1-Prescribe prednisolone

2-Refer for liver transplant

3-Supportive nutritional care

Fig. A.109 Treatment of ALD. See also Chaps. 66 and 67. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. See also Figs. A.7–A.21 and chapters on AH

(16) Follow up of laboratory parameters

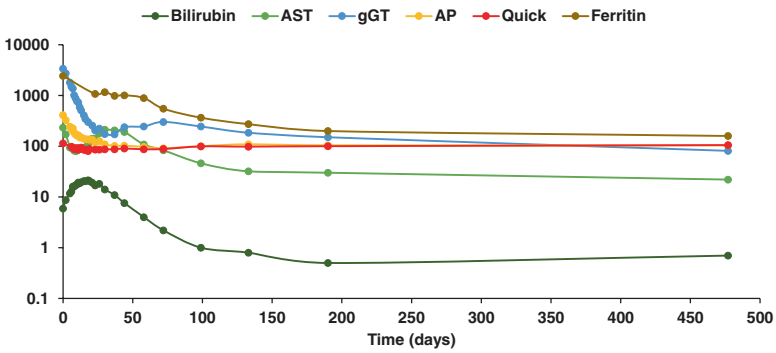

Fig. A.110 Laboratory markers in ALD. See also Chap. 37. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. Note how liver markers improve over more than 12 months of abstaining from alcohol

Fig. A.111 Follow-up of liver stiffness measurement: See also Chaps. 7 and 42. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. Note how liver stiffness improves over more than 12 months of abstaining from alcohol

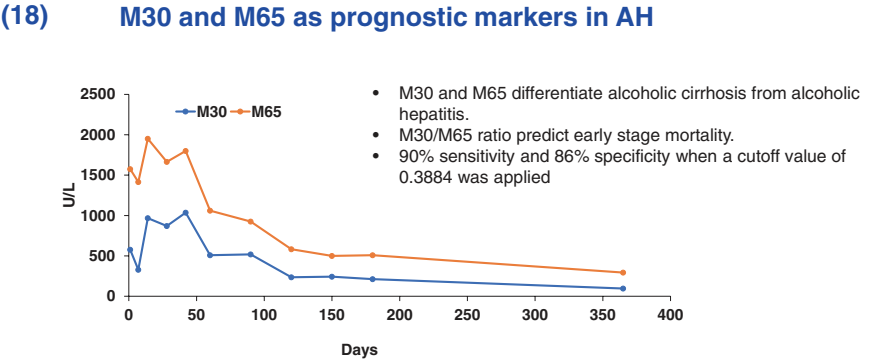

Fig. A.112 Apoptosis marker: See also Fig. A. 31 and A.32. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019. Note how markers of apoptosis and necrosis (M30 and M65) improve over more than 12 months of abstaining from alcohol. (Woolbright BL et al., *Gene Expr*. 2017. Mueller S et al. *Hepatology*. 2017;66(1):96–107)

(19) Long term management

- Referral to addiction center
- Absolute abstinence and future liver transplant
- Screening gastroscopy to exclude esophageal varices

Fig. A.113 Managment of ALD: see especially part III and X of the book. Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019

(20) Current challenges and future directions

For better management, there is a strong need for the following issues to be solved:

- Selection criteria for early liver transplantation
- The need for systematic screening for sub-clinical infection before starting prednisolone
- Alternative treatment protocols
- See chapters on AH and ACLF and book parts 8 and 10.

Fig. A.114 Elshaarawy, O./Mueller, S. Presented in Grand Round at EASL Vienna 2019

Appendix B: Patient Data from a Heavy Drinking Cohort[1]

Sebastian Mueller

Abstract This appendix provides tables with preliminary data from a heavy drinking cohort (Heidelberg) which has been collected prospectively for the last 15 years. These data are aimed at stimulating the interdisciplinary discussions in the area of alcohol-related diseases and providing non-clinicians with "real-life" data from such patients. Besides basic patient characteristics, mortality data and comparison between specific cohort such as alcohol-related liver disease versus non-alcoholic fatty liver (ALD) disease (NAFLD) are provided. Additional tables compare ALD cohorts with and without anemia or with and without advanced fibrosis. Moreover, complete, unfiltered results from specific correlation analyses are shown such as correlation with status of mortality, status of severe alcoholic hepatitis, degree of erythrophagocytosis, transaminase elevation and ferroptosis. Of note, the data not only include medical history, broad clinical characterization, ultrasound and elastography data but also hepatic immunostaining, mRNA expression, specific protein data from the serum, genetics and hepatic lipidomics. The data will hopefully also help to identify future scientific projects and to compare data from in vitro and animal models with data from human drinkers.

Keywords Alcohol, Alcohol-related diseases, Mortality, Laboratory, Lipidomics, Alcohol-related diseases, Anemia, Alcohol-related liver disease, Liver cirrhosis, Patient characteristics, PNPLA3, MCV

[1] Due to space limitations, not all abbreviations could be listed in the abbreviation list of the front matter, but they should be identifiable in the internet. To facilitate the search, parameters are associated in some tables with categories to better allocate their source, e.g. from histological, serum, ultrasound or lipidomics studies.

Univariate Correlation (Spearman Rho) with All-Cause Death in Heavy Drinkers (Complete)

See Tables B.10 and B.11.

Table B.10 Univariate correlation (Spearman Rho) with all-cause death in heavy drinkers. Parameters for analysis included routine and special laboratory, general information, medical history, comorbidities and morphometric data. A number of $n = 777$ was included with 127 deceased patients. Parameters are shown in descending order of the absolute correlation coefficient r (ignoring plus/minus signs). Please note that, in contrast to univariate Cox regression analysis, the observation time is not considered

Spearman rho correlation with status dead (1 or 0)			
Parameter	Category	*r*	*P*
Liver stiffness (kPa)	Ultrasound	0.299	**6.0E−17**

Hepatic steatosis (US) (0–3)	ultrasound	0.035	3.9E−01

Table B.11 Spearman rho correlations with death in the Heidelberg cohort. Complete list. Sorted in descending order according to absolute *r* value. $P < 0.05$ in bold, <0.1 in cursive. Since the clarification of all abbreviations would exceed the space limit of the book, they are assigned to categories, e.g. lipidomics, histology or routine laboratory. Additional information is provided about whether the sample was measured prior (1) to or 1 week after (2) alcohol detoxification

Spearman Rho Correlation of Alcoholic Hepatitis (AH) Status

See Tables B.12 and B.13.

Table B.12 Spearman Rho correlation of alcoholic hepatitis (AH) status (n = 25) with total cohort of heavy drinkers (n = 1063). Note that parameters were first sorted according to P value and then according to absolute r value in descending order. Number of available parameters are shown in right column. Importantly, markers of hemolysis are significantly associated with AH but also deficiency in folic acid and lipidomics parameters

	AH		
Spearman Rho correlation with AH status	*r*	*P*	*N*

Transferrin saturation (%)	0.060	8.4E−02	844

Table B.13 Comparison between alcoholic hepatitis (AH) and alcoholic cirrhosis matched for histological fibrosis. Twenty-five patients with AH were histologically matched with patients with alcoholic liver cirrhosis. Only 7/25 (28%) had a liver biopsy, 2 with F3 fibrosis and 5 with F4 cirrhosis. All patients in the cirrhosis group had histologically proven liver cirrhosis F4. Also note that AH scores, leukocyte count and signs of hemolysis are higher in the AH group

Characteristics and Significant Differences Between ALD and NAFLD

See Table B.14.

Table B.14 Characteristics and significant differences between ALD and NAFLD patients matched for gender, fibrosis and age. Parameters are sorted in ascending order according to their level of significance of the difference between ALD and NALFD. Significant differences between both groups are indicated in bold letters. ALD, alcohol-related liver disease; NAFLD, non-alcoholic fatty liver disease. For Kleiner score see Fig. A.14

Spearman Rho Correlation of Parameters with the Erythrophagocytosis Marker CD163

See Table B.15.

Table B.15 Spearman Rho correlation of parameters with the erythrophagocytosis marker CD163. Positive correlations are shown on the left (descending order) and negative on the right. Note that carrier proteins such as APO A1, transferrin or albumin are negatively associated with hemolysis, while markers of hemolysis and liver damage are positively correlated

ALD Patients with Ineffective Erythropoiesis (Elevated Ferritin, 52.7%) with Anemia vs No Anemia

See Tables B.16 and B.17.

Table B.16 Routine parameters in heavy drinkers with ineffective erythropoiesis that best discriminate those with anemia from those without anemia. Ineffective erythropoiesis was considered when ferritin was elevated (52.7% of total group). Note that bilirubin carrier albumin and iron carrier transferrin are downregulated in the anemia group

Table B.17 Special iron-related parameters, marker of erythropoiesis and cytokines in heavy drinkers with ineffective erythropoiesis with and without anemia. Iron-related parameters include important upstream regulators of hepcidin. Reticulocytes boost after alcohol detox and under elevated erythropoietin (EPO). Hepcidin is non-significantly suppressed in the anemia group. Data on upstream regulators are non-conclusive: BMP6, IL1ß and IL6 are suppressed, but ERFE is also suppressed (negative regulator). These patient data underline that, in addition to specific regulation of hepcidin, iron homeostasis is controlled by other mechanisms, e.g. erythrophagocytosis and most likely efferocytosis. Numbers (1 or 2) after each parameter refer time before or after alcohol detoxification

Correlation with Levels of AST/GOT in Heavy Drinkers

See Tables B.18 and B.19.

Table B.18 Correlation with levels of AST/GOT in heavy drinkers. AST correlates highly with markers of necrosis and apoptosis (M65/M30), but also markers of RBC/heme turnover such as LDH, ferritin and CD163. AST levels are also highly associated with lipidomics parameters. As is discussed in the chapter on AST, most of serum AST elevation is due AST derived from red blood cells

Differences Between High and Normal MCV in Heavy Drinkers

See Tables B.20, B.21, B.22, B.23, B.24, and B.25.

Table B.20 Various parameters (mortality, hematopoiesis, iron) in heavy drinkers grouped according to red blood cell size (MCV). Note, that drinkers with signs of hemolytic anemia (high MCV, signs of hemolysis, decreased hemoglobin) have a three-times increased mortality. Hemolytic anemia is also not due to the lack of folic acid and vitamin B12. Potential other causes are related either directly to RBC or bone marrow toxicity

Groups	Units	Normal range	*P**	High MCV >96	Normal MCV 80–96	Low MCV <80	All

Table B.21 Various parameters (hemolysis, liver) in heavy drinkers grouped according to red blood cell size (MCV). Hemolytic anemia is also tightly linked to liver damage, as shown by elevated transaminases, bilirubin and liver stiffness. Although sigs of hemolysis occur already prior to the onset of liver damage, progressing cirrhosis further deteriorates RBC turnover. CD163, the hemoglobin-haptoglobin scavenging receptor is also highest in the high MCV group

Parameters in Heavy Drinkers That Discriminate Between Low and High Hemoglobin

See Tables B.26, B.27, B.28, and B.29.

Table B.26 Parameters (demographics, ultrasound, scores) in heavy drinkers that discriminate between low and high hemoglobin. A hemoglobin of 14 g/dL was used as cut-off value. Parameters are grouped into categories and sorted according to the *P* value. Only patients with ineffective erythropoiesis (elevated ferritin) were used which represent 55.7% of the total cohort. Number of patients used for *T*-test are shown in cursive letters. A *P* value <0.05 is depicted in bold

Haptoglobin	g/L	0.3–2.0	1.3	*93*	1.5	*136*	1.1E−01
CD91	µg/mL		5.6	*25*	7.0	*19*	2.3E−01
Hemopexin	mg/mL		0.37	*25*	0.45	*19*	4.3E−01

Table B.29 Parameters (genes) in heavy drinkers that discriminate between low and high hemoglobin. For details see Tables B.26 and B.27 hemoglobin of 14 g/dL was used as cut-off value. Parameters are grouped into categories and sorted according to the *P* value. Only patients with ineffective erythropoiesis (elevated ferritin) were used which represent 55.7% of the total cohort. Number of patients used for *T*-test are shown in cursive letters. A *P* value <0.05 is depicted in bold. ALD patients were genotyped for four polymorphisms known to affect liver disease progression (MBOAT7, PNPLA3, HSD17B13, TM6SF2)

Parameter	Units	Normal range	Hb < 14 g/L		Hb > 14 g/L		*P*
			Mean	*N*	Mean	*N*	
Genes							
MBOAT7 GG			0.23	*131*	0.33	*210*	**4.5E−02**
MBOAT7 GC			0.56	*131*	0.48	*210*	1.2E−01
TM6SF2 TT			0.00	*126*	0.01	*207*	2.6E−01
HSD17B13 TA/TA			0.10	*77*	0.06	*166*	3.4E−01
PNPLA3 CG			0.37	*135*	0.40	*221*	5.7E−01
TM6SF2 CC			0.87	*126*	0.85	*207*	6.2E−01
PNPLA3 CC			0.53	*135*	0.52	*221*	7.2E−01
PNPLA3 GG			0.10	*135*	0.09	*221*	7.4E−01

Correlation of Ferroptosis Marker ACSL4 (Long-Chain-Fatty-Acid—CoA Ligase 4) with Various Clinical and Laboratory Markers from a Heavy Drinking Cohort

See Table B.30.

Table B.30 Correlation of ferroptosis marker ACSL4 (long-chain-fatty-acid—CoA ligase 4) with various clinical and laboratory markers from a heavy drinking cohort. ACSL4 mRNA was assessed in liver biopsies from heavy drinkers using Western blotting and subsequent densitometry. Parameters were first sorted according to *P* value and then, in descending order, according to the absolute correlation coefficient (Spearman Rho correlation). Numbers of samples are indicated in the far-right column. ACSL4 converts free long-chain fatty acids into fatty acyl-CoA esters, preferentially arachidonate. Note that this ferroptosis markers is highly correlated with markers of hemolysis or iron (CD163, liver iron, haptoglobin, ERFE), liver damage (Mallory hyaline, lobular inflammation) and directly with the Maddrey score. Maximum 21 samples were available for analysis. *P* is given in bold if smaller than 0.05

		ACSL4/β-actin		
Parameter	Category	*r*	*P*	*N*
ERFE (ng/mL)	Special laboratory	0.943	**4.8E−03**	6
CD163 (µg/mL)	Special laboratory	0.886	**1.9E−02**	6
Liver iron conc. (RTS, µg/g ww)	Iron	0.729	**2.1E−03**	15
Gender	General information	−0.567	**7.3E−03**	21
Haptoglobin (g/L)	Special laboratory	−0.516	5.9E−02	14
APRI	AST/platelets	0.600	**1.4E−02**	16
Mallory hyaline 0–1	Histology	0.517	**1.6E−02**	21
Bilirubin (µmol/L)	Laboratory	0.502	**4.0E−02**	17
Lobular inflammation 0–3	Histology	0.452	**4.0E−02**	21
MBOAT7 CC	Genes	0.451	**4.6E−02**	20
Alcohol consumption (g/day)	Alcohol	−0.442	5.8E−02	19
Maddrey	Score	0.433	6.4E−02	19
Ballooning 0–2	Histology	0.428	5.3E−02	21
