An initial pre-anesthetic evaluation includes reviewing accessible medical records, ordering appropriate preoperative tests, requesting appropriate consultations, and performing a thorough history and physical examination. Although most children have undergone a thorough evaluation by their pediatric cardiologist and cardiac surgeon, the history should not only address cardiopulmonary reserve but also other multisystem co-morbidities that may affect anesthetic management. A review of the child's medical record should assess the child's underlying congenital heart pathology and whether that pathology is repaired or palliated; previous surgery, anesthetic experiences and complications, and diagnostic and therapeutic interventions; current medications and medication history; and drug or food allergies.

A child's functional status will reveal information about their cardiopulmonary reserve. Functional status is assessed differently at different ages. Feeding difficulties with associated tachypnea, dyspnea, and diaphoresis with subsequent growth abnormalities and frequent pulmonary infections indicate limited cardiopulmonary reserve in the neonate and infant. School-aged children may exhibit decreased activity level or exercise intolerance with an inability to keep up with their peers, whereas older children may not only display fatigue, dyspnea, and orthopnea but may also verbalize chest pain, palpitations, and pre-syncope or syncope. Furthermore, recent changes in baseline activity indicate a further decline in cardiopulmonary reserve.

Recent upper (URI, upper respiratory infections) and lower respiratory tract infections (RTI) should be noted, as both may affect airway reactivity for 2–8 weeks [12]. RTI may additionally affect pulmonary vascular resistance (PVR), which may be poorly tolerated in those children with bidirectional cavopulmonary anastomosis (Glenn procedure), total cavopulmonary anastomosis (Fontan), underlying pathology, shunt physiology, or pulmonary vascular disease. The increased risk of breath-holding, airway obstruction, and laryngospasm with subsequent changes in ventilation and oxygenation poses an increased risk to children with limited cardiopulmonary reserve.

The recent COVID-19 pandemic has heightened our awareness of the potential risk of proceeding with elective procedures in the face of a URI, even in asymptomatic patients, and the need to protect healthcare providers as well as other patients when planning unavoidable procedures on such patients [13]. Even in the asymptomatic SARS-COVID-19 polymerase-chain-reaction (PCR) positive patient, the incidence and degree of respiratory complications are higher than in children with other UTIs. Careful screening, identification of at risk-patient, selective scheduling, and safe practice with protective personal equipment for the care providers are essential lessons learned from this pandemic that will be applicable and useful for any future similar viral pandemics [14].

Laboratory tests are available to potentially confirm the diagnosis of an RTI. Nasopharyngeal swabs or aspirates may detect common viral infections, but, depending on the phase of the infection, they may offer limited sensitivity. White blood cell counts are a poor indicator of infection, especially in neonates and children with immature or impaired immune systems. Chest radiograph findings typically lag behind the presentation of clinical symptoms in children with lower RTIs and are often of little utility. Children with URIs undergoing cardiac surgery have an increased incidence of postoperative complications when compared with children without a URI. The recommended period for recovery from a URI and avoiding perioperative respiratory adverse events is a 4- to 6-week period for the recovery of mucosal and ciliary function in children scheduled for cardiac surgery or catheterization, especially if airway instrumentation is planned [15, 16]. Children with underlying congestive heart failure (CHF) who present with a URI pose a dilemma for the perioperative team. It may be challenging to distinguish baseline CHF symptoms as noted earlier from URI symptoms. Furthermore, although decreased respiratory reserve in children with a respiratory tract infection may place the child at risk for perioperative complications, the need for surgical expediency given the CHF may obviate the URI symptoms, and it may be prudent to proceed with surgery to prevent further progression of the CHF.

The physical examination further assesses the child's general condition. Observation of the child during the pre-anesthetic evaluation may be the most valuable component of the physical examination. Is the child active, playful, age-appropriate, lethargic, or in failure to thrive compared with similarly aged children? Vital signs, including weight and height, heart rate, respiratory rate, blood pressure, and oxygen saturation (SpO_2) should be recorded. Failure to thrive with reduced weight and height indicates limited cardiopulmonary reserve and functional status. Blood pressure variation between extremities suggests an unexpected coarctation of the aorta. Tachypnea is one of the earliest signs of CHF. Cyanosis is usually recognized when the SpO_2 is 85% or lower and is associated with unrepaired or palliated CHD from decreased pulmonary blood flow and right-to-left shunting, but children with left-to-right shunting may also have desaturation from pulmonary edema [17]. Progressive cyanosis or frequent cyanotic episodes suggest the potential for rapid cardiopulmonary decompensation intraoperatively. Pre-ductal and post-ductal oxygen saturations should be recorded in an infant with an unrepaired defect. If the pre-ductal (right arm) saturation is higher than the post-ductal saturation, deoxygenated blood from the pulmonary circulation enters the descending aorta through a patent ductus arteriosus (PDA). This differential cyanosis may occur with persistent pulmonary hypertension of the newborn and left-heart abnormalities, such as

aortic arch hypoplasia, interrupted aortic arch, critical coarctation of the aorta, and critical aortic stenosis.

The remainder of the physical examination should be a detailed evaluation of the airway, chest, and heart, with any changes from baseline noted. Wheezing and rales on lung auscultation indicate not only reactive airway disease, chronic lung disease, or an acute pulmonary infection but also CHF. Auscultation of the heart should ideally be performed in a quiet setting with the child being calm and cooperative. Heart sounds, pathologic murmurs, particularly a different murmur from previously documented, gallop rhythms, and the presence of a thrill representing a palpable murmur should be noted. Hepatomegaly, jugular venous distension, and peripheral edema indicate CHF, from either left- or right-sided pathology. Jugular venous distension is of limited value in neonates and infants but may provide qualitative information about central venous pressure in older children [18]. Heart sounds and murmurs are influenced by patient position during auscultation as well as the period of the respiratory cycle during which the heart sound or murmur is being evaluated. Repositioning the child from supine to sitting decreases venous return suddenly and improves the auscultation of heart sounds and murmurs. Innocent murmurs increase in intensity in the supine position. Diminished peripheral pulses and delayed capillary refill indicate reduced systemic perfusion. The peripheral pulse will be reduced in the arm in which the subclavian artery to pulmonary artery shunt (Blalock–Taussig shunt) was constructed; the blood pressure will also be reduced in that ipsilateral arm. Finally, clubbing may indicate long-standing cyanosis. New or different physical examination findings from baseline necessitate further evaluation, which may include a chest radiograph, electrocardiogram (ECG), or echocardiogram.

Current and potential vascular access sites should be assessed, as it is frequently difficult to obtain access in children with CHD. Parents often have insight and knowledge about previous vascular access that can facilitate the selection of sites for potential vascular access. Children with CHD often have multiple previous arterial and venous cannulations that may result in trauma or thrombosis to those vessels. That information is additionally valuable when considering what potential sites to access. Arterial access should be avoided on the side where a Blalock–Taussig shunt was constructed as peripheral pulses and blood pressure will be reduced in that ipsilateral arm.

The airway evaluation is an essential component of the preoperative evaluation of children with CHD, particularly those with chromosomal abnormalities and syndromes. Airway evaluation should include a history of noisy breathing that may indicate airway compression from supraglottic or subglottic obstruction; for example, children with aortic arch obstruction have a 27% incidence of subglottic airway compression that becomes more symptomatic postoperatively following an end-to-side aortic arch reconstruction [19]. Previous airway history also includes previous airway interventions and complications and previous surgery to the face and neck. Airway physical examination includes assessing body mass index, patency of nares, degree of mouth opening, tongue size, palate shape and size, mandibular size, and neck mobility. Mandibular size with micrognathia and retrognathia is associated with difficult mask ventilation and intubation [20]. Many chromosomal abnormalities and syndromes that are associated with CHD, including trisomy 13, 18, and 21, DiGeorge syndrome and Turner syndrome, have an abnormal airway examination that may indicate possible difficult mask ventilation or intubation. Patients with conotruncal abnormalities, including pulmonary atresia, truncus arteriosus, and interrupted aortic arch are at increased risk for DiGeorge syndrome or velocardiofacial syndrome (partial deletion of chromosome 22q11.2). All neonates and infants with reduced functional residual capacity and increased oxygen consumption require a patent airway to prevent cardiorespiratory decompensation, but children with cyanotic CHD or pulmonary vascular disease are particularly at risk of inadequate ventilation and oxygenation from a compromised airway. Previous anesthetic records should always be reviewed for any potential difficulty in mask ventilation and/or intubation along with any airway adjuncts used during mask ventilation, intubation, or extubation.

Children with trisomy 21 frequently present for surgical and other interventions at various stages of life. As these children's age progresses, the risk of hypotonia, atlanto-axial instability, and spinal cord compression increases [21]. Many centers have adopted an algorithm to approach these patients and decide on the imaging needed and the best approach to the airway [22]. The algorithm applies standard cervical spine series with flexion and extension views in older trisomy 21 patients, or patients with any signs or symptoms of atlanto-axial instability. An atlanto-dens interval >4.5 mm or a neural canal width <14 mm provides indirect evidence of cervical spine instability and will require confirmation by magnetic resonance imaging (MRI). If confirmed, these findings in the preoperative period are significant for a high risk of atlanto-axial instability and the need for a neurosurgical consult, potential surgical fusion, or, at a minimum, a modification of airway management and intraoperative positioning.

The finding of poor laryngoscopic view, reported as a Cormack and Lehane [23] grade III or IV, is significantly higher in children with CHD, with a reported incidence of 3.5%, twice as high as the general pediatric population. This incidence was higher in patients below 1 year of age (5.6%) and in those with concomitant chromosomal and genetic abnormalities [24].

Approximately 25–40% of children with CHD may have associated anomalies, which may include neurologic, airway, gastrointestinal, hematologic, endocrine, syndrome, or chromosomal abnormalities [25]. Approximately 5–10% of children with CHD have a known chromosomal abnormality – the most common abnormalities associated with congenital heart disease are listed in Table 18.2. (see Chapter 8 for further discussion of genetic syndromes and CHD).

Congestive heart failure

Similar to adults, children can have significant cardiac decompensation, resulting in poor peripheral perfusion and the inability to adequately support vital organ function. Unlike adults, where CHF is most commonly caused by myocardial ischemia and dysfunction, children may have CHF despite normal myocardial vascularity and function.

AL Grawany

Table 18.2 Chromosomal and genetic defects, syndromes and congenital heart disease

Chromosome, genetic, or phenotypic abnormality	Incidence	Associated CHD	Extracardiac anomalies
		Common chromosomal defects	
Trisomy 21 (Down syndrome)	1 : 650	CAVC, primum ASD, VSD	Mid-facial and mandibular hypoplasia, micrognathia, macroglossia, epicanthal folds, simian creases, pronounced hypotonia, atlanto-axial subluxation
Trisomy 13 (Patau syndrome)	1 : 7,500	VSD, PDA, BAV	Mid-facial hypoplasia, cleft lip, microphthalmia, microcephaly, developmental delay
Trisomy 18 (Edward syndrome)	1 : 7,000	Malalignment VSD, TOF, DORV	Prominent occiput, short neck, low set ears, small mandible, clenched fists
Monosomy X (XO-Turner syndrome)	1 : 2,500	BAV, AS, coarctation	Triangular facies with slanting palpebral fissure, short stature, webbed neck, difficult airway, lymphedema
22q11 deletion (DiGeorge–velocardiofacial syndrome)	1 : 4,000	Conotruncal anomalies, IAA, truncus arteriosus	Thymic hypoplasia, hypoparathyroidism, immunodeficiency, hypocalcemia, renal anomalies, learning disability
7q11 deletion spectrum (Williams syndrome	1 : 20,000	Valve and supravalvular AS, coronary ostial anomalies, peripheral PS	Elfin facies, friendly "cocktail" personality, developmental delay, short stature, hypercalcemia
		Common genetic defects	
Noonan syndrome (12q22 single gene defect)	1 : 2,000	HCM, PS, ASD, TOF, coarctation	Short webbed neck, micrognathia, dental malocclusion, cognitive delay, vertebral anomalies, pectus excavatum
Ehler–Danlos syndrome (variable gene mutation COL5A1)	1 : 5,000	AV/MV prolapse, aortic dissection	Temporomandibular joint dislocation, hyperextensibility of skin and joints, poor wound healing
Marfan syndrome (FBN1 single fibrillin gene defect)	1 : 5,000	Aortic root dilation/aneurysm, MVP	Airway abnormalities (high arched palate), pectus excavatum, scoliosis, joint dislocations
Duchenne muscular dystrophy (absent dystrophin gene Xp21)	1 : 3,500	Cardiomyopathy, conduction abnormality	Progressive respiratory failure, severe scoliosis, muscle wasting
		Syndromic Associations	
VACTERL	**V**ertebral, **A**nal, **C**ardiac (VSD, TOF), **T**racheoesophageal, **R**enal, and **L**imb defects		
CHARGE	**C**oloboma, **H**eart defect (TOF, Truncus), **C**hoanal atresia, **R**etardation, **G**enitourinary, **E**ar abnormalities		

CAVC, complete atrioventricular canal defect; ASD, atrial septal defect; VSD, ventricular septal defect; PDA, patent ductus arteriosus; BAV, bicuspid aortic valve; TOF, tetralogy of Fallot; DORV, double outlet right ventricle; AS, aortic stenosis; IAA, interrupted aortic arch; PS, pulmonary stenosis; HCM, hypertrophic cardiomyopathy, AV, aortic valve; MV, mitral valve; MVP, mitral valve prolapse.

This may occur in the presence of significant volume overload (in shunt lesion) or pressure overload (in obstructive lesions), and frequently in patients with single-ventricular physiology, especially those with a systemic right ventricular morphology. CHF is characterized by reduced cardiac output and increased venous pressure in the systemic and/or pulmonary venous systems, often secondary to an abnormality in the myocardium. Cardiomyopathy is an abnormality of the myocardium. Cardiomyopathies are classified as dilated, restrictive, hypertrophic, arrhythmogenic, or unclassified [26]. Other causes of CHF in children include volume overload secondary to large left-to-right shunts, valvar regurgitation, and obstructive pathology. The classification of heart failure focuses primarily on the severity of illness. The New York Heart Association classification, which ranges from I (asymptomatic) to IV (heart failure with symptoms at rest), was designed for adults but may also be used for older children. The Ross Heart Classification Scale also ranges from I to IV but may be used in infants (see Table 18.3). Accurate assessment and grading of CHF in children require consideration of age, activity, and compensatory mechanisms. Thus the revised Ross Classification has five different age groups with the scaling system (0–2) evaluating different activities and findings per age group [27]. The Canadian Cardiovascular Society has established recent guidelines for the age-appropriate diagnosis of CHF, using commonly encountered symptoms, with recommendations for further investigations (brain natriuretic peptide [BNP], endomyocardial biopsy) and a stepwise introduction for medical therapy to optimize children with CHF prior to surgery and intervention [28].

The prevalence of heart failure-related hospitalization for children <18 years has not changed with time, amounting to 11,000–14,000 admissions annually. In a retrospective analysis of the largest pediatric admissions database, the Healthcare Cost and Utilization Project Kids' Inpatient Database, between 1997 and 2006, pediatric heart failure-related admissions were at the rate of 14.5–17.9/100,000 children. Although the prevalence has not changed significantly, the overall mortality is 7%, significantly higher than the overall expected mortality of 0.4% for all pediatric admissions with no, or compensated, heart disease. The hospital

Table 18.3 Ross classification of congestive heart failure in children

Stage	Presentation
A	Intact function but recognized to have a risk factor for the development of heart failure, e.g., exposure to cardiotoxic chemotherapy or a valvular abnormality that imposes a volume or pressure overload on the ventricle
B	Presymptomatic state where there is discernible myocardial dysfunction, including chamber enlargement or reduced systolic function. Never had signs or symptoms of heart failure
C	Present or past state of symptomatic heart failure. Includes patients with New York Heart Association (NYHA) class II and III disease as well as patients who have had signs or symptoms but are asymptomatic by virtue of heart failure treatment
D	Advanced heart failure requires specialized therapy such as intravenous inotropes or mechanical circulatory support

(Source: Ross [27]. Reproduced with the permission of Springer Nature.)

length of stay is significantly longer, and the outcome is clearly influenced by co-morbid conditions [29].

Children with limited cardiopulmonary reserve should be identified preoperatively as those children at the highest risk of perioperative morbidity and mortality. Preoperative evaluation should include the degree and progression of symptoms and heart failure therapy. The anesthesiologist should communicate directly with the treating cardiologist to assess the child's functional and clinical status. Additionally, strategies and decisions for escalation of care should be discussed with the child's parents, cardiologists, anesthesiologists, and/or intensivists. This might include the potential need for extracorporeal membrane oxygenation or other circulatory support devices. Infants with CHF often have difficulty feeding, diaphoresis with feeding, inadequate growth, and frequent pulmonary infections. Older children with CHF have symptoms similar to adults, including dyspnea at rest or exertion, orthopnea, angina, and peripheral edema. The clinical findings are similar to those seen in adults, with some variations specific to children. Common findings include tachycardia, shortness of breath, difficulty feeding, and lethargy. Hepatomegaly is frequently a characteristic sign of right-sided CHF, with edema seen in the sacral area (especially in babies) as well as the lower extremities. Left-sided CHF is manifested with pulmonary congestion, gallop on auscultation, and poor peripheral perfusion with cold and clammy skin. Children with CHF have low baseline blood pressure from the combination of diuretic therapy, angiotensin-converting enzyme (ACE) inhibitors, and beta-blocker therapy. Preoperative volume status should be assessed, as these children often have intravascular hypovolemia that is exacerbated by preoperative fasting. Children with CHF who are in-patients often have disease progression with increased perioperative risk. Those children who are treated with inotropes, vasodilators, and inodilators have the potential to deteriorate significantly with anesthetic exposure, and the ability to escalate support to maintain cardiac output is limited. B-type natriuretic peptide (BNP) is a hormone that is synthesized and released into the circulation by the ventricular myocytes in response to volume expansion and increases in myocardial wall stress. The marker is useful for assessing the functional status and cardiac function in those children with CHF. BNP is age- and gender-dependent, so higher BNP values are found in older female patients [30, 31]. Hypoxemia directly increases BNP production and is elevated in uncorrected or palliated single-ventricle patients.

Pulmonary arterial hypertension

Children with CHD and pulmonary hypertension (PAH) are at significant risk for perioperative cardiac complications, whether in the cardiac operating room, the catheterization laboratory or for non-cardiac procedures or imaging studies [32]. The preoperative assessment can be done using the clinical presentation, imaging studies, and, most importantly, cardiac catheterization information that reports the pulmonary/systemic pressure ratio and the reactivity of the pulmonary vascular bed [33]. Important information preoperatively is the response of the pulmonary vascular bed to oxygen, hyperventilation and inhaled nitric oxide and intravenous (IV) dilators. It is essential to consider the medical regimen for managing the patient, the potential benefit of additional therapy, and the safest interventions [34]. The preoperative use of single or combination therapy, including prostacyclin analogs (Treprostinil/Remodulin), endothelin receptor antagonists (Bosentan), and phosphodiesterase inhibitors (Sildenafil) even for a short period can have significant impact on intraoperative risk and postoperative outcomes, especially in patients with severe PAH [35, 36]. Children on multiple therapies may be unsafe to proceed with an intervention without a period of optimization, or a procedure may preferably be done at the bedside, avoiding the triggering effects of motion, temperature change, and stimulation on pulmonary vascular resistance (PVR). Chapter 33 has a comprehensive review of the assessment, therapy, and potential outcomes for children with CHD and PAH.

The neonates and premature infants

Neonates and premature infants continue to present the most critically ill group of patients with CHD requiring preoperative evaluation and urgent interventions. Early recognition and appropriate preparation result in a significant improvement in outcome. The American Heart Association (AHA) thus recommends routine oximetry screening on all neonates prior to discharge to prevent delayed diagnosis of critical CHD. The estimated sensitivity for detection is 70% and the risk of false-positive screening oximetry that results in further evaluation is only 0.035% of infants screened within 24 hours of birth [37].

There is a significant negative linear relationship between perioperative mortality of preterm and near-term infants with CHD and gestational age, decreasing significantly for the same lesion as gestational age approaches 40 weeks [38]. It is also evident that the neurodevelopmental outcome, studied as various domains of language, cognition, and visual or fine motor skills up to 4 years of age, is improved in infants and children with various CHDs when delivery (spontaneous or elective/induced) is at 39–40 weeks' gestation [39]. The preoperative preparation and multidisciplinary discussion should examine the gestational age of the fetus with CHD and the best timing and location of delivery for a neonate with critical CHD [40].

AL Grawany

Although small for gestational age and low birth weight are strong independent predictors of mortality in the first year of life following repair of CHD [41], delay of interventions neither compromises nor improves the outcome. For neonates <2 kg, survival following surgical or interventional repair of CHD was determined by prenatal diagnosis (improved), type of cardiac lesion (worse), with defects including pulmonary venous malformations, and associated extracardiac defects [42].

Medications

Children with CHD are often taking numerous medications, including diuretics, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs) beta-blockers, anti-arrhythmics, and digoxin. These medications should be continued preoperatively until the time of the surgical procedure. Reports in the adult literature suggest that ACE inhibitors and ARBs may cause prolonged hypotension during anesthetic induction and should be discontinued at least 24 hours prior to the surgical procedure [43]. Digoxin is discontinued 24 hours prior to the surgical procedure, as serum levels may be potentially toxic postoperatively [44, 45]. The American College of Chest Physicians recently published guidelines for antithrombotic therapy in children [46]. Children with systemic-to-pulmonary artery shunts, a history of shunt or conduit thrombosis, mechanical or biological prosthetic heart valves, transcatheter interventions or device placement, treatment of Kawasaki disease, and risk factors for the thromboembolic phenomenon, such as bicaval pulmonary anastomosis, are often taking antithrombotic therapy. No specific guidelines exist for discontinuation of antithrombotic medications prior to elective surgery in children. Aspirin irreversibly inhibits cyclooxygenase for the life of the platelet, approximately 10–14 days [47]. Clopidogrel also irreversibly inhibits platelet aggregation. A child taking preoperative aspirin and/or clopidogrel to maintain shunt patency should continue these medications, as the risk of shunt thrombosis is greater than that of perioperative bleeding. Immediately discontinuing aspirin preoperatively does not reduce the risk of perioperative bleeding, given aspirin's long half-life. There should be a discussion with the child's cardiologist, surgeon, and anesthesiologist regarding the optimal timing for stopping these medications. Children who are taking warfarin for their antithrombotic medication should discontinue the warfarin 3–5 days prior to the surgical procedures. The international normalized ratio will usually fall below 2.0 in approximately 2–3 days and will normalize in 4–6 days [48]. Patients should be admitted 2–3 days prior to the surgical procedure to start a bridging regimen of IV heparin. Cessation of the IV heparin 3–6 hours prior to the surgical procedure does not increase the risk of perioperative bleeding [49].

Prostaglandin E_1 (Alprostadil) maintains ductal patency in ductal-dependent lesions, such as pulmonary atresia with or without VSD, tricuspid atresia, HLHS, interrupted aortic arch, or severe coarctation of the aorta. The dose, usually between 0.0125 and 0.1 μg/kg, is adjusted to maintain appropriate oxygenation without signs of over-circulation, decreased systemic diastolic blood pressure, and appropriate acid-base status. Common side effects of prostaglandin E_1 infusion include apnea, fever, flushing, tachycardia or bradycardia, and platelet dysfunction; rarely, cardiac arrest can occur, with the prostaglandin being a contributing factor.

Children who have undergone heart or lung transplantation are often taking multiple immunosuppressive medications that should be continued through the perioperative period to reduce the risk of acute rejection. Finally, children who are taking other medications, such as those for reactive airway disease, gastroesophageal reflux, and seizure disorder, should continue these medications until the surgical procedure (Box 18.1).

Box 18.1: Examples of pre-anesthetic medication instructions

Medications to be continued until the procedure:
- Beta-blockers
- Anti-arrhythmics (unless instructed by electrophysiology to hold)
- Anti-seizure medications
- Pulmonary hypertensive therapy
- Thyroid replacement
- Asthma and COPD medications

Medications to be held the morning of the procedure:
- Diuretics
- Hydralazine
- Nifedipine
- Oral hypoglycemics

Medications to be held 12–24 hours prior to the procedure:
- ACE-inhibitors and angiotensin receptor blockers
- Theophylline

Medications that may be held for several days and require a discussion:
- Anticoagulants (coumadin, antiplatelet agents, heparin related agents)
- Herbal medications

Medications that need planning relative to start time on the day of the procedure:
- Insulin infusions and insulin pumps
- Heparin infusions

Electrocardiographic evaluation, pacemakers, and defibrillators

Children with CHD frequently have rhythm disturbances that require anti-arrhythmic therapy and are manifest on a preoperative ECG. A 12-lead ECG with adequate length of lead II recording for diagnosis of arrhythmias and assessment of changes from baseline is an important component in the evaluation for cardiac surgery. Even if it is "normal" (i.e., normal sinus rhythm without any evidence of chamber enlargement or repolarization abnormalities, etc.), the formal 12-lead ECG serves as a comparison to the postoperative state if ECG changes are suspected and thus should be obtained before any cardiac surgery. If the patient has a history of significant arrhythmia or suspicion for changing rhythm status, a 24-hour Holter monitor is an extremely valuable test to assist in planning for the management of cardiac rhythm during the procedure. Chapter 22 presents an extensive discussion on ECG and arrhythmia analysis and treatment.

Pacemakers and implantable cardioverter defibrillators, collectively referred to as cardiac rhythm management devices

(CRMDs), are commonly used in children with CHD due to either congenital, acquired, or iatrogenic rhythm disturbances. These devices may be placed temporarily (postoperatively) or as permanent due to intrinsic heart disease (common with CCTGA and cardiomyopathies) or they may be acquired following cardiac operations due to scarring, patches, and morphologic chamber changes (as with repaired tetralogy of Fallot). The preoperative period is a critical time to prepare the child with a CRMD for a safe perioperative period. The primary step is to obtain a detailed history of the indication, timing, and type of device placed. Devices have a standard nomenclature established by the North American Society of Pacing and Electrophysiology (NAPSE). An understanding of the position/nomenclature used is essential: I, chamber (s) paced; II, chamber(s) sensed; III, response to sensing; IV, rate modulation; V, multi-site pacing capability. It is important to obtain an ECG to identify pacer spikes and rate, and a chest radiograph to examine the location of the generator and the pacing leads/wires. The CRMD should be interrogated by a programmer, a manufacturing consultant, or an electrophysiologist and its battery life examined [50]. Children are more vulnerable than adults to faster battery generator utilization (due to heart rate) or dislodged/fractured leads (growth changes) or to receiving inappropriate shocks, as shown in a large pediatric CRMD series [51]. The CRMD should be reprogrammed for elective surgery to an asynchronous mode at a rate appropriate for the age and metabolic demands of the patient and the planned procedure, with all anti-tachycardia function turned off. The location of the generator must be clearly marked and noted to plan the necessary approach to avoid or limit electromagnetic interference intraoperatively [52]. For urgent or emergency procedures, a magnet may be placed on a CRMD to revert the device to a fixed rate, asynchronous pacing mode where no cardiac activity is sensed. Caution must be used when applying a magnet, as the preset rate may not be sufficient for the metabolic demands and may be dependent on the battery voltage and life of the generator. A regular 90 Gauss magnet will deactivate the anti-tachycardia function of an implantable cardioverter-defibrillator, but not reset an asynchronous pacing mode. Thus, for all children with a CRMD, whether the device is reprogrammed or a magnet is used, perfusion must be monitored with a waveform monitoring device (pulse oximeter or arterial line wave) throughout the operative procedure until the magnet is removed or the device is interrogated and reprogrammed [53]. Chapter 22 contains a detailed discussion of the management of CRMDs.

KEY POINTS: PREOPERATIVE EVALUATION

- A detailed history of cardiac symptoms, diagnostic and therapeutic procedures, and complications is crucial for peri-anesthetic planning.
- Non-cardiac problems, such as genetic or dysmorphic syndromes leading to difficult airway management, are frequently encountered in the CHD population.
- CHF, PAH, neonatal and premature patients, medication management, and pacemakers and defibrillators all deserve special attention in CHD patients.

Laboratory evaluation

Standard laboratory testing for all children undergoing cardiac interventions must include an assessment of the hematologic status, coagulation testing, serum electrolytes, and kidney function tests (creatinine and blood urea nitrogen [BUN]). Liver function tests (bilirubin, aspartate aminotransferase, and alanine aminotransferase) are assessed when there is suspicion of hepatic dysfunction. Preparation of components for blood transfusion is essential and will require antibody screening and cross-matching. The hemoglobin concentration may reveal anemia and necessitate priming of the cardiopulmonary bypass (CPB) circuit with red blood cells. Children with chronic hypoxemia have significant hematological consequences. Chronic hypoxemia increases erythropoietin activity, increasing hematocrit, hemoglobin, and viscosity, and allow increased oxygen delivery without a sustained increase in cardiac output. However, oxygen delivery can be reduced from red cell rigidity if the hematocrit exceeds 65% [54]. Hyperviscosity is associated with cerebral arterial and sinovenous thromboses, particularly in those children who are dehydrated, have fever, or have iron deficiency. All children with chronic cyanosis should have preoperative hemoglobin and hematocrit. Hematocrit >60% is an indication for preoperative IV fluid therapy. Preoperative phlebotomy is not advocated unless the child is experiencing severe symptoms of hyperviscosity syndrome, such as headaches, dizziness, impaired mental status, visual disturbances, muscle weakness, or paresthesias in the absence of dehydration or iron deficiency [55]. Repeat phlebotomies have been shown to increase the risk of cerebrovascular accidents by causing chronic iron deficiency, resulting in microcytosis and increased blood viscosity. Volume resuscitation and iron replacement therapy should be started prior to elective phlebotomy. Approximately 20% of children with polycythemia have other abnormal hematologic laboratory tests, including prolonged prothrombin and thromboplastin time, thrombocytopenia, platelet dysfunction, hypofibrinogenemia, and accelerated fibrinolysis [29]. Furthermore, all children with CHD undergoing CPB are at risk for intraoperative and postoperative hemostatic derangements. A baseline platelet count, prothrombin time, partial thromboplastin time, and fibrinogen level should be evaluated preoperatively in all children. A screen for antibodies and a crossmatch for RBCs should be performed to ensure that compatible blood is available, particularly for a child who may have had prior exposure to blood products and developed serum antibodies.

Serum electrolytes should be evaluated in children taking diuretics or ACE inhibitors, as both may result in a significant imbalance in the metabolic state. Neonates and infants are at risk for both hypoglycemia and hypocalcemia [56]. This is more prevalent in patients with specific syndromes (as Beckwith–Wiedemann) and those receiving parenteral nutrition. Signs and symptoms of hypoglycemia and hypocalcemia are subtle in neonates and infants, including jitteriness, fussiness, tachypnea, and tachycardia. Children with DiGeorge syndrome, with abnormal parathyroid gland dysfunction, are at risk for perioperative hypocalcemia and should have a preoperative calcium level evaluated. They are

AL Grawany

also at risk for infections due to immune deficiency and will require irradiated blood products whenever needing a transfusion. Children with Down syndrome have an approximately 10% incidence of congenital or acquired thyroid dysfunction and should have preoperative thyroid function tests performed [57]. Preoperative arterial blood gases may reflect the degree of cardiopulmonary reserve. An arterial PaO_2 of 30–40 mmHg and peripheral O_2 saturation <70% indicate poor cardiopulmonary reserve. Metabolic acidosis, assessed from base status, anion gap, and lactate, reflects maldistribution of cardiac output, particularly in those children with ductal-dependent systemic circulation and CHF. Preoperative BUN and creatinine should be assessed in children who are at risk for reduced systemic perfusion and perioperative renal impairment.

KEY POINTS: LABORATORY EVALUATION

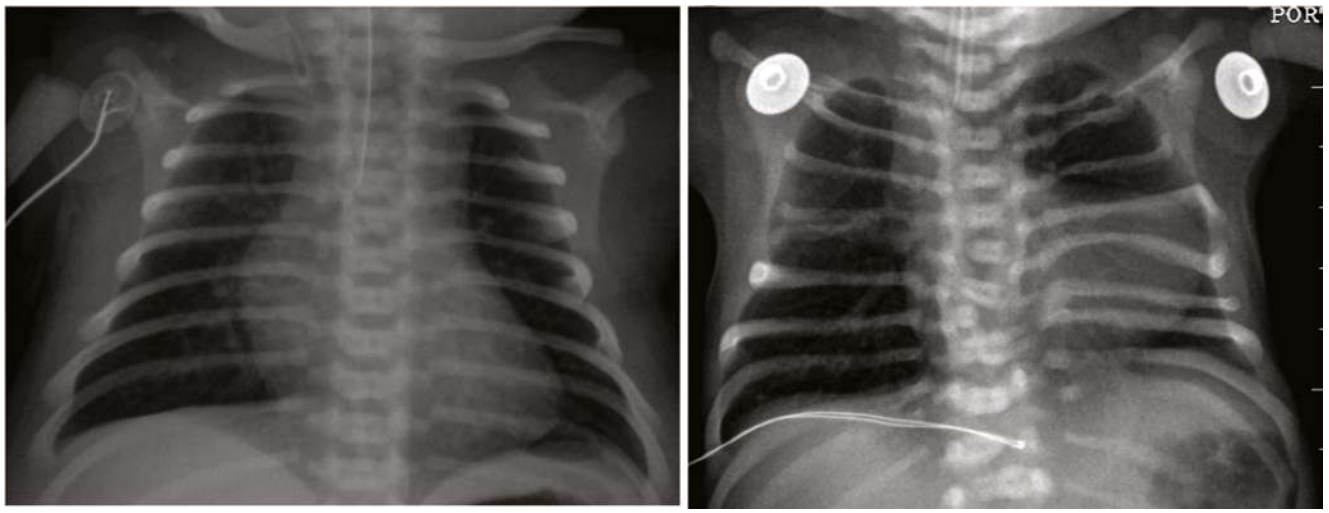
- Hemoglobin level is a key preoperative laboratory value, with elevated levels indicating compensatory response to chronic hypoxemia.
- Platelet count, prothrombin and partial thromboplastin times, and fibrinogen level should be obtained before cardiac surgery.
- Electrolytes and BUN/creatinine should be assessed in patients on diuretic therapy.
- Other laboratory tests are guided by signs/symptoms, and previous history of organ dysfunction (e.g., hepatic, hypoglycemia, hypocalcemia).
- A 12-lead ECG is an important diagnostic tool before cardiac surgery.

Preoperative imaging studies

Imaging is essential to identify subjects with CHD to establish the need for treatment and the optimal mode of treatment, define anatomy and hemodynamics for treatment planning, monitor for complications after treatment, and determine the appropriate timing of repeat intervention. In the preoperative period, imaging is required to assess pulmonary vascularity, clarify hemodynamic status, confirm cardiovascular anatomy, determine airway patency, assess the position of vital catheters and tubes, and screen for acute conditions such as hemorrhage, edema, or infection.

Commonly used imaging modalities include chest radiography, echocardiography, cardiac catheterization, MRI, and computed tomography (CT). There are some overarching considerations for imaging utilization in the setting of CHD. Chest radiographs provide essential preoperative information about pulmonary vascularity and physiology of CHD as well as the status of the vital lines and tubes. Transthoracic echocardiography (TTE) is the most important preoperative diagnostic imaging tool in the majority of situations but is less reliable with poorer acoustic windows as patients age and in the postoperative state. Cardiac catheterization is used less frequently for diagnosis but is essential to determine pulmonary to systemic blood flow, and saturations and pressures in cardiac chambers and vessels in complex lesions. Cardiac MR (CMR) is a noninvasive modality that is excellent for a comprehensive assessment of cardiac morphology and function but requires sedation or anesthesia in young children. Cardiac CT is excellent for extracardiac anatomy and is a brief study that requires minimal to no sedation. The choice among cardiac catheterization, echocardiography, CT, or MRI for diagnostic anatomic information frequently benefits from the multidisciplinary discussion. All imaging modalities have a role in preoperative evaluation, preparation, and decision-making, and their relative utility depends on the specific disease and natural history. A good example is the assessment of the child with CHD and pulmonary hypertension, where all investigative procedures contribute important complementary information for the evaluation of the cause, degree, reactivity, and prognosis of pulmonary hypertension [58].

Chest radiography



In an era of advanced technology and continuous refinement of imaging modalities for greater safety, efficiency, and accuracy, the role of the humble chest radiograph may be questioned. However, a careful review of a preoperative chest radiograph is essential for the best preparation of a patient with CHD scheduled for cardiac intervention.

The chest radiograph provides pertinent information about the cardiac size and chamber enlargement. A significant increase in the cardiothoracic ratio (>0.5) reflects cardiomegaly, which can be due to increased volume load to a cardiac chamber, valve regurgitation, or poor function with cardiac dilatation. A careful examination of the bronchovascular markings and lung fields can differentiate between children with a significant increase in pulmonary blood flow and those with obstruction to flow due to either anatomic or physiologic etiology [59] (Figure 18.1).

The chest radiograph also provides information on the airway, especially in patients with risk of vascular mediated airway compromise (vascular ring, pulmonary sling, enlarged pulmonary arteries, aneurysmal aortic dilation) [60].

The surgical and anesthesia teams must review the chest radiograph prior to any repeat sternotomy, to prepare for the potential risk of vascular structure injury during dissection. A narrow retrosternal space on lateral radiograph reflects an adherent vascular anatomy with risk of injury to the innominate vein, right ventricle, or a pulmonary artery conduit [61].

Similarly, chest radiographs provide information on the location of vascular lines (especially umbilical catheters in neonates), which can help them with the decision to use them during the procedure for valid pressure monitoring and various medication infusions. Umbilical venous lines located in the hepatic silhouette may not have passed through the ductus venosus and carry the risk of portal vein thrombosis [62]. Using umbilical artery catheters for blood pressure monitoring and blood gas sampling carries significant risks of renal artery thrombosis and lower extremity emboli, if present at or below the renal arteries, and should ideally be identified at the level of the third lumbar vertebra on chest radiography [63, 64].

(A) (B)

Figure 18.1 Chest radiography. (A) Newborn with dextro-transposition of the great arteries, the egg-on-string appearance of the cardiac silhouette and increased pulmonary vascularity. (B) Newborn female with tetralogy of Fallot, ventricular septal defect, pulmonary atresia, ductal-dependent pulmonary blood flow, and decreased pulmonary vascularity. Note the skeletal abnormalities (VACTERL syndrome).

Echocardiography

TTE has long been considered the reference standard in evaluating neonates and children with CHD prior to cardiac interventions. The feasibility of obtaining clear images with multiple acoustic windows, easy access, minimal need for sedation, and low-risk results in TTE are the most common imaging tool in the preoperative period. Most anatomic diagnoses can be obtained confidently with TTE, and the reporting process has become well-standardized to provide the anesthesiologist in the preoperative period with information on structural abnormalities, function, chamber size as well as physiologic parameters.

The anesthesiologist should consider the echocardiographic parameters to evaluate a specific lesion preoperatively, to clearly understand the anatomy and the degree of decompensation, and to plan the best approach for intraoperative care. Following a stage I repair of HLHS, infants are at risk for recoarctation of the aorta (in 20% of patients) at subsequent stages of repair. There are useful TTE parameters for evaluating recoarctation, including peak isthmus velocity >2.5 m/s and coarctation index (ratio of the narrowest region of the descending thoracic aorta to the distal descending aorta diameter) <0.7, which can guide the preoperative risk assessment [65].

A review of TTE to evaluate ventricular function is important, especially in the presence of confounding variables that can bias the estimation of function, such as valvular regurgitation with a large ejection fraction. In patients with significant mitral regurgitation, ventricular dysfunction may be difficult to assess in the preoperative evaluation. Useful echocardiography tools include attention to the regurgitant fraction, the effective ejection fraction, and a higher E/E ratio (ratio of mitral peak velocity to early diastolic velocity of the mitral annulus), which are associated with increased mortality and adverse outcome [66].

An understanding of the morphologic parameters that identify a borderline left or right ventricle is important in the preoperative evaluation of children with CHD. In children with a hypoplastic tricuspid valve, and a borderline right ventricular chamber, parameters including atrioventricular valve index (right-to-left atrioventricular valve area <0.5) and right/left ventricular length ratio (<0.7) are useful in the preoperative preparation (Figure 18.2) [67, 68].

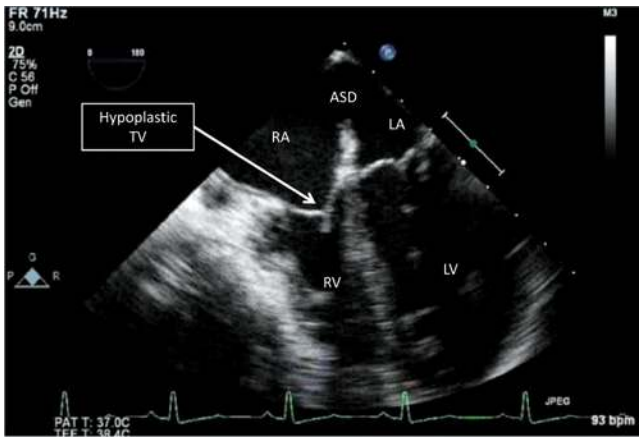


Figure 18.2 Echocardiography: 3-year-old with the hypoplastic right ventricle, small tricuspid annulus, and an atrial septal communication (RV, right ventricle; LV, left ventricle; ASD, atrial septal defect; RA, right atrium; LA, left atrium, TV, tricuspid valve).

However, although a reliable tool in many circumstances, TTE has its limitations. Inter-observer variability in the interpretation of echocardiographic findings affects agreement on anatomic as well as functional data and can significantly impact the planned intervention as well as the extent of anesthetic preparation. Echocardiographic prenatal diagnosis of CHD can have up to 50% variability of anatomic detection of defects [69]. The interpretation of function can also vary significantly among investigators using current guidelines. In a study of 175 children with dilated, hypertrophic and

restrictive cardiomyopathy, agreement among investigators on the grading of diastolic dysfunction was poor (<36%) due to the large range of normal pediatric reference values [70]. The diagnosis of left ventricular endocardial fibroelastosis (EFE) and left ventricular non-compaction (LVNC) can also be challenging. In a series of 104 children with LVNC preoperatively, the agreement between observers on the number and degree of trabeculations was <60%, and on the absolute diagnosis of EFE/LVNC was <67% [71]. Chapter 15 has a complete review of echocardiography applications and limitations in CHD.

Cardiac catheterization

Cardiac catheterization is described in detail in Chapter 34. This discussion will focus on the interaction of cardiac catheterization with other imaging modalities for the diagnosis of CHD, and the role of anesthesiologists in facilitating combined non-invasive and invasive diagnostic evaluations in the same patient encounter.

In the current era, it is rare to use cardiac catheterization for the primary diagnosis of CHD or for evaluation after surgery. The majority of catheterizations in children are performed for planned interventions, or to complete and complement a difficult diagnosis, providing additional diagnostic information to other imaging modalities. Many children with single-ventricle physiology can undergo staged repair without cardiac catheterization [70], with reliance on information from less invasive studies such as echocardiography, CT, and MRI. However, there remains a small subset of children in whom evaluation of the branch pulmonary arteries, reconstructed aortic arch, or coronary arteries is insufficient with TTE, CT, or MRI, and cardiac catheterization is integral in the preoperative evaluation [72].

Similarly, the evaluation of children with idiopathic or CHD-related pulmonary hypertension is critical in the preoperative preparation of these patients. The anesthesiologist should review the catheterization report for the degree of increased PVR, the ratio of right/left ventricular pressure, and the response to pulmonary vascular dilators, most importantly oxygen and nitric oxide inhalation. Patients presenting with catheterization data showing a pulmonary artery pressure >50% of systemic arterial pressure, a PVR of >4 Wood units, and a failure to respond to vasodilator therapy have a significant risk in the perioperative period [73].

The anesthesiologist must review the catheterization report to learn information regarding the complete anatomic diagnosis, associated anomalies, shunt direction and degrees, pressures and gradients, and ventricular function [74]. A demonstration of the value of a catheterization report is presented in Figure 18.3 showing a child with pulmonary atresia and intact ventricular septum who had undergone several staged repairs. The catheterization report can identify important preoperative information, including tricuspid annular size, presence of right ventricular dependent coronary fistulae, and bidirectional Glenn pressure, all of which have prognostic value. The degree and direction of shunting across the atrial septum can be assessed from the stepwise changes of saturation between chambers provided in the catheterization report.

There is an increasing trend towards combining non-invasive imaging like sedated echo, CT, or MR with cardiac catheterization under a single anesthesia encounter. In addition to decreasing the risks related to repeat induction/recovery for separate procedures, this approach also allows complementary information from CT/MR vascular anatomy or MR flow assessment to abbreviate the catheterization protocol accordingly, thereby reducing the need for prolonged sedation or unnecessary radiation exposure. Interventional CMR is also becoming available in more institutions due to recent technological advances with low-field CMR, and MR compatible guidewires and catheters, and will also benefit from a similar hybrid information-gathering approach [75]

A complete review of cardiac catheterization indications, interpretation, and anesthetic management is presented in Chapter 34.

Magnetic resonance imaging

MRI plays an important complementary role to echocardiography in the evaluation of cardiac morphology and function in children with CHD in the preoperative and postoperative periods. Recent technological advancements including free-breathing capabilities, improved image resolution, ultrashort imaging time, and real-time imaging, along with a burgeoning trained user-base, increasing accessibility to MRI scanners, a steady stream of clinical validation studies, and the lack of ionizing radiation have all combined to significantly expand the indications for MRI in pediatric cardiovascular disease over the past several years. Most patients under the age of 8 years who undergo a cardiac MRI study will need either IV sedation or general anesthesia with endotracheal intubation. Endotracheal intubation, often with pharmacologically induced muscle relaxation, is needed if breath-holding is desirable. IV sedation is a preferred alternative to intubation among parents and many anesthesiologists have two important requirements: anesthesiologists experienced in administering IV sedation in patients with CHD; and the ability to modify the MRI sequences for free-breathing acquisition.

Cardiac MRI is a dynamic user-dependent examination, and changes to the protocol will be needed based on real-time evaluation of the initial sequences. The pulse sequences used include [76]:

- *Black-blood sequences* – These sequences provide multi-slice static images, with an excellent spatial resolution with thin slices even in neonates. They provide an overview of vascular anatomy, spatial chamber relationships, airway morphology, and abdominal visceral anatomy, and form an important part of the preoperative evaluation.
- *Bright-blood sequences* – These sequences have an excellent temporal resolution, allowing multi-phase evaluation across the cardiac cycle, and optimal myocardial and blood pool contrast. They are used for ventricular functional assessment and to evaluate valvar morphology and intracardiac morphology, to determine veno-atrial connections, and to track the course of the extracardiac vasculature. Alternatively, free-breathing whole-heart coverage utilizing a three-dimensional steady-state free precession (3D SSFP) sequence with respiratory navigator gating has been

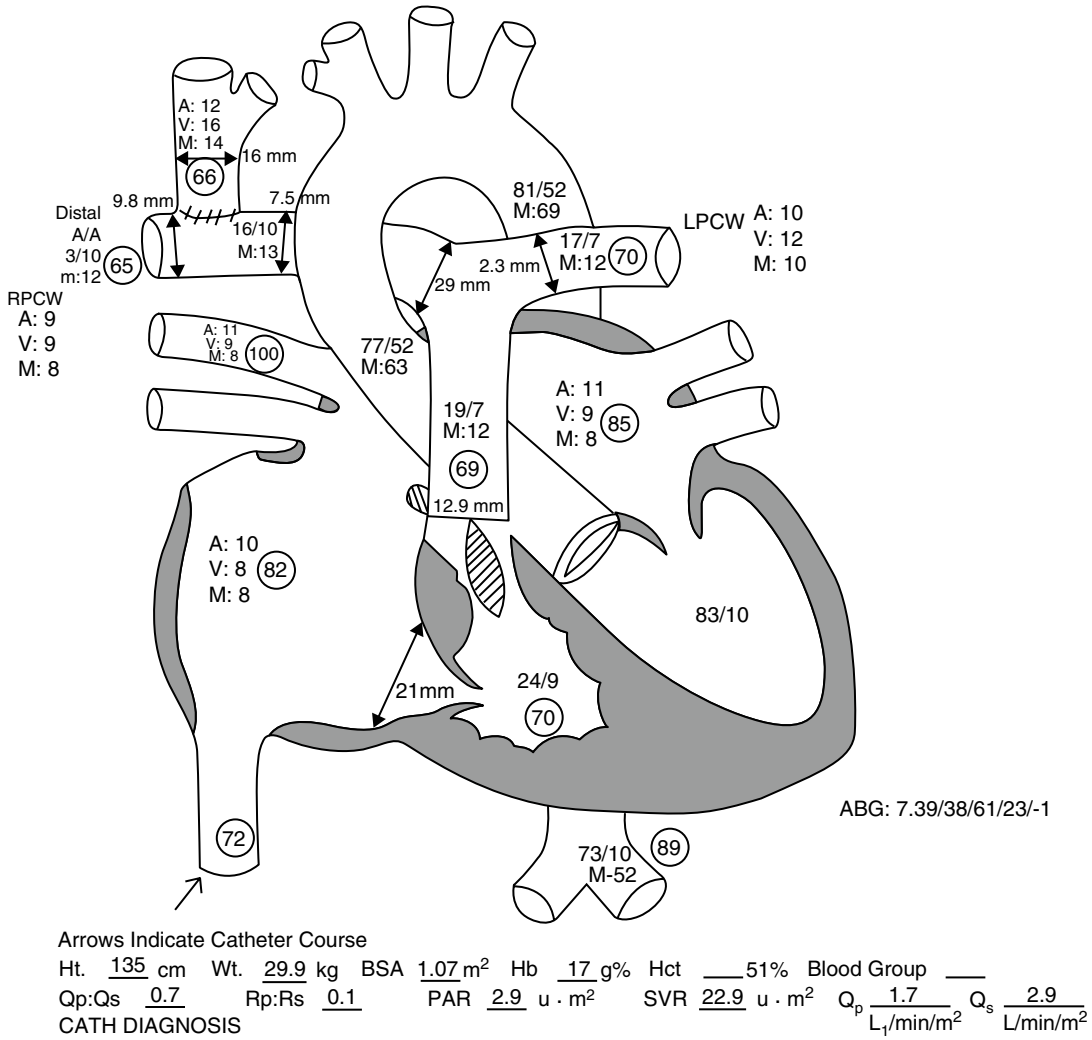

Figure 18.3 Cardiac catheterization diagram of the patient in Figure 18.2 showing anatomy, pressure, and resistance measurements. BSA, body surface area; Hb, hemoglobin; Hct, hematocrit; Qp: Qs, pulmonary to systemic blood flow ratio; Rp: Rs; pulmonary to systemic resistance ratio; PAR, pulmonary artery resistance, Wood units; SVR, systemic vascular resistance; Qp, pulmonary blood flow; Qs, systemic blood flow; ABG, arterial blood gas. Circled numbers are measured oxyhemoglobin saturations, uncircled numbers are pressures in mmHg. Numbers followed by mm are diameter measurements.

used to provide comprehensive static, high-resolution morphologic bright-blood evaluation of intracardiac morphology and extracardiac vascular anatomy in one sequence.

- *Flow velocity mapping* – This sequencing is accomplished by a gradient echo-based pulse sequence known as phase contrast. Phase-contrast imaging is based on the principle that moving protons, such as those in flowing blood, when experiencing a specific bi-polar gradient, will accumulate a predictable phase shift that is proportional to their velocity. Phase-contrast imaging can be used to quantify stroke volume, valvar regurgitation, Qp/Qs, differential pulmonary artery flow, venous return, coronary flow, and pressure gradients across stenoses using the modified Bernoulli equation.
- *Magnetic resonance angiography* – The most common sequence used is the contrast-enhanced magnetic resonance angiography (CEMRA) performed in dynamic fashion following bolus injection of gadolinium; this provides a high-resolution three-dimensional (3D) dataset, with its main application being the evaluation of the extracardiac thoracic vasculature, including the pulmonary arteries, pulmonary veins, aorta, systemic veins, and collateral blood supply to the lungs. Techniques of post-processing include multi-plane reformatting, maximum-intensity projection, volume rendering, and virtual angioscopy. Gadolinium contrast agent has recently been discovered to be associated with the development of nephrogenic systemic fibrosis, predominately in adult patients with acute or chronic renal failure. Therefore, thoughtful determination of the benefits and risks in children with CHD is essential.
- Recently, accelerated time-resolved 3D phase-contrast MRI techniques (4D flow) using ECG gating and advanced navigator respiration control have been increasingly used for comprehensive morphological, functional, and flow

AL Grawany

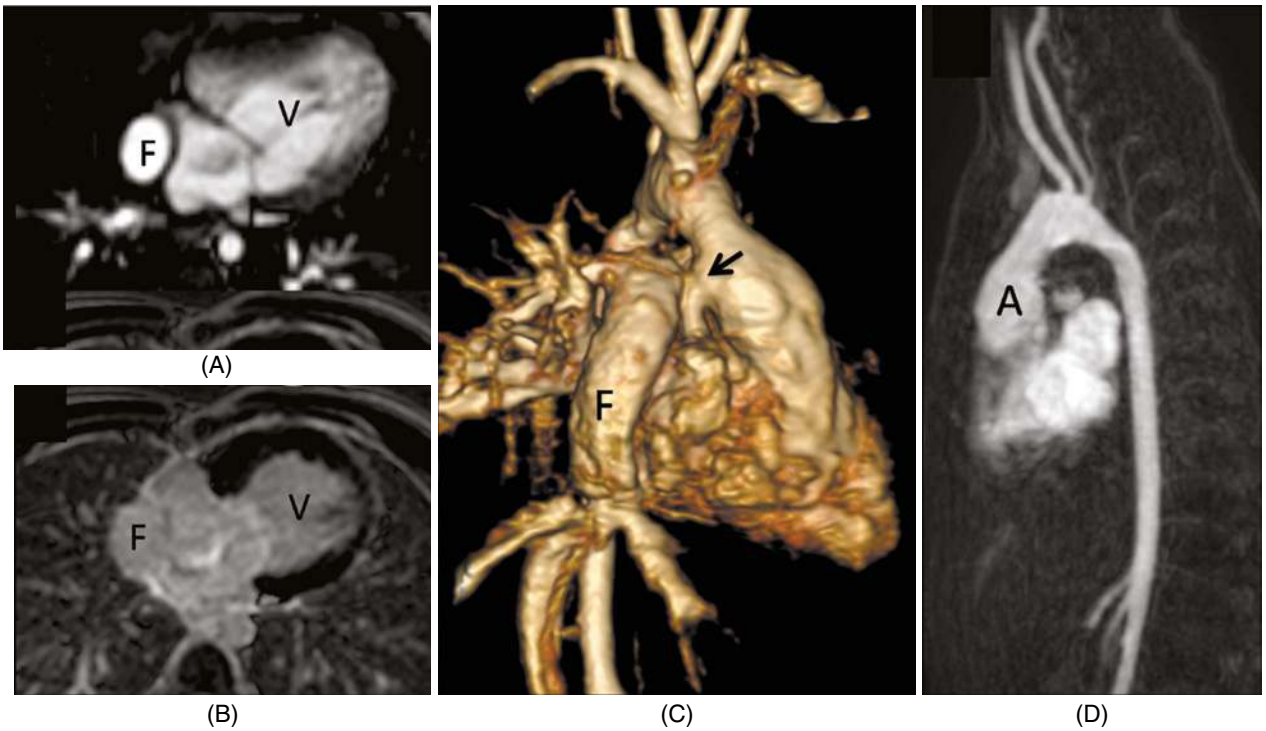

Figure 18.4 A 4-year-old male child with a history of hypoplastic left heart syndrome, status post-stage 3 palliations with an extracardiac Fontan, with a questionable thrombus within the Fontan circuit on echocardiography, for which magnetic resonance imaging was performed. (A) Bright blood image. (B) Delayed enhancement image showing a widely patent Fontan conduit (F) without any intraluminal filling defects to suggest thrombosis. V, ventricle. (C) Anterior projection of a three-dimensional volume rendering demonstrating the entire fat plane from the hepatic veins to the right pulmonary artery, as well as the Damus–Kaye–Stansel anastomosis after a Norwood procedure (black arrow). evaluation of large vascular geometries. With the addition of blood pool contrast agents to enhance the signal, it is possible to exploit the information in the acquired flow-sensitive 4D data to derive angiographic and functional information, although most sites also perform additional high-resolution angiographic sequences for morphology. Such techniques offer the potential to perform unsupervised free breathing 10–15 minute examinations of children with CHD, requiring minimal or no sedation [77]

The use of MRI has primarily been to define anatomy that is problematic to image using two-dimensional echocardiography, including stenotic branch pulmonary arteries, abnormal pulmonary venous drainage, aortic coarctation, complicated 3D interrelationships, and vascular rings. MRI is the non-invasive gold standard for measurement of ejection fraction, ventricular volumes, regurgitant fraction, differential pulmonary blood flow, and Qp/Qs. The major benefit of MRI compared with other imaging modalities is the complete avoidance of ionizing radiation. Image quality for echocardiography is also limited in older children due to less optimal ultrasound windows because of larger distances with growth; many children have also had previous cardiac surgery, which may affect images due to scar tissue and distortion of anatomic relationships. Particularly in older children or adults who do not require sedation, MRI can be another option for imaging, often adding important benefits beyond echocardiography. Unlike echocardiography, MRI is not done to determine the initial cardiac anatomy but is utilized for the imaging of regions that are more problematic to quantitatively evaluate with echocardiography, including right ventricular ejection fraction and flow into the pulmonary circulation. The perioperative utility of MRI includes an important role in determining the timing of surgery for some lesions. Repeated measurement of right ventricular volume, ejection fraction, and pulmonary regurgitant fraction is now an important tool in decision-making regarding the timing of pulmonary valve replacement after tetralogy of Fallot repair; a right ventricular volume of 170 mL/m^2 or more is an indication for valve replacement used by many institutions [78]. Before superior cavopulmonary anastomosis and Fontan operations (Figure 18.4). MRI is becoming essential for non-invasive imaging of the status of the right and left pulmonary arteries, pulmonary veins, aortic arch, atrioventricular valves, and ventricular function apart from venous and aortopulmonary collaterals [79]. If interventional catheterization procedures are not required before these operations, MRI is increasingly used in lieu of cardiac catheterization to obtain anatomic information as well as some functional data to plan the surgery.

Computed tomography

Congenital heart disease is one of the areas that has benefited tremendously from advances in CT technology. The scientific literature of the 1980s and early 1990s describes the use of helical CT mainly for anomalies involving the great vessels, including diagnosis of pulmonary and systemic venous anomalies, coarctation, and vascular rings. Today, ECG-gated

multi-detector CT is the non-invasive gold standard for coronary artery imaging and has been used for evaluation of cardiovascular morphology, myocardial wall motion and function, valvular morphology and function, myocardial perfusion and viability, vessel wall characterization, postoperative changes and stent patency [80]. It is considered an important complementary modality to echocardiography and MRI for all forms of heart disease.

The latest advances in CT scanner technology including dual-source scanner, wide-detector scanner, higher x-ray tube power, high-efficiency detectors, and improved image processing have further consolidated the role of cardiovascular CT in children, particularly in unsedated patients with higher heart rates. The increased scanning speed could be traded, if desired, for improved longitudinal resolution, increased volume of coverage, or improved image quality. This allows for considerable flexibility in CT protocols, especially in small children who cannot lie still, or cannot suspend respiration.

Sedation is rarely required with current CT scanners, in contrast to MRI, which requires at least sedation, and often general anesthesia in young children. Short scan times have documented utility in critically ill patients, and pediatric patients who are unable to breathe-hold. These techniques have obviated the need for breathe-holding and sedation for most indications even in neonates and infants. However, some indications still require intubation and breath-holding in children who are unable to cooperate, including assessment of coronary CT stenosis, RV dependent coronary circulation, or coronary hooding in William syndrome. The main concerns regarding CT are that ionizing radiation exposure occurs in all cases, and IV contrast is necessary in most. Although the risk posed by radiation from CT is minimal, it is real and must be balanced against the benefits of the examination. When performed for appropriate indications with proper technical parameters, especially in newer generation scanners, the benefits far exceed the very small individual risk. It is important to think in terms of what needs to be seen, rather than what can be seen. The term used for this low-risk approach is "As Low As Reasonably Achievable" (ALARA). Based on the clinical indication, the size of the patient, and the anatomical region of interest, a number of parameters may be adjusted in CT to achieve a high-quality study with the lowest radiation exposure possible. Besides strictly limiting the indications for pediatric CT to those in which diagnostic information cannot be obtained from an alternative non-radiation imaging modality such as echocardiography or MRI, there are several means of decreasing the radiation dose, including confining the study to the anatomical region of interest, using a volumetric technique rather than a helical technique, using a larger pitch, decreasing the tube current (mA) to a minimum, shielding of sensitive areas such as the breast, thyroid, gonads, bone marrow and the eye, avoiding the need for repeat examinations by attention to meticulous technique, including use of proper immobilization and sedation, and restricting the dose-intensive retrospective ECG-gated approach to a few indications which require such a technique, such as coronary artery stenosis imaging. Most questions in pediatric cardiac imaging can be answered with prospectively ECG triggered or un-gated studies, which have significantly lower radiation exposure than retrospectively gated studies.

A number of new applications, covering almost every part of the body, have evolved based on the major advantages offered by the multi-detector scanners: improved volume coverage, temporal resolution, and spatial resolution. Some of these applications include coronary imaging, evaluation of aortopulmonary collaterals in pulmonary atresia (Figure 18.5), ventricular function, high-resolution imaging of the lungs, and dynamic airway imaging (Figure 18.6) [81].

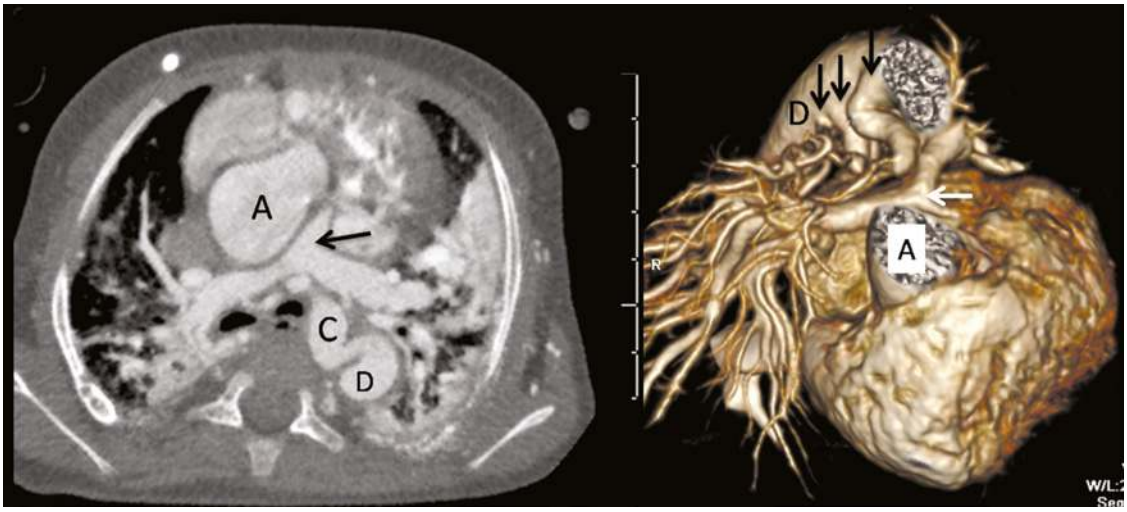

Figure 18.5 One-day-old female with tetralogy of Fallot and pulmonary atresia. A contrast-enhanced computed tomography (CT) scan was ordered to evaluate the status of the pulmonary arteries after echocardiography showed non-confluent branch pulmonary arteries. (A) Transverse image at the level of the branch pulmonary arteries. (B) Right anterior oblique projection of a three-dimensional volume rendering from an unsedated and ungated CT. They clearly demonstrate the confluence of the branch pulmonary arteries (black arrow on A and white arrow on B), and multiple major aortopulmonary collaterals (black arrows on B) arising from the descending aorta (D). Labels: A, ascending aorta; C, largest collateral from the descending aorta.

AL Grawany

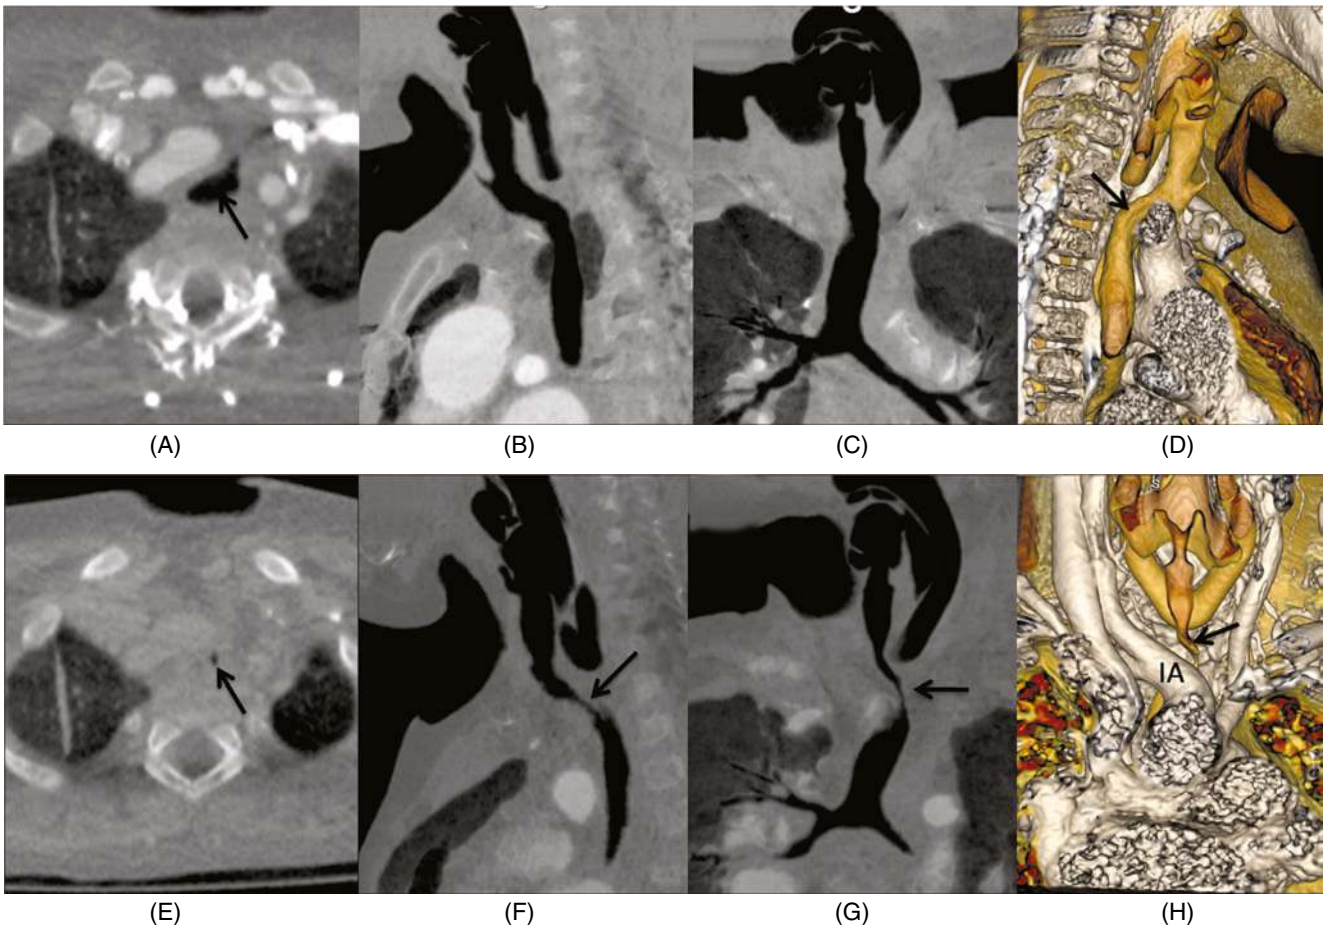

Figure 18.6 A 3.5-year-old female with a history of bilateral lung transplant secondary to filamin A deficiency, presenting with severe stridor related to innominate artery compression of the trachea. Dynamic computed tomography (CT) imaging was performed in inspiration (images A–D), and in expiration (images E–H). (A, E) Axial images at the level of the innominate artery crossing the trachea in inspiration and expiration, respectively, demonstrating a widely patent lumen in inspiration, and near-complete collapse in expiration. (B, F), (C, G) and (D, H) are similar paired inspiratory/expiratory images in the sagittal, coronal, and volume-rendered projections, respectively, showing dynamic narrowing of the trachea (black arrow) at the level of the innominate artery (IA).

Choice of echocardiography, CT, or MRI for non-invasive assessment of CHD

Echocardiography plays a central role in the non-invasive delineation of CHD at all ages. The failure rate with echocardiography increases in the postoperative setting and in older children, when acoustic windows diminish. In the preoperative period, there are numerous examples involving the *extracardiac vasculature*, in which the lack of optimal acoustic windows results in the inadequate characterization of pathology by echocardiography. These include aortic coarctation, anomalous pulmonary veins, scimitar syndrome, systemic venous anomalies, branch pulmonary artery stenosis, and anomalous coronaries. The role of MRI and CT in characterizing the extracardiac vasculature in such patients is well established [82]. On the other hand, echocardiography is quite successful, in the vast majority of cases, in delineating the *intracardiac pathology*, including atrial, ventricular and great arterial situs, the segmental connections, ventricular function, the status of the atrial and ventricular septum and the cardiac valves. But, even in expert hands, some intracardiac defects remain difficult to diagnose by echocardiography. There are an increasing number of papers in the literature addressing the role of MRI as a troubleshooting modality in such situations. A good example is decision-making regarding single- vs. biventricular repair in children with borderline hypoplasia of the left ventricle, in which ventricular volumetry using MRI complements the assessment of intracardiac anatomy by echocardiography. In a series of 154 neonates with left-sided obstructive lesions and a borderline left ventricular volume that underwent an acceptable biventricular repair, only 8% had echocardiographic inclusion criteria to have a good long-term outlook after repair [83]. Echocardiography consistently underestimates left ventricular volume, compared with MRI, and may unfairly preclude some patients from a biventricular repair pathway [84].

Imaging with MRI and CT plays an important role in the postoperative setting when echocardiography windows typically diminish. Examples include tetralogy of Fallot, complex two-ventricle repair, and single-ventricle repair. The goals of postoperative imaging are assessment of ventricular and valvular function, surveillance of grafts, conduits and baffles, early detection of complications, and determination of timing of repeat surgical intervention.

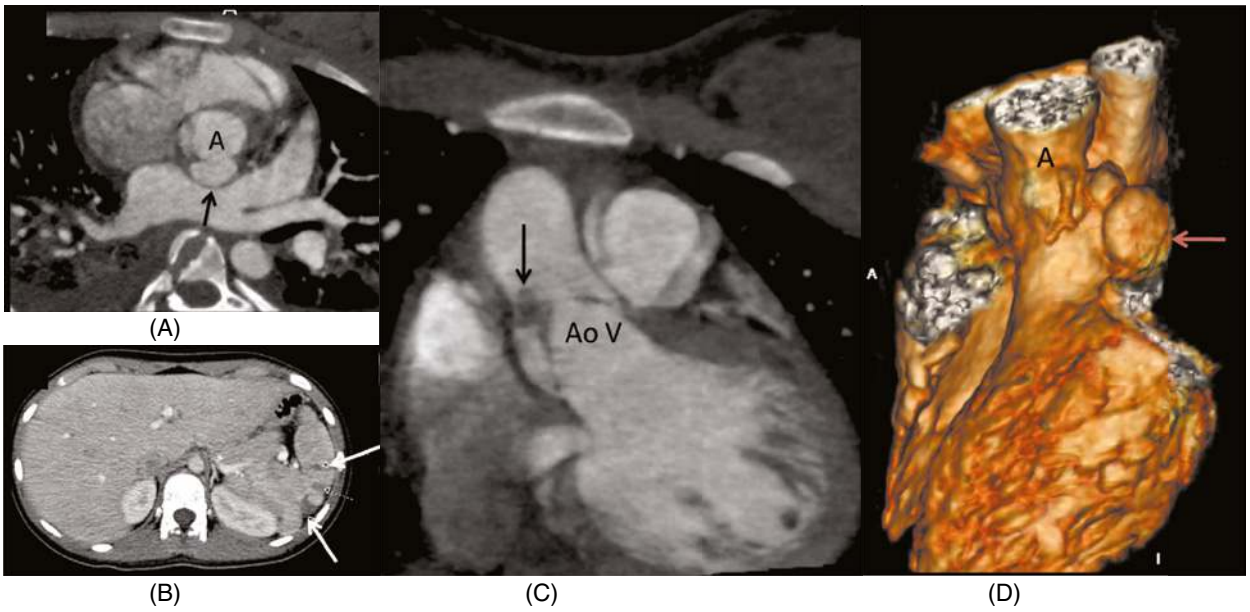

Figure 18.7 Electrocardiogram-gated computed tomography (CT) angiography of the heart in an 18-year-old female with infective endocarditis of the aortic valve and left ventricular outflow tract (LVOT) pseudoaneurysm. (A) Transverse image at the level of the LVOT below the aortic valve demonstrating a 25 × 24 mm wide mouth and extending into the mitral-aortic intervalvular fibrosa. A, ascending aorta. (B) Axial contrast-enhanced image of the upper abdomen demonstrating multiple wedge-shaped hypodensities within the spleen, representing small embolic infarcts. (C) Coronal LVOT view demonstrating thickened aortic valve leaflets (Ao V) and bulky irregular rotations involving the right leaflet. (D) Lateral projection from a three-dimensional volume rendering demonstrating the large subvalvular pseudoaneurysm of the LVOT (pink arrow). CT is helpful for evaluation of the emergent conditions, offering high-resolution imaging of the heart and vasculature without the need for sedation or breath-holding in most cases, and reduces to time spent in the imaging suite. A, ascending aorta.

MRI enjoys a clear superiority over CT for evaluation of intracardiac anatomy, flow, and function. But in situations where the clinical question is restricted to the morphology of the extracardiac vasculature, including the coronaries, pulmonary arteries, aorta, and pulmonary or systemic veins, CT is comparable to MRI (Figure 18.7). Examples of indications appropriate for CT include, but are not limited to, evaluation of total or partial anomalous pulmonary venous return, pulmonary vein stenosis, systemic and pulmonary venous anatomy in heterotaxy, branch pulmonary artery stenosis, confluence and size of branch pulmonary arteries and presence of systemic-pulmonary arterial collaterals in pulmonary atresia, vascular rings, anomalous coronaries, and the presence and severity of coarctation. While MRI provides a more comprehensive evaluation of cardiac form and function in these patients, including calculation of ventricular volumes and function, Qp/Qs, differential pulmonary flow, gradient estimation, and quantification of valvular regurgitation, it is uncertain if the additional information provided by MRI alters clinical decision-making.

There are a few instances where CT is indispensable, as in the presence of pacemakers, aneurysm clips, vascular coils, clips, stents, and thoracic scoliosis rods. CT has the potential to assess the patency of stents or metallic prostheses placed across pulmonary arteries, baffles, coronary arteries, and aortic branches. The spatial resolution of CT is superior to MRI, with the ability to reconstruct up to 0.3 mm in the *z*-axis. Studies have shown that CT is superior to MRI for the evaluation of coronary artery stenosis. One important advantage of CT angiography, when compared with contrast angiography, or even magnetic resonance angiography, is the ability to visualize the vessel wall. CT also provides better delineation of the airway, mediastinal abnormalities, and the pulmonary parenchyma. Other advantages of CT include a reduced need for sedation in young patients, a very short procedure time, and the widespread availability of CT scanners and trained personnel.

In situations where there is a need for serial evaluation, as in the monitoring of aortic root dilatation in tetralogy of Fallot or after a Ross procedure, size of coronary aneurysms in Kawasaki disease, or aortic wall thickness in familial hypercholesterolemia, MRI may be a better choice than CT because of the risk of cumulative radiation dose associated with MRI.

With an increase in awareness of the long-term side effects of sedation, and the advent of new generation CT scanners which freeze respiratory and cardiac motion, decrease radiation exposure by 70 to 80% in children compared with 64 slice scanners, interactive display techniques, and post-processing tools, including 3D printing, and quantitative myocardial and lung perfusion, there has been a significant shift in practice pattern favoring CT over MR for major indications in the setting of CHD.

A comparison between CT and MRI in CHD is given in Table 18.4.

Head ultrasound and other brain imaging modalities

The risk of neurodevelopmental impairment is the most significant concern following repair of CHD, especially in the vulnerable neonatal period. The presence of preoperative neurologic injury increases the risk of extension of the deficit postoperatively and in the long term. However, the most reliable imaging tool to use for neonates to detect brain injury remains controversial. Although head ultrasound (HUS)

AL Grawany

Table 18.4 Computed tomography (CT) and magnetic resonance imaging (MRI) in congenital heart diseases

	CT	MRI
Need for sedation	With new generation scanners, sedation is needed only in a minority of cases, but with 64-slice or older scanners, most children <5 years need sedation	Required in almost all patients <8 years, and most patients <11 years
Duration of sedation	Very short	Long
Intravenous contrast	Excellent safety record, but the risk of an allergic reaction, renal dysfunction, extravasation	No risk of allergic reaction or renal dysfunction Small risk of nephrogenic systemic fibrosis in patients with moderate to severe renal insufficiency
Spatial resolution	Better. True isotropic resolution	Good. Near isotropic resolution
Temporal resolution	Good	Better
Dynamics on angiogram	Multiple dynamics are possible, but not preferred in children due to radiation risk	Multiple dynamics routinely performed, with separation of right-sided, left-sided, and venous structures
Flow	No flow quantification is possible	Flow quantification possible, including stroke volume, Qp: Qs, regurgitant fraction, a gradient across the stenosis
Function	Quantitation of ventricular function possible, but less temporal resolution, along with increased radiation	Quantitation of biventricular function with an excellent temporal resolution
Duration of study	Very short (less than 1 minute)	Long (30–60 minutes)
Contraindications	Acute renal failure, anaphylaxis to iodinated contrast	Pacemakers, AICD
Compatibility with coils, stents and metallic prostheses	Compatible. Metal causes only minimal artifact. Best non-invasive means of evaluating stent patency	Stents and prostheses cause local loss of signal. Hence, stent patency cannot be reliably assessed. Steel coils can cause a large artifact, resulting in a non-diagnostic study. Platinum coils cause less artifact
Health risks	Radiation	Overheating of the body
Ideal indications	Coronary stenosis imaging, anomalous coronaries, emergent studies like aortic dissection or occluded BT shunt, vessel wall evaluation, airway evaluation, need to avoid sedation	Conditions requiring serial studies, screening studies, or conditions requiring evaluation of flow, valvular and ventricular function, and chamber morphology

AICD, automatic implantable cardioverter-defibrillator; BT shunt, Blalock–Taussig shunt; Qp: Qs, pulmonary: systemic blood flow.

continues to be a routine tool in many pediatric cardiac centers, a recent report clearly showed that HUS was not indicated especially in asymptomatic patients. In a series of 167 near- or full-term infants scheduled for cardiac surgery, HUS had evidence of brain injury in 3% of patients compared with 26% on MRI. More importantly, 80% of the HUS findings were false positives [85]. Similar to other reports, abnormal preoperative brain MRI findings are seen in 25–40% of infants with CHD, and correlated with short- and long-term neurodevelopmental impairment. The most common abnormalities seen were white matter injuries, intraventricular hemorrhage, and stroke [86]. Thus, whether there are no symptoms or suspicion of a preoperative injury, routine HUS is not the preferred screening tool, and brain MRI is a more reliable modality. It is important to state that the presence of clinically silent preoperative brain injury on MRI has a low risk of progression and should not delay or preclude clinically indicated and urgent cardiac surgery [87].

KEY POINTS: PREOPERATIVE IMAGING STUDIES

- Chest radiographs are essential preoperative information and play an important role in determining the physiology of CHD.
- Transthoracic echocardiography is the mainstay of preoperative diagnostic imaging but is less reliable with poorer windows as patients age and in the postoperative state.
- Cardiac catheterization is used less frequently for diagnosis but is essential to determine pulmonary to systemic blood flow, PVR, and saturations and pressures in cardiac chambers and vessels in complex lesions.
- Cardiac MRI is a non-invasive modality that is excellent for extracardiac anatomy but requires sedation or anesthesia in young children.
- Cardiac CT is excellent for extracardiac anatomy and is a brief study that requires minimal to no sedation, but it does expose developing patients to ionizing radiation.
- The choice among cardiac catheterization, echocardiography, CT, or MRI for diagnostic anatomic information is complicated and deserves multidisciplinary discussion, including with the anesthesiologist.

Preoperative preparation

Preoperative fasting

The American Society of Anesthesiologists published revised preoperative fasting guidelines in 2017 [88]. These guidelines until recently were the same for children with CHD [89]. Preoperative fasting remains liberalized to allow oral

hydration with clear fluids up to 2 hours prior to the surgical procedure. No increase in gastric volume or acidity has been shown in children with CHD with these liberalized guidelines [90]. Liberal oral hydration is particularly important in children who are cyanotic, polycythemic, those children with outflow tract obstruction, such as hypertrophic cardiomyopathy and aortic stenosis, bicaval pulmonary anastomosis, and shunt-dependent physiology. Children allowed clear liquids on the morning of the surgery were found to be less clinically dehydrated as measured by dry mucous membranes and delayed capillary refill [91]. Preoperative dehydration may be reduced by pre-admitting high-risk children, such as those mentioned earlier, and starting IV hydration until the procedure. If a surgical procedure is delayed, children should be allowed clear oral hydration through the delay. Additionally, liberal oral hydration reduces the risk of hypoglycemia in high-risk children, particularly infants less than 6 months of age who have impaired glycogenolysis and gluconeogenesis and immature glycogen stores. Finally, despite the liberalization of clear oral hydration, *nil per os* (NPO) times should still be verified to reduce the risk of gastric aspiration.

Recently, the need for a minimal period of 2 hours of fasting, and the risk of pulmonary aspiration in children was challenged [92]. Reports have consistently shown the safety of extending clear fluid intake in small children, and even adults to an hour or less prior to the scheduled procedures. Using ultrasound examination of gastric volume, and study of gastric pH, have shown a better physiologic state with less acidosis and accumulation of ketones, more stable hemodynamics at induction and no change in the incidence of aspiration with a liberal approach to fluid intake [93–95]. In addition, the incidence of nausea and vomiting, as well as emergence delirium, is significantly improved. Consequently, multiple societies, including the Society for Pediatric Anesthesia, Association of Pediatric Anesthetists of Great Britain, European Society of Pediatric Anesthetists, and others have endorsed this approach of liberal fluid intake (5 mL/kg) up to 1 hour prior to procedures [96].

Preoperative psychological preparation and premedication

The goal of premedication is to decrease preoperative anxiety, facilitate parental separation, improve cooperation at induction, and reduce sympathetic response at induction. Premedication should be integrated as part of the preoperative assessment. Premedication should not be the rescue solution to the lack of proper preoperative preparation and interaction with the child and family. Preoperative assessment begins with the psychological preparation of the child and the family by developing a rapport with the child and the family. Young children, children with high baseline anxiety, and those with previous negative interactions are at high risk for extreme preoperative anxiety [97]. Pharmacologic premedication is one aspect of multimodal therapies, such as behavioral preparation programs, parental presence at induction, and distraction techniques. Many children have had multiple previous non-cardiac procedures, cardiac surgery, or cardiac catheterizations, and their concerns may be different from the child who has not had been previously anesthetized.

There are multiple benefits to premedication. It eases parental separation and facilitates induction by reducing the amount of inhalational or IV agents necessary for induction. Cyanotic CHD is not a contraindication to premedication. Premedication not only decreases oxygen consumption and increases oxygen saturation in cyanotic children but also achieves sedation and anxiolysis with minimal hemodynamic or respiratory effects. However, respiratory depression with impaired ventilation and oxygenation may occur with multimodal therapy or overdose. An anesthesiologist should be immediately available during and after premedication to monitor ventilation and oxygenation.

Numerous sedative-hypnotics have been used as premedications. Midazolam is the most commonly administered premedication and may be administered by different routes (intranasally 0.3 mg/kg, orally 0.5–1 mg/kg, rectally 0.5–1.0 mg/kg, IV 0.05 mg/kg). The oral route is the most well-tolerated and easily administered. Although increasing doses of 0.75 and 1 mg/kg of oral midazolam are also efficacious, increased ataxia, diplopia, and dysphoric reactions were observed at these higher doses [98]. The nasal route is uncomfortable secondary to the burning sensation and bitter taste. The rectal route has largely been abandoned because the absorption and plasma concentrations are unpredictable. Reliable sedation and anxiolysis were achieved in more than 75% of children at 7.7 ± 2.4, 12.5 ± 4.9, and 16.3 ± 4.2 minutes after intranasal, oral, and rectal administration, respectively [99]. IV midazolam 0.05–0.2 mg/kg is an effective premedication with minimal hemodynamic and respiration effects in those children with an *in situ* IV access.

Intramuscular ketamine 2–5 mg/kg also provides rapid and effective premedication in 5–20 minutes, particularly in those children who are unwilling to accept an oral premedication, secondary to behavioral problems or cognitive issues, or who do not have IV access. Oral ketamine 2–10 mg/kg may also be combined with oral midazolam 0.5 mg/kg to decrease the incidence of adverse events with ketamine and shorten the onset time of anxiolysis. Intranasal sufentanil 2–4 μg/kg is also effective but is used infrequently in children as it may precipitate chest wall rigidity.

Most recently, intranasal dexmedetomidine 0.5–1 μg/kg has been used as a premedication although the onset of action is delayed at 45 minutes [100]. In a meta-analysis of 11 randomized controlled trials, nasal dexmedetomidine was more effective than oral or nasal midazolam as a pre-procedural sedative with a safe profile and no respiratory depression [101]. Dexmedetomidine has been successfully used as a sole agent for sedated transthoracic echocardiography, with a nasal atomizer dose of 1.5–3 mcg/kg in children with cyanotic or acyanotic heart defects, and no desaturation events [102].

Infective endocarditis antibiotic prophylaxis

Infective endocarditis (IE) remains a significant risk for patients with CHD, with a cumulative incidence of 1.1–6/1,000 children, compared with 1.7–6.2/100,000 in the general population. In a large, population-based cohort study of the Quebec CHD Database from 1988 to 2010, the highest risk was with cyanotic lesions, endocardial cushion defects and left-sided obstructive lesions [103]. Invasive dental procedures, cardiac

AL Grawany

surgery within 6 months and age <3 years also increased IE incidence and outcome. The AHA revised the indications for bacterial endocarditis prophylaxis in 2007 [104]. The AHA does not recommend prophylaxis for children undergoing routine gastrointestinal, urologic, and genitourinary procedures with no infected tissue involvement. The indications for bacterial endocarditis prophylaxis have been narrowed significantly compared with previous guidelines and are shown in Box 18.2 and the antibiotic regimens are listed in Box 18.3. Chapter 35 presents additional information about IE prophylaxis.

Box 18.2: Indications for infective endocarditis prophylaxis

- Prosthetic cardiac valve
- History of infective endocarditis
- Unrepaired cyanotic congenital heart defect, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
- Repaired congenital heart defect with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibits endothelialization)
- Cardiac transplantation recipients with cardiac valvular disease

(Source: Adapted from Wilson et al. [104].)

Box 18.3: Treatment regimens for infective endocarditis

Standard general prophylaxis
Amoxicillin
Adult dose: 2 g per os (PO)
Pediatric dose: 50 mg/kg PO; not to exceed 2 g/dose

Unable to take oral medication
Ampicillin
Adult dose: 2 g intravenous/intramuscular (IV/IM)
Pediatric dose: 50 mg/kg IV/IM; not to exceed 2 g/dose

Allergic to penicillin
Clindamycin
Adult dose: 600 mg PO
Pediatric dose: 20 mg/kg PO; not to exceed 600 mg/dose

Allergic to penicillin
Cephalexin or other first- or second-generation oral cephalosporin in equivalent dose (do not use cephalosporins in patients with a history of immediate-type hypersensitivity penicillin allergy, such as urticaria, angioedema, anaphylaxis)
Adult dose: 2 g PO
Pediatric dose: 50 mg/kg PO; not to exceed 2 g/dose

Azithromycin or clarithromycin
Adult dose: 500 mg PO
Pediatric dose: 15 mg/kg PO; not to exceed 500 mg/dose

Allergic to penicillin and unable to take oral medication

Clindamycin
Adult dose: 600 mg IV
Pediatric dose: 20 mg/kg IV; not to exceed 600 mg/dose

(Source: Adapted from Wilson et al. [104].)

Sickle cell disease

The primary clinical manifestations of sickle cell disease are associated crises, including vaso-occlusive, pulmonary dysfunction (acute chest syndrome), and aplastic; infection from splenic dysfunction; and chronic organ damage from chronic sickling, including sickle cell nephropathy, cerebral vascular accidents, and pulmonary hypertension.

There is a concern that CPB may cause sickling and complications such as hemolysis and vaso-occlusive crises from the combined effects of a stressful insult, cooling, and slow red blood cell transit time through the pump. Subsequently, preoperative exchange transfusion is often recommended. There are reports of intraoperative exchange transfusion with the CPB circuit to reduce the sickle cell load [105, 106]. The preoperative transfusion in Sickle Cell Disease Study Group randomized children between an aggressive preoperative exchange transfusion (lowering hemoglobin S to <30%) and a less aggressive simple transfusion (raising hemoglobin to >10 g/dL). Complications related to transfusion were twice as common in the exchange transfusion arm, with no difference in perioperative complications [107]. The exact safe percentage of sickle cell hemoglobin for CPB had never been calculated, but a value of <30%, as with other forms of surgery on these children, has been suggested [108]. Chapter 11 presents additional information about sickle cell disease and CPB.

KEY POINTS: PREOPERATIVE PREPARATION

- Preoperative fasting guidelines are identical for CHD and non-CHD patients; however, CHD patients with systemic-to-pulmonary shunts, cyanosis, and left ventricular outflow tract lesions must not be allowed to become hypovolemic preoperatively.
- Standard premedications, including midazolam, ketamine, and dexmedetomidine, may be used safely in CHD patients, but they must be monitored closely for respiratory depression and desaturation.
- Infective endocarditis prophylaxis is an important consideration in CHD, and the patient's cardiac condition and procedural indication must be assessed to avoid unnecessary antibiotic administration.

Risk stratification

There is an increased risk of perioperative cardiac arrest in children with CHD undergoing both cardiac and noncardiac surgery and diagnostic procedures. The Pediatric Perioperative Cardiac Arrest (POCA) registry reported that 34% of perioperative cardiac arrests over an 11-year period occurred in children with CHD [109]. More than half (54%) of the cardiac arrests in these children were in the general operating rooms, compared with 26% in the cardiac operating rooms and 17% in the cardiac catheterization laboratory. The highest incidence of intraoperative cardiac arrest occurred in children with single-ventricle physiology, and arrests in children with severe aortic stenosis and cardiomyopathy were associated with the highest mortality rates. Three-quarters of

the perioperative cardiac arrests in children with CHD were in children less than 2 years of age, and approximately 75% of the perioperative deaths in children with CHD occurred in children with severe aortic stenosis, cardiomyopathy, and single-ventricle physiology. Additional large databases have also confirmed an increased risk of perioperative cardiac arrest and mortality in children undergoing non-cardiac procedures [110, 111]. Although there are multiple published reports for the management of children with CHD, there is no established methodology to address the magnitude of incremental risk conferred by the degree of severity and compensation of the heart disease [112–118]. The methods available for predicting risks in children with CHD, such as the Risk Adjustment for Congenital Heart Surgery (RACHS-1) score, the Aristotle Basic Complexity (ABC) Score, the original Society of Thoracic Surgeons and the European Association for Cardiothoracic Surgery Mortality score (STS-EACTS score), and the more recently developed Society of Thoracic Surgeons STAT Score are limited to children undergoing only cardiac surgery. These scores risk-stratify children on the complexity of the cardiac surgical procedure rather than the underlying pathophysiology and child's degree of clinical compensation [119–121]. The Risk Adjustment in Congenital Heart Surgery-**1** (RACHS-1) stratifies anatomic diversity into six categories based on age, type of surgery, and in-hospital mortality, using in-hospital mortality as the outcome measure. Category 1 has the lowest in-hospital mortality and category 6 has the highest (Table 18.5). The RACHS-1 method was developed to adjust for baseline case-mix differences for comparing discharge mortality, using a combination of judgment-based and empirical methodologies. The ABC Score assigns a score to each operation, ranging from 1.5 to 15 (with 15 the most complex, based on the primary procedure of the operation). Each procedure is next assigned an index level, which is an integer range of 1 through 4, based on the initial basic score. The ABC Score provides a broad generalization of complexity by dividing surgical procedures from complexity levels. The fundamental principle of the ABC Score is to define the complexity as a constant for the challenge presented by a given surgical procedure. The complexity is the sum of three factors or indices: the potential for operative mortality, the potential for operative morbidity, and the technical difficulty of the operation. The score further discriminates by incorporating two patient modifiers: procedure-dependent factors, including anatomic factors, associate procedures, and age at procedure; and procedure-independent factors, including general factors such as weight. Mortality is calculated on the basis of admission, but only the index operation is analyzed, with the index operation defined as the first operation of the admission that is of operation type "CPB" or "No CPB cardiovascular." The numerator is the number of index operations performed during hospitalizations in which children died before discharge, and the denominator is the number of index operations. The ABC Score classifies more operations, whereas the RACHS-1 discriminates better at the higher end of complexity. The primary objective of the Aristotle Basic Complexity Score is to evaluate and compare surgical management and performance and not predict operative mortality for an individual patient. A recent abstract reported the perioperative complications of children with CHD undergoing non-cardiac procedures using the RACHS-1 score in one tertiary care pediatric cardiac center [122]. The original STS-EACTS estimated procedure-specific mortality that accounted for procedures with a sample size but converted these procedure-specific mortality estimates into a scale from 1.0 to 5.0. The procedures with similar mortality estimates were then grouped into five smaller homogenous categories to minimize within category variation and maximizing between-category variation, allowing for meaningful interpretation of procedures with potentially small sample size. The subsequent STAT CHDS incorporated these STAT mortality categories to identify "positive" and "negative" institutional outliers with identification of centers with similar, higher, and lower center-level mortality rates relative to aggregate rates within each category [123] These comparisons with the revised STAT CHDS can aid in quality assessment and quality improvement initiative (Table 18.6). Unfortunately, these scores are a surgical risk stratification score used to compare inter-institutional perioperative morbidity and mortality

following cardiac surgery rather than risk-stratifying children for non-cardiac surgery and diagnostic procedures.

Preoperative risk assessment of adults with acquired heart disease has helped to identify patients at risk for perioperative complications following non-cardiac surgery. Several risk scoring systems have been developed and validated to identify high-risk adult patients undergoing cardiac and non-cardiac surgery, including those by the AHA and the American College of Cardiology (ACC), the EUROSCORE, and the Cleveland Clinic score [123, 124]. The AHA/ACC system risk stratifies clinical predictors of increased preoperative risk into major, intermediate, and minor predictors. These clinical predictors place adults undergoing non-cardiac surgery into high (>5%), intermediate (1–5%), and low (<1%) risk for perioperative complications. Risk adjustment for adult heart disease is potentially easier than pediatric heart disease as there is less variation in anatomy and pathophysiology.

Risk stratification of children with CHD is challenging due to the smaller number of patients and the higher number of procedure types. Six primary requirements are needed to facilitate meaningful multi-institutional analysis of outcomes: common language; mechanism of data collection; the mechanism for evaluating case complexity; the mechanism to ensure and verify completeness and accuracy of the data; collaboration between medical and surgical subspecialties; and mechanism to obtain longitudinal follow-up data. The development of a risk stratification scoring system for children with CHD undergoing non-cardiac procedures may not only help identify children at increased risk for perioperative complications but also aid in resource utilization. For example, it can be used to determine whether the procedure can be performed safely in an outpatient surgery center or whether it needs to be performed in a tertiary center with cardiothoracic surgery and intensive care back-up based on the child's score. Does a poorly compensated child with a high-risk score need to see their cardiologist to optimize medical management prior to their elective procedure? Does that child need additional diagnostic tests or cardiac interventions prior to the procedure? Adult literature on preoperative conditioning has greatly improved outcomes for adults undergoing cardiac and non-cardiac surgery. Simple maneuvers, such as smoking cessation, starting beta-blockers, statins, aspirin, or an exercise program, can mitigate risk. A scoring system may also be valuable for children with CHD. Can we take certain steps to change a child with a high-risk score to a lower score?

Recent studies have attempted to identify high-risk children with CHD for non-cardiac surgery. Faraoni et al. identified predictors for in-hospital mortality in children with CHD following non-cardiac surgery and developed a risk stratification score that can help decision-making and the development of perioperative management guidelines. Eight preoperative markers were strong predictors of in-hospital mortality, including status as an emergency procedure, severe CHD (e.g., children with uncorrected CHD, children with documented pulmonary hypertension, children with ventricular dysfunction requiring medications, or children listed for heart transplant), single ventricle physiology, surgery within 30 days after initial surgery, need for inotropic support, history of pre-operative CPR, acute or chronic kidney injury, and pre-operative mechanical ventilation [124] Scores ≤ 3 were associated with low risk of mortality, scores ranging from 4 to 6 associated with medium risk, and scores ≥ 7 associated with high risk (Table 18.7). Even though this study did identify high-risk children, in-hospital mortality following non-cardiac surgery is a rare event. Although this cohort reported in-hospital mortality of 4.7%, children with minor CHD were excluded from the analysis, making the true in-hospital mortality rate likely much lower [125] Previous studies have reported an in-hospital mortality rate

Table 18.7 Multivariate risk stratification score to predict postoperative mortality

Emergency procedure	Risk score
Severe SHD	+1
Single Ventricle Physiology	+1
Surgery within 30 days	+1

of 1.06–1.3% in children with CHD following non-cardiac surgery [126]. Furthermore, the data from this cohort was obtained from the administrative database of the ACS NSQIP Pediatric rather than a prospective robust CHD-focused clinical database. Faraoni et al. further attempted to estimate the surgical risk of non-cardiac surgery on the 30-day mortality in children with CHD. The procedure were defined as either low-surgical risk (quartiles 1–3) or high surgical risk (quartile 4) (Table 18.8). Integration of high-surgical risk in the previously above noted factors did not improve prediction of 30-day mortality beyond patient comorbidities and the severity of the cardiac lesion [127]. Lee et al. identified high-risk children for perioperative cardiovascular and respiratory events [128]. Cardiovascular events were defined as inotropic use, cardiac arrest, pulmonary hypertensive crisis, and arrhythmias whereas respiratory events were defined as bronchospasm, laryngospasm, failed intubation/extubation, and oxygen desaturation. The incidence of cardiovascular events was 11.5% and of respiratory events was 4.7%. Age, ASA score ≥ 3, emergency procedure, major and severe CHD, single-ventricle physiology, and mild-severe ventricular function were associated with an increased incidence of perioperative cardiopulmonary complications. These studies have attempted to identify children with CHD at risk for significant perioperative cardiopulmonary complications. A further enhanced risk stratification tool would further identify the degree of pathophysiologic derangement or compensation, helping determine if it is appropriate for the anesthetic to be administered by an anesthesiologist who usually takes care of adults, a pediatric anesthesiologist, or even someone whose practice is limited to pediatric cardiac cases. A score incorporating more detailed patient factors could potentially provide crucial information to the child, the child's family, and the entire perioperative team, including the anesthesiologist, the surgeon, the cardiologist, and the pediatrician. A sample, but

AL Grawany

not validated scoring system, may have the advantage of simple application and the ability to quickly identify children with decompensated or high-risk CHD, incorporating various aspects of the child's pathophysiologic condition (Table 18.9).

KEY POINTS: RISK STRATIFICATION

- CHD patients are significantly more likely to suffer cardiac arrest during anesthesia than patients without heart disease; over 50% of arrests occur outside the cardiac operating room or catheterization laboratory.
- There are several risk stratification methods for hospital mortality after cardiac surgery
- Children at high risk for significant perioperative cardiopulmonary morbidity and mortality following noncardiac surgery include those undergoing emergency procedures, severe CHD, single-ventricle physiology, previous surgery within 30 days, preoperative inotropic support, preoperative CPR, preoperative acute or chronic kidney injury, or preoperative mechanical ventilation.
- An enhanced risk assessment strategy for CHD would additionally take into account the degree of pathophysiologic derangement or compensation.

Introduction

The advances in pediatric cardiology and cardiac surgery over the past 35 years have resulted in a substantial decrease in morbidity and mortality associated with congenital heart disease (CHD). Most congenital heart lesions are now amenable to either anatomical or physiological repair early in infancy. Opinion regarding the optimal timing of corrective surgery for infants with symptomatic CHD regardless of their age or weight has undergone radical change over the past several decades. Rather than the previous strategy of initial palliation followed by correction in early childhood, the current approach favors complete repair within days to weeks of birth, if feasible. Advances in diagnostic and interventional cardiology, the evolution of surgical techniques, management of cardiopulmonary bypass (CPB), as well as refinements in postoperative care have all contributed to the successful strategy of early corrective two-ventricle repair. Most recently, this approach has been extended to include premature and low birthweight (LBW) neonates also. However, the low mortality achieved with two-ventricle repairs has not been the experience in LBW neonates undergoing palliation for single-ventricle defects, such as hypoplastic left heart syndrome (HLHS).

Cardiac surgery in the premature and very LBW neonate presents additional challenges for the anesthesiologist. As for any pediatric cardiac procedure, a thorough understanding of the pathophysiology of the heart defect and planned surgical procedure and anticipation of specific postoperative problems are essential. There are further considerations, however, when providing anesthesia to the premature and LBW neonates: immaturity of the airway, lungs, cardiovascular system, liver, kidney, and central nervous system makes these infants more susceptible not only to surgical but also to anesthetic complications. Finally, as the limits for managing CHD continue to be extended, fetal cardiac interventions (FCIs) emerge as the next challenging frontier.

This chapter will describe general principles relevant to anesthesia for the newborn, including the premature and LBW neonate with CHD. The impact of prematurity, the outcome of cardiac surgery in the premature and LBW neonate, and new directions with transcatheter ductus arteriosus stenting and FCIs will be discussed.

Approach to treatment in the neonate

Early palliation

In the early days of cardiac surgery for neonates, particularly those born prematurely, initial palliation or medical management of congenital cardiac defects was preferred. With technical limitations for various surgical techniques and relatively high risks associated with CPB in small babies, a successful repair often required a certain size or weight. Although the actual "target" weight that a neonate should achieve before the repair was never well documented, newborns with a weight of less than 2.5 kg were considered at higher risk.

The goal of palliative procedures is to control pulmonary blood flow sufficiently to allow for growth, whilst avoiding excessive blood flow to the pulmonary circulation that impairs systemic perfusion and volume overloads in the systemic ventricle. Nevertheless, palliation with a pulmonary artery (PA) band or a modified systemic-to-pulmonary artery shunt, such as a modified Blalock–Taussig (BT) shunt, can be technically demanding procedures in neonates and tend to be even more problematic in those with LBW (see Table 19.1).

Systemic-to-pulmonary artery shunt

While the originally described BT shunt directly connected the subclavian to the pulmonary artery, in contemporary practice a modified version of the procedure is used with an interposition polytetrafluoroethylene (PTFE) (Gore-Tex) graft between the subclavian or innominate artery and pulmonary artery. The size and length of the tube graft as well as the site selected for the proximal anastomosis are critical. A relatively large shunt may lead to excessive pulmonary blood flow, congestive heart failure (CHF), and possible pulmonary vascular obstructive disease (PVOD). Conversely, a small shunt can result in inadequate pulmonary blood flow, lower arterial oxygen saturation (SaO_2), possible shunt thrombosis, and poor growth of the pulmonary arteries making further repair more challenging. Assuming a normal cardiac output and hematocrit, absence of pulmonary venous desaturation and unrestricted mixing of systemic and pulmonary venous return in the atrium, an ideal SaO_2 between 80 and 85% indicates a relatively balanced circulation with a pulmonary to systemic blood flow ratio (Qp: Qs) close to 1:1.

Table 19.1 Complications of palliative surgery

	Early complications	Late complications
Systemic-to-pulmonary artery shunt	Excessive pulmonary blood flow	Distortion of pulmonary arteries
	Heart failure	
	Inadequate pulmonary blood flow	Asymmetrical growth of the pulmonary arteries
	Cyanosis	Pulmonary vascular obstructive disease
	Shunt obstruction: Thrombus Mechanical	
Pulmonary artery banding	Band too loose: excessive pulmonary blood flow	Complications at band site: Distortion and residual stenosis after repair Aneurysm
	Band too tight: inadequate pulmonary blood flow	Complications proximal to band site: Right ventricular hypertrophy Subaortic stenosis Pulmonary valve stenosis
		Complications distal to the band: pulmonary artery stenosis

KEY POINTS: EARLY PALLIATION

- This was the classical approach in the early days of pediatric cardiac surgery due to technical limitations.
- Typical procedures are pulmonary artery banding or systemic-to-pulmonary artery shunt.
- The goal is adequate control of pulmonary blood flow to allow for growth without pulmonary overcirculation, cyanosis, inadequate systemic perfusion, or volume load on the ventricle.
- It is often technically challenging and is associated with many potential early and late complications.
- Recent advances with catheter-based intervention have allowed stenting of the ductus arteriosus to become an alternative to the modified BT shunt in selected patients.

A further problem of a small shunt is the likelihood of outgrowing the shunt size causing progressive cyanosis and requiring earlier surgical intervention. On the other hand, if a larger shunt size (i.e., ≥4.0 mm) is used in a newborn, the excessive pulmonary blood flow may compromise systemic perfusion, cause ventricular volume overload, heart failure, and prolonged postoperative recovery. In our experience, a shunt of 3.5 mm is the optimal size to use in a neonate weighing between 3 and 4 kg. If a 3.0 mm long shunt is used, the risk for acute thrombosis in the early postoperative period is increased, even in LBW neonates. The introduction of anticoagulation with heparin is important once hemostasis has been secured after surgery. Early platelet inhibition with an intravenous glycoprotein IIb/IIIa inhibitor may help reduce the risk of early thrombosis [1]. The mortality rate after neonatal modified BT shunt remains high, particularly for infants weighing less than 3 kg. A large multicenter study from the Society of Thoracic Surgeons Congenital Heart Surgery Database reported an in-hospital mortality rate of 7.2% with a 13% rate of serious morbidity in neonates undergoing modified BT shunt placement without concomitant procedures [2]. Patients weighing <2.5 kg had a four-fold increase in odds of death.

KEY POINTS: SYSTEMIC-TO-PULMONARY ARTERY SHUNT (E.G., MODIFIED BT SHUNT)

- Shunt geometry is critical.
- If the shunt is too large, there is a risk of pulmonary overcirculation, CHF, and the development of PVOD.
- If the shunt is too small, the risk is of inadequate pulmonary blood flow and cyanosis, shunt thrombosis, and early surgery.
- Late complications are distortion and/or asymmetrical growth of pulmonary arteries, and PVOD.

Transcatheter ductus arteriosus stent

Recent advances in transcatheter techniques and device technology have allowed stenting of the ductus arteriosus to be a successful alternative to surgically placed modified BT shunt in patients with ductus-dependent cyanotic CHD. Although patients undergoing ductal stenting have a higher reintervention rate, retrospective multicenter cohort studies support an early survival advantage and shorter ICU stay for infants with ductal stenting [3, 4]. Ductal stent additionally avoids potential operative complications of modified BT shunt placement including vocal cord paralysis, chylothorax, and surgical site infection.

Attention to the ductal morphology is critically important in planning ductal stent placement. CT imaging, in addition to echocardiography, is helpful to delineate ductal anatomy and plan the access site to achieve the straightest trajectory to the ductus. A ductus off the underside of the aortic arch may be successfully approached with left carotid or axillary artery access. While in the past access to these vessels would usually occur via surgical cutdown, there are increasing reports of the safety of percutaneous access [5, 6]. Technical success can be achieved even with a highly tortuous ductus [7]. Prostaglandin E_1 is typically discontinued 6–12 hours prior to the procedure to ensure the ductus is restrictive prior to stenting. Ductal stenting is not without some risk. Complications include ductal spasm, dissection, thrombosis, and stent embolization. Appropriate surgical and extracorporeal membrane oxygenation (ECMO) backup is essential. Drug-eluting stents may decrease reintervention rates and in-stent stenosis [8]. Although immunosuppressive levels of sirolimus may occur for a prolonged period following neonatal stent implantation, negative outcomes related to immunosuppression have not been reported yet [9]. Dual antiplatelet therapy is commonly used to reduce the risk of stent thrombosis.

Banding of the pulmonary artery

Banding of the main PA to reduce pulmonary blood flow can also be a challenging palliative procedure. If the band is too tight, severe cyanosis may occur, and if the band is too loose, the increase in pulmonary blood flow will contribute to CHF and possible PVOD. Distortion of the pulmonary artery secondary to migration of the band may contribute to both proximal and distal artery stenoses and complicate later repair, but can also lead to right ventricular hypertrophy, subaortic stenosis and pulmonary valve stenosis, depending on the relationship of the great arteries to the ventricular outflow tract. Determining the correct size of a band at the time of surgery is difficult. There are no accurate formulas for band size, and the hemodynamic changes at the time of band placement must be closely observed. Ideally, the banded PA will result in an increase in systemic systolic blood pressure of approximately 20%, and, depending on the underlying pathology, a fall in SaO_2 to around 85% breathing room air. The pressure gradient across the band can also be directly measured. Usually, a pressure difference of approximately 50% proximal to the distal across the band is sufficient. Monitoring hemodynamic changes at the time of PA band placement is essential, and anesthetic techniques that could decrease ventricular function or cardiac output are best avoided. Therefore, an opioid technique is most often necessary, and extubation should be delayed until the hemodynamic effect of the band is determined as the patient emerges from anesthesia and starts to wean from mechanical ventilation.

KEY POINTS: BANDING OF THE MAIN PULMONARY ARTERY

- Difficult intraoperative adjustment with constant monitoring of hemodynamic changes requires a stable anesthetic technique with minimal negative effects on ventricular function.
- The goals are an increase in systemic blood pressure by 20%, a decrease in SaO_2 to 85% on room air, and a pressure gradient of 50%.
- Late complications are migration of the band, distortion, stenosis or aneurysms of pulmonary arteries, right ventricular hypertrophy, subaortic stenosis, and pulmonary valve stenosis.

The case for early complete repair

As noted previously, whenever possible, early two-ventricle repair of congenital cardiac defects is the preferred approach in the modern era. Avoiding the long-term consequences of excessive volume and pressure overload on the ventricles and pulmonary vasculature as well as the potentially detrimental effect of chronic hypoxia, early repair allows for more normal growth and development. The considerable advances in cardiac surgery and CPB techniques have contributed to a dramatic reduction in mortality following cardiac surgery in newborns [10–12], but these patients nevertheless remain at risk for significant end-organ impairment, particularly neurological injury [13].

Medical management alone, with the goal of controlling pulmonary blood flow and volume overload on an immature myocardium, is often extremely difficult and unsuccessful. Long-term effects associated with pulmonary overcirculation, chronic volume and/or pressure load on the ventricles, and cyanosis may substantially alter growth and development and lead to myocardial and pulmonary injury which will influence the outcome of subsequent repairs. In most newborns with a large left-to-right shunt, the imbalance

- Cardiomegaly
- Hepatomegaly
- Gallop rhythm

Increased respiratory work
- Tachypnea
- Grunting
- Flaring of alae nasi
- Chest wall retraction

Increased metabolic work
- Failure to thrive
- Poor weight gain

between pulmonary and systemic blood flow will increase as pulmonary vascular resistance (PVR) falls in the first few weeks of life and the physiologic nadir in hematocrit is reached. The clinical manifestations of an infant with CHF are shown in Box 19.1. Tachypnea and the additional work of breathing, secondary to an increase in pulmonary blood flow and total lung water, raise the metabolic demand and the percentage of the total cardiac output directed toward respiratory muscle work (most notably, the diaphragm). This essentially diverts cardiac output from other metabolically active functions, particularly from the splanchnic circulation and absorption of enteral nutrition. The abnormal circulatory physiology is unable to meet metabolic needs and patients fail to achieve normal growth.

KEY POINTS: EARLY COMPLETE REPAIR

- The current strategy of choice is early two-ventricle repair within days to weeks after birth.
- This is possible with recent advances in diagnostic imaging, surgical and CPB techniques, anesthesia, and postoperative intensive care.
- It avoids the long-term detrimental effects of volume and pressure load on immature ventricles as well as chronic hypoxia and polycythemia on growth and development.

Special considerations for the neonate

Although the risk for early mortality in neonates undergoing cardiac surgery may be increased, randomized and prospective studies comparing early surgery versus medical management in hopes of weight gain in neonates with critical lesions have not been performed. Such has been the nature of many of the advances in CHD management. For example, infants with an increased pulmonary blood flow who undergo delayed surgical intervention often fail to thrive and are at risk of recurrent respiratory infections. Their work of breathing and energy expenditure is significantly increased, and cardiomegaly with hyperinflated lung fields is evident on chest radiograph. Cardiac surgery and CPB may be delayed because of concerns for intercurrent infection and the risk of exacerbation or reactivation of inflammatory lung processes, which in turn may cause intrapulmonary shunting and severe hypoxemia, pulmonary hypertension, and prolonged mechanical ventilation. The early repair or palliation of defects to limit pulmonary overcirculation and volume load on the systemic ventricle will often avoid these complications.

The optimal timing of delivery of neonates with CHD is now felt to be at 39–40 weeks' gestation. The former practice of elective delivery at earlier gestational ages (e.g., 36–37 weeks) is associated with higher mortality and should be avoided unless there are clear maternal or fetal indications [14, 15].

The management of neonates in the immediate postoperative period after a two-ventricle repair can be a challenge, but with substantially improved outcomes, mortality alone is no longer a reliable index against which to measure or compare new or alternative treatments in this group of patients. The focus should rather shift to long-term quality of life, ongoing need for reintervention, and hospital admissions. Survival after palliative procedures in patients with complex single-ventricle defects remains lower, although there has been a steady improvement in mortality and longer-term outcomes [16].

Limited physiologic reserve

Care of the critically ill neonate requires an appreciation of the special structural and functional features of immature organs. The neonate appears to respond more quickly and extremely to physiologically stressful circumstances; this may be expressed in terms of rapid changes in, for example, pH, lactic acid, glucose, and temperature [17].

The physiology of the preterm and full-term neonate is characterized by a high metabolic rate and oxygen demand (two- to three-fold increase compared with adults), which may be compromised at times of stress because of limited cardiac and respiratory reserve. The myocardium in the neonate is immature: contractile tissue constitutes only 30% of the myocardial mass, compared with 60% in mature myocardium. In addition, neonates have a lower velocity of shortening, a diminished length–tension relationship, and a reduced ability to respond to afterload stress [18, 19]. Because the compliance of the myocardium is reduced, the stroke volume is relatively fixed, cardiac output is heart rate-dependent, and the Frank–Starling relationship is functional only within a narrow range of left ventricular end-diastolic pressure compared with the mature myocardium. The cytoplasmic reticulum and T-tubular system are underdeveloped, and the neonatal heart is dependent on the trans-sarcolemmal flux of extracellular calcium both to initiate and sustain contraction. It is important to note that much of this information is derived from animal data.

Cardiorespiratory interactions are important in neonates and infants. In simple terms, ventricular interdependence refers to the fact that a relative increase in ventricular end-diastolic volume and pressure causes a shift of the ventricular septum and diminishes the diastolic compliance of the opposing ventricle [20]. This effect is particularly prominent in the

immature myocardium. Therefore, a volume load from an intracardiac shunt or valve regurgitation, and a pressure load from ventricular outflow obstruction or increased vascular resistance, may lead to biventricular dysfunction. For example, in neonates with tetralogy of Fallot and severe outflow obstruction, hypertrophy of the ventricular septum may contribute to diastolic dysfunction of the left ventricle and an increase in end-diastolic pressure. This does not improve immediately after repair in the neonate as it takes some time for the myocardium to remodel. A persistent volume load to the left ventricle following surgery, such as from a residual ventricular septal defect (VSD), may further exacerbate this situation.

The mechanical disadvantage of an increased chest wall compliance and reliance on the diaphragm as the main muscle of respiration limits ventilatory capacity in the neonate. The diaphragm and intercostal muscles have fewer type I muscle fibers (slow-contracting, high-oxidative fibers for sustained activity) and this contributes to early fatigue when the work of breathing is increased. In the newborn, only 25% of fibers in the diaphragm are type I, reaching a mature proportion of 55% by 8–9 months of age [21]. The diaphragmatic function may be significantly compromised by raised intra-abdominal pressure such as from gastric distension, hepatic congestion, and ascites.

The tidal volume of full-term neonates is between 4 and 6 mL/kg and, because of the above mechanical limitations, minute ventilation is dependent on respiratory rate. The resting respiratory rate of the newborn infant is between 30 and 40 breaths/min, which provides the optimal alveolar ventilation to overcome the work of breathing and match the compliance and resistance of the respiratory system. When the work of breathing increases, such as with parenchymal lung disease, airway obstruction, cardiac failure, or increased pulmonary blood flow, a larger proportion of total energy expenditure is required to maintain adequate ventilation. Infants, therefore, fatigue readily and fail to thrive.

The neonate has a reduced functional residual capacity (FRC); FRC is determined by the balance between the chest wall and lung compliance. Closing capacity is increased in newborns with airway closure occurring during normal tidal ventilation [22]. Neonates have reduced oxygen reserve, and in conjunction with the increased basal metabolic rate and oxygen consumption that is two to three times adult levels, are at risk for hypoxemia. Atelectasis and hypoxemia do not occur in the healthy neonate because FRC is maintained by dynamic factors including tachypnea, breath stacking (early inspiration), expiratory breaking (expiratory flow interrupted before zero flow occurs), and from laryngeal breaking (auto positive end-expiratory pressure). The propensity of the neonatal capillary system to leak fluid out of the intravascular space is especially pronounced in the neonatal lung [23], in which the pulmonary vascular bed is almost fully recruited at rest and the increases in lymphatic flow required to handle elevated mean capillary pressures (due to augmented pulmonary blood flow) are limited [24].

The glomerular filtration rate is generally low at birth but normalizes over the first few months of life. Urinary sodium excretion increases slowly during the first 2 years of life, and the inability of immature kidneys to concentrate urine and to excrete acute water and sodium loads makes fluid management in neonates, especially preterm infants, difficult. Urinary acidification capability is limited in neonates and the bicarbonate threshold is reduced. Thus, premature infants have decreased serum bicarbonate levels and lower serum pH (a non-anion gap acidosis). Neonates tolerate fluid restriction poorly, so fasting should be kept to a minimum and intravenous (IV) fluid started early; however, excessive fluid administration (as after CPB) is also poorly tolerated.

Drug pharmacodynamics and kinetics may be different in the newborn because of immature hepatic and renal function. In addition to altered drug metabolism, protein binding and clearance, the drug volume of distribution is affected by the increase in total body water of the neonate compared with the older patient. The dosing of drugs that mainly depends on renal excretion will have to be reduced and, if possible, the plasma concentration should be closely assessed to avoid accumulation and side effects. Larger doses of furosemide are needed to induce diuresis in neonates compared with adults.

The caloric requirement for neonates, especially preterm neonates, is high (100–150 kcal/kg/24 hours) [25]. Supplying adequate nutrition can be a difficult task, especially if the total amount of fluid, administered either parenterally or enterally, must be restricted, as is the case in premature neonates with CHD. Hyperosmolar feedings have been associated with an increased risk of necrotizing enterocolitis (NEC) in the preterm neonate or in the full-term neonate who has decreased splanchnic blood flow of any cause (e.g., left-sided obstructive lesions).

KEY POINTS: LIMITED PHYSIOLOGIC RESERVE

- The immature myocardium has fewer contractile elements, poor compliance, fixed stroke volume, heart rate-dependent cardiac output, and an immature T-tubular system.
- There is also ventricular interdependence.
- Limited ventilatory capacity results in early respiratory muscle fatigue. Closing capacity is increased.
- Immature hepatic and renal function leads to altered drug pharmacokinetics and pharmacodynamics.
- There is a high metabolic demand (100–150 kcal/kg/day) and oxygen demand (6–8 mL/kg/min).

Stress response

In general terms, the "stress response" is a systemic reaction to injury, with hemodynamic, endocrinologic, and immunologic effects (Box 19.2). Stress and adverse postoperative outcomes have been linked in critically ill newborns and infants. This is not surprising given their precarious balance of limited metabolic reserve and increased resting energy demand. Metabolic derangements, such as altered glucose homeostasis, acidosis, salt and water retention, and a catabolic state contributing to protein breakdown and lipolysis, are commonly seen following major stress in sick neonates and infants [17]. This complex of maladaptive processes may be associated with prolonged mechanical ventilation and intensive care unit (ICU) stay as well as with increased morbidity and mortality.

AL Grawany

Box 19.2: Systemic response to injury

Autonomic nervous system activation
- Catecholamine release
- Hypertension, tachycardia, vasoconstriction

Endocrine response
- Anterior pituitary: ↑ ACTH, GH

Metabolic response
- Protein catabolism
- Lipolysis
- Glycogenolysis/gluconeogenesis
- Hyperglycemia
- Salt and water retention

Immunologic responses
- Cytokine production
- Acute-phase response
- Granulocytosis

ACTH, adrenocorticotropic hormone; GH, growth hormone; T_4, thyroxine; T_3, triiodothyronine.

The neuroendocrine stress response is activated by afferent neuronal impulses from the site of injury, traveling via sensory nerves through the dorsal root of the spinal cord to the medulla and hypothalamus. Anesthesia can therefore have a substantial modulating effect on this neuroendocrine pathway by virtue of providing analgesia and loss of consciousness. Outcomes after major surgery in neonates and infants may be improved when the stress response is attenuated. This was initially reported in two controlled, randomized trials comparing N_2O/O_2/curare anesthesia with or without fentanyl in neonates undergoing patent ductus arteriosus (PDA) ligation [17], and with or without halothane in neonates undergoing general surgery [26]. Fentanyl doses as low as 10 μg/kg may be sufficient for effective baseline anesthesia in neonates, although larger doses are necessary for prolonged anesthesia [27].

It is important to distinguish between suppression of the endocrine response and attenuation of hemodynamic response to stress. Because of their direct effects on the myocardium and vascular tone, anesthetic agents can readily suppress the hemodynamic side-effects of the endocrine stress response. However, the postoperative consequences of the endocrine stress response, in particular fluid retention and increased catabolism, remain unabated. Relying on hemodynamic variables to assess the level of "stress" is therefore often inaccurate. Metabolic indices such as hyperglycemia and lactic acidosis are also indirect markers of "stress", particularly as they are influenced by other factors such as cardiac output and catecholamine levels.

The effect of surgical stress has been specifically evaluated in neonates and infants undergoing cardiac surgery. Wood et al. first demonstrated a substantial increase in epinephrine and norepinephrine levels in response to profound hypothermia and circulatory arrest in infants [28]. The hormonal and metabolic response was further characterized by Anand et al. and noted such response to be more extreme and distinct from that seen in adults [29]. In addition to an increase in catecholamine, glucagon, endorphin, and insulin levels, hyperglycemia and hyperlactatemia persisted into the postoperative period. In an important subsequent study, Anand and Hickey compared a high dose sufentanil technique with halothane/morphine anesthesia in 45 neonates undergoing cardiac surgery and deep hypothermic CPB [30]. They reported a significant attenuation of hormonal and metabolic responses to surgery and bypass in the sufentanil group, with less postoperative morbidity and mortality. A conclusion from these studies supported the notion that reducing the stress response with high-dose opioid anesthesia and extending this into the immediate postoperative period is important to reduce the morbidity and mortality associated with congenital heart surgery in neonates.

These studies were performed over two decades ago. During the intervening period, there have been substantial changes in the perioperative care of infants with heart disease as well as in the management of CPB in general; along with these changes, outcomes have considerably improved. Changes in surgical practice, especially the timing of surgery, have altered the perioperative course of numerous defects and reduced the incidence of certain pathophysiologic consequences. Currently, it is less likely to see neonates in the immediate post-bypass period with extensive peripheral edema, anasarca, or other associated complications such as impaired ventricular function, reactive pulmonary hypertension, and substantial alterations in lung compliance and airway resistance. For example, just one or two decades ago, postoperative pulmonary hypertensive crises were relatively common events in infants who had been exposed to weeks or months of high pulmonary pressure and flow, such as truncus arteriosus, complete atrioventricular canal defects, and the transposition of the great arteries with VSDs. High-dose opioids were an important management component for patients at risk for pulmonary hypertensive crises. In current practice, however, these patients are operated upon at an earlier age and are therefore less likely to have significant or irreversible changes in the pulmonary vascular bed. Consequently, a strategy of high-dose opioid anesthesia to blunt the stress response may be a less critical determinant of outcome.

Further, it has been well demonstrated that high-dose opioid anesthetic techniques do not consistently block the endocrine stress response to cardiac surgery. The dose of sufentanil used by Anand and Hickey was extremely high and difficult to translate to the more common practice of fentanyl-based anesthesia. More recent studies in neonates, infants, and older children undergoing cardiac surgery have demonstrated attenuation of the pre-bypass endocrine and hemodynamic response to surgical stimulation with a variety of anesthetic techniques. These studies have included high-dose fentanyl (50 μg/kg) either by bolus or infusion [31, 32], high-dose bolus fentanyl (25–150 μg/kg) with or without low-dose isoflurane [33], remifentanil infusions at various rates (0.25–5 μg/kg/min) [34], and more recently low-dose fentanyl (10-25 μg/kg) with dexmedetomidine [35, 36]. Based upon the lack of significant stress responses reported in these studies, it is reasonable to conclude that there was appropriate neuraxial inhibition in these patients and that they were adequately anesthetized during the surgery. It is not possible to conclude, however, that one technique is superior to

another. No specific dose-response between plasma opioid level and level of hormone or metabolic stress response has been established, nor has a specific benefit been demonstrated for the method or route of opioid administration, i.e., bolus or continuous infusion.

The use of lower doses of opioids may reduce the duration of mechanical ventilation and ICU length of stay by avoiding the resulting respiratory depression from a high-dose opioid technique [37]. Recent studies have described successful early extubation of neonates undergoing heart surgery involving CPB with general anesthesia using low-dose fentanyl, volatile anesthetic agent and dexmedetomidine, administered as a continuous infusion without loading [37–39].

KEY POINTS: STRESS RESPONSE

- Systemic response to injury from surgical trauma includes autonomic nervous system activation, endocrine, metabolic and immunologic effects
- Can be associated with prolonged mechanical ventilation, ICU stay, and increased morbidity and mortality
- High dose opioid strategies do not consistently block neuroendocrine stress response during bypass but remain the main component of anesthetic management of neonates undergoing cardiac surgery

Systemic inflammatory response to CPB

Besides the surgical stimulus, additional factors contributing to the stress response include the effects of CPB, i.e., hypothermia, contact activation, hemodilution, and non-pulsatile flow [40–42]. It is well recognized that the exposure of blood elements to the non-endothelial surfaces of the CPB circuit, along with ischemia–reperfusion injury, induces a systemic inflammatory response with activation of numerous signaling cascades including complement, thrombotic, fibrinolytic, proinflammatory cytokine and oxygen-free radical pathways. These effects are magnified in neonates due to the higher bypass circuit surface area and priming volume relative to patient blood volume.

Cytokines stimulate the production of acute-phase proteins in the liver (i.e., C-reactive protein, fibrinogen, α_2-macroglobulin, and other anti-proteinases), stimulate the adhesion molecule cascade, increase protein catabolism, and augment the release of adrenocorticotropic hormone from the anterior pituitary [43, 44]. In contrast to the effect of anesthesia in the pre-bypass phase, anesthesia techniques have not been demonstrated to consistently obtund the stress responses to bypass [30, 32, 45]. This is primarily because CPB introduces a second mechanism for triggering the stress response independent of surgical stimulation. The inflammatory response and its clinical manifestation are even more pronounced in very LBW and premature newborns, in part due to the immaturity of the responding systems, low receptor density, and low vascular tone. The immature myocardium is more vulnerable to reactive oxygen species due to developmental differences compared to the adult heart, and additionally because of depleted antioxidant reserve in those with cyanotic heart disease [46].

The endothelial glycocalyx plays a key role in vascular integrity. The glycocalyx is vulnerable to several perioperative insults including ischemia-reperfusion, inflammation, and hypervolemia. Shedding of the glycocalyx in infants undergoing CPB is increased following aortic clamping (ischemia of the heart and lungs) and greatest with global ischemia during deep hypothermic circulatory arrest (DHCA) [47]. Diminution of the endothelial glycocalyx increases capillary permeability to water, solutes, and colloids, leading to tissue edema and potential multi-organ dysfunction. Total lung water is increased with an associated decrease in lung compliance and an increase in the alveolar-to-arterial O_2 gradient. Myocardial edema leads to impaired ventricular systolic and diastolic function. A secondary fall in cardiac output by 20–30% is common in neonates in the first 6–12 hours following surgery, contributing to decreased renal function and oliguria [48]. Sternal closure may need to be delayed due to mediastinal edema and associated cardiorespiratory compromise when the closure is attempted. Ascites, hepatic congestion, and bowel edema may affect mechanical ventilation, cause ileus, and delay feeding.

In recent years, numerous strategies have evolved to limit the effect of the endothelial injury resulting from the systemic inflammatory response to CPB. Significant advances in circuit miniaturization and reducing blood-contacting surfaces have been made [49]. A variety of anti-inflammatory treatment modalities have been studied, including leukocyte depletion, neutrophil adhesion blockade, and heparin coating of the CPB circuit to reduce complement and leukocyte activation. To date, no single treatment has been shown to attenuate the endothelial reaction and clinical response following CPB in neonates and infants. The most important strategy remains limiting both the time spent on bypass and the use of DHCA. This is clearly dependent, however, upon surgical expertise, experience, and patient anatomy and size. Recent advances in perfusion technology allow lower body perfusion during arch reconstruction by direct cannulation of the innominate artery and descending aorta with the full flow at mild hypothermia. These techniques should reduce splanchnic and renal ischemia-reperfusion injury; however, further clinical research is needed to demonstrate improved patient outcomes [50].

Attenuation of the stress response with deep anesthesia and hypothermia, the use of antioxidants such as mannitol, perioperative treatment with anti-inflammatory agents such as corticosteroids, adjustments in prime composition to maintain hematocrit and oncotic pressures, and finally ultrafiltration during rewarming or immediately after bypass are all attempts to further limit the clinical consequences of the inflammatory response. Corticosteroids are routinely given to infants undergoing cardiac surgery with CPB to ameliorate the inflammatory response but are of uncertain benefit [51]. In a recent multicenter trial, 1 mg/kg of dexamethasone after anesthesia induction was found to have little or no effect on mortality or major complication among 394 randomized infants (median age, 6 months) undergoing cardiac surgery with CPB [52]. A larger placebo-controlled study is currently enrolling 1,200 infants to investigate the safety and efficacy of methylprednisolone administered into the CPB pump prime [53].

Conventional CPB delivers hyperoxic perfusion. Normoxic management of CPB may reduce oxidative stress, particularly in cyanotic infants [54]. The addition of nitric oxide to

AL Grawany

sweep gas during CPB may have a myocardial protective effect following ischemia-reperfusion. A randomized controlled trial showed a lower incidence of low cardiac output state with the delivery of nitric oxide to the CPB circuit, with the benefit most marked in children less than 6 weeks of age [55]. Multicenter trials of these interventions delivered individually or in combination are needed to confirm improvements in clinical outcomes, whilst accounting for significant inter- and intra-hospital heterogeneity in practice [56].

An increase in glucagon levels, insulin resistance, and steroid administration may contribute to significant hyperglycemia following bypass in neonates. Tight glycemic control can be achieved with a low hypoglycemia rate after cardiac surgery in children, but it does not significantly change the infection rate, mortality, length of stay, or neurodevelopmental outcome, as compared with standard care [57, 58]. The use of insulin must be undertaken with caution, and frequent measurement of glucose levels is essential because of the risk of unintended hypoglycemia. In addition to the activation of stress hormones during CPB, triiodothyronine (T_3) levels have been shown to be low in neonates after CPB and may remain low for up to 48 hours after surgery, particularly if a sick euthyroid state develops and there is decreased conversion of thyroxine to the active T_3 in peripheral tissues [59].

Hemofiltration has become a technique commonly used to hemoconcentrate and possibly remove inflammatory mediators (complement, endotoxin, and cytokines) during or after CPB [60–63]. Hemofiltration techniques include "modified ultrafiltration" whereby the patient's blood volume is filtered after completion of the bypass, "conventional hemofiltration" whereby both the patient and circuit are filtered during rewarming on bypass, and "zero-balance ultrafiltration" in which high-volume ultrafiltration essentially washes the patient and circuit blood volumes during the rewarming process [64]. High flow rates during modified ultrafiltration have been shown to transiently decrease the cerebral circulation in young infants compared with lower blood flow rates; this could be important in newborns after CPB who may have altered cerebral autoregulation [65].

Early clinical experience suggested improved systolic and diastolic pressures after modified ultrafiltration, as well as improved pulmonary function with reductions noted in PVR and total lung water [60, 61]. While modified ultrafiltration post-bypass has been shown to improve early hemodynamic and pulmonary function, the initial increase in pulmonary compliance may not be sustained beyond the immediate post-ultrafiltration period [66]. These techniques are useful to hemoconcentrate and remove total body water, but they do not prevent the inflammatory response. The advantages of hemofiltration may be less relevant with developments in CPB circuit miniaturization [67].

Peritoneal dialysis has been recommended to treat total body fluid overload, particularly during low output states following infant cardiac surgery. Recent studies have reported successful prevention of fluid overload with continuous peritoneal dialysis, without significant morbidity and hemodynamic effects [68, 69]. In addition to decompressing the abdomen, which may, in turn, improve respiratory mechanics and requirements for mechanical ventilation, peritoneal dialysis also assists with postoperative fluid balance and may have the potential benefit of removing proinflammatory cytokines [70].

KEY POINTS: SYSTEMIC INFLAMMATORY RESPONSE TO CPB

- It is triggered by exposure of blood elements to non-endothelial surfaces of the bypass circuit.
- There is an activation of numerous signaling cascades: complement, thrombosis, fibrinolysis, cytokines, and oxygen-free radical pathways.
- There is an exaggerated response in neonates due to relatively large CPB circuit surface and prime volume as well as immature organ systems.
- Clinical manifestations are increased lung water, decreased lung compliance, capillary leak, myocardial edema and decreased cardiac output, bowel edema, and ascites.
- There are various preventive strategies, but no single treatment has proven to be fully effective yet. Strategies include limiting bypass and DHCA times, attenuation of the stress response, corticosteroids, antioxidants, ultrafiltration, and peritoneal dialysis.

Neurologic injury

Neurodevelopmental and behavioral disabilities remain prevalent in survivors after neonatal congenital heart surgery. The etiology is multifactorial regarding timing and mechanisms. Brain magnetic resonance imaging (MRI) data performed both before and after newborn cardiac surgery using hypothermic bypass demonstrates a disturbing incidence of white matter injury and the development of periventricular leukomalacia (PVL) [71–79]. Pathogenesis of PVL in premature infants relates to three interacting factors. There is an incomplete development of the vascular supply of the cerebral white matter, impairment in cerebral blood flow regulation, and thirdly, the maturation-dependent vulnerability of the oligodendroglial precursor cell to ischemia-reperfusion injury [80]. Term neonates with CHD may share similar vulnerabilities to white matter injury with hypoxia/ischemia. Elevations of brain lactate on MR spectroscopy, indicating impaired cerebral metabolism, are found in over half of patients with CHD before neonatal surgery [81]. In neonates with transposition of the great arteries, preoperative brain injury is associated with hypoxemia and a longer time to surgery [71].

Adverse neurological outcomes are multifactorial after bypass and may be secondary to the duration of CPB [82, 83], rate and depth of cooling [84–86], perfusion flow rate [87], duration of circulatory arrest, pH management on bypass [10], hematocrit [11, 88–90], and embolic events. Strategies to optimize cerebral protection during deep hypothermic bypass, with or without circulatory arrest, include longer duration of cooling (>20 minutes), the use of the pH-stat strategy of blood gas management (addition of CO_2 to the oxygenator), and maintenance of a higher hematocrit (>25%) [91, 92].

Deep hypothermia (≤18 °C) with circulatory arrest or antegrade cerebral perfusion may be necessary for selected neonates undergoing cardiac surgery to facilitate the surgical procedure, e.g., reconstruction of the aortic arch. In the past, DHCA was associated with a high incidence of obvious neurological injury manifesting as postoperative seizure activity

and choreoathetosis. While there may be no optimal "safe" duration of DHCA, the accepted limit has been reduced over the years from approximately 60 minutes to 30 minutes at temperatures <20°C [12, 93]. Multiple studies have compared neurological outcomes in neonates undergoing aortic arch reconstruction using either DHCA or antegrade cerebral perfusion and found no difference in neurodevelopmental outcome or new postoperative MRI injury [93–98]. It remains debatable whether more prolonged use of antegrade cerebral perfusion is as safe as a short run of DHCA.

The risk of brain injury in newborns is clear and supports the use of routine perioperative neurologic monitoring with technology such as near-infrared spectroscopy (NIRS), transcranial Doppler assessment of cerebral blood flow velocity, and continuous EEG [91, 99, 100]. Multiple studies of infants undergoing cardiac surgery have found associations between diminished cerebral oxygen delivery, as indicated by NIRS monitoring, and worse neurodevelopmental outcome and/or increased white matter injury on MRI [101–103]. Yet prospective studies on the effects of interventions in response to low cerebral oximetry measurements on neurologic outcomes are lacking.

With improvements in neurologic protection over recent years, the incidence of perioperative clinical seizures has declined substantially. However, subclinical seizures remain common with as many as 7% of postoperative neonates experiencing electroencephalographic only seizures (69% focal; 62% electrographic status epilepticus) [104]. Recognition of the incidence of subclinical seizures has led to increasing consensus on the benefit of routine use of continuous EEG monitoring after neonatal cardiac surgery. Data demonstrating a beneficial effect of aggressive management of perioperative electrographic seizures on long-term neurodevelopment outcomes are lacking.

Given the known risks associated with complex CHD, regular neurodevelopmental assessment throughout childhood and targeted multidisciplinary therapy are critical to optimizing outcomes and quality of life of patients [105]. The plasticity of the immature nervous system is such that it responds well to well-timed, family-centered high-quality early intervention [106, 107]. See Chapter 14 for an extensive discussion of neurological monitoring, risk factors, and outcomes.

KEY POINTS: NEUROLOGICAL INJURY

- Long-term neurodevelopment is an important outcome marker for pediatric cardiac surgery.
- The causes of neurological injury are multifactorial; it can happen *in utero*, as pre-, intra-, and post-operative events, or as a result of CPB management strategy.
- There is no "safe" duration of DHCA, and the accepted limit is now ~30 minutes at <20 °C.
- Cerebral protection during DHCA involves slow cooling (>20 minutes), higher hematocrit (>25%), and pH-stat management.
- There has been a change in practice toward antegrade cerebral perfusion as an alternative to DHCA.

Premature infants and low birth weight neonates

For term newborns with a weight >2.5 kg, positive outcomes after cardiac surgery and CPB are well established, and early complete repair is currently considered the standard of care. More recently, the improving survival of premature and LBW neonates has added a new dimension to the management of CHD. Although the technical aspects of CPB in small neonates are challenging, recent surgical advances allow routine corrective repair of complex heart disease in neonates weighing less than 2,000 g. In our experience, neither gestational age nor patient size precludes successful complete repair of lesions such as tetralogy of Fallot, truncus arteriosus, and transposition of the great arteries.

In addition to the physiologic limitations previously described for any newborn, the effects of the underlying cardiac disease and the implications of the surgical interventions, typical complications of prematurity must be considered. The management of respiratory distress syndrome, fluid overload, NEC, and intraventricular hemorrhage can be extremely challenging in premature babies with CHD. Many of these complications can influence the timing and achievability of complete surgical repairs. Even with technically successful repairs in premature and LBW neonates, the effects on future development and the potential need for re-interventions have not been established and will require further investigations and long-term follow-up [108, 109]. Table 19.2 summarizes the major challenges in the perioperative management of premature infant [110].

Pulmonary function

The immature airway and lungs of premature and very LBW neonates predispose them to hypoxia and ventilation difficulties. Lung compliance is reduced because the alveoli are primarily composed of thick-walled saccular spaces. The very compliant chest wall results in a significant mechanical disadvantage with lower FRC and O_2 reserve, and early respiratory muscle fatigue. Dead space ventilation as a proportion of tidal volume is increased. Production of surfactant begins between 23- and 24-weeks' gestation and may be inadequate until 36-weeks' gestation [111]. Respiratory distress syndrome (RDS) from surfactant deficiency results in low lung volumes and poor compliance, increased intrapulmonary shunt, and ventilation/perfusion (V/Q) mismatch, leading to severe hypoxia. Immature respiratory drive, increased pulmonary edema due to patent ductus arteriosus, pulmonary infections, ventilator-associated lung injury, atelectasis, and secondary surfactant deficiency contribute to respiratory failure [112]. Invasive ventilation and high concentration oxygen give rise to bronchopulmonary dysplasia (BPD) by inducing heterogenous lung injury with regions of atelectasis and other regions of hyperinflation, airway smooth muscle hyperplasia, interstitial fibrosis and pulmonary vascular remodeling.

With the introduction of antenatal steroids and intratracheal surfactants, both morbidity and mortality of RDS and BPD have decreased [112]. Standard of care has shifted to initial treatment with non-invasive ventilatory support in preterm infants

AL Grawany

Table 19.2 Physiologic challenges for management of the premature neonate with congenital heart disease

System	Physiologic challenges	Considerations for perioperative management
RDS, apnea of prematurity	• RDS may contribute to poor oxygenation. • Oxygenation goals not well defined in preterm • Permissive hypercapnia reduces BPD in preterm infants but may alter hemodynamics in CHD patient • Premature neonates at risk for apnea	• Intubation and surfactant/positive pressure ventilation may be necessary • SUPPORT trial found lower oxygenation goals reduced BPD and ROP but increased mortality. • Consider ventilator strategies utilizing permissive hypercapnia. • Utilize caffeine for apnea due to improved survival without neurodevelopmental impairment in VLBW infants. Aminophylline prevents apnea in term neonates on prostaglandin but not studied in premature neonates.
Preoperative genetic testing	• Genetic abnormalities more common in infants with CHD (especially trisomy 13, 18, 21, and 22q11.1 deletions) • DiGeorge syndrome occurs in 12% of infants with CHD; common in conotruncal lesions	• Karyotype and/or specific testing for 22q11.2 deletion (DiGeorge syndrome) may be warranted.
Neurologic Imaging	• Up to 50% with preoperative white matter injury or stroke • Risk factors are hypoxemia and time to surgery.	• Obtain early cranial ultrasound. • Preoperative MRI when indicated/feasible

without cardiorespiratory failure at birth. Less invasive surfactant administration methods show potential in improving long-term outcomes [113]. A target SpO_2 of 90-95% in infants with gestational age <28 weeks until 36 weeks' postmenstrual age is recommended based on three large clinical trials that showed a lower SpO_2 range had a greater rate of mortality [114]. The demographic profile of BPD has shifted to earlier preterm infants (<29 weeks gestational age). The effect of BPD on the outcome of cardiac surgery in the current era is unknown.

The potential for RDS is another important consideration for premature infants undergoing CPB. Lung injury post-cardiac surgery is triggered by shear forces and contact of blood with the non-endothelial surfaces of the extracorporeal circuit, resulting in activation of a systemic inflammatory response [115]. In addition, significant depletion of surfactant may occur [116], and when combined with endothelial injury, can contribute to pulmonary hypertension and altered lung compliance in the immediate postoperative period. Except for individual case reports and small single-center studies [117, 118], there are no data to support prophylactic use of surfactant, pre- or post-CPB.

Excessive pulmonary flow from certain cardiac defects will increase total lung water and prevent or delay weaning from ventilatory support in the LBW or premature newborn. Although RDS with increased PVR will limit pulmonary blood flow initially, as the lung injury resolves and the PVR decreases, pulmonary blood flow will substantially increase. For premature infants without RDS, the pulmonary vascular tone is typically low, and pulmonary blood flow may be extremely high in cardiac defects with a large left-to-right shunt, such as truncus arteriosus. Medical management with mechanical ventilation, diuretics, inotropic support, and afterload reduction is often ineffective in treating systemic hypoperfusion due to significant run-off to the pulmonary circulation. As a result, continuing conservative treatment while waiting for an appropriate weight gain is often not a reasonable option, and surgical intervention is the only alternative. Palliation with a pulmonary artery band to limit pulmonary blood flow is technically challenging in LBW or premature newborns, and subsequent distortion of the pulmonary arteries may severely complicate future surgical procedures. Therefore, early complete surgical repair may be indicated to provide optimal conditions for growth and development.

A similar problem arises in cyanotic LBW or premature neonates with ductus-dependent pulmonary blood flow. A longer-term infusion of prostaglandin E_1 may be considered, but may result in unwanted inherent side-effects (apnea, edema, gastric outlet obstruction). In addition, the run-off across a large ductus is difficult to control and systemic hypoperfusion may develop. Low concentrations may be used (0.01 μg/kg/min), but a clear dose-response relationship between ductal size and PGE_1 concentration has not been demonstrated. Palliation with a modified BT shunt or ductal stent is possible, but potential problems are a distortion of the pulmonary arteries, thrombosis or stenosis and reduced pulmonary blood flow, or, on the other hand, excessive flow across the shunt, resulting in systemic hypoperfusion and cardiac failure from volume overload. Therefore, the side-effects of palliation could further impair growth and development, and the best alternative may be early surgical repair. Successful repair in LBW and premature infants with tetralogy of Fallot has been reported [119, 120]. The postoperative course of these patients is often prolonged and characterized by restrictive right ventricular physiology. Nevertheless, if complete repair has been accomplished without significant residual lesion, this early anatomic correction provides the best option for longer-term survival and growth.

Premature and LBW infants with single-ventricle physiology are difficult to manage, and an adequate balance between the ductus-dependent pulmonary or systemic flow may not be achieved. Systemic hypoperfusion (NEC, renal hypoperfusion) and feeding intolerance are commonly encountered.

In general, size limitations are a considerable problem in newborns who require stage I palliation for conditions such as HLHS. Balancing systemic and pulmonary blood flow in an LBW newborn after a Norwood operation can be challenging. The hybrid procedure is an alternative to the Norwood palliation that may be preferable in the LBW neonate. The hybrid technique is performed in the catheterization laboratory or a special angiography operating room suite. After exposure through a median sternotomy, both pulmonary arteries are banded and the patents ductus arteriosus is stented via the main pulmonary artery under fluoroscopic guidance. The hybrid procedure does not require CPB, thereby avoiding the potential cannulation problems and risk for additional neurologic injury [121, 122]. Retrospective studies suggest a survival benefit of the hybrid procedure in premature and LBW neonates, but prospective randomized studies are lacking [123–126]. A novel, nonsurgical palliation for newborns with HLHS using endoluminal pulmonary banding and duct stenting has recently been described [127].

KEY POINTS: PULMONARY FUNCTION IN PREMATURE AND VERY LBW NEONATES

- There is a mechanical disadvantage (reduced lung compliance, increased chest wall compliance, low FRC), surfactant deficiency, increased V/Q mismatch, and early fatigue of respiratory muscles.
- BPD and RDS may complicate management and preclude early extubation.
- There is pulmonary edema and increased work of breathing due to increased pulmonary blood flow with certain types of CHD.

Cardiac function

Fetal cardiac myocytes are morphologically different from those of adults. The fetal myocyte is smaller, has only one nucleus and fewer myofibrils, which are less well organized [128]. In the third trimester, a period of rapid cardiac growth, primarily driven by cardiomyocyte hyperplasia occurs. Birth results in a switch in the growth of the myocardium from the fetal hyperplastic to the adult hypertrophic pattern [128]. Preterm birth necessitates abnormal myocyte hypertrophy to achieve a normal postnatal cardiac mass [129]. At birth, the preterm heart tends to be more globular. Clinically stable preterm infants have a normal left ventricular systolic function but altered diastolic function, with greater dependence on atrial contraction [130, 131]. Echocardiography data suggests the left ventricular systolic performance in premature infants during early life is preserved in the setting of a lower afterload [132]. Altered diastolic dysfunction persists at 3 months of age in preterm infants [129]. The morphological and functional cardiac impairments in individuals born preterm are apparent in neonatal life persist across childhood and into young adulthood [133]. This population may be more vulnerable to cardiovascular disease as they age [134].

Necrotizing enterocolitis

CHD is an important predisposing factor for developing NEC [135]. The incidence of NEC in neonates undergoing cardiac surgery is around 2-4% [136–138]. Epidemiologic evidence suggests that the most common form of NEC in the premature neonate is triggered by inflammatory and microbial processes and not by a preceding ischemic event [139]. In contrast, NEC in term infants with CHD appears to be a clinically distinct entity and is due primarily to intestinal ischemic injury [135, 139]. CHD lesions with the highest risk of NEC are those with significant systemic to pulmonary circulation runoff, specifically HLHS, aortopulmonary window, truncus arteriosus, and patients with episodes of poor systemic perfusion [137]. Persistent diastolic flow reversal in the abdominal aortic Doppler profile is associated with an increased risk of NEC in term infants with CHD [140].

Clinical signs of NEC include abdominal distension, feeding intolerance, temperature, and glucose instability, hemepositive or frank blood in the stool, abdominal guarding, and tenderness. Abdominal radiographic examinations may demonstrate distension or an abnormal gas pattern, pneumatosis, portal venous gas, or intraperitoneal air consistent with perforation. Thrombocytopenia and leukocytosis are usually evident on blood examination. If NEC results in perforation or severe bowel ischemia, the neonate may develop sepsis with hypotension, capillary leak, poor perfusion, and edema. On most occasions, patients can be treated medically with antibiotics, vasoactive support, and parenteral nutrition; less frequently, laparotomy and bowel resection may be necessary [141, 142]. The key to management is to improve perfusion and O_2 delivery to the splanchnic system. Therefore, once hemodynamically stable without clinical signs of sepsis, early cardiac surgical intervention to improve splanchnic perfusion is preferable. In a single-center retrospective study, Cheng et al. found patients with proven NEC (without perforation) who underwent early cardiac surgery had a higher survival rate than those managed medically and with delayed surgery (75% vs. 44%) [143].

NEC is associated with increased hospital length of stay, worse neurodevelopmental outcomes and higher mortality [136, 144, 145]. Recent research has focused on earlier recognition and risk stratification. Splanchnic NIRS and biomarkers, such as intestinal fatty acid-binding protein, show early promise [146–148]. Little evidence exists to guide safe feeding and considerable variation exists in feeding practices, particularly in neonates with duct-dependent lesions. Unfortified human milk feeding and standardized feeding protocols may reduce the risk of NEC.

KEY POINTS: NECROTIZING ENTEROCOLITIS

- There is an increased frequency of NEC in patients with CHD, with a run-off to the pulmonary circulation and poor systemic perfusion leading to mesenteric ischemia.
- NEC is associated with increased mortality and prolonged hospitalization.
- Early cardiac surgery in a patient with proven NEC can improve survival.

AL Grawany

Intraventricular hemorrhage

Intraventricular hemorrhage (IVH) results from bleeding into the lateral ventricle following rupture of fragile microvessels within the subependymal germinal matrix [149]. The risk of intraventricular hemorrhage (IVH) decreases with increasing gestational age. The incidence of severe IVH (grade 3 and 4) from a NICHD Neonatal Research Network study was 38%, 26%, and 7% of infants born at 22, 24, and 28 weeks of gestation, respectively [150]. Antenatal corticosteroids and delayed cord clamping decrease the risk [151, 152]. Nearly all cases of IVH in preterm infants occur within the first 5 days of postnatal life [153]. Morbidity due to IVH is related to severity grade. Grade 1 and 2 IVH generally have a favorable prognosis, whilst up to 60% of infants with grade 3 or 4 IVH develop cerebral palsy or cognitive delay [154, 155]. Post-hemorrhagic hydrocephalus complicates 1%, 4%, 25% and 28% of cases of grades 1 through 4 IVH, respectively [156].

The pathogenesis relates to developmental immaturity of the germinal matrix and impairment of cerebral autoregulation [157, 158]. The fragility of the thin-walled capillaries makes them more prone to rupture spontaneously or because of inadequate cerebral autoregulation to stressors, such as hypoxia, hypercarbia, or hypotension [158]. There are no prospective data suggesting an increased risk for IVH in LBW infants if they undergo early repair and CPB [159, 160]. Nevertheless, there is increasing data from MRI examinations of the newborn brain in the perioperative period that support the notion that the immature brain is vulnerable to injury related to cardiac surgery and CPB, particularly in watershed distributions [81, 161, 162]. It is unknown whether the premature or LBW neonate has an even higher risk.

The diagnosis of IVH before surgery is important, because of the potential for extension of the hemorrhage with surgical stress, CPB, anticoagulation and changes in blood pressure. As a baseline, we routinely perform a cranial ultrasound in all premature (<35 weeks' gestation) neonates prior to cardiac surgery. There are no clear guidelines regarding the management of premature neonates with IVH prior to surgery. Delaying surgery is prudent to lower the risk of extension of the bleed and additional neurologic injury. This may not be possible for all defects; however, in general, our practice is to wait approximately 7–10 days before undergoing surgery with CPB.

KEY POINTS: INTRAVENTRICULAR HEMORRHAGE IN PREMATURE AND VERY LBW NEONATES

- Risk of IVH decreases with increasing gestational age.
- IVH in the premature infant results from the immaturity of the germinal matrix blood vessels and impairment of cerebral autoregulation.
- There is concern regarding the expansion of preexisting IVH with surgical stress, CPB, anticoagulation, increased fibrinolytic activity and sudden changes in cerebral perfusion pressure.
- Preoperative cranial ultrasound in premature neonates is recommended.

Outcome after congenital heart surgery

Several early studies evaluated the overall outcome of preterm and very LBW infants undergoing congenital heart surgery [119, 120, 159, 163–166]. Prematurity and low birth weight were shown to be independent risk factors for increased morbidity and mortality. Data from the Society of Thoracic Surgeons Congenital Heart Surgery Database showed significantly increased operative mortality in infants weighing less than 2.5 kg compared with infants weighing 2.5–4 kg following both two-ventricle repairs and single-ventricle palliation [163]. Lower weight at the time of surgery remained strongly associated with mortality risk after stratifying the population by Risk Adjustment for Congenital Heart Surgery (RACHS) score and Aristotle Basic Complexity levels. More recent data have shown mortality rates have remained higher for LBW infants than for normal-weight infants, even after considering the effects of confounders [109, 167–171].

Hickey et al. found that in infants requiring cardiac intervention, the relationship between birthweight and survival is non-linear with an inflection point at 2.0 kg, below which there is a marked decline in survival [109]. Increasingly, surgeons have moved toward 2.0 kg as the cut-off to define low weight for cardiac surgery. Low birthweight infants are at a higher risk of death, even in the absence of CHD. Anderson et al. used epidemiologic modeling to describe the additive risk of performing cardiac surgery in 118 neonates with birth weight ≤2.0 kg after accounting for baseline risks of low birth weight [168]. Cardiac surgery was estimated to increase the risk of mortality by around 10% when compared to similar-weight infants not requiring surgery. Approximately half of the risk of mortality in the low-weight surgical cohort could be explained by the infant's birth weight alone.

It is difficult to separate out the impact of preterm birth from LBW on outcome in neonates born with a congenital heart defect. In a single-center study that included 146 patients weighing <2.5 kg at the time of surgery, Kalfa et al. found that gestational age <36 weeks at birth was an independent risk factor for early mortality [171]. Using outcome data from the Single Ventricle Reconstruction trial, Miller et al. found that preterm delivery, but not LBW, was independently associated with an increased risk of death at age 6 years. They concluded that preterm birth and LBW, although often concomitant, are not equivalent, impacting outcomes after the Norwood procedure through mechanisms independent of perioperative course [169]. Of note, LBW was associated with worse neurodevelopment outcomes despite the similar length of stay and complications.

While it is preferable to correct congenital cardiac defects early after birth to promote normal growth and development, this may be difficult to achieve in the premature and very LBW neonate [119, 120, 159, 164]. The causes are multifactorial and include technical issues related to small cardiac structures and cannulation requirements for CPB, the immaturity of organ systems (especially the lungs, myocardium, and germinal matrix in the brain), increased risk of bleeding from coagulopathy after CPB, and an immature stress response that may increase the risk for infection and promote a catabolic state in a newborn with limited nutritional reserves. All these factors contribute directly to the increased mortality risk as well as longer duration of

mechanical ventilation, intensive care, and hospital stay for the premature and LBW newborn undergoing cardiac surgery. However, intentional delay to achieve weight gain and maturation in patients with congenital heart defects requiring intervention does not appear to improve survival rate [109].

Despite advances in surgical and CPB techniques and improved outcomes, LBW neonates remain a challenging population for both surgeons and anesthesiologists. A reasonable conclusion from the later studies described here is 2.0 kg is an important cutoff point, with LBW and premature newborns < 2.0 kg having a higher risk for mortality and morbidity regardless of the surgical procedure. In addition to size limitations, end-organ immaturity, co-morbidities, and chromosomal anomalies are important contributing factors to adverse outcomes. Careful attention to detail is essential, and optimal management requires the close collaboration of a multidisciplinary perioperative team.

KEY POINTS: OUTCOME OF CARDIAC SURGERY IN PREMATURE AND VERY LBW NEONATES

- Successful cardiac surgery can be performed in premature and very LBW neonates but with increased risk due to immaturity. There is no survival benefit with medical management and delayed surgery.
- There is increased mortality for neonates weighing ≤2.0 kg for two-ventricle repair and single-ventricle palliation.
- End-organ immaturity, type of cardiac lesion, co-morbidities, and chromosomal anomalies are all contributing factors to adverse outcomes.

Patent Ductus arteriosus occlusion in premature neonates

In recent years the availability of devices for transcatheter PDA occlusion in premature neonates has made this the approach of choice in many institutions, rather than surgical PDA ligation performed at the bedside in the neonatal ICU, or in the operating room [172, 173]. One such device is the Amplatzer Piccolo Occluder (Abbott, Abbott Park, IL) which is U.S. FDA approved for patients as small as 700 g. There are published reports of PDA occlusion in patients weighing as little as 600 g. This procedure is done via a transvenous approach with a 4 Fr sheath in the femoral vein, without any arterial access due to the high risk of occlusion in these small patients. The procedure is performed as a combination angiographic and transthoracic echocardiography (TTE) imaging approach, and a long sheath is advanced through the right atrium, right ventricle, and pulmonary artery into the PDA, where the occluder is deployed (Figure 19.1). Before deploying the device, fluoroscopy, angiography, and TTE are utilized to ensure proper placement, avoiding occlusion of the descending aorta, or branch pulmonary arteries. Although there have been no prospective controlled trials directly comparing transcatheter PDA occlusion vs. surgical PDA ligation in premature infants, retrospective comparison studies report faster improvement in respiratory function with the transcatheter approach. Case series of PDA occlusion in infants report successful occlusion rates of over 90%, with failures most often due to the encroachment of the device into the branch pulmonary arteries or descending aorta, resulting in the removal of the device and referral for surgical PDA ligation. Major complications are reported in 5-10% of infants <2 kg [174, 175]. In a report of 100 patients 700–2,000 g undergoing PDA occlusion with the Piccolo device, the success rate was 99% [176]. Five patients had worsening tricuspid regurgitation without clinical manifestations, two had intraprocedural and one postprocedural device migration, there were two cases of aortic obstruction, and two major hemorrhages and one case of hemolysis.

Anesthetic considerations include transport from the NICU to the catheterization laboratory in a heated isolette to maintain patient temperature, catheterization laboratory heated to 80° F and forced-air warming and other temperature maintenance strategies. A neonatal ventilator may be required for small patients, and a large leak around the endotracheal tube is often present. Packed red blood cells need to be available, which should be less than 7 days old or checked for K+ <8 meq/L. Arterial monitoring is not usually employed unless an arterial catheter is already present. Potential complications include severe tricuspid regurgitation with sheath passage, atrioventricular block, and device embolization. Flushing of the sheath is minimized to reduce the risk of volume overload, and heparin is typically not utilized in the flush. Pressure on the thorax or abdomen from the TTE probe may affect respiratory or hemodynamic stability in these tiny patients. There are also reports of PDA occlusion performed at the bedside with portable fluoroscopy and TTE.

Fetal cardiac intervention

Advances in fetal echocardiography have improved accuracy in the diagnosis and evaluation of CHD, which has in turn led to improved counseling and perinatal management. Studies have shown, specifically for HLHS and transposition of the great arteries, that prenatal diagnosis results in an improved preoperative condition and possibly decreased mortality [177, 178]. However, there are few studies that document the natural history of cardiac growth and physiological changes in individual fetal cardiac malformations or the timing of their impact during fetal growth. Unfortunately, there is no specific animal model of cardiac malformations that is like the human fetus to provide insights into pathophysiology and effects on development or to aid in developing management strategies. Nonetheless, we know that the normal development of the heart and great vessels in the fetus requires normal blood flow patterns. For example, changes in ventricular growth and function can be seen on serial fetal echocardiograms in a fetus with aortic or pulmonary valve stenosis [179], leading to ventricular hypoplasia, fibrosis, and often abnormalities of the coronary arteries, systemic arterial and pulmonary venous morphology [180]. In a worst-case scenario, fetal critical aortic stenosis may progress

AL Grawany

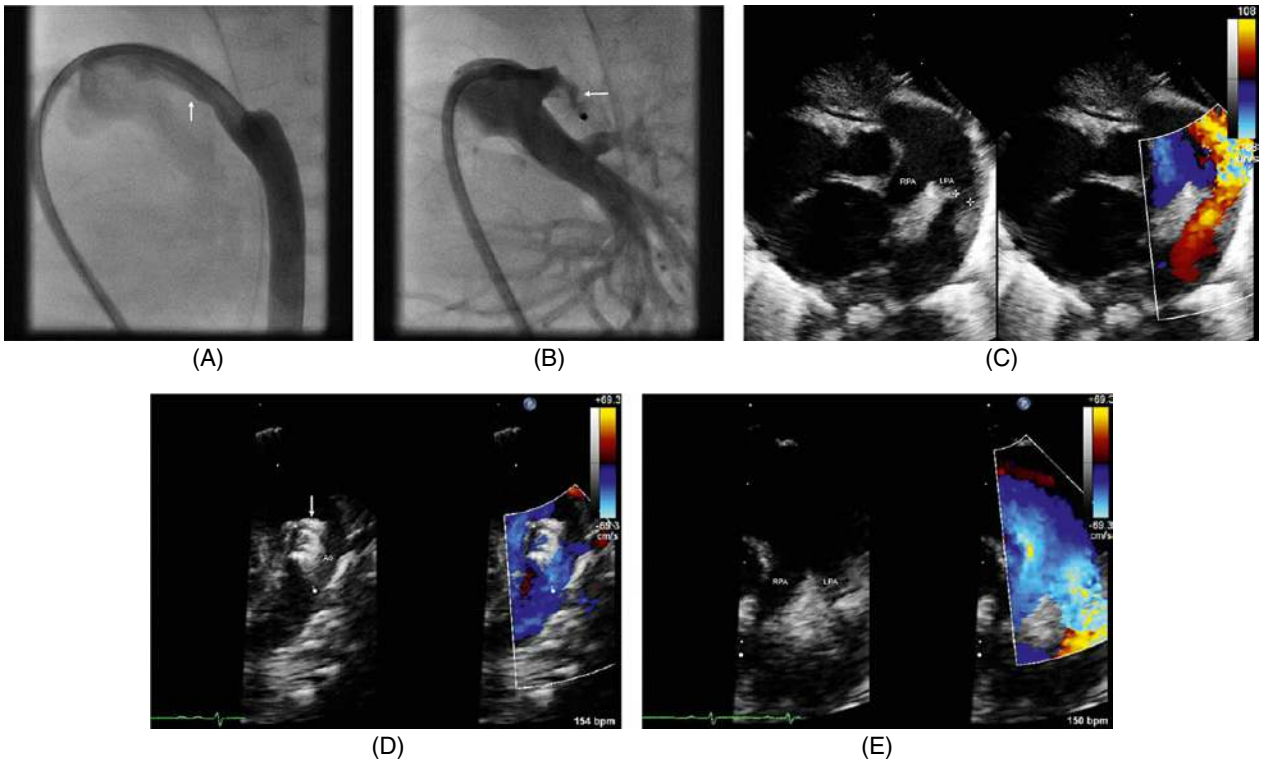

Figure 19.1 Ductus arteriosus closure in a premature infant. (A) Descending aortic angiogram through a 4-Fr-long sheath that has been advanced transvenously through the ductus arteriosus (*arrow*) of a 2-month-old, ex-30-week premature infant weighing 1.2 kg. Note that no arterial access was obtained in the patient, in order to avoid the risk of arterial trauma. (B) Angiogram in the main pulmonary artery after device positioning, but before full release showing the good position of a 4-mm AVP II device (Abbott, Abbott Park, IL) (*arrow*) in the ductus arteriosus. (C) Transthoracic echocardiography (2D and corresponding color images) performed in the cardiac catheterization laboratory before ductus arteriosus device deployment showing the large ductus arteriosus (between markers). The right pulmonary artery (RPA) and left pulmonary artery (LPA) are also visualized. (D) Transthoracic echocardiography (2D and corresponding color images) performed in the cardiac catheterization laboratory after ductus arteriosus device deployment (*arrow*) showing unobstructed flow in the descending aorta (Ao). (E) Transthoracic echocardiography (2D and corresponding color images) performed in the cardiac catheterization laboratory after ductus arteriosus device deployment showing unobstructed flow in right pulmonary artery (RPA) and left pulmonary artery (LPA). (Source: Eilers et al. [172]. Reproduced with permission from Springer Nature.)

to HLHS in a proportion of cases, resulting in univentricular circulation. One of the major reasons for interventions in the fetus, therefore, is to enhance blood flow patterns to allow for better *in utero* development of the heart and improve postnatal outcomes. This "flow theory" is based on the concept that normal flow across the foramen ovale, atrioventricular and semilunar valves contributes to normal growth of the ventricles. Obviously, other motives for FCI include improving survival in fetuses at high risk of prenatal or neonatal death and to allow recovery under the most supportive *in utero* conditions with periods of enhanced wound healing and myocyte proliferation [181, 182]. The recognition that certain CHDs can evolve *in utero* and that early intervention may improve outcomes has led to the evolution of FCIs (Table 19.3).

Transplacental pharmacotherapy of the fetus

Historically, the first FCIs were pharmacological interventions to treat fetal tachyarrhythmia or heart block. In 1975, Eibschitz et al. described the use of propranolol, given to the mother, to treat fetal ventricular tachycardia [184]. Digoxin and many other antiarrhythmic medications (sotalol, amiodarone, flecainide) followed over the years [185–189]. This transplacental pharmacotherapy is usually effective in the non-hydropic fetus. Still, fetal deaths occur in approximately 10% of all fetal arrhythmia patients, and at a higher rate in fetuses with hydrops. Fetal AV block has been treated with transplacental sympathomimetic agents and/or dexamethasone (for autoimmune-related cases) [190–193]; however, the impact on outcome is not well defined. Fetal pacing has been attempted where the fetus is too premature to be delivered and other medical therapies have failed to control heart failure and hydrops [194–196], but so far there has been no successful medium- or long-term outcome in humans.

Prenatal non-steroidal anti-inflammatory drug (NSAID) therapy has recently been described to achieve ductus arteriosus constriction and reduce circular shunt physiology in fetuses with severe Ebstein anomaly and pulmonary regurgitation [197]. Circular shunt, due to unrestricted ductal flow in presence of significant pulmonary and tricuspid regurgitation, is a major risk factor for perinatal mortality. Early results of NSAIDs are encouraging; prolonging gestation and improving survival where ductal constriction is achieved.

Table 19.3 Congenital heart conditions that can potentially be treated with fetal cardiac intervention (FCI)

Condition	Actual or possible FCI
Risk for *in utero* progression	
Fetal AS and evolving HLHS	Balloon aortic valvuloplasty
PA/IVS and evolving HRHS	Pulmonary valvuloplasty
Premature closure of PDA and pulmonary hypertension	Ductal stenting
Absent pulmonary valve with evolving bronchomalacia	Pulmonary arterioplasty and/or valvuloplasty
Risk for fetal or early neonatal death	
Fetal tachycardia with hydrops	Maternal antiarrhythmic therapy
Anomalies causing hydrops	Maternal digoxin
Congenital heart block	Maternal sympathomimetic therapy, pacemaker
Severe Ebstein malformation	Maternal NSAID therapy
Severe congenital MS with AS and intact atrial septum	Balloon aortic valvuloplasty, atrial septoplasty
HLHS with intact atrial septum	Atrial septoplasty/stenting
TAPVR with obstruction	Stenting of obstructed vertical vein

FCI, fetal cardiac intervention; AS, aortic stenosis; HLHS, hypoplastic left heart syndrome; PA, pulmonary atresia; IVS, intact ventricular septum; HRHS, hypoplastic right heart syndrome; PDA, patent ductus arteriosus; MS, mitral stenosis; TAPVR, total anomalous pulmonary venous return, NSAID, non-steroidal anti-inflammatory drug.
(Source: McElhinney et al. [183]. Reproduced with permission of Wolters Kluwer Health, Inc.)

Open fetal cardiac interventions

Open FCIs involve surgical incisions into the uterus or access via a surgical trocar ≥3 mm in diameter as in most fetoscopic approaches. Unfortunately, incisions of this size or larger seem to be associated with an extremely high incidence of preterm labor (80%) [198]. Over the past 25 years, experimental cardiac surgery in fetal lamb and other animal models has resulted in increased knowledge of the cardiovascular and placental response to extracorporeal circulatory bypass. Fetal bypass, using the placenta as an oxygenator, leads to significant post-bypass placental dysfunction with impaired fetal gas exchange, reduction in uterine blood flow, and significant fetal stress response [199–201]. Despite many problems, these models have shown that cardiac surgery on the lamb fetus with survival to full term is technically possible. So far, open fetal heart surgery in humans has only been attempted a few times [183].

Catheter-based fetal cardiac interventions

Ultrasound-guided, percutaneous, catheter-based FCI is a technique that allows for *in utero* treatment of a small subset of CHD. The potential candidates for FCI fit into one of two categories: diseases that progress from the time of mid-gestation diagnosis to birth; and diseases that carry a high risk of demise *in utero* or perinatally [202]. To date, the main target lesions for FCI are aortic stenosis with evolving HLHS, HLHS with an intact or restrictive atrial septum, and pulmonary atresia with the intact ventricular septum (PA/IVS) with concern for worsening right ventricular hypoplasia. Careful patient selection is crucial. Currently, there is still a significant risk of fetal demise, unknown long-term outcomes, and a potential risk for the mother [202].

An FCI program must be multidisciplinary, with collaboration between neonatologists, obstetricians (specialized in prenatal diagnosis and fetal medicine), pediatric cardiologists, and anesthesiologists (fetal and obstetric) [203]. The procedures are performed in the hospital where the mother is the patient, to offer the best care for the pregnant woman. Various anesthesia techniques have been described for the management of the mother during fetal procedures, including IV sedation with local anesthesia, spinal or epidural anesthesia, general anesthesia, and combined techniques [204]. In the current era, maternal conscious sedation with epidural anesthesia or local anesthesia by injection of lidocaine along the planned needle trajectory from the skin to the uterine wall is used for FCI [203–205]. With greater awareness of the fetal stress response and pain perception [206–209], all fetuses now receive analgesia with 20–50 μg/kg fentanyl, administered intramuscularly or into the umbilical vein [210, 211]. A muscle relaxant is administered to the fetus to facilitate positioning and achieve immobility.

Monitoring of the fetus is usually limited to heart rate and basic contractility via ultrasound or echocardiography. Under continuous ultrasound guidance, a special 18- or 19-gauge cannula is passed through the maternal abdomen, uterine wall, and fetal chest wall into the fetal heart (either LV, RV or RA, depending on the procedure to be performed) (see Figure 19.2). Balloon positioning for inflation is based on external measurements and ultrasound imaging, and it is inflated when in the correct position (Figure 19.3). Procedural outcomes for FCI have improved since the procedures were initially attempted in the early 1990s, for example, the technical success rate for fetal aortic valvuloplasty is currently around 94% [203]. Intraoperative fetal cardiac complications remain common. Especially during procedures requiring

ventricular access, fetal hemodynamic changes including bradycardia and ventricular dysfunction may occur before balloon insertion, during inflation, or even after the instruments have been removed [212]. Fetal resuscitation drugs must be immediately available. Intracardiac, or less commonly, intramuscular administration of epinephrine and/or atropine are used for sustained fetal bradycardia. Hemopericardium is another common problem during FCIs. Hemodynamically significant hemopericardium should be drained promptly as the effusion has the tendency to coagulate within a few minutes [203]. Fetal demise rates of 4 to 17% have been reported following FCI [205, 213, 214]. Most recent data suggests that FCI has a low risk of maternal complication and a negligible impact on the further course of pregnancy and delivery [205, 213, 214].

Fetal aortic valvuloplasty for aortic stenosis with evolving HLHS is the most commonly performed FCI. Successful valvuloplasty leads to improvement in left heart hemodynamics, specifically antegrade aortic arch flow and bidirectional patent foramen ovale flow, in ~50% of fetuses [202]. In the Boston Children's Hospital cohort, improved technical success rate and modified selection criteria have led to an increased likelihood of biventricular circulation. In the recent era, 59% of liveborn patients that underwent fetal aortic valvuloplasty had a biventricular outcome [214]. Among those who achieved biventricular circulation, the vast majority required further surgical and/or catheter-based interventions after birth, including interventions on the aortic valve, mitral valve and aortic arch, and endocardial fibroelastosis resection. Medium- and long-term survival and LV function data are not yet available.

Fetuses with membranous pulmonary atresia, intact ventricular septum, and evolving hypoplastic right heart can also be candidates for FCI. The *z*-score (number of standard deviations below normal for gestational age) of the fetal tricuspid annulus and qualitative assessment of RV size are used to predict the potential growth of the RV and therefore chances for a biventricular circulation [215, 216]. Fetuses with technically successful fetal pulmonary valvuloplasty have stable z-scores of right heart structures, in contrast to fetuses with unsuccessful fetal pulmonary valvuloplasty who experience progressive RV and tricuspid valve hypoplasia [202]. In the largest published experience from the International Fetal Cardiac Registry, 31% of 16 fetuses with pulmonary atresia or severe pulmonary stenosis had postnatal biventricular circulation after fetal pulmonary valvuloplasty [213].

For fetuses with HLHS and intact or restrictive atrial septum, FCI has been used to prevent severe neonatal hypoxia and death, and to reduce the lung disease that accompanies chronic *in utero* pulmonary venous hypertension [202]. FCI on the atrial septum is typically performed at 24–30 weeks' gestation in selected fetuses, selected based on abnormal pulmonary vein Doppler profile, a sensitive and specific predictor of severe neonatal distress. The atrial septum is commonly thickened, and most centers attempt to maintain patency of the atrial communication by placing an atrial septal stent. No survival benefit to date has been demonstrated from fetal FCI on the atrial septum [217]. Many of the atrial communications become smaller in late gestation and significant lung disease has already developed in most of these fetuses by midgestation [202].

In summary, FCIs are technically feasible and can improve short-term outcomes in selected patient groups but are associated with a significant risk of fetal demise (~10%) and the potential for maternal harm. Long-term benefits are still to be determined, and the discussion regarding biventricular repair at all costs vs. univentricular palliation is ongoing. Further advances in imaging and equipment technology will allow better patient selection and earlier, possibly even more complex, interventions. Multi-center efforts to collect short- and long-term outcome data will be important to assess the effectiveness and safety of FCIs.

KEY POINTS: FETAL CARDIAC INTERVENTIONS AND SURGERY

- Fetal cardiac interventions can be classified into pharmacological, open, and catheter-based interventions.
- The rationale for FCI is the prevention of fetal demise or early neonatal death and/or ventricular hypoplasia in cases of critical aortic stenosis or pulmonary atresia by restoration of more normal blood flow patterns.
- Currently, percutaneous closed interventions, using 18- or 19-gauge access cannulas, guidewires, and balloon catheters, are mainly used to treat selective patient groups with documented short-term benefits:
  - Fetal aortic stenosis with evolving HLHS
  - Fetal PA/IVS with evolving right heart hypoplasia
  - Fetal HLHS with intact or highly restrictive atrial septum.
- Catheter-based FCI is associated with a 45% risk of significant intraoperative hemodynamic instability requiring fetal resuscitation and a ~10% risk of fetal demise.

Delivery room emergencies in complex congenital heart disease

Because of the increasing frequency of accurate prenatal diagnosis of CHD, and improved outcomes when infants with complex CHD are born in a cardiac surgical center, a multidisciplinary approach to emergent post-delivery resuscitation and operative or catheter treatment is crucially important in the highest risk patients [218, 219]. Although the cardiovascular anesthesiologist is not usually present in the delivery room, they must be involved in collaborative planning for the delivery, and preparations for emergent catheter, operative, or bedside intervention. The logistics of resuscitation in the delivery room, vs. transport to the site of interventional care should be planned as far in advance as possible. Tables 19.4 and 19.5 present CHD lesions and strategies for immediate postdelivery resuscitation and treatment [220]. Not surprisingly, several of the highest risk lesions post-delivery are also candidates for fetal therapy (see above). These include HLHS with an intact or restrictive atrial septum, obstructed TAPVR, severe Ebstein anomaly, and congenital complete heart block. Delivery in a cardiac center as close to the site of intervention as possible, i.e., catheterization laboratory or cardiac operating room, is essential. In some cases, direct transfer is indicated; cesarean delivery in an adjacent OR for the highest risk patients has been described. The *ex-utero* intrapartum therapy (EXIT) procedure has been reported in the management of HLHS with an intact atrial septum, either as sole support while surgical atrial septectomy is performed before full delivery of the infant, or as a bridge to the institution of CPB for the atrial septectomy [221, 222].

Table 19.4 Emergent neonatal cardiac intervention (ENCI) classification system

ENCI risk	Level	Emergent neonatal cardiac intervention	PGE dependent	Mode of delivery an issue	NICU acuity level	Neonatologist present in DR	Critical care transport needed	Cardiology, CT surgery, CTICU, OR/Cath lab on standby	Examples of CHD
I	Low risk	No	No	No	Low	No	No	No	ASD, VSD, mild PS

Introduction

The adult congenital heart disease (ACHD) population is in constant growth due to improvements in diagnosis and treatment. In the last 70 years, the survival rate improved five times from 15% in the early 50s to more than 90% in the current era [1, 2]. In a comprehensive prevalence study in the province of Quebec, the median age of all individuals with severe congenital heart disease (CHD) in 1985 was 11 years and increased to 17 years in 2000. At that time, the ACHD population exceeded for the first time the children living with severe CHD. Currently, the ratio continues to rise in favor of the adult populations [3]. Worldwide the estimated prevalence of CHD population has also increased by 18% from 1990 to 2017 [4]. This increase is mostly due to increased survival rate in middle to higher income countries since the prevalence rates of CHD at birth has changed modestly.

The are several challenges facing the anesthesiologist taking care of patients with ACHD. First, the ACHD population requires anesthesia often to treat residual cardiac defects, arrhythmias, and heart failure since most of these patients have sequelae from their initial repair or palliation or the natural progression of the CHD. Second, access to medical information and previous surgical intervention is challenging since the transition of care from pediatric to adult service is not seamless [5, 6]. Finally, ACHD patients with moderate-to-severe disease by anatomic and or physiological criteria have an increased perioperative risk in cardiac and in non-cardiac surgery [7, 8]. Risk stratification is key to optimize high risks patients perioperatively and define the best setting for treatment and recovery [9].

The perioperative risk of patients with ACHD is related to the anatomical complexity of CHD, physiologic status and acquired comorbidities. The 2018 American Heart Association (AHA)/American College of Cardiology (ACC) Guideline for the Management of ACHD adds the patient's present physiological condition to the classic anatomical classification of CHD [10]. Traditional severe anatomical conditions include cyanotic CHD (unrepaired or palliated), double-outlet ventricle, interrupted aortic arch, mitral atresia, single ventricle, pulmonary atresia, transposition of the great arteries (TGA), and truncus arteriosus. From the physiological standpoint, higher

AL Grawany

risk patients include those in symptomatic heart failure (New York Heart Association Functional Class III–IV), severe aortic enlargement (diameter ≥ 5.0 cm), arrhythmias refractory to treatment, severe hypoxemia (saturation at rest <85%), and severe pulmonary hypertension (systemic or supra-systemic, Eisenmenger syndrome) and/or refractory end-organ dysfunction. Certainly, acquired comorbidities affect patients with ACHD more commonly than the general population. These include metabolic syndrome (central obesity, dyslipidemia, hypertension, and diabetes mellitus), renal dysfunction, liver failure, restrictive lung disease, developmental delays, and acquired neurological injury [11–15]. Despite a higher incidence of metabolic syndrome coronary artery disease prevalence is similar to the overall population. Restrictive lung disease is not only related to CHD but also to the number of thoracotomies [16].

There is no well-defined pathway to treat patients with ACHD. The treatment options are two, adult hospitals or children's hospitals without a clear best choice. Adult hospitals carry the expertise of treating adult patients with acquired disease but lack the CHD knowledge. Alternatively, children's hospitals have the skills to treat CHD, but they do not have the experience to treat adult-acquired disease [17]. Independently of the type of facility successful ACHD centers use a team approach with a wide variety of providers including pediatric, and ACHD cardiologists, surgeons, and pediatric cardiovascular anesthesiologists. Currently, in the United States, there are only 41 Adult Congenital Heart Association (ACHA) accredited programs in a total of 25 states to treat over a million patients. ACHA accredited programs have better outcomes than those without that expertise. ACHD programs need to develop a transitional program to decrease the attrition to follow-up. A comprehensive survey of patients with ACHD in North America identified that 42% of patients (mean age 19 ± 9.1 years) had gaps in the care of more than 3 years. This survey excluded adults cognitively incapable of responding directly to the survey and probably underestimates the gaps in care. The most common reasons cited for gaps in care were "feeling well," "changing or losing insurance," and "financial problems" for severe cardiac lesions. Many patients with ACHD perceive themselves as normal individuals who have had a heart problem in the past that is "fixed," and fail to appreciate the need for follow-up [18].

The goals of this chapter are to analyze the noncardiac sequelae of CHD and review the ACHD pregnancy consideration and the more prevalent cardiac lesions. Finally, the chapter will address the ACHD heart failure management (e.g., ventricular assist device and transplantation) and the management of the patient with ACHD for cardiac and noncardiac surgery.

Noncardiac sequelae of CHD

Pulmonary sequelae

Pediatric patients who undergo cardiothoracic operations are at increased risk of developing scoliosis [19]. The described risk factors include female gender, developmental delay, and presence of genetic syndrome (e.g., Down's or DiGeorge's). Traditionally thoracotomy has been described as a risk factor for developing scoliosis but newer rib sparing surgical approaches had challenged this concept [20]. The mechanism of this predisposition is probably multifactorial including surgical injury, diaphragmatic palsy, chest remodeling due to cardiomegaly, and asymmetric growth post-thoracotomy or sternotomy. Consequently, restrictive lung function is prevalent in surgically repaired CHD patients, and up 50% of these patients have restrictive spirometry testing profiles [21]. Patients with ACHD have decreased exercise tolerance based on oxygen consumption (VO_2) index, diminished forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC), and significant restriction compared with normal (Figure 20.1) [22]. A diminished pulmonary function may have consequences postoperatively either in the recovery room or intensive care unit (ICU), and the ability to wean from the ventilator and needs to be addressed in the preoperative visit [23]. Moderate-to-severe impairment of FVC is a predictor of mortality in ACHD [24]. Figure 20.2 shows a representative patient with severe pulmonary sequelae.

Pulmonary arterial hypertension

Pulmonary arterial hypertension (PAH) is a major perioperative risk factor in ACHD and is defined as an increase in mean pulmonary arterial pressure (PAPm) ≥25 mmHg at rest as assessed by right heart catheterization [25, 26]. PAH associated with ACHD can be classified into four groups:

1. *Systemic-to-pulmonary shunt with increased pulmonary vascular resistance (PVR)*. These shunts may be unrestricted atrial septal defects (ASDs), ventricular septal defects (VSDs), patent ductus arteriosus (PDA), or surgically created shunts such as the Blalock–Taussig (BT), Waterston, and Potts' shunts. A long-standing left-to-right shunt with a pulmonary-to-systemic flow ratio (Qp:Qs) exceeding 2:1 creates shear stresses and changes in the endothelium, and subsequent hypertrophy of the smooth muscle potentially causing PH. These defects are amenable to closure if the PVR index is <4 WU.m^2. If the PVR is higher than 4 but <8 WU.m^2 fenestrated closure could be attempted if there is a good response to disease-targeting therapy (DTT).
2. *Eisenmenger syndrome*. Long-standing systemic to pulmonary shunts leads to systemic pulmonary pressures and shunt reversal to right-to-left, and cyanosis will ensue. Defect closure is contraindicated and supportive therapy with anticoagulation and DTT is indicated.
3. *Primary pulmonary hypertension attributed to CHD, and yet the CHD lesion is quite mild*. Minor defects, such as a small ASD, and not considered the cause of PH. The clinical course of this type of PAH is like idiopathic PAH. The management is like Eisenmenger syndrome refraining from closing the defects and starting DTT.
4. *Pulmonary hypertension due to left heart disease*. Causative lesions include a regurgitant or stenotic systemic atrioventricular (AV) valve, aortic insufficiency (AI), or a failing systemic ventricle.

The anesthetic management of PH and weaning from cardiopulmonary bypass must be tailored to avoid vasoconstrictive triggers, minimizing PVR by optimal oxygenation, alkaline pH, and the use of the pulmonary vasodilators (e.g., nitric oxide, NO). In ICU, DTT should be started before attempting to wean ventilatory support and iNO. The DTT includes three pathophysiological pathways: the endothelin

pathway (endothelin-1 receptor antagonists), NO pathway (phosphodiesterase type-5 inhibitors), and prostacyclin pathway (prostanoids). Bosentan an endothelin-1 receptor antagonist has shown long-term symptomatic benefits in exercise capacity in ACHD patients with PH [27]. Phosphodiesterase type 5 inhibitors besides the vasodilatory effect in pulmonary vasculature have a beneficial effect at a microcirculatory level in patients with ACHD [28]. Iloprost, a prostanoid, produces pulmonary vasodilation through the prostacyclin pathway, improves right ventricular function and exercise capacity in Eisenmenger patients [29].

Eisenmenger syndrome is a challenge, as the anesthesiologist must deal with both PH and the potential to exacerbate the right-to-left shunt, resulting in worsening cyanosis. It is more likely to present in patients with large and complex septal defects. The median survival after diagnosis of Eisenmenger syndrome is reported to be 35–60 years [30]. Patients with Eisenmenger syndrome will present for heart-lung transplantation, but outside of this context, interaction with an anesthesiologist will be limited to diagnostic investigations and noncardiac surgery. Generally, Eisenmenger patients are easier to manage than patients with primary PH, as the right ventricle (RV) is robust and accustomed to a high afterload. Bennet et al. showed that hypotension is common during induction of Eisenmenger's patients regardless of the agent used. The use of preemptive use vasopressor is recommended [31–33]. Manes et al. presented the survival data of ACHD patient with PH. The patients with small or corrected defects have the worse outcomes [34]. Chapter 33 contains an extensive discussion of PAH.

Hematological sequelae

Patients with cyanotic heart disease have erythrocytosis, an increase in the red cell line in response to hypoxia. Relative to the red cells there is a deficiency in vitamin K-dependent clotting factors, fibrinogen, and platelets [35]. Particularly single ventricles or cyanotic patients have an increased risk of thrombosis yet are frequently coagulopathic intraoperatively [36, 37]. Phlebotomy is inappropriate unless there are extreme symptoms of hyperviscosity, as iron

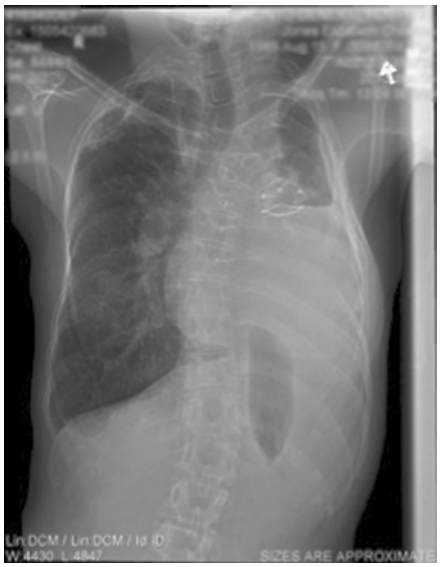

Figure 20.2 26-year-old with pulmonary atresia and right ventricle (RV) to pulmonary artery (PA) conduit. The patient's weight is 45 kg, and the previous history includes pneumonectomy at age 16 years, paralyzed vocal cord, asthma, bronchiectasis, kyphoscoliosis. Forced expiratory volume in 1 second (FEV1) is 600 mL (20% of normal). The patient has RV–PA conduit obstruction with an RV pressure of 48/25 mmHg, and elevated pulmonary vascular resistance at 8–10 Wood units.

deficiency with microcytosis is an independent risk factor for stroke, thrombosis, and hemoptysis [38].

Renal sequelae

Impaired renal function, as in patients with acquired heart disease, is a significant predictor of morbidity and length of stay in ACHD surgery [39]. Kwiatkowski et al. in a retrospective study described the principal risk factors for developing acute kidney injury after ACHD surgery [40]. Older age (≥35 years), preoperative left ventricular (LV) dysfunction, preoperative arrhythmia, longer bypass time, and vancomycin use were significant risk factors. The Acute Dialysis Quality Initiative Group has defined the range of renal dysfunction using the so-called "RIFLE classification system" (Box 20.1), which has been endorsed by the Multi-societal Database Committee for Pediatric and Congenital Heart Disease and further subdivided into renal insufficiency and renal dysfunction [41]. A total of 1,102 adult patients attending the Royal Brompton Hospital in London over a period between 1999 and 2006 had a serum creatinine measured and a glomerular filtration rate calculated. Renal dysfunction was mild in 41% of patients and moderate or severe in 9%. Not surprisingly, severe renal impairment correlated with increased mortality over the 4-year follow-up period [42].

Box 20.1: The RIFLE classification system

- Risk (R)—1.5-fold increase in serum creatinine, >25% decrease in glomerular filtration rate, or urine output <0.5 mL/kg/hour for 6 hours
- Injury (I)—two-fold increase in serum creatinine, >50% decrease in glomerular filtration rate, or urine output <0.5 mL/kg/hour for 12 hours
- Failure (F)—three-fold increase in serum creatinine, serum creatinine >4 mg/dL, >75% decrease in glomerular filtration rate, urine output <0.3 mL/kg/hour for 24 hours, or anuria for 12 hours
- Loss (L)—persistent acute renal failure defined as the need for renal replacement therapy for >4 weeks
- End-stage renal disease (E)—need for renal replacement therapy for >4 weeks.Source: Welke et al. [43]. Reproduced with permission of Cambridge University Press.

Neurological sequelae

Surgical, perfusion and interventional strategies allow early intervention in the neonatal period, with improved survival but with a concerning incidence of neurodevelopmental complications in survivors [44]. In CHD the lifetime impact of cardiovascular disease on neurovascular disease changes. In early childhood, neurodevelopmental disorders are the central issue but with age epilepsy, stroke and dementia become more prevalent [45]. Interestingly, the increased risk of epilepsy is also seen in nonsurgical CHD patients indicating the presence other neurodevelopmental factors unrelated with the perioperative period [46].

Patients with ACHD have an elevated risk of ischemic and hemorrhagic stroke [47]. Lanz et al. in a retrospective, population-based cohort study showed that almost 8% of patients with ACHD will experience a stroke in adulthood [48]. The risk of stroke was to 9–12 times higher in younger patients (<55 years old) up and only double older patients (55–64 years old). Severe ACHD and left-sided lesions carry the highest risk of stroke. The greatest predictors of ischemic stroke in patients with ACHD are heart failure, diabetes mellitus, and recent myocardial infarction. The thirty-day mortality after stroke is comparable to the general population.

Early-onset dementia is more prevalent in patients with ACHD, and the burden of this disease is likely to increase with the growing population [49]. Patients with ACHD carry several risk factors for dementia including genetic disorders (e.g., Down syndrome), stroke, heart failure, atrial fibrillation, and diabetes mellitus. ACHD centers must acknowledge and accommodate some aspects of the pediatric anesthesia practice. Inhalational inductions are less practical, and premedication with hypnotics, and occasionally intramuscular ketamine, may be necessary. Patients' impressions made on the first anesthetic encounter at the adult facility will influence future attitudes toward anesthetic care, and compliance with future visits.

Hepatic sequelae

ACHD is associated with liver dysfunction. The mechanism of liver failure is multifactorial secondary to CHD, surgical repair or palliation, or blood transfusion [50]. Liver dysfunction is caused by passive venous congestion (e.g., central venous hypertension) or low-output cardiac syndrome (LCOS). Tricuspid insufficiency and right ventricular failure cause liver failure by passive venous congestion. ACHD linked with passive venous congestion are repaired tetralogy of Fallot (TOF) with pulmonary insufficiency, Ebstein's anomaly, single ventricle physiology (e.g., Fontan and Glenn), TGA with atrial switch repairs (e.g., Mustard-Senning). Elevation of indirect bilirubin and prolonged international normalized ratio (INR) without affecting of the aminotransferases is typical in central venous hypertension. CHD conditions that cause LCOS, such as aortic coarctation or LV outflow tract obstruction, cause hepatic ischemia and eventually fibrosis. The ischemic burden is worse in the presence of an increased hepatic sinusoidal pressure.

Acute ischemic hepatitis caused by LCOS is characterized by marked early rises of transaminases, followed by later increases in bilirubin and prothrombin time.

Fontan patients are the highest ACHD risk group to develop liver failure with an incidence of over 40%, 30 years after the initial procedure [51]. Failing Fontan physiology patients are prone to develop liver fibrosis earlier due to the continuous back pressure on the sinusoids secondary to elevated non-pulsatile central venous pressure (CVP). There is a strong correlation between hepatic fibrosis and high hepatic venous pressures, low cardiac index, and ventricular function. The gold standard for diagnosis of Fontan associated liver disease is the percutaneous liver biopsy under ultrasound guidance. Transvenous biopsies can be obtained at the time of the cardiac catheterization and transhepatic gradient can be measured. An elevated hepatic venous pressure gradient >5 mmHg is indicative of parenchymal liver disease. Gradients over 10 mmHg are associated with portal hypertension complications (e.g., ascites and variceal hemorrhage) [52, 53].

Model for End-stage Liver Disease (MELD-XI) scores, excluding INR scores, is used to classify the severity of liver disease in ACHD. The advantage of the MELD-XI score is that the INR is excluded, and many patients with Fontan circulation are taking warfarin. In addition, there is a statistically significant correlation between MELD-XI values and hepatic total fibrosis scores [52]. Once a Fontan patient is diagnosed with cirrhosis, close surveillance for hepatocellular carcinoma and esophageal varices assessment is recommended.

There is no specific treatment for Fontan-associated liver disease. Medical treatment should optimize Fontan physiology by increasing cardiac output (e.g., afterload reduction) and decreasing CVP (e.g., diuretics). Additional etiologies of liver injury should be avoided with immunization (e.g., hepatitis A and B) and limiting other toxins (e.g., alcohol or obesity). Combined heart and liver transplant is the ultimate treatment of failing Fontan physiology with associated liver disease. Hofer et al. recently reviewed the anesthetic management of combined heart–liver transplantation in patients with Fontan-associated liver disease. The authors recommend keeping the transpulmonary pressure gradient close to 5 mmHg by optimizing preload, reducing PVR, and preserving single ventricular function [54]. Chapter 30 contains additional discussion of heart-liver transplantation.

KEY POINTS: NONCARDIAC SEQUELAE OF CHD

- Patients with ACHD can experience a wide range of noncardiac sequelae:
  - Pulmonary—restrictive lung disease and PAH
  - Hematological—erythrocytosis, polycythemia, and coagulopathy
  - Renal dysfunction—mild in 41%, moderate or severe in 9%
  - Neurological sequelae—developmental delay, cerebral abscess, stroke, and early dementia
  - Hepatic sequelae—hepatic congestion, dysfunction, and cirrhosis from right heart failure or elevated cavopulmonary pressures.

Vascular access considerations

Patients with ACHD undergo multiple interventions during infancy and childhood so by the time the reach adulthood the central and peripheral vascular access may be compromised. The use of ultrasound for vascular access is recommended in potential difficult intravenous access patients such as the ACHD population [55]. Chue et al. describe a 3.6% incidence of complications after femoral cannulation for percutaneous interventions in patients with ACHD [56]. The complications included hematoma and pseudoaneurysm.

The preoperative visit should include examining the extremities for cut-down scars and measuring blood pressure in all extremities. Planning for major cardiac surgery should consist of venous Doppler or magnetic resonance imaging (MRI) of the femoral vessels, central veins and arterial and venous studies. Computed tomography or MRI of the chest is essential to delineate the intrathoracic anatomy and the relationship between the heart and great vessels to the sternum [57]. The anesthesiologist should discuss plans for emergent cannulation of the femoral vessels in the event of a cardiac injury at sternotomy. Cardiac or vascular injury upon resternotomy in ACHD is more common in patients with extracardiac conduits and dilated structures (e.g., aorta, RV, or right atrium) [58]. One of the approaches to high-risk sternotomy patients is establishing cardiopulmonary bypass through peripheral cannulation before sternotomy [59].

Unrestricted shunts

There are two types of unrestricted shunts. First, simple shunts, such as ASDs, VSDs, large PDAs, and aortopulmonary collaterals have a left-to-right shunt in the presence of normal or low PVR, and pulmonary blood flow may exceed systemic blood flow. Second, complex congenital lesions palliated with systemic-to-pulmonary artery shunt (e.g., BT, Waterston–Cooley, or Potts' shunt) to augment pulmonary blood flow who may develop unilateral PAH. The Australian National registry for PAH in ACHD found that, of the first 50 registrants, 47 had systemic-to-pulmonary artery shunts [60]. At rest, breathing room air, these patients may have a 2:1 or as much as a 3:1 shunt ratio of pulmonary to systemic blood flow. The anesthesiologist should avoid 100% oxygen ventilation since it will lower the patient's PVR, converting a 2:1 shunt to a 4–5:1 shunt, causing metabolic acidosis from diminished systemic oxygen delivery. Unrestricted left-to-right shunts can reverse with a profound decrease in systemic vascular resistance (SVR). The coronary circulation is dependent on the diastolic pressure and will compete with the run-off into the pulmonary circulation when the PVR decreases by hyperventilation and 100% oxygen. After induction, baseline conditions should be targeted, maintaining the patient on a FiO_2 that recreates their room air oxygen saturations at rest to avoid increasing the shunt fraction and coronary ischemia. Ventilation should be at lung volumes close to functional residual capacity (FRC) and maintain a normal $PaCO_2$.

Pregnancy

The increase in adults living with CHD also reflected in the obstetrical population, with increasing numbers of women with ACHD needing pregnancy care. For example, in one

analysis, the number of women with ACHD presenting for delivery increased from 6.4 to 9.0 per 10,000 delivery hospitalizations [61]. Effective communication among the care team is essential, and anesthesiologists play a crucial role in assuring appropriate care for women with ACHD during pregnancy, labor, and delivery. Anesthesiologists must understand the effect of pregnancy on the cardiovascular system, the unique physiology of each patient's cardiac lesion or surgical repair, and the cardiovascular impact of various anesthetic techniques used on labor and delivery.

Relevant physiologic changes during pregnancy

A growing fetus requires increased oxygen delivery to the uteroplacental unit. Cardiac output increases by approximately 50% during pregnancy by increasing heart rate and stroke volume to keep up with the demand. Plasma volume significantly increases during pregnancy, reaching its peak around the early third trimester. Sympathetic tone increases in the first trimester (Figure 20.3) [62]. Transthoracic echocardiography (TTE) demonstrates increased cardiac performance and progressive LV remodeling. LV mass and LV end-diastolic diameter increase, while LV strain decreases. These values return to normal in the postpartum period [63]. Systemic and PVRs both decrease. Mean arterial blood pressure decreases before returning to near-normal values at the end of the third trimester [64]. Central filling pressures typically remain normal. Pregnancy is also associated with dilutional anemia. It is a hypercoagulable state with increases of most coagulation factors, a decrease in Protein S activity, and acquired Protein C resistance [65].

Labor and delivery bring additional cardiovascular demands that place stress on the heart. Autotransfusion from uterine contractions increases plasma volume and cardiac output up to 50% more than the pregnancy baseline throughout labor. In addition, painful contractions increase heart rate and SVR. During delivery, there is a large autotransfusion from uterine involution. This autotransfusion increases the circulating volume up to 100% over the baseline pregnant state, potentially overwhelming an already fragile circulation. As a result, it is a typical time for heart failure to occur [66, 67].

Cardiac risk assessment before and during pregnancy

Cardiac and fetal risk during pregnancy and the postpartum period depends on the nature of the patient's cardiac lesion, pre-pregnancy functional status, and general health. Simple lesions, such as a repaired ASD or mild pulmonic stenosis, do not carry a significantly increased risk over the general population. However, complex ACHD, such as a Fontan circulation or unrepaired cyanotic heart disease, poses a greater risk to the patient and may become life threatening [68].

Ideally, patients with ACHD should plan their pregnancy after consultation at a tertiary care center with a cardio-obstetric team. The team should consist of a high-risk obstetrician, cardiologist, and obstetric anesthesiologist, all of whom have experience caring for patients with ACHD. Other experts should be consulted as necessary and include a cardiac anesthesiologist, cardiothoracic surgeon, cardiovascular intensivist, geneticist, neonatologist, hematologist, and others. In addition, preconception counseling should give the woman a clear understanding of the risks of pregnancy for her and her child. In some cases, additional testing and procedures may be warranted before it is deemed safe to embark upon pregnancy. Exercise testing is a valuable tool to aid in maternal and fetal risk stratification. Lack of a chronotropic response to exercise is predictive of both maternal and neonatal events [69]. Once pregnancy is confirmed, high-risk patients should be referred to a tertiary care program with expertise in pregnancy in ACHD.

Estimation of maternal and fetal risk during pregnancy and the postpartum period considers the mother's underlying cardiac condition and the presence or absence of risk

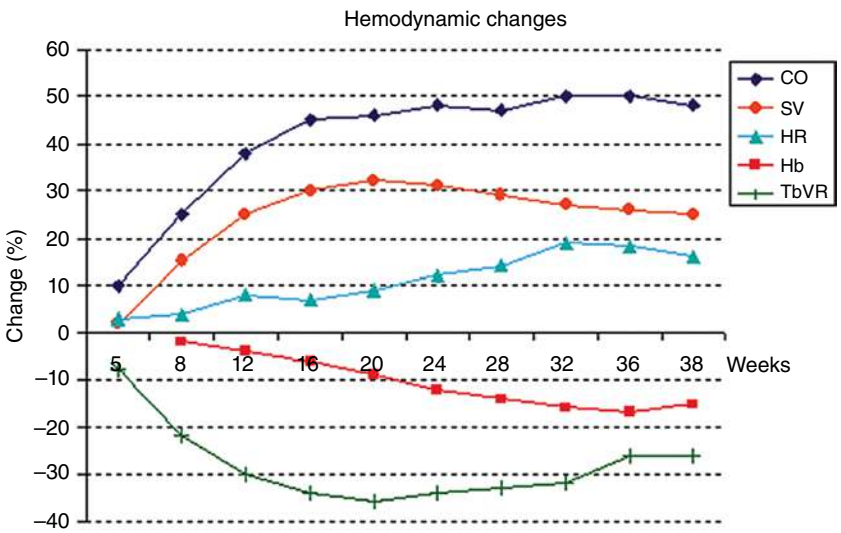

Figure 20.3 Hemodynamic changes in pregnancy. CO, cardiac output; SV, stroke volume; HR, heart rate; Hb, hemoglobin; TPVR, total peripheral vascular resistance. (Source: Ruys et al [62]. Reproduced with permission of Elsevier).

factors. The modified WHO (mWHO) pregnancy classification is regarded as the most accurate risk classification [64]. However, multiple risk scores are based on studies that have examined maternal and fetal risk in patients with cardiac disease. The mWHO classification is presented in Table 20.1 [68]. Its assessment of risk is based purely on underlying cardiac condition, assuming the mother is otherwise optimized.

In 2001, a large prospective observational trial examined 599 pregnancies in women with CHD (74%), acquired heart disease (22%) and arrhythmia (4%). A primary cardiac event occurred in 80 pregnancies (13%). Everyday cardiac events included heart failure and arrhythmia. They proposed four predictors of maternal cardiac complication (the CARPREG I score): prior cardiac event or arrhythmia, NYHA class >II or cyanosis, left heart obstruction, and systemic ventricular dysfunction [70]. An updated risk index, CARPREG II, was published in 2018. It included 1938 pregnancies in women with congenital (63.7%) and acquired (22.9%) heart disease. The new score incorporates different risk elements, including lesion-specific variables, patient-specific variables, and one process of care variable. It is outlined in Table 20.2 and Figure 20.4 [67]. The maternal complication rate was 16%, unchanged from their 2001 study. Arrhythmia (9.3%) and heart failure (6.2%) remained the most common cardiac events. Arrhythmias were most likely to occur in the antepartum period, where heart failure was most observed in the third trimester or the early postpartum period [67].

Table 20.2 CARPREG II risk stratification index

PREDICTOR	SCORE
Prior cardiac events or arrhythmias	3
Baseline NYHA III-IV or cyanosis	3
Mechanical valve	3
Ventricular dysfunction	2
High-risk left-sided valve disease/left ventricular outflow tract obstruction	2
Pulmonary hypertension	2
Coronary artery disease	2
High-risk aortopathy	2
No prior cardiac intervention	1
Late pregnancy assessment	1

AL Grawany

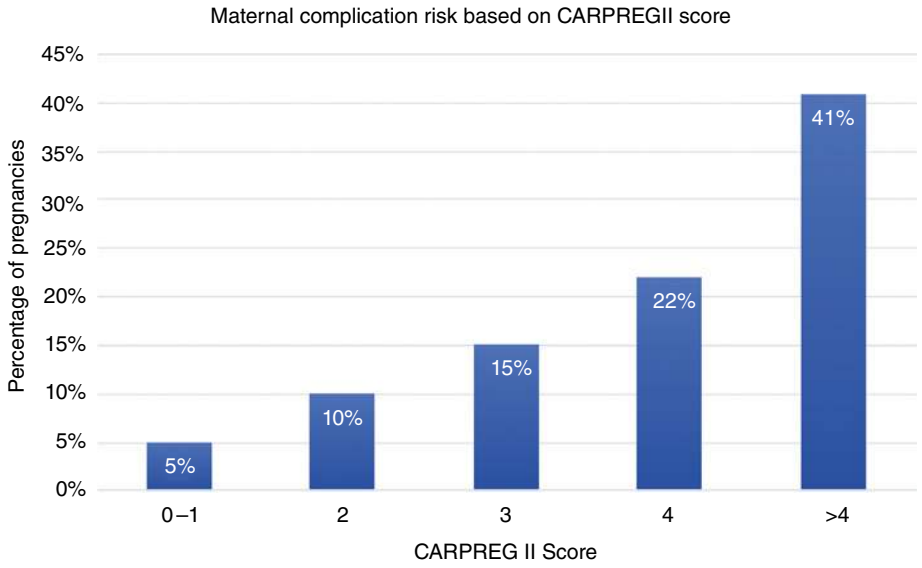

Figure 20.4 Maternal complication risk based on CARPREGII score. (Source: Silversides et al [67]. Reproduced with permission of Elsevier).

In a more extensive retrospective review from the ZAHARA group, 1802 pregnancies were observed in women with ACHD. The maternal cardiac complication rate was 7.6%. The most common maternal cardiac complications were arrhythmias (4.7%) and heart failure (1.6%). They confirmed several risk factors from the CARPREG studies. In addition, they identified further risk factors: the use of cardiac medication before pregnancy and systemic and pulmonic AV valve regurgitation in the context of complex ACHD [71]. A smaller study, examining 90 pregnancies in women with ACHD, identified two additional risk factors: impaired sub pulmonary ventricular systolic dysfunction and severe pulmonary regurgitation [72]. Single ventricle physiology was a risk factor for maternal cardiac events in a ACHD population [73].

External validation and comparison of the CARPREG I, ZAHARA, and mWHO risk classification systems in a ACHD population was undertaken in 2014. The mWHO score was best able to discriminate risk for cardiovascular events. In addition, a combination of the mWHO score, the total number of cardiovascular predictors, and disease complexity further improved prediction [74].

Maternal obstetric and fetal risks

The most common fetal complications in women with ACHD include premature birth (12–19%) and small for gestational age (SGA) birth weight. In addition, neonatal death occurred at a higher rate than the general population, ranging from 2.8–5%. There was also a higher observed incidence of intrauterine growth restriction (IUGR), neonatal intensive care (NICU) admission, and neonatal CHD [70–74]. The increase in premature births has two causes: preterm labor and iatrogenic premature delivery due to maternal health status or decompensation. Risk factors for fetal complications include maternal NYHA class >II, cyanosis, maternal anticoagulation, left heart obstruction, mechanical valve, cardiac medications during pregnancy, single ventricle physiology, severe pulmonary hypertension, smoking, and multiple gestations.

Patients with ACHD are at elevated risk for preeclampsia and postpartum hemorrhage (PPH). Risks for preeclampsia included nulliparity, systemic lupus erythematosus (SLE), and aortic coarctation [61]. In addition, several studies have identified CHD as an independent risk factor for PPH, and patients with Fontan circulation had a particularly elevated risk [75–77]. Peripartum anticoagulation and cyanosis are other identified risk factors for PPH [70].

Care during pregnancy

Anticoagulation

While anticoagulation during pregnancy is a risk factor for PPH and neonatal complications, for some conditions, the additional thrombotic risk conferred by pregnancy and the catastrophic effect of a thrombus in these conditions is significant. These conditions include a Fontan circulation or the presence of a mechanical valve [78–81]. The balance of risk and benefit for anticoagulation in pregnant patients with ACHD is an individualized decision.

Low-molecular-weight heparin (LMWH) is the preferred anticoagulant during pregnancy. Neither unfractionated heparin (UFH) nor LMWH crosses the placenta. LMWH is the anticoagulant of choice over UFH due to its reliability and relative ease of dosing. It is also associated with fewer injection site reactions and carries a lower risk of heparin-induced thrombocytopenia (HIT). However, the longer half-life LMWH and the inability to completely reverse its anticoagulant effect may limit the ability to provide neuraxial anesthesia. Warfarin is typically avoided during pregnancy as it is associated with well-known fetal malformations, particularly with exposure in the first trimester. Alternatives to warfarin should be used if clinically feasible. Direct oral anticoagulants have gained popularity for anticoagulation for several indications. However, there is scant data for use during pregnancy, and they are not recommended [82].

The presence of a mechanical valve is a known risk factor for cardiac complications [64, 67, 71]. The main risks are

valve thrombosis and bleeding complications related to anticoagulation. In a 2015 study, women with a mechanical valve only had a 58% chance of having an event-free pregnancy, 4.7% experienced valve thrombosis, which carried a 20% mortality rate. Hemorrhage occurred in 23% of patients, usually around the time of delivery [83]. Management of anticoagulation in this population is a challenge. Multiple studies have shown an increased risk of thrombosis in mechanical valve patients treated with LMWH vs. warfarin [83–86]. Warfarin is optimal for thrombosis prevention and is recommended for use during pregnancy in patients with a mechanical valve despite the risk of embryopathy. Patients may remain on warfarin during their entire pregnancy, or warfarin can be changed to LMWH or UFH for the first trimester and again after 36 weeks [64].

Cardiac procedures during pregnancy

Patients may present in pregnancy for cardiac interventional procedures or cardiac surgery. Ideally, cardiac procedures will occur in the second trimester when organogenesis is complete, and the risk of premature labor is still low. The uterus must be double shielded from radiation exposure during catheterization. Appropriate fetal monitoring is indicated both for intervention if the fetus is viable and to optimize hemodynamics in response to fetal distress. Discussion with the obstetric team should take place on the response to the diagnosis of fetal distress. The anesthesiologist should be cardiac trained with ACHD expertise. Cardiac surgery and perfusion should be on standby, and appropriate ICU resources available for the mother and fetus. Maternal cardiac surgery should only be performed during pregnancy if it is urgent, as in LV obstruction with symptoms at rest, or emergent, as in aortic dissection or a thrombosed mechanical systemic AV valve. Cardiac surgery during pregnancy and the use of cardiopulmonary bypass carries a high risk of fetal mortality. Normothermic perfusion, mean arterial pressure (MAP) >70 mmHg, minimal CPB times, and bypass pump flows >2.5 L/min/m^2 are optimal to minimize fetal risk. Hypocapnia, which ordinarily may be used for patient's dependent on a low PVR (TOF, Ebstein's anomaly, and Fontan circulation), has adverse effects causing uteroplacental vasoconstriction and fetal hypoxia and should therefore be avoided. If the fetus is viable, a caesarean section (C-section) may precede the urgent cardiac surgery [69, 87, 88].

Delivery planning

Multidisciplinary collaboration is essential to planning a safe delivery for mother and baby. Thoroughly assessing each patient's risk and anticipated complications allow mobilization of appropriate resources and determining who needs to be involved in the patient's delivery. Additional teams consulted may include ICU, cardiac surgery, cardiac anesthesia, and others. The team should also determine the optimal delivery mode, location, timing, and anesthetic plan.

The delivery hospital must have the necessary resources to care for the patient and handle any likely complications. This level of care depends on the estimate of the patient's risk and severity of her condition. For example, low-risk patients, mWHO class I and II, estimated cardiac event risk <10%, could safely be delivered at a local hospital. Patients with an intermediate risk (mWHO class II-III, calculated risk 10–19%) should deliver at a higher-level referral enter, while extraordinary risk patients (mWHO class II or IV) should refer to a tertiary care center experienced in the care of patients with ACHD [64, 89].

The mode of delivery determines birth location within the hospital, need for invasive monitoring, access to the escalation of care, and ability to perform emergency surgery quickly. The team should determine what resources and monitoring are necessary for delivery and then decide which location in their hospital best fulfill those needs. For example, if a C-section is planned, the operating room should be equipped to accommodate standard C-section needs in addition to possible contingencies, including demand for emergent ECMO cannulation or transesophageal echocardiography (TEE) and neonatal resuscitation.

Vaginal delivery is preferred in patients with ACHD unless an obstetric indication for C-section is present. Elective C-section based on maternal cardiac disease is not recommended, as it does not confer maternal benefit but may carry increased neonatal risk [90]. Vaginal delivery is associated with decreased blood loss and a lower risk of venous thromboembolism. For certain patients, an assisted vaginal delivery minimizes Valsalva and has beneficial hemodynamic effects. C-section recommendations include acute intractable heart failure, patients presenting in labor on oral anticoagulants, aggressive aortopathy, and severe pulmonary hypertension [64].

During labor, painful contractions can lead to tachycardia, hypertension, and hyperventilation. Early labor epidural placement can mitigate these unwanted effects. Sympathectomy associated with epidural local anesthetic administration causes vasodilation and can lead to hypotension. Therefore, cautious administration of a pre-load or co-load of IV fluid before or during epidural placement is beneficial. If the plan is to assist the second stage, good sacral nerve root coverage is required. The use of a combined spinal-epidural (CSE) or dural puncture epidural (DPE) technique achieves good sacral coverage. Opioid-only intrathecal injection (10 mcg Fentanyl) should be used in CSE to minimize the extent of sympathectomy and prevent hypotension. For patients with intracardiac shunts, consider using saline rather than air for the loss of resistance technique to minimize inadvertent air injection into a blood vessel during epidural placement. We do not advise the use of epinephrine in the epidural test dose. The intravascular injection of epinephrine could be detrimental to patients at high risk of arrhythmia. An alternative test dose is epidural fentanyl 50–100 mcg [91].

For patients undergoing C-section, neuraxial anesthesia is preferred over general anesthesia. In Figure 20.5, the advantages, and disadvantages of each are outlined. The selection of neuraxial technique depends on the physiology and severity of the patient's cardiac lesion. Spinal anesthesia produces a quick onset, reliable, dense surgical block. However, it is also accompanied by a rapid sympathectomy which causes an acute decrease in preload and afterload. Preload-dependent patients or severe (mWHO III-IV) lesions will not tolerate the sympathectomy. Epidural anesthesia can be titrated to ensure a slower onset and slow start

AL Grawany

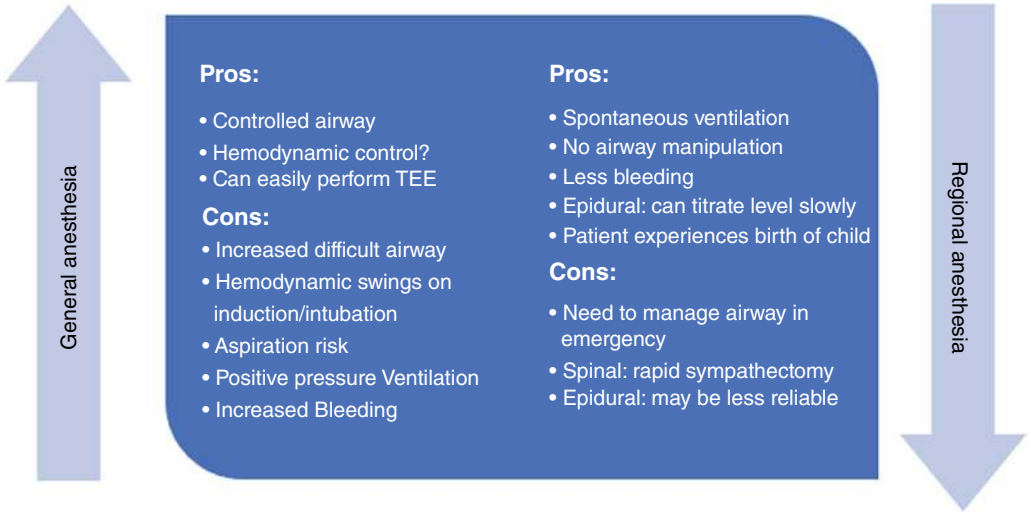

Figure 20.5 Advantages, and disadvantages of the administration of general vs. neuraxial anesthesia for cesarean section.

sympathectomy but may produce a less dense or unilateral block that is inadequate for surgical anesthesia. A CSE with intrathecal opioids or a sequential CSE, in which a small dose of local intrathecal anesthetic (2.5–5 mg 0.75% hyperbaric bupivacaine) is given and then supplemented with a local epidural anesthetic, can provide the balance between a reliable, dense block and the need for slow titration to avoid rapid sympathectomy, decreased SVR, and hypotension. Neuraxial anesthetic dosing recommendations for cesarean delivery are summarized in Table 20.3.

Anticoagulated patients require general anesthesia, and those unable to lay flat, critically ill requiring mechanical ventilation, or emergent delivery. Induction and maintenance of anesthesia should balance obstetric and cardiac considerations. In obstetric patients, increased aspiration risk leads to the use of rapid sequence induction. One should avoid opioids before delivery due to concern for neonatal sedation and respiratory depression. However, patients with high-risk cardiac lesions may require a slower induction to prioritize hemodynamic stability. Therefore, the administration of opioids to blunt the hypertensive response to laryngoscopy may be reasonable.

Adequate monitoring for the patient during delivery, whether vaginal or C-section, is vital for early recognition of maternal warning signs. For vaginal delivery, intermittent noninvasive blood pressure and pulse oximetry are essential for cardiac patients. Telemetry during and after delivery is mandatory for patients at risk for arrhythmia. For patients at higher risk of decompensation, invasive arterial blood pressure or CVP monitoring can be considered. Point of care TTE can be helpful to serially monitor cardiac function in patients with depressed systemic ventricular ejection fraction. For C-sections, standard monitors are sufficient for low and intermediate-risk patients. High-risk patients will likely require invasive arterial blood pressure or CVP monitoring and possibly pulmonary artery (PA) catheter placement. In patients who are under general anesthesia, TEE can be used.

Patients with ACHD need an individualized transfusion plan before delivery since they have an elevated risk of PPH. Most uterotonic medications have cardiovascular effects and need to be administered with caution. The hemodynamic results of commonly used uterotonic drugs are summarized in Table 20.4 [92]. Tranexamic acid (TXA) reduced PPH mortality in the WOMAN trial, which included over 20,000 women worldwide. There was no difference in cardiac failure, thromboembolism, or seizure between the TXA and placebo groups [93].

KEY POINTS: PREGNANCY IN ACHD

- Pregnancy in ACHD is associated with a 7–16% incidence of adverse cardiac events.
- Assess the cardiac pregnancy risk using the mWHO classification.
- High-risk conditions include
  - Severe systemic ventricular dysfunction
  - Fontan circulation
  - Cyanosis
  - Pulmonary hypertension
  - Left heart obstruction
  - Mechanical valve.
- Premature birth, neonatal death, preeclampsia, and PPH are more common in patients with ACHD.
- Multidisciplinary planning, fetal monitoring, and backup plans for maternal or fetal instability are necessary for anesthesia during pregnancy.
- Bypass cases should maintain MAP >70 mmHg and high flows for fetal protection.
- Anticoagulation during pregnancy is problematic, with LMWH preferable to warfarin
- Vaginal delivery is preferred; neuraxial techniques can be utilized with careful titration and hemodynamic monitoring.

Table 20.3 Neuraxial anesthetic dose recommendations for cesarean delivery in CHD patients

	Mild-moderate CHD		Severe CHD (mWHO III-IV)	
	Spinal/CSE	**Epidural In-situ**	**CSE**	**Epidural In-situ**
Local Anesthetic	12 mg (1.6 mL 0.75%) hyperbaric bupivacaine	2% lidocaine with 1:200,000 epinephrine and sodium bicarbonate (total 20 mL)[a]	*Intrathecal*: None, or up to 5 mg 0.75% hyperbaric bupivacaine *Epidural*: 2% lidocaine with 1:200,000 epinephrine and sodium bicarbonate (total 20 mL)	2% lidocaine with 1:200,000 epinephrine and sodium bicarbonate (total 20 mL)
Local anesthetic administration	Single shot	Bolus 5 mL increments of LA until a T4 level obtained (may take 15–20 mL)	Bolus 2–3 mL increments of LA every few minutes with careful attention to hemodynamics until a T4 level obtained (may take 15–20 mL)	Bolus 2–3 mL increments of LA every few minutes with careful attention to hemodynamics until a T4 level obtained (may take 15–20 mL)
Opioid	10–15 mcg Fentanyl, 0.15 mg PF morphine (Intrathecal)	100 mcg Fentanyl (with initial bolus) 2–3 mg PF morphine (after delivery)	10–15 mcg Fentanyl, 0.15 mg preservative free morphine (Intrathecal)	100 mcg Fentanyl (with initial bolus) 2–3 mg PF morphine (after delivery)
Fluids	Preload or co-load with 1L warm crystalloid	As clinically indicated during surgery	Use caution with pre-load or co-load. If given, consider lower volume (250–500 mL) given over 30–60 minutes	As clinically indicated during surgery
Pressor/inotrope	Phenylephrine infusion 0.5 mcg/kg/min at time of intrathecal injection. Can be weaned off after baby is delivered	Phenylephrine bolus as needed	• If intrathecal LA used: phenylephrine infusion 0.5 mcg/kg/min at time of intrathecal injection. • In patients with severely reduced EF, consider epinephrine or dobutamine (2–3 mcg/kg/min) at the time of delivery. Can be weaned off by the end of surgery	• Phenylephrine or epinephrine bolus as needed. • In patients with severely reduced EF, consider epinephrine or dobutamine (2–3 mcg/kg/min) at the time of delivery. Can be weaned off by the end of surgery

Abbreviations: LA= Local anesthetic; PF= preservative free; EF= Ejection fraction

[a] In a 20 mL syringe, mix 18 mL 2% lidocaine + 2 mL bicarb (1 meq/mL) + 100 mcg epinephrine (0.1 mL of 1 mg/mL epi)

Table 20.4 Hemodynamic effects of common uterotonic medications

	Class	CV effect	Special considerations
Oxytocin	n/a	With rapid IV bolus: • Vasodilation • Hypotension • Tachycardia • Myocardial ischemia (rare)	Safest when given as a slow bolus (<2 units/min) or a continuous infusion (18–36 units/hour)
Methergine	Ergot alkaloid that increases smooth muscle contraction	• Hypertension • Coronary vasospasm (rare) • Myocardial ischemia (rare)	• Dose: 0.2 mg IM • Avoid in patients with hypertension, preeclampsia, severely reduced systemic ventricular function, aortopathy, L→R shunts
Carboprost	Prostaglandin F2 alpha analogue	• Bronchoconstriction • Increased pulmonary artery pressure	• Dose: 0.2 mg IM • Avoid in patients with reactive airway disease, shunt lesions, right heart dysfunction, pulmonary hypertension
Misoprostol	Prostaglandin E1 analogue	None	• Safe for patients with CHD • Administered via sublingual, rectal, or vaginal routes
Tranexamic acid	Antifibrinolytic	• None shown over control groups in WOMAN trial	• Dose: 1 g over 10 minutes, repeat in 30 minutes if bleeding continues

Abbreviations: IM = intramuscular

Adults with down syndrome

Down's syndrome is the most common chromosomal disorder, with an incidence of 1 in 700 live births in the United States each year [94]. Due to advances in congenital heart surgery and respiratory disease care, most Down's patients reach adulthood, with a median life expectancy of 58 years [95]. de Graaf et al. estimated the Down's syndrome population in the United States to be about 200,000 with a growing adult component and stabilized pediatric due to elective terminations. Around 40–50% of Down's syndrome patients have CHD, most commonly AV canal defects (37%) [10]. Hospitalization rates in the United States, using the Nationwide Inpatient Sample from 1998 to 2009 for adults with and without Down syndrome aged 18–64 years, revealed that 11.5% of all hospital admissions (9,088/78,793) for CHD were patients with Down syndrome. Patients with Down syndrome had higher in-hospital mortality (odds ratio 1.8) and were less likely to have cardiac procedures or surgery (odds ratio 0.3) [96]. Down syndrome patients in this study were also more likely to have cyanosis, secondary polycythemia, heart failure, and pulmonary hypertension. Co-morbidities include deficiencies in cognition and a tendency toward infection. Dementia may occur as early as 40 years, and the prevalence of dementia is 50–70% at 60 years. Other issues include acquired mitral valve disease, atlanto-axial instability, obstructive sleep apnea syndrome (OSAS), hearing loss, diabetes, osteoporosis, and epilepsy [97].

The preoperative visit must include a thorough history, assessment of atlanto-axial instability with recent flexion and extension views of the cervical spine and risk assessment for OSAS. Increasingly, the indication for intervention is the decrease in functional capacity, and the cardiac function should have an objective assessment to ascertain whether the cause is cardiac or onset of dementia. In the normal population, the onset of dementia is heralded by a change in memory, whereas in Down syndrome, it is often a behavior change. The plan for induction and emergence of anesthesia should involve caregivers available and interested. In patients with the unstable cervical spine, videolaryngoscopy is beneficial since it produces less upper cervical spine motion [98]. The disposition should be to areas that advanced respiratory support can be provided, such as continuous positive airway pressure (CPAP) [99].

Psychological issues

As outlined in the introduction, many patients with ACHD are lost to follow-up because they feel well and perceive themselves as an average person who had heart problems in childhood that were "fixed." In addition, many patients will have parents in attendance who are well versed in the history of their adult child's health and may have difficulty taking a secondary supportive role in decision-making. This issue is genuine if a spouse is designated as the substitute decision-maker for the patient, should they encounter a prolonged length of stay in the cardiovascular ICU. While empowering the patients with ACHD, sensitivity to these issues is an essential consideration in discussing high-risk procedures.

There is a wealth of literature addressing the psychological well-being, quality of life, and life satisfaction of adults living with CHD. In a prevalence study, Khanna et al. showed that 33% of the patients with ACHD were diagnosed with a mental illness. The most common conditions were mood disorders (13%), anxiety disorders (13%), and substance-related disorders (6%) [100]. More complex lesions requiring more interventions, and the presence of a congenital syndrome increased the likelihood of mental illness.

When the quality of life is measured about psychosocial, occupational, and environmental aspects, they are as happy as, or happier than, the public [101]. Another study found that patients with ACHD were more resilient than the general population [102]. Interestingly, quality of life does not correlate to CHD subtype, cyanosis, personal resources, or family environment [68]. These studies are done in an outpatient setting and not in the context of hospital admission with a change in health status. One in four patients with ACHD will die from heart failure. Diminished quality of life in patients with heart failure correlates with female sex and younger age, and it seems reasonable to experience depression and frustration at not being able to do activities [103]. As more patients with ACHD present for transplant or palliation, this will need to be addressed by ACHD multidisciplinary teams.

The anesthesiologist-intensivist, as a multidisciplinary team member, must ensure that the patient has a clear understanding of the anesthetic risks and the implications for their quality of life. In addition, the patient needs to have realistic expectations of how the intervention will improve their activities of daily living and exercise tolerance and over what time frame. Frank and explicit discussion of the role of the substitute decision-maker in the presence of the patient and the substitute decision-maker should ideally occur in advance of the procedure, with an opportunity to review questions should they arise before the morning of the intervention or surgery. At times, psychological counselling may be offered to help the patient through this process and support them in communicating their wishes for limits of care to their families.

Cardiac lesions

Lesions in this section are discussed in detail in individual chapters but are focused on pediatric congenital cardiac patients. This section will concentrate on the unique consideration for the patient with ACHD in both cardiac surgery and noncardiac surgery, starting with general reviews followed by lesion-specific discussions. There will be a brief discussion of the anesthetic issues unique to the adult for each of these lesions: ASDs, levo-transposition of the great arteries (L-TGA), and Ebstein's anomaly. Bicuspid aortic valve and the associated aortopathies are managed in adult practices independent of referral ACHD centers and will not be described here

Atrial septal defects and Shunts

Patent Foramen Ovale (PFO)

The foramen ovale is an essential component of fetal circulation. Generally, there is an abrupt reversal of the interatrial pressure gradient at the time of birth, allowing functional closure of the foramen ovale. Thus, anatomic closure occurs during infancy in most populations, but in up to 25%, closure is incomplete, and a potential inter-atrial communication exists into adulthood. It is possible to miss a PFO only by color flow Doppler. A contrast study (agitated normal saline injection, or agitated blood: saline in a 1:10 ratio) increases the sensitivity

of TEE. The contrast medium injected during the Valsalva maneuver is released when contrast is visualized within the right atrium to exploit the reversal of inter-atrial pressure gradients maximally. To further increase the sensitivity of the test injecting via a lower-body vein, the Eustachian valve preferentially directs blood from the inferior vena cava (IVC) toward the inter-atrial septum. The surgeries in which intraoperative closure of the PFO is almost mandatory are right-sided open-heart surgery on the beating heart and those clinical scenarios in which altered loading conditions produce a significant right-to-left shunt postoperatively. Those settings include heart transplantation, where right atrial pressure increases significantly, and implantation of a left ventricular assist device (LVAD) considerably offloads the left heart [104]. Thus, a PFO at cardiac surgery is not unique to congenital cardiac anesthesia, although it is a remnant of the fetal circulation.

Atrial Septal Defects (ASDs)

An ASD is one of the most common forms of CHD, representing 7% of CHD in childhood and 30–40% in adulthood. There are four types of ASDs. These are well described in Chapter 26 but warrant discussion as ASD is one of the lesions commonly present in the adult.

1. Secundum ASD is the most common type of defect, representing 75% of ASDs. It may be associated with mitral valve prolapse.
2. Ostium primum type ASDs are considerably less common, comprising 15% of cases. They are considered a form of AV canal defect and may be associated with a cleft anterior left AV valve leaflet or, less commonly, a cleft in the septal leaflet of the right AV valve.
3. Sinus venosus defect represents 10% of septal lesions. The superior vena cava (SVC) type of sinus venosus defect is considerably more common than the IVC type, and both types are associated with partial anomalous pulmonary venous return (PAPVR). Pulmonary venous drainage results in a left-to-right shunt. Chronic right-sided volume overload may lead to pulmonary hypertension, which is more common in patients with two veins with anomalous return or other associated conditions, such as ASD [105].
4. Coronary sinus type ASD is rare and results from unroofing the coronary sinus into the left atrium (LA), such that blood may drain from the LA to the RA via the coronary sinus. It is essential to identify an associated left-sided SVC, because of the risk of inadvertent systemic delivery of retrograde cardioplegia and the possibility of a relatively small SVC and its implications for bicaval cannulation.

Unrepaired ASDs first presenting in adulthood is associated with new-onset fatigue, arrhythmias, cerebrovascular events, or an incidental murmur during routine physical examination. Secundum ASDs represent the most common form of ASD, and large shunts (Qp: Qs >1.5:1) require closure unless severe pulmonary hypertension has developed. The contraindication for closure is the systolic PA pressure >2/3 of systemic systolic pressure or PVR >2/3 of SVR. Percutaneous device closure is the preferred technique, although significant defects or without an adequate septal rim need surgical closure. At specialized ACHD centers, nonsecundum ASDs should be repaired. A large single center series of 784 patients having ACHD surgery over a period 2004–2015 had 167 patients with septal lesions repaired, and none experienced the composite adverse outcome of death, acute kidney injury and or prolonged ICU stay, and survival to 1 year was 100% [106].

Created shunts and fenestrations

Many adults underwent Potts and Waterston shunting during childhood. The Potts shunt extends from the descending aorta to the left PA, while the Waterston shunt extends from the ascending aorta to the right PA. These shunts increase blood flow to the ipsilateral lung, over time leading to unilateral pulmonary hypertension that cannot be estimated with a simple TR jet to calculate RV systolic pressure. The original BT and modified BT shunt with a Dacron conduit from the subclavian artery to the ipsilateral PA can also cause unilateral pulmonary hypertension and differential left and right lung flow. BT and modified BT shunts decrease arterial pressure, which may, in turn, lead to diminished growth in the ipsilateral arm. Removal of the shunt during repair procedures in childhood often leads to restoring blood flow to the arm. When assessing a patient with a prior systemic artery to PA shunt for noncardiac surgery, remember to consider the patient's position while asleep, thoracotomy, nephrectomy, prone, and whether there is differential blood flow to each of the lungs. Ask the patient if they prefer to sleep in one position, check the blood pressure in both arms, assess the patient in the surgery position for 5 to 10 minutes with oximetry. Examples of surgically created fenestrations include defects in the interatrial septum during Ebstein's anomaly repair or in a Fontan tunnel wall or conduit wall. These "pop-off" valves shunt when there is inadequate RV function/compliance. However, they are also potential sources of right-to-left shunting and paradoxical emboli.

Noncardiac Surgery in Septal Lesions

The size and direction of the shunt depend on the balance between PVR and SVR. Reducing PVR (hyperoxygenation and hyperventilation) and increasing SVR (vasopressor use) can increase left-to-right shunting, leading to pulmonary overperfusion and reduced systemic blood flow. Although such changes do not lead to cyanosis, patients will exhibit reduced cardiac output. Conversely, in patients with cyanosis, increasing PVR or decreasing SVR will exacerbate the right-to-left shunt and worsen hypoxemia without decreasing systemic cardiac output. Thus, the anesthesiologist must be adept at manipulating PVR and SVR. Generally, one should strive to maintain the patient's baseline oxygen saturation level, heart rate, and blood pressure in their ambulatory life when they are well.

KEY POINTS: ATRIAL SEPTAL DEFECT, SHUNTS, AND PAPVR

- PFO should be closed if symptomatic and during surgery for other defects.
- Secundum ASD is the most common type; pulmonary vascular disease is rare
- PAPVR is commonly associated with sinus venosus ASD and must be repaired by patch-baffle at the time of ASD surgery.
- Assess patients with systemic to PA shunts with a mind to the surgical positioning and differential pulmonary blood flow.

Ventricular septal defect (VSD)

A VSD is the most common congenital cardiac lesion in the adult population, excluding the bicuspid aortic valve, with a prevalence of 0.3 per 1,000, representing around 10% of ACHD. The anatomical considerations and classification of VSDs are described in detail in Chapter 26. Briefly,

i. Membranous defects, located in the membranous septum, are associated with TOF and abnormalities of the septal leaflet of the tricuspid valve. They are the most common defects (70%).
ii. Inlet VSD is located between the mitral and tricuspid valves and represents a form of endocardial cushion defect, and as such, may be associated with primum ASD and cleft mitral valve.
iii. Outlet, supracristal, or infundibular lesions are located just below the semilunar valves and are associated with prolapse of the right coronary cusp of the aortic valve and AI.
iv. Muscular VSDs may be congenital or acquired, single or multiple, and minor defects frequently close spontaneously in childhood.

The hemodynamic significance of a VSD depends on several factors: the size of the defect, the pressure gradient across the VSD, and the PVR. An isolated VSD will initially facilitate left-to-right shunting, which will significantly increase pulmonary blood flow in those VSDs with higher shunt volumes. Over time, this increased flow may result in changes in the pulmonary vasculature, which may lead to elevations of PVR, and eventually shunt reversal and Eisenmenger physiology. The anesthetic considerations for these various hemodynamic concerns are discussed in Chapter 26. The risk of endocarditis for all patients is not insignificant, even those with minor defects, and patients should receive prophylaxis according to current guidelines [10].

Outside of the developing world, most patients who reach adulthood with unrepaired VSDs have small lesions of little hemodynamic significance. Indications for repairing these lesions include Qp:Qs >1.5–2:1, evidence of LV volume overload, elevated PVR, or abnormalities of surrounding structures (such as aortic regurgitation in an outlet or infundibular VSD). Surgical correction traditionally occurs via a right ventricular approach, and, as such, conduction disturbances are common postoperatively. Multiple "Swiss cheese"-type muscular VSDs may be technically challenging repair and present for PA banding or hybrid approach instead [107].

Patent ductus arteriosus

A small PDA may present in adulthood for the first time with a left-to-right shunt and subsequent LV volume overload, dilation, and failure. General principles relating to patients with left-to-right shunts should be applied, as discussed earlier. Eisenmenger syndrome may eventually develop, resulting in the disappearance of the classical "machinery" murmur and differential clubbing and cyanosis of the lower limbs only [108].

Coarctation of the Aorta

Aortic coarctation is frequently associated with the bicuspid aortic valve, PDA, and mitral valve abnormalities. LV pressure overload results in concentric LV hypertrophy and diastolic dysfunction. Arterial hypertension occurs in the upper limbs, with relative hypotension in the lower limbs. More severe coarctation may result in the development of collateral vessels to maintain distal perfusion. In addition, longstanding hypertension results in accelerated coronary artery disease, risk of stroke, and aortic dissection.

Although aortic coarctation is frequently stented or repaired in childhood, it may recur in adulthood. Aneurysm formation may also be a late complication of repair. Less commonly, a patient may present for the first time in adolescence with upper body hypertension. Over the past decade, stenting is the technique of choice for primary, recurrent coarctation in adults and, in some instances of aneurysms [109, 110]. Guidelines suggest intervention when the gradient exceeds 20 mmHg or when proximal hypertension is explained by the narrowing, even if the gradient is <20 mmHg. In some cases, open repair is required. The approach is via left thoracotomy and requires lung isolation and collapse of the left lung. The presence of well-developed collaterals will prevent excessive proximal hypertension on clamping of the aorta. Left heart bypass or circulatory arrest is needed to intervene in the aorta. This procedure requires detailed planning and a team accustomed to lung isolation. Postoperatively, hypertension is common and may persist. Open repair of coarctation or aneurysm that is periductal is well within the skill set of a cardiac anesthesiologist in adult-acquired practice where acquired thoracic aneurysms are repaired.

Pulmonary valve stenosis (PS)

Pulmonary stenosis is a relatively common lesion, representing approximately 8–10% of all CHD lesions. It may occur as an isolated phenomenon, associated with other defects such as ASD, VSD, or PDA, or as part of the constellation of features of TOF (see later). The stenosis is most commonly at the valve level but may also be supravalvular or subvalvular. Valvular PS is associated with Noonan syndrome. Supravalvular PS may occur in association with Noonan, DiGeorge, and congenital rubella syndromes.

Although many patients with more severe lesions present and are treated in the neonatal period or early childhood, a proportion of patients with the milder disease will remain asymptomatic until adulthood. In these patients, indications for intervention include right ventricular outflow tract (RVOT) gradient >64 mmHg, symptomatic PS, decreased RV function, double-chambered RV (RV chamber divided in two by anomalous muscle bands), significant arrhythmias, ASD or VSD with right-to-left shunting [111]. Balloon valvuloplasty is generally the first-line treatment. However, patients with more complex anatomy, infra-valvular stenosis, or additional associated defects require surgical repair. Open repair typically takes the form of open valvulotomy with or without a transannular patch. Valve replacement rarely is the initial surgical treatment.

In adulthood, patients who have previously had interventions for PS frequently present either recurrent stenosis or hemodynamically significant pulmonary regurgitation (see Figure 20.6). Therefore, intervention is indicated in all cases of symptomatic pulmonary regurgitation and an objective decrease in exercise capacity, progressive RV dilatation, RV systolic dysfunction, tricuspid regurgitation, or sustained atrial or ventricular dysfunction arrhythmias.

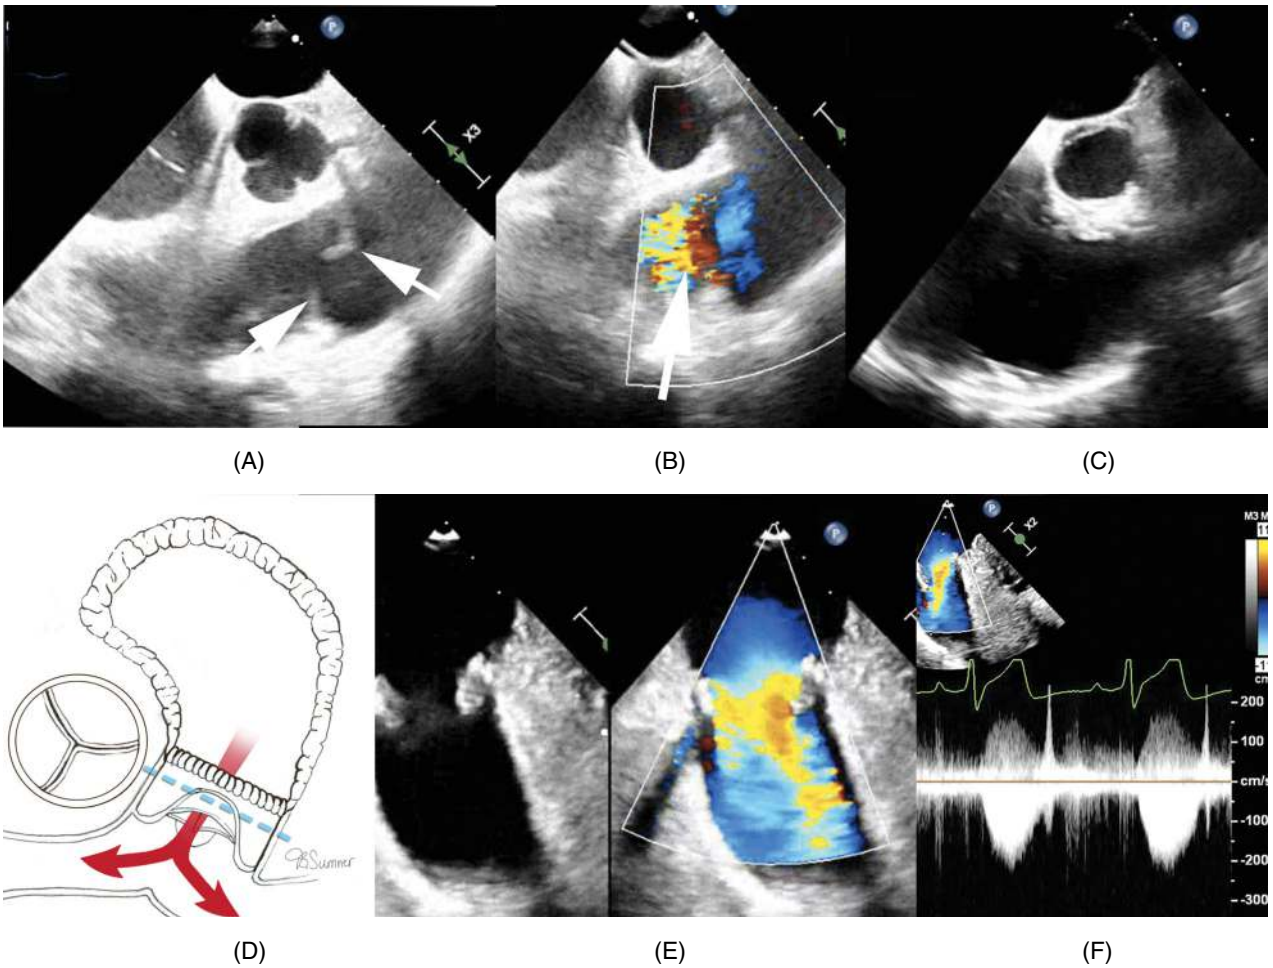

Figure 20.6 Preoperative TEE of an adult patient with congenital PS post balloon dilation palliation as an infant presenting with severe PI for PV replacement; (A) Mid esophageal RV inflow and outflow view showing dysplastic pulmonary valves with lack of coaptation (white arrow); (B) same view with color flow Doppler displaying free PI (white arrow); (C) post CPB RV inflow outflow view with poor visualization of the PV; (D) illustration exhibiting the replaced pulmonary valve in caudal view; (E) epicardial echocardiography showing the PV replacement with 29 mm Epic St. Jude tissue valve 2-D and color flow Doppler; (F) same view color flow Doppler displaying mild flow acceleration across the pulmonary valve, peak 2.2 m/s and trivial regurgitation. Abbreviations: TTE, transesophageal echocardiography; PS, pulmonary stenosis; PI, pulmonary insufficiency; RV, right ventricle; CPB, cardiopulmonary bypass. Percutaneous pulmonary valve replacement or transcatheter pulmonary valve implantation

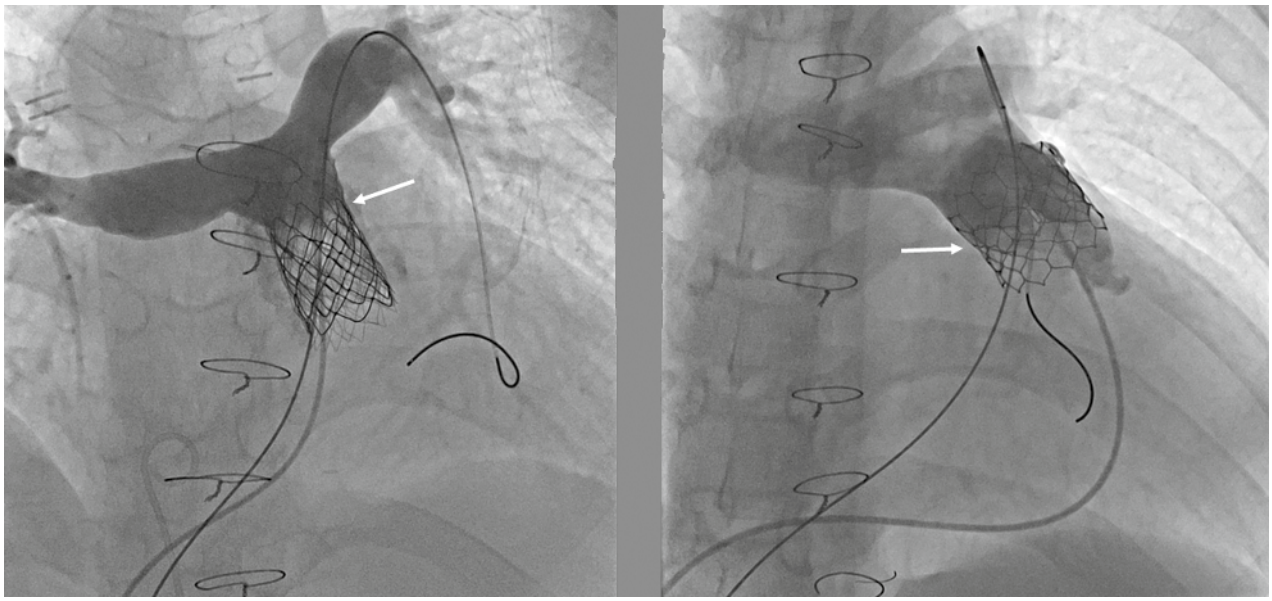
Percutaneous pulmonary valve replacement was introduced in the early 2000s with the original case reported by Bonhoeffer in a 12-year-old with a stenotic RV to PA conduit [112]. Initial indications were in dysfunctional RVOT and RV to PA conduits. It has expanded to patients with PS or PI with previous transannular patches in their original repair and valve in valve stented tissue bioprosthetic valves. There are two commonly available balloon-expandable valves, the Melody® valve (Medtronic, Minneapolis, MN, USA), a bovine internal jugular valved conduit sewn over a bare metal platinum–iridium stent, and the Sapiens valve (Edwards Lifesciences Corp., Irvine CA, USA), a bovine pericardial valve mounted on a cobalt-chromium alloy frame. Although the morbidity and mortality for surgical pulmonary valve replacement is less than 1% in most series, the mortality is far less in the percutaneous approach, albeit with an increase in post-procedural right-sided endocarditis [113–115]. Table 20.5 describes the transcatheter heart valve size recommendations and clinical cases are showed in Figures 20.7 and 20.8.

TOF, pulmonary atresia with an RA to PA conduit, and pulmonary homograft dysfunction post-Ross procedure are all common reasons for a TPVRI. Although the patients have a much-reduced length of stay in the hospital, there is a need for careful planning, assessment of comorbidities, a contingency plan for urgent open repair, and a post-procedural monitored environment. Deep anesthesia with muscle relaxation while deploying the percutaneous valve is desirable to avoid coughing with balloon dilation causing pulmonary hemorrhage, manifesting as a pulmonary hemorrhage, or mal-deployment/embolization. Complications also include fracture of the conduit/stent, failure to deploy due to too large an annulus, and damage to the tricuspid valve. The pulmonary valve annulus is close to the left main coronary artery, and compression can manifest with ventricular ectopy, ischemic changes in the electrocardiogram, and wall motion abnormality [116, 117].

Table 20.5 Transcatheter Heart Valve size recommendations are based on native valve annulus size, as measured by transesophageal echocardiography, or computed tomography



Transcatheter valve type	THV Size (mm)	Native valve annulus size by TEE/CT (mm)
Melody valve	20	Up to 20
(Medtronic)	22	Up to 22
SAPIEN 3	20	16–19
(Edwards)	23	18–22
	26	21–25
	29	24–28

Abbreviations: THV, Transcatheter Heart Valve; TEE, transesophageal echocardiography; CT, computed tomography.

Tetralogy of Fallot

TOF is the most common repaired cyanotic defect in the ACHD population, and these patients frequent the electrophysiology laboratory, urgent and emergent cardioversion lists, interventional suite for percutaneous valve and branch PA dilatation, and the operating room for pulmonary valve replacement, RVOT plication/remodeling and tricuspid valve repair/annuloplasty. Rarely does an adult present for primary correction in the developed world. Most older adults will present for a re-intervention or surgery, having had a palliative systemic-to- PA shunt for cyanosis followed by a repair as a child. Younger adults were likely diagnosed in utero and had medical therapy in the first few weeks to months of life and subsequent correction at 3–6 months [118, 119]. Most patients will have had a transannular patch to widen the RVOT at the time of repair, and over time they will develop pulmonary insufficiency, RV dilatation, and eventually tricuspid regurgitation due to RV dilatation. A smaller percentage of adults will have restriction of their RVs, which correlates with having had a transannular patch, elevated troponins immediately after repair, inotropic requirements, and prolonged time in the ICU. The restriction appears to protect the RV from ventricular dilatation due to pulmonary insufficiency [120]. The optimal timing of a pulmonary valve replacement with or without an RV plication and a tricuspid valve annuloplasty has been challenging to define, but a consensus amongst reference centers is forming. Intervening before RV end-diastolic volumes of 160 mL/m^2 or end-systolic volumes of 80 mL/m^2 and before QRS duration reaching 180 ms suggest improving RV remodeling and reducing the risk of sustained ventricular tachycardia, atrial arrhythmias, and sudden death [121].

The burden of arrhythmias for adult TOF is substantial, both atrial and ventricular, along with a lifelong risk of sudden death. A multi-institutional cross-sectional study found at least one type of clinically sustained arrhythmia in 79% of TOF patients >18 years with a median age of 36 [120]. Atrial arrhythmias, flutter, and fibrillation, correlate with tricuspid regurgitation and older age of repair. Ventricular arrhythmias and sudden death correlate with increased QRS duration and repair at an older age. The assessment of RV function and mass by magnetic resonance is now the gold standard. A multicenter registry, the INDICATOR cohort, of TOF adults has shown that RV hypertrophy, RV dysfunction, and LV dysfunction are defined by magnetic resonance correlate with sustained ventricular tachycardia [122]. Similarly, a report from the INDICATOR cohort post adult pulmonary valve replacement found 8% patients experienced sudden

Abbreviations: PV, pulmonary valve; RVOT, right ventricular outflow tract; TTE, transesophageal echocardiography; RV, right ventricle; PR, pulmonary regurgitation.

death or sustained ventricular tachycardia post pulmonary valve replacement with a median follow-up of 6.5 years, older age at PVR and pre-PVR RV hypertrophy, and dysfunction was predictive of shorter time to postoperative death and sustained VT [122].

Arrhythmia, electrophysiology, and diagnostic procedures

Symptomatic atrial arrhythmias, ventricular tachycardia, and catastrophic ventricular tachycardia/ventricular fibrillation are essential to the anesthesiologist as the hemodynamic considerations of TOF. The adult cardiac anesthesiologist will experience an increasing exposure to TOF patients for electrophysiological mapping, ablation, and insertion of prophylactic defibrillators. The management of hemodynamics depends on the predominance of stenosis or regurgitation of the pulmonary outflow tract. Patients with hypokinetic dilated RV due to pulmonary regurgitation will benefit from spontaneous ventilation and afterload reduction. Those with residual outflow tract gradients will need adequate preload.

Cardiac surgery

Management of the adult TOF patient for a pulmonary valve replacement with or without RV plication, tricuspid valve annuloplasty, or cryoablation is the most common surgical procedure in the Society of Thoracic Surgeons' database with a low <1%, 30-day mortality in a referral center for ACHD surgery. The hemodynamic goals must focus on maintaining RV contractility, minimizing PVR, and avoiding arrhythmogenic triggers. Intravenous and inhalational agents that diminish contractility have minimal effects on the PVR and minimal arrhythmogenic potential. Ventilation should be at or close to FRC, with minimal positive end-expiratory pressure (PEEP), and converted to a spontaneous ventilation mode, when possible, once in the postoperative or ICU setting. Along with recognizing the detrimental effects of long-term pulmonary

insufficiency and RV dilatation due to transannular incisions, adult anesthesiologists will see an increasing number of young adults with residual stenosis and outflow tract obstruction for both the operating room and catheterization laboratory. Anticipation of and a treatment plan for both atrial and ventricular arrhythmias is essential [123].

In developed nations, adults who have unrepaired TOF frequently come from developing countries and have anatomy favorable to surviving as an adult. They will have all the anesthetic considerations of living with cyanotic heart disease, as well as the co-morbidities described previously in this chapter. The anesthetic management of an unrepaired TOF patient for definitive repair is described in Chapter 28. There are a few special considerations for the adult patients [124]. Patients who survive will likely have aortopulmonary collaterals that can be problematic in the operating room and postoperative ICU management. Preoperative coil embolization of extensive collaterals will reduce the run-off of aortopulmonary collaterals, which will lower MAP on bypass. However, the pulmonary vasculature may not be well developed, and patients will have less lung reserve. Postoperatively, the pulmonary vasculature will have a total cardiac output and additional left-to-right shunting from pulmonary collaterals, and there will be a risk of life-threatening pulmonary hemorrhage, which may require lung isolation and definitive management in the interventional suite or operating room.

Non-cardiac surgery

Management for the adult repaired TOF for noncardiac surgery will be tailored to the predominant pathology of the RV and pulmonary outflow tract as stated in the discussion of the arrhythmia, electrophysiology, and diagnostic procedures. Comorbidities resulting from living with a dilated and pressure or volume-loaded right heart such as congestive cirrhosis are needed to be evaluated in the preoperative period. Arrhythmias, both atrial and ventricular, are common, and a preemptive drill with the intraoperative surgical and nursing team at the start of the case is warranted and includes suitable placement of defibrillator pads and a test of contact before prepping. Inotropes to assist with RV dysfunction and pulmonary vasodilators may be necessary. Anesthetic techniques and post-anesthetic pain management should be mindful of keeping the PVR low. Appropriate postoperative monitoring in an ICU setting for heart failure and arrhythmia is critical.

Pulmonary atresia

Pulmonary atresia is a heterogeneous diagnosis and has three broad categories. Pulmonary atresia is the absence of direct communication between the ventricular chamber/s and the pulmonary vasculature [125]. It is classifieds as:

1. Pulmonary atresia with an intact ventricular septum is an extreme form of TOF. With an adequately sized ventricle, an intervention is an RV to PA conduit or a "two ventricle repair."
2. Pulmonary atresia with VSD patients shares the intracardiac anatomy of TOF without direct communication between the RV and the PA. These patients may have a "two ventricle repair" with the closure of the VSD and an RA to PA conduit.
3. There is a 3rd group of pulmonary atresia, VSD, and complex univentricular anatomy types with additional defects not suitable for biventricular repair. Patients may have an absence of the main PA, and extensive aortopulmonary collaterals supply the pulmonary vasculature.

The Royal Brompton group reported their experience of a large population of patients labeled as Pulmonary atresia, 227 patients, mean age 25.5 ± 8.7 years, over a median follow-up of 8.8 years. The patients represented the full spectrum described above and were categorized in one of the three groups above based on original anatomy, and group 1 was subdivided into repaired (a) and unrepaired (b). Interestingly all three groups had no difference in survival (78%) and, there was no significant difference in survival between groups between repaired and unrepaired patients [125].

Anesthetic management will depend on the anatomy and type of repair the patient has or has not had in childhood. Many will be managed like TOF with an RV to PA conduit and. Others may be complex single ventricles with aortopulmonary collaterals and segmental pulmonary hypertension and unrepaired or palliated with a Fontan circulation.

KEY POINTS: PULMONARY STENOSIS, TETRALOGY OF FALLOT, PULMONARY ATRESIA

- PS is common and may be asymptomatic until adulthood when right heart failure occurs.
- TOF is the most common ACHD repaired cyanotic defect; pulmonary valve replacement and arrhythmia treatment are common procedures
- Pulmonary Atresia is a heterogenous diagnosis and should be managed based on the original anatomy and the surgical intervention (*two ventricle repair* or Fontan)

Congenitally corrected transposition of the great arteries

L-TGA is also called congenitally corrected transposition of the great arteries (ccTGA), and this is also called congenitally corrected or L-transposition of the great vessels, terms that confuse many. The term implies that the patients are "born corrected or physiologically compatible with life." These patients have both AV discordance and ventricular-great artery (VA) discordance; the RA connects to the morphological LV that is subpulmonic; the LA connects to a morphological RV which is subaortic. L-TGA is one of the rare CHD with adult presentation that on echocardiography appears erroneously as a normal four-chamber heart; however, the RV and LV (the tricuspid valve is more apically placed).

Most of these patients have VSDs (60–80%), sub-valvular or valvular pulmonic stenosis (30–50%), and abnormalities of the systemic AV valve (up to 90%) that is described as Ebstein's-like with moderate-to-severe systemic AV valve regurgitation [126].

In the absence of associated anomalies, these patients present in the second and third decades of life with systemic AV

valve regurgitation and symptoms of heart failure. Arrhythmia is a frequent presentation, including complete heart block with increasing age and atrial arrhythmias, usually a symptom or consequence of a more significant problem such as a failing systemic RV with tricuspid regurgitation. Much like the Mustard and Senning patients (see later), they are managed like a patient with dilated cardiomyopathy and likely have a degree of PAH and may be on a transplant or mechanical assist pathway (see Figure 20.9).

Surgical interventions depend primarily on the associated anomalies. The patients with PS who have subpulmonic LVs are trained for systemic pressures and may be candidates for an atrial and arterial "double switch" operation. Patients without subpulmonic obstruction can be considered for sequential PA banding to train the LV for a potential "double switch." It is a staged process that requires multiple surgical interventions, and many patients improve with the PA band alone, which causes a septal shift due to increased LV pressures and improvement in the systemic RV geometry with less tricuspid regurgitation. This palliation may be a destination on its own, or the patient can proceed to a combined Mustard/Senning with either an arterial switch or a Rastelli procedure [127, 128]. Additional details about surgical approaches to L-TGA are presented in Chapter 29.

Dextro-transposition of the great arteries (D-TGA)

D-TGA mustard or senning baffle

Dextro-transposition of the great arteries (D-TGA) patients has atrial–ventricular concordance and ventricular–great artery discordance (see Figure 20.10). The RV is the subaortic and systemic ventricle. Although rarely done now, many adults live with atrial baffle repairs, which redirect the atrial blood to the opposite ventricle (see Figure 20.11). The Senning and Mustard operations were the standard of care, often with a prior temporizing systemic-to-pulmonary artery shunt, until the mid-1980s when the arterial switch became the preferred method. Retrospective reviews reveal the good quality of life until the fourth decade with 25-year survival

rates of 91% in Senning) and 76% in Mustard [129]. The drawback is that the RV remains as the systemic ventricle [129]. Patients with a Mustard or Senning repair frequently have baffle leaks, obstruction or narrowing of the SVC, IVC or pulmonary veins, atrial sinus arrhythmias, sick sinus syndrome, and inevitably systemic ventricular failure with systemic (tricuspid valve) AV valve regurgitation [130].

The anatomy can appear complicated; however, there is a physiological correction. A red cell will traverse the cardiopulmonary circulation in an appropriate sequence but with reversed roles of the ventricles. Central venous access can be challenging, as the catheters may get caught up in the baffle or make an abrupt turn from the LV back to the PA. The patients are frequently pacemaker-dependent with multiple central vein manipulations in the past and narrowed SVC. Hemodynamically, D-TGA with a subaortic RV repair presents like a dilated cardiomyopathy with a failing systemic ventricle with AV valve regurgitation. Agents to promote contractility and systemic afterload reduction are the goals.

Case reports of PA banding in adults to train the subpulmonic LV for systemic pressure and subsequent take-down of the Mustard baffle and arterial switch had mixed success, with significant morbidity and mortality [131]. Adult patients may present for revision of an obstructed baffle. Far more frequently they are scheduled for pacemaker, defibrillator, and electrophysiology procedures. Cardiac transplantation is technically challenging and may not be possible due to PAH.

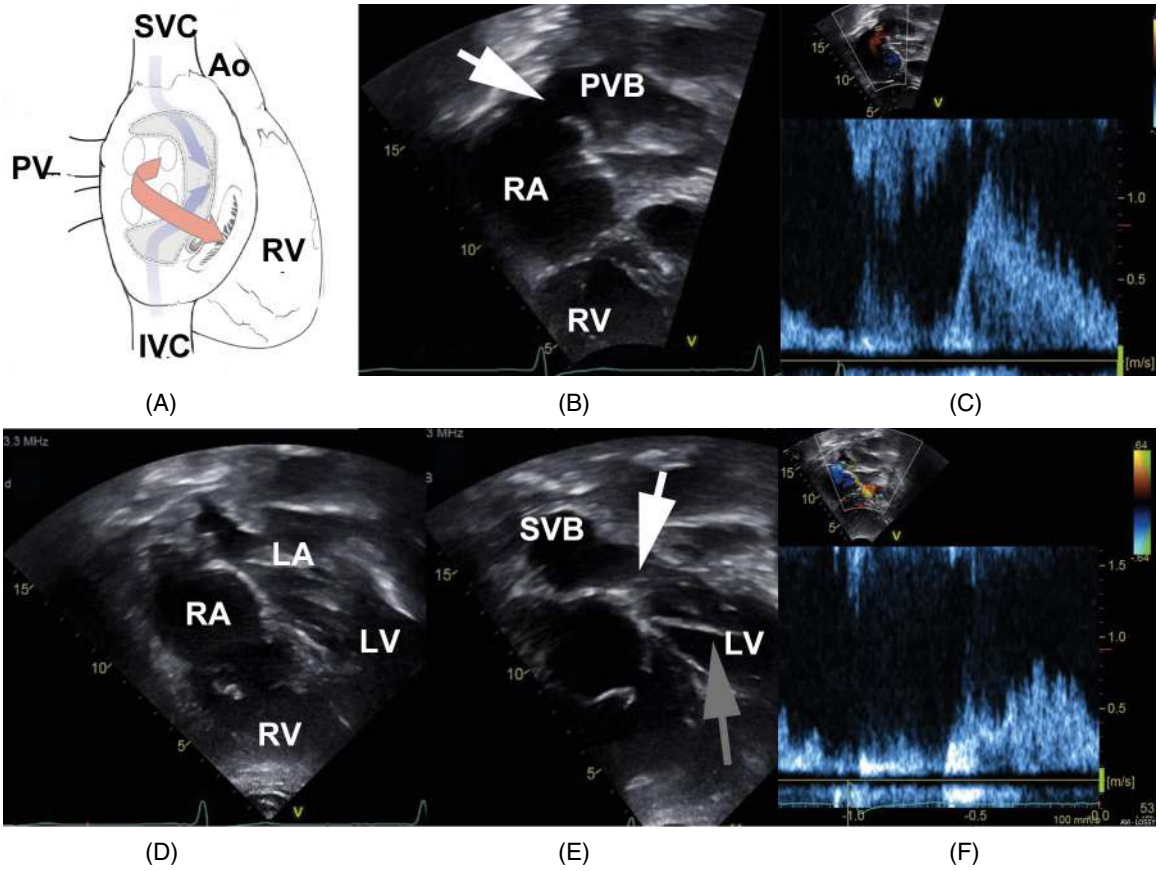

Figure 20.11 (A) Illustration of the Mustard procedure with pulmonary venous baffle to the RV (red arrows) and systemic venous baffle to the LV (blue arrows); (B) TTE echocardiography apical four-chamber view showing the pulmonary venous baffle to the RA (white arrow); (C) Pulse wave Doppler displaying unobstructed pulmonary vein baffle flow; (D) same window exhibiting moderately dilated and hypertrophied systemic RV; (E) identical view focusing in the systemic venous baffle (white arrow) with a transvenous pacemaker through the baffle (gray arrow); (F) open by pulse wave Doppler. Abbreviations: TTE, transthoracic echocardiography; PV, pulmonary veins; SVC, superior vena cava; Ao, aorta; RV, right ventricle; IVC, inferior vena cava; PVB, pulmonary venous baffle; RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle; SVB, systemic venous baffle.

D-TGA with an arterial switch

In the late 1970s and early in the 1980s, CHD pediatric centers moved from the Senning, and Mustard repairs to the Jatene or arterial switch operation [132]. These patients have yet to reach adult centers in large numbers. Still, complications include coronary artery perfusion defects and aneurysms of the neo-aortic root [133]. The advantage is that the LV is the systemic ventricle, with AV and VA synchrony restoration.

D-TGA with VSD and PS and a Rastelli repair

Patients with D-TGA, VSD, and PS in childhood are amenable to Rastelli repair. This procedure entails an LV tunnel through the VSD to the aorta and extracardiac conduit that connects the RV to the central PA. The systemic ventricle is the LV; however, these patients return for obstruction of their conduits. These are surgical cases with considerable risk of entry into the conduit on sternotomy in the past. Still, increasingly these patients are dealt with in the interventional suite for TPVRI and balloon dilatation of the conduit. Freedom from death or transplant at 20 years is disappointing in this population at 58% [134].

KEY POINTS: TRANSPOSITION OF THE GREAT ARTERIES

- L-TGA may be asymptomatic until adulthood; arrhythmia, including heart block and heart failure, are the usual presenting signs.
- D-TGA patients' historical treatment was Mustard or Senning intra-atrial baffling until the 1980s; problems include frequent arrhythmias and systemic RV failure.
- The arterial switch became the standard treatment for D-TGA in the late 1980s; adults may have coronary artery perfusion defects and neo-aortic aneurysms.

Ebstein's anomaly

Ebstein's anomaly is a rare anomaly, less than 1% of all CHD, characterized by apical displacement of the septal and posterior leaflets of the TV (Figure 20.12). These leaflets may lack chordae and are therefore attached directly to the ventricular wall. The anatomic change results in tricuspid regurgitation, and atrialization, and reduced functional size of the RV. The anterior leaflet of the tricuspid valve may be large and redundant, resulting

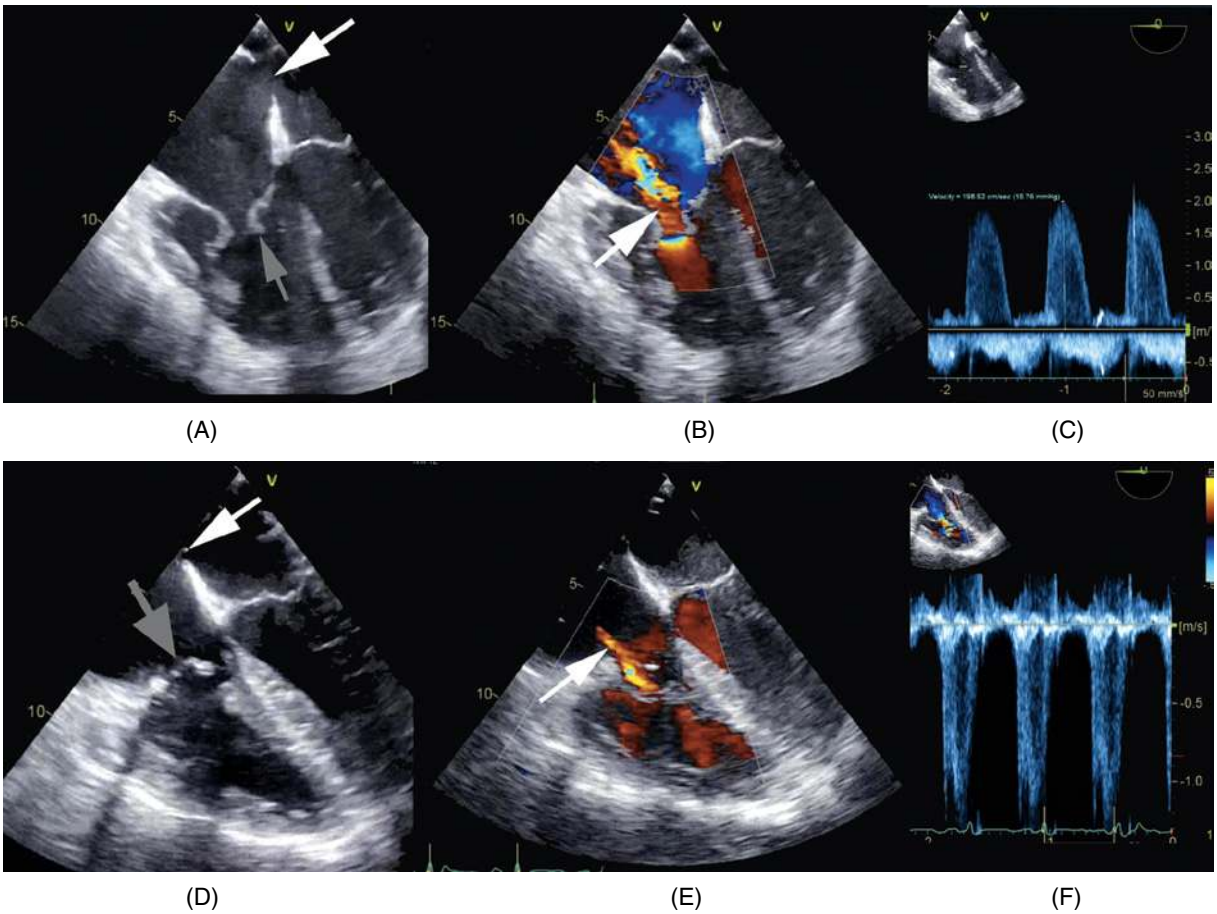

Figure 20.12 Pre-operative TEE of Ebstein's anomaly showing mid esophageal four-chamber view (A) Ebsteinoid/dysplastic tricuspid valve with apical displacement of the septal leaflet (gray arrow), lack of leaflets coaptation and large ASD (white arrow); (B) Color flow Doppler of the same view compatible with moderate-to-severe TR (white arrow); (C) Continuous wave Doppler displaying a dense jet with a peak velocity of 2.0 m/s confirming moderate-to-severe TR; Postoperative TEE post TV repair, ring annuloplasty and ASD closure at the mid esophageal four-chamber view (D) annuloplasty ring (gray arrow), small ASD (pop-off); (E) Continuous wave Doppler with trivial TF jet (white arrow); (F) Pulse wave Doppler of the TV inflow revealing mild stenosis (mean gradient of 5 mmHg) Abbreviations: TEE, transesophageal echocardiography; ASD, atrial septal defect; TR, tricuspid regurgitation; TV, tricuspid valve.

in RVOT obstruction. Ebstein's anomaly is frequently associated with other cardiac anomalies, particularly ASD. Secundum ASD occurs in over 90% of individuals [135].

Those with relatively milder disease may present for the first time in adulthood, often presenting as new onset of an atrial arrhythmia. The context may be surgical (e.g., acute cholecystitis, appendicitis) or labor and delivery. The degree of abnormality lies on a broad spectrum of natural history and severity, depending on the degree of displacement of the tricuspid valve leaflets, and the degree of shunting across a PFO or secundum ASD. The first presentation beyond the fifth decade is rare; however, patients may present as late as the eighth decade [136]. Older patients most commonly present with arrhythmias, but paradoxical embolus may occur in those with ASD or PFO.

Arrhythmia, electrophysiology, and diagnostic procedures

A European multicenter study reported 32 patients (mean age 24 ± 15 years) with atrial arrhythmia of which re-entry tachycardia was the most common (69%), previous surgery in 9 (32%), prior catheter based ASD closure in 3 (9%). More than 60% of the patients had been on a median of 2 (range 1–4) antiarrhythmics and had a median of 2 (range 1–26) previous cardioversions [137].

Several factors must consider in the management of Ebstein's. First, the amount of RV dysfunction followed by shunting at the atrial septum level. The latter could cause paradoxical emboli or reverse shunting and hypoxemia. Ideally, light conscious sedation with oxygen supplementation and avoidance of elevated $PaCO_2$.

In DC cardioversions, pre-oxygenate the patient and hyperventilate before administering hypnotics. Wait for spontaneous ventilation rather than assist positive breath manual ventilation. Be mindful that the circulation time to render the patient unconscious may be prolonged and resist the temptation to supplement with additional doses. A small dose of benzodiazepines may reduce the total quantity of propofol and lessen the drop in systemic blood pressure and the risk of shunting.

Cardiac surgery

The Cone repair was introduced by Da Silva and colleagues and adopted throughout the cardiac surgical community [138]. The repair is not exclusive to pediatrics or adults. Two

recent series from the Mayo Clinic (USA) and the Institute Jacques-Cartier (Massey, France) had patient populations with median ages of 19 years and 34 years [139, 140]. There is not a reliable predictor of right heart failure post repair. In the Mayo clinic series, 24% of patients had a bidirectional cavopulmonary anastomosis or "one and half" ventricular repair. Also, 13% had an early re-operation for re-repair or valve replacement.

A concurrent anti-arrhythmia procedure, such as the Maze procedure, is frequently performed. In addition, the RV function might be inadequate post-repair and need support with milrinone and epinephrine. The aim is to minimize PVR and support systemic blood pressure. Conversion to spontaneous ventilation and early extubation is desirable. A relatively fast sinus rhythm appropriate for the age and judicious volume administration is critical. Good communication between the operative and ICU team with a goal for early spontaneous ventilation is vital. Chapter 28 contains an extensive discussion of Ebstein's anomaly and surgical approaches.

Noncardiac surgery

Ebstein's anomaly is high risk and merits referral to a cardiac reference center for management. Ideally, for elective procedures, a consultation with the multidisciplinary ACHD team and, in emergent cases, contact with the ACHD cardiology team and a congenital cardiac anesthesiologist.

A quarter of the patients had a bidirectional cavopulmonary (Glenn) shunt in the Mayo series [139]. The SVC anastomosed to the confluence of the left and right PAs. Care should be taken when placing central lines in these patients, as trauma may occur with the introducer, the wire, or the line itself, and a non-congenital cardiac anesthesiologist may miss this nuance and not appreciate that the line will transduce PA pressures.

As with TOF and failing hypokinetic RVs, patients with Fontan or total cavopulmonary connection will benefit from spontaneous ventilation techniques where possible. If positive pressure ventilation is indicated, it should be at a volume close to FRC. The RV might need support with milrinone, epinephrine or dobutamine, or a combination. For patients that have high right atrial pressures or cavopulmonary pressure, the head-down position can exacerbate it. MAP may have to be supported to ensure an adequate cerebral perfusion pressure.

Reversal of left to right shunt can occur even in the presence of device closure of an ASD. Many anesthetic agents, both intravenous and inhalational, are vasodilators that, in conjunction with positive pressure ventilation and insufflation of air or CO_2 into a body cavity, can raise intrathoracic pressure and PVR consequence, cause shunt reversal.

Single-ventricle anatomy/Fontan physiology

In an adult practice, patients with Fontan and Glenn shunt with single-ventricle physiology have been, for the most part, patients with tricuspid atresia, pulmonary atresia, and double inlet left ventricle, with morphological LVs as their systemic ventricles. However, increasingly, cardiac anesthesiologists see adults with hypoplastic left heart syndrome (HLHS) and systemic RVs. Fontan and Baudet first described the surgical correction of tricuspid atresia in 1971 [141]. There have been subsequent modifications to the procedure, all of which are present in adults followed in ACHD programs (see Figure 20.13) [142]. Most ACHD programs converted to either the lateral tunnel or the total cavopulmonary connection in the mid-1990s. Patients with a Fontan circulation will present for various interventions, including conversion of an RA to PA Fontan to a cavopulmonary connection, cardioversion, epicardial pacemakers, mapping, and ablation, and, in some cases, transplant.

The Australian New Zealand Fontan Registry has reported 413/1428 (29%) survivors of the Fontan procedure that underwent a late cardiothoracic reintervention (median 4.2 years, 30 days to 33 years) post-Fontan [143]. Excluding transplants and extracardiac Fontan conversions (ECFC), the proportion of patients with a dominant LV was consistent at 58% in both the late reintervention group and the no late intervention

group. The prevalence of the atriopulmonary Fontan is diminishing and at the time of publication was 15% (see Table 20.6). Forty-nine patients underwent Fontan conversion to ECFC at a median time of 18 years (range 5–29 years), and 31 patients underwent a heart transplant post-Fontan with a median time of 8 years (range 3 months–33 years)

Catheter-based interventions occurred in 220/413 (53%), of which fenestration closure was the most common (32%) median age 1.7 years (1 month–23 years) followed by catheter-based ablation of arrhythmia (13%) median age 20 years (3–31 years). Late re-operations occurred in 209 patients with pacemaker-related procedures occurring in 176 patients at a median age of 8.2 years (3.5–18 years). The remaining surgical interventions were in a pediatric age group with median ages less than 8 years and ranged into the late adolescent age. All late interventions described are markers for increased mortality [143].

The Mayo Clinic published their admissions experience of Fontan patients 18+ years over 25 years 1990–2015. There were 853 hospital admissions in 367 patients median age 31y +/− 7 years with a Fontan circulation, of which 259 (71%) had an atriopulmonary Fontan. Most of the admissions were arrhythmia-related 282 (33%), management, cardioversion, mapping, ablation, or heart failure-related 169 (20%). A minority had either cardiac 133 (16%) or noncardiac surgery 51 (9%)[144] (see Table 20.7).

Table 20.7 Procedures and outcomes of inpatient Fontan patients

	N	LOS (d)	In-hospital mortality
Fontan conversion/ revision	78 (9%)	6 (4–9)	10 (13%)
Valve replacement/ repair	41 (7%)	5 (4–8)	5 (12%)
Epicardial pacemakers/ defibrillators[a]	14 (2%)	3 (2–5)	0
Non cardiac procedures requiring GA	51 (9%)	3 (2–6)	1 (2%)

Most anesthetic encounters will be for nonsurgical interventions. Still, there will be cardiac and noncardiac surgical care in adults, rarely for a Fontan conversion/revision &/or transplant (see Figures 20.14 and 20.15). The physiological considerations are the same for the encounters but increasing complexity when the procedure conflicts with the physiological goals. A standard same-day procedure frequently will require in-hospital postoperative admission.

Arrhythmia, electrophysiology, and diagnostic procedures

The is no direct vascular access to the heart in lateral tunnel Fontan or a total cavopulmonary connection challenging the anesthesiologists. Challenges exist for cardioversion, mapping, and atrial ablation arrhythmias. Cardioversion of the adult Fontan can be safe but requires planning [145].

Arrhythmia is a significant complication of the original Fontan conversion and often signals the beginning of failing Fontan circulation and subsequent decreases in quality of life. Medical management is usually ineffective at preventing arrhythmia recurrence, and the required electrophysiological studies are complex and time-consuming but less so than a Fontan conversion. Early referral for radiofrequency ablation or Fontan conversion is essential as a longer duration of arrhythmia is a risk factor for arrhythmia recurrence [146].

The goals in an electrophysiology intervention are to maintain spontaneous ventilation without inadvertently raising the $PaCO_2$ of the patient and adversely affecting the PVR and diminishing trans pulmonary blood flow. Transconduit mapping is possible with radiofrequency transeptal techniques. Fenestrations to the atrium from the lateral tunnel or the conduit of the cavopulmonary connection are a restricted window for the electrophysiologist, akin to painting an interior room of a house through a small window in an exterior wall while standing on a ladder. Remote magnetic navigation uses retrograde access; however, it is a costly setup and not widely available [147]. The procedures are lengthy for both the anesthesiologist and the patient. The patient must not be too sedated so that the electrophysiologist physician can map the arrhythmia and yet should be comfortable to remain still for several hours. Conversion to a spontaneously breathing technique with a supraglottic airway is an option. Recovery in a monitored environment is essential. A checklist for cardioversion in the Fontan patient is presented in Table 20.8.

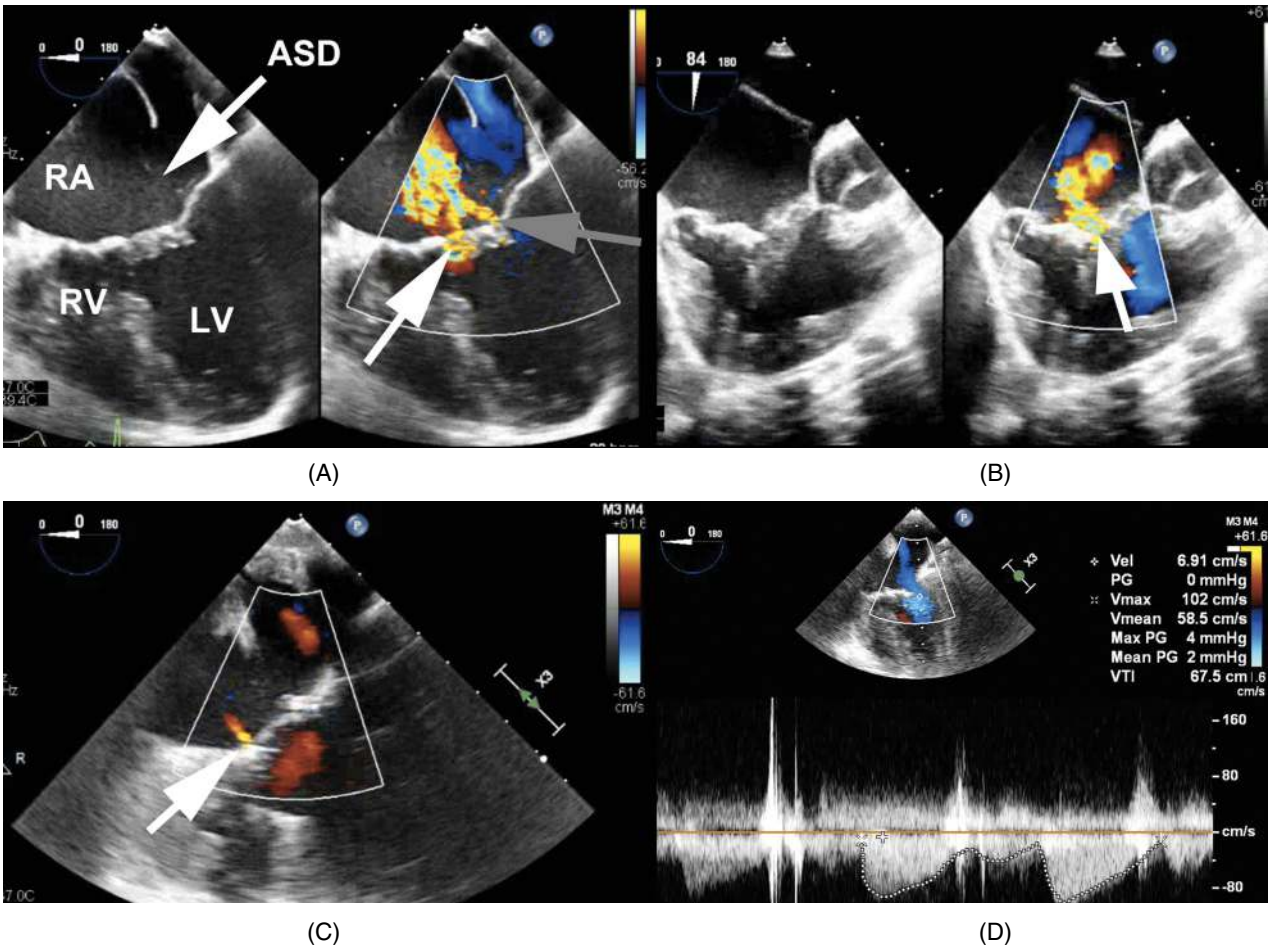

Figure 20.14 TEE images of a Fontan patient with unbalanced CAVC Rastelli type 3 (hypoplastic RV) with an unrestrictive primum ASD (white arrow) and severe AVV regurgitation who underwent AVV repair; (A) Mid esophageal four-chamber view showing a complex AVV regurgitation jet with two different components, a bigger jet along commissures between the superior bridging, inferior bridging, and right lateral leaflets (white arrow) and a smaller regurgitant jet between the superior bridging and inferior bridging leaflets (gray arrow); (B) Mid esophageal two-chamber view displaying the complex AVV regurgitation (arrow); (C) Mid esophageal four-chamber view exhibiting trivial regurgitation post AVV repair; (D) Pulse wave Doppler at the same window without evidence of AVV stenoses with a mean gradient of 2 mmHg. Abbreviations: RA, right atrium; RV, right ventricle; ASD, atrial septal defect; LV, left ventricle; AVV, atrioventricular valve.

Fontan conversion

Several centers have published successful case series of Fontan conversion with concomitant arrhythmia surgery. The median age varies from late teens to early adulthood [148, 149]. The goal is to improve hemodynamic and loss of energy in the blood flowing into the PA, lessen the risk of thrombo-embolic events, and prevent atrial dilatation and subsequent arrhythmias. A recent publication of a multicenter study of 522 adult patients found atrial arrhythmias were substantially lower with a total cavopulmonary connection Fontan compared to atrio-pulmonary Fontan. The median duration of follow-up was 11.6 years. Forty of the 522 patients underwent conversion from an atrio-pulmonary Fontan [25] or a lateral tunnel [12], and three had the transformation of an intracardiac to an extracardiac circulation [150].

Fontan conversions are a high-risk surgical procedure due to the complex anatomy and multiple previous operations. The anesthetic and ICU goals are to use agents and ventilation strategies that minimize PVR. Intraoperative or early ICU extubation is the goal. Conversion to an ECFC may improve quality of life and lessen the arrhythmia burden, but it is uncertain if this will translate to improved mortality. An extensive follow-up cohort in Boston found no difference in long-term survival between RA to PA connection Fontan and total cavopulmonary connections [150]. An analysis of 683 adult survivors in the Australian New Zealand Fontan registry found survival at 30 years of age was 86% for patients with atriopulmonary Fontan versus 93% for patients with an extracardiac Fontan. The differences in survival may be due to an era effect rather than technique, and the most common mode of death was cardiac failure. Only 9/683 had a conversion, and it is uncertain if conversion at an adult will translate to improved survival [151].

Noncardiac surgery and the patient with a Glenn Shunt, Hemi-Fontan, or Fontan

Reference centers cannot meet the demands of obstetrical and noncardiac of all patients with complex CHD. However, those with single ventricles, Glenn with a "One and a Half"

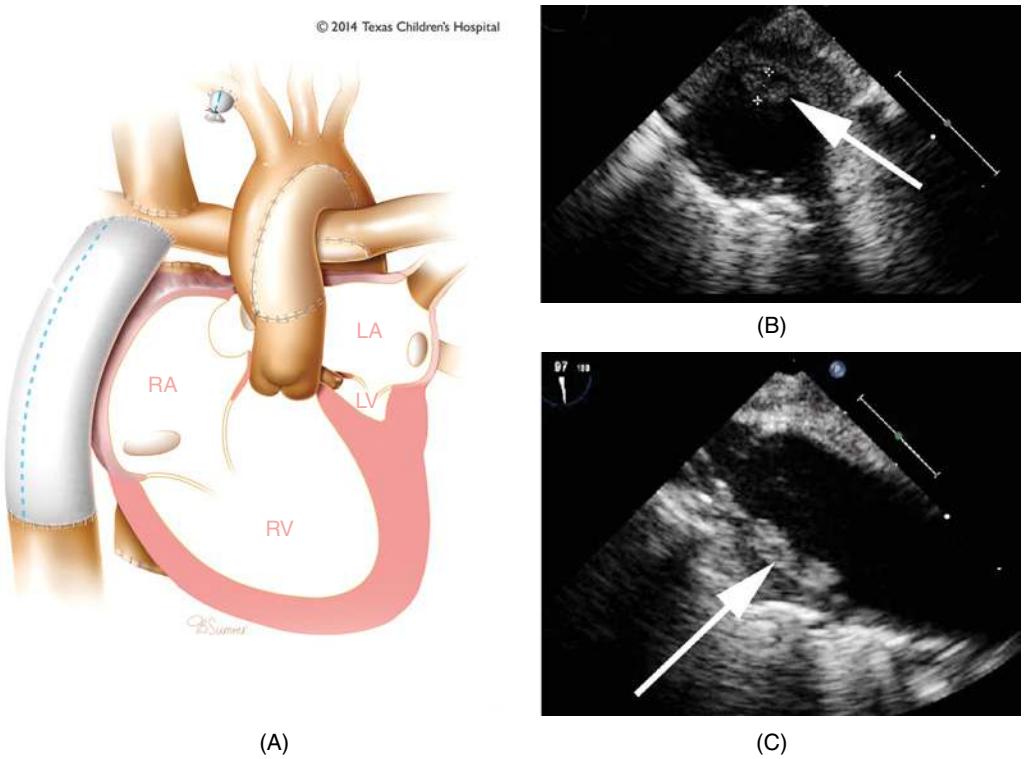

Figure 20.15 (A) Illustration of the Fontan circulation in HLHS; (B) TEE short axis view showing an immobile echo density visualized in the posterior wall of the Fontan baffle (white arrow); (C) TEE long axis view displaying another immobile echo density in the anterior medial wall of the Fontan baffle (white arrow). ventricle repair, and those with Fontan palliation must be reviewed by a multidisciplinary team or referred for management. Patient preference is a significant driver of choosing to go to a reference center rather than stay in the community. The Mayo Clinic group analyzed 538 noncardiac procedures in 154 Fontan patients (mean age, 30 years) from 1990 to 2015. A broad range of procedures and anesthetics were included, except for neurosurgical/intracranial. Fifty-one (9%) of the patients required general anesthesia. Overall, hypoxia was the most common intraoperative and postoperative complication, followed by hypotension and arrhythmia [152].

Multidisciplinary team consultation assessing the procedure's impact on single ventricle physiology patients must be evaluated by an interdisciplinary team. For example, a college student living away from home, with good systemic ventricular function and free of arrhythmias, needing dental extractions can be managed in a regional hospital setting with clear lines of referral to the reference center if required. Alternatively, a patient with decreased single ventricular function needing an urgent intrabdominal procedure will need care in a tertiary center. Neurosurgical patients (e.g., spinal instrumentation) merit both a cardiac anesthesiologist and a subspecialty neurosurgical anesthesiologist.

A classic Glenn shunt is an SVC directly anastomosed to the right PA. A bi-directional Glenn shunt is the SVC anastomosed to the confluence of the left and right PAs. When placing central lines in patients with Glenn shunts; trauma may occur with the introducer, the wire, or the line itself. Fontan patients have no "pump" for systemic venous return to get to the LA. For successful management, they must have adequate right-sided filling pressures, low PVR, unobstructed pulmonary vein inflow to the LA, AV synchrony, a competent systemic AV valve with laminar inflow, no outflow tract obstruction, and reduced afterload for the systemic ventricle. Patients may have had a fenestration from the Fontan connection to the systemic or common atrium, and precautions for venous emboli to the systemic circulation will be needed. Conversion to the spontaneous breathing mode of ventilation and early extubation are the objectives at the end of surgery.

KEY POINTS: SINGLE-VENTRICLE/FONTAN ANATOMY

- Early Fontan palliations due to right heart failure and arrhythmias necessitate conversion to lateral tunnel or extracardiac connections in some adults.
- Treatment of HLHS with the Fontan operation since the 1980s has created a growing population of young adults with failure of the systemic RV.
- Avoidance of prolonged positive pressure ventilation and hypovolemia are important anesthetic considerations.
- Arrhythmia procedures, mapping/ablation, pacemakers, and cardioversion are frequent in the adult Fontan and require careful planning and backup during emergencies.

Heart failure in ACHD

End-stage heart disease (ESHD) is particularly prevalent in single ventricle physiology (e.g., Fontan), systemic RV (d-TGA after Mustard/Senning or L-TGA), severe PAH (e.g., Eisenmenger-Syndrome), and severe valvular heart disease (e.g., post-CAVC repair) [153]. Traditionally, the treatment of ESHD is an orthotropic heart transplant. Patients with ACHD listed for transplant spend more time in the waiting list due to antibody sensitization to red cell antigens, and complex anatomy requiring specific graft allocation (e.g., need for extensive PA or aortic reconstruction). Formerly rare, patients with ACHD are now increasingly supported with VAD. Earlier use of VAD before the development of multiorgan failure increases survival in the ACHD population [154]. Only 5% of the adult heart transplant population are patients with ACHD [155]. Failing Fontan patients due to the high incidence of liver and renal failure need to be listed early even though multi-solid organ transplantation has been performed successfully [156]. Patients with Fontan circulation, complex anatomy, and PAH have a higher surgical risk [157].

Noncardiac surgery in the adult with CHD

Congenital cardiac anesthesiologists and intensivists have an exceptional understanding of ACHD patient's unique physiology. They must play a leadership role, providing care directly or advising colleagues in the community how best to provide care for these patients and when it is necessary to transfer care. This expertise is not limited to the operating room but should also be available in preoperative optimization and planning, postoperative monitoring, and pain management [158–161]. There are patient factors that will bias toward management at the tertiary referral center (see Table 20.9). Should an event occur in an ACHD center, there is much more latitude in the deployment of staff to assist in a hemodynamic or volume resuscitation.

Laparoscopic and video-assisted is becoming the standard for general surgical, gynecological, and urological operations.

Table 20.9 Red flags for referral to a reference center

Cyanosis or a deterioration in oxygenation from baseline	☐
Single ventricle	☐
Glenn or Fontan palliations	☐
Pulmonary hypertension	☐
New onset of arrhythmia or difficult rate control in an established atrial arrhythmia	☐
Systemic hypotension in relation to the patient's baseline	☐
Systemic ventricle dysfunction	☐

For example, thoracic surgery utilizes air insufflation, as the chest wall is rigid, and CO_2 is not needed. PVR will rise if the lung is atelectatic during one-lung ventilation but not from absorption insufflated CO_2. Similarly, in robotic surgery, insufflation of air with mechanical tenting of the abdominal wall is used. Insufflation of CO_2 might affect the PVR, but minimally invasive approaches improve postoperative recovery. Patient positioning (e.g., prone, lateral, Trendelenburg, or reverse Trendelenburg) may exacerbate or alleviate this conflict. The team should have a clear plan for conversion to an open procedure. Although challenging for the anesthesiologist, the patient benefits from a closed procedure and avoids the complications of a large incision. Additional benefits include less intravenous opioid use and will be less likely to have chest splinting, atelectasis, and elevated $PaCO_2$.

Head and neck and upper airway surgery with either a controlled airway or suspension laryngoscopies for glottic and subglottic complications of prolonged intubation are not unusual cases in patients with ACHD. It is not the choice of anesthesia agents but the maintenance of physiologic goals that is the challenge. Spontaneous ventilation in a PVR dependent patient will eliminate the concerns of positive pressure ventilation impeding blood flow from the vena cavae and right to the LA. Laryngoscopy and bronchoscopy with jet ventilation are challenging procedures in single ventricle, PAH, and shunt physiology patients.

Major spine surgery in the prone position is demanding in ordinary circumstances and, more so in patients with ACHD. Retrospective single-center reviews of complex CHD adolescent patients highlight multidisciplinary team planning and perioperative management [162, 163]. Pulmonary function evaluation preoperatively is indicated [164]. In larger, multilevel cases, considerable blood loss can occur, and blood conservation strategies are required. In addition, the technical challenges of spinal instrumentation in patients with complex cardiac disease merit a multidisciplinary anesthesia team (e.g., cardiac and neuro anesthesia). The one teaching hospital death in a long series of Eisenmenger syndrome adults for noncardiac surgery was an inpatient who had come in for spinal instrumentation [165].

Many patients will be receiving ongoing monitoring and support in an established ACHD center; however, frequently, a surgeon will be the patient's first contact with a specialist physician in several years of having been lost to follow-up. Community anesthesiologists and surgeons are in a unique situation to identify a patient at risk and, in addition to pre-, intra-, and postoperative care, reconnect them to an ACHD team for subsequent care. The consultant

AL Grawany

ACHD anesthesiologist can facilitate the surgery and act as a resource for the noncardiac anesthesiologist [158].

Conclusions

The survivor ACHD patient of a pediatric intervention or presenting for the first time as an adult may need anesthesia care for diagnostic, therapeutic, noncardiac surgery, cardiac surgery, and ICU management. The skills, knowledge, and career experience of a congenital cardiac anesthesiologist are vital to the care of this unique patient population. In addition, as the proportion of adults living with CHD continues to dominate the congenital cardiac population increasing resources at reference centers and the ability to support patients in the community setting with outreach and referral lines is essential to the well-being of these patient populations.

Introduction: Hemodynamic management following congenital heart disease surgery: a goal-directed approach

Guidelines delineate limits within which decisions can be made regarding the management of specific clinical problems to improve outcome. A more prescriptive approach often takes the form of "goal-directed" therapy, and the key to the success of any goal-directed therapy is the selection of the specific goal [1]. A meta-analysis of randomized studies of adult patients [2] in various postoperative settings demonstrated a strong relationship between the duration and magnitude of oxygen debt and outcomes in high-risk patients. There was a significant improvement in survival when pulmonary artery catheter goal-directed therapy was administered early or prophylactically (within 12–24-hour postsurgery or before organ failure occurred) to increase the cardiac index and oxygen delivery (DO_2). The aim of this goal-directed therapy was intervention before hemodynamic compromise or critical organ system compromise occurred, because no amount of extra oxygen would rescue irreversible oxygen debt, organ failure, or cell death. Maintaining adequate tissue oxygenation, which is accomplished by optimizing oxygen transport balance, i.e., maintaining systemic DO_2 and minimizing oxygen consumption (VO_2), should prevent oxygen debt and improve outcome. In complex and high-risk situations, such as following congenital heart disease (CHD) surgery, the use of evidence-based clinical guidelines and associated goal-directed therapy has the potential to improve clinical outcomes. Preventing oxygen debt is probably the ultimate goal when treating children who have undergone surgery for CHD.

The VO_2/DO_2 balance following CHD surgery

In 1995, Wernovsky et al. published a prospective study comparing deep hypothermic circulatory arrest and continuous low-flow cardiopulmonary bypass in neonates undergoing the arterial switch operation [3]. The perfusion strategy assignment was not associated with the postoperative hemodynamics. However, the hemodynamic measurements performed on 122 patients revealed that during the first

AL Grawany

postoperative night, the cardiac index decreased by average 30% in almost one quarter of patients. Consequently, much effort has been put into augmenting CO, and the PRIMACORP study [4] demonstrating the benefit of the preventive use of a potent vasodilator to increase CO was a milestone in the field. Later on, using continuous respiratory mass spectroscopy to measure oxygen consumption, arterial, superior vena cava (SVC), and pulmonary venous saturations to measure DO_2 in 14 neonates undergoing the Norwood procedure, Li et al. [5] reported low CO and systemic DO_2 during the first 12 postoperative hours; VO_2 was high postoperatively and progressively decreased over the first 24 hours. The decrease in VO_2 during the first 24 h was the main contributor to improving the VO_2/DO_2 balance, pointing to the rationality of postoperative strategies to decrease VO_2 in critical cases.

A pathologic imbalance between VO_2 and DO_2 is thought to be the mechanism underlying anaerobic metabolism, multisystem organ failure, and death. The oxygen extraction rate (OER), calculated as

$$\mathrm{OER} = \mathrm{VO_2} / \mathrm{DO_2} \tag{21.1}$$

might best reflect the oxygen consumption/delivery balance. The normal ratio of four to five times the amount of DO_2 to VO_2 suggests considerable reserve, and decreasing this factor (or increasing the OER) reflects less cardiovascular reserve. At high DO_2, VO_2 remains both stable and oxygen supply independent. During periods of reduced DO_2, aerobic metabolism is maintained initially through increased oxygen extraction by the tissues. Through this mechanism, VO_2 remains independent of DO_2 until a critical OER is reached. At that point, which is generally thought to correspond to an OER between 0.5 and 0.6, [6], VO_2 becomes oxygen supply-dependent and drops linearly to zero if DO_2 decreases further. An OER above 0.5 has a positive predictive value of 74% for postoperative death in infants following CHD surgery [7]. The inflection point between the two slopes of the DO_2 curve indicates the critical level of DO_2. An illustration of these relationships is shown in Figure 21.1.

The relationship is altered further when VO_2 increases. When VO_2 increases, which is common in the postoperative period, the critical DO_2 also increases, as shown in Figure 21.1,

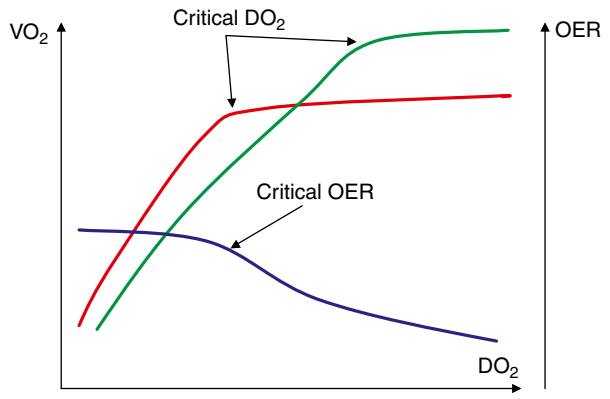

Figure 21.1 Pathophysiological changes in the relationship between oxygen consumption (VO_2) and oxygen delivery (DO_2). (Source: Squara [8]. Reproduced with permission of Springer Nature.)

meaning that a VO_2/DO_2 imbalance occurs at higher DO_2 levels. Therefore, it follows that one of the postoperative strategies is to increase DO_2 to delay the point at which a VO_2/DO_2 imbalance may occur.

The Fick equation states that

$$\mathrm{CO} = \mathrm{VO_2} / \left(\mathrm{CaO_2} - \mathrm{CvO_2}\right) \tag{21.2}$$

where CO is the cardiac output, and CaO_2 and CvO_2 are the oxygen content of arterial and venous blood, respectively. At steady state, on the basis of the law of mass conservation, oxygen consumption and delivery must be equal.

$$\mathrm{VO_2} = \mathrm{DO_2} \tag{21.3}$$

In the setting of CHD, DO_2 is a resultant of several factors.

In the absence of intracardiac shunting, CO is equivalent to the systemic output (Q_S) and the pulmonary output (Q_P).

$$\mathrm{CO} = \mathrm{Q_S} = \mathrm{Q_P} \tag{21.4}$$

and systemic DO_2 is a linear function of CO and CaO_2:

$$\mathrm{DO_2} = \mathrm{CO} \times \mathrm{CaO_2} \tag{21.5}$$

These indexes change slightly in patients with univentricular physiology, as described below [9, 10].

Following the first stage of the Norwood palliation, the systemic and pulmonary circulations become parallel, and the single ventricle assumes both the systemic and the pulmonary output:

$$\mathrm{CO} = \mathrm{Q_S} + \mathrm{Q_P}. \tag{21.6}$$

If making the assumption that the pulmonary oxygen uptake equals VO_2, then one can write separately:

$$\mathrm{Q_S} = \frac{\mathrm{VO_2}}{\left(\mathrm{CaO_2} - \mathrm{CvO_2}\right)} \tag{21.7}$$

and

$$\mathrm{Q_P} = \frac{\mathrm{VO_2}}{\left(\mathrm{CpvO_2} - \mathrm{CaO_2}\right)} \tag{21.8}$$

where $CpvO_2$ is the pulmonary venous blood oxygen content.

We can combine these equations as follows:

$$\mathrm{DO_2} = \frac{\mathrm{CO} \times \mathrm{CpvO_2}}{\left(1 + \mathrm{Q_P}/\mathrm{Q_S}\right) - 2/\left(\mathrm{Q_P}/\mathrm{Q_S}\right)} \tag{21.9}$$

which shows that DO_2 is a complex function of CO, pulmonary venous oxygen content, VO_2 and Q_P/Q_S ratio [9].

Following the bidirectional Glenn anastomosis, the blood that normally drains into the right atrium (RA) from the SVC is redirected to the pulmonary artery, and forms a combined upper systemic and pulmonary circulation, which is in parallel with the lower systemic circulation. The overall CO is a sum of the upper and lower systemic output:

$$\mathrm{CO} = \mathrm{Q_{SVC}} + \mathrm{Q_{IVC}} \tag{21.10}$$

Since $Q_P = Q_{SVC}$, it results that

$$\mathrm{CO} = \mathrm{Q_P} + \mathrm{Q_{IVC}} \tag{21.11}$$

On the other hand,

$$VO_2 = k \times VO_2 + (1-k) \times VO_2 \quad (21.12)$$

states that the whole-body VO_2 is the sum of the upper body oxygen consumption ($k \times VO_2$) and that of the lower body [$(1 - k) \times VO_2$], where k is the fraction consumed by the upper body.

If making the assumption that oxygen uptake through the pulmonary circulation equals VO_2, then one can write separately:

$$Q_{SVC} = \frac{(VO_2 \times k) = Q_P}{(CpvO_2 - CaO_2)} \quad (21.13)$$

and

$$Q_{IVC} = \frac{(VO_2 \times (1-k))}{(CaO_2 - CvO_2)} \quad (21.14)$$

We can combine these equations as follows:

$$DO_2 = CO \times CpvO_2 - (1 + Q_{SVC} / Q_{IVC}) \times \frac{((1-k) \times VO_2)}{(Q_{SVC} / Q_{IVC})} \quad (21.15)$$

which shows that DO_2 is a complex function of cardiac output, pulmonary venous blood oxygen content, lower body oxygen consumption and Q_{SVC}/ Q_{IVC} ratio [10].

To resume, albeit in a majority of patients, the postoperative DO_2 is a linear function of CO and CaO_2, there are cases where DO_2 is a complex function of several other factors. Thus, if the goal is to balance postoperative VO_2/DO_2, then focusing on CO alone is probably not the right strategy.

Changes in systemic oxygen balance have been well-documented in adults and children undergoing surgery with cardiopulmonary bypass (CPB) [5, 11, 12], with VO_2 increasing and DO_2 decreasing within the first 8–12 hours postoperatively. Fortunately, increases in VO_2 are usually closely paralleled by changes in DO_2, and OER varies little in patients with stable cardiac function postoperatively [11].

Mechanisms underlying increases in VO_2 following CHD surgery

Evidence suggests that 50% of the postoperative increase in VO_2 in adults is due to inflammatory responses, and that variations in VO_2 are strongly correlated with the circulating levels of endotoxin, tumor necrosis factor and interleukin-6 concentrations [12].

Alterations in pulmonary function following cardiac surgery result in increased work of spontaneous breathing, which may require the redistribution of up to 15–20% of CO away from other organs [13]. Additionally, even when sedation and neuromuscular blockade was maintained to obviate the confounding effects of spontaneous ventilation, movements, agitation, and pain on VO_2, Li et al. [11] demonstrated a mean 14.7% increase in VO_2 within 4 hours of CHD surgery. The main determinants of this increase were a low age and an increase in central temperature, with an approximate 11% rise in VO_2 per degree of increase in central temperature following hypothermic CPB [11].

Box 21.1 Factors responsible for a postoperative increase in oxygen consumption

- Systemic inflammatory response
- Fever
- Spontaneous breathing
- Consciousness, pain anxiety
- Catecholamines: endogenous and exogenous
- Enteral nutrition

Source: Adapted from Bronicki et al. [18].

The increase in VO_2 is more substantial in children than in adults for several additional reasons. First, young infants have greater resting VO_2 and experience greater inflammatory responses when compared with older patients with CPB. Deep hypothermia is more frequently used during pediatric cardiac operations, and active rewarming restores only 65% of the heat loss, with muscles and subcutaneous fat remaining hypothermic at the end of CPB [14]. Strong biochemical and hormonal stress responses occur in young children following cardiac surgery, further increasing VO_2 [15].

Finally, treatments used in an effort to improve CO may have complex or even adverse effects. Catecholamines augment cardiac contractility and DO_2 and also stimulate VO_2 through their effect on myocardial work and metabolic rate [16]. If the increase in DO_2 is greater than the increase in VO_2, then catecholamines will improve overall balance of tissue oxygenation. In neonates, however, catecholamines have additional thermogenic actions through their effect on brown adipose tissue [17], resulting in an exaggerated increase in VO_2 (Box 21.1).

Mechanisms underlying reduced DO_2 following CHD surgery

Equation (21.5) shows that DO_2 decreases are a result of a reduction in CaO_2, or a reduction in CO. Equation (21.5) can be rewritten as:

$$DO_2 = CO \times (\text{hemoglobin}(g/dL) \times 1.34 \times SaO_2 + PaO_2 \times 0.003) \quad (21.16)$$

The main determinants of CaO_2 are the hemoglobin concentration and SaO_2. The ideal hemoglobin concentration and management of perioperative transfusions largely depend on age and on the underlying CHD and will not be discussed further. Postoperative bleeding is a major risk factor of low cardiac output syndrome (LCOS), through on the other hand, hypoxemia following cardiac surgery is multifactorial. CPB and reperfusion result in an intense generalized inflammatory reaction and diffuse endothelial damage accompanied by an increased vascular permeability, both of which induce pulmonary injury. Alveolar and interstitial edema, which may or may not be clinically apparent, reduce dynamic lung compliance and increase the ventilation/perfusion mismatch. A reduction in functional residual capacity (FRC) after anesthesia and thoracic surgery may result in worsening of hypoxia.

AL Grawany

However, the major driver of a low postoperative DO_2 is LCOS. LCOS is a common complication following CHD surgery in infants. Wernovsky et al. reported that 25% of neonates following the arterial switch operation showed a decline in cardiac index to <2 L/min/m^2, which typically occurred between 6 and 18 hours after surgery [3]. The prevalence of LCOS in other studies was even higher, reaching 40% [19, 20]. This fall in the cardiac index was associated with an increase in systemic vascular resistance (SVR) of approximately 25%, and an increase in pulmonary vascular resistance (PVR) of nearly 40% over baseline values [3]. These findings were confirmed experimentally, showing a 15% decrease in CO occurring 2–4 hours after CPB in piglets [21]. The decrease in CO was concomitant with a 19% increase in PVR and an equivalent increase in systemic arterial elastance, both reversed by the preventive use of milrinone and levosimendan (which are systemic and pulmonary vasodilators).

It appears that, by contrast with most of the adults, neonates and infants develop LCOS with high SVR and PVR following CPB. Under normal circumstances, increased afterload is accompanied by a compensatory increase in ventricular contractility to maintain the stroke volume, known as ventriculovascular coupling. During experimental post-cardiac surgery LCOS, it has been shown that there is a lack of compensatory increase in ventricular contractility [21], and that therapeutic interventions aiming at reducing afterload actually prevented a reduction in CO. Figure 21.2 shows ventricular pressure–volume loops while varying afterload, preload, and inotropy. It shows that an increased afterload results in a decrease in the stroke volume and an increase in the workload, and thus VO_2, of the ventricle. However, several myocardial stresses occur during cardiac surgery, including ischemia–reperfusion injury, inflammatory response, cardioplegia, and oxidative stress, and will invariably cause some degree of postoperative myocardial oxygen debt and dysfunction. Thus, an increase in the afterload creates a challenging situation, where the myocardium has to cope with an increased VO_2 while recovering from oxygen debt.

Evidence suggests that even patients undergoing atrial septal defect closure with short CPB and cross-clamping durations suffer from left ventricle (LV) systolic dysfunction, with a decrease in end-systolic elastance by 40% (Figure 21.3); this occurs independently of the type of cardioplegia and age [22]. Myocardial function is further impaired in patients undergoing complex repairs requiring ventriculostomies and large pericardial patches, in whom myocardial stunning is common. Myocardial dysfunction in neonates may be even more pronounced; neonates are known to have a relatively fixed stroke volume and their CO is known to be highly dependent on heart rate. They have diminished myocardial reserves to increase contractility, due to the immaturity of the neonatal myocardium: greater noncontractile component of myocardium, decreased norepinephrine stores, lower sarcoplasmic reticulum content, and high reliance on extracellular calcium regulation. In univentricular hearts, these reserves are marginal, and efforts to improve DO_2 by intropic agents, which increase the myocardial VO_2, are more likely to be associated with adverse effects.

CPB results in early dysfunction of the pulmonary endothelium and an increase in PVR [23]. Endothelial dysfunction is a consequence of the systemic inflammatory responses, alongside ischemic insult to the parenchyma itself, which occurs as a consequence of exclusive bronchial perfusion during bypass. Bronchial perfusion is further reduced in deeply cyanosed patients, or in those who have major aortopulmonary collaterals, in whom a significant backflow from the aorta to the branch pulmonary arteries via the pulmonary circulation is observed. Endothelial dysfunction is accompanied by sequestration of activated neutrophils within the pulmonary microcirculation, capillary leak and increased extravascular water levels, reduced surfactant function, atelectasis, and an increased pulmonary shunt. Additional postoperative factors, such as pain, hypoxia, hypercarbia, and acidosis, may cause an increase in PVR, particularly in neonates. Increased PVR can be particularly problematic in neonates, in whom PVR is already high, and in young infants with increased preoperative pulmonary blood flow. Right ventricular (RV) failure due to acute pulmonary hypertension (PHT) is often associated with LCOS and hypotension which, added to the increased

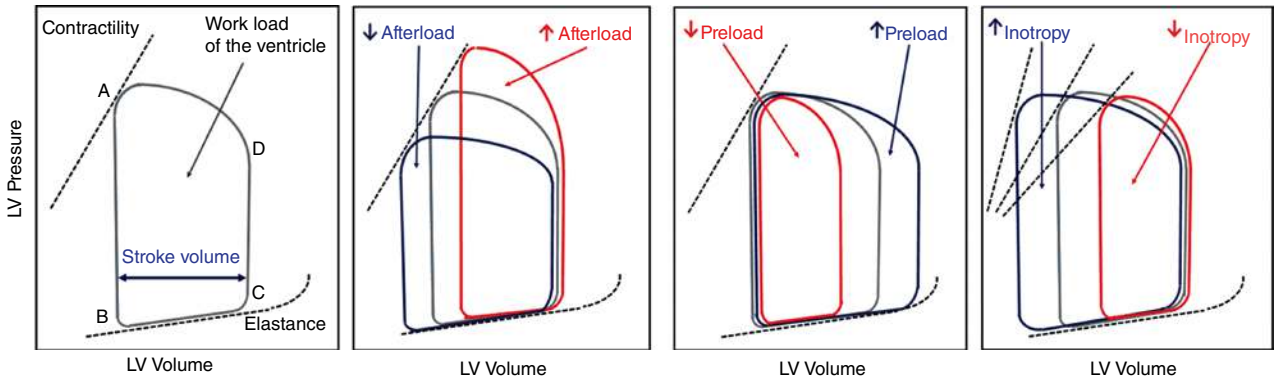

Figure 21.2 Ventricular pressure volume loops and effect of varying afterload, preload or inotropy on the stroke volume and work load. An increased afterload, as seen in post-CHD surgery in infants, results in a decrease in the stroke volume and an increase in the workload of the ventricle, a challenging postoperative situation. Decreasing the afterload results in an increased stroke volume and an equivalent work load of the ventricle. Both the increase in preload and inotropy result in an augmented stroke volume, with a concomitant increase, however, in the workload of the ventricle. It appears that, in the context of post-CHD surgery LCOS in infants, vasodilators increase the stroke volume without affecting myocardial oxygen demand, and represent, therefore, the most effective option. A: aortic valve closes, B: mitral valve opens, C: mitral valve closes, D: aortic valve opens.

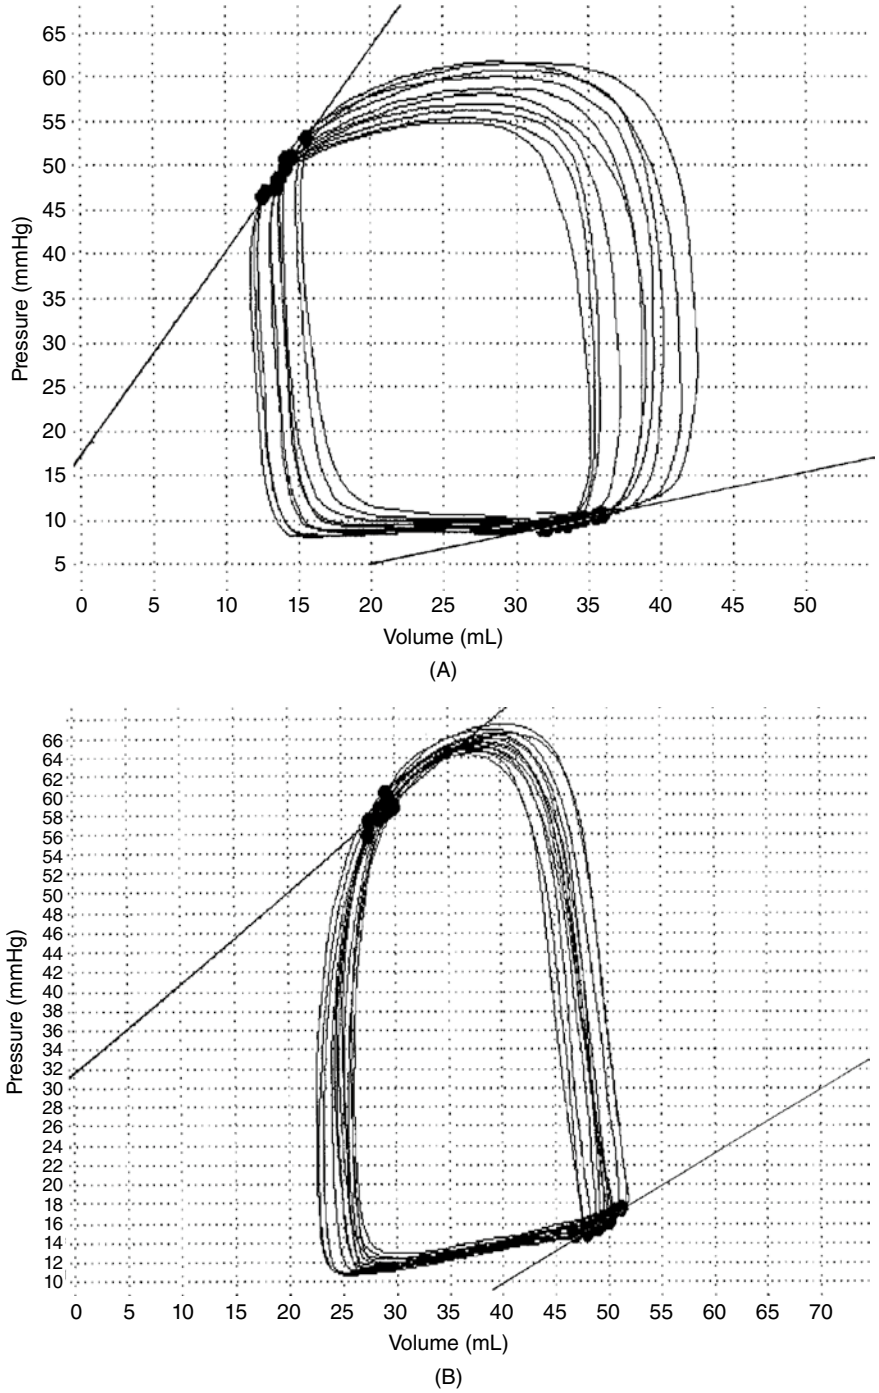

Figure 21.3 Left ventricular pressure–volume loops from infants and children undergoing closure of atrial septal defect with short bypass and cross-clamping durations. (A) Pre-bypass; (B) post-bypass (Source: Chaturvedi et al. [22]. Reproduced with permission of Elsevier.)

RV pressure, reduces the RV coronary perfusion pressure, and may further reduce RV contractility. Even transient pulmonary pressure overload may induce persistent RV failure.

Finally, LCOS may develop due to various reasons specific to the underlying CHD and to the surgical procedure. Coronary diastolic perfusion may be decreased following a systemic–pulmonary anastomosis as seen following the Norwood procedure, and results in dysfunction of the single ventricle. Nearly, 50% of patients undergoing repair of tetralogy of Fallot have isolated diastolic RV dysfunction [24], and may develop LCOS due to insufficient preload of the LV. High PVR results in dysfunction of the cavo-pulmonary anastomosis following a bidirectional Glenn or a Fontan procedure, to a decrease of the single-ventricle preload, and to LCOS (Boxes 21.2 and 21.3).

AL Grawany

Box 21.2: Factors responsible for a postoperative decrease in DO_2

- LCOS due to:
  - Increased LV and/or RV afterload
  - Myocardial stunning
  - Pulmonary endothelium dysfunction
  - Underlying CHD-specific causes
- Hypoxemia
- Anemia

Box 21.3: Limitations of the cardiovascular reserve in neonates

- Decreased contractile reserve
- Cardiomyocyte contains fewer and poorly organized proteins
- Immature sarcoplasmic reticulum
- Decreased myocardial compliance
- Increased circulatory demands due to greater oxygen consumption

Source: From [18].

KEY POINTS: THE VO_2/DO_2 BALANCE FOLLOWING CHD SURGERY

- Pathologic imbalance between VO_2 and DO_2 is the mechanism of anaerobic metabolism, multiorgan failure, and death.
- VO_2 commonly increases after CHD surgery mainly due to inflammation and postoperative stress response.
- DO_2 commonly decreases after CHD surgery mainly due to LCOS, a result of inflammation, myocardial stunning, and pulmonary dysfunction.

Improving postoperative oxygen transport balance: preventive and therapeutic interventions

As mentioned before, the goal of the postoperative hemodynamic manipulation is the optimization of the VO_2/DO_2 balance. Sedation and analgesia lead to substantial falls in postoperative VO_2 [11], which could suffice to maintain the VO_2/DO_2 balance in critical situations where it is not possible to further increase the DO_2. Treatment of hyperthermia reduces the VO_2 by 11% for every degree of reduction in body temperature [11]. Anti-inflammatory strategies have been reported to have similar effects, probably by acting on both the inflammatory state and hyperthermia [25]. In addition, mechanical ventilation with muscle relaxation reduces VO_2 by more than 20%, and as well as stabilizing pulmonary gas exchange, it can preserve the limited DO_2 for other vital organs [13]. On the other hand, blood transfusions cause a significant increase in DO_2; transfusion thresholds are specific to age and dependent upon the underlying CHD; and limitations are due to increases in blood viscosity and PVR.

The major priorities, nevertheless, both intra- and postoperatively, are the prevention and early treatment of the LCOS, and this section will focus on the pharmacological treatment of LCOS. The pharmacologic optimization of CO in children with cardiac surgery involves the manipulation of systolic and diastolic myocardial function, preload, SVR, and PVR.

The prospective study published by Wernovsky et al. in 1995 [3], including invasive hemodynamic measurements in 122 neonates undergoing the arterial switch operation, demonstrated an average 30% drop in cardiac index in almost one quarter of patients, while PVR and SVR increased. The lowest measurement typically occurred 9–12 hours after surgery. Evidence supporting preventive drug therapy for LCOS is derived primarily from the landmark PRIMACORP study [4], which reported a 55% reduction in the risk of postoperative LCOS after administration of high-dose milrinone. As a result, preventive drug therapy for LCOS in at-risk patients has become common practice, as revealed by two recent international surveys among pediatric cardiac centers [26, 27].

The ventricular pressure–volume loops shown in Figure 21.2 illustrate the possible therapeutic options to increase the stroke volume in case of a reduced CO with increased afterload. Increasing preload results in an increase in the stroke volume according to the Frank–Starling law, with a concomitant increase, however, in the workload of the ventricle. Ischemia–reperfusion injury and myocardial edema resulting from aortic cross-clamping aggravates the physiological stiffness of the neonatal myocardium, and it follows that the beneficial potential of volume administration is limited by an excessive increase in the atrial pressure. Inotropic agents augment the stroke volume too, however, their benefit is limited by the concomitant increase in the workload, and thus VO_2, of the ventricle. By contrast, vasodilators increase the stroke volume without affecting myocardial oxygen demand, and represent, therefore, the most effective option in the setting of postcardiac surgery LCOS in infants.

In the pediatric cardiac setting, the use of cardiovascular drugs is often based on extrapolating the underlying pathophysiology and pharmacodynamics from adult studies, and on anecdotal experience. In 2008, Pasquali et al. published a survey on the use of off-label cardiovascular medications in children as assessed by the Pediatric Health Information System [28]. The study included observations from 31,432 patients, median age 10.4 months, and reported that 78% of all patients received at least one cardiovascular drug off-label. The risk of a neonate receiving at least one drug off-label was 11% higher than that of an older patient. The most common cardiovascular drugs used off-label were furosemide, epinephrine, dopamine, lidocaine, and milrinone. It is also important to note that there are no clinical trials that have produced recommendations with regards to dosing. Therefore, the suggested dose ranges here should be considered as "guides."

The drugs currently used for the acute hemodynamic management of CHD patients have inotropic, chronotropic, lusitropic, vasoconstrictor, systemic, and/or pulmonary vasodilator effects. Most of the cardiovascular drugs have mixed and dose-dependent effects, therefore, a functional classification has been proposed, according to their inotropic and peripheral vascular effects into: inodilators, inoconstrictors, vasodilators, and vasoconstrictors [29]. The most commonly used agents are displayed in Table 21.1 and Figure 21.4, according to their potencies and dose-dependent hemodynamic effects.

Most cardiovascular agents in clinical use exert their cardiovascular effects by interacting with adrenergic receptors in the heart and vessels. Vascular α_1-adrenergic receptors increase SVR by constricting the mesenteric, skin, and renal

Table 21.1 Classification of the most popular inotropic and vasoactive agents

Peripheral vascular effect	Inotropic effect	
	Yes	No
Vasoconstriction	**Inoconstrictors**	**Vasoconstrictors**
	Epinephrine Dopamine	Norepinephrine Vasopressin Phenylephrine
Vasodilation	**Inodilators** Milrinone Dobutamine Levosimendan	**Vasodilators** Nitroglycerin Nitroprusside Phenoxybenzamine

arterioles while redistributing blood flow from the peripheral veins into the arterial circulation. Myocardial β_1 receptors, and to a lesser extent, β_2-adrenergic receptors, increase HR and cardiac contractility. Vascular β_2 receptors, and to a lesser extent, β_1 receptors, oppose the vasoconstrictive effects of α_1 receptors and reduce vascular tone, especially in the skeletal muscle. The location and effects of adrenergic receptors are shown in Table 21.2. Vasopressin 1a receptors (V_{1a}) mimic and augment the vasoconstrictive effect of α_1 receptors.

Table 21.2 Adrenergic receptor sites and physiologic actions

Receptor	Receptor location site	Action
α_1	Vascular smooth muscle	Arterial vasoconstriction
	Heart	↑ inotropic activity
α_2	Vascular smooth muscle	Vasoconstriction of venous capacitance vessels
	Presynaptic sympathetic nerve terminals	Local feedback, inhibition of norepinephrine release
β_1	Heart	↑ inotropic and chronotropic activity ↑ atrio-ventricular node conduction velocity
β_2	Vascular smooth muscle	Vasodilation peripheral vasculature
	Bronchial smooth muscle	Bronchodilation
D_1	Vascular smooth muscle (renal, splanchnic, cerebral)	Vasodilation
	Renal tubules	↓ Na reabsorption
D_2	Presynaptic sympathetic nerve terminals	↓ norepinephrine release

Inotropic agents

The most commonly used inotropic agents are β-adrenergic agonists (catecholamines) and phosphodiesterase type 3 inhibitors. These agents exert positive inotropic and chronotropic effects by increasing the intracellular calcium concentration via an increase in cyclic adenosine monophosphate (c-AMP) and activation of the protein kinase pathway in cardiac myocytes, as shown in Figure 21.5. c-AMP, in turn, activates calcium channels and lead to increased cytosolic calcium, which improves the contractility of the actin–myosin system through its binding with troponin C. A newer class of inotropes is calcium sensitizers, which binds cardiac troponin C, stabilizes calcium-induced conformational changes, and increases contractility by promoting a prolonged interaction between actin and myosin filaments. They do not increase cytosolic calcium concentrations.

β-adrenergic receptor agonists

Catecholamines play an important role in the management of LCOS after cardiac surgery. Endogenous catecholamines, such as dopamine, epinephrine, and norepinephrine, are synthesized from tyrosine, which undergoes several transformations to yield dopamine. A portion of the dopamine is then transported into vesicles from the cytoplasm where it is converted to norepinephrine, the main neurotransmitter in the human nervous system. The final step in the pathway,

Table 21.3 Hemodynamic effects of the most popular vasoactive and inotropic drugs

Drug	Receptors	Inotropy	Chronotropy	SVR	PVR	Renal vascular resistance	Cardiac output
Epinephrine < 0.1 μg/kg/min	β_1, β_2 > α_1 (agonist)	↑	↑	↔ ↓	↔ ↓	↓	↑↑
>0.1 μg/kg/min	α_1 > β_1, β_2	↑	↑	↑	↑	↑	↑
Dopamine < 3 μg/kg/min	D_1, D_2 (agonist)	↔	↔	↔	↔	↓	↔
4–8 μg/kg/min	β_1, β_2 > α_1	↑	↑	↔ ↓	↔	↔	↑
>8 μg/kg/min	α_1 > β_1, β_2	↑	↑	↑	↑	↑	↔
Dobutamine	β_1 > β_2, α_1 (agonist)	↑	↑	↓	↓	↔	↑↑
Milrinone	PDE3 inhibitor	↑	↑	↓	↓	↓	↑
Levosimendan	Troponin C, ATP-dependent K channel	↑	↑	↓	↓	↓	↑
Norepinephrine	α_1 > β_1, β_2 (agonist)	↔ ↑	↓	↑↑	↑	↑↑	↔ ↓
Vasopressin	V_{1a} (agonist)	↔	↓	↑	↑	↑	↔ ↓
Phenylephrine	α_1 (agonist)	↔	↓	↑	↔	↑	↔ ↓
Nitroglycerine Nitroprusside	Guanylate cyclase activator	↔	↔ ↑	↓	↓	↓	↑
Phenoxybenzamine	α_1, α_2 (antagonist)	↔	↔ ↑	↓	↓	↓	↑
Inhaled Nitric oxide	Guanylate cyclase activator	↔	↔	↔	↓↓	↔	↔ ↑
Sildenafil	PDE5 inhibitor	↔	↔	↔	↓↓	↔	↔ ↑

ATP: adenosine triphosphate; c-AMP: cyclic adenosine monophosphate; PDE3: phosphodiesterase type 3; PDE5: phosphodiesterase type 5; PVR: pulmonary vascular resistance; SVR: systemic vascular resistance.

which converts norepinephrine to epinephrine, occurs in the adrenal medulla. Endogenous catecholamines are hormones and neurotransmitters that influence a multitude of physiological functions; however, synthetic catecholamines, such as dobutamine and isoproterenol, target-specific receptors resulting in selective effects (Table 21.3). The half-life of catecholamines is approximately 2–5 min, which allows for rapid titration. Since the breakdown of catecholamines by the catechol-O-methyl-transferase and monoamine oxidase is ubiquitous, dosage adjustments are not necessary, even in patients with renal, hepatic, or any other organ dysfunction.

Epinephrine

Epinephrine has a potent agonist of α_1-, β_1-, and β_2-adrenergic receptors (Table 21.3), approximately 100-fold more potent as an inotrope than dobutamine or dopamine. Low epinephrine doses (0.01–0.1 μg/kg/min) are used to increase stroke volume and to a lesser extent HR through a β_2-adrenergic effects. Combined with afterload reduction through peripheral vasodilatation, low epinephrine doses increase CO, and is therefore recommended in patients with severe systolic dysfunction. At somewhat higher concentrations, β_1-adrenergic receptors are activated resulting in increased myocardial

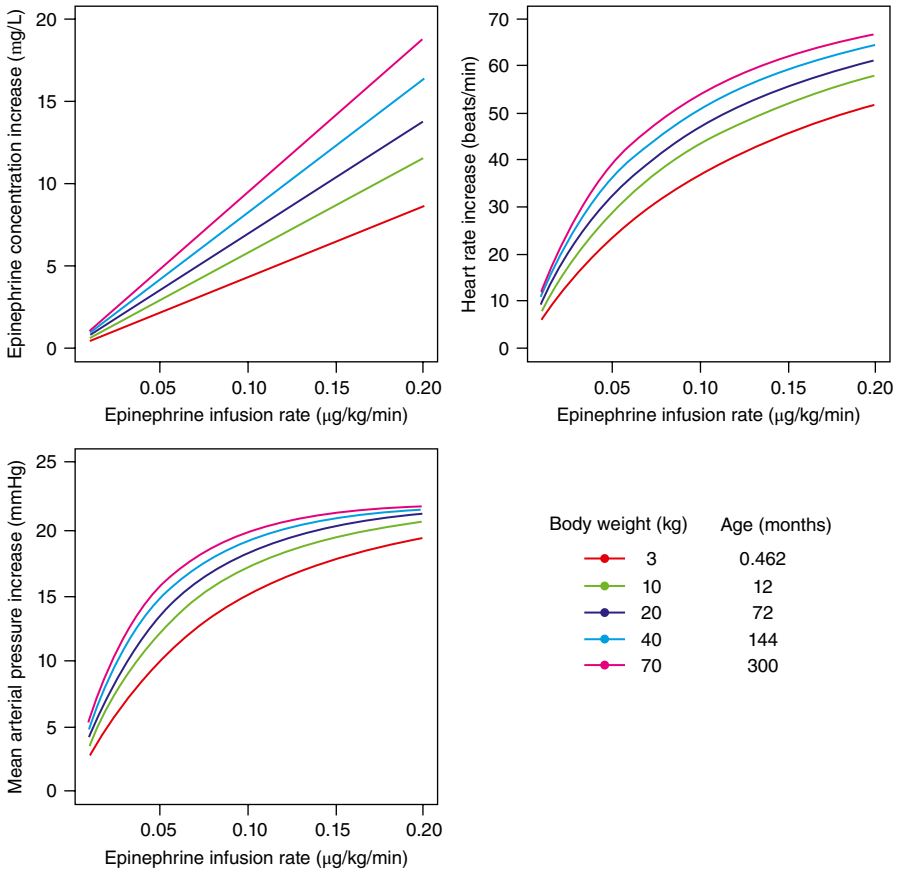

Figure 21.6 Simulation of the relationship between different epinephrine concentrations and hemodynamic responses in children with different ages and weights. (Source: Oualha et al. [33]. Reproduced with permission of Springer Nature.)

conduction, increased sinoatrial node discharge, increased force of contraction, and increased rate of rise of the intramural pressure. High concentrations of epinephrine may produce serious atrial and ventricular dysrhythmias if the myocardium is sensitized by infarction, surgery, or myocarditis. Higher epinephrine doses (>0.1 μg/kg/min) produce increasing α_1-receptor-mediated vasoconstriction. This results in increased afterload and increase the myocardial workload, which are undesirable early after CPB, and may be detrimental in infants with functionally univentricular circulation. Even though epinephrine constricts renal and cutaneous arterioles, renal function and skin perfusion may improve due to increased CO. However, high infusion rates (>1–2 μg/kg/min), conditions in which the α_1-adrenergic responses predominate, may exacerbate multiorgan system failure.

Epinephrine is largely used in the postoperative management of CHD [26, 32], although evidence-based data are currently lacking, and dosing regimens are extrapolated from adult studies. However, the amplitude of the hemodynamic response to epinephrine is difficult to predict. Although the effect of epinephrine is primarily dependent on the plasma concentration, a recent report shows that both age and body weight may play a role in the large between-subject pharmacokinetic and pharmacodynamic variability observed in children undergoing CHD surgery [33]. The smaller the patient, the smaller the increase in heart rate and blood pressure for a given epinephrine concentration and severity of illness, as shown in Figure 21.6 [33]. It is likely that the postnatal development of the myocardial contractility is associated with changes in the modulatory effects of β-adrenergic receptor signaling.

During cardiopulmonary resuscitation, the α_1-adrenergic-mediated vasoconstriction induced by epinephrine increases aortic diastolic pressure and, thus, coronary perfusion pressure, which is a critical determinant of successful resuscitation from cardiac arrest. The American Heart Association-recommended dose of epinephrine for children experiencing bradycardia, asystole, or pulseless arrest is 0.01 mg/kg intravenously, which may be repeated at 3–5-min intervals, up to 1 mg per dose [34].

Dopamine

Dopamine stimulates the dopaminergic D_1 (postsynaptic) and D_2 (presynaptic) receptors located in several vascular beds; it also binds α- and β_1-adrenergic receptors, although with lower affinity (Table 21.3) doses (> 8 μg/kg/min) induce vasoconstriction via α_1-adrenergic receptor stimulation. Increased PVR has been reported with dopamine doses higher than 7.5 μg/kg/min.

The sensitivity of infants to dopamine is controversial, and neonates may exhibit a clinical response to doses as low as 0.5–1 μg/kg/min [30]. Li et al. [35] studied the effects of 5 μg/kg/min of dopamine in neonates undergoing the Norwood

procedure. Dopamine did not increase DO_2 and seemed to cause an increase in myocardial VO_2. A dopamine infusion of 5 μg/kg/hour had a significant thermogenic effect, and termination of the infusion was associated with a substantial 20% reduction in the total VO_2 [35].

Dobutamine

Dobutamine is administered as a racemic mixture of two compounds, namely, a strong β_1-agonist, and a weak α and β_2 agonist. The end result is a drug with broad receptor specificity, a strong dose-dependent increase in stroke volume, heart rate and CO, and a variable effect on arterial pressure (Table 21.3). It modestly lowers the SVR, except at high doses (> 10–15 μg/kg/min) when dose-dependent α_1-adrenergic receptor agonism may become more prominent. Low doses, up to 5 μg/kg/min, increase stroke volume without significant tachycardia, however, doses above 10 μg/kg/min produce worsening tachycardia with minimal further increase in CO due to declining stroke volume from decreased diastolic filling time. Dobutamine significantly increases the myocardial VO_2 and is frequently used to stress the myocardium.

Comparison with phosphodiesterase inhibitors demonstrates similar improvement in stroke volume, although dobutamine induces a more profound decrease in LV filling pressures and vascular resistance [36]. Dobutamine induces a greater increase in heart rate than milrinone, and the beneficial increase in coronary blood flow may be outweighed by an increase in myocardial VO_2 [36]. Higher doses of dobutamine (>15 μg/kg/min) can predispose to the development of atrial or ventricular arrhythmias. Despite its widespread use, the exact role of dobutamine in pediatric therapeutics remains unclear, and its use following cardiac surgery remains controversial because of excessive tachycardia, arrhythmias, and variable effect on SVR.

Norepinephrine

Norepinephrine is a potent α_1-receptor agonist and mild β_{1-} agonist with minimal β_2 activity. Increasing doses of norepinephrine may increase CO in some patients through augmentation of venous return, however, it may reduce CO due to the strong increase in afterload in patients with cardiac dysfunction. Norepinephrine reduces myocardial VO_2, due to a reflex reduction in heart rate. By increasing diastolic pressure, norepinephrine increases coronary perfusion. Norepinephrine is mainly used as a vasopressor and will be discussed later.

Side effects of catecholamines

The use of catecholamines comes at a price, namely to place continual stress on an organ that is already failing, and placing an increased demand for oxygen at a time when supply is critically limited. Catecholamines increase the myocardial VO_2 through their inotropic and chronotropic effects and induce arrhythmogenesis. These are due to an increase in intracellular calcium concentration, produced by an increase in c-AMP. This is particularly problematic in the neonatal myocardium, in which the functional reserve is limited and which operates under already maximal adrenergic stimulation. If such an increase is not accompanied by a proportional increase in coronary blood flow, a mismatch between myocardial VO_2 and DO_2 may result.

When inotropes are used for the management of adults with acute heart failure, there is an increase in in-hospital mortality when compared with management without inotropes [37]. Results from the European Society of Cardiology Heart Failure Long-term registry have shown a detrimental association between the use of inotrope and/or vasopressor and both in-hospital and long-term mortality [38]. Both dopamine and epinephrine were associated with the highest risk of death in adults [38, 39]. The recent guidelines of the European Society of Cardiology for the treatment of acute heart failure restrict the use of inotropic agents to patients with symptomatic hypotension and poor perfusion [40].

For many years, it has been acknowledged that chronic exposure to catecholamines can exert a toxic effect on the myocardium and increase apoptosis. *In vitro* studies in cultured cardiac myocytes show that tonic exposure to norepinephrine increases the number of apoptotic myocytes via stimulation of the β_1-adrenergic receptor pathway [41]. Although the link between myocardial apoptosis and myocardial failure remains to be proven, these observations provide a rational to limit the use of β_1-agonists following cardiac surgery. In addition, the variability in the pharmacologic effect of β-agonists in neonates makes their use very challenging in this age group. Studies of myocardial biopsies identified an adult-like myocardium, with low-density and high-affinity β-adrenergic receptors, and a fetal-like myocardium, with high-density and low-affinity β-adrenergic receptors [42]. Neonates had the highest density and the lowest affinity β-adrenergic receptors of all, and they have lower affinity β receptors in the LV when compared with the RV (whereas immature and adult hearts did not have ventricular differences) [42]. Additionally, experimental studies demonstrated downregulation of the LV β-adrenergic receptors during chronic hypoxemia [43].

Long-term exposure of myocardial β-adrenergic receptors to circulating endogenous or exogenous catecholamines leads to receptor desensitization, which is mediated by uncoupling of the receptor–effector system and by a decrease in receptor density. In patients with severe cardiac failure, β_1-adrenergic receptor density is selectively reduced due to exposure to endogenous norepinephrine. It has been shown that the severity of the left-to-right shunt and of PHT is correlated with norepinephrine levels in pediatric CHD patients [44]. Consistently, children with severe CHD were found to have an up to 50% reduction in the number of right auricle β-adrenergic receptors, with the lowest receptor densities found in critically ill neonates with congenital aortic stenosis and transposition of the great arteries [45].

Catecholamines increase the overall metabolic rate, which manifests as an increase in the overall VO_2. β_1, β_2, and particularly β_3-adrenergic receptors, as well as dopaminergic receptors are densely expressed at high levels in brown adipose tissue, which is abundant in human neonates, where it plays a crucial role in nonshivering thermogenesis. Catecholamines, especially norepinephrine and dopamine, simulate heat production by stimulating fatty acid oxidation and uncoupling the respiratory chain from adenosine triphosphate (ATP)

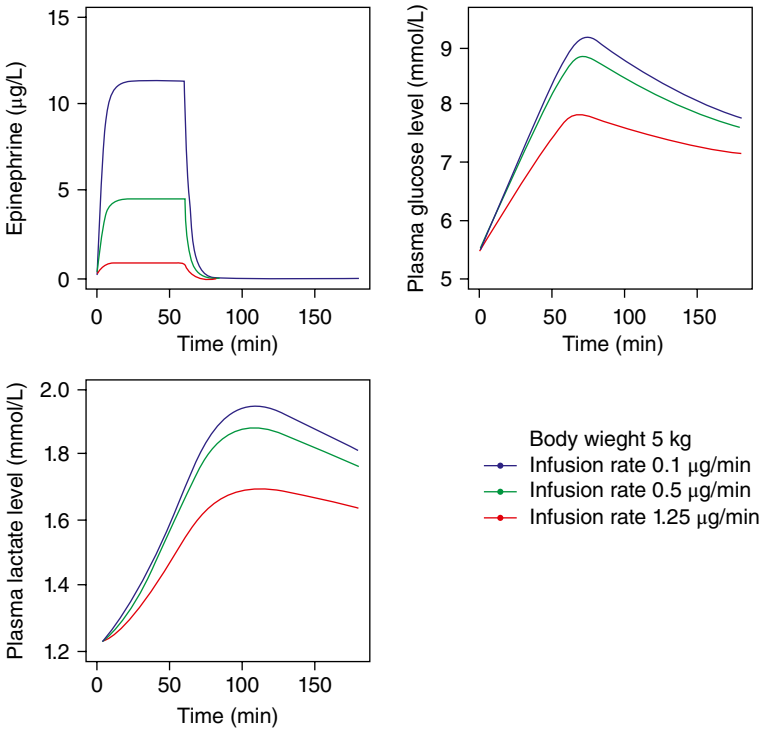

Figure 21.7 Time-course simulations of epinephrine concentration, plasma glucose and lactate levels following 0.02–0.25µg/kg/min epinephrine infusions in a child weighting 5 kg. (Source: Oualha et al. [33]. Reproduced with permission of Springer Nature.)

synthesis; thus, neonates may be particularly susceptible to the metabolic effects of catecholamines, which may increase VO_2 to much higher levels than in older patients. Catecholamines also accelerate aerobic glycolysis and induce insulin resistance, a phenomenon that is exacerbated in younger patients, resulting in a concentration-dependent increase in glycemia and lactate production, as shown in Figure 21.7 [33].

In view of the aforementioned challenges, the use of β-adrenergic receptor agonists for the prevention and/or management of LCOS following CHD surgery should be questioned, particularly considering that the evidence of their use is based solely on pharmacological action rather than an assessment of meaningful clinical outcomes.

Inhibitors of phosphodiesterase type 3

Bipyridines were developed in the 1980s to improve myocardial contractility in the chronically failing ventricle. They selectively inhibit intracellular cardiac phosphodiesterase type 3, thereby slowing the degradation of c-AMP. This results in a positive inotropic effect through increased intracellular calcium levels during excitation–contraction coupling, and a positive lusitropic effect through faster sequestration of calcium that is released into the sarcoplasmic reticulum due to the concomitant activation of phospholamban (Figure 21.5). Vasodilation occurs in both arterial and venous vessels, via increased c-AMP and opening ATP-sensitive potassium channels in vascular smooth muscle cells (Figure 21.8). Arrhythmogenicity is mediated by an increase in intracellular c-AMP and calcium levels. No tachyphylaxis is observed.

Amrinone

Amrinone, the prototype bipyridine, acts mainly as a vasodilator, and has some inotropic effects [47–49]. Amrinone is metabolized in the liver via N-acetylation and is then excreted in the urine; slow acetylators show a two-fold increase in the half-life, compared with that of rapid acetylators [50]. The half-life is about 2 hours, and clearance is reduced in patients with hepatic and renal failure. Reversible dose-dependent thrombocytopenia is common during prolonged therapy. The common dosage is 5–10 µg/kg/min. Amrinone is now rarely used since milrinone became available.

Milrinone

Milrinone is the most popular bipyridine drug, and it is the one that has been subjected to careful evaluation in the placebo-controlled multicenter PRIMACORP trial [4]. It has a half-life of about 1 hours, which decreases linearly with age and increases in the presence of renal failure [51].

The drug shows inotropic and vasodilatory effects, although it appears that the increase in CO is mainly related to the vasodilatory effect [52]. Chang et al. reported that, when given to neonates with LCOS, milrinone increased the cardiac index from 2.1 to 3.1 mL/min/m^2, concomitant with a reduction in filling pressures, in SVR by approximately 30%, and in PVR by about 25% [53]. These improvements in global hemodynamics were associated with an improvement in the myocardial VO_2/DO_2 ratio [53]. The multicenter PRIMACORP trial [4], including 238 neonates and infants demonstrated that the prophylactic administration of high-dose milrinone (i.e., a bolus of

75 μg/kg, followed by an infusion of 0.75 μg/kg/min) decreased the incidence of LCOS from 25.9% to up to 11.7%, whereas a low dose (a 25 μg/kg/min bolus followed by a 0.25 μg/kg/min infusion) had no effect, when compared with placebo.

In an experimental study under constant ventricular leading conditions, milrinone only very slightly increases heart rate and stroke volume [52]. Thus, unlike dopamine, milrinone does not increase myocardial VO_2 [36] nor myocardial OER (17). Instead, milrinone reduces coronary vascular resistance, suggesting that it exerts a protective effect on the myocardium. Furthermore, the positive lusitropic properties make milrinone a useful drug when LCOS results from diastolic ventricular dysfunction.

The pulmonary vasodilator effect of milrinone has been demonstrated in infants with PHT, and it is largely dependent on the degree of pre-existing PHT and the severity of ventricular dysfunction [53]. Milrinone induces pulmonary vasodilatation by increasing pulmonary vascular c-AMP levels, and, possibly, by attenuating the release of inflammatory cytokine [54].

Hypotension is a commonly reported side effect, occurring particularly during the administration of the loading dose. Ensuring an adequate preload can minimize it. The incidence of tachyarrhythmia increases up to three-fold when using common dosing regimens of milrinone (a loading dose of 50 μg/kg, followed by a 0.25–1 μg/kg/min continuous infusion), independent of the concomitant use of catecholamines and of disease severity. As a result, many centers use milrinone without a loading dose, and begin the infusion by the end of CPB. However, a recent pharmacokinetic study of milrinone in a wide pediatric age range demonstrated that age, disease, and surgery differently impact the pharmacokinetics of milrinone, and that current milrinone dosing for LCOS is suboptimal to maintain the therapeutic target range across the entire pediatric age range [55]. It is likely that hypotension and arrhythmogenesis are responsible for the huge variability in the dosing regimens used at different centers [32]. Thrombocytopenia is less common (4%) and is seen when the infusion duration exceeds 3 days [56].

Milrinone is the drug most commonly used for the prevention and treatment of LCOS in CHD surgery [26, 27, 32]. However, the recent Cochrane meta-analysis on its prophylactic use following CHD surgery [57] yielded a very disappointing conclusion indicating a lack of evidence of effectiveness on the incidence of LCOS and on mortality. For methodological reasons, the meta-analysis excluded many valuable reports, and included only 393 participants from a mixed population aged 0–12 years. However, because of their specific physiology, including noncompliant ventricles and a high baseline sympathetic tone [58], neonates and young infants are the most likely to develop LCOS with high SVR and PVR, and to benefit from prophylactic milrinone.

Calcium sensitizers

Levosimendan, a pyridazinone–dinitrile, binds cardiac troponin C and stabilizes calcium-induced conformational changes, which, in turn, promotes the prolonged interaction between actin and myosin filaments during systole, and increases myocardial contractility, as shown in Figure 21.5 [59]. The resulting increase in contractility is unmatched by milrinone [21]. Levosimendan has vasodilatory effects, which are mediated by opening ATP-sensitive potassium channels in the systemic, pulmonary, and coronary vascular smooth muscle cells [59–61]. In adult patients, levosimendan is responsible for a 45% increase in the coronary blood flow and a 9% reduction in myocardial oxygen extraction [62]. The impact of levosimendan on mitochondrial functions prevents calcium overload during ischemia–reperfusion injury and protects the myocardium against damage [63]. Levosimendan reduces the time constant for diastolic relaxation and improves diastolic function [21]. By improving the diastolic function, it is of particular interest when LCOS is due to LV or RV diastolic dysfunction, a common finding in patients with residual obstruction of the left or right outflow tract. It is also of particular interest in neonates in whom the ventricles are less compliant. Levosimendan has weak pulmonary vasodilator effects in the normal circulation [64], but has a potent effect in preconstricted pulmonary circulation [60]. In addition, it may attenuate endothelin-1-induced vasoconstriction, which would be of particular relevance in the post-CPB setting [61]. Experimental work demonstrated an increase in the RV myocardial efficiency when levosimendan was used to treat RV hypertrophy and failure [65], and it has been proposed for the treatment of RV failure in patients with PHT [66]. When given after cardiac surgery in adults, levosimendan is associated with an approximately 50% reduction of the risk of acute kidney injury and renal replacement therapy [67]. Finally, levosimendan improves the recovery of diaphragmatic dysfunction and increases the chances of successful weaning from mechanical ventilation [68].

The pharmacokinetic profile of levosimendan, which is unaffected by age, makes it highly attractive for clinical use. The recommended dosage is an intravenous (i.v.) bolus of 12 μg/kg over 10 min, followed by a 2 μg/kg/min continuous infusion. Its biotransformation in the intestinal tract gives rise to an intermediate metabolite, OR 1,855, which is inactive, and which is further metabolized in the liver by acetylation into OR 1,896. OR 1,896 is a long-lasting active metabolite whose concentration peaks at 36 hours after a 24-hour infusion and remains stable up to Day 8; it is still detectable up to 12 days after levosimendan withdrawal [69]. Dosing adjustments are not required in patients with mild hepatic or renal failure.

A randomized controlled study of milrinone and levosimendan conducted in neonates [69] showed that patients in the milrinone group had a greater requirement for other inotropes during the first hours postsurgery. Cerebral regional saturation monitoring suggested that both drugs caused a time-dependent improvement in blood flow and oxygen availability, but infants on levosimendan showed significantly higher peripheral intravascular oxygenation and a lower difference in the central-to-peripheral temperature gradient [69]. Another randomized controlled trial in neonates undergoing complex surgeries reported an almost 40% decrease in the incidence of LCOS when compared with more conventional milrinone and epinephrine infusions, along with a significant reduction in lactate concentrations 6 hours postoperatively [70]. In patients younger than 5 years

undergoing cardiac surgery, levosimendan given postoperatively was at least as efficacious as milrinone, and did not increase myocardial VO_2 at 24 and 48 hours postoperatively [71]. Troponin values were significantly lower in the levosimendan group, suggesting a cardioprotective effect [71].

Because levosimendan does not increase the intracellular c-AMP and calcium concentrations, tachycardia and hypotension are less severe than that reported for milrinone, although common during the loading dose [69, 71]. In contrast to those of catecholamines, the effects of levosimendan are not attenuated in patients with chronic heart failure, in whom β-adrenergic receptors are downregulated, or by concomitant use of β-blockers. The development of tolerance has not been reported to date.

There are currently no official indications regarding the use of levosimendan in patients less than 18 years of age. As a matter of fact, the drug has been studied and used as a rescue therapy both in the pediatric intensive care unit (PICU) and the operating room. The pediatric experience with levosimendan given prophylactically for cardiac surgery in children less than 5 years was summarized in a recent meta-analysis [72], which, for methodological reasons, only included five randomized controlled trials with a total of 212 participants. Compared with standard inotrope treatments, levosimendan did not reduce mortality or the incidence of LCOS; however, levosimendan significantly reduced time to extubation and length of stay and reduced the risk of circulatory support and of heart transplantation. Levosimendan has potential appeal in children with CHD and may prove to have an important role in the prevention and early treatment of LCOS in high-risk patients after cardiac surgery; however, its application warrants more detailed investigation.

Vasoconstrictors

Norepinephrine

Norepinephrine has potent α- and β_1-adrenergic receptor agonist activity, but little β_2 activity, as shown in Table 21.3. Therefore, infusion of norepinephrine results in increased SVR because the α-adrenergic stimulation is not opposed by β_2-adrenergic stimulation. As a vasopressor, norepinephrine is 100-fold more potent than dopamine and three to five times more potent than epinephrine.

Norepinephrine is used in the pediatric setting of shock with profound hypotension; it should be administered after intravascular volume repletion, and its use is best guided by knowledge of the CO and SVR. Although more commonly used in adults, a vasodilatory inflammatory response to CPB may be present in some children early after surgery and is often responsive to norepinephrine. Norepinephrine may also enhance coronary flow in patients with diastolic run-off after systemic-to-pulmonary shunt. The dosage is usually titrated to mean or diastolic arterial pressure, and low doses (0.01–0.05 μg/kg/min) should be sufficient for hemodynamic stabilization.

However, injudicious use of norepinephrine compromises blood flow within organs, for example, renal, splanchnic, and hepatic blood flow is reduced in healthy individuals. Infusion of norepinephrine may increase blood pressure, and yet not improve clinical indices of perfusion, and this type of poor clinical response is usually associated with a persistent low cardiac index. Importantly, the pharmacokinetics of norepinephrine in children is not well known. Norepinephrine should be titrated and used at the lowest dose to maintain the mean arterial pressure; doses > 0.5–1 μg/kg/min are considered very high.

Arginine vasopressin

Arginine vasopressin (AVP) plays a vital role in the maintaining normal arterial blood pressure by regulating venous capacitance and arterial resistance. Vasopressin acts on V_{1a} receptors in the peripheral vasculature to cause intense vasoconstriction through activation of protein kinase C (Table 21.3), ultimately leading to an influx of intracellular calcium. The rationale behind the use of exogenous AVP in the critically ill patients is that neurohypophyseal stores of AVP may become exhausted, leading to vasodilatory shock [73]. Another theoretical advantage of AVP is that it does not rely on adrenergic receptors, which may be downregulated in the presence of chronically elevated catecholamines. Also, signal transmission via adrenergic receptors may be impaired under conditions of metabolic acidosis. AVP depletion following CHD surgery has also been reported in children [74], as well as good response to the vasopressor AVP infusion ranging from 0.0001 to 0.002 U/kg/min in neonates, infants, and children with low postoperative blood pressure and adequate cardiac function [74, 75]. More recently, it has been suggested that lower doses of AVP 0.0003 U/kg/min initiated in the operating room could be beneficial in neonates with complex surgeries, such as the Norwood procedure or the arterial switch operation, to decrease the requirement for fluid resuscitation and catecholamines, and shorten the duration of intensive care stay [76].

A recent meta-analysis showed that AVP did not confer a survival advantage in adults suffering from vasodilatory shock [77]. Also, safety data for AVP are lacking; a prospective randomized study of critically ill children requiring prolonged mechanical ventilation showed that AVP was associated with an increased incidence of oliguria and hyponatremia [78].

Phenylephrine

Phenylephrine is a pure peripheral α_1-adrenergic receptor agonist, as shown in Table 21.3, and is used as a bolus or infusion to treat acute cases of low systemic blood pressure or SVR. The pure α_1 effects can result in reflex slowing of the heart rate, although this is not as pronounced in young infants as it is in adults. Its main use in CHD is to acutely raise SVR in cases where either ventricle is compromised by outflow obstruction. Such is the case of tetralogy of Fallot, where low SVR lead to increased right-to-left intracardiac shunting and cyanosis, and in hypertrophic cardiomyopathy or other left-sided lesions, in which the gradient across the obstruction is increased by low SVR. A bolus dosing of phenylephrine, such as used on CPB to increase perfusion pressure, is 0.5–5 μg/kg, whereas infusion doses range from 0.02 to 0.3 μg/kg/min.

Systemic vasodilators

The tolerance of systemic vasodilators is affected by the intravascular status, or by any actual or potential outflow

tract obstruction; in such cases, systemic vasodilatation may have disastrous consequences. Careful imaging should be performed to exclude outflow tract obstruction in case of a doubt, prior to administering the vasodilator, and a very low dose or a short acting agent should be given first.

Nitric oxide donors: nitroglycerin and sodium nitroprusside

Nitric oxide donors mimic the effect of endogenous NO, and by activating guanylate cyclase they lead to increased cyclic guanosine monophosphate (c-GMP) production and vasodilation (Table 21.3). Low-to-moderate doses of nitroglycerin (3 μg/kg/min) increase venous capacitance without affecting the arterial resistance vessels [79]. As a result, ventricular filling pressures fall, whereas the stroke volume is unaffected. High-dose nitroglycerin and nitroprusside increase venous capacitance and reduce SVR; thus, filling pressures fall and the stroke volume and CO rise significantly. Major indications for the use of nitroglycerin include myocardial ischemia, systemic hypertension, volume overload, congestive heart failure, and pulmonary edema. The net effect is usually an improvement in the myocardial VO_2/DO_2 ratio. Efficacy has been demonstrated following CHD surgery [80].

Tolerance occurs after more than 24 hours of i.v. therapy, and abrupt weaning after prolonged i.v. infusions may result in rebound hypertension. Extremely rare side effects are methemoglobinemia and cyanide toxicity, which result from the release of nitrite ions when the drug is metabolized.

Phenoxybenzamine

Phenoxybenzamine is a long acting α_1- and α_2-adrenergic receptor blocker, as shown in Table 21.3, and is advocated by some groups for the routine perioperative management of infants undergoing cardiac surgery involving hypothermic CPB. It has gained popularity for infants undergoing the Norwood operation, in whom systemic vasoconstriction occurs additionally in response to failing systemic perfusion (such as seen at $SaO_2 > 80\%$). Such a situation was traditionally managed by manipulating the medical gases to increase PVR and lower SVR. Hoffman et al. carried out a prospective study of phenoxybenzamine use following the Norwood operation [81], where patients received 0.25 mg/kg phenoxybenzamine at the start of CPB, followed by 0.25 mg/kg/24 hours for up to 48 hours postoperatively if the target $SvO_2 > 50\%$ and target Q_P/Q_S ratio of 0.8–1.2 were not reached. There was no evidence of hemodynamic deterioration at high SaO_2 [81], suggesting that α-adrenergic receptor blockade is an effective approach to modifying the intense sympathetically mediated vasomotor responses in these infants. However, the irreversible α-receptor blockade and prolonged effect has limited its popularity.

Phentolamine

Phentolamine is a reversible α-adrenergic receptor blocker. Its use is justified by the observation of elevated plasma catecholamine concentrations and increased SVR following CPB. A randomized trial of phentolamine in CHD surgery reported that administration of 0.2 mg/kg of phentolamine during cooling and rewarming for cardiac surgery reduced plasma lactate levels, indicating better tissue perfusion; in addition, the nasopharyngeal–rectal temperature gradient decreased four-fold, whereas systemic VO_2 increased [82].

Hydralazine

Hydralazine dilates precapillary arterioles. Most studies of hydralazine were performed in the 1980s, in which the drug was used to treat hypertension following CPB in adults. Hydralazine can be used to treat postoperative hypertension in children (1–5 μg/kg/min), or in other situations that require a reduction in preload, such as severe myocardial dysfunction and extracorporeal membrane oxygenation (ECMO). However, the vasodilatory effect is limited by reflex tachycardia; therefore, β-adrenergic receptor blockers and sodium nitroprusside are preferred.

Nesiritide

Nesiritide is a recombinant form of human B-type natriuretic peptide, which is normally produced by the ventricular myocardium. It binds with the A- and B-type natriuretic peptide receptors of the vascular endothelium and smooth muscle, which leads to increased c-GMP production and vasodilation. It increases the glomerular filtration rate and inhibits sodium reabsorption, exerting a strong diuretic effect. Nesiritide was first believed to be beneficial for the treatment of acute decompensated congestive heart failure. Although it has also been found beneficial for the prevention of acute kidney injury following cardiac surgery in adults [83], the results of the largest study performed to date showed that nesiritide does not affect mortality or prevent rehospitalizations in adults [84]. No major hemodynamic effect has been reported when used after CHD surgery [85], but an improved urine output. The recommended dose range for infusion in infants and children with heart disease is 0.01–0.03 μg/kg/min.

Pulmonary vasodilators

In the early 1990s, PHT was a major cause of post-CHD surgery mortality [86]. Overall survival has improved since then and the reported incidence of severe PHT (defined as a ratio of pulmonary-to-systemic arterial pressure >1) has dropped to 2% [87], most likely due to a better understanding of the pathophysiology of PHT, earlier surgical correction in patients at high risk of PHT, and refinement of intraoperative techniques, including ultrafiltration.

It is accepted that an important pathological characteristic of pulmonary vascular reactivity in patients with CHD is dysfunction of the pulmonary endothelium [88]. Such dysfunction suppresses the intrinsic endothelium-dependent vasodilatory mechanisms, including the nitric oxide c-GMP system. c-GMP is generated by the interaction between NO and guanylate cyclase, and it is the final messenger in the pathway that mediates vascular smooth muscle relaxation. It is metabolized by the phosphodiesterase type 5, which is the major phosphodiesterase in the lung; phosphodiesterase type 5 expression is upregulated in patients with PHT and

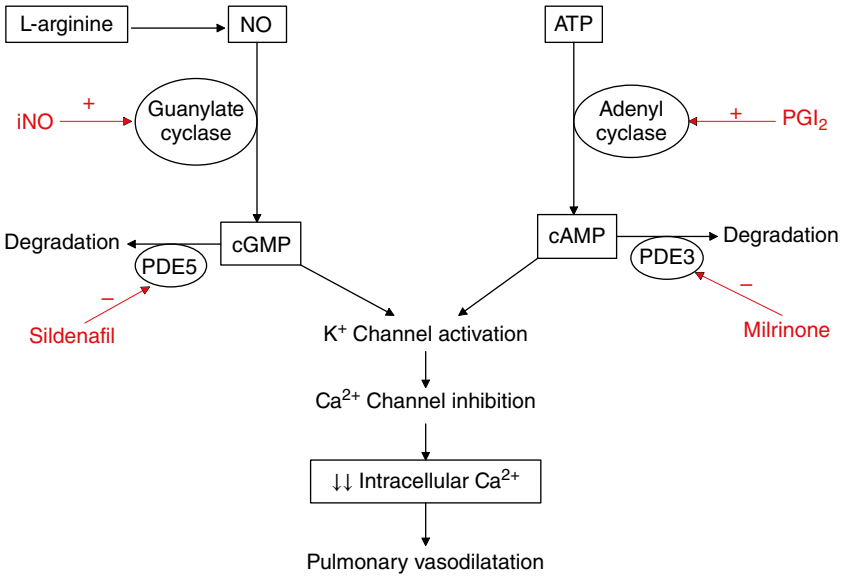

Figure 21.8 Schematic representation of the postulated mechanism of action of pulmonary vasodilators in the endothelial cell. (Source: Adapted from Ghofrani et al. [46].)

after CPB, causing increased turnover of c-GMP. A schematic representation of the mechanism of action of pulmonary vasodilators is shown in Figure 21.8.

Pulmonary vasodilators are commonly used to lower PVR and to treat acute postoperative PHT in patients with preoperative pulmonary overcirculation, or pulmonary venous obstruction. In addition, children undergoing cavopulmonary connections for single-ventricle lesions require low PVR for surgical success. Finally, pulmonary vasodilators are used to reduce the RV afterload, which is often increased following heart transplantation [89]. Historically, the standard therapy for lowering PVR included the induction of respiratory alkalosis due to the known effects of pH on pulmonary artery pressure and PVR; however, although hyperventilation reduces PVR, this comes at the expense of a subsequent increase in SVR and reduction in CO [90]. Other factors are used to lower PVR, including sedation, lung recruitment to improve oxygenation, and metabolic alkalosis.

Inhaled nitric oxide

Inhaled nitric oxide (iNO) has been used for more than two decades to selectively reduce PVR. iNO produces pulmonary vasodilation in ventilated lung regions by activating endothelial guanylate cyclase, resulting in increased levels of c-GMP, which, in turn, relaxes pulmonary vascular smooth muscle. iNO crosses the alveolar–capillary membrane leading to immediate pulmonary vasodilation. High-affinity binding and immediate inactivation of iNO activity by hemoglobin limits the action of the drug in the pulmonary circulation.

An early study by Miller et al. reported that iNO concentrations as low as 2 ppm reduced PVR by approximately 40%, and improved CO by approximately 15% [91]. The pulmonary/systemic artery pressure ratio predicts the response to iNO, with a greater response seen in those with a high ratio (≥0.50). The use of iNO has become more common, and a randomized double-blinded study demonstrated its usefulness as a prophylactic treatment in patients at risk of PHT: patients treated with iNO suffered fewer PHT episodes and could be extubated more quickly [92]. Morris et al. [90] demonstrated that iNO was as effective as hyperventilation for reducing PVR; however, unlike hyperventilation, iNO did not increase SVR or reduce CO. iNO significantly improves oxygenation, lowers the transpulmonary gradient by 40–50%, and reduces central venous pressure by 15–20% in hypoxic patients undergoing Fontan-type procedures [93].

There are inherent problems with iNO, which may limit its use. These include a suboptimal response in some patients, the development of rebound PHT upon withdrawal after even relatively short periods of use, and the mode of delivery, which generally, though not necessarily, requires endotracheal intubation. Moreover, the individual responses to iNO are variable. Abrupt withdrawal of iNO or rapid reductions in the dose may lead to rebound PHT [94], even in patients with no pre-existing PHT. Rebound is due to the downregulation of endogenous NO synthase in the pulmonary vascular endothelium and a reduction in guanylate cyclase activity. Rebound PHT responds to reinstitution of iNO; however, an interesting pharmacological solution is the addition of sildenafil, a selective inhibitor of phosphodiesterase type 5, which prevents the breakdown of c-GMP until c-GMP levels become naturally replete. As such, a single i.v. dose of 0.4 mg/kg sildenafil before weaning from iNO prevents rebound PHT in neonates and infants [95].

iNO has few side effects. However, the binding of NO to hemoglobin gives rise to methemoglobin; therefore, methemoglobin levels should be routinely monitored particularly in patients receiving prolonged therapy. Nitrogen dioxide is a byproduct of NO administration and can injure the lung parenchyma; therefore, its concentrations should be maintained below 5 ppm. The initial dose of iNO is usually set at 20 ppm, and reasonable attempts to wean the patient off it should be made every 12–24 hours.

iNO has had an undisputed impact on the management of PHT, and it continues to warrant consideration as adjunctive therapy for some of the more severe patients. However, a recent meta-analysis concluded that iNO does not reduce short-term mortality [96]. It also concluded that there was insufficient information to determine whether it has an impact on neurodevelopmental outcome, long-term mortality and length of hospital stay [96]. iNO is not specifically approved by the US Food and Drug Administration (FDA) for the treatment of post-surgical PHT, although it is approved for the treatment of persistent PHT in term neonates.

Arginine and citrulline are substrates for NO synthase. In addition, arginine, an essential amino acid due to the inability to increase its *de novo* synthesis, plays a central role in cell proliferation, protein synthesis, energy metabolism, and ammonia detoxification, and the question of its relationship with postoperative inflammation and organ dysfunction has been raised. Arginine depletion has been reported after CPB, together with increased expression of arginase, and a fall in both citrulline and glutamine; the mechanism remains uncertain, however, plasma arginine concentrations recovered after day 5 and initiation of enteral feeding [97]. Although the link with NO synthesis has been made, research in the domain of oral arginine or citrulline supplementation has remained inconclusive, with a consequent increase in the plasma concentrations but no impact on the occurrence of PHT postoperatively [98].

Sildenafil

Sildenafil is a selective inhibitor of phosphodiesterase type 5, which increases c-GMP levels in the pulmonary vascular endothelium, as shown in Figure 21.8. When administered orally to healthy subjects, the bioavailability of sildenafil is only approximately 40%. Also, critically ill children may show unpredictable enteral absorption, therefore, i.v. sildenafil may be more appropriate in such cases. Sildenafil is metabolized in the liver, and it has a half-life of about 4 hours. Oral pediatric doses are between 1 and 5 mg/kg, but the greater bioavailability of the i.v. preparations allows effective doses of 0.5 mg/kg.

Sildenafil is at least as effective as iNO for reducing increased PVR in children with CHD [99], and it enhances the pulmonary vasodilator effects of iNO [100]. The use of sildenafil facilitates the successful weaning of patients off iNO [95]. Nevertheless, unlike iNO, because sildenafil is relatively nonselective, systemic administration is associated with a significant increase in intrapulmonary shunting and a clinically nonsignificant fall in arterial blood pressure [99, 100], which may sometimes outweigh its benefits. Intrapulmonary shunting is caused by vasodilatation of the pulmonary arterioles supplying nonventilated areas of the lung, and results in hypoxia.

Although currently approved for use in adults with PHT, sildenafil is extensively used off-label to treat neonates, infants, and children with PHT since 2005. A recent randomized controlled trial of sildenafil for the long-term therapy of children with PHT (STARTS-1) [101], including idiopathic PHT, and PHT associated with connective tissue disease and CHD, demonstrated a decrease in pulmonary artery pressure and PVR with medium and high-dose sildenafil, and no significant change with low-dose sildenafil. However, in the long-term extension study (STARTS-2) [102], there was increased mortality noted at 3 years associated with high-dose sildenafil in children with idiopathic PHT, but not in those with CHD-related PHT. Review of these data by the FDA and European Medicines Agency resulted in contradictory recommendations; sildenafil was approved in Europe in 2011 with a later warning on avoidance of the use of high-dose sildenafil, and the FDA released warnings against the use of sildenafil in pediatric patients aged 1–17 years. In view of the limitations of the START-2 extension study and in view of the Pediatric Pulmonary Hypertension Network consensus, the FDA warning was later revised to add that health care providers should consider the risk and benefits of sildenafil for the individual patient. Tadalafil and vardenafil are two other phosphodiesterase type 5 inhibitors that are currently under investigation.

Prostaglandins

Prostaglandins (PGs) are the main metabolites of the arachidonic acid pathway. They are generated and released by the endothelium, bind to receptors on the underlying arterial smooth muscle, thereby activating adenyl cyclase, increasing c-AMP levels, and inducing smooth muscle relaxation as shown in Figure 21.8. Although PGs are rapidly metabolized by the pulmonary circulation, doses large enough to induce pulmonary vasodilation also induce systemic vasodilation. Inhaled PGs show more selective vasodilator properties than i.v. preparations and, like iNO, they prevent a ventilation/perfusion mismatch by redistributing blood flow to the ventilated aerosol-accessible regions.

PGE_1 was the first PG to be isolated. It is used extensively to maintain the patency of the ductus arteriosus in neonates whose systemic or pulmonary circulation is dependent on ductal patency. In addition, i.v. PGE_1 has been used to treat PHT. Side effects occur in 20–40% of patients treated with higher doses (0.05–0.1 µg/kg/min), but they are reversible upon reverting to a low dose or discontinuing the drug. Nevertheless, the most common side effects, that is, hypotension, apnea, and hyperpyrexia, may complicate the postoperative course and outweigh any potential benefits.

Prostacyclin (PGI_2) was first identified in 1976, and early studies of the use of i.v. PGI_2 in children suggest that it induces highly selective pulmonary vasodilation within the pulmonary vascular bed, where it is inactivated during a single circulation time. However, the efficacy and pulmonary selectivity of the i.v. PGI_2 formulation, epoprostenol, following CHD surgery is similar to that of i.v. PGE_1 [103]. The inhaled formulation, iloprost, also shows good pulmonary selectivity. It also has a longer half-life (25 min), although repeated inhalation is needed for optimum clinical effectiveness. Iloprost may be used as routine therapy of PHT in countries where iNO is not available because of its prohibitive cost [104], since it has been shown to have similar efficacy to iNO in children with CHD [105]. Finally, iloprost may be useful in children who do not respond to iNO therapy or as a rescue therapy when other treatments have failed [104]. Other PGI_2 analogues, such as treprostinil (inhaled), or beraprost (oral) may have potential utility for the treatment of postoperative PHT in children.

Other strategies to improve circulatory function

Corticosteroids

The actions of corticosteroids on the cardiovascular system are mediated via both genomic and nongenomic effects: they exert anti-inflammatory effects by modulating the transcription of RNA and the subsequent synthesis of proinflammatory proteins, and they represent an adjunct therapy that reduces the need for high doses of inotropes by decreasing the reuptake of norepinephrine.

High-dose corticosteroids have strong anti-inflammatory effects and are largely used in the perioperative period [91]. Corticosteroid treatment is associated with lower hyperthermia-related increases in VO_2, reduced fluid requirement, a shorter length of hospital stay [20], and improves myocardial protection [106]. Altogether, modulation of CPB-mediated inflammation by corticosteroids seems clinically beneficial in pediatric patients, especially when targeted to younger and more complex patients. Although the dosing regimen used in children was empirically set at 30 mg/kg prior to CPB, followed by 30 mg/kg at the start of CPB, a recent survey of 36 cardiac surgery centers showed that administration and dosing regimens were mainly based on provider preferences [107].

On the other hand, corticosteroids inhibit norepinephrine uptake by non-neuronal cells, thereby increasing norepinephrine concentration at α-adrenergic receptor sites; additionally, by inhibiting the catechol-O-methyltransferase enzyme, they lead to increases in the plasma norepinephrine concentrations. Corticosteroids also increase cytosolic calcium availability in myocardial and vascular smooth muscle cells and improve capillary integrity in patients with capillary leak syndrome. Finally, they inhibit PGI_2 production and the induction of NO synthase, thereby limiting the pathologic vasodilation associated with the inflammatory response. Corticosteroids can be considered for children with LCOS; however, a formal definition of adequate steroid dosing is required.

Interestingly, the use of low doses (100 mg/m^2/day of a hydrocortisone equivalent) may be sufficient for use as a rescue protocol in children with LCOS [108]. A recent randomized trial in neonates demonstrated that a prophylactic 50 mg/m^2 bolus at the end of CPB, followed by a 50 mg/m^2/day continuous infusion reduced the incidence of LCOS [109]. Therefore, adrenal insufficiency has often been invoked in patients with postoperative LCOS following CPB, which might be similar to what is seen in patients with septic shock, and which can be reversed by the administration of a "substitutive" dosage range. Recent work reported a significant decline in the cortisol response to adrenocorticotropic hormone stimulation throughout the first 24 hours following CPB in infants, associated with increased fluid resuscitation and longer length of stay [110]. Another hypothesis is the suppression of the hypothalamic–pituitary–adrenal axis due to exposure to high-dose perioperative corticosteroids [111], which brings additional arguments against the extensive use of high dosages.

Controversy regarding the perioperative use of corticosteroids is ongoing, and the most recent randomized trials of corticosteroids in neonates with CPB reported no improvement in postoperative outcomes with, however, an improvement in fluid balance and shortening of time to extubation [112–114]. Similar conclusions were drawn from the most recent meta-analysis of the prophylactic use of corticosteroids in CHD surgery [115]. By contrast, a very large study based on data obtained from the Pediatric Heath Information Systems Database, including 46,730 children from 38 US centers from 2003 to 2008, was able to show that the use of corticosteroids was associated with a greater risk of infection, a greater postoperative requirement for insulin, and, finally, longer length of hospital stay (96). The association with morbidity was more prominent in the low-risk group. Similar conclusions were drawn from a subset study restricted to neonates [116].

Thyroid hormone

Thyroid hormone levels are depressed after CPB. Triiodothyroxine (T_3) supplementation has been used in an attempt to increase cardiac index postoperatively with encouraging initial results (99,100): increased cardiac index, decreased inotropic requirement, better fluid balance and shorter time to extubation. Recent meta-analysis of T_3 trials evaluated the impact on clinical outcomes in children and infants with CHD surgery [117, 118]. They reported a very wide variability of dosages, ranging from 0.4 to 5 μg/kg over a 24-hour period, and a wide variation in the duration of therapy, ranging from a single dose at the end of CPB to continued hormone therapy for the duration of intensive care unit (ICU) stay. The inotrope scores were significantly lower in the T_3 group; however, there was no difference in cardiac index, the duration of mechanical ventilation, ICU stay or mortality. No adverse events or delay in the postoperative recovery of thyroid function were reported either.

Beta-adrenergic receptor antagonists

β-adrenergic receptor blockers are beneficial for the management of chronic heart failure in both children and adults because they improve functional status. Patients with chronic heart failure show a downregulation of β-adrenergic receptors due to increased sympathetic tone; β-blockers, such as propranolol, metoprolol, and carvedilol increase the number of myocardial β-adrenergic receptors and improve myocardial function.

In the acute setting of CHD surgeries, β-blockers reduce the effects of increased sympathetic tone on the RV infundibulum and heart rate in patients with tetralogy of Fallot, thereby improving RV filling. Esmolol, a short-acting β_1-receptor selective antagonist, is well suited for the perioperatively treatment of tetralogy of Fallot patients [119]. Esmolol (100–700 μg/kg/min) controls postoperative hypertension following coarctation repair [120] and avoids reflex tachycardia that results from the use of selective vasodilators.

Calcium

Administration of calcium in the form of calcium chloride or calcium gluconate helps improve the inotropic function of the heart in patients with hypocalcemia. This is especially important in neonates, in whom plasma membrane Na–Ca

exchange and calcium influx channels play a greater role than the sarcoplasmic reticulum in regulating intracellular calcium concentrations; therefore, neonates are highly dependent on extracellular calcium. Neonates receive significant amounts of citrated blood products; however, citrate binds calcium and causes hypocalcemia. Calcium is also a major role in excitation–contraction coupling in smooth muscle, and functions as a vasoconstrictor.

However, routine administration of calcium salts upon termination of CPB is a subject of debate. Elevated intracellular calcium levels are associated with injury and cell death during ischemia and reperfusion [121]. This is further aggravated in the neonatal myocardium, where the sarcoplasmic reticulum is underdeveloped and does not insure calcium uptake in the case of an elevation in intracellular calcium levels.

Sodium bicarbonate

Buffering acidosis is essential in patients with, or at risk of, high PVR. The deleterious effect of acidosis on PVR, particularly in hypoxemic conditions, was demonstrated experimentally more than 50 years ago [122], and the patterns of PVR variations as a response to changes in pH are shown in Figure 21.9. More recently, it has been shown that the administration of sodium bicarbonate to increase pH in infants with increased PVR reduces PVR by approximately 50% and increases cardiac index by approximately 35%, even if hypercapnia is present [123]. This agrees with a previous study showing that pH plays a major role in regulating PVR, and that metabolic alkalosis is as effective as respiratory alkalosis for treating hypoxia-induced pulmonary vasoconstriction [124].

Lactic acid levels increase due to cellular hypoxia, and lactic acidosis is an adaptive mechanism that enables an organism to survive hypoxic conditions. Lactic acidosis moves the dissociation curve for hemoglobin to the right, thereby allowing improved oxygen transfer to the tissues. Therefore, while extreme values of acidemia (pH < 7.2) interfere with myocardial performance and responses to catecholamines, and should be buffered, a pH lower than normal is essential for adaptation. Bicarbonate buffering has several side effects, including paradoxical intracellular acidosis and further impairment of cardiac function [125], a risk of hypernatremia, the creation of a hyperosmolar state, and a risk of intraventricular hemorrhage in neonates.

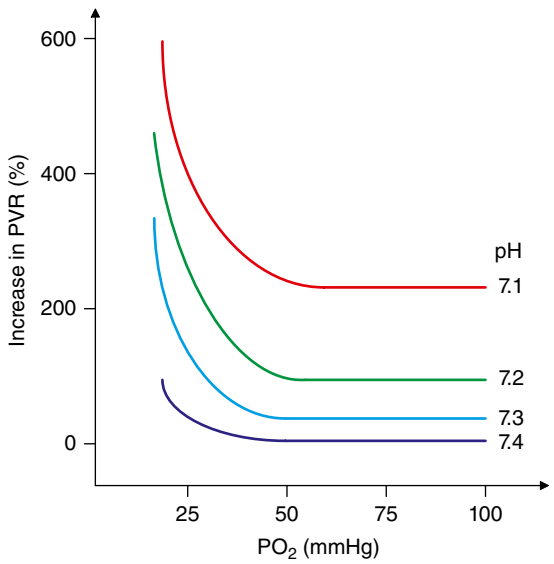

Figure 21.9 Patterns of pulmonary vascular responses to changes in pH and PO_2. (Source: Rudolph & Yuan [122]. Reproduced with permission of The American Society for Clinical Investigation.)

Isoproterenol

Isoproterenol, a nonselective β-adrenergic receptor agonist, is a synthetic derivative of norepinephrine. Isoproterenol has more chronotropic than inotropic effects and lowers the SVR. It is used to treat hemodynamically significant bradycardia and during cardiac anesthesia in the denervated heart immediately after transplantation. High doses of isoproterenol can be arrhythmogenic, and it is often used in electrophysiologic studies. Isoproterenol induces an increase in myocardial VO_2, whereas DO_2 decreases as a result of reduced coronary diastolic filling; this may exacerbate or induce ischemia. Therefore, patients receiving isoproterenol should be volume replete.

Fenoldopam

Fenoldopam is a selective D_1-receptor agonist that shows potent vasodilatory effects, particularly in the renal, mesenteric, coronary, and skeletal muscle vascular beds. Fenoldopam maintains adequate renal perfusion while reducing blood pressure at the same time. Few data are available regarding its use following CHD surgery. Small, albeit randomized, studies show that it is safe in neonates and has a beneficial effect on kidney function following CPB when high doses are used (1 μg/kg/min) [126, 127].

Current practices

Two recent surveys describe the current international practice variation: the EuLoCOS-Ped European survey [27, 32], completed in 2009, collecting information from 90 centers from 31 European countries, and the survey of the Pediatric Cardiac Intensive Care Society (PCICS) [26], completed in 2015, reporting practices in 62 centers, 69% of whom were North American. Medical treatment of LCOS is constrained by a lack of appropriate drug and dosing guidance as acknowledged by the respondents of the European survey [27, 32]. Overall, the EuLoCOS survey alone reports 24 different drug regimens to prevent LCOS, and 39 drug regimens to treat LCOS [27, 32]. Besides, as mentioned before, 78% of all patients receive at least one cardiovascular drug off-label, with surgical CHD patients receiving a median of three drugs off-label [28]. Dobutamine alone is licensed for use as inotropic support in children with LCOS in Spain and Germany [128], although, efficacy data are lacking in neonates.

Preventive LCOS therapy is a common practice, reported in 77.8% of all pediatric cases in the EuLoCOS survey. However, there is a large variability in the choice of drugs being used, as shown in Table 21.4. The distribution of the timing of administration is different as well. In 64%

LCOS: low cardiac output syndrome, PVR: pulmonary vascular resistance, SVR: systemic vascular resistance
Results from the EuLoCOS survey 2009 (left) [27, 32] and from the Pediatric Cardiac Intensive Care Society (PCICS) survey 2015 (right) [26].

of all cases, milrinone in prophylactically administered in European centers to prevent LCOS, however, the dosage and duration of administration differ substantially among hospitals: the bolus dose varies from 20 to 300 µg/kg, the maintenance infusion ranges from 0.2 to 1 µg/kg/min, and the duration varies between 6 and 168 hours. The dose of milrinone appears to be less than that recommended by PRIMACORP [4], which may be due to concerns about the potential side effects, particularly hypotension and age-specific pharmacokinetic differences in drug elimination [51]. In 32% of cases, milrinone is associated with a catecholamine in the EuLoCOS survey: dopamine, dobutamine, epinephrine, and levosimendan are used in about 16% of cases each, with a large variety of dosages. Of the PCICS respondents, 97% use milrinone to prevent LCOS, most of the time in association with a catecholamine: epinephrine in 43%, dopamine in 36%, dobutamine in 11% and levosimendan in 11% of cases. The high percentage of centers using catecholamines as a preventive therapy, 32% in EuLoCOS and 94% in the PCICS survey, is surprising in view of their serious side effects mentioned before.

The therapeutic strategies to treat LCOS, such as reported by the EuLoCOS and PCICS surveys, are shown in Table 21.4. In keeping with the European survey [32], the six drugs that constitute 90% of total drug use to treat LCOS in children are milrinone, dopamine, dobutamine, epinephrine, levosimendan, and methylprednisolone. Milrinone monotherapy was the preferred drug regimen for the initial treatment of LCOS with elevated SVR, epinephrine was the preferred first add-on drug and levosimendan was added as the next step. Milrinone monotherapy was the treatment of choice for the initial treatment of LCOS with elevated PVR, the first and second add-on drugs were iNO and PGI_2 derivatives. The PCICS survey revealed milrinone being used as a first choice in only 42% of cases with LCOS, whereas catecholamines (epinephrine and dopamine) were used in 51% of cases. This, again, is surprising in the context of postcardiac surgery LCOS, where the major therapeutic objectives are the decrease of LV and RV afterload, and avoidance of myocardial oxygen debt.

Inotropic and vasoactive scores

Inotropic and vasoactive scores are derived from summing the maximum dose rates, using correction factors to account for differential units of measurement of inotropes and vasopressor medications administered in the first 24 hours after cardiac surgery. The inotropic score (IS) was first proposed in the Boston Circulatory Arrest Study [3] to quantify the pharmacologic cardiovascular support given postoperatively. Later on, it has

AL Grawany

often been used as a measure of illness severity following cardiac surgery in children even though the score was not created for this purpose. Gaies et al. [129] proposed expanding the IS to include other commonly used vasoactive medications, such as milrinone, vasopressin, and norepinephrine, and called it the vasoactive-inotrope score (VIS). The scores are calculated as:

$$\begin{aligned} \text{IS} = {} & \text{Dopamine dose}\,(\mu\text{g/kg/min}) \\ & + \text{Dobutamine dose}\,(\mu\text{g/kg/min}) \\ & + 100 \times \text{Epinephrine dose}\,(\mu\text{g/kg/min}) \end{aligned} \tag{21.17}$$

$$\begin{aligned} \text{VIS} = {} & \text{IS} + 10 \times \text{Milrinone dose}\,(\mu\text{g/kg/min}) \\ & + 10{,}000 \times \text{Vasopressin dose}\,(\text{units/kg/min}) \\ & + 100 \times \text{Norepinephrine dose}\,(\mu\text{g/kg/min}) \end{aligned} \tag{21.18}$$

In the absence of a specific pediatric cardiac scoring system for the prediction of postoperative outcome, the VIS has been adopted by many centers as an estimator of the severity of critical illness. A multicenter analysis of data reported to the Pediatric Cardiac Critical Care Consortium [130] showed that the maximum VIS calculated in the first 24 hours after cardiac intensive care unit (CICU) admission was strongly and significantly associated with morbidity and mortality, and a maximum VIS $\geq$ 20 predicted an increased likelihood of clinical outcomes, such as mechanical circulatory support, cardiac arrest, renal replacement therapy, neurologic injury, or mortality. Furthermore, when comparing the predictive ability of LCOS, as defined by clinical parameters, and of the VIS for postoperative outcomes, it appeared that clinically derived LCOS was not associated with early postoperative outcomes, whereas the VIS was correlated with durations of mechanical ventilation, ICU stay, and total hospital charges [19]. Our inability to diagnose LCOS based on clinically available parameters alone is acknowledged [131], therefore, the VIS has the opportunity to be considered for inclusion into scoring systems as a metrics or diagnostic criterion to improve current definitions of LCOS.

Individualized perioperative hemodynamic management

In the large majority of cases, children undergo biventricular repair and develop variable degrees of myocardial stunning due to CPB-related injury. Most often, they require either a so-called "hands-off" approach, with minimal intervention and careful observation, or a gentle inodilation therapy. However, the ideal therapeutic approach for one type of circulatory physiology may be detrimental in another, therefore, it is difficult to provide general guidelines for hemodynamic management. An excellent educational review published by Shekerdemian in 2009 [132] highlights the need for an individualized strategy, based on a sound knowledge of the underlying physiologies. Examples of individualized hemodynamic management strategies are shown in Table 21.5.

Abnormalities of diastolic function following right heart surgery. After repair of tetralogy of Fallot, an LCOS is seen in nearly 50% of patients, as a result of RV diastolic failure [24]. This is most likely the result of the exposure of the hypertrophied RV to CPB and reperfusion injury. RV function may further alter due to right ventriculostomy, and especially when the incision is extended across the pulmonary annulus. Transannular patches result in massive pulmonary regurgitation and RV volume overload. In addition, if the pulmonary arteries are hypoplastic, than the RV afterload is increased too. Finally, there is invariably some degree of right bundle branch block after surgery, causing ventricular asynchrony.

Because systolic function is intact, inotropic agents are of little benefit. LCOS results from inadequate RV filling, which is compounded by a reduction in the effective compliance of the LV. During diastole, the hypertensive RV alters the normal trans-septal pressure gradient, causing the ventricular septum to bow into the LV [24]. Spontaneous ventilation, or negative pressure ventilation if the patient's clinical status does not allow extubation, have been shown to improve hemodynamics [133, 134]. Fluid administration is of some benefit; however, the benefit is limited because volume load increases the RV end-diastolic pressure and volume, and rapidly results in RV dilation, tricuspid regurgitation and further decrease in RV output. Therefore, fluid administration should be careful and rapidly relayed by low-dose vasoconstrictors.

Early palliation for functionally univentricular circulation. In infants with a functionally univentricular heart, the total CO is distributed from a single ventricular stroke volume to the systemic and pulmonary circulations, and the relative distribution of flow is dictated by their respective vascular resistances. In these patients, it is usually necessary to maintain a well dilated systemic vasculature, while controlling the PVR.

Using computer simulations to study the single-ventricular circulation, Barnea et al. [9] demonstrated that high values of Q_P/Q_S are always associated with low DO_2, which is only partially compensated by increases in CO. Ideally, Q_P/Q_S should be kept below 1.5, and a Q_P/Q_S ratio between 0.8 and 1.2 with a $SvO_2 > 50\%$ have become the targets of postoperative managements following the Norwood procedure [81]. Li et al. [5] demonstrated that the largest amount of DO_2 variability is due to Q_S and RVS, and vasodilation of the systemic circulation is acknowledged as a major contributor to the improvement of DO_2. Manipulations of the pulmonary circulation have only minor effects [5]. Accordingly, Hoffman et al. [81] demonstrated that the most effective approach to improve the inefficiency of the single-ventricle circulation is to alter the intense sympathetically mediated systemic vasoconstriction using potent α-adrenergic receptor blockers, such as phenoxybenzamine.

Following the Norwood procedure with a systemic-to-pulmonary anastomosis for hypoplastic left heart syndrome, the neonate has a unique convergence of several physiologic vulnerabilities: myocardial dysfunction following ischemia, reperfusion, and CPB, potential limitations of a morphologically right single ventricle and potential aorto-coronary flow limitation. Because of the risk of additional myocardial ischemia due to a drop in diastolic arterial pressure, excessive systemic vasodilation and hypotension should be avoided and/or treated. The Sano modification has proven to increase very short-term survival by improving the coronary perfusion of the single ventricle [135]; however, long-term results did not improve.

Table 21.5 Examples of individualized postoperative hemodynamic management

Underlying physiology	Hemodynamic considerations	Target effect	Current recommendations
Biventricular circulation early after CPB	Increased afterload ± Myocardial dysfunction	None Vasodilation or inodilation Gentle inotropic stimulation	None Milrinone Low-dose epinephrine or dobutamine
Severe systolic dysfunction	Myocardial dysfunction Increased afterload	Increased inotropy Vasodilation	Low-dose epinephrine or dobutamine Milrinone Levosimendan Consider CPS
Diastolic dysfunction	Good systolic function Hypertrophied and noncompliant ventricle	Preload increase Slight vasoconstriction	None Careful fluid administration Low-dose norepinephrine
Univentricular circulation, early palliation	Q_P/Q_S ratio dictated by their respective vascular resistances	Favor Q_S through afterload reduction Gentle inotropic stimulation if needed	Phenoxybenzamine Dobutamine or low-dose epinephrine Milrinone
Systemic-to-pulmonary artery anastomosis	Systolic function is usually good Myocardial ischemia due to diastolic runoff	Inodilation to increase systemic perfusion Minimal vasoconstriction to maintain diastolic perfusion pressure Stable PVR	Low-dose epinephrine Norepinephrine
Postop. Fontan	Systolic function is usually good Passive pulmonary blood flow	Pulmonary vasodilation	Oxygen, iNO Milrinone
Postop. bidirectional cavopulmonary anastomosis	Systolic function is good Pulmonary blood flow is passive and equals SVC flow	Pulmonary vasodilation has little effect	None
Residual outflow tract obstruction	Good systolic function	Preload increase Vasoconstriction	Careful fluid administration Norepinephrine

CPB: cardiopulmonary bypass, CPS: cardiopulmonary support; iNO: inhaled nitric oxide; PVR : pulmonary vascular resistance; Q_P/Q_S: Pulmonary blood flow / systemic blood flow ratio, SVC = superior vena cava

Fontan operations and bidirectional cavopulmonary (Glenn) anastomosis. LCOS is the main cause of morbidity and mortality in this group. After the Fontan operation, Q_P is a passive diastolic flow, extremely sensitive to changes in intrathoracic pressure. Therefore, the key to optimising CO often lies in achieving early extubation, as advocated by Fontan himself. Besides, oxygenation is significantly improved by pulmonary vasodilators, which facilitate passive flow into the pulmonary arteries and increase Q_P. When given in hypoxic patients after Fontan operations, iNO lowers transpulmonary gradient by 40–50% and decreases central venous pressure by 15–20% [93]. In such situations, the addition of 0.5 µg/kg/min of milrinone to the regimen results in a synergistic effect, with a further fall in the transpulmonary gradient and a significant improvement in the oxygenation indices [136]. Other factors may alter oxygenation, and are less susceptible to medical therapy: pulmonary venous admixture, systemic venous collaterals, and pulmonary arterio-venous malformations.

As in the case of Fontan circulation, the pulmonary flow following a Glenn anastomosis is passive diastolic and sensitive to changes in the intrathoracic pressure, and keep the upper body elevated, as well as early extubation are key strategies to optimize CO. As shown in equation (21.15), following the Glenn anastomosis DO_2 is a complex function of CO and Q_{SVC}/Q_{IVC} ratio, where Q_{SVC} equals Q_P. Thus, cerebral and pulmonary circulations are connected exclusively in series with each other, and the cerebral and pulmonary autoregulatory mechanisms are in direct competition with each other. There are limited pharmacological options to increase Q_P in this situation, and oxygen or pulmonary vasodilators have only marginal effect; because cerebral autoregulatory feedback loops override the pulmonary ones, the main factor to increase cerebral blood flow, and as a consequence Q_P and global CO, is hypercarbia [137]. This will be discussed in detail later on.

Residual obstruction to systemic or pulmonary outflow. In a minority of children, an LCOS can be directly attributable to residual anatomic lesions. They do not generally respond to medical treatment, and most often require invasive intervention.

In case of significant residual obstruction of the systemic outflow, as seen after relief of aortic stenosis, or after double outlet right ventricle repair, or of the pulmonary outflow, as seen after tetralogy of Fallot repair, reoperation is needed in order to fully relieve the obstruction. However, until this is achieved, a reduction of the preload or afterload with vasodilators is generally not desirable, as it may result in an acute

AL Grawany

fall in cardiac output. An active inotrope-oriented strategy is not desirable either, since inotropes may increase the outflow obstruction, and the best strategy is to maintain ventricular preload plus low-dose vasoconstrictors.

KEY POINTS: IMPROVING POSTOPERATIVE OXYGEN TRANSPORT BALANCE

- Inodilators are the most effective and the most commonly used drugs in the setting of CHD surgery, both for the prevention and treatment of LCOS.
- Milrinone and epinephrine are the preferred drugs; however, levosimendan has desirable properties and is a promising alternative.
- Catecholamines have significant metabolic side effects, increase myocardial VO_2, and may have variable effects in CHD patients due to variability in receptor function.
- The pharmacological agents used to improve oxygen transport balance should be chosen based on the underlying pathophysiology.

Cardiopulmonary interactions

Mechanical ventilation plays a crucial role in the hemodynamic management of patients following CHD surgery [138]. It is easy to underestimate the effects of ventilation on the cardiovascular system or to misinterpret cardiopulmonary interactions as primary cardiovascular events. Both spontaneous and mechanical ventilation induce changes in intrapleural, intrathoracic pressure, and in lung volume, which can independently affect the key determinants of cardiovascular performance. In 1948, Cournand et al. [139] showed that CO was reduced in patients receiving intermittent positive pressure ventilation via a mask. This study, one of the first to investigate cardiopulmonary dynamics during mechanical ventilation, showed that CO was inversely correlated with RV filling pressure, which was, in turn, directly influenced by the ventilator settings.

A reduction of FRC after anesthesia and thoracic surgery may cause atelectasis, hypoxia, and respiratory failure. CPB and reperfusion injury result in an intense general inflammatory reaction and diffuse endothelial damage with an increase in vascular permeability. Alveolar and interstitial edema, which may or may not be clinically apparent, reduces dynamic lung compliance (the ratio of the tidal volume to peak inspiratory pressure) and increases the ventilation/perfusion mismatch [138]. Mechanical ventilation reverses the inevitable reduction in FRC caused by anesthesia and thoracic surgery, but high mean airway pressures may be necessary to provide equivalent gas exchange in less compliant lungs. This can result in a decrease in CO. Four decades ago, Jenkins et al. [140] demonstrated the cardiopulmonary effects of stopping mechanical ventilation after open-heart surgery in 17 children: FRC, pH, and PaO_2 were significantly reduced, whereas RV stroke index significantly increased. The mean FRC on spontaneous ventilation was below normal levels, despite continuous positive airway pressure, and there was a significant increase in PVR in patients with an FRC that fell below 22 mL/kg while on spontaneous ventilation.

Effects of changes in intrathoracic pressure

Effects of changes in intrathoracic pressure on the left heart

The aortic transmural pressure (aortic pressure–intrathoracic pressure) increases during spontaneous inspiration, due to the fall in pleural pressure. As such, the afterload of the LV increases, which may cause pulmonary edema in patients with poor LV function when weaning from mechanical ventilation. Conversely, positive pressure ventilation decreases the afterload of the LV by decreasing the transmural pressure of the LV, and improves VO_2/DO_2 indirectly, by reducing the work of breathing and the negative inspiratory swings in intrathoracic pressure. LV failure and pulmonary edema are also associated with an increased intrathoracic blood volume. By limiting venous return, a positive intrathoracic pressure, or even simply the use of positive end-expiratory pressure, can improve the hemodynamic.

Effect of changes in intrathoracic pressure on the right heart

In the absence of a left-to-right shunt, the CO is equivalent to the systemic venous return. The systemic venous return depends on the pressure gradient between the extrathoracic veins and the RA pressure. Spontaneous inspiration induces a negative intrapleural pressure and increases the RA transmural pressure (RA pressure–intrathoracic pressure). As a result, the RA increases in size and the RA pressure falls. This favors venous return and increases RA filling. Conversely, during positive pressure inspiration, the RA transmural pressure decreases, the size of the RA decreases and the RA pressure increases, thereby lowering the gradient for venous return, and causing it to decelerate. This phenomenon is aggravated in case of hypovolemia and of gas trapping associated with obstructive airway disease. Circulatory reflexes (adrenergic-mediated reductions in venous capacitance and renin-angiotensin-aldosterone system induced volume expansion) increase the circulatory filling pressure in an attempt to maintain the pressure gradient for venous return. Volume loading and ventilatory strategies to reduce the intrathoracic pressure can be used to compensate and augment venous return.

Effects of changes in intrathoracic pressure on PVR

PVR is the main determinant of RV afterload and is directly affected by changes in lung volume. PVR depends on the balance between the vascular tone of the alveolar vessels, and that of the extra-alveolar or parenchymal vessels. PVR can increase at either extreme of lung volume, as shown in Figure 21.10 [138]. When the lung is inflated above the FRC, the alveolar vessels become compressed due to alveolar distension. As the lung volume falls towards the residual volume, the terminal airways collapse, which in turn causes alveolar collapse; this ultimately results in hypoxic pulmonary vasoconstriction. When ventilating near "normal FRC," the impact on PVR and RV afterload is minimal.

High-frequency oscillatory ventilation allows lung volume to be maintained near FRC and avoids the detrimental effects of large wings in lung volume on PVR.

Delayed sternal closure

Leaving the sternum open causes a substantial increase in the total respiratory system compliance. Pericardial and sternal closures produce constrictive effects and may interfere with efficient mechanical ventilation after cardiac operations. This is important for infants in whom considerable capillary leak and edema may develop after CPB, and in whom cardiopulmonary interactions have a significant impact on immediate postoperative recovery. Delayed closure is also used electively in high-risk neonates, as a means of maintaining hemodynamic and respiratory stability during the initial postoperative period [141]. Delayed sternal closure is not associated with an increased risk of surgical site infections. Significant hemodynamic changes are seen at the time of sternal closure: atrial pressure and heart rate increase, and mechanical ventilation requirements increase as a result of reductions in total respiratory system compliance, tidal volume, and expired CO_2, as shown in Figure 21.11 [142]. Significant increases in the fraction of inspired oxygen, peak inspiratory pressure and ventilatory rate may be required to maintain tidal volume and gas exchange. After a sustained negative fluid balance is achieved, the sternum can be successfully closed within a couple of days; a retrospective study performed at a large tertiary care center suggested a mean of 3–4 days [141].

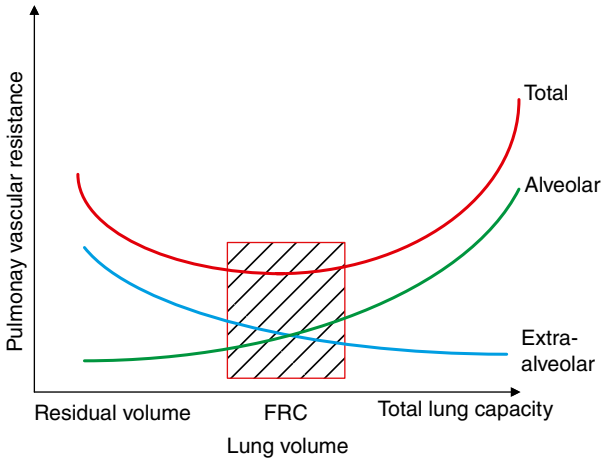

Figure 21.10 Schematic representation of the relation between lung volume and the pulmonary vascular resistance. (Source: Shekerdemian & Bohn [138].)

Individualized management of the ventilation parameters and cardiopulmonary interactions

As with cardiovascular drugs, appropriate ventilation for one child may be unsuitable for another, depending on the underlying physiology and circulatory status. An illustration of the variability in the ventilation targets according to the underlying pathology is shown in Table 21.6.

Systolic LV dysfunction. Patients with systolic LV dysfunction benefit from positive pressure ventilation. This is particularly so in infants with transposition of the great arteries and an intact ventricular septum being operated late after birth, and in those after repair of the anomalous left coronary

AL Grawany

Table 21.6 Examples of individualized postoperative management of cardiopulmonary interactions

Underlying physiology	Spontaneous respiration	Positive pressure ventilation	Guide for routine ventilation
Systolic dysfunction early after CPB	Negative intrapleural pressure increases LV afterload	Reduced work of breathing Reduces LV afterload and RV preload through avoiding negative swing in pleural pressure	Positive pressure ventilation is beneficial Consider extubating to CPAP
Tetralogy of Fallot with restrictive RV	Negative intrapleural pressure increases RV preload and diastolic pulmonary artery flow	Reduced RV preload and diastolic pulmonary artery flow	Low airway pressures early after surgery Early extubation
Postop. Fontan	Negative intrapleural pressure improves pulmonary flow, which is passive	Reduced preload and pulmonary flow	Low airway pressures early after surgery Early extubation
Postop. bidirectional cavopulmonary anastomosis	Negative intrapleural pressure improves pulmonary flow, which is passive	Reduced pulmonary flow Increased cavopulmonary pressures	Keep upper body elevated Mild respiratory acidosis while ventilated Early extubation
Systemic-to-pulmonary artery anastomosis	Preoperative tachypnea may result in respiratory alkalosis, pulmonary overcirculation and systemic hypoperfusion	Enables pre- and postoperative control of the pulmonary flow	Stable PVR, maintain normal $PaCO_2$ and pH Little role for hypoxic gas mix

CPAP: continuous positive airway pressure; CPB: cardiopulmonary bypass, LV: left ventricle; $PaCO_2$: partial arterial carbon dioxide tension; RV: right ventricle
(Source: Adapted from Shekerdemian [132].)

artery from the pulmonary artery. Elective continuous positive airway pressure ventilation should be considered routinely after tracheal extubation.

Diastolic RV dysfunction and Fontan circulation. Patients with RV diastolic impairment have responses to positive pressure ventilation, which are very different from those with systolic dysfunction. Isolated RV diastolic dysfunction is seen in nearly 50% of patients with a tetralogy of Fallot repair [24] and can result in LCOS due to impediment of the pulmonary blood flow. If the patient's clinical status allows, a method of ventilation that permits patient-initiated breathing will result in a lower intrathoracic pressure than if all breaths are ventilator derived. It is also suggested that negative pressure ventilation, which increases pulmonary blood flow by up to 67% in patients suffering from RV diastolic dysfunction, might be a useful hemodynamic tool in such cases [134]. Postoperative care should include the use of conservative airway pressure aiming for early extubation.

A very similar situation is seen in patients following the Fontan operation. Pulmonary blood flow in the Fontan circulation is predominantly passive, and depends on adequate venous return to a low resistance, unobstructed pulmonary circulation. The pulmonary blood flow is very dependent on a low intrathoracic pressure, and augmented by a negative intrathoracic pressure, such as seen during spontaneous respiration. During positive pressure ventilation, the pulmonary blood flow is compromised, and therefore, early extubation is often the key to optimizing CO. Negative pressure ventilation has been tried in Fontan patients with an LCOS in whom early extubation was not possible: pulmonary blood flow increased by 42% and CO improved by an increase in stroke volume [143].

Bidirectional cavopulmonary (Glenn) anastomosis. There are similarities between the pulmonary circulation of patients after bidirectional cavopulmonary anastomosis and those with the Fontan circulation, in that the Q_P is preload-dependent and relies upon a low resistance and unobstructed pulmonary bed. Similar to Fontan patients, they should be ventilated with conservative airway pressures, aiming early extubation. A consequence of circulation following Glenn anastomosis is that cerebral and pulmonary circulations are connected exclusively in series with each other. Thus, the cerebral and pulmonary autoregulatory mechanisms are in direct competition with each other: the brain vasculature dilates in response to hypercarbia, and the lung vasculature vasoconstricts, and the opposite holds true for hyperoxia [144]. The result is that the cerebral autoregulatory feedback loops override the pulmonary one, and hypercarbia markedly increases cerebral blood flow, and as a consequence Q_P, oxygenation indices and the global CO. A prospective observational study in infants undergoing the Glenn anastomosis showed that when increasing $PaCO_2$ from 35 to 45 and 55 mmHg, cerebral blood flow and Q_P increased, as did CO. It was also suggested that the effect of CO_2 on global oxygenation was not the result of selective cerebral vasodilatation, but rather a consequence of an increase in Q_S and decrease in SVR [137]. Both oxygen and iNO, which are potent pulmonary vasodilators, have little impact [145], and hyperventilation with alkalosis does not improve systemic oxygenation after the Glenn anastomosis [146].

Postoperative PHT. Postoperative PHT may complicate the recovery of infants after repair of obstructed pulmonary venous drainage, or after closure of large left-to-right shunts. Ventilatory targets should include low/normal $PaCO_2$, the absolute avoidance of hypoxia and of agitation or stress, and

sedation boluses should be routinely considered before endotracheal suction in high-risk patients.

Systemic-to-pulmonary artery anastomosis. In patients with hypoplastic left heart syndrome before or after a systemic-to-pulmonary artery anastomosis, ventilation was used to induce pulmonary vasoconstriction through deliberate acidosis and hypoxia, with the intention of decreasing pulmonary perfusion and increasing systemic perfusion. This, however, is now questioned, since it has been shown that the main driver of an improvement in systemic DO_2 is systemic vasodilation; modest additional inspired oxygen, a normal $PaCO_2$, and a normal acid–base balance result in further improvement of the systemic DO_2 [5].

KEY POINTS: CARDIOPULMONARY INTERACTIONS

- PPV can compromise RV function by decreasing venous return (preload).
- PPV can improve LV function by decreasing ventricular transmural pressure gradient (afterload).
- PPV near normal FRC has the least effect on PVR.
- Sternal closure exacerbates cardiopulmonary interactions.
- The management of cardiopulmonary interactions depends on the pathophysiology of the underlying CHD.

Monitoring

Estimating the adequacy of DO_2 in pediatric patients with CHD is challenging. In addition to findings on physical examination, parameters derived from electronic monitoring have become a major quantitative description of patient state. There are no specific recommendations for the monitoring following pediatric cardiac surgery. The European Society of Pediatric and Neonatal Intensive Care (ESPNIC) has established recommendations for the monitoring of critically ill children based upon expert consensus [147]. There is a strong agreement upon the fact that there is no single clinical parameter that allows evaluation of the global hemodynamic status in children, and that hemodynamic therapy should not be titrated solely based on clinical signs. The periodical evaluation and serial longitudinal assessment of clinical and hemodynamic monitoring parameters is also strongly recommended, in order to assess response to therapy.

Clinical hemodynamic variables and standard perioperative monitoring

Although clinical hemodynamic variables, such as heart rate, capillary refill, core peripheral temperature gap and fluid balance are the mainstay of critical care management in CHD patients, they are poor predictors of adverse outcomes. Standard and routinely perioperative monitoring parameters include invasive blood pressure, central venous pressure, pulse oximetry, and continuous capnography in intubated patients.

Invasive blood pressure monitoring is indicated during cardiac surgery with CPB. Although it does not provide direct information about CO, evidence point to the utility of the quantification of respiratory variation in blood pressure as an indicator of preload responsiveness [148]. Central venous pressure is commonly placed for the perioperative period of CHD surgery, and it is thought to be a surrogate for RV preload, although sensitive to ventricular compliance. Many centers additionally monitor left atrial pressure through a left atrial line placed intraoperatively. It is an indicator of the LV preload, although the relationship between left atrial pressure and LV preload varies with changes in LV compliance, which are common following CPB. Left atrial lines are mostly used in neonates, in patients with hypoplasia and/or outflow obstruction of the LV, and in those with mitral surgeries; they also allow for the calculation of the transpulmonary gradient in patients who undergo staged single-ventricle palliation.

Pulse oximetry is a standard of care in pediatric anesthesia since the 1990s, and has greatly reduced the incidence of perioperative hypoxic injury. There are, nevertheless, important sources of error inherent to pulse oximetry, such as movement, dyshemoglobinemia, tissue pigment, and LCOS; it is acknowledged that it tends to overestimate arterial saturation as the arterial saturation decreases.

Capnography, an indicator of $PaCO_2$, identifies endotracheal tube displacement, airway obstruction, and is an indicator of pulmonary perfusion during resuscitation. However, the end-tidal PCO_2–$PaCO_2$ gradient widens with a reduction in pulmonary blood flow, such as seen in LCOS, obstruction to pulmonary blood flow or pulmonary hypertensive crisis.

Despite of their widespread adoption, none of these parameters quantifies DO_2, and the identification of inadequate DO_2 before hypoxic–ischemic insult occurs relies on the ability of the clinician to interpret these parameters. Such a limitation can be illustrated by taking the postoperative period following the Norwood operation as an example. Using simulations of the single-ventricle circulation, Barnea et al. [9] demonstrated a nonlinear relationship between DO_2 and SaO_2 (Figure 21.12, panel A). As SaO_2 increases, DO_2 increases, reaches a peak, and then decreases rapidly. Peak DO_2 occurs at $Q_P/Q_S < 1$. However, following the Norwood operation, Q_P/Q_S is commonly about 1.5. When $Q_P/Q_S > 1$, slight increases in SaO_2 are associated with large decreases in DO_2.

Another illustration of these limitations is fluid balance, another commonly monitored clinical parameter. A positive fluid balance has a detrimental impact on organ function in critically ill children, as shown by the dose–response relationship between increasing degrees of fluid overload and the length of mechanical ventilation and PICU stay [149]. However, factors, such as bleeding and hypovolemia, use of perioperative ultrafiltration, use of diuretics, and postoperative acute kidney failure can bias fluid balance in the setting of CHD surgery. On the other hand, the most critically ill patients require more initial fluid resuscitation; thus, it is unclear whether fluid balance is simply the result of the severity of illness or is an independent contributor to multiorgan dysfunction. Furthermore, the most important challenge is likely to be the assessment of acute fluid redistribution which is a consequence of the inflammatory response to CPB, variable

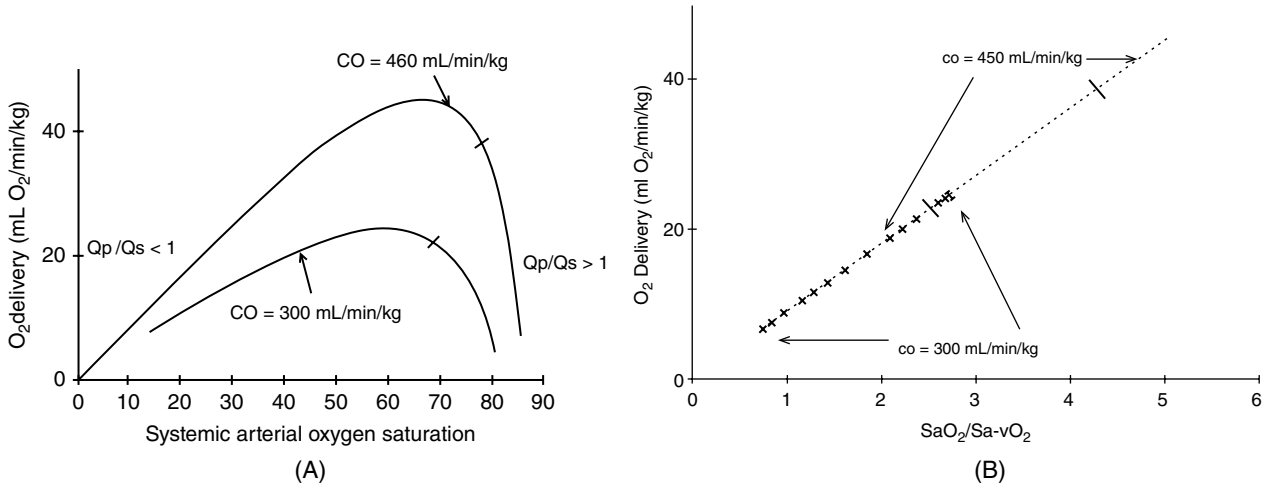

Figure 21.12 Simulations of the relationship between oxygen-derived parameters and systemic oxygen delivery (DO_2) following the Norwood operation. The curves shown in panel A were generated by setting the cardiac output (CO) at 300 and 450 mL/min/kg and varying the Q_P/Q_S ratio from 0.2 to 10. The short line on each curve represents the point at which $Q_P/Q_S = 1$. Note that similar low and high DO_2 can be generated with several combinations of CO and SaO_2. As an example, at a SaO_2 of 70%, DO_2 can range between 21.9 and 45 mL O_2/min/kg, depending on CO. Note that in the region of the curves, where $Q_P/Q_S > 1$, small variations in SaO_2 result in large changes in DO_2. As an example, for the curve generated by setting CO at 450 mL/min/kg, increasing SaO_2 from 80 to 85%, decreases DO_2 from 34.1 to 14.6 mL/min/kg. By contrast, as shown in panel B, the oxygen excess factor ($\Omega = SaO_2/(SaO_2\text{-}SvO_2)$) is independent from the CO, whether 300 mL/min/kg (light dashed line with Xs) or 450 mL/min/kg (heavy dashed line), and it has a linear relationship with the systemic DO_2. (Source: From Barnea et al. [9]. Reproduced with permission of Wolters Kluwer Health, Inc.)

degrees of capillary leak syndrome, and concomitant organ dysfunction.

In the postoperative setting of CHD surgery, ultrasonography has become a standard diagnostic and monitoring tool. Although there are no specific recommendations in the CHD surgery setting, the international Euro-American panel of pediatric and neonatal experts in Point-of-care ultrasound of the ESPNIC has recently reviewed the literature and established guidelines for the ultrasound-based monitoring of critically ill children [150]. Ultrasonography is an excellent tool to obtain hemodynamic information and aid clinical decision making by assessment of preload, of fluid responsiveness, of pulmonary artery pressure along with diagnosis of pericardial effusion and qualitative assessment of cardiac function. Lung ultrasonography may also be helpful to detect pneumonia, pneumothorax, or pleural effusions, and particularly to evaluate lung edema in the context of heart failure [151].

Assessment of cardiac output

In current practice, direct measurement of cardiac output is rare. However, our ability to accurately estimate CO, based on clinical parameters, is poor [131]. The clinical estimate of CO is even more challenging in single-ventricle patients with parallel circulation. The assumption that objective measurement, and hence manipulation, of hemodynamic variables may improve outcome, supports the need for a safe, accurate and repeatable technique for measurement of cardiac index in critically ill children. Unfortunately, the use of invasive techniques, such as percutaneous insertion of pulmonary artery catheters, may be judged to have an unfavorable risk/benefit ratio in children, despite their ability to provide information relevant to optimizing CO. The main technologies and devices used to monitor CO following CHD surgery in children are listed in Table 21.7. They are all based by on the estimation of the stroke volume. Thus, the sinus rhythm is required to derive an accurate CO estimate.

Systems for monitoring cardiac output

Intermittent thermodilution through a pulmonary artery catheter has been the gold standard method for CO monitoring since the late 1960s. This method is, nevertheless, invasive, so that, the use of the pulmonary artery catheter decreased in the 1990s. Development of the less invasive monitoring of CO using the transesophageal Doppler started in the 1990s. The ESPNIC recommendations for the monitoring of critically ill children [147] propose ultrasound-based methods for the initial assessment of unstable patients. Thermodilution techniques are reserved for cases in which reliable absolute CO measurements are deemed necessary, and for which it is recommended to use an invasive and, if possible, continuous CO monitoring [147].

Transpulmonary dilution methods. Transpulmonary thermodilution (TPTD) was developed in the 1990s. Although less invasive than the initial thermodilution method through a pulmonary artery catheter, a dedicated central venous line and a central arterial line are required. In contrast to the pulmonary artery catheter method, cold saline is injected in a central vein instead of the RA, and blood temperature is measured in a systemic artery instead of the pulmonary artery. TPTD estimates CO through the analysis of the arterial thermodilution curve, and, according to the Stewart–Hamilton equation, CO is inversely proportional to the area under the indicator time curve. TPTD has the unique advantage of being able to estimate at the bedside extravascular lung water, which quantifies the volume of pulmonary edema and quantifies the degree of a pulmonary capillary

Table 21.7 Nonexhaustive list of the available cardiac output monitoring systems validated in children with congenital cardiac operations

Technology	System	Invasiveness	Mechanism	Advantages	Clinical issues
Transpulmonary dilution methods	Vigilance II® (Edwards Lifescience, Irvine, CA, USA)	++	TPTD	Gold standard for continuous CO monitoring. Continuous pulmonary pressure and SvO_2 monitoring	Requires a dedicated central venous catheter and a femoral artery catheter.
	COstatus® (Transonic Systems Inc, Ithaca, NY, USA)	++	Transpulmonary ultrasound dilution with saline	Uses an existing central venous and arterial catheter Quantification of intracardiac shunts.	Intermittent CO estimation. Sensitive to changes in vasomotor tone
Ultrasound-based methods	CardioQP® (Deltex Medical; Irving, Texas, USA)	0/+	Transesophageal Doppler ultrasound	Continuous CO monitoring Minimally invasive	Requires manipulation for proper position Operator-dependent
	USCOM® (USCOM Ltd, Sydney, New South Wales, Australia)	0	Suprasternal Doppler ultrasound	Noninvasive CO measurement	Intermittent CO estimation Operator-dependent
Pulse contour analysis	PICCO® (Pulsion, Feldkirchen, Germany)	++	Pulse contour analysis Calibration by TPTD	Continuous CO monitoring. Continuous SvO_2 monitoring. Good accuracy.	Requires a central venous catheter and a specific femoral artery catheter. Requires periodic external calibration by TPTD.
	FloTrac/Vigileo® (Edwards Lifescience, Irvine, CA, USA)	+	Pulse contour analysis	Continuous CO monitoring. Self-calibration.	Requires a dedicated arterial catheter. Sensitive to changes in vasomotor tone.
	Mobil-O-Graph® (I.E.M GmbH, Stalberg, Germany)	0	Pulse contour analysis through a cuff placed around the arm.	Continuous CO monitoring. Self-calibration.	Only investigated in patients > 10 years
	ClearSite® (Edwards Lifescience, Irvine, CA, USA) Formerly known as Nexfin®	0	Pulse contour analysis through a finger cuff with infrared photoplethysmography	Continuous CO monitoring. Self-calibration.	Motion artefacts
Thoracic bioimpedance	ICON® (Cardiotronic/Osypka Medical, Inc, La Jolla, CA, USA)	0	Bioimpedance In small infants: 4 electrodes placed on the left leg, chest, neck and cheek or forehead In older children: 4 electrodes placed on the left chest and left side of the neck	Continuous CO monitoring	Reliable in critically ill patients 1 day to 19 years old
	Aesculon® (Osypka, Medical GmbH, Berlin, Germany and San Diego, CA, USA)	0	Bioimpedance 4 electrodes placed on the left chest and left side of the neck	Continuous CO monitoring	Underestimates CO in children
	PhysioFlow® (Neumedx, Philadelphia, PA, USA)	0	Bioimpedance 6 electrodes placed on the thorax and left side of the neck	Continuous CO monitoring	Underestimates CO in children
Bioreactance	NICOM® (Cheetah Medical, Wilmington, Delaware, USA)	0	Bioreactance 4 double electrodes placed on the thorax.	Continuous CO monitoring	Reliable CO values in patients > 10 kg with normal heart anatomy CO values not reliable in patients with cardiac defects

CO: Cardiac output; TPTD: Transpulmonary thermodilution; ++: Invasive; +: Minimally invasive; 0: Noninvasive

AL Grawany

leak. The new Vigilance II monitor (Edwards Lifescience, Irvine, CA) uses thermal energy emitted by a filament located on the catheter to continuously calculate cardiac output using the thermodilution principle. TPTD is implemented and serves for the external calibration of several pulse contour analysis monitors.

COstatus (Transonic Systems Inc., Ithaca, NY, USA) is a novel monitoring device, which uses an extra-corporeal arterio-venous loop and two ultrasound sensors, one on each side of the loop. The changes in the transit time of the ultrasound beam, crossing the loop when body temperature saline is injected, are used to calculate CO via the Stewart–Hamilton equation. COstatus is considered an accurate CO monitor in infants [154].

To obtain a reliable measurement of CO using transpulmonary dilution methods, the following conditions must be met: (i) constant blood flow; (ii) minimal loss of the indicator; (iii) complete mixing of the indicator in the blood; and (iv) a single passage of the indicator. Several of these conditions are violated after CHD surgery. The blood flow is not constant in the presence of valvular regurgitations. Left-to-right intra- or extracardiac shunting (collaterals) result in loss of the indicator. Finally, there is always a degree of recirculation of the indicator, which increases in the presence of a right-to left intracardiac shunting. In such situation, continuous CO monitoring is still feasible, although it should be viewed as a method that measures a trend rather than an absolute value. In a very original manner, using data from the aforementioned artifacts, the COstatus monitor can detect shunts and estimate the Q_P/Q_S ratio of the intracardiac shunts [155].

Ultrasound-based methods quantify the stroke volume (and hence the CO) by measuring the aortic or pulmonary valve velocity time integral, and the valve annulus diameter. The technique requires a trained operator and can be performed using transthoracic and transesophageal echocardiography. Transesophageal Doppler probes have been designed specifically to assess descending aortic flow and to calculate CO, with either a built-in nomogram or M-mode measurement to calculate the aortic diameter. Decreasing probe sizes allow placement in pediatric patients of ≥3 kg. Major biases, however, may prevent the correct estimation of CO using transesophageal Doppler [156]. Errors are due to the angle of insonation, the assumption of specific flow profiles across the vessels when calculating average flows, and to the measurement of the cross-sectional area of the vessel being imaged. Additionally, the assumption is made that there is a constant flow between the ascending and the descending aorta, which is not always the case in the setting of CHD. Finally, the measurement is highly operator-dependent because the device requires manual positioning of the probe for optimum signal acquisition. The reported accuracy of ultrasound-based methods is controversial; when compared with TPTD, minimally invasive techniques like the CardioQP esophageal Doppler monitor underestimates CO [157, 158], whereas the ultrasonic cardiac output monitor (USCOM) appears reliable in children when operated by trained users [159]. Normal ranges of the cardiovascular parameters measured using the USCOM have recently been published for a large age range [160].

Pulse contour analysis of intra-arterial blood pressure waveform is used by mini-invasive systems aiming to estimate CO continuously. The arterial pressure waveform is a complex physiological signal that is determined by the interaction of LV stroke volume, SVR, and vascular compliance. Thus, the CO estimate is highly dependent on vasomotor tone and vascular compliance, and, because of the nonlinear pressure–volume relationship within the arterial circulation, requires repeated recalibration by a compliance independent system. The pulse contour analysis monitors are more or less invasive, depending on the arterial pressure measurement method: dedicated arterial catheter or external sensor/finger cuff, and on the calibration method: external calibration by TPTD or self-calibration. Minimally invasive devices require an arterial catheter, whereas noninvasive devices use the volume clamp method by a finger cuff, or applanation tonometry by a sensor placed on the skin over the radial artery. External calibration uses TPTD, whereas self-calibration is based on the compensation for aortic compliance using demographic and biometric data, and on the estimation of the vascular tone from the mean arterial pressure. Relatively little and somewhat disappointing data are available in the setting of CHD surgery. The PICCO® (Pulsion, München, Germany) device has been validated in CHD surgery, and found to be as accurate as TPTD [161]. Frequent recalibration is required when the vasomotor tone changes, which is the case in the postoperative cardiac setting. The Mobil-O-Graph® (I.E.M GmbH, Stolberg, Germany) device has been used in patients older than 10 years; at low CO values, however, the monitor overestimated the CO when compared with echocardiography measurements [162]. In children with cardiac transplant, cardiomyopathies or PHT undergoing cardiac catheterization, the FloTrac®-estimated CO showed poor agreement with TPTD [163].

Bioimpedance cardiometry measures changes in thoracic electrical bioimpedance during the cardiac cycle via electrodes placed on the skin. The change in orientation of the red blood cells in the aorta, from random during diastole to an aligned or parallel orientation during systole, causes changes in electrical conductivity and electrical impedance. Electrovelocimetry relates the maximum rate of change of impedance to peak aortic blood acceleration during the cardiac cycle to estimate stroke volume. Reported accuracy of these devices on pediatric populations is controversial. In an observational study, the ICON® device provided real-time hemodynamic information regarding developing hemodynamic events and successfully tracked the rapid response to interventions in children 1 day–19 years old [164]. The Aesculon® monitor (Osypka Medical, Berlin, Germany and San Diego, CA, USA) is one of the most studied in CHD surgery setting. It provides CO estimates which showed good agreement with those derived from the direct Fick-oxygen principle in children undergoing diagnostic heart catheterization [165]. In neonates undergoing the arterial switch operation, it provides similar estimates to those derived by transthoracic Doppler-estimated CO [166]. However, the same device underestimated the CO when compared with transthoracic echocardiography in older infants [157], and underestimates the CO when compared with TPTD [167]. Similar results were reported with the PhysioFlow® device

(NeuMeDx, Philadelphia, PA) during cardiac catheterization in children with CHD [168]. Arrhythmia and pleural effusions may limit its use.

Bioreactance cardiometry is the analysis of the variation in the frequency spectra of a delivered oscillating current that occurs when the current traverses the thoracic cavity. The NICOM® monitor (Cheetah Medical, Wilmington, Delaware, USA) provided CO values which showed a good correlation with echocardiography-estimated CO in pediatric patients > 10 kg with normal heart anatomy, but underestimated CO in patients with ventricular septal defects [169].

Despite lots of efforts to implement them, the reliability of such mini- or noninvasive devices is under question. A meta-analysis of CO monitoring devices in adults found that no noninvasive device or technology was interchangeable with TPTD: the percentage of error was 42% for bioimpedance and 45% for noninvasive pulse contour analysis, where a maximum of 30% error is considered acceptable [170]. A meta-analysis of mini-invasive CO monitors in children showed that bioimpedance cardiometry provided the smallest bias and lowest percentage error when compared with TPTD [171].

Near infra-red spectroscopy

Near-infrared spectroscopy (NIRS) provides real time information regarding regional tissue oxygenation (rSO2) and oxygen uptake/consumption balance in a volume of tissue to a depth of approximately 2.5–3 cm. The parameter displayed is a relative number calculated using an algorithm calibrated from *in vivo* and *in vitro* models. In children with CHD requiring CPB, prolonged perioperative cerebral desaturation < 45%, as assessed by NIRS, has been associated with reduced DO_2 and/or increased extraction rate of the brain, abnormal brain magnetic resonance findings, and worsened neurodevelopmental outcomes [172, 173]. Phelps et al. reported that a cerebral rSO_2 value below 55% in the first 48 hours after surgery had been highly predictive of an adverse outcome in 50 infants who had undergone the Norwood procedure [174]. Therefore, cerebral NIRS monitoring has become a standard in many pediatric cardiac centers.

Despite significant efforts during the last two decades aiming at the definition of normal ranges and lower safety margins, consensus regarding these important targets has not yet been reached. Pediatric anesthesiologists have adopted common adult patient intervention limits like an absolute value <55% or a 20% drop from baseline. These thresholds have been recently questioned, since it has been shown that a decrease in perioperative cerebral rSO_2 of less than 20% is associated with negative behavioral changes on postoperative day 7 in noncardiac pediatric patients [175].

However, an NIRS monitoring strategy focusing exclusively on the brain is inappropriate to assess the amount of O_2 available to organs with perfusion regulated by different neurohormonal mechanisms, and the concept extended from the initial purpose of cerebral monitoring. Multisite NIRS monitoring is a new trend, with some initial evidence of its capability to detect early stage LCOS. Several authors showed that the linear combination of postoperative somatic and cerebral rSO_2 is a reliable indicator of postoperative LCOS, lactate concentration, morbidity and mortality [176, 177]. Averaged cerebral and renal rSO_2 < 65% predicted a lactate level > 3 mmol/L within 24 hours of CHD surgery [176].

Hoffman et al. [177] designed an original two-site method using cerebral and somatic probes. Oxygen extraction by the brain is high (about 35%), and flow–metabolism coupling is achieved by an autoregulatory mechanism. By contrast, the oxygen extraction of the kidney is low (10–15%), and renovascular resistance is under tight sympathetic control. Under normal conditions, renal rSO_2 is 15–20% higher than brain rSO_2. In the early stage of LCOS, the vascular resistance increases, and flow is redistributed to preserve cerebral blood flow at the expense of somatic perfusion: the perfusion of the kidney and renal rSO_2 are expected to drop dramatically, whereas cerebral rSO_2 remains high, and the gradient narrows or becomes negative. According to Hoffman et al. [177], the somatic–cerebral rSO_2 gradient below 10%, can be used to assess shock and the risk of anaerobic metabolism, as suggested in Figure 21.13. In infants at rest, somatic sensors provide similar rSO_2,

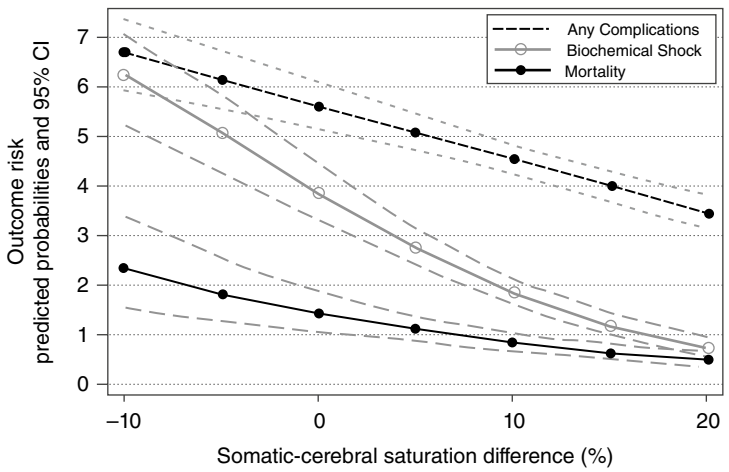

Figure 21.13 The somatic–cerebral saturation gradient estimates the adequacy of DO_2 and is associated with outcome. Data from the Children's Hospital of Wisconsin hypoplastic left heart syndrome stage I perioperative database comparing the probability of complications and postoperative somatic–cerebral saturation gradient assessed hourly for 48 hours. (Source: From Tweddel et al. [177]. Reproduced with permission of Elsevier.)

regardless of whether they are positioned on the kidney, arm, or thigh; however, renal rSO_2 has the largest variability in response to flow and pressure variations [178], suggesting that monitoring of renal rSO_2 may provide the largest amount of information with regard to somatic perfusion.

NIRS measures of hemoglobin saturation are heavily venous-weighted, correlate with regional venous saturation, and can, therefore, be used as a noninvasive surrogate for regional SvO_2. This enables the calculation of another increasingly used parameter, fractional regional tissue oxygen extraction:

$$\text{FTOE} = \frac{(SaO_2 - rSO_2)}{SaO_2} \tag{21.19}$$

This composite parameter reflects the regional DO_2/consumption balance, and represents an estimation of end-organ perfusion. Because different organs have different flow–metabolism relationships, estimation of global oxygen economy is improved by probing fractional tissue oxygen extraction (FTOE) from multiple organ beds. NIRS is currently the best available tool to continuously and noninvasively measure regional tissue-oxygenation and perfusion.

Several factors may interfere with the NIRS measurements. Those that are specific to its use as a cerebral monitor include $PaCO_2$, cerebral autoregulation, and extracerebral contamination of the signal, while others include light contamination, interference between the two probes, dark skin, the arterio-venous ratio in the tissue, and drugs that modify vasomotricity. The use of the somatic–cerebral rSO_2 gradient avoids the variability of the NIRS signal related to cyanosis.

Mixed venous saturation

Mixed venous saturation (SvO_2) provides an estimate of global oxygen balance by measuring the postextraction systemic O_2 saturation, and it is therefore more directly related to tissue oxygenation than to CO measurement.

If we ignore dissolved oxygen, then equation (21.1) can be rewritten as

$$\text{OER} = \frac{(SaO_2 - SvO_2)}{SaO_2} \tag{21.20}$$

Thus

$$SvO_2 = (1 - \text{OER}) \times SaO_2 \tag{21.21}$$

and since SaO_2 is often kept > 0.9, one can roughly estimate that

$$SvO_2 = 1 - \text{OER} \tag{21.22}$$

This simple relationship indicates that SvO_2 is directly related to OER [179]. The critical OER level defined by the onset of anaerobic metabolism is approximately 0.5–0.6. Therefore, it follows that the critical SvO_2 is approximately 40–50%. SvO_2 levels less than 50% should be carefully considered and acted upon and SvO_2 levels between 50 and 70%, therefore, low, must be interpreted in the context of the adequacy of tissue oxygenation [18].

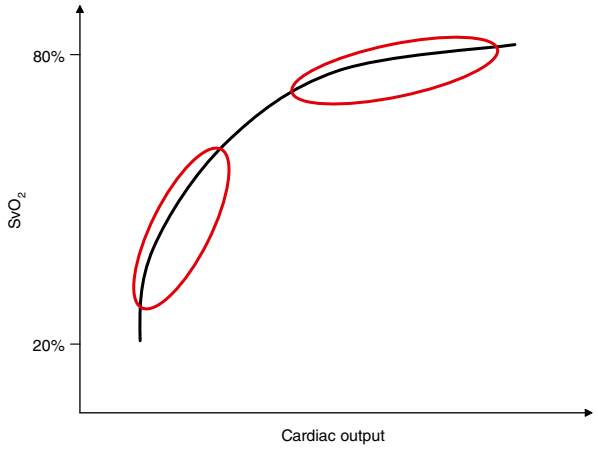

Figure 21.14 The relationship between mixed venous saturation (SvO_2) and cardiac output, based on the Fick equation. (Source: Adapted from Walley [179].)

The O_2 extraction and, thus, venous saturation levels vary across various organs and SvO_2 is a mix of venous saturation of all organs. As CO falls, blood flow is redistributed to maintain vital organ perfusion. Oxygen saturation falls first in the IVC, and it is accompanied by a less severe drop in SvO_2. As CO falls further, the SVC and jugular saturations begin to decrease. Figure 21.14 illustrates the relationship between CO and SvO_2 according to the Fick equation, and suggests that when CO is high, minor variations in CO are related to large variations in SvO_2, and that when CO is low, large variations in CO are related to minor variations in SvO_2. Thus, SvO_2 measurements perform poorly when SvO_2 is clinically irrelevant (high CO) but perform well in clinically relevant situations where DO_2 may be inadequate.

A true SvO_2 should reflect complete mixing of the returning systemic venous blood, making the pulmonary artery the most accurate sampling site. The difference between the venous saturation when drawn from a thoracic central line with the tip placed in the RA or SVC ($ScvO_2$) and SvO_2 is primarily due to mixing of less saturated blood from the coronary sinus in the RA. However, the heterogeneity of flow and metabolic demand within and between organs under critical conditions, and decreased cerebral oxygen uptake during sedation, also play a role. Nevertheless, there is an excellent correlation between SvO_2 and the $ScvO_2$.

$ScvO_2$ has the potential to predict adverse events following CHD surgery [180]. A $ScvO_2$ drop to 40% for more than 18 min, or below 50% for more than 35 min, were highly predictive of multiorgan failure, reoperation or reopening of the chest, and a need for extracorporeal support [180]. Following the Norwood operation, reductions in SvO_2 reflected tissue hypoxia despite apparently normal hemodynamic parameters, and continuous SvO_2 monitoring has the potential to improve survival [181]. Data from continuous $ScvO_2$ monitoring demonstrated that only 32% of the SvO_2 variance could be explained by SaO_2 variations following the Norwood operation, and that the main driver of DO_2 improvement was intense afterload reduction [81].

The interpretation of SvO_2 following early palliation with systemic-to-pulmonary anastomosis in infants with a functionally univentricular hearts require some special attention.

Traditionally, SaO_2 has been used as a rough index of Q_P/Q_S ratio, and systemic vasoconstriction has been reported in response to failing systemic perfusion at SaO_2 above 80%. It has also been suggested that SvO_2 levels as low as 55% may represent ideal hemodynamics for a patient with a single ventricle [182] due to complete mixing of the arterial and venous blood. Using computer simulations to study the single-ventricular circulation, Barnea et al. [9] provided a subtle interpretation of the oxygenation parameters. The total CO is distributed from a single ventricular stroke volume to the systemic and pulmonary circulations. The relative distribution of flow is dictated by their respective vascular resistances. Slight increases in SaO_2 may be associated with large decreases in DO_2, as shown in Figure 21.12, panel A. Also, high values of the Q_P/Q_S ratio are always associated with low DO2, which is only partially compensated by increases in CO. Ideally, the Q_P/Q_S ratio should be kept below 1.5, therefore, a Q_P/Q_S ratio between 0.8 and 1.2 and $SvO_2 > 50\%$ have been provided as targets for hemodynamic optimization [81]. However, taken alone, SaO_2, SvO_2, or the Q_P/Q_S ratio cannot be used to maximize DO_2, and equation (21.9) shows that DO_2 is a complex function of both the CO and the Q_P/Q_S ratio. The index that should best guide therapy to increase DO_2 is the oxygen excess factor:

$$\Omega = DO_2/VO_2 \tag{21.23}$$

If dissolved oxygen is ignored, then this can be rewritten as

$$\Omega = \frac{SaO_2}{(SaO_2 - SvO_2)} \tag{21.24}$$

A linear relationship has been demonstrated between Ω and DO_2, irrespective of the CO, as shown in Figure 21.12, panel B [9]. The normal ratio is of 4 to 5 times the amount of DO_2 to VO_2. It is commonly accepted that Ω should be beyond 3.5 following the Norwood procedure, and any intervention that increases Ω is considered beneficial (Box 21.4).

The interpretation of SvO_2 following CHD surgery can be overestimated in the presence of residual left-to-right shunting. Also, because sympathetic tone increases vascular resistance in splanchnic-mesenteric beds as CO falls, the relative contribution of desaturated blood from those regions to the measured SvO_2 level is reduced and critical regional ischemia may occur in the absence of a critical reduction in whole-body SvO_2.

Box 21.4: Oxygen extraction ratio and mixed venous oximetry

Oxygen extraction ratios based on mixed venous oximetry
- 25% – normal
- 30–40% – increased
- 40–50% – impeding shock
- 50–60% – shock, elevated lactate levels

Normal oxygen extraction ratios for central venous oximetry
- Right atrium – 25%
- Jugular vein – 35%
- Superior vena cava – 30%
- Inferior vena cava – 20%

Blood lactate

The majority of the ATP pool is produced via oxidative phosphorylation, which generates 36 molecules of ATP/molecule of glucose. The first stage of oxidative phosphorylation is the conversion of glucose to pyruvic acid, which occurs in the cytoplasm. The second stage is the oxidation of pyruvic acid into acetyl coenzyme A, which occurs in the mitochondria as part of the Krebs cycle. Lactate is generated by the reaction between pyruvic acid and reduced nicotinamide adenine dinucleotide (NAD) and requires either oxygen for reconversion into pyruvic acid or energy for conversion to glucose. The normal lactate/pyruvate ratio is approximately 10:1.

Oxidative phosphorylation can only occur when the mitochondrial PO_2 is > 1 mmHg (normally in the order of 4–20 mmHg). Connett et al. [183] defined the thresholds of cell hypoxia 40 years ago. The first threshold is crossed when cell oxygen decreases, but ATP production is maintained at a level sufficient to match ATP demand by metabolic adaptation: increase in glycolysis and changes in the phosphorylation state of the mitochondria. The second threshold is crossed when the steady state of ATP turnover can only be maintained by supplementary production of ATP via anaerobic glycolysis. This is a low efficiency pathway which results in only two molecules of ATP per molecule of glucose and leads to rapid ATP depletion in high energy-consuming organs, such as the brain, liver, and kidney. At this stage, ATP production becomes oxygen limited, a state that defines dysoxia.

During hypoxia, the consumption of glucose increases to 90% of the total substrate consumed. It follows, therefore, that excess lactate accumulates under anaerobic conditions. The normal reference value for lactate in critically ill patients is traditionally considered to be <2 mmol/L. Lactic acidosis develops when the lactate concentration exceeds 5 mmol/L. The rapid increase in lactate production following exposure to hypoxia has been demonstrated experimentally: when PaO_2 decreased from 100 to 40 mmHg, lactate levels increased from 2 to 6 mmol/L within 15 min, reaching 10 mmol/L within 30 min [184]. Likewise, restoration of normal DO_2 results in a rather prompt return to normal levels [185]; the half-life of lactate in the blood is less than 10 min.

For many years, blood lactate levels have been seen as a surrogate marker of CO and used to predict outcomes in high-risk patients [186, 187]. Charpie et al. found that increased initial lactate levels or an increase in lactate of 0.75 mmol/L per hour after complex CHD surgeries were associated with a poor outcome [186]. Rossi et al. incorporated serial lactate measurements into a therapeutic algorithm during the postoperative period aiming to increase the DO_2 and/or decrease the VO_2; blood lactate levels that continued to increase or remained persistently high (>10 mmol/L) despite maximal medical therapy were taken to indicate a requirement for mechanical cardiopulmonary support, as shown in Figure 21.15 [187]. The result was a three-fold reduction in mortality in high-risk patients [187]. Unlike SvO_2, lactate levels have the same significance in single-ventricle patients as they do in patients with biventricular physiology. A persistent lactate concentration >10 mmol/L always indicates severe physiologic derangement and increased risk for mortality.

There are several biases in the interpretation of mild hyperlactatemia. The use of epinephrine creates a disparity

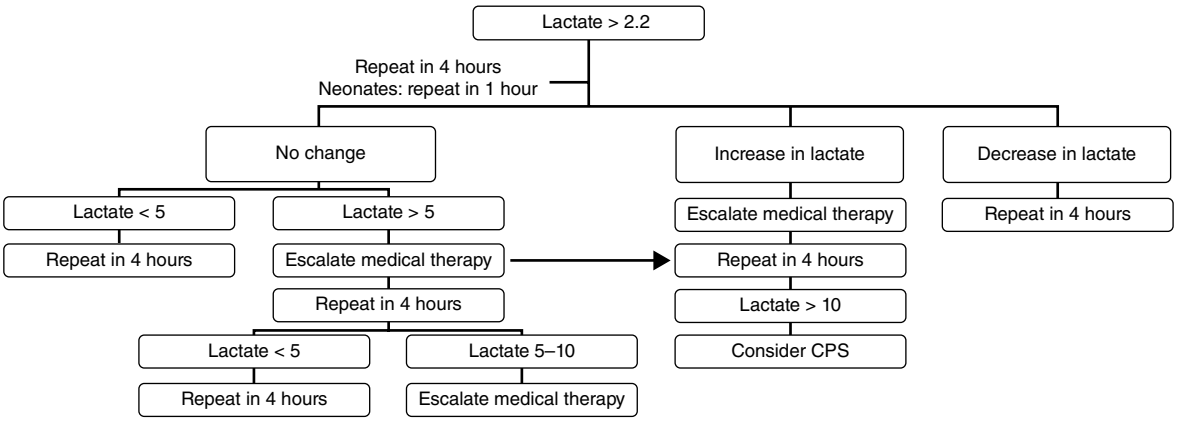

Figure 21.15 Example of algorithm for the postoperative management of patients based on serial lactate determinations. (Source: Rossi et al. [187]. Reproduced with permission of Springer Nature.)

between the rate of peripheral glycolysis and mitochondrial oxidative capacity through increased muscular and hepatic glycogenolysis (via a β_2-adrenergic stimulation), through inhibition of glycogen synthesis, and through limitation of the rate at which pyruvic acid enters the Krebs cycle. As it accumulates, pyruvic acid is converted into lactate so as to preserve intracellular supplies of NAD and ATP. Lactate also accumulates if hepatic and renal clearance is impaired. Lactate delivery via red blood cell transfusions may also result in mild hyperlactatemia [188].

Central venous to arterial CO_2 difference

Venous to arterial CO_2 partial pressure difference ($AVCO_2$) measures the circulatory clearance of tissue CO_2 and is correlated with CO. Under aerobic conditions, CO_2 is the end product of all energy production pathways. Under anaerobic conditions, there is an extra CO_2 production which results from the buffering of lactic acidosis by bicarbonate. CO_2 is extremely diffusible and its elimination through the lungs is not impaired during LCOS, therefore, $PaCO_2$ will remain normal even in the case of profound acidosis, whereas the venous CO_2 will increase. Widening of $AVCO_2$ represents an imbalance between CO and tissue CO_2 production. The potential to detect acidosis through capnography is well known, however, exhaled CO_2 is multifactorial and difficult to monitor in patients on spontaneous ventilation. Importantly, the correlation between $AVCO_2$ and CO is not influenced by pulmonary venous desaturation, intracardiac shunting and anemia, which may decrease DO_2 independent of CO, and which impact oxygen-derived parameters, such as $ScVO_2$. For the same reason, $AVCO_2$ measurements are valid in patients with single ventricle, and have a stronger correlation with CO compared with oxygen-derived parameters. An observational study in patients < 90-day old undergoing cardiac surgery reported an independent association between $AVCO_2$ at admission to the cardiac PICU and postoperative mortality [189]. Patients with poor outcome had a median $AVCO_2$ of 8.3 mmHg upon admission, whereas those with a good outcome had a median 5.4 mmHg. Importantly, $AVCO_2$ increased over the hours following PICU admission and peaked after 12–24 hours at a median of 10.5 mmHg: this evolution over time may mirror the presence of postoperative LCOS.

Current practices

Monitoring practices vary worldwide. Among the respondents at the 2014 PCICS survey [26] 99% reported monitoring lactate and 89% reported monitoring SvO_2; only 25% of the respondents, however, reported using multisite NIRS and only 32% exploited the core peripheral temperature gap. Among pediatric cardiac anesthesiologists in the United States, a larger percentage (78%) are reported to routinely use multisite NIRS monitoring in combination with serial lactate measurements [190]. The PCICS respondents used echocardiography routinely as a tool for hemodynamic monitoring in 53% of cases and used minimally invasive CO monitoring or Doppler hemodynamic CO monitoring in 3% of cases. An Italian survey among pediatric cardiac centers revealed the availability of pulmonary arterial catheter and TPTD in 43% of the centers, and pulse contour methods in 29% of the centers [191], although the percentage of cases in which these tools were indeed used to monitor patients was not reported.

It appears, nevertheless, that the estimation of the VO_2/DO_2 balance relies more on surrogate markers than on more accurate and invasive measurement methods. This is coherent, knowing that even accurate CO measurements might be misleading during the postoperative period: a normal CO might be inadequate at times of increased oxygen demand, and a lower CO may be sufficient during times of lower oxygen demand. Besides, intracardiac shunting and small patient size make techniques, such as thermodilution CO monitoring difficult. Surrogate markers, such as SvO_2 and lactate concentration are predictors of adverse clinical outcomes. Nevertheless, the inability to readily and reliably assess global and regional tissue perfusion remains a challenge in this patient group. Therefore, the use of NIRS measured regional saturations might become a central parameter.

KEY POINTS: MONITORING

- Invasive and noninvasive CO monitors have limited utility in CHD surgery and to date have not been demonstrated to improve outcome.
- NIRS is the best monitor to date for tissue oxygenation, can predict low CO and poor outcome.

- Mixed venous saturation and blood lactate concentration are excellent and very popular surrogate estimators of the VO_2/DO_2 balance, their serial measurements can predict poor outcome.

Conclusion

The fundamental requirement of postoperative hemodynamic management is to match oxygen consumption and delivery, in order to prevent oxygen debt and sustain cellular metabolism. Although the quest for new therapeutic possibilities is ongoing, it is likely that one of the greatest opportunities comes from using existing therapies more effectively. The indicators used to achieve the desired therapeutic goal must be easy to obtain and safe, and invasive techniques may be judged to have an unfavorable risk/benefit ratio in children. Nevertheless, it is unwise to focus on maximizing DO_2 and/or minimizing consumption alone, while ignoring regional and tissue perfusion. Therefore, hemodynamic monitoring requires a paradigm shift towards tissue oxygenation, away from more conventional parameters. Finally, our therapeutic interventions must be associated with an improved outcome; as such, the impact on surrogate physiological endpoint is insufficient evidence of clinical efficacy.

Introduction

The practice of pediatric cardiovascular anesthesiology has evolved significantly over the years, expanding beyond the operative setting to many non-surgical environments. Anesthetic care for infants, children, and adolescents who have or are at risk for, cardiac rhythm disturbances is now provided at various locations, including operating rooms, critical care units, emergency facilities, treatment rooms, and cardiac catheterization/electrophysiology laboratories. The same is true for other patients with congenital heart disease (CHD) beyond childhood. General knowledge of arrhythmia diagnosis and management is essential for anesthetic care in any of these settings, although in some cases, consultation with a specialist is required. This chapter provides a practical approach to pediatric cardiac arrhythmias and rhythm disturbances most commonly affecting patients with CHD, focusing on the diagnosis, mechanisms, and acute management strategies. A brief review of anti-arrhythmic drug (AAD) therapies and the basic principles of cardiac pacing in children, as applicable to the practice of anesthesia, is also presented.

Cardiac rhythm disturbances

Sinus bradycardia

Sinus bradycardia is characterized by a heart rate below the norm for the patient's age and by a normal, sinus P wave. Slow heart rates can be observed during sleep or may be secondary to a high vagal tone. During significant sinus bradycardia, an escape rhythm may arise from the atrium, junction, or ventricle. In otherwise healthy children, this is usually a benign rhythm with no hemodynamic consequences. Patients with certain forms of CHD, however, are more prone to slow heart rhythms that may indeed be clinically significant. Those with heterotaxy syndromes are included in this category because of the absence, displacement, or hypoplasia of the true sinus node in these patients [1].

Intraoperatively, sinus bradycardia can result from vagal stimulation during induction of anesthesia, laryngoscopy, endotracheal intubation, or tracheal suctioning. Sinus bradycardia may also be related to drug administration (e.g., opioids) or other mechanisms of increased parasympathetic activity. This type of sinus bradycardia rarely results in significant hemodynamic compromise and can usually be

treated by removing the stimulus or by administering a chronotropic agent such as atropine or epinephrine (See Box 22.1). Slow sinus rates can be seen during cardiac surgical manipulations around the sinus node or after interventions such as the closure of atrial septal defects (ASDs) and cardiac transplantation.

Sinus bradycardia can also be due to hypoxemia, hypothermia, hypotension, drugs, acidosis, electrolyte abnormalities, or increased intracranial pressure. Hypoxemia-related bradycardia should be treated promptly with oxygenation and ventilation as appropriate. The approach to other forms of secondary sinus bradycardia should focus on addressing the underlying cause. For worrisome low heart rates, particularly in small infants, drugs such as atropine or glycopyrrolate, should be considered. Ongoing bradycardia with clinical evidence of compromised cardiac output requires immediate escalation of therapy that, in most cases, includes epinephrine administration, cardiopulmonary resuscitation, and consideration of temporary pacing.

Low atrial rhythm

A low atrial rhythm is characterized by atrial activation that spreads upward from a focus on the low atrium. The electrocardiogram (ECG) shows inverted P waves in the inferior leads (II, III, and aVF). A slow atrial rhythm implies that another region of the heart has assumed the pacemaker activity of the sinus node. Although this rhythm may be associated with conditions that affect sinus node function intraoperatively, it is most commonly the result of surgical manipulation (Figure 22.1). In most individuals, this is a normal variant and rarely has a hemodynamic consequence.

Box 22.1: Acute therapy of bradycardia

- Treat primary causes – hypoxemia, hypothermia, acidosis, hypotension, anemia, hypoglycemia, hypothyroidism
- Consider causative drugs – opioids, beta-blockers, digoxin
- Consider potential effect from cardiac surgical manipulation
- Drug therapy
  - Atropine – 0.02–0.04 mg/kg IV (minimum dose 0.1 mg; maximum dose 0.5 mg [child], 1.0 mg [adolescent])
  - Epinephrine – 1 μg/kg IV bolus (lower dose may also be effective); infusion, start at 0.02 μg/kg/min, may increase to 2.0 μg/kg/min
  - Isoproterenol – infusion, 0.01–2.0 μg/kg/min
- Temporary atrial pacing – transcutaneous, transesophageal, intracardiac, epicardial

Sinus node dysfunction

Sinus node dysfunction often termed sick sinus syndrome, encompasses a spectrum of disorders characterized by slow or irregular heart rates that have a variety of escape rhythms and that frequently alternate with the periods of tachycardia. The respondent's tachycardia may be atrial tachycardia, atrial flutter, or atrial fibrillation. The term tachycardia-bradycardia syndrome is frequently used to characterize this association. The surgical interventions most likely to be associated with sinus node dysfunction include extensive atrial baffling procedures, such as Mustard and Senning operations, and the Fontan procedure. The management of symptomatic patients may include pacemaker implantation, pharmacological therapy for tachyarrhythmias, atrial antitachycardia pacing (ATP), and, in some cases, transcatheter or surgical ablation.

Sinus tachycardia

Sinus tachycardia is more commonly seen in the perioperative period than sinus bradycardia. It is often the result of painful stimuli or stress, hypovolemia, anemia, medications (e.g., inotropic agents), a high catecholamine state, surgical manipulation, or fever. Sinus tachycardia can often be differentiated from pathologic supraventricular arrhythmias by its variability in rate and its normal P-wave axis. Treatment is directed at the underlying cause. Prolonged periods of sinus tachycardia may impair diastolic filling time, limit ventricular preload, and compromise systemic cardiac output. Patients at higher risk of hemodynamic compromise have substantial ventricular hypertrophy or non-compliant

Figure 22.1 *Low atrial rhythm*. Intraoperative tracing depicting a single electrocardiographic lead (lead II), arterial blood pressure tracing (ART), and central venous pressure (CVP) waveform. Note the negative P-wave morphology in the first portion of lead II, consistent with atrial activation arising from the low atrium. The second half of the recording shows a change in the P-wave morphology (positive) and a slightly faster heart rate as the atrial impulse later originates from the high atrium (likely the sinus node).

AL Grawany

("stiff") ventricles with associated diastolic dysfunction, such as in certain types of cardiomyopathies or obstructive outflow lesions (e.g., tetralogy of Fallot).

Junctional rhythm

Junctional rhythm is characterized by QRS complexes with a morphology identical to that of sinus rhythm without preceding P waves. This arrhythmia is thought to originate in the bundle of His. It often occurs in patients with sinus bradycardia or with sinus node dysfunction. In this rhythm, there is normal atrioventricular (AV) nodal conduction, but it is sometimes difficult to determine if the junctional beats are slightly faster than the atrial beats or there is 1 : 1 ventriculoatrial (V:A) conduction retrograde through the AV node. During surgery, this may occur as a result of cardiac manipulation and dissection around the right atrium. In addition to the ECG features described above, the arterial and venous pressure waveforms can change during junctional rhythm (Figure 22.2). The central venous pressure tracing may show a tall *a* wave, termed as *cannon a wave*, which is due to late atrial contraction against a closed tricuspid valve. An associated decrease in stroke volume and cardiac output, resulting from the absence of the normal atrial systolic contribution to ventricular filling, may manifest as a reduction in systemic arterial blood pressure. Temporary atrial pacing at 10–20 beats/min (bpm) above the junctional rate can be used to document normal AV nodal conduction, and it frequently restores AV synchrony.

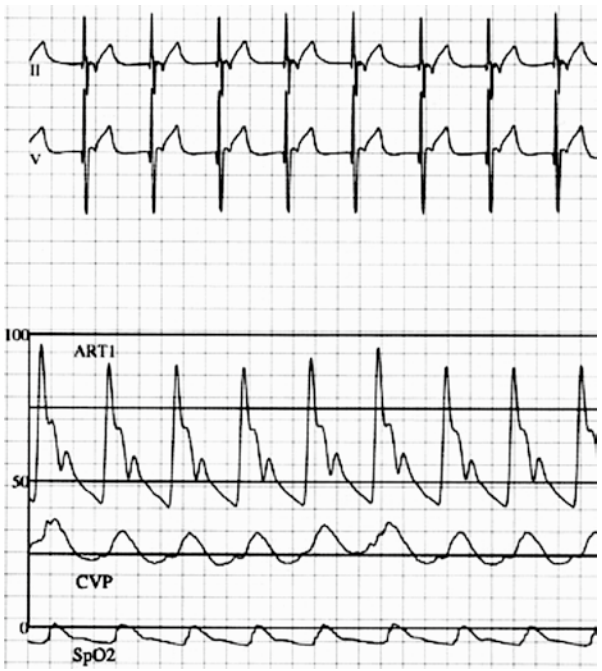

Figure 22.2 *Junctional rhythm*. Intraoperative recording showing the features of a junctional rhythm. Note the retrograde (negative) P wave after each QRS complex. The central venous pressure tracing shows prominent cannon *a* waves corresponding to right atrial contraction against increased resistance from a closed tricuspid valve. This may result in decreased ventricular filling and reduced cardiac output. ART1, systemic arterial blood pressure (scale 0–100 mmHg); CVP, central venous pressure (scale 0–60 mmHg); SpO_2, arterial oxygen saturation by pulse oximetry.

KEY POINTS: CARDIAC RHYTHM DISTURBANCES

- Sinus bradycardia may be due to vagal stimulation or drugs; it is important to exclude hypoxemia, hypothermia, hypotension, acidosis, electrolyte abnormalities, or increased intracranial pressure as potential etiologies.
- Low atrial rhythm is usually due to surgical manipulation.
- Sinus node dysfunction is more commonly seen after Mustard, Senning, and Fontan operations.
- Sinus tachycardia may be due to painful stimuli/stress, hypovolemia, anemia, medications, a high catecholamine state, surgical manipulation, or fever; treatment should be directed at the underlying cause.
- Junctional rhythm may occur due to surgical manipulation/dissection around the atrium; the central venous pressure tracing characteristically displays a tall *a* wave, and blood pressure may decrease due to loss of the atrial kick.

Conduction disorders

Bundle branch block

In an unoperated patient, bundle branch block is an uncommon ECG finding. An incomplete right bundle branch block (RBBB) pattern or intraventricular conduction delay can be seen in patients with right ventricular volume overload (e.g., ASDs, anomalous pulmonary venous drainage). In rare cases, an RBBB can be congenital and idiopathic. An RBBB pattern is frequently seen in postoperative patients after interventions for lesions such as tetralogy of Fallot, right ventricular outflow tract pathology, and AV septal defect (AVSD; also referred to as AV canal or endocardial cushion defect). This conduction abnormality may be related to a ventriculotomy incision, resection of infundibular muscle, damage to the moderator band, or, in some cases, closure of a ventricular septal defect (VSD). A left bundle branch block (LBBB) pattern is uncommon but may be found after surgical procedures involving the left ventricular outflow tract.

Atrioventricular block

First-degree AV block

First-degree AV block is characterized by a prolonged PR interval beyond what is considered normal for age. Each P wave is followed by a conducted QRS complex. This type of rhythm disturbance can be a normal variant in healthy individuals but can also be seen in a variety of disease states (e.g., structural heart defects associated with stretching of the atria, rheumatic fever). In general, a prolonged PR interval in an otherwise healthy child is a benign condition and requires no treatment.

Second-degree AV block

There are four types of second-degree AV block. The two predominant types, Mobitz type I (Wenckebach) and Mobitz type II, involve a periodic failure to conduct atrial impulses

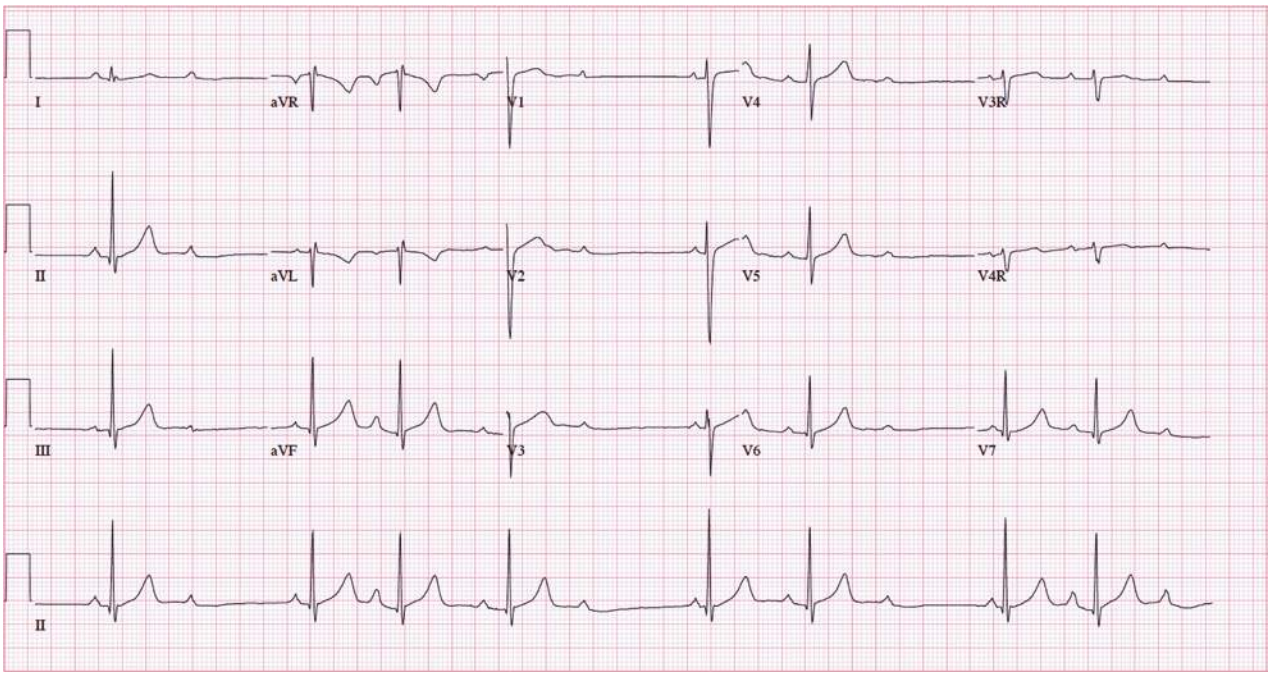

Figure 22.3 *Mobitz type I second-degree atrioventricular block (Wenckebach).* The tracing shows progressive lengthening of the PR interval and eventual failure of an atrial impulse to conduct.

to the ventricle. In *type I second-degree AV block*, the PR interval lengthens progressively until the next atrial impulse cannot be conducted to the ventricle. These failures of conduction manifest on the surface ECG as P waves without associated QRS complexes and concomitant shortening of the RR intervals (Figure 22.3). This rhythm disturbance can occur during periods of high vagal tone and is generally considered a benign phenomenon that requires no therapy.

In the less frequent *type II second-degree AV block*, there is a constant PR interval before an atrial impulse that suddenly fails to conduct. This conduction abnormality is more concerning because of its potential for progression. It can be seen in patients after surgery for CHD and is thought to be due to damage to the His bundle or distal conduction system.

The third type of second-degree AV block is *two to one AV block* (2:1). In 2:1, every second P wave is blocked. In most cases, this is a type of Mobitz type I or Wenckebach block and is secondary to high vagal tone. It is rare for 2:1 to progress to a higher degree of AV block or to require treatment.

The fourth type of second-degree AV block is a *high-grade AV block*, which is evidenced by two or more non-conducted P waves in succession that would normally be expected to conduct. Temporary pacing and close patient observation may be warranted because hemodynamically significant bradycardia or continued progression of the conduction deficit may ensue.

Third-degree (complete) AV block

Third-degree AV block is characterized by the total failure of atrial impulses to be conducted to the ventricles. There is complete dissociation of the electrical activity between the atria and ventricles, and the ventricular rate is usually slow and regular. In third-degree AV block, the ventricular escape rate may be narrow (if originating from the perinodal region) or wide (if originating from within the ventricle). The diagnostic feature on the ECG is that all atrial impulses that should be conducted to the ventricle fail to do so (Figure 22.4).

Complete AV block may be either congenital or acquired. Congenital complete AV block in infants with otherwise structurally normal hearts may be due to intrauterine exposure to maternal antibodies associated with collagen vascular diseases (e.g., lupus). Patients at high risk of complete AV block include those with congenitally corrected transposition (L-transposition of the great arteries with ventricular inversion) and those with polysplenia (left atrial isomerism) [1]. Acquired postoperative AV block is thought to result from damage to the compact AV node or bundle of His and may be transient or permanent. The surgical procedures most commonly associated with the onset of complete AV block include repair of AVSD, closure of VSD, resection of obstructive subaortic tissue, and interventions in patients with congenitally corrected transposition [2]. In children, reported incidences of surgical AV block are as high as 2–4%. Normal conduction eventually recovers in more than 60% of patients, usually within the first 10 postoperative days [3, 4]. Acute treatment includes temporary pacing (either AV sequential pacing or ventricular pacing only). If the rate of the junctional escape rhythm is high enough to support stable hemodynamics, temporary pacing can be set as a backup with close monitoring of the underlying cardiac rhythm. Important considerations in patients with surgical AV block include careful surveillance for the return of AV conduction and frequent evaluation of temporary pacing wire thresholds. The ventricular output of the temporary pacemaker should be set well above the capture threshold to increase the margin of safety (please refer to the section on temporary pacing).

AL Grawany

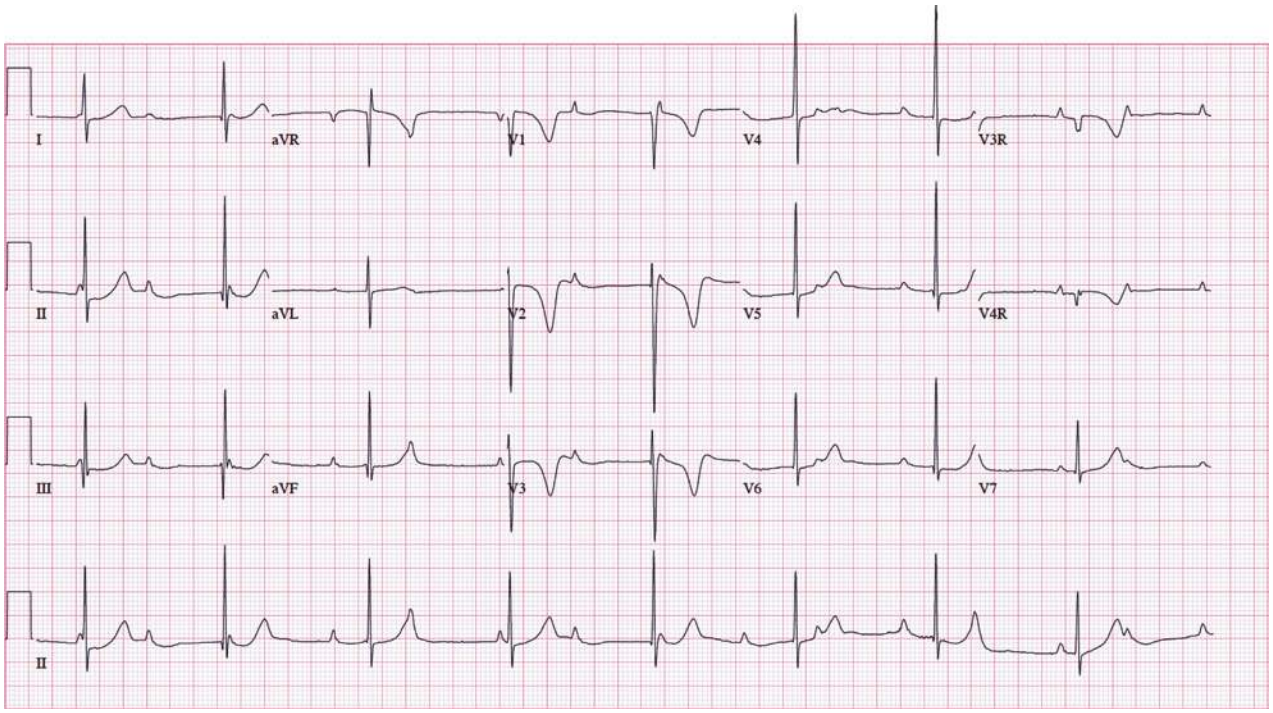

Figure 22.4 *Complete atrioventricular block*. Surface electrocardiogram showing complete dissociation between the atria and ventricles, related to inability of the atrial impulses to be propagated to the ventricular myocardium. Note that the ventricular rate is regular.

Permanent cardiac pacing is generally indicated in patients who do not recover from complete AV block within 10–14 days after surgical intervention. A small minority of patients have late recovery of their native AV nodal conduction after surgically acquired complete AV block [3, 4].

When providing anesthetic care to a patient with complete AV block but no implanted pacemaker, the following should be considered:

- *Drugs and resuscitation equipment*. Immediate availability of emergency agents such as isoproterenol and epinephrine, in addition to resuscitation equipment, is essential.
- *Transcutaneous cardiac pacing*. Equipment (pacing pads and unit) should be available in case extracardiac pacing becomes necessary. Placing the pacing pads before anesthetic induction may be prudent.
- *Access to temporary transvenous pacing*. Although insertion of a temporary pacing catheter before anesthetic care has been suggested in children with complete AV block, a retrospective study of this approach showed that using this catheter routinely had no benefit [5].

KEY POINTS: CONDUCTION DISORDERS

- First-degree AV block and Mobitz type I second-degree AV block are usually benign and do not require therapy.
- Mobitz type II and advanced second-degree AV block may progress and require pacemaker therapy.
- Patients with complete AV block with and without pacemakers require special anesthetic and surgical considerations.

Supraventricular arrhythmias

Premature atrial contractions

Isolated premature atrial contractions (PACs) are relatively common in infants and small children. The early P waves frequently have an abnormal axis and morphology and are typically followed by a normal QRS complex. Atrial bigeminy is characterized by a PAC that follows every sinus beat (Figure 22.5). On occasion, the PACs block at the AV node or conduct aberrantly, displaying an abnormally wide QRS. Blocked PACs can mimic bradycardia, and aberrantly conducted PACs can resemble ventricular ectopy. Most PACs are benign, requiring no therapy. An investigation may be warranted in cases of symptomatic, frequent, or complex (multifocal) PACs. This type of rhythm can be the result of irritation from a central venous catheter or other type of intracardiac line. Radiographic or echocardiographic assessment of catheter/wire tip position should be considered because appropriate adjustments can eliminate the atrial ectopy.

Supraventricular tachycardia

Supraventricular tachycardia (SVT) is the most common clinically significant arrhythmia in infants and children. This rhythm disturbance is characterized by a narrow or "usual" complex QRS morphology and can occur in structurally normal hearts, as well as in various forms of CHD. "Usual" complex describes a QRS morphology in tachycardia similar to that seen during normal sinus rhythm. This is important because patients with CHD often have abnormalities on their baseline ECG, including a bundle branch block pattern. On occasion, widening of the QRS duration in SVT can be due to aberrancy in the right or left bundle branches or to the

Figure 22.5 *Atrial bigeminy*. Intraoperative recording obtained from a child after creation of a Glenn anastomosis, showing a premature atrial contraction after each sinus beat during atrial bigeminy. Note that the premature atrial complexes have a different P-wave morphology from that of the sinus beats, because the premature complexes originate from a region of the atrium other than the sinus node. The variability in the arterial blood pressure shown in the tracing is due to the shortened diastolic filling time during the premature beats. ART1, systemic arterial blood pressure (scale 0–100 mmHg); LA3, left atrial pressure (scale 0–100 mmHg); PA2, pulmonary artery pressure (scale 0–100 mmHg); SpO_2, arterial oxygen saturation by pulse oximetry.

tachycardia mechanism itself (i.e., antidromic SVT; refer to the discussion later in this chapter). When the QRS complex is wide, distinguishing between supraventricular and ventricular tachycardia can be challenging.

Two general categories of SVT are recognized: *automatic and reentrant*. These can be differentiated by evaluating characteristics of the tachycardia (Table 22.1). The most common mechanisms of SVT and their ECG features are noted in Table 22.2. Evaluation of a tachyarrhythmia usually includes a surface 15-lead ECG and a continuous rhythm strip to document onset, termination, and response to medications (e.g., adenosine) or pacing maneuvers. Strips obtained from the bedside or transport monitors are helpful for determining tachycardia rate, but they are usually not sufficient for definitive diagnosis or to distinguish among tachycardia mechanisms.

Atrial electrogram

In the postoperative patient, an atrial electrogram (AEG) can be useful in both diagnosis and management of rhythm problems. This type of ECG recording is obtained from the temporary atrial wires placed toward the end of surgery (Figure 22.6). Typically, atrial wires emerge on the right side of the chest wall and ventricular wires on the left side, although this configuration may vary. Although both a standard 15-lead ECG and an AEG record the same electrical cardiac activity, these electrical sequences display distinctly different configurations in different leads. On an AEG, the P waves are larger in amplitude, making them easily recognizable because the recording is obtained from wires attached directly to the atrial myocardium. Therefore, in situations in which P waves are not clearly identified on a surface ECG, an AEG may assist in defining atrial activity and the relationship between atrial and ventricular depolarization (Figure 22.7). Such recordings can help clinicians to differentiate between atrial and junctional arrhythmias [6]. For example, during junctional tachycardia, the AEG displays P waves that are either superimposed on the R waves or dissociated from them. In most reentrant SVTs, the PR interval is longer than the RP interval, whereas in sinus rhythm, the PR interval is shorter than the RP interval. An AEG is also helpful in defining the type of an AV block if present and can facilitate the differential diagnosis of sinus node dysfunction vs. various degrees of AV block.

AEGs can be obtained from bedside monitors (Figure 22.6) or standard 15-lead ECG machines [7]. With a bedside or operating room monitor, it is best to use a rhythm strip with two or more channels so that AEG and ECG recordings can be viewed simultaneously. There are various ways to obtain an AEG along with a standard tracing, depending on various equipment-related factors (e.g., the recorder, epicardial wires, lead configuration).

The following methods of obtaining an AEG require the use of a standard 15-lead ECG machine:

- If *two atrial wires* are present, each lead is attached to the connectors that usually correspond to the right and left arm leads (an alligator clip can be used, if necessary). This allows for a bipolar AEG (large deflection of atrial depolarization with trivial or no signal representative of ventricular activity) to be recorded in lead I. The chest (precordial) leads provide ECG standard tracings. By

AL Grawany

Table 22.1 Characteristics of supraventricular tachycardia mechanisms

Features of the tachycardia	Automatic	Reentrant
Onset and termination	"Warm-up" at initiation, "cool-down" at termination	Abrupt
Mode of initiation	Spontaneous	Premature beats
Ability to initiate/terminate with timed premature beats	No	Yes
Variation in tachycardia rate	Wide	Narrow
Response to catecholamines	Increased rate	None or slight rate increase
Response to adenosine	None	Termination
Response to drugs that increase refractoriness	Variable	Slowing or termination
Response to overdrive pacing	Transient suppression, quick resumption	Termination
Response to cardioversion	None	Termination

Table 22.2 Mechanisms and electrocardiographic features of supraventricular tachycardia

Diagnosis	Electrocardiographic features
Automatic tachycardias	
Ectopic atrial tachycardia or atrial ectopic tachycardia	Atrial rates of 90–330 bpm Incessant rhythm From atrial focus distinct from the sinus node Abnormal P-wave morphology and/or axis Distinct P waves preceding QRS complexes No influence of AV block on tachycardia
Junctional ectopic tachycardia	Narrow QRS tachycardia Incessant rhythm AV dissociation (often) Atrial rate slower than the ventricular rate Capture beats frequently seen (QRS complexes slightly earlier than expected from antegrade conduction of normal sinus impulses)
Reentrant tachycardias	
Atrial flutter	Sawtooth pattern or more discrete undulating P waves (leads II, II, aVF) Variable rates of AV conduction seen (1:1, 2:1, 3:1, or 4:1)
Atrioventricular reentrant tachycardia (accessory pathway-mediated from concealed bypass tract or Wolff-Parkinson-White syndrome)	P waves immediately following the QRS complex, on ST segment or T wave AV block results in termination of tachycardia
Atrioventricular nodal reentry tachycardia	P waves buried within QRS and not discernible AV block results in termination of tachycardia

AV, atrioventricular

evaluating the atrial activity as displayed by the AEG (lead I) and the ventricular impulses represented by the QRS complexes on the chest leads (V1–V6), the electrical sequence of cardiac events can be assessed.

- If only a *single atrial lead* is available, this can be attached to one of the chest leads to obtain a corresponding AEG. In this case, the limb leads can be used to provide a reference for ventricular activity (Figures 22.6 and 22.7).
- An *alternate lead configuration* may utilize a single atrial lead and a skin lead as a substitute for the arm leads to obtain an atrial tracing in lead I , and other leads serve as a reference. A rhythm strip should be printed out so that the recordings can be examined.

In addition to assisting in arrhythmia diagnosis and the selection of appropriate treatment, temporary atrial wires can be used for rapid atrial pacing in attempts to terminate SVT due to reentrant mechanisms or to overdrive suppress an automatic focus.

General management principles for SVT

Management of SVT depends on the clinical status of the patient, the type of tachycardia, and the precise electrophysiologic mechanism that is causing SVT (Table 22.3). If the tachyarrhythmia is associated with significant hemodynamic compromise, emergent therapy is indicated. Synchronized

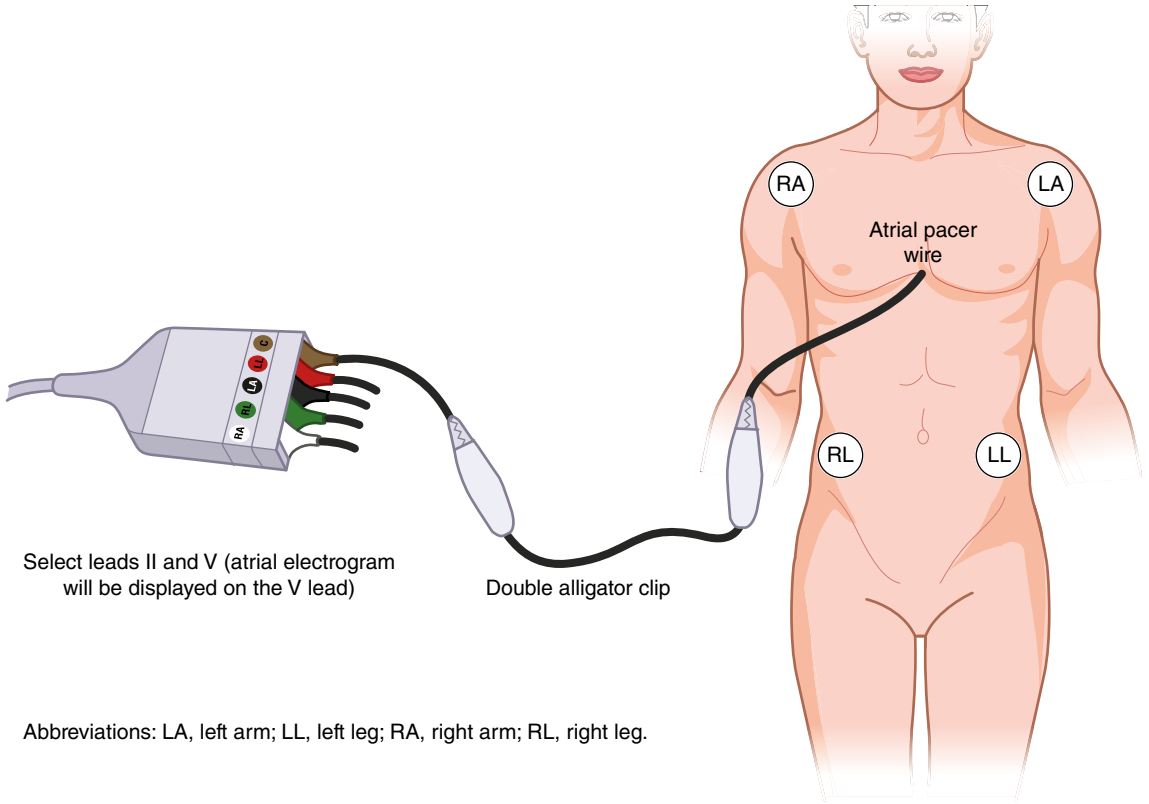

Figure 22.6 *Procedure to obtain an atrial electrogram*. Setup for recording an atrial electrogram by using a bedside (or operating room) monitor and a double alligator clamp to connect the atrial temporary pacing wire to the chest (C) or V lead (brown-colored). Alternate lead configurations may be used as described in the text to obtain equivalent tracings.

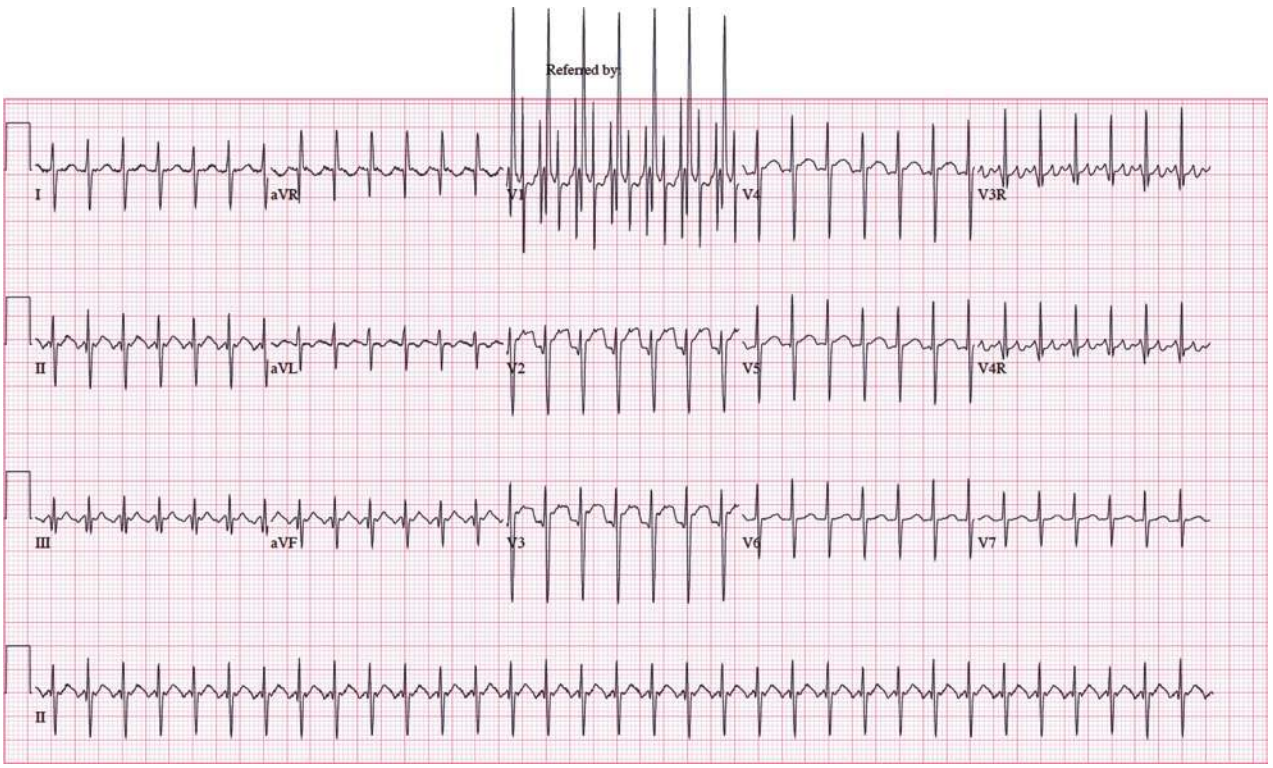

Figure 22.7 *Atrial electrogram*. Full electrocardiographic tracing with an atrial electrogram in lead V1. Note the easily discernible P waves in the atrial electrogram, which confirm that the rhythm is that of atrial flutter with 2:1 conduction.

AL Grawany

Table 22.3 Acute therapy of perioperative arrhythmias without evidence of hemodynamic compromise

Rhythm disturbance	Treatment considerations
Sinus bradycardia	See Box 22.1
Sinus tachycardia	Correct underlying cause
Premature atrial contractions	Evaluate the position of a central venous line or intracardiac catheter Assess/correct electrolyte disturbances (e.g., hypokalemia)
Focal (ectopic) atrial tachycardia or atrial ectopic tachycardia	Correct fever, electrolyte abnormalities Adequate sedation Consider the potential detrimental role of inotropes/vagolytics ß-blockers – use with caution if depressed cardiac function Digoxin Procainamide Amiodarone Sotalol Flecainide Propafenone Ivabradine
Multifocal (chaotic) atrial tachycardia	As in ectopic atrial tachycardia Goals are rate control and decreased automaticity
Accelerated junctional rhythm	Correct fever Consider the potential detrimental role of inotropes/vagolytics Temporary atrial pacing
Junctional ectopic tachycardia	Correct fever and electrolyte abnormalities Consider the potential detrimental role of drugs (e.g., inotropes) Adequate sedation (dexmedetomidine) Surface cooling to 34–35 °C Temporary atrial pacing (for JET rates <180 bpm) Amiodarone Hypothermia plus procainamide Sotalol Ivabradine
Atrial flutter	Adenosine to confirm the diagnosis Atrial overdrive pacing Digoxin Procainamide Amiodarone Sotalol Propafenone
Atrial fibrillation	Digoxin (except in Wolff–Parkinson–White syndrome) ß-blockers Procainamide Quinidine Amiodarone Sotalol
Atrioventricular reentrant tachycardia or atrioventricular nodal reentrant tachycardia	Consider vagal maneuvers Adenosine Atrial overdrive pacing Procainamide Amiodarone Sotalol
Premature ventricular contractions	Identify and treat underlying cause Lidocaine
Ventricular tachycardia	Lidocaine Amiodarone Procainamide Sotalol Magnesium (for *torsades de pointes*) ß-blockers Phenytoin (for digitalis toxicity)
Ventricular fibrillation	Lidocaine (adjunct to defibrillation/prevent recurrence) Amiodarone (adjunct to defibrillation/prevent recurrence)

direct-current cardioversion (0.5–1.0J/kg) should be considered for a patient with any acute tachyarrhythmia associated with low cardiac output, recognizing that this approach does not always restore normal sinus rhythm.

Atrial tachycardias

The automaticity of atrial tissue accounts for the majority of supraventricular arrhythmias in this group [8]. In general, these rhythm disorders are more recalcitrant and difficult to treat than reentrant ones.

Focal atrial tachycardia

Focal atrial tachycardia (AT) originates from a single focus in the atrium outside of the sinus node. In the past, this rhythm disturbance was thought to be due solely to enhanced automaticity. Thus, it was often referred to as an automatic or ectopic AT (EAT; also known as atrial ectopic tachycardia, or AET). In rare cases, however, focal AT is triggered or microreentrant in origin and is not due to a true ectopic focus. These forms of AT cannot be easily differentiated on the basis of the surface ECG alone. The clinical characteristics of EAT follow those outlined in Table 22.1 for automatic tachycardias. EAT may be incessant or episodic. The diagnosis is made by identifying abnormal P-wave morphology, axis, or both on a surface ECG or rhythm strip (Figure 22.8). Also, the PR interval may differ from that in sinus rhythm. Atrial rates in EAT are faster than usual sinus rates for the age and physiologic state of the patient. If the atrial rates are very rapid, some of the atrial impulses may not be conducted to the ventricles because of AV node refractoriness.

Ectopic AT is relatively rare and is generally found in two different clinical scenarios [9, 10]. A child with a structurally normal heart can develop EAT as a primary phenomenon. In older children, EAT can be incessant and, on rare occasions, lead to the development of ventricular systolic impairment or result in dilated cardiomyopathy due to the chronicity of the tachycardia. In neonates and infants, EAT often follows a more benign course and frequently resolves spontaneously early in life. A patient with CHD can also develop EAT in the postoperative period after cardiac surgery. In such cases, EAT tends to be episodic and transient, usually resolving within days. It has been reported that postoperative patients who developed EAT tended to have a lower preoperative oxyhemoglobin saturation, increased inotropic support both pre- and postoperatively, and a previous atrial septostomy [11]. No specific cardiac repair has been associated with the development of EAT.

Management principles for postoperative EAT

- *General considerations*. The management of postoperative EAT includes the treatment of fever if present, adequate sedation, correction of electrolyte abnormalities, and the withdrawal of medications that cause sympathetic stimulation (e.g., inotropic agents) or have vagolytic properties.
- *Anti-arrhythmic therapy*. The institution of pharmacologic treatment is based on overall heart rate, the duration of the tachycardia, and the hemodynamic status of the patient. Treatment relies on clinical judgment and is influenced by ventricular function. There are no large studies on antiarrhythmic drug efficacy in postoperative EAT. Medications such as esmolol, procainamide, and amiodarone can be effective in slowing the tachycardia rate [12]. Oral agents (class I, II, and III drugs) can also be of benefit. Digoxin has a minimal effect on the atrial focus but can decrease the ventricular response by slowing AV conduction [13].

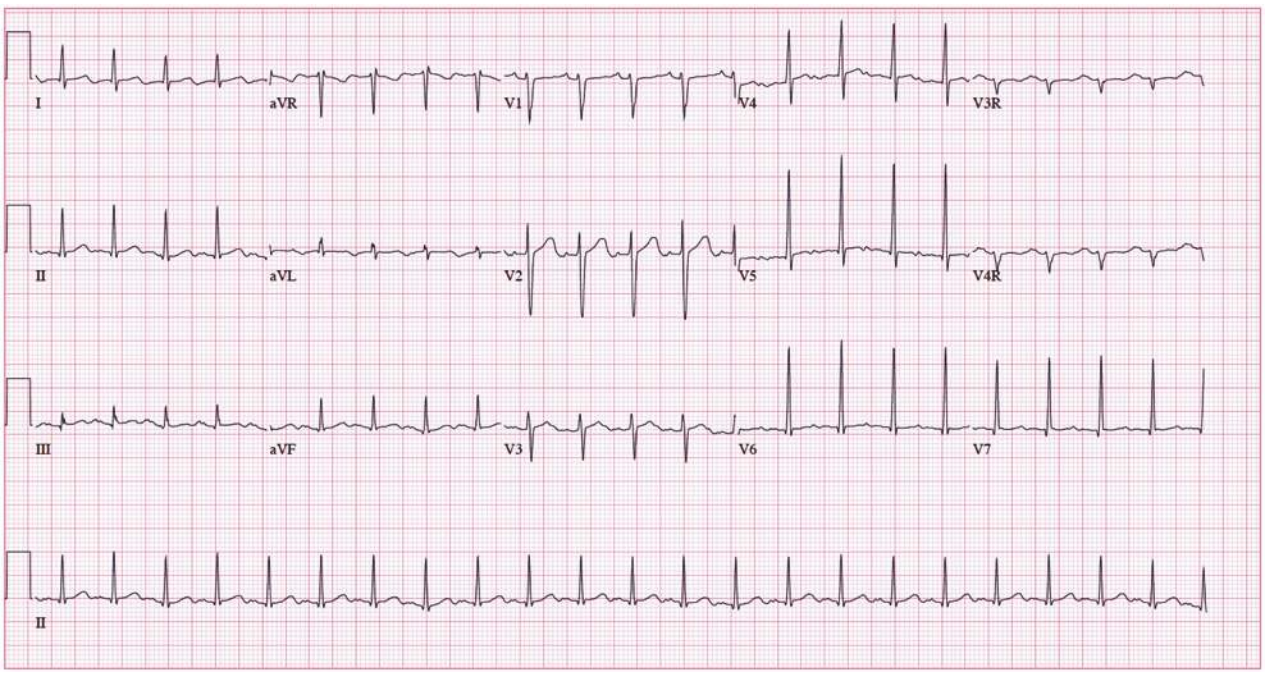

Figure 22.8 *Ectopic atrial tachycardia*. Fifteen-lead electrocardiogram in a 6-year-old child with ectopic atrial tachycardia. The characteristic features of the tachycardia are shown, including a faster-than-expected heart rate for age and an abnormal P-wave axis (left atrial focus).

AL Grawany

- *Ablation therapy*. In very few postoperative patients, EAT can be incessant and life-threatening, and consideration should be given to transcatheter ablation of the atrial focus [14]. It has been reported that propofol anesthesia may not be appropriate for children undergoing catheter ablation of EAT, because administering this drug may terminate the tachycardia and prevent it from being induced by isoproterenol infusion (See Chapter 34) [15].
- *Other modalities*. Atrial pacing and cardioversion are unlikely to resolve EAT.

Multifocal atrial tachycardia

Multifocal atrial tachycardia (MAT), also known as chaotic atrial rhythm, is an uncommon atrial arrhythmia characterized by multiple (at least three) P-wave morphologies [16]. These different morphologies correspond to multiple foci of automatic atrial activity. Characteristic ECG features include variable PP, RR, and PR intervals and typical atrial rates that exceed 100 bpm. MAT can be seen in young infants without structural heart disease, in postoperative CHD patients, and in children with non-cardiac medical conditions [17, 18]. Treatment focuses on ventricular rate control or decreasing automaticity, or both. Drugs such as digoxin, procainamide, flecainide, amiodarone, and propafenone have been found to be successful in converting MAT to sinus rhythm in children [19]. Adenosine, pacing, and direct-current cardioversion are usually ineffective.

Junctional tachycardias

The automaticity of junctional tissue accounts for the majority of supraventricular arrhythmias in this group [8]. These rhythm disorders tend to be somewhat resistant to standard pharmacological therapy.

Accelerated junctional rhythm

Accelerated junctional rhythm is an arrhythmia that arises from the AV junction. Characteristics of this automatic rhythm include a narrow or "usual" QRS pattern with no preceding P wave. There is either VA dissociation, with ventricular rates faster than atrial rates, or the presence of 1 : 1 VA conduction retrograde via the AV node. Temporary atrial pacing at a rate of 10–20 bpm faster than the junctional rate often re-establishes AV synchrony and effectively suppresses the automatic junctional rhythm. Changes in the patient's physiologic state (including fever), chronotropic agents, and endogenous catecholamines can stimulate the automatic junctional focus, increasing junctional rates. This rhythm is usually well-tolerated and is easily managed with temporary pacing and control of the patient's underlying physiologic state.

Junctional ectopic tachycardia

Junctional ectopic tachycardia (JET) is another automatic rhythm that arises from the AV junction. It is a narrow or "usual" complex tachycardia without preceding P waves. It is distinguishable from accelerated junctional rhythm on the basis of the patient's heart rate and hemodynamic status. This tachyarrhythmia has been classically defined by heart rates above 160 or 170 bpm with resultant hemodynamic compromise [20]. The diagnosis of JET has also been considered if the junctional rate exceeds the 95th percentile of heart rate for age [21]. There is either VA dissociation with ventricular rates faster than atrial rates or the presence of 1:1 VA conduction (Figure 22.9). If 1:1 VA conduction is identified, a trial of adenosine or rapid atrial pacing may be beneficial to differentiate JET from other reentrant forms of SVT on an AEG.

This type of tachycardia typically occurs in the immediate postoperative period and usually results in hemodynamic instability and significant morbidity and may contribute to mortality [22–24]. It occurs most commonly after surgical intervention for tetralogy of Fallot, VSD, AVSD, transposition of the great arteries, and total anomalous pulmonary venous return [25]. Other risk factors for the development of JET are long ischemic cross-clamp and cardiopulmonary bypass times, young age, and the need for inotropic support [26, 27]. Excessive retraction of tissues to allow for intracardiac surgical exposure anecdotally has also been linked to JET. Several strategies have been used to decrease the incidence of postoperative JET. The administration of magnesium during cardiopulmonary bypass decreases the incidence of postoperative JET, its use appears to be more effective in higher complexity surgeries [28, 29]. Another strategy that has shown promise in the reduction of postoperative JET is the use of dexmedetomidine in the perioperative period [30, 31].

Management principles for postoperative JET

Numerous therapies have been advocated for JET [23, 24, 26, 32]. Strategies for acute care include the following:

- *General considerations*. Core temperature cooling (to 33–35 °C) in the younger patient by the use of cooling blankets, fans, or cold compresses has been shown to be of benefit in reducing the tachycardia rate [33–35]. Shivering, if significant, should be minimized to prevent potentially detrimental increases in oxygen consumption. Additional suggested approaches include withdrawing or decreasing vagolytic agents and any medications associated with catecholamine stimulation and correcting abnormal levels of electrolytes, especially magnesium, potassium, and calcium.
- *Atrial pacing*. Temporary atrial pacing at heart rates 10–20 bpm above the JET rate establishes AV synchrony and often improves hemodynamics. However, if the JET rate is faster than 180 or 190 bpm, overdrive atrial pacing often confers a little benefit.
- *Anti-arrhythmic medications*. The two most widely used drugs for JET are amiodarone and procainamide [26, 32, 36–38]. *Amiodarone* has a longer onset of action and a longer half-life than procainamide. The drug has been shown to reduce the heart rate in JET patients during the initial bolus infusion [36, 37]. Core cooling is often continued but is not generally needed for efficacy. Administering amiodarone may be a way to avoid having to evaluate clinical signs reflecting the adequacy of cardiac output (distal peripheral perfusion, skin temperature) in a patient with hypothermia and tachycardia. Amiodarone does not directly influence ventricular function and is generally thought to cause less likelihood of hypotension during the initial bolus infusion than procainamide does. However,

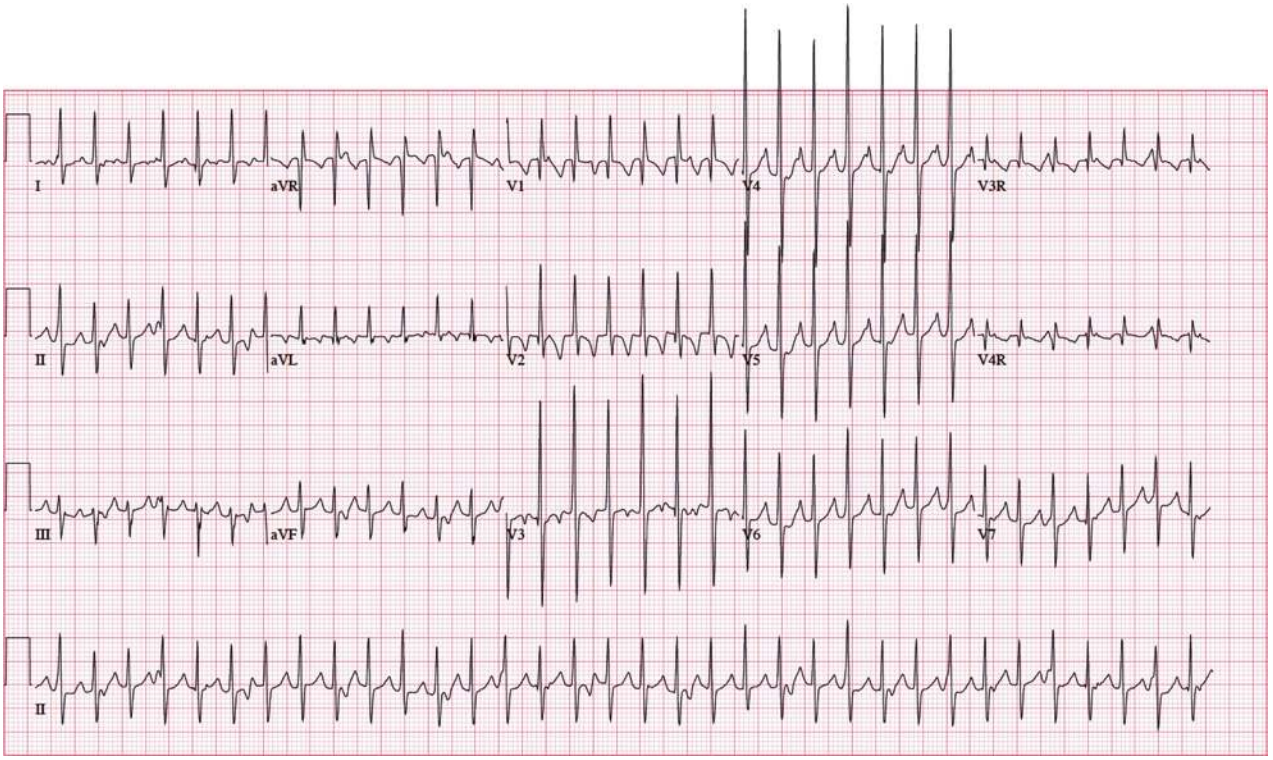

Figure 22.9 *Junctional ectopic tachycardia*. Fifteen-lead electrocardiogram in a postoperative patient with junctional ectopic tachycardia after corrective surgery for tetralogy of Fallot. The tachyarrhythmia is characterized by a narrow QRS complex and atrioventricular dissociation.

the drug should be administered with caution, given its potential adverse events (hypotension, bradycardia, AV block). The benefits of *procainamide* are that it has a faster onset of action and a shorter half-life than amiodarone. However, procainamide appears to be effective mainly when used with core cooling. It may also cause a decrease in systemic vascular resistance, with resultant hypotension, particularly during bolus infusions. Procainamide can also have negative inotropic properties. Usually, a fluid bolus or other volume expander should be given before or during procainamide therapy to maintain adequate hemodynamics. Both amiodarone and procainamide have been shown to be effective in the treatment of JET in published retrospective studies; however, the main determinant of drug selection in clinical practice is influenced by physician/institutional preference. Because amiodarone and procainamide can each cause QT prolongation and proarrhythmic side effects, these two drugs should not be administered concomitantly. Intravenous *sotalol* has been shown in case reports to be of use in the management of post-operative JET. Further studies are needed to determine the safety and efficacy of *sotalol* in the management of postoperative JET [39]. Another novel anti-arrhythmic agent that has shown promise in the management of JET is *ivabradine* (alone and in combination with amiodarone) [40–43]. *Ivabradine* is available only for oral administration, so its use is limited to patients that can tolerate oral medications. Anecdotal evidence suggests that digoxin loading can slow the JET rate, but this has not been well documented in the literature. ß-blockers and calcium-channel blockers can depress myocardial contractility, a feature that may limit their use in the immediate postoperative period. In this regard, a short-acting agent such as *esmolol* may offer a larger margin of safety. The use of intravenous (IV) class IC agents such as *propafenone* and *flecainide* has been reported, but these drugs have not been studied extensively for JET [44–46]. The natural history of perioperative JET is that it resolves within 2–5 days after the surgical intervention. Long-term anti-arrhythmic therapy is usually not necessary. Rarely, extracorporeal membrane oxygenator (ECMO) support may be necessary for incessant hemodynamically significant JET not responding to other therapies.

- *Cardioversion* is generally considered ineffective in terminating JET.
- *Catheter ablation* of the junctional focus should be considered only as a last resort, because it can result in complete AV block, given that postoperative JET is usually transient [47, 48].

Reentrant supraventricular tachycardias

Reentry, also known as "circus" movement or reciprocation, implies that a single stimulus or excitation wave front returns and reactivates the same site or tissue from which it originated. Reentrant forms of SVT may or may not involve accessory pathways.

Atrial flutter

Atrial flutter is a rhythm disturbance confined to the atrial myocardium. The electrophysiologic basis for this arrhythmia involves reentry within the atrium itself. The typical or

AL Grawany

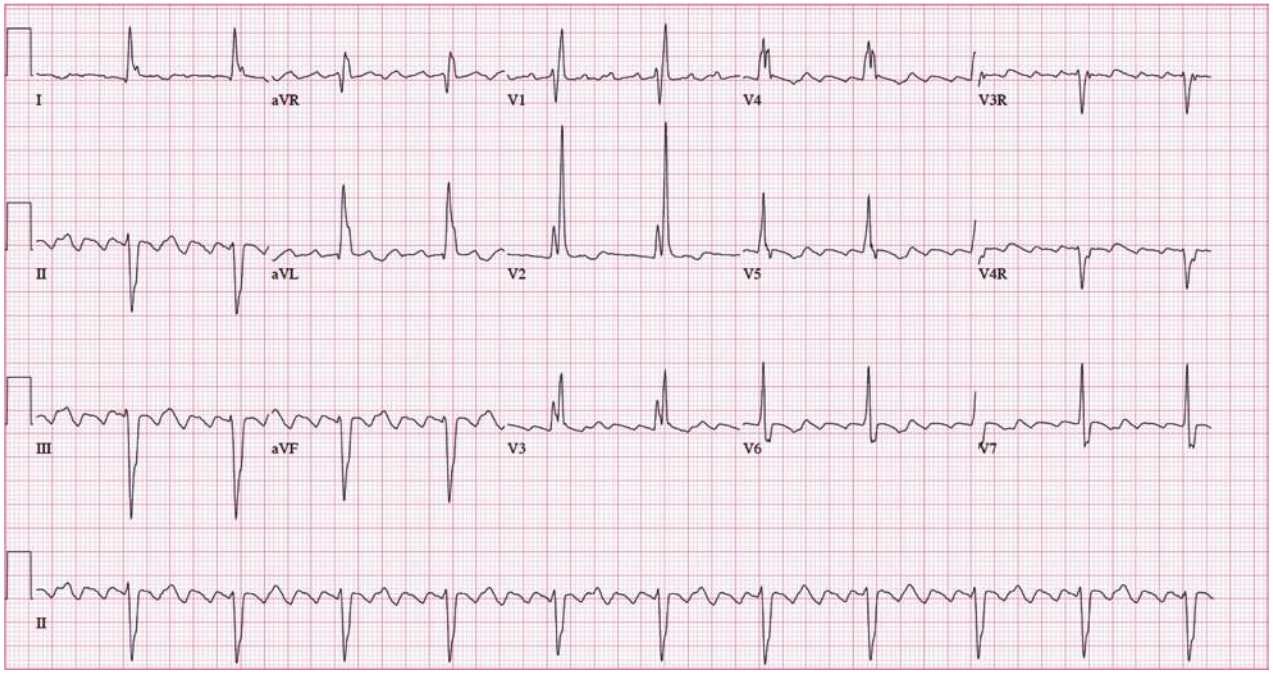

Figure 22.10 *Atrial flutter*. Surface electrogram showing the typical features of atrial flutter: sawtooth flutter waves and 4:1 atrioventricular conduction.

classic form of atrial flutter is characterized by a negative sawtooth P-wave pattern and atrial rates that exceed 300 bpm (Figure 22.10). This form of atrial flutter is occasionally seen in otherwise healthy neonates but is relatively uncommon in children. In patients with CHD, slower atrial rates and varying P-wave morphologies are more frequently seen than in those without CHD. This is due to anatomic abnormalities related to suture lines, scars, or fibrosis from a previous surgery involving atrial tissue. This form of "scar flutter" is commonly termed intra-atrial reentrant tachycardia (IART) [49]. It is one of the most common arrhythmias in postoperative patients with structural heart disease and is considered the cause of significant morbidity after certain types of surgical interventions [50]. Procedures that involve extensive atrial suture lines, such as atrial redirection procedures (Senning or Mustard operations) and those associated with atrial dilation (Fontan surgery) pose a particularly high risk of atrial flutter. The possibility of atrial flutter is suggested by the abrupt onset of a rapid atrial rhythm that remains relatively regular over time. AV nodal conduction accounts for variability in the ventricular response rate. Rapid clinical deterioration is likely; fast ventricular rates frequently require prompt intervention.

Management principles for atrial flutter

- *Adenosine* will not terminate tachycardia but may assist in confirming the diagnosis by uncovering flutter waves during AV block.
- *Atrial overdrive pacing* is a safe and effective way to rapidly terminate atrial flutter by using a transesophageal or transvenous pacing catheter or epicardial wires [51]. After the atrial cycle length is assessed, rapid atrial stimulation is performed in short bursts to attempt an interruption of the reentry circuit.
- *Synchronized cardioversion* is the treatment of choice in any patient with unstable hemodynamics. Placement of the cardioversion pads over the front and back of the hemithorax may be necessary to provide a shock vector through the entire atrium, which is usually thickened in patients with CHD.
- *Pharmacologic agents* such as digoxin, procainamide, sotalol, and amiodarone can be used in urgent situations. Drugs for controlling the ventricular response in atrial flutter include ß-blockers and calcium-channel blockers. Important considerations regarding drug selection are patient age, underlying ventricular function, and whether there is sinus node dysfunction (a concomitant problem in patients with recurrent atrial flutter). Ibutilide and sotalol are available for rapid termination of atrial flutter and have been used in postoperative pediatric and adult patients with CHD [52–55].
- *Long-term drug therapy* is frequently necessary in patients with CHD because of the potential for recurrence and associated rapid AV conduction.
- *Pacemaker therapy*, *atrial anti-tachycardia pacing*, and *radiofrequency ablation* are additional modalities often used for long-term management of atrial flutter.

Atrial fibrillation

Atrial fibrillation is a complex arrhythmia that can be due to either multiple reentrant circuits or focal points within the pulmonary veins. In the majority of cases, it originates in the left atrium (in contrast to atrial flutter, which is generally considered a disease of the right atrium). In children, this tachyarrhythmia is less frequent than atrial flutter. The atrial rates are rapid and irregular, ranging from 400 to 700 bpm. Ventricular response rates are variable but generally range between 80 and 150 bpm. Patients at potential risk for atrial

fibrillation include those with an enlarged left atrium (e.g., rheumatic heart disease, severe AV valve regurgitation), pre-excitation syndromes, structural heart disease (Ebstein anomaly, tricuspid atresia, ASDs), and cardiomyopathies.

Management principles for atrial fibrillation

- Its management principles are similar to those for atrial flutter except that atrial overdrive pacing is not effective in terminating the arrhythmia.
- *Cardioversion* is more likely to be required, and higher amounts of energy may be needed. As in the case of atrial flutter, the placement of cardioversion pads should be optimized by using a front and back configuration over the chest. Anticoagulation and consideration of transesophageal echocardiography for evaluating intracardiac thrombi are recommended before cardioversion if atrial fibrillation has been present more than 48 hours [56, 57].

Atrioventricular reentrant tachycardia and atrioventricular nodal reentrant tachycardia

Atrioventricular reentrant tachycardia (AVRT) is the most common type of SVT in infancy and childhood. It is mediated by an accessory pathway between the atrium and ventricle. The tachycardia circuit typically consists of conduction from the atrium, down the AV node, through the bundle of His and ventricles, and then up the accessory connection back to the atrium. This form of SVT is referred to as *orthodromic SVT* and occurs in patients with Wolff–Parkinson–White syndrome (WPW; Figure 22.11), concealed accessory pathways, and permanent junctional reciprocating tachycardia. In contrast, in *antidromic SVT*, conduction travels from the atrium, down the accessory connection, through the ventricles, up the AV node, and back to the atrium. The QRS complex in this form of SVT is wide. Antidromic tachycardia can occur in patients with WPW and other pre-excitation variants (Mahaim tachycardia).

Atrioventricular nodal reentrant tachycardia (AVNRT), or reentry within the AV node, is most likely in adolescents or young adults. In AVNRT, the AV node has two physiologically distinct components, designated the "slow" and "fast" AV nodal pathways. The typical form of AVNRT consists of antegrade conduction (from the atrium to the ventricle) via the slow pathway, followed by retrograde conduction (back to the atrium) via the fast pathway.

Both AVRT and AVNRT have clinical characteristics typical of reentrant tachycardia mechanisms as listed in Table 22.1. The two can often be distinguished by closely evaluating the surface ECG during sinus rhythm and tachycardia. In orthodromic AVRT, the P wave can be seen immediately after the QRS complex or in the ST segment or T wave (Figure 22.12). The reason for this P-wave location is that a set time is necessary for conduction to proceed from the ventricles through the accessory pathway back to the atrium. In contrast, in AVNRT, the P wave is buried in the QRS complex and is often not discernible (Figure 22.13). This is the case because the tachycardia circuit is within the AV node, and the atria and the ventricles are activated almost simultaneously. Patients with structurally normal hearts, as well as those with CHD, can have either AVRT or AVNRT. Ebstein malformation of the tricuspid valve is frequently associated with AVRT secondary to one or multiple accessory pathways. The accessory connections in this condition are usually right-sided. Congenitally corrected transposition can be associated with an Ebstenoid left-sided AV valve, and left-sided accessory pathways can be identified in a subset of patients.

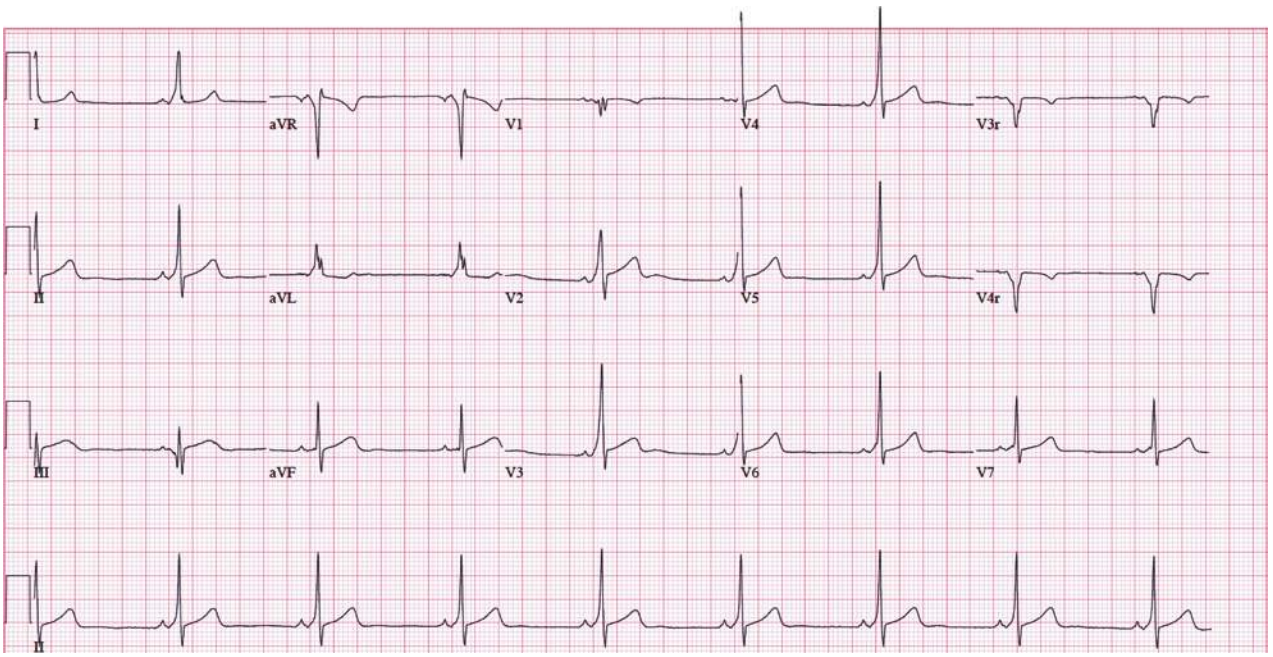

Figure 22.11 *Wolff–Parkinson–White syndrome.* Surface electrocardiogram depicting the shortened PR interval and characteristic delta wave (slurring and slow rise of the initial upstroke of the QRS complex) in the Wolff–Parkinson–White pre-excitation syndrome during normal sinus rhythm.

AL Grawany

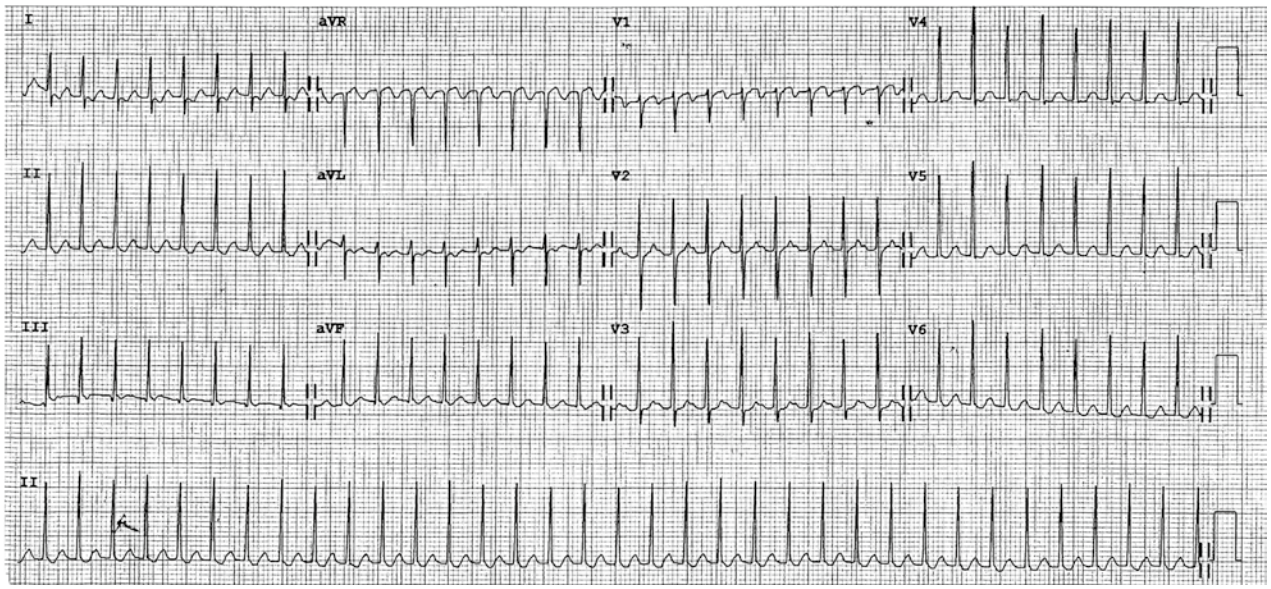

Figure 22.13 *Atrioventricular nodal reentrant tachycardia*. Electrocardiogram showing a narrow-complex tachycardia. There is no evidence of a retrograde P wave because it is obscured by the QRS complex, secondary to simultaneous atrial and ventricular activation.

Management principles for AVRT or AVNRT

- *Direct current synchronized cardioversion* (0.5–1.0 J/kg) should be performed in hemodynamically unstable patients. A lower energy setting is adequate if paddles are used directly on the heart (epicardial paddles). Cardioversion should also be considered in stable patients when potential rapid clinical deterioration is anticipated or after an unsuccessful conventional therapy.
- In stable patients, tachycardia can be rapidly terminated with *vagal maneuvers* (Valsalva maneuver, coughing, gag reflex stimulation, ice to the face, Trendelenburg position), which enhance parasympathetic influences [58].
- *Adenosine* is the first-line drug therapy for SVT [59–62]. Other agents (digoxin, edrophonium, ß-blockers, calcium-channel blockers, phenylephrine, dexmedetomidine, sotalol) have been used in acute treatment with variable

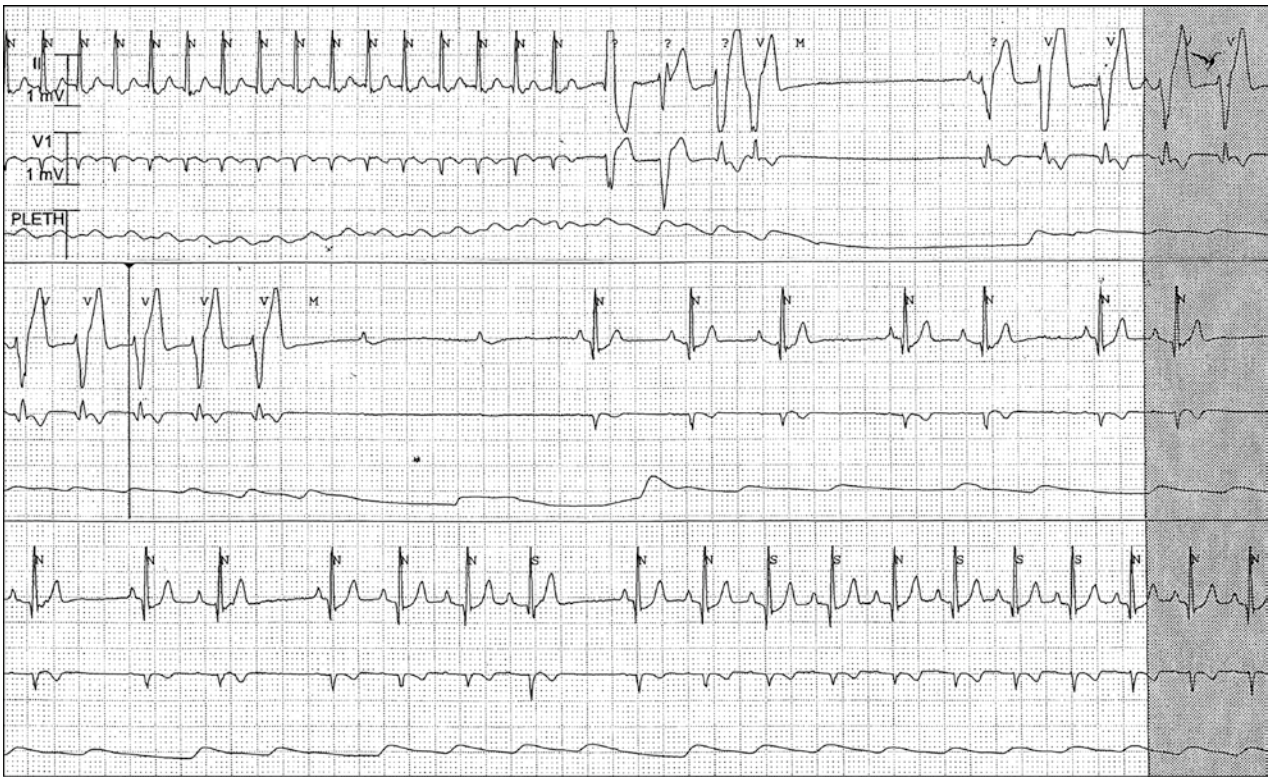

Figure 22.14 *Adenosine treatment of supraventricular tachycardia*. Tracings showing effects of an adenosine bolus administered during supraventricular tachycardia (*upper panel*). Upon termination of the tachycardia, several ventricular beats are seen (right half of upper panel), followed by just atrial beats (*middle panel*) and restoration of sinus rhythm (*lower panel*).

results; however, serious adverse effects can be seen. Continuous ECG monitoring is recommended, as well as the availability of atropine and other emergency drugs is ensured, because transient bradycardia may follow tachycardia termination (Figure 22.14). During short-term pharmacologic therapy, backup pacing may be appropriate, depending on the drug and clinical status of the patient.

- *Rapid atrial pacing* can be performed with a transesophageal electrode catheter or via temporary atrial pacing wires. Beforehand, one must ensure that there is no ventricular capture by the catheter or temporary wires at the desired output site. Rapid atrial pacing is performed by pacing the atrium at 10–20% faster than the SVT rate for a period of up to 15 seconds, which typically terminates the tachycardia. In a patient with a high catecholamine state, SVT can be successfully terminated but rapid recurrence is possible. In this case, a higher level of patient sedation and limiting catecholamine stimulation should be considered.
- *Anti-arrhythmic medication* can be instituted once the tachycardia has terminated or if it terminates and then reinitiates. For perioperative patients unable to take oral medications, parenteral therapy may include procainamide, sotalol, or amiodarone. β-blockers and calcium-channel blockers may be less desirable in such cases because of their negative effects on myocardial contractility; a short-acting agent, such as esmolol, may offer a larger margin of safety.
- *Transcatheter ablation* may be warranted in patients with a history of SVT who would prefer not to take medications, or in those with incessant tachycardia that cannot be controlled with medications. Success rates for transcatheter ablation exceed 95%.

KEY POINTS: SUPRAVENTRICULAR ARRHYTHMIAS

- Premature atrial contractions can be due to irritability from an intracardiac wire/catheter, therefore, tip position should be evaluated.
- SVT is the most common clinically significant arrhythmia in the pediatric age group; it is characterized by a narrow or "usual" complex QRS morphology.
- SVTs are categorized into automatic and reentrant types; these can be differentiated by evaluating features of tachycardia.
- Atrial electrograms facilitate the diagnostic assessment of tachyarrhythmias and can be obtained using bedside/operating room monitors or full ECG recordings.
- The management of postoperative JET includes consideration of overdrive temporary atrial pacing to restore AV synchrony, sedation, mild hypothermia, and drugs.
- Any acute rhythm disturbance requires prompt evaluation of hemodynamics.
- In the stable patient, vagal maneuvers, drug therapy, and rapid atrial pacing may be considered to terminate a supraventricular arrhythmia.

- Synchronized cardioversion is first-line therapy for unstable reentrant supraventricular arrhythmias.
- A wide QRS tachycardia should always be considered of ventricular origin until proven otherwise.

Ventricular arrhythmias

Ventricular arrhythmias are rhythm disorders that arise distal to the bifurcation of the common His bundle. These are relatively rare in young children and more common in patients with underlying genetically abnormal cardiac sodium or potassium channels and in adolescents or young adults with previously operated CHD. Patients with ventricular rhythm abnormalities may have few or no symptoms, or they may be gravely ill. Evaluation should include reviewing the medical history for findings suggestive of associated cardiovascular pathology or potential cause of the arrhythmia, analyzing the ECG, and, most importantly, assessing the hemodynamic state.

Premature ventricular contractions

Premature ventricular contractions (PVCs) are premature beats that originate in the ventricular myocardium. These are characterized by the following: premature QRS complexes not preceded by premature atrial activity; a QRS morphology that differs from that in sinus rhythm; a long QRS duration for the patient's age (a frequent but not universal finding); and abnormalities of repolarization. In patients with a structurally normal heart, PVCs of a single QRS morphology (uniform) without associated symptoms are generally considered benign. Premature ventricular contractions that merit further investigation include those that have multiple morphologies (multiform) on ECG, occur with moderate frequency, and are associated with symptoms or occur in a patient with an abnormal heart.

Ventricular ectopy in the perioperative period can be secondary to myocardial irritation from intracardiac catheters or direct surgical stimulation. Additional causes include respiratory (hypoxemia), electrolyte (hypokalemia), and metabolic derangements (acidosis). Isolated PVCs can also be due to pharmacologic agents (e.g., recreational drugs), myocardial injury, poor hemodynamics, and prior complex surgical intervention.

Ventricular tachycardia

Ventricular tachycardia (VT) is defined as three or more consecutive ventricular beats occurring at a rate greater than 120 bpm in adults, or more than 20% greater than the preceding sinus rate. The QRS morphology in VT is different from that in sinus rhythm and is usually wide for the patient's age. Electrocardiographic features that support this diagnosis include AV dissociation; intermittent fusion (i.e., a QRS complex of intermediate morphology occurring between two other QRSs with distinctly different morphologies); QRS morphology of VT similar to that of isolated PVCs; and tachycardia rate in children usually below 250 bpm. An RBBB QRS morphology is most common in infants with VT, whereas in older children, an LBBB pattern is more frequent with wider QRS morphologies.

Various qualifiers have been proposed to further characterize VT. The classification of VTs as monomorphic (one QRS morphology) or polymorphic (multiple QRS morphologies) is based on the evaluation of the QRS pattern in multiple ECG leads. VT is considered to be sustained or non-sustained if it lasts more or less than 30 seconds, respectively.

Acute onset of VT in pediatric patients may be due to hypoxia, acidosis, electrolyte imbalance, or metabolic problems. In the perioperative or immediate postoperative setting, the onset of VT can suggest myocardial ischemia or coronary artery injury, or both. This arrhythmia can also occur in patients with depressed myocardial function, poor hemodynamics, prior surgical interventions, myocardial tumors, cardiomyopathies (hypertrophic, dilated, left ventricular non-compaction, arrhythmogenic right ventricular dysplasia), myocarditis, acute injury (trauma), and primary sodium or potassium channel abnormalities (long QT syndrome, Brugada syndrome; see sections that follow). Among patients with CHD and ventricular arrhythmias, those at higher risk include older patients who have undergone tetralogy of Fallot repair and individuals with significant residual hemodynamic abnormalities. In patients with structural heart disease, the following potential causes of ventricular ectopy have been proposed: inadequate myocardial protection during the surgical procedure, chronic pressure or volume loads, residual or recurrent pathology, and scar formation at the ventriculotomy site.

Monomorphic VT

Although occasionally seen in patients with otherwise normal hearts, monomorphic VT is more common in those with underlying cardiac abnormalities. In the abnormal heart, tachycardia is thought to originate from a reentrant focus in scarred or damaged myocardial tissue. The ECG findings include a wide regular QRS rhythm of uniform morphology (Figure 22.15).

Polymorphic VT

Torsades de pointes

Torsades de pointes, or torsades ("twisting of the peaks"), refers to a form of polymorphic VT. The characteristic ECG feature is a varying QRS morphology manifested as positive and negative oscillations of the QRS direction that twists around an isoelectric baseline (Figure 22.16). Polymorphic VT may occur in long QT syndromes, can be secondary to drug therapy or neurologic pathology, or can result from myocardial ischemia. Torsades may terminate spontaneously or degenerate into ventricular fibrillation (VF).

Long QT syndromes

Long QT syndrome (LQTS) is an electrical disturbance that affects ventricular repolarization and predisposes children to arrhythmias such as *torsades de pointes*, VT, VF, and bradyarrhythmias [63–65]. The disorder is associated with a propensity for syncope, cardiac arrest, and sudden death.

LQTS can be congenital (inherited) or acquired. The congenital varieties are predominantly the result of genetic defects in the sodium or potassium channels responsible for maintaining electrical homeostasis in the heart. The

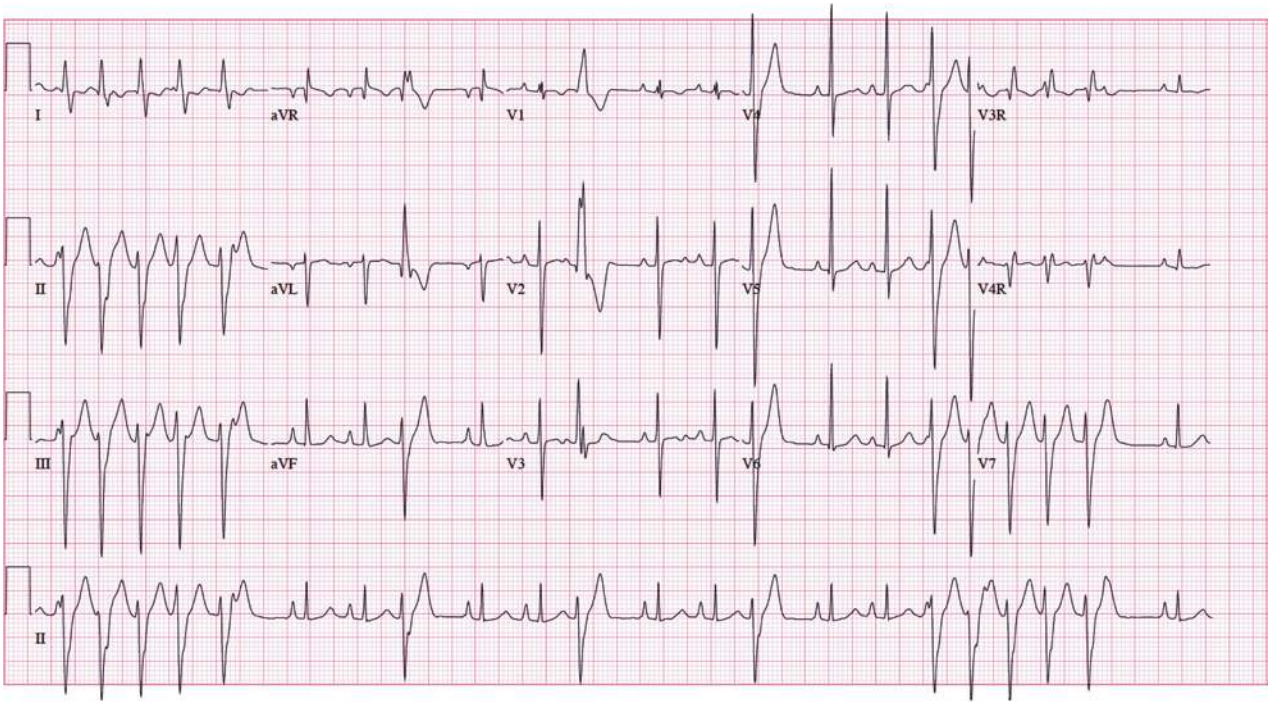

Figure 22.15 *Monophorphic ventricular tachycardia*. Electrocardiogram showing runs of a uniform wide-complex rhythm consistent with non-sustained ventricular tachycardia. The runs are separated by a few beats of normal sinus rhythm.

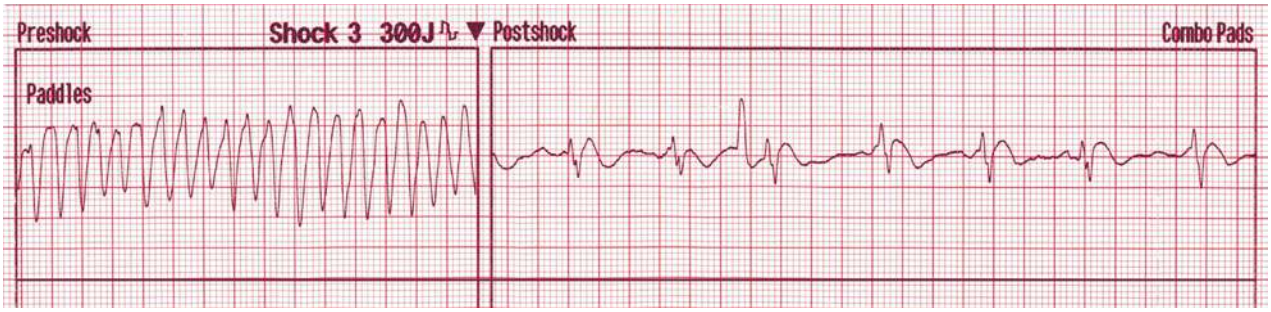

Figure 22.16 *Torsades de pointes*. The typical positive and negative oscillations of the QRS complexes in torsades are shown in this tracing (left panel). Because the arrhythmia was sustained and associated with significant hemodynamic compromise, cardioversion was performed, which terminated the tachyarrhythmia (right panel).

incidence of LQTS is not clearly known, but it is estimated that one in 5,000 individuals are gene carriers of the congenital form. The autosomal dominant variety, Romano–Ward syndrome, represents the most common form of congenital LQTS. The Jervell and Lange–Nielsen syndrome has an autosomal recessive pattern of inheritance and, in addition to QT prolongation, is characterized by deafness. Genetic testing is commercially available for LQTS-causing defects. Although efforts to develop gene-specific therapy are underway, all patients with LQTS are treated similarly at present.

Suggested clinical diagnostic criteria for LQTS are based on ECG findings, clinical history, and family history [66]. The hallmark of the disorder is the prolongation of the corrected QT interval (QTc) on the resting ECG (Figure 22.17). It should be noted, however, that individuals with LQTS may not display the repolarization abnormality manifested as QT interval prolongation. Several equations can be used to determine the QTc, the most common one being Bazett's formula:

$$\text{Corrected QT} = \text{measured QT interval} / \text{square root of preceding RR interval}$$

A QTc >0.47 seconds is considered abnormal regardless of the patient's age.

Management principles in LQTS

- *ß-adrenergic blockade*. An important aspect of perioperative management is ensuring adequate ß-adrenergic blockade and minimizing sympathetic stimulation, because this may trigger tachyarrhythmias. Premedication

AL Grawany

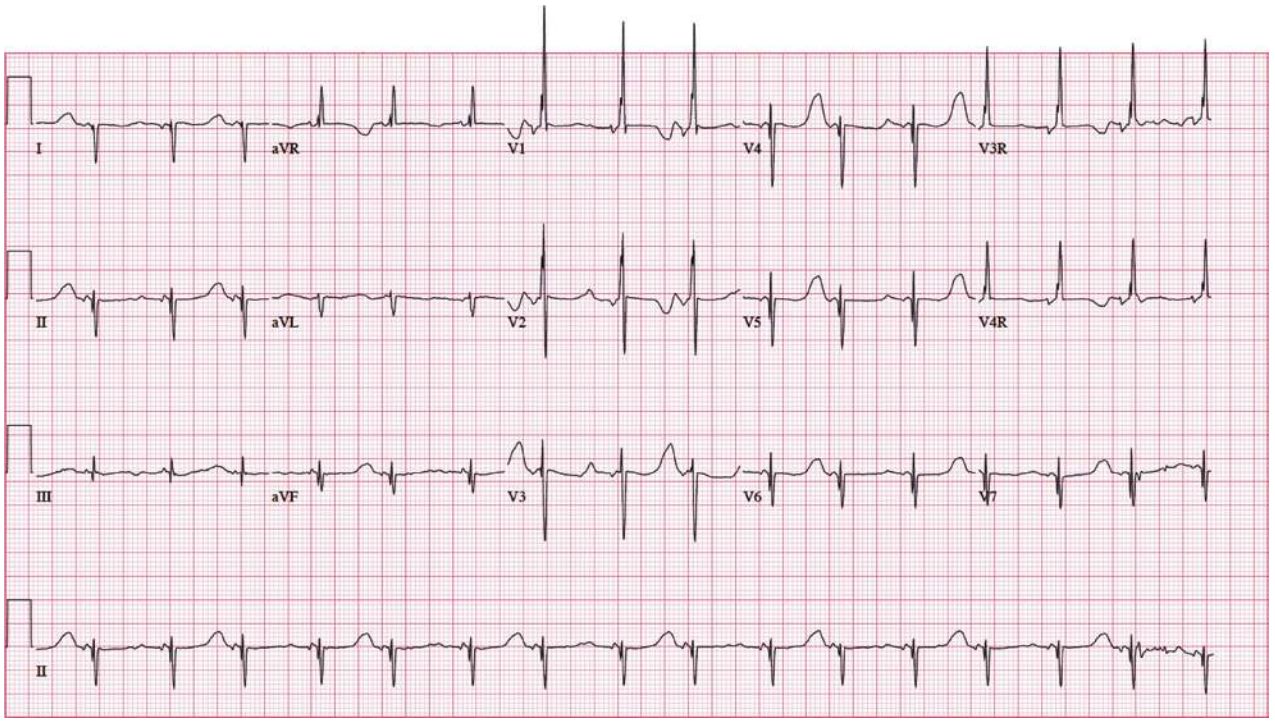

Figure 22.17 *Long QT syndrome*. Electrocardiographic recording from a child with long QT syndrome. The corrected QT interval is 0.58 seconds. Note the presence of T-wave alternans (alternating T-wave morphologies), a classic but uncommon finding in patients with long QT syndrome.

with midazolam can minimize anxiety and pain, which can also trigger arrhythmias.

- *Perioperative management*. Conditions and drugs associated with QT interval prolongation should be avoided [67]. Electrolyte abnormalities (e.g., hypokalemia, hypocalcemia, hypomagnesemia) should be corrected before surgery. Intravenous lidocaine (1.5 mg/kg) given before laryngoscopy and intubation has been shown to prevent QT prolongation that can be seen during the time of airway instrumentation and can be considered [68]. Intraoperative tachyarrhythmias can be treated with additional doses of ß-blockers and magnesium. Other beneficial drugs include phenytoin and lidocaine. Although several agents routinely used in anesthetic practice increase the QT interval (IV medications and volatile agents), in most cases these drugs are administered without untoward effects. Care should be taken in managing postoperative nausea because some antiemetics can cause QT prolongation and can increase the risk of arrhythmias. A study in children with LQTS documented an increased risk of adverse events (2.6%) during anesthetic emergence in those who received both neuromuscular blockade reversal drugs anticholinergic/anticholinesterase medication) and ondansetron. One event was described as torsades and was treated successfully [69]. These observations suggest an increased vulnerability during periods of enhanced sympathetic activity (emergence) and after the administration of drugs associated with QT interval prolongation. A comprehensive list of drugs that prolong the QT interval or may induce torsades can be found in the frequently updated and highly valuable website of The Arizona Center for Education and Research on Therapeutics (https://crediblemeds.org/index.php/login/dlcheck).
- *Postoperative care*. Patients should be closely monitored until they emerge from anesthesia and their QTc returns to preoperative values. Adequate pain control should be provided to minimize adrenergic responses that can trigger arrhythmias.

Acquired forms of long QT may result from electrolyte disturbances (hypokalemia, hypocalcemia, hypomagnesemia), drug therapy (anti-arrhythmic agents, antipsychotic drugs), and neurologic or endocrine abnormalities. Therapy in such cases should focus on correcting the underlying cause.

General management principles for VT

- A wide QRS tachycardia should always be considered to be of ventricular origin until proven otherwise, although some atypical forms of supraventricular arrhythmias may mimic VT.
- A critical aspect of caring for patients with an acute ventricular rhythm abnormality is promptly evaluating their hemodynamics. In general, sustained ventricular arrhythmias are poorly tolerated and deserve immediate attention. Unstable patients require cardiopulmonary resuscitation and electrical cardioversion.
- Pharmacological therapy may be indicated in stable patients to treat VT or to prevent its recurrence. Recommended agents include amiodarone, lidocaine, procainamide, sotalol, and ß-blockers. The choice of an agent depends on the associated clinical scenario.

- Electrical cardioversion in *torsades de pointes* should be performed only if the arrhythmia is sustained. In patients with frequent but non-sustained runs of torsades, cardioversion is of no benefit and may be detrimental. Magnesium sulfate is considered the first-line drug and lidocaine may also have a role in therapy. Procainamide and amiodarone are relatively contraindicated because they can cause QT prolongation.
- Pacing and isoproterenol may be considered for polymorphic VT associated with acquired QT prolongation such as that related to the proarrhythmic effects of certain drugs, particularly in the setting of long pauses in the cardiac cycle.

Brugada syndrome

Brugada syndrome (BrS) is a genetically determined disease characterized by a distinct ECG pattern (RBBB with coved- or saddle-shaped ST elevation in leads V1–V3) (Figure 22.18) [70]. Various genetic defects that lead to abnormalities in sodium and calcium currents have been identified in affected patients [71]. The inheritance pattern is usually autosomal dominant, although there is vast genetic heterogeneity. The genetics of this condition has been linked to phenotype severity [72]. This syndrome has rarely been reported in children [73]. It had been shown that infants with rapid VT and conduction abnormalities, but no cardiac or metabolic abnormalities, are likely to have disease-causing mutations in genes for the cardiac depolarizing channels in regions with BrS [74].

Clinically, the importance of BrS is related to its strong propensity for ventricular arrhythmias. It is thought to be responsible for 5–20% of all sudden deaths in people with structurally normal hearts. It probably remains underdiagnosed and has a national prevalence of approximately 5 in 10,000 individuals. The ECG features are often concealed or transient. In patients with suspected BrS and a normal ECG pattern, administering a sodium-channel blocker can unmask the classic pattern. Anti-arrhythmic medications appear to have limited efficacy in preventing recurrences of ventricular arrhythmias and prolonging survival in patients with BrS. Only patients with implantable cardioverter-defibrillators (ICDs) appear to be protected from sudden death. A promising new therapeutic option for patients with BrS is the possibility of epicardial ablations in the region of the right ventricular outflow tract. Epicardial ablations have been shown to eliminate the ECG findings in BrS as well as ventricular arrhythmia inducibility at the time of the study. Further data are needed to determine whether epicardial ablations prevent ventricular arrhythmias in the long term. This can potentially decrease the need for ICD in this patient population [75–77]. From the standpoint of anesthetic care, it is of note that many events in patients with BrS occur during rest or sleep, implicating sedation and

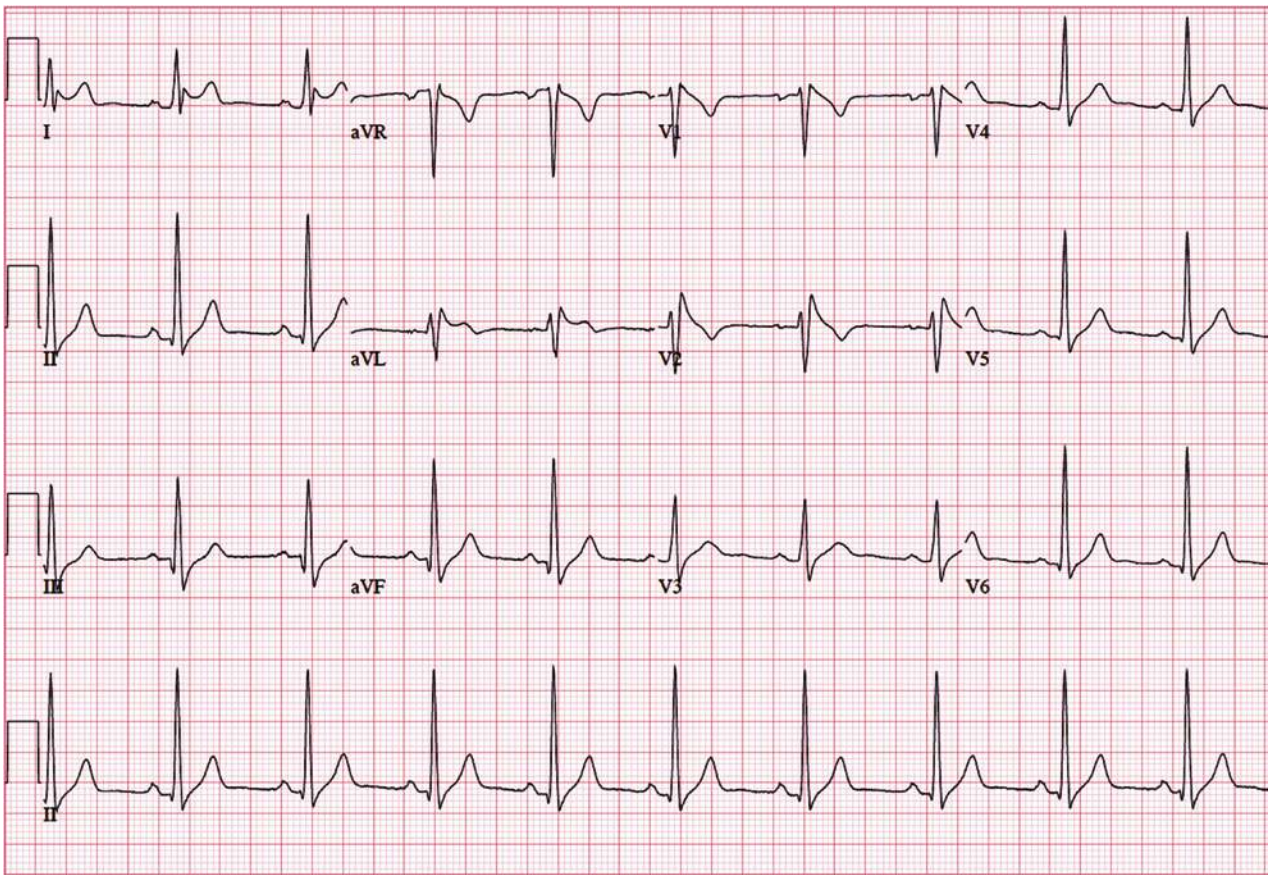

Figure 22.18 *Brugada syndrome*. Surface electrocardiogram from a child with Brugada syndrome. Note the characteristic findings of right bundle branch QRS morphology and ST-segment elevation in the right precordial leads.

AL Grawany

anesthesia as the time of risk. Perioperative considerations also include factors associated with further intraventricular conduction delay or ST-segment elevation potentially leading to arrhythmias (drugs, electrolyte abnormalities, and fever) [78]. In particular, sodium channel blockade should be avoided. For an updated list of drugs to be avoided in BrS, refer to www.brugadadrugs.org.

Catecholaminergic polymorphic ventricular tachycardia

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is an inherited cardiac channelopathy characterized by polymorphic VT triggered by adrenergic stimulation. It can be caused by a mutation in the ryanodine receptor 2 (*RYR2*) or in the cardiac calsequestrin (*CASQ2*) genes. It has an incidence of approximately 1 in 10,000. It usually presents as syncope precipitated by exercise, but it can also present as sudden death. Pharmacological therapy is provided primarily with ß-blockers, particularly nadolol [79]. Several studies have also shown benefits from using flecainide in conjunction with ß-blockade [80–82], and currently, many patients are started on dual therapy. In select patients, the placement of an ICD may be warranted. This form of therapy has to be used judiciously because shocks can trigger an electrical storm secondary to the adrenergic surge that follows a discharge. Left cervical sympathetic denervation can be considered in patients who are not able to tolerate ß-blockers, who have recurrent arrhythmias despite maximal medical therapy, or who meet the criteria for ICD placement but in whom ICD cannot be placed [83].

Management principles for CPVT

Adrenergic surges. Patients undergoing surgical procedures or other interventions associated with a high level of stimulation have special considerations. Extreme care should be taken to minimize adrenergic surges because the latter can trigger ventricular arrhythmias in such patients. Adequate anxiolysis and pain control should be achieved during any surgical or nonsurgical procedure that may be stimulating.

Ventricular fibrillation

VF is an uncommon arrhythmia in children. It is characterized by chaotic, asynchronous ventricular depolarizations that fail to generate an effective cardiac output. The ECG in VF shows low-amplitude, irregular deflections without identifiable QRS complexes. A loose ECG electrode may mimic these surface ECG features; therefore, immediate clinical assessment of cardiac output (i.e., checking for a pulse) should be performed and adequate ECG pad contact ensured when VF is suspected.

Management principles for VF

- *Immediate defibrillation* (initial dose of 2–4 J/kg for the transthoracic approach) is the definitive therapy because VF is lethal if left untreated. If the first shock is unsuccessful, a second shock should be delivered at double the energy dose. Infant paddles are generally recommended for those weighing less than 10 kg. Adult paddles are suggested for children weighing over 10 kg in order to reduce impedance and maximize current flow.
- *Adequate airway control* (*oxygenation*, *ventilation*) *and chest compressions* should be rapidly instituted during preparation for defibrillation or between shocks if several defibrillation attempts are needed.
- *Adjunctive pharmacologic agents* for VF include amiodarone and lidocaine. The American Heart Association's current guidelines for cardiopulmonary resuscitation and emergency cardiac care recommend using amiodarone or lidocaine as the first-line anti-arrhythmic drugs for refractory shock, pulseless VT, and VF [62, 84, 85].
- *Additional therapies* such as mechanical circulatory support should be considered.

The most widely accepted management strategies for perioperative ventricular rhythm disturbances without associated hemodynamic compromise are summarized in Table 18.3.

KEY POINTS: VENTRICULAR ARRHYTHMIAS

- Premature ventricular contractions of uniform QRS morphology are generally benign in the structurally normal heart and in asymptomatic patients; however, they may also result from myocardial irritation or other serious causes.
- VT is characterized by QRS morphology that is different than that in sinus rhythm and is usually wide.
- VT requires prompt evaluation of hemodynamic status, as it may rapidly convert to VF, resulting in cardiac arrest.
- In LQTS, perioperative ß-blockade is essential and although caution must be exercised with drugs and conditions that prolong the QT, in most cases anesthetic management is uneventful.
- VF requires the institution of cardiopulmonary resuscitation and immediate defibrillation; a loose ECG electrode should be excluded.

Pharmacologic therapy of cardiac arrhythmias

Anti-arrhythmic drugs exert their effects primarily by blocking sodium, potassium, or calcium channels, or by altering the adrenergic tone. These drugs are generally classified according to their presumed mechanisms of action and electrophysiologic effects. The well-known drug classification scheme introduced by Vaughan Williams (Table 22.4) and modified over the years is frequently used [86]. Although an oversimplification, this classification may help predict response to therapy. Appropriate drug selection requires an understanding of the mechanism of the arrhythmia and the putative effects of the agent. This section discusses pharmacologic therapy for arrhythmias, focusing on the agents that are most frequently used for acute management in children (Table 22.5) [87]. It is emphasized that perioperative consultation with a specialist

Table 22.4 Classification of anti-arrhythmic agents

Class and action	Drugs
Class I: sodium-channel blockers. Drugs may be subclassified into IA, IB, and IC categories	
IA agents – moderately depress phase zero upstroke of the action potential, slow conduction, and prolong repolarization. Effectively slow conduction in atria, ventricles, and accessory connections	Procainamide Quinidine Disopyramide
IB agents – shorten action potential duration and result in minimal alteration of conduction. These agents are usually not effective in the treatment of supraventricular tachycardia	Lidocaine Mexiletine Phenytoin
IC agents – significantly depress phase zero upstroke, with marked slowing of conduction but little change in refractoriness	Flecainide Propafenone
Class II: β-adrenergic receptor blockers. Anti-arrhythmic effects result from slowing conduction and decreasing automaticity, particularly in the sinoatrial and atrioventricular nodes	Esmolol Atenolol Metoprolol Propranolol
Class III: potassium-channel blockers. Primarily prolong action potential duration, with resultant prolongation of refractoriness	Amiodarone Sotalol Bretylium Ibutilide
Class IV: calcium-channel blockers with predominant sites of action in the sinoatrial and atrioventricular nodes.	Verapamil Diltiazem
Others	Atropine Digoxin Adenosine Ivabradine Magnesium sulfate

Table 22.5 Intravenous anti-arrhythmic agents

Agent	Dosing	
Adenosine		100 μg/kg rapid bolus, increase by 50 μg/kg every 2 minutes, up to 300 μg/kg maximum
Amiodarone	Load	5 mg/kg over 30–60 minutes
	Infusion	5–10 μg/kg/min
Digoxin	Load	20–30 μg/kg (divide as 1/2, 1/4, 1/4 every 8 hours), dose is age-dependent
	Maintenance	7–10 μg/kg/day divided every 12 hours orally
Diltiazem	Load	0.25 mg/kg up to 20 mg bolus over 2 minutes
	Infusion	0.1–0.3 mg/kg/hr, may increase up to 15 mg/hour
Esmolol	Load	500 μg/kg over 1–2 minutes
	Infusion	50 μg/kg/min starting dose, may increase gradually to 400 μg/kg/min
Flecainide (not available in the United States)		1–2 mg/kg over 5–10 minutes
Magnesium sulfate		25–50 mg/kg (up to 2 g) over 20–30 minutes
Lidocaine	Load	1 mg/kg every 5 minutes up to three times
	Infusion	20–50 μg/kg/min
Phenytoin		1–3 mg/kg over 10–15 minutes
Procainamide	Load	10–15 mg/kg over 30 to 45 minutes
	Infusion	40–50 μg/kg/min
Propafenone (not available in US)	Load	1 mg/kg over 10 minutes
	Infusion	4–7 μg/kg/min
Propranolol		0.05–0.15 mg/kg over 5 minutes
Sotalol	Load	1 mg/kg over 1 hour or 30 mg/m^2 over 15–30 minutes
	Infusion	120 mg/m^2/day may increase up to 200 mg/m^2/day
Verapamil		0.05–0.30 mg/kg over 3–5 minutes, maximum 10 mg, not under 12 months of age

should be considered while caring for patients with rhythm disturbances or those receiving chronic anti-arrhythmic therapy as necessary.

Class I agents

The largest group of anti-arrhythmic drugs are sodium-channel blockers. The relatively large size of this class of agents has led to its subclassification into IA, IB, and IC groups on the basis of each drug's cellular actions. Group IC consists of oral drugs only and is not discussed in this chapter.

Class IA agents

The class IA drugs include procainamide, quinidine, and disopyramide. Their predominant electrophysiologic effect is the prolongation of both myocardial repolarization (QT interval) and the action potential. The mechanism of action is primarily related to the inhibition of the fast sodium channels. The anticholinergic (vagolytic) properties of these drugs account for their more pronounced effects at fast heart rates.

Procainamide

Procainamide is a potent sodium-channel blocker and, to a lesser extent, a potassium-channel blocker. This drug slows atrial conduction (prolongs the PR interval) and lengthens the QRS duration and QT interval. Procainamide is useful in the management of both atrial and ventricular arrhythmias [26, 38, 88, 89]. The suppression of abnormal automaticity accounts for its usefulness in the treatment of EAT, JET, and VT. The drug is generally more effective than lidocaine in acutely terminating sustained VT.

Procainamide can be administered via the oral, IV, or intramuscular routes. For the treatment of acute arrhythmias, IV loading (doses of 10–15 mg/kg) over a period of 30–45 minutes is usually required. The lower end of the loading dose spectrum is suggested for younger patients. Continuous ECG monitoring and frequent blood pressure assessments are recommended during the loading phase. This drug is rapidly distributed after IV injection. After the

AL Grawany

loading dose is administered, an infusion is frequently initiated at the rate of 30–50 μg/kg/min. Monitoring plasma levels is advisable, and the maintenance infusion rate should be adjusted as needed to achieve therapeutic levels between 4 and 8 μg/mL. The drug is eliminated by the kidneys (50–60%) and through hepatic metabolism (10–30%). Hepatic acetylation generates N-acetylprocainamide (NAPA), a metabolite with anti-arrhythmic (class III) properties.

Potential side-effects of procainamide include hypotension due to blocking of alpha-adrenergic receptors and decreased systemic vascular resistance during rapid IV administration. Significant QT prolongation and proarrhythmia are also well described. Additional non-therapeutic effects include negative inotropy and AV block. Gastrointestinal symptoms, a lupus-like syndrome, and blood dyscrasias can also occur.

Class IB agents

Class IB drugs include lidocaine, mexiletine, phenytoin, and tocainide. These drugs inhibit fast sodium channels and shorten both the action potential duration and the refractory period.

Lidocaine

Lidocaine is a short-acting agent with primary effects on the ventricular myocardium. It is one of the anti-arrhythmic drugs that are more commonly used in operating rooms and intensive care units. It is effective for suppressing frequent ventricular ectopy and warning arrhythmias and for preventing the recurrence of VT and VF [90–93].

An initial IV bolus of 1 mg/kg is recommended that can be repeated after several minutes if ineffective. The maintenance infusion rate ranges between 20 and 50 μg/kg/min. Lidocaine is rapidly metabolized in the liver by microsomal enzymes. Therefore, drugs associated with altered microsomal enzyme activity and conditions that can potentially reduce hepatic blood flow (e.g., severe congestive heart failure) may impair drug metabolism. Monitoring drug levels is advisable during continuous infusion.

Lidocaine toxicity from excessive plasma concentrations can result from poor cardiac output or from hepatic or renal failure. Elevated plasma levels beyond the therapeutic range can cause gastrointestinal symptoms (nausea and vomiting), central nervous system pathology (paresthesias, tremor, confusion, seizures), and, in rare instances, hemodynamic perturbations.

Class II agents

The class II drugs (esmolol, atenolol, metoprolol, and propranolol) block ß-adrenergic receptors to variable extents (receptor selectivity and intrinsic sympathomimetic activity) depending on the specific agent. Anti-arrhythmic effects result from slowing conduction and decreasing automaticity, particularly in the sinoatrial and AV nodes. These drugs universally decrease sympathetic activity through the ß-receptor blockade.

Esmolol

Esmolol is a predominant $ß_1$-selective (cardioselective) adrenergic receptor-blocking agent with a rapid onset and a very short duration of action. The drug's primary electrophysiologic effect is inhibiting sinoatrial and AV conduction. Esmolol's brief elimination half-life after IV injection (approximately 9 minutes) has made this drug desirable for use in perioperative and intensive care settings. Esmolol is commonly used to control heart rate and blood pressure and to manage a variety of tachyarrhythmias (supraventricular and ventricular) [94, 95].

An IV loading dose of 100–500 μg/kg (over 1–2 minutes) can be administered. This is followed by a continuous infusion, starting at 50–100 μg/kg/min and titrated to effect. Because of esmolol's short half-life, blood levels of the drug can be rapidly altered by increasing or decreasing the infusion rate, and the drug can be rapidly eliminated by discontinuing the infusion.

Most of the reported adverse effects related to esmolol therapy have been mild and transient. Reported cardiovascular side effects include bradycardia, sinus pauses, AV block, hypotension, and negative inotropy. These are most likely to be seen during bolus therapy.

Class III agents

The class III drugs (amiodarone, sotalol, bretylium, ibutilide) block potassium channels and increase action potential duration and refractoriness in atrial and ventricular muscle and in Purkinje fibers. These agents should be avoided in patients with LQTS.

Amiodarone

Amiodarone has a wide spectrum of actions with multiple and complex electrophysiologic effects that encompass all four anti-arrhythmic drug classes. Class I drug actions include inhibition of fast sodium channels. Class II and IV effects result in depression of sinus node automaticity and function and slowing of AV and His–Purkinje system conduction. As a class III agent, amiodarone delays repolarization and increases action potential duration, thereby prolonging refractoriness in all cardiac tissues and accessory connections if present. In addition to blocking potassium channels, amiodarone has vagolytic properties, weakly blocks calcium channels, and noncompetitively blocks α- and ß-adrenergic receptors. The efficacy of this agent has been documented against many supraventricular (EAT, atrial flutter and fibrillation, reentrant arrhythmias involving accessory pathways, JET), and ventricular arrhythmias (VT and VF) [37, 96–98]. The usefulness of this drug in the treatment of life-threatening tachyarrhythmias accounts for its expanding role in emergency cardiovascular management. In patients with an ICD, amiodarone may affect defibrillation thresholds.

Intravenous therapy requires a loading dose because of amiodarone's rapid plasma disappearance during the distribution phase. The suggested dose in children is 5 mg/kg over 1 hour (may be given rapidly for life-threatening arrhythmias; max. dose 300 mg). The same dose is then infused over 12 hours and repeated if necessary. Amiodarone binds extensively to most tissues, which explains its extremely prolonged elimination and thus its unusually long half-life (average 58 days).

Amiodarone administration can result in sinus bradycardia and AV block. Hypotension and cardiovascular collapse

is another potential complication of IV therapy and is probably due to calcium chelation [99]. Electrocardiographic effects include PR, QRS, and QTc prolongation. There are significant drug interactions while using amiodarone that merit discussion. Co-administration with other anti-arrhythmic agents (digoxin, procainamide, flecainide, quinidine, phenytoin) can result in increased levels of these drugs. The concomitant use of the drug with ß-blockers or calcium-channel antagonists should raise concerns about potential synergistic effects on conduction tissue. Several adverse effects have been reported with long-term oral therapy in children. These include skin discoloration, corneal microdeposits, alterations in hepatic and thyroid function, pulmonary fibrosis, and neurologic disturbances.

Sotalol

Sotalol is another class III anti-arrhythmic that also has some weak beta-blocker effects. Its main anti-arrhythmic effect is by prolonging repolarization, thereby prolonging refractoriness in cardiac tissue. Intravenous sotalol has shown promise in the acute termination of supraventricular arrhythmias (EAT, atrial flutter, reentrant arrhythmias involving accessory pathways) and ventricular arrhythmias [39, 53–55, 100, 101]. When given for acute termination of arrhythmia the suggested dose for intravenous sotalol is 1 mg/kg over 1 hour or 30 mg/m^2 over 15 minutes. Sotalol has also been shown to be safe and effective in the chronic management of both supraventricular and ventricular arrhythmias [102]. Close monitoring of the QTc interval and telemetry is needed, particularly during initiation of therapy, as *torsades de pointes* is a potential adverse effect, particularly in patients with associated CHD. In rare cases, hypoglycemia has been reported in patients with poor oral intake [103].

Ibutilide

Ibutilide is a class III agent approved in the adult population for acute intravenous therapy of atrial flutter and fibrillation of recent onset (<90 days) [104–106]. Like other drugs that prolong ventricular repolarization, this agent can cause excessive QT prolongation and polymorphic VT, which necessitates careful patient selection and monitoring during drug administration. The clinical experience with ibutilide in pediatric patients is extremely limited [107, 108].

Class IV agents

The class IV drugs, also known as calcium-channel blockers (verapamil, diltiazem, nifedipine), inhibit the slow inward calcium current.

Verapamil

The actions of this drug are mediated through the prolongation of conduction time and refractory period in nodal tissue. Verapamil has been shown to be effective for managing SVT and certain types of VT [109–111].

Verapamil should not be used in young children (<1-year-old) because of its potential to cause severe hemodynamic compromise (refractory hypotension, myocardial depression, asystole and cardiovascular collapse) [112, 113]. The detrimental effects are related to calcium-channel blockade and uncoupling of excitation-contraction in myocardial cells. In older children (>1-year-old), verapamil is infused in a dose of 0.1 mg/kg. The concomitant use of verapamil and ß-blocking agents can result in serious cardiovascular side-effects and is therefore not recommended. In patients with WPW syndrome, verapamil can enhance the ventricular response rate of atrial fibrillation and lead to hemodynamic compromise.

Other agents

Atropine

Atropine sulfate, an antimuscarinic, parasympatholytic drug, accelerates sinus or atrial pacemakers and enhances AV conduction. Atropine is recommended for the treatment of symptomatic bradycardia caused by increased vagal activity or AV block, such as vagally mediated bradycardia during intubation. Atropine may be considered in the treatment of bradycardia associated with poor perfusion or hypotension; however, epinephrine is probably more effective for this condition. Efforts to ensure adequate oxygenation and ventilation and to exclude hypothermia should precede pharmacologic therapy of bradycardia.

The recommended dose is 0.02 mg/kg, with a minimum single dose of 0.1 mg and a maximum single dose of 0.5 mg in a child and 1.0 mg in an adolescent or young adult. The dose can be repeated 5 minutes later, to a maximum total dose of 1.0 mg in a child and 2.0 mg in an adolescent. In the absence of IV access, atropine (0.02 mg/kg) can be administered tracheally or intramuscularly, although with less reliable absorption than through the IV route. Small doses can be associated with transient heart rate slowing. Atropine can also rarely cause cardiac arrhythmias.

Digoxin

Digitalis glycosides have been used for many years in the management of certain arrhythmias. The electrophysiologic effects of digoxin are the result of its direct effects on cardiac tissues (through inhibition of the sarcolemmal sodium pump) and indirect effects via the autonomic (parasympathetic) nervous system. Digoxin increases the refractory period and decreases the conduction velocity of the specialized cardiac conduction system, slows the sinus rate (primarily by enhancing vagal discharge), and shortens the refractory period in atrial and ventricular muscle.

Digoxin can be effective in the treatment of a wide spectrum of supraventricular arrhythmias, such as SVT, atrial flutter, atrial fibrillation, and chaotic AT. In patients with WPW syndrome, digoxin is not recommended because it may alter the conduction properties of the accessory pathway and lead to malignant arrhythmias (VT and VF) during atrial flutter or fibrillation.

Digoxin can be administered orally or parenterally. Given that the onset of its effect may be delayed (up to 5 hours), this drug is less than ideal for treating acute symptomatic tachycardias. Despite this limitation, digitalis glycosides remain useful in controlling the ventricular response in atrial tachyarrhythmias, particularly during atrial flutter or fibrillation.

AL Grawany

A common loading algorithm uses a total oral digitalizing dose of 30–50 μg/kg. Half of this amount is given initially, followed by two doses at 6-hour intervals of 25% of the total dose. For IV use, the total digitalizing dose is reduced to 75% of the total oral dose given following a similar scheme. Maintenance doses of digoxin are 7–10 μg/kg/day. Digoxin binds tightly to peripheral tissue proteins, and drug excretion is via the kidneys. Dose adjustments are indicated in cases of renal impairment or congestive heart failure.

The co-administration of digoxin with other anti-arrhythmic agents (amiodarone, quinidine, verapamil) requires an adjustment (reduction) in the digoxin dose and monitoring of plasma levels. Toxic manifestations of digitalis therapy can be classified as cardiac and non-cardiac. Digoxin toxicity can cause virtually any type of cardiac rhythm disturbance. Non-cardiac manifestations of digitalis toxicity include gastrointestinal problems (nausea, vomiting, anorexia), neurologic symptoms (headache, lethargy, weakness, confusion, seizures), and visual disturbances. Although non-specific, non-cardiac symptoms are the earliest manifestations of digitalis toxicity.

Adenosine

Adenosine is a purine agonist, with effects mediated by the activation of the A_1 adenosine receptor, leading to activation of adenylate cyclase and intracellular cyclic adenosine monophosphate (cAMP) production. The electrophysiologic effects are secondary to an increase in potassium conductance and depression of the slow inward calcium current, resulting in transient sinus slowing or AV nodal block. This accounts for its therapeutic value in terminating arrhythmias that involve the AV node. Adenosine is the drug of choice for acute treatment of SVT [59, 60, 62, 114–116]. Adenosine can also aid the diagnosis of atrial tachyarrhythmias and may be useful in the differentiation of wide QRS tachycardias [116].

To terminate SVT, a bolus of IV adenosine is rapidly injected, preferably into a central vein, at initial doses of 100–150 μg/kg, followed by a rapid normal saline flush. The dose can be doubled up to a maximum of 300 μg/kg (or an adult dose of 6–12 mg). The effects of the drug are seen within 10–20 seconds. It is extremely useful to obtain an ECG recording during its administration because the response to adenosine may provide an insight into the mechanism of tachycardia. Adenosine is rapidly metabolized by erythrocytes and endothelial cells, accounting for its extremely short half-life (<10 seconds).

Cardiac side-effects include sinus pauses, sinus bradycardia, AV block, atrial and ventricular arrhythmias, and reflex sinus tachycardia. These effects are generally transient and may only necessitate supportive care. However, the availability of temporary pacing and an external defibrillator may be prudent. Adenosine should be used with caution in patients who have undergone cardiac transplantation because the electrophysiologic effects of this agent are increased in the denervated heart. Other unwanted effects are transient and generally well tolerated. These include flushing, shortness of breath, bronchospasm, and chest pressure. On very rare occasions, hypotension may occur.

Ivabradine

Ivabradine is a novel anti-arrhythmic drug that works by selectively inhibiting the pacemaker or "funny" current (I_f) in both the sinus and AV node. The I_f current is generated by a nonselective, hyperpolarization-activated cyclic nucleotide-gated transmembrane channel that allows for sodium influx into the cell and potassium efflux from the cell. By inhibiting this channel, ivabradine causes a decrease in the slope of diastolic depolarization and thus causes a reduction in heart rate. One of its benefits is that it causes a reduction in heart rate without affecting cardiac inotropy or systemic vascular resistance [41]. Its use was initially in adult patients with heart failure but applications in pediatric automatic arrhythmias are growing. Small case series and case reports have demonstrated good early results in the management of junctional and atrial ectopic tachycardias. For postoperative junctional tachycardias in pediatric patients, ivabradine has been used alone or in combination with amiodarone with promising results [40, 42, 43]. At this time the drug is only FDA approved for oral use and therefore limited to patients in which the oral route is available. Ivabradine's cardiac side effects include bradycardia, and atrial fibrillation, and its most common non-cardiac effect is visual disturbances. Ivabradine is metabolized by CYP3A4 so its use should be avoided in conjunction with CYP3A4 inhibitors as they can increase toxicity [41].

Magnesium sulfate

Magnesium is a major intracellular cation, a co-factor in multiple enzymatic reactions, and an important regulator of numerous cardiovascular processes. Magnesium sulfate therapy is indicated as adjunct management for arrhythmias in patients with documented hypomagnesemia or *torsades de pointes* [117]. Magnesium deficiency is frequently seen in patients with other electrolyte abnormalities (hypokalemia and hypocalcemia). Rhythm disturbances associated with hypomagnesemia resemble those with hypokalemia or digitalis toxicity.

In *torsades de pointes*, IV infusion (over several minutes) of 25–50 mg/kg (up to 2 g) is recommended. Approximately 70% of plasma Mg^{2+} is ultrafiltered by the kidney, and the remainder is bound to protein. Side-effects associated with drug administration include flushing, diaphoresis, muscle weakness, and central nervous system depression. Magnesium levels well above the therapeutic range can lead to serious morbidities, such as cardiac conduction defects, respiratory depression, and circulatory collapse.

Dexmedetomidine

Dexmedetomidine is an α_2-adrenoceptor agonist with primarily sedative properties recently shown to have anti-arrhythmic effects as well. The exact mechanism of these effects is not well understood. It appears that central α_2- adrenoceptor-mediated enhancement of vagal neural activity plays a potential role [118]. A prospective observational study showed that during the perioperative period after cardiac surgery, receiving a continuous infusion of dexmedetomidine lowered patients' risk of ventricular and supraventricular arrhythmias [30]. Other studies have also shown that the drug has a high success rate in the conversion of SVT [119, 120].

KEY POINTS: PHARMACOLOGIC THERAPY OF CARDIAC ARRHYTHMIAS

- Anti-arrhythmic agents suppress abnormal rhythms or restore normal rhythm and conduction by their effects on blocking sodium, potassium, or calcium channels, or by altering the adrenergic tone.
- Agents are usually categorized based on their mechanism of action into five main classes (Vaughan Williams classification).
- Some drugs have multiple sites of action, complicating the classification of these pharmacologic agents.
- Class III drugs should be avoided in patients with LQTS.
- The co-administration of certain anti-arrhythmic agents can result in increased levels of these drugs and potential synergistic effects on conduction.

Pacemaker therapy in children

Pacemaker nomenclature

Pacemaker nomenclature as established by the North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group is detailed in Table 22.6 [121]. The generic pacemaker (NBG) code has five positions. The first position or letter of the code refers to the chamber(s) paced, the second to the chamber(s) sensed, the third to the pacemaker's response to sensing, and the fourth to programmability and rate modulation. The fifth position is restricted to anti-tachycardia function and is used infrequently.

Permanent cardiac pacing

Advances in pacemaker technology, including enhancements in programmability and miniaturization of units, have resulted in the increasing use of these devices in infants and children [122]. Guidelines for device-based therapy of cardiac rhythm abnormalities have been published by various organizations and modified over the years [123–126]. Box 22.2 lists indications for children, adolescents, and patients with CHD for which there is general agreement that a pacemaker should be implanted (class I) and for which these devices are used frequently but diverging opinions exist regarding benefits (class II). The recommendations for bradycardia management for adult CHD were subsequently revised as noted in Box 22.3.

Box 22.2: Recommendations for permanent pacing in children, adolescents, and patients with congenital heart disease

Class I (indicated; benefit >>>> risk)
- Advanced second- or third-degree AV blocks associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output
- Sinus node dysfunction with correlated symptoms during age-inappropriate bradycardia. The definition of bradycardia varies with the patient's age and expected heart rate
- Postoperative advanced second- or third-degree AV block that is not expected to resolve or that persists at least 7 days after cardiac surgery
- Congenital third-degree AV block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction
- Congenital third-degree AV block in an infant with a ventricular rate <55 bpm or with congenital heart disease and a ventricular rate <70 bpm

Class IIa (reasonable; benefit ≫ risk)
- Prevention of recurrent episodes of IART in patients with CHD and sinus bradycardia; sinus node dysfunction may be intrinsic or secondary to anti-arrhythmic therapy
- Congenital third-degree AV block beyond the first year of life with an average heart rate <50 bpm, abrupt pauses in the ventricular rate that are two or three times the basic cycle length, or associated with symptoms due to chronotropic incompetence
- Sinus bradycardia, complex CHD, and either a resting heart rate <40 bpm or pauses in ventricular rate >3 seconds
- CHD and hemodynamic impairment due to sinus bradycardia or loss of AV synchrony
- Syncope that remains unexplained after careful evaluation of possible causes in a patient with prior CHD surgery complicated by transient complete heart block and residual fascicular block

Class IIb (may be considered; benefit ≥ risk)
- Transient postoperative third-degree AV block that reverts to sinus rhythm with residual bifascicular block
- Congenital third-degree AV block in asymptomatic children or adolescents with an acceptable rate, narrow QRS complex, and normal ventricular function
- Asymptomatic sinus bradycardia after biventricular repair of CHD with a resting heart rate <40 bpm or pauses in ventricular rate >3 seconds

AV, atrioventricular; CHD, congenital heart disease; IART, intra-atrial reentrant tachycardia.
Source: Epstein et al. [124]. Reproduced with permission of Elsevier.

In general terms, potential indications for pacemaker implantation can be listed as follows.
- Symptomatic sinus bradycardia
- Recurrent bradycardia-tachycardia syndromes
- Congenital complete AV block
- Advanced second- or third-degree AV block

An important consideration in patients with CHD is the correlation of symptoms with recommended criteria for

Table 22.6 Generic pacemaker code

Box 22.3:

Recommendations for Management of Bradycardia in Adults With Adult Congenital Heart Disease
Referenced studies that support recommendations are summarized in.

COR	LOE	RECOMMENDATIONS
I	B-NR	1. In adults with adult congenital heart disease (ACHD) and symptomatic SND or chronotropic incompetence, atrial based permanent pacing is recommended.
I	B-NR	2. In adults with ACHD and symptomatic bradycardia related to atrioventricular block, permanent pacing is recommended.
I	B-NR	3. In adults with congenital complete atrioventricular block with any symptomatic bradycardia, a wide QRS escape rhythm, mean daytime heart rate below 50 bpm, complex ventricular ectopy, or ventricular dysfunction, permanent pacing is recommended.
I	B-NR	4. In adults with ACHD and postoperative second-degree Mobitz type II atrioventricular block, high-grade atrioventricular block, or third-degree atrioventricular block that is not expected to resolve, permanent pacing is recommended.
IIa	B-NR	5. In asymptomatic adults with congenital complete atrioventricualar block, permanent pacing is reasonable.
IIa	B-NR	6. In adults with repaired ACHD who require permanent pacing for bradycardic indications, a bradycardia device with atrial antitachycardia pacing capabilities is reasonable.
IIa	C-EO	7. In adults with ACHD with preexisting sinus node and/or atrioventricular conduction disease who are undergoing cardiac surgery, intraoperative placement of epicardial permanent pacing leads is reasonable.
IIb	B-NR	8. In adults with ACHD with pacemakers. atrial-based permanent pacing for the prevention of atrial arrhythmias may be considered.
III: Harm	B-NR	9. In selected adults with ACHD and venous to systemic intracardiac shunts, placement of endocardial pacing leads is potentially harmful.

Abbreviations: *COR* class (strength) of recommendation); *LOE* (quality) of evidence; *B-NR* level b, nonrandomized; *C-EO* level c, consensus of expert opinion.

pacemaker placement in view of the physiologic alterations associated with structural heart disease or postoperative intervention(s). The use of these devices in young patients and those with CHD presents unique challenges and considerations, some of which are highlighted in the sections that follow [127, 128].

Implantation techniques

Permanent pacemaker implantation is performed via either the transvenous or the epicardial approach. These procedures usually take place under sterile conditions in the cardiac catheterization laboratory/electrophysiology suite, or in the operating room. In most infants and small children, the procedure requires a general anesthetic. In a select group of patients, mainly composed of older adolescents and adults, and depending on several factors, these types of procedures can be performed under local anesthesia with supplemental IV sedation.

The transvenous technique uses the subclavian vein as the most common site for access [129]. Under fluoroscopic guidance, pacing leads are advanced into the right atrium or ventricle, or both, and are fixed to the endocardium. After adequate lead sensing, capture thresholds, and impedances are documented, and the leads are attached to a generator, which is typically positioned in the pectoral region. The following are considered contraindications to transvenous pacing: intracardiac communication with the potential for right-to-left shunting, prosthetic tricuspid valve, unsuitable anatomy for transvenous access to cardiac chambers, and small patient size (<10 kg). Advantages of the transvenous route include greater generator longevity (because of lower pacing thresholds) and lower incidence of lead fractures, particularly in active children [130]. The disadvantages are potential narrowing or thrombosis of venous pathways, lead dislocation, risk of systemic embolization in patients with an intracardiac shunt, and possible endocarditis.

For epicardial implantation, the leads are attached to the epimyocardial surface of the heart. After appropriate testing, the leads are tunneled to the generator pocket [131]. This approach requires a subcostal, subxiphoid, thoracotomy, or sternotomy incision. Advantages of epicardial implantation include the ability for placement independent of cardiovascular pathology and avoidance of lead-related venous complications. Disadvantages include the invasiveness of the approach, higher incidence of lead failure, and early generator-battery depletion.

Leadless pacemakers have recently become available and have been used in adults with promising results [132].

The leadless pacemakers consist of a fully contained system that is placed via a transvenous approach in the right ventricle. Initial devices were limited to ventricular pacing, ventricular sensing and ventricular inhibition only (VVI setting), but newer devices have capabilities of ventricular pacing, dual chamber sensing and dual chamber inhibition (VDD) programming allowing for AV synchrony. Their use in the pediatric population is limited to small series. Although encouraging results have been demonstrated, several limitations exist for their widespread use in the pediatric population. These include the large size of the delivery sheath (27 French) and risk for vascular complications, and the limit of single-chamber pacing. Even with the new devices with VDD capabilities, the maximum track rate is 115 bpm which significantly limits its ability to provide AV synchrony in the pediatric population. Another concern is that although the leadless pacemakers are theoretically retrievable, long-term experience and data on retrievability are limited [133–135]. Thus, leadless pacemakers are mostly used for patients that require limited backup pacing.

Hardware selection and programming of devices

A variety of hardware options are available for cardiac pacing in infants and children. The selection of a particular generator system, a mode for pacing, and type of pacing leads is influenced by several factors, including patient size, indications for pacing, the requirement for specific programmability options, underlying cardiac pathology, and anticipated need for generator longevity.

Both single- and dual-chamber units are commercially available for permanent pacing in pediatric patients. Dual-chamber devices provide the benefit of AV synchrony, thereby allowing for the maintenance of the atrial contribution to ventricular filling, enhancing cardiac output, and lowering atrial pressures.

Cardiac resynchronization therapy (CRT) requires placing two separate pacing leads in the right and left ventricles (biventricular pacing). The leads are implanted using a transvenous (left ventricular pacing accomplished via lead in the coronary sinus) or epicardial approach. The goal is to allow for electrical and mechanical synchrony in patients with intraventricular conduction delays in order to improve hemodynamics. This type of therapy is being increasingly used in pediatric patients. The most common indication is ventricular dyssynchrony related to a variety of cardiac diagnoses [136–144]. A recent single-center study has shown that for pediatric patients with symptomatic heart failure and electrical dyssynchrony, the use of CRT therapy has led to improved heart transplant-free survival and decreased mortality compared to a control group [145].

Pacemaker malfunction

Pacemaker malfunction is most frequently caused by complications related to lead placement and integrity, failure to pace, failure to capture, under-or oversensing, phrenic nerve stimulation, and pacemaker-mediated tachycardia [146]. Pacemaker troubleshooting usually requires a 15-lead ECG, a rhythm strip, device interrogation to determine pacing and sensing thresholds, lead impedances, generator battery status and magnet rate, and a chest radiograph.

Children are considered to be at higher risk for lead failure and fracture than adults. These problems result in inappropriate pacemaker sensing or capture (underpacing or overpacing) and the potential need for pacemaker revision. Adjusting pacemaker settings can temporarily remedy these issues.

Perioperative considerations

Patients with cardiac rhythm devices require special perioperative considerations (Box 22.4). The preoperative assessment of the patient with a pacemaker should include a complete history, with emphasis on indications for initial implantation, pacemaker dependency and underlying rhythm, coexistent cardiovascular pathology (structural or acquired), the functional status of the patient, and symptomatology. In addition, a focused physical examination should be performed that includes planned or existent pocket generator location [147]. Preoperative testing should be undertaken as indicated, including a chest radiograph that shows the number, position, and integrity of the pacing leads. If pacemaker details are needed but are not available, the device may have a code that can be read on a chest radiograph and used to identify the unit's manufacturer/model.

Device interrogation should be part of a complete preoperative evaluation in all patients with implanted pacemakers who are scheduled for surgical intervention (cardiac or noncardiac) [147–150]. Consultation with a pediatric cardiologist/electrophysiologist to obtain details of unit type, settings, date of and indications for implantation, and underlying rhythm is highly recommended. The patient's pacemaker card, if available, may also provide relevant information.

Box 22.4: Perioperative management of patients with cardiac rhythm devices

Preoperative preparation
- Determination of the type of device and indication for pacing/ICD
- Assessment of underlying rhythm and pacemaker dependency
- Evaluation of device function (pacemaker check, ECG, CXR)
- Consideration of reprogramming to the asynchronous pacing mode
- Deactivation of rate-adaptive functions
- Disabling of anti-tachycardia function/defibrillation mode as appropriate

Intraoperative management
- Intraoperative monitoring (continuous ECG, monitoring of effective cardiac output; e.g., pulse oximetry, cuff blood pressure, arterial line)
- Availability of backup temporary pacing and cardioversion-defibrillation equipment
- Immediate availability of drugs (isoproterenol, emergency agents)
- Avoidance of electromagnetic interference (bipolar electrocautery preferable; place grounding pad so current passes far away from the pacemaker and leads)
- Availability of magnet (not to replace preoperative evaluation or to be used instead of reprogramming device)

Postoperative considerations
- Continuous ECG monitoring, pulse oximetry, cuff pressure, or arterial line
- Immediate availability at all times of backup pacing and cardioversion-defibrillation equipment
- Interrogation of the device, reprogramming as needed
- Reactivation of special modes (anti-tachycardia, defibrillation mode for ICDs, and others)

CXR chest radiograph, ECG electrocardiogram, ICD implantable cardioverter-defibrillator.

AL Grawany

Results of a recent 15-lead ECG should also be reviewed. Reprogramming may be necessary before the planned procedure to avoid potential problems with pacemaker malfunction related to electromagnetic interference (EMI), such as that produced by electrocautery or radiofrequency ablation. If there is a significant risk of EMI and the patient is pacemaker-dependent, it is recommended that the pacemaker be reprogrammed to asynchronous mode [116]. The introduction of bipolar leads, improved filters, and circuit shields has made modern devices less susceptible to EMI. The rate-responsive mode, if turned on, should be deactivated, as should anti-tachycardia modes. Several case reports suggest that incomplete perioperative evaluations can lead to adverse outcomes [151, 152]. Pacemaker dysfunction has been found in up to 12% of patients undergoing preoperative interrogation before undergoing non-cardiac surgery, highlighting the importance of preoperative assessment [153].

Regarding intraoperative management, it should be considered that unipolar electrocautery can interfere with pacemaker function, so bipolar electrocautery is preferred. The diathermy grounding pad should have good skin contact and be placed as far away from the device as possible. In addition to routine perioperative monitoring, which includes ECG and pulse oximetry, other modalities that confirm pulse generation during pacing, such as manual pulse palpation, auscultation (via precordial or esophageal stethoscope), and invasive arterial blood pressure monitoring, should be considered. Chronotropic agents and alternate pacing modalities (transcutaneous, transvenous, transesophageal, epicardial) should be readily available in the event of pacemaker malfunction and inadequate underlying heart rate. If defibrillation is required, the current should not be applied to or passed directly through the pulse generator, because this may damage the device circuitry.

A magnet should always be accessible to allow for transient asynchronous pacing if required. Most generators respond to magnet application by pacing asynchronously at a fixed rate (atrium paced, no atrial sensing or inhibition [AOO], ventricle paced, no ventricular sensing or inhibition [VOO], or dual chamber paced, no dual chamber sensing or inhibition [DOO]). It should be emphasized, however, that the settings of the asynchronous programmed stimuli for magnet mode vary among pacemaker units. Furthermore, at the generator end of life, the pacing rate on magnet application may differ (i.e., be slower) from the pre-specified magnet rate or cause pacing to stop altogether. In some cases, the application of a magnet over a programmable pacemaker during EMI (i.e., cautery) may result in generator reprogramming [154]. Therefore, a magnet should never be considered a substitute for preoperative pacemaker interrogation or programming, nor should it be used routinely over a pacemaker generator during surgery or to offset potential EMI. After the procedure is completed, the device should be retested and programmed to baseline settings as appropriate.

For further depth on this topic, the reader is referred to the updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices published in 2020 [147].

Temporary cardiac pacing

The transvenous and epicardial routes are commonly used for temporary pacing, although the transthoracic (transcutaneous) and transesophageal approaches are also suitable in some cases. Indications for temporary cardiac pacing are not as clearly defined as those for permanent pacing [155]. The literature suggests that there is no need for the routine placement of temporary epicardial pacing wires after congenital heart surgery [156–158]. However, in patients who undergo surgical interventions such as the Fontan operation or procedures performed under circulatory arrest, or who have intraoperative arrhythmias, postoperative temporary pacing has been shown to improve hemodynamics; thus, such patients may benefit from the placement of epicardial pacing wires at the time of surgery [159].

Temporary pacing is achieved by placing special wires in the atrial and/or ventricular epimyocardium toward the completion of the surgical procedure and before sternal closure [6, 155, 160]. As previously stated, atrial wires usually exit to the right of the sternum and ventricular wires to the left. Wires should be clearly labeled to prevent confusion if there is no institutional convention. Pacing in the atrium and ventricle is termed AV sequential pacing. During pacing, the electrical impulse originates at the pulse generator – in this case, a temporary pacing box – and then flows through the wires. Unipolar and bipolar epicardial pacing leads are available. A unipolar lead is a single wire conductor (electrode at the tip), whereas a bipolar lead has two conductors within a single wire. During unipolar pacing, the electrical current flows from the electrode in contact with the heart (cathode, negatively charged) to a wire placed in the subcutaneous tissue that serves as the electrode (anode, positively charged) receiving the electrical impulse after the cardiac tissue is depolarized. In bipolar pacing, the electrical current flows through the electrode at the distal tip of the lead wire (negative cathode), and after stimulation of the heart, the signal returns to the more proximal electrode (positive anode). Bipolar systems tend to require less energy for pacing, and there is less electrical interference during sensing. The negative cathode (the epicardial wire in unipolar systems; the distal epicardial wire in bipolar units) should be clearly labeled; this is the wire that should be connected to the negative terminal of the pulse generator.

Several programmable settings are available in the external temporary pulse generator (single- or dual-chamber device). Depending on the unit, these include pacing rate, atrial or ventricular output amplitude (milliamperes, mA), atrial or ventricular sensitivity (mV) or asynchronous mode, A-V interval (milliseconds), post-ventricular atrial refractory period, and upper rate tracking. The most important parameters to be adjusted are rate, chamber output, and pacing mode. Adjustments in optimal sensing and pacing parameters are guided by the testing of thresholds. The following is a brief overview of pacemaker settings and how these parameters are adjusted:

- *Rate*. This should be set at a physiological rate for age, or to provide adequate cardiac output during the postoperative state. If overdrive suppression of an arrhythmia is needed, the rate is usually set 10–20% higher than the arrhythmia rate.
- *Sensitivity*. The sensing threshold represents the *minimum electrical activity that the pacemaker is able to sense*. The lower the sensitivity setting, the less electrical activity is required by the pacemaker to sense, or greater sensitivity. To determine sensitivity, the pacemaker rate is set lower than the

underlying rate in a synchronous pacing mode (AAI, VVI or DDD). The sensitivity number is then increased (lowering sensitivity) until the sense indicator on the generator stops flashing (this implies that the mode is being changed to asynchronous pacing; see below). The sensitivity setting (number) on the generator is then decreased (increasing sensitivity) until the sense indicator flashes with each cardiac depolarization. This setting represents the sensing threshold. Sensitivity is then set at half of the sensing threshold. Typically, if no underlying rhythm is present, sensitivity is set at 2 mV. It should be emphasized that setting the sensitivity to a higher number renders the pacemaker insensitive, meaning that the mode is changed from demand to asynchronous or fixed-rate pacing. Conversely, using a very low sensitivity setting could make the pacemaker oversensitive, potentially risking pacemaker inhibition (failure to pace) by inappropriate sensing of events that are interpreted as electrical cardiac activity.

- *Capture thresholds*. This parameter indicates the minimum amount of energy (current intensity) required to stimulate the action potential in the myocardium. To determine this setting, the pacemaker rate should be set above the underlying rate so that the pacemaker is consistently pacing the chamber being tested. The output is then slowly decreased until there is no longer capture of this chamber. *The minimum output at which capture is still present is the capture threshold*. *The output should be set at twice the capture threshold to increase the margin of safety*. Setting the output too high results in a higher incidence of inflammation and fibrosis at the lead connection and higher capture thresholds. Care should be taken during capture threshold testing in patients with no underlying rhythm.
- *AV delay*. This represents the PR interval. In most cases, this parameter is set automatically according to rate or to between 100 and 150 ms.

Temporary pacing may be necessary for maintaining adequate cardiac output in patients with bradyarrhythmias, abnormal AV conduction, AV asynchrony, and inadequate heart rates for the physiologic state [161]. It may also be helpful in individuals at risk of high-degree AV block and can be used to suppress, overdrive, or terminate tachyarrhythmias. As previously discussed, atrial recordings obtained through temporary pacing wires can also provide diagnostic information in certain types of rhythm disorders. In the care of patients who depend on temporary pacing for maintenance of adequate hemodynamics, it is extremely important to be attentive to pacemaker settings and capture thresholds, which should be interrogated on a daily basis [160]. Testing should include determining underlying rhythm, whether ongoing pacing is needed, and the battery status of the temporary pacemaker. It is preferred to lower the pacing rate until the endogenous rhythm comes through to determine the underlying rhythm, rather than decreasing the output until capture is lost, pausing or turning off the pacemaker, or detaching the leads. Alternate means of pacing should be available in the event of lead or pacemaker failure or malfunction. A second pulse generator and the battery should be available at all times. Temporary pacing can be discontinued when the indication for pacing resolves or when the transition to a permanent pacing system is required.

External cardiac (transcutaneous) pacing

In the mid-1980s, a transcutaneous external cardiac pacing system was patented and introduced by Dr. Paul Zoll [162]. Over the ensuing years, there was renewed interest in the field and further enhancements in the technology. Most devices currently available for transcutaneous pacing combine defibrillation/cardioversion capabilities and external pacing features. In children, emergency transthoracic pacing can be considered as a temporizing measure for symptomatic bradycardia (secondary to abnormal sinus node function or to complete AV block) [163]. Because transcutaneous pacing results in simultaneous atrial and ventricular activation, it should be recognized that optimal hemodynamics may not be achievable. This pacing modality has not been found to be effective in the treatment of asystole in children.

Transcutaneous pacing electrodes (pads) are selected according to patient size (smaller ones for children <15 kg). When gel pads are applied prophylactically, an ECG tracing obtained directly from the pads confirms adequate skin contact and proper cable attachment to the unit in case pacing is required. Device settings for pacing typically include heart rate and current output (mA). Most available models provide the option for demand or fixed pacing mode. After the desired heart rate and pacing modality are selected, the output is increased until capture is achieved. In emergency situations, pacing should be initiated at or near the maximum current output, and once the capture is documented, pacing can be gradually decreased to 5–10 mA above the capture threshold. Sedation may be necessary to improve pacing tolerance in the awake patient because this mode of pacing can be associated with discomfort (burning skin sensation, contraction of skeletal muscles). Prolonged periods of transcutaneous pacing can result in serious burns or skin trauma in infants and young children. In addition to monitoring for pacemaker capture by an ECG, ongoing clinical assessment of pulse, blood pressure, and adequacy of cardiac output should be undertaken.

Transesophageal overdrive pacing

An esophageal catheter can be used for atrial sensing, which provides diagnostic information and enables discrimination between supraventricular tachyarrhythmias. Using the esophageal route also allows for overdrive pacing of a variety of supraventricular rhythm disorders (e.g., atrial flutter, SVT). For this purpose, an electrode catheter is inserted into the esophagus and advanced to a location that corresponds roughly to the region behind the atrial mass, and an AEG is obtained to better position the catheter. Local anesthesia of the nasopharynx or oropharynx and/or sedation is generally necessary for introducing the catheter and preventing discomfort during atrial pacing. Standard cardiorespiratory monitoring should be performed throughout the procedure, and airway support should be provided as necessary. Emergency drugs and cardioversion/defibrillation equipment should be made readily available.

Implantable cardioverter-defibrillators

The primary purpose of an ICD is to prevent sudden death in patients at high risk. Although sudden cardiac death is

AL Grawany

uncommon in pediatric patients, those with certain conditions are at sufficiently high risk to make them suitable candidates for ICD implantation. These conditions include hypertrophic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, LQTS, BrS, and a history of near sudden death events [164, 165]. Placement of an ICD may also be warranted in pediatric patients with operated CHD or a history of malignant arrhythmias.

Device implantation involves lead and generator placement. An issue of concern is the high rate of lead failure, which is reportedly 21% in children and young adults [166]. A subcutaneous ICD that does not require transvenous lead placement is also available but does not provide any pacing capabilities except for temporary post-shock pacing [167, 168]. At present, experience in the pediatric age group with ICD devices, in general, is limited but growing, and is reported mostly in a retrospective fashion [168–174]. Prospective trials are required to establish guidelines for use, address safety concerns, and evaluate long-term issues specific to children.

Anesthetic considerations in patients with ICDs relate primarily to potential surgical EMI (from electrocautery) and the need for an available external cardioverting/defibrillating device. Perioperative consultation with a specialist is therefore essential. In most cases, the device must be deactivated or adjusted before surgery. The application of a magnet temporarily deactivates most, not all devices; thus, it is not a substitute for reprogramming and should only be considered in emergencies. Careful evaluation and device programming are advisable at the conclusion of the surgical intervention to ensure patient safety.

KEY POINTS: PACEMAKER THERAPY IN CHILDREN

- Indications for permanent pacing in children in most cases relate to symptomatic sinus bradycardia, recurrent bradycardia-tachycardia syndromes, congenital complete AV block, and advanced second- or third-degree AV block.
- Patients with implanted cardiac rhythm devices require special perioperative considerations during anesthetic care.
- Temporary pacing wires are placed toward the end of surgery in patients who may require or potentially benefit from pacing perioperatively; the wires also serve to assist in arrhythmia recognition/treatment.
- The most important settings for temporary cardiac pacing are heart rate, chamber output, and pacing mode.
- Temporary pacemaker settings and thresholds should be interrogated on a daily basis in the postoperative period.
- A magnet should never be used as a replacement for preoperative pacemaker interrogation or reprogramming, nor should it be used intraoperatively to offset potential EMI.

Summary

A significant portion of cardiac anesthesia practice involves caring for patients affected by cardiac rhythm disturbances or who may develop perioperative or periprocedural arrhythmias. It is well recognized that patients with CHD, both children and adults, represent a subgroup who are particularly vulnerable to the negative hemodynamic consequences associated with alterations of cardiac rhythm. Adequate knowledge of cardiovascular diseases affecting cardiac rhythm, arrhythmia mechanisms, diagnosis, drug therapy, and alternative therapeutic options is essential for optimal patient care and limiting related morbidity.

Introduction

Airway and ventilatory management of infants and children with congenital heart disease (CHD) during diagnostic and therapeutic procedures presents unique challenges to the anesthesiologist. This is a consequence of the interplay of a range of congenital airway abnormalities, cardiopulmonary interactions, and adverse effects of surgery and cardiopulmonary bypass on the respiratory system. Few other clinical situations will tax the skills of an anesthesiologist as the management of a child with CHD and a difficult airway. Children with cardiovascular disease may be intolerant of the myocardial depressant effects of many anesthetics, limiting the options available in managing their airway and circulation during induction of anesthesia. Children with cyanotic congenital heart disease experience rapid oxygen desaturation during periods of apnea associated with tracheal intubation. Moreover, in patients with single-ventricle disease, the very use of positive-pressure ventilation may limit pulmonary blood flow, leading to rapid decompensation. Developing a plan that allows safe airway and ventilatory management without hemodynamic compromise requires preparation, skill, and familiarity with a range of techniques of tracheal intubation and mechanical ventilation.

Choosing the appropriate endotracheal tube (ETT)

The narrowest portion of a child's larynx is at the level of the cricoid cartilage, as opposed to adult patients whose limiting airway diameter is at the level of the vocal cords (rima glottidis). Uncuffed ETTs have traditionally been used in young children because a seal may be created between the tracheal mucosa and the tube at the level of the cricoid cartilage so that a cuff may not be needed to create a seal [1]. A disadvantage of uncuffed ETTs is that the placement of an ETT with a gas leak at low inflating pressures (e.g., <15 cm H_2O) results in excessive leak around the endotracheal tube when lung compliance is poor. This is particularly important for thoracic or cardiovascular surgery because lung compliance may be reduced as a result of surgical traction, pulmonary edema, or atelectasis related to cardiopulmonary bypass (CPB). This results in a greater percentage of gas leak around the ETT. Gas leakage representing more than 50% of tidal volume has been demonstrated in the setting of decreasing lung compliance [2]. Associated decreases in minute ventilation may lead to hypoxemia due to atelectasis and intrapulmonary shunt as well as dangerous elevations in $PaCO_2$ related to decreased alveolar ventilation. Table 23.1 presents a scheme for selection of ETT size in infants and children.

Table 23.1 Endotracheal tube sizes used in pediatric patients

Age	Size (mm ID)
Preterm	
<1000 gm	2.5
1000–2500 gm	3.0
Term Neonate – 6 months	3.5
6 months to 1 year	4.0
1–2 years	4.0–5.0
Beyond 2 years	$\frac{\text{Age (years)}}{4} + 4$

In addition to the risk of inadequate alveolar ventilation, there are other hazards associated with placement of a loose fitting ETT. Lung function measurements are commonly used to guide mechanical ventilation in the postoperative period. A variable leak around the ETT results in inaccurate measurements of exhaled tidal volumes, lung compliance, and airway resistance. A significant gas leak around the ETT also results in environmental pollution from either inhaled anesthetic agents or nitric oxide [3]. Lastly, an inadequate seal around the ETT may increase the risk of pulmonary aspiration should gastric contents be regurgitated during positive pressure ventilation.

Traditional airway management has included the use of uncuffed ETTs in children under the age of 8 years. However, there is limited scientific evidence to support this practice. Since the mid-1990s, advancements in the materials used in the ETT cuff, the shape of the cuff itself, and the relative outer diameter of the inflated cuff have lowered the risk for airway injury with the use of cuffed ETT's [4–6]. Cuffed endotracheal tubes are now routinely placed in infants and children, and the incidence of clinically significant airway complications is very low [7]. The use of cuffed ETTs during anesthesia reduces the need for repeated laryngoscopy and tracheal intubation, allows use of lower fresh gas flows, and limits environmental contamination with anesthetic gases [2]. There is no difference in the incidence of airway complications in pediatric patients intubated with cuffed vs. uncuffed endotracheal tubes during anesthesia or in pediatric intensive care units [7, 8]. However, the need to exchange endotracheal tubes is significantly greater when using uncuffed ETTs. Decreased lung compliance from the effects of cardiopulmonary bypass may increase the leak around the endotracheal tube in children after heart surgery, and a cuffed ETT may be partially deflated to compensate for such changes. In a retrospective review of 809 children <2 years old undergoing cardiac surgery over a 4-year period, the incidence of subglottic stenosis (17/809 or 1.08%) was not affected by the use of uncuffed vs. cuffed ETTs. The most important risk factors for subglottic stenosis were younger age and prolonged (>96 hours) postoperative intubation [9]. There is some evidence suggesting that children with CHD require larger endotracheal ETTs regardless of the duration of surgery [10]. Given this information, the pediatric patient requiring lengthy surgical intervention for congenital heart disease and/or a significant period of post-operative mechanical ventilation will generally benefit from the use of a cuffed endotracheal tube.

A disadvantage of using cuffed ETTs is that their outer diameter is approximately 0.3–0.5 mm larger than uncuffed ETTs with the same inner diameter. As a result, a tube with an inner diameter one size (i.e., 0.5 mm ID) smaller is recommended when a cuffed ETT is placed. The reduction in ETT internal diameter results in greater resistance to gas flow and an increased risk of occlusion of the ETT with blood and tracheal secretions. While a reduction of the tracheal tube diameter by only 0.5 mm might not be expected to effect a clinical change, gas flow resistance increases exponentially at smaller tube diameters. While a reduction in tracheal tube size from 8.0 mm ID to 7.5 mm ID increases airway resistance by 29%, a change from a size 4.0 mm ID to a 3.5 mm ID tube results in an increase of 71%, and a change from a 3.5 mm ID tube to a 3.0 mm ID tube increases resistance by 85%. The increase in resistance is even more profound if turbulent airflow occurs in smaller tracheal tubes. In addition, use of ETTs with a smaller internal diameter may result in the need to use smaller suction catheters, limiting the ability to effectively clear blood and secretions from the airways.

The Microcuff® endotracheal tube (Kimberly Clark; Roswell, GA) has been developed for pediatric patients. This ETT includes a true high-volume / low-pressure cuff, eliminates the Murphy eye in order to optimize cuff position at the tip of the endotracheal tube, and includes an ultrathin cuff that provides an outer diameter-to-inner diameter ratio similar to uncuffed endotracheal tubes. The Microcuff® ETT may decrease the incidence of micro-aspiration around the ETT cuff. While conventional PVC cuffs create folds and channels when inflated that allow fluid to leak past the cuff, the cuff on the Microcuff® ETT is designed to minimize those channel openings to create a more effective tracheal seal. The cuff length and shape of Microcuff® ETTs are also designed for better contact with tracheal contours to increase protection against fluid leakage. Of note, the lack of a Murphy eye eliminates a channel for gas exchange in the case of an ETT placed too distally in the trachea or in the right mainstem bronchus.

Two studies including 575 patients age 0–5 years have found a low incidence of post-extubation stridor, and a tracheal tube exchange rate of <3% when cuffed ETTs are used in children [11, 12]. A combined analysis of 3 controlled randomized trials of cuffed vs. uncuffed ETTs in 2804 children less than 8 years of age concluded that there was no difference the incidence of post-extubation stridor requiring treatment with racemic epinephrine or corticosteroids, or of the need for reintubation or need for ICU care [13]. In patients who underwent surgery for congenital heart disease and were managed with Microcuff® ETTs, a retrospective review of 208 patients weighing less than 5 kg found no cases of tracheal stenosis. However, 20.9% of patients developed stridor requiring treatment with racemic epinephrine and 2 patients had severe stridor requiring reintubation [14].

Orotracheal vs. nasotracheal intubation

While orotracheal intubation is performed more commonly than nasotracheal intubation for most surgery in children, many centers routinely place nasal ETTs in children undergoing cardiac surgery. Intraoperative transesophageal echocardiography (TEE) may cause dislodgement of an oral ETT, although

a low incidence of airway complications during pediatric TEE among children who were orally intubated has been reported [15]. Of the 1650 patients studied, 3 (0.2%) developed a right mainstem advancement of the ETT and 8 (0.5%) were inadvertently extubated. Nasal ETTs are more readily secured to the face, and movement of the ETT is less likely during manipulation of the TEE probe. While nasal intubation may minimize risk of pressure injury from the ETT to the lips, there is a greater risk of damage to nasal alae and, in older children, of sinusitis from long-term nasotracheal intubation [16–18]. These risks may increase if nasotracheal intubation is utilized infrequently and care providers in the post-operative phase (e.g., respiratory therapists, bedside nurses, etc.) are unaware of the need to monitor for such complications. Therefore, for patients whose operative course predicts a lengthy ICU stay, institutional familiarity with nasotracheal intubation should be considered in advance. The risk of bleeding from nasal mucosal or adenoidal trauma is especially problematic in the fully anticoagulated patient. This risk is minimized by the routine use of topical vasoconstrictor drugs (e.g., oxymetazoline), adequate lubrication, and warming of the ETT prior to placement. Excessive pressure should not be used during advancement of the tube through the nose and nasopharynx. Prior to advancing the ETT into the nasopharynx, a soft, lubricated, tapered suction catheter can be affixed to the tip of the ETT and advanced through the nasopharynx; it can be gently pulled through the mouth using a laryngoscope and Magill forceps, guiding the ETT into the oropharynx. The catheter acts as a guide permitting easier passage of the nasal ETT through the nasal passages and nasopharynx. The catheter is then removed from the ETT, allowing placement of the ETT into the trachea using the laryngoscope and Magill forceps [19].

Because ETTs can be placed more easily and rapidly via the oral route, oral intubation is preferred for rapid sequence intubation or during emergencies. Once adequate ventilation and oxygenation have been provided and the stomach is suctioned, the ETT may be exchanged for a nasal tube under direct visualization. In general, the nasal passages of children will accommodate the same size ETT as would be used for oral intubation.

An analysis of 26,754 cardiac surgery cases from the multicentered Congenital Cardiac Anesthesia Society database compared the outcome of patients who had oral vs. nasal endotracheal intubation [20]. Nasal intubation was performed in 41% of neonates, 38% of infants, 15% of school aged children, and 2% of adolescents; about 80% of neonates and infants had cuffed ETT. There were fewer accidental extubations in neonates who were nasally intubated (0% vs. 0.37%). However, after 12 months of age nasal intubation was associated with an increased risk of infection (mediastinitis, wound infection, pneumonia, septicemia). The duration of mechanical ventilation and hospital stay were not different between groups.

The difficult airway

The incidence of noncardiac congenital airway anomalies is believed to be greater among children with congenital heart disease than in the general population. Certain genetic disorders are clearly associated with both airway anomalies and congenital heart disease, including CHARGE and velocardiofacial (DiGeorge) syndrome (22q11 deletion). Children with these anomalies should have a complete airway examination, including endoscopic subglottic examination, by an otolaryngologist prior to cardiac surgery. In older, cooperative patients, the airway should be examined as with adult patients, including mouth opening, dentition, mandibular size, hyomental distance, and neck mobility. Studies in adults have shown that examination of the airway can help predict difficulty of intubation and mask ventilation [21]. No such studies have been performed in infants and children, and it is not known whether assessing mouth opening using a tongue depressor in a nonverbal child is predictive of difficulty with intubation. Assessment of an infant's airway should include an assessment of neck mobility and the appearance of the mandibular size when viewed in profile. Children with micro- or retrognathia are more likely to manifest difficult mask ventilation and/or difficult intubation.

The incidence of difficult intubation is higher among children with CHD. A study of 11,219 children from the population at large undergoing general anesthesia found 1.35% of patients had difficult intubation, defined as a Cormack-Lehane view of Grade 3 or higher [22]. The incidence for cardiac surgical patients was 3.6%, a higher incidence than any other group surgical group, including craniofacial surgery. Neonates and infants had a higher incidence of difficult intubation, 2.5% for the general population and 6.9%, for the cardiac surgical group. These same authors reported a detailed analysis of 1,177 pediatric cardiac surgery cases [23]. Interestingly, Trisomy 21 was not associated with difficult intubation; however, 9 of 29 patients (31%) with other genetic/dysmorphic syndromes were found to have difficult intubation (Table 23.2) [23]. They again found a higher incidence associated with younger age; difficult intubation was found in 5.6% of patients less than 12 months vs. 1.7% for older children.

A separate retrospective database review of 4,797 patients with CHD from a single center undergoing 8,657 anesthetics for cardiac and non-cardiac procedures found the incidence of difficult intubation to be about the same as that reported for the general pediatric population - 53 (1.1%) of the patients had a Cormack-Lehane grade 3 or higher [24]. In this report, 16.7% of patients had a genetic or dysmorphic syndrome, including Trisomy 21 (6%), velocardiofacial syndrome (3.6%), and CHARGE association (3%). Altogether 2.4% of patients required 3 or more intubation attempts. Video laryngoscopy was utilized in 7.7% of patients and fiberoptic bronchoscopy

in only 4 patients (0.1%). A significant percentage (18.2%) of patients had a congenital or acquired upper or lower airway anomaly (Tables 23.3 and 23.4).

During embryologic development, the tracheobronchial tree and the pulmonary vasculature develop together, and therefore, abnormalities of the pulmonary vasculature are often associated with abnormalities of the airway. This was confirmed in a review of 564 patients with tetralogy of Fallot/pulmonary atresia/major aortopulmonary collateral arteries (TOF/PA/MAPCAs) where 37% of the patients had velocardiofacial syndrome. Difficult intubation was noted in 5% of patients, and the incidence was not different among those with or without a chromosome anomaly [25]. Over 40% of the patients had perioperative bronchoscopy and/or chest CT scan and half of these patients had an upper or lower airway abnormality.

Efficient airway management with minimal periods of interrupted oxygenation and ventilation is of the utmost importance in infants and children with heart disease. Especially at risk are patients with cyanotic lesions, poor ventricular function (systolic and/or diastolic), and pulmonary hypertension. In children with cyanotic heart disease, the oxygen saturation of coronary blood is decreased. Additional oxygen desaturation during airway management may result in critically diminished oxygen delivery to cardiac myocytes. Coupled with the increase in plasma catecholamines associated with airway maneuvers, causing increased myocardial oxygen demand, significant myocardial ischemia may ensue. Children with low cardiac output have compromised coronary blood flow at baseline, and a decrease in oxygen saturation in coronary blood occurring while oxygen demand is increased during airway management may also result in severe myocardial hypoxia-ischemia. In children with pulmonary hypertension, a similar increase in plasma catecholamine concentrations coupled with any rise in $PaCO_2$ may cause an acute exacerbation in pulmonary vascular resistance and cardiac arrest. While anesthetic agents may prevent marked increases in sympathetic response to laryngoscopy and tracheal intubation, they may also cause myocardial depression and systemic hypotension, resulting in reduced coronary blood flow causing ischemia. Given these elevated risks for decompensation, and the relatively high frequency of airway anomalies, robust preoperative airway assessment and the preparation for a potential difficult intubation (e.g., ensuring availability of a video laryngoscope) is recommended.

Intubation of the patient with a difficult airway

A modification of the American Society of Anesthesiologists algorithm for the management of the patient with a difficult airway can be applied to children [26] (Figure 23.1). Specialized airway equipment should be prepared, checked and available in the operating room. Box 23.1 lists recommendations for equipping a difficult airway cart. In addition to equipment, additional personnel skilled in airway management should be immediately available for assistance.

When the difficult airway is recognized prior to the induction of anesthesia, control of the airway can be performed with the patient awake, following sedation, or after the induction of anesthesia with inhalation agents. Awake, nonsedated, direct laryngoscopy can be accomplished in neonates but may be difficult, traumatic, and have significant adverse hemodynamic consequences. Placement of a supraglottic airway (SGA) after application of topical anesthesia to the airway in an awake infant has been described as an

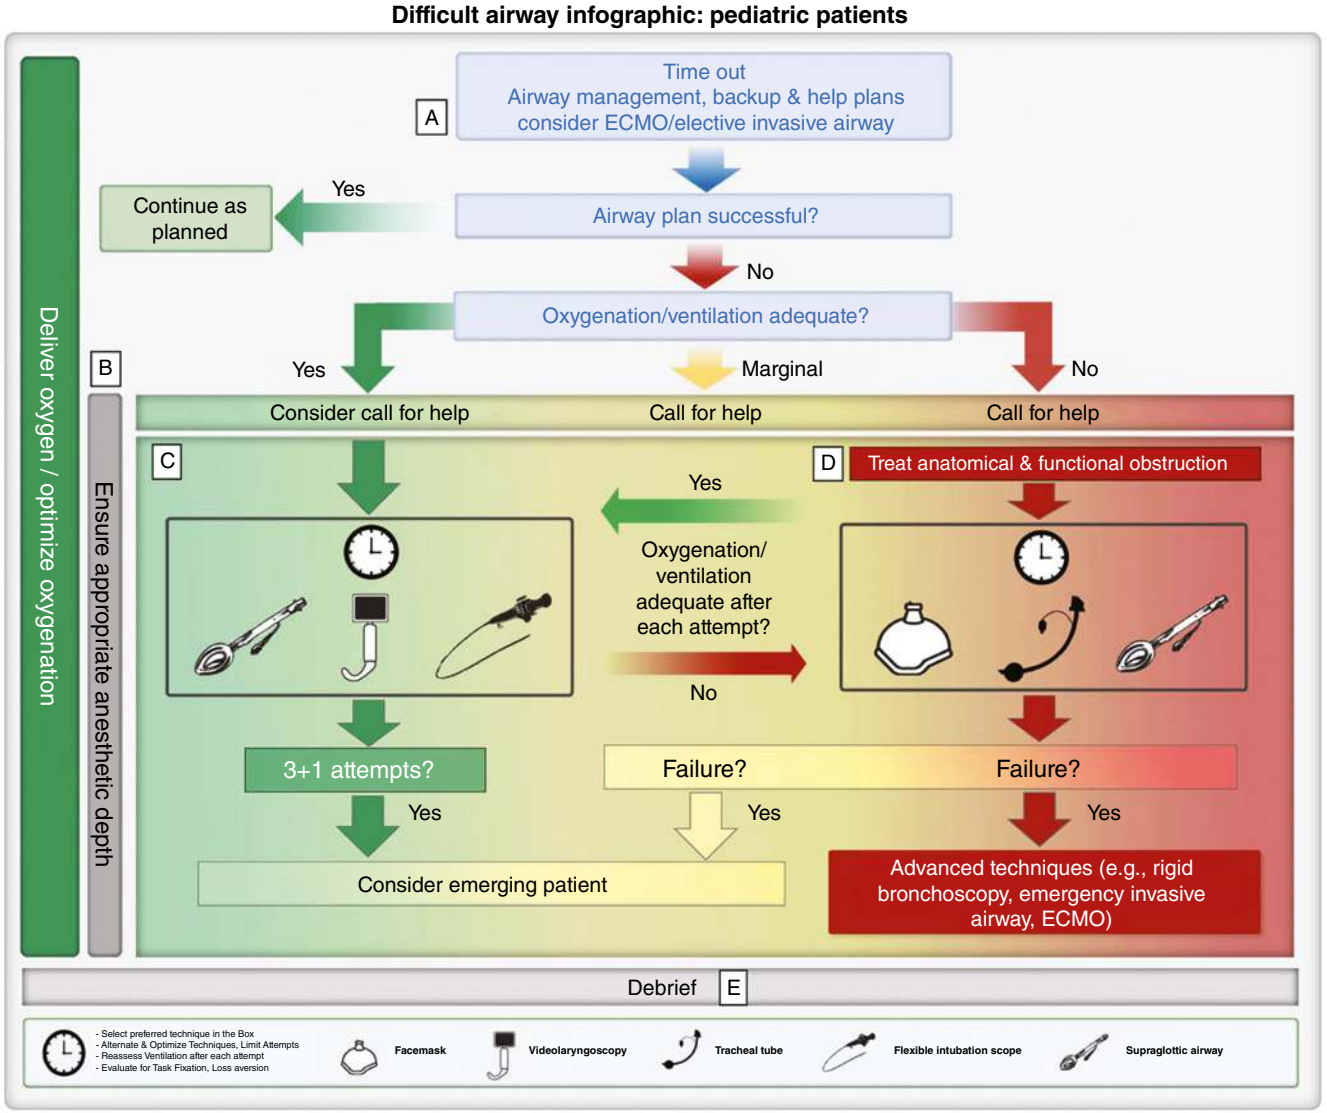

Figure 23.1 Difficult airway infographic: Pediatric patient example. (A) Time Out for identification of the airway management plan. A team-based approach with identification of the following is preferred: the primary airway manager and backup manager and role assignment, the primary equipment and the backup equipment, and the person(s) available to help. Contact an ECMO team/otolaryngologic surgeon if noninvasive airway management is likely to fail (e.g., congenital high airway obstruction, airway tumor, etc.). (B) Color scheme. The colors represent the ability to oxygenate/ventilate: green, easy oxygenation/ventilation; yellow, difficult or marginal oxygenation/ventilation; and red, impossible oxygenation/ventilation. Reassess oxygenation/ventilation after each attempt and move to the appropriate box based on the results of the oxygenation/ventilation check. (C) Nonemergency pathway (oxygenation/ventilation adequate for an intubation known or anticipated to be challenging): deliver oxygen throughout airway management; attempt airway management with the technique/device most familiar to the primary airway manager; select from the following devices: supraglottic airway, videolaryngoscopy, flexible bronchoscopy, or a combination of these devices (e.g., flexible bronchoscopic intubation through the supraglottic airway); other techniques (e.g., lighted stylets or rigid stylets may be used at the discretion of the clinician); optimize and alternate devices as needed; reassess ventilation after each attempt; limit direct laryngoscopy attempts (e.g., one attempt) with consideration of standard blade videolaryngoscopy in lieu of direct laryngoscopy; limit total attempts (insertion of the intubating device until its removal) by the primary airway manager (e.g., three attempts) and one additional attempt by the secondary airway manager; after four attempts, consider emerging the patient and reversing anesthetic drugs if feasible. Clinicians may make further attempts if the risks and benefits to the patient favor continued attempts. (D) Marginal/emergency pathway (poor or no oxygenation/ventilation for an intubation known or anticipated to be challenging): treat functional (e.g., airway reflexes with drugs) and anatomical (mechanical) obstruction; attempt to improve ventilation with facemask, tracheal intubation, and supraglottic airway as appropriate; and if all options fail, consider emerging the patient or using advanced invasive techniques. (E) Consider a team debrief after all difficult airway encounters: identify processes that worked well and opportunities for system improvement and provide emotional support to members of the team, particularly when there is patient morbidly or mortality. Developed in collaboration with the Society for Pediatric Anesthesia and the Pediatric Difficult Intubation Collaborative: John E. Fiadjoe, M.D., Thomas Engelhardt, M.D., Ph.D., F.R.C.A., Nicola Disma, M.D., Narasimhan Jagannathan, M.D., M.B.A., Britta S. von Ungern-Sternberg, M.D., Ph.D., D.E.A.A., F.A.N.Z.C.A., and Pete G. alternative to awake direct laryngoscopy [27]. Fiberoptic-guided intubation of the older, cooperative patient using topical anesthesia and intravenous sedation is a safe and effective alternative. Maintaining oxygenation via nasal cannula, nasopharyngeal airway with 15 mm connector, modified Ring-Adair-Elwyn ETT, or heated humidified high-flow nasal cannula should be considered during difficult airway management [28].

Inhalation induction of anesthesia using sevoflurane with maintenance of spontaneous ventilation is commonly performed in infants and children with a difficult airway. Intravenous access is established prior to mask induction. If the patient develops airway obstruction during the induction of anesthesia, immediate attempts are made to relieve the obstruction by head extension, jaw thrust, use of continuous positive airway pressure, and insertion of an oropharyngeal or nasopharyngeal airway. Oropharyngeal airway use may be of particular benefit in patients with glossomegaly such as those with Trisomy 21. If mask ventilation is inadequate and not improved with the above maneuvers, insertion of an SGA should be attempted. If positive pressure ventilation can be delivered via the SGA, the SGA can be used as a guide for insertion of an ETT or can be exchanged for an ETT with the use of a fiberoptic bronchoscope (FOB). If an SGA fails to provide a patent airway, preparations should be made for an emergency cricothyrotomy (see below). If mask ventilation is possible with either a face mask or SGA, neuromuscular relaxation can be used in order to optimize laryngoscopy. Recent data indicates that neuromuscular blockade can facilitate difficult mask ventilation and successful tracheal intubation. Moreover, with the ability of sugammadex at 16 mg/kg dose to reverse even profound neuromuscular blockade from non-depolarizing drugs, this approach can now be utilized with more confidence [3].

If mask ventilation is possible, but tracheal intubation is not readily achieved, one should optimize head and neck positioning and consider use of an alternate laryngoscope blade or video-laryngoscope to better visualize the larynx (the latter is often utilized as a primary device when difficult intubation is anticipated). Repeated attempts at direct laryngoscopy may lead to swelling and/or bleeding in the airway and the inability to perform adequate mask ventilation. After 3 failed attempts at direct laryngoscopy, the use of an SGA should be considered. For the majority of pediatric patients, insertion of an SGA provides a patent airway, a method of delivering positive pressure ventilation, and facilitates fiberoptic intubation.

For the patient with the known difficult airway requiring endotracheal intubation (e.g., those with predictably lengthy OR courses or predicted to require mechanical ventilation after surgery), visualization of the airway may be aided by video laryngoscopy. Devices such as the Glidescope

video laryngoscope (Verathon Medical, Bothwell, WA, USA) provide a highly angulated blade with a distal camera lens. The curve of this blade is designed to visualize structures "behind" the anatomic curve of the larynx, thereby aiding practitioners in obtaining a meaningful view of the vocal cords. The device is available in a wide range of pediatric sizes and some clinical studies demonstrating reduced time to intubation through its use [29]. However, the curve of this device requires a unique placement technique and not all practitioners may be familiar with its use. In addition, the disposable plastic blade cover is bulky and may interfere with passage of the ETT. The C-MAC (Karl Storz Endoscopy, Tuttlingen, Germany) couples standard Miller and Macintosh blades of multiple sizes with a distal fiberoptic lens. This allows for both direct laryngoscopy and/or video laryngoscopy using one device. Moreover, the angulation and distal position of the fiberoptic lens can provide an improved view of the difficult airway. Several studies have demonstrated improved pediatric intubation times with the use of this device [30].

Video laryngoscopy has become an essential tool in the management of the difficult intubation in patients of all ages, and a number of devices are available. Recent studies report the first attempt success rate is significantly higher with a video larygoscope than standard direct laryngoscopy in infants with normal airways [31]. In addition, a standard-blade video laryngoscope has a higher success rate on the first attempt (and eventual successful intubation) compared to a hyper-angulated blade video laryngoscope among infants less than 5 kg [32] (Figure 23.2).

Fiberoptic-guided tracheal intubation

The development of FOBs with small diameters has facilitated the use of fiberoptic-guided intubation in infants and young children. The FOBs designed for use with a 3.5 mm ID ETT or smaller do not have an associated suction channel. Fiberoptic guided tracheal intubation can be performed via the nose, mouth, or LMA under sedation and topical anesthesia or under general anesthesia. The nasal route may be preferred because it tends to maintain the scope in the midline, facilitating visualization of the larynx. Repeated practice in children with normal airways is recommended in order to acquire and maintain the skills essential to be proficient with the use of the FOB.

Fiberoptic-guided tracheal intubation can also be performed through a supraglottic airway device (SGA) (Figure 23.3) [28]. This technique is reported to have higher first attempt success rate than video-laryngoscopy (54% vs. 36%) in infants less than 1 year of age with difficult intubations; with no difference at older ages [33]. Once the SGA is

appropriately positioned, the FOB is passed through the opening of the SGA into the trachea. An ETT is passed into the trachea over the FOB, which is then used to confirm appropriate positioning. When a standard ETT is used, only a short length of the ETT remains outside the SGA, making maintenance of ETT position and removal of the LMA difficult. A variety of techniques have been described to facilitate safe removal of the LMA while maintaining the ETT in place. First, a specially designed, long ETT can be placed over the FOB. Second, a tracheal tube exchange catheter (Cook Critical Care, Inc., Bloomington, IN) can be passed through the ETT into the trachea after which both the ETT and SGA are removed. An ETT is passed over the exchange catheter into the trachea. Third, the ETT can be made temporarily longer by wedging a half size smaller ETT into the proximal end, or by cutting the 15 mm adapter and using it to connect two ETTs of the same size together. After placement of the combined ETTs through the SGA, the SGA and proximal ETT are removed and the 15 mm adapter is replaced. Lastly, long forceps typically used for rigid bronchoscopy, can be used to hold the ETT while the SGA is removed. An alternative to fiberoptic intubation through the SGA, is "blind" passage of the ETT through the SGA into the trachea. Intubating SGAs have been developed for this purpose and are now available as smaller sizes. In younger children, the epiglottis frequently folds inside the SGA [34]. While this may not cause airway obstruction, traumatic injury to the epiglottis may occur from blind passage of an ETT.

Several other methods for controlling the airway of patients with a difficult airway have been described. These include the use of a lighted stylet, Combitube ® (esophageal tracheal airway), retrograde transtracheal intubation, blind nasal intubation, use of other specialized laryngoscopes with or without video capability, and digital (tactile) techniques. The reader is referred to a textbook of general pediatric anesthesiology for more detailed descriptions of these alternative techniques for intubation.

Emergency cricothyrotomy

In the rare instance in which mask ventilation and placement of an SGA do not provide adequate oxygenation and ventilation and tracheal intubation cannot be performed, percutaneous cricothyrotomy may be lifesaving. Percutaneous tracheotomy kits are available (Cook Critical Care, Inc., Bloomington, IN) that are designed to facilitate pediatric tracheotomy tube placement through the cricoid membrane using the Seldinger technique [35].

The difficult extubation

Tracheal extubation of patients with risk factors for difficult reintubation presents a challenge to the anesthesiologist and intensive care physician. Infants and children with congenital heart disease are at a high risk for adverse consequences associated with oxygen desaturation, hypercapnia, and hemodynamic instability prior to or during attempted reintubation. Respiratory distress signaling the need for reintubation may develop at a time when a physician with the greatest expertise in airway management is not immediately available, e.g., late at night. This can occur in the recovery room or intensive care unit, where equipment and other conditions may be less optimal than those encountered in the

AL Grawany

operating room. In addition, reintubation may be technically more difficult than the initial intubation due to airway edema, bleeding, secretions, and poor patient cooperation. Fiberoptic intubation or other alternative techniques may be extremely difficult or impossible under these circumstances.

Practice guidelines set forth by the American Society of Anesthesiologists Task Force for the Management of the Difficult Airway recommend that anesthesiologists have a preformulated strategy for extubating patients with a difficult airway [36]. This may include placement of a device through the indwelling ETT that serves as a stent over which the ETT can be replaced if the patient fails extubation. Accordingly, tracheal extubation of patients with a difficult airway has been performed over a guidewire, FOB, gum-elastic bougie, and a jet stylet [37–40].

Because of their relatively large outer diameter, airway exchange catheters are not suitable for use in infants or small children for maintenance of airway access following tracheal extubation. The smallest available Cook Airway Exchange Catheter (CAEC, Cook Medical, Bloomington, IN), for example, has a 3.0 mm outer diameter [41]. In infants, this may severely limit gas flow around the catheter during spontaneous breathing. For young children, the use of a 0.018″ guidewire for maintenance of airway access following tracheal extubation has been reported [44]. The guidewire used was Teflon™-coated and had a floppy, curved tip designed to minimize tissue trauma during placement. This guidewire facilitates placement of the smallest CAEC over which a 3.5 mm ID ETT may be advanced, a method similar to previously described reports [42, 43].

Airway and ventilatory management for thoracic surgery

Ventilation / perfusion in the lateral decubitus position

Several pediatric cardiovascular surgical procedures are performed in the lateral decubitus position, including patent ductus arteriosus (PDA) ligation, insertion of a systemic to pulmonary shunt, repair of coarctation of the aorta, and unifocalization of the pulmonary arteries. Significant ventilation-perfusion (V/Q) abnormalities may occur in this position under general anesthesia. During awake spontaneous breathing, ventilation is normally distributed preferentially to dependent regions of the lung so that there is a gradient of increasing ventilation from the most non-dependent to the most dependent lung segments. Because of gravitational effects, perfusion normally follows a similar distribution, with increased blood flow to dependent lung segments. Therefore, ventilation and perfusion are normally well matched. During thoracic surgery, several factors may act to adversely affect V/Q matching. First, general anesthesia, neuromuscular blockade, and mechanical ventilation cause a decrease in functional residual capacity of both lungs. In addition, compression of the dependent lung in the lateral decubitus position may cause atelectasis. In certain circumstances (e.g. patients with cardiomegaly and/or dextroposition of the heart), simple positioning in the decubitus position can cause the myocardial mass to compress or obstruct the airways. Meanwhile, retraction and/or single lung ventilation result in collapse of the operative lung. Hypoxic pulmonary vasoconstriction (HPV), which acts to divert blood flow away from the under-ventilated lung, thereby minimizing V/Q mismatch, may be diminished by inhalational anesthetic agents and other vasodilating drugs. These factors apply equally to infants, children, and adults.

The overall effect of the lateral decubitus position on V/Q mismatch, however, is unique in infants. In adults with unilateral lung disease, oxygenation is optimal when the patient is placed in the lateral decubitus position with the healthy lung dependent (“down”) and the diseased lung non-dependent (“up”) [44]. This is presumably related to an increase in blood flow to the dependent, healthy lung and a decrease in blood flow to the non-dependent, diseased lung due to the hydrostatic pressure (or gravitational) gradient between the two lungs. This phenomenon optimizes V/Q matching in the adult patient undergoing thoracic surgery in the lateral decubitus position.

In infants with unilateral lung disease, however, oxygenation is improved with the healthy lung “up.” [49]. Several factors account for this discrepancy between adults and infants. Infants have a soft, easily compressible rib cage that cannot fully support the underlying lung. Therefore, functional residual capacity is closer to residual volume, making airway closure likely to occur in the dependent lung even during tidal breathing [45]. When the adult is placed in the lateral decubitus position, the dependent diaphragm has a mechanical advantage, since it is “loaded” from abdominal pressure. This pressure is reduced in infants, thereby reducing the functional advantage of the dependent diaphragm. The infant’s small size also results in a reduced hydrostatic pressure gradient between the non-dependent and dependent lungs. Consequently, the favorable increase in perfusion to the dependent, ventilated lung is reduced in infants. This may be especially true for infants with systemic-to-pulmonary artery shunts, e.g., modified Blalock-Taussig, PDA, or multiple aorto-pulmonary collateral arteries (MAPCAs), in whom systemic pressure may be maintained in the pulmonary arterial circulation.

Finally, infants have increased oxygen consumption compared to adults, predisposing them to hypoxemia. Infants normally consume 6–8 mL of oxygen per kg/min compared with 2–3 mL/kg/min in the adult [46]. The functional residual capacity of the lung serves as an oxygen reservoir when ventilation ceases. An infant will more rapidly consume oxygen from the diminished oxygen reservoir that is produced during surgery in the lateral decubitus position. Infants with cyanotic congenital heart disease are at an increased risk of life-threatening oxygen desaturation during thoracic surgery.

Single-lung ventilation (SLV)

Prior to 1995, nearly all thoracic surgery in children was performed by thoracotomy. However, today many thoracic procedures can be performed using video-assisted thoracoscopic surgery (VATS). Reported advantages of VATS include smaller chest incisions, reduced postoperative pain, and more rapid postoperative recovery compared with thoracotomy [47–49]. VATS is now being utilized for PDA occlusion in some centers. Open thoracotomy is generally performed for more complex procedures, including repair of coarctation of the aorta and pulmonary artery unifocalization.

Single lung ventilation (SLV) is desirable during VATS as well as open thoracotomy because lung deflation improves visualization of thoracic contents and may reduce lung injury caused by the use of retractors. Because of the technical challenges and potential time-consuming nature of achieving SLV, especially in small children and infants, a discussion with the surgeon is important to determine whether SLV is necessary. May cardiothoracic operations can be accomplished successfully with a "pack and retract" technique that allows access to the posterior mediastinum and vascular structures, e.g., aorta and PDA. When SLV is deemed necessary, there are several different techniques that can be used in children.

Single lumen endotracheal tube (ETT)

The simplest means of providing SLV is to intentionally intubate the non-surgical mainstem bronchus with a conventional single lumen ETT. When the left bronchus is to be intubated, the bevel of the ETT is rotated 180° and the head turned to the right [50]. The ETT is advanced into the bronchus until breath sounds on the operative side disappear. A FOB may be passed through or alongside the ETT to confirm or guide placement. When a cuffed ETT is used, the distance from the tip of the tube to the proximal cuff must be shorter than the length of the bronchus so that the cuff is entirely in the bronchus [51]. This technique is simple and requires no special equipment other than a FOB and may be the preferred technique of SLV in emergency situations such as airway hemorrhage or contralateral tension pneumothorax.

Problems can occur when using a single lumen ETT for SLV. If a smaller, uncuffed ETT is used, it may be difficult to provide an adequate seal of the intended bronchus. This may prevent the operative lung from collapsing adequately, or fail to protect the healthy, ventilated lung from contamination by purulent or bloody material from the contralateral lung. It is not possible to suction the operative lung using this technique. Hypoxemia may occur due to obstruction of the upper lobe bronchus, especially when the short right mainstem bronchus is intubated. Microcuff® endotracheal tubes (Kimberly Clark, Roswell, GA) have a thinner walled cuff positioned near the tip of the endotracheal tube and therefore may be advantageous for use in SLV.

Variations of this technique have been described, including intubation of both bronchi independently with small ETTs [52–55]. One mainstem bronchus is initially intubated with an ETT, after which another ETT is advanced over a FOB into the opposite bronchus.

Balloon tipped bronchial blockers

A Fogarty embolectomy catheter or an end-hole, balloon wedge catheter may be used for bronchial blockade to provide single lung ventilation [56–59]. Placement of a Fogarty catheter is facilitated by bending the tip of its stylette toward the bronchus on the operative side. A FOB may be used to position the catheter and confirm appropriate placement. An example of a method for placing an end-hole catheter outside the ETT is intentional intubation of the bronchus on the operative side with an ETT. A guidewire is then advanced into that bronchus through the ETT. The ETT is removed and the blocker is advanced over the guidewire into the bronchus. An ETT is then reinserted into the trachea alongside the blocker catheter. The catheter balloon is positioned in the proximal mainstem bronchus under fiberoptic visual guidance or fluoroscopy. With an inflated blocker balloon the airway can be completely sealed, providing more predictable lung collapse and better operating conditions than with an ETT in the bronchus.

A potential problem with this technique is dislodgement of the blocker balloon into the trachea. The inflated balloon will then block ventilation to both lungs and/or prevents collapse of the operated lung. The balloons of most catheters currently used for bronchial blockade have low volume, high pressure properties and over-distension can damage or even rupture the airway [60]. It has been reported, however, that bronchial blocker cuffs produced lower "cuff to tracheal" pressures than double lumen tubes [61]. When closed tip bronchial blockers are used, the operative lung cannot be suctioned and continuous positive airway pressure (CPAP) cannot be provided to the operative lung if needed.

Adapters are available that facilitate ventilation during placement of a bronchial blocker through an indwelling ETT [62, 63]. A 5 French endobronchial blocker that is suitable for use in children with a multiport adapter and FOB is commercially available (Cook Critical Care, Inc., Bloomington, IN) [64]. The risk of hypoxemia during blocker placement is diminished and repositioning of the blocker may be performed with fiberoptic guidance during surgery. Even with use of an FOB with a diameter of 2.2 mm, however, the indwelling ETT must be at least 4.5 mm ID to allow passage of the catheter and FOB. The use of this technique, therefore, is generally limited to children over the age of 18 months. Even in toddlers and children, passage of a suction catheter alongside the blocker catheter may be difficult.

Univent tube

The Univent™ tube (Fuji Systems Corporation, Tokyo, Japan) is a conventional ETT with a second lumen containing a small tube that can be advanced into a bronchus [65–67]. A balloon located at the distal end of this small tube serves as a blocker. Univent™ tubes require a FOB for successful placement. Univent™ tubes are available in sizes as small as a 3.5 and 4.5 mm ID for use in children over six years of age [68]. Because the blocker tube is firmly attached to the main ETT, displacement of the Univent™ blocker balloon is less likely than when other blocker techniques are used. The blocker tube has a small lumen which allows egress of gas and can be used to insufflate oxygen or suction the operated lung, but this feature is only present in size 6.0 and larger Univent™ tubes.

A disadvantage of the Univent™ tube is the large amount of cross sectional area occupied by the blocker channel, especially in the smaller size tubes which have a disproportionately high resistance to gas flow [69]. The Univent™ tube's blocker balloon has low volume, high pressure characteristics so mucosal injury can occur during normal inflation [70, 71].

AL Grawany

Double lumen tubes (DLTs)

All DLTs are essentially two tubes of unequal length molded together. The shorter tube ends in the trachea and the longer tube in the bronchus. DLTs for older children and adults have cuffs located on the tracheal and bronchial lumens. The tracheal cuff, when inflated, allows positive pressure ventilation. The inflated bronchial cuff allows ventilation to be diverted to either or both lungs and protects each lung from contamination from the contralateral side.

The smallest cuffed DLT is 26 Fr (Rusch, Duluth, GA), and may be used in children as young as 8 years old. The lumens of this DLT are small in diameter, and therefore, passage of a FOB or suction catheter is limited. DLTs are also available in sizes 28 and 32 Fr (Mallinckrodt Medical, Inc., St. Louis, MO) suitable for children 10 years and older.

DLTs are inserted in children using the same technique as in adults [72]. The tip of the tube is inserted just past the vocal cords and the stylet is withdrawn. The DLT is rotated 90 degrees to the appropriate side and then advanced into the bronchus. In the adult population the depth of insertion is directly related to the height of the patient [73]. No equivalent measurements are yet available in children. If fiberoptic bronchoscopy is used to confirm tube placement, a scope with a small diameter and sufficient length must be available [74].

A DLT offers the advantage of ease of insertion as well as the ability to suction and oxygenate the operative lung with CPAP. Left DLTs are preferred to right DLTs because of the shorter length of the right main bronchus [75]. Right DLTs are more difficult to position accurately because of the greater risk of right upper lobe obstruction.

DLTs are safe and relatively easy to use. There are very few reports of airway damage from DLTs in either adult or pediatric patients. Their high volume, low pressure cuffs should not damage the airway if they are not overinflated with air or distended with nitrous oxide while in place. In a study of 30 children aged 5 months-18 years with a median weight of 28 kg undergoing SLV with various devices including DLTs and bronchial blockers, the intracuff pressures in the tracheal and bronchial cuffs were measured [76]. Median tracheal cuff pressure was 32 cm H_2O (range 11–90), median bronchial cuff pressure 44 cm H_2O (range 10–100), and 65% of tracheal cuffs and 70% of bronchial cuffs had pressure exceeding the recommended 30 cm H_2O. A higher rate of overinflation was seen with bronchial blockers, vs. DLT or selective bronchial intubation. There were no clinical complications in the study, but the authors advised inflating the cuffs carefully and considering pressure monitoring of inflated cuffs.

Guidelines for selecting appropriate tubes (or catheters) for SLV in children are shown in Table 23.5. There is significant variability in overall size and airway dimensions in children, particularly in teenagers. The recommendations shown in Table 23.5 are based on average values for airway dimensions. Larger DLTs may be safely used in large teenagers.

Recent data concerning bronchial diameters and single lung ventilation in small children

In recent years, additional data about bronchial diameters in young children have become available through high resolution CT scanning and have informed selection criteria for sizes of bronchial blockers, double lumen ETTs, and other devices. One scheme is displayed in Table 23.6 [77]. In smaller children less than 2 years of age, extraluminal placement of a bronchial blocker is the only viable technique (besides endobronchial intubation) to provide SLV because of the small diameter of the ETT relative to the blocker catheter and FOB utilized for placement. Larger children who can accept a 5.0 mm ID ETT or larger are candidates for intraluminal blocker placement (Figure 23.4). Approaches to place the extraluminal bronchial blocker in small children include the "bending the rules" approach (Figure 23.5), and the intra-to extraluminal approach (Figure 23.6).

Table 23.7 summarizes the strategies for SLV in infants and young children, with the advantages and disadvantages of each method [80].

Ventilatory management during thoracic surgery

During two-lung ventilation, tidal volumes of 6–8 mL/kg are typically used at a respiratory rate that provides normocapnia. When one lung is ventilated, the delivered tidal volume should be reduced to 4–5 mL/kg, and the respiratory rate increased in order to avoid excess inspiratory pressure to the ventilated lung. Pressure control ventilation can also be used, in which case attention must be directed at tidal volumes, which may be decreased with manipulation of the thoracic contents. Pulse oximetry and capnography reflect trends in the changes in oxygenation and ventilation but monitoring of arterial blood gas tensions is important to accurately determine PaO_2 and $PaCO_2$ during single lung ventilation in infants and children with congenital cardiac disease. Hypercapnia and hypoxemia may cause a reduction in cardiac output, as may hyperinflation of the ventilated lung.

Hypoxemia is commonly encountered during thoracic surgical procedures, especially in children with CHD and preexisting hypoxemia, impaired myocardial function, and/or pulmonary hypertension. Hypoxemia develops from one or

more possible mechanisms. The conducting passages of the operative lung are intentionally obstructed during single-lung ventilation and/or from surgical retraction and compression of the operative lung. Secretions in the airways as well as surgical and hydrostatic compression may also compromise gas flow through the conducting passages of the dependent lung. The reduction in ventilation to the operative lung produces regional hypoxemia that induces hypoxic pulmonary vasoconstriction (HPV), which will reduce ventilation/perfusion (V/Q) mismatch. However, HPV may be impaired in children with CHD. It has been shown in a dog model that HPV is impaired by elevated pulmonary arterial pressure and by low mixed venous oxygen tension, both of which are commonly encountered among children with CHD [78, 79]. Retraction of the operative lung may compress the mediastinum, impairing cardiac filling and reducing cardiac output These changes, in turn, cause a decrease in mixed venous oxygen concentration and exacerbate hypoxemia from intracardiac and/or intrapulmonary shunting.

Severe hypoxemia should be treated immediately by increasing the FiO_2 to 1.0 and by confirming patency of the ETT. A suction catheter should be passed through the ETT to clear secretions and/or blood from the lumen. Irrigation with sterile saline may be beneficial. If the ETT remains occluded, an FOB may be used to determine the site of obstruction and to reestablish patency of the ETT. The surgeon should be informed, and compression of the lung and/or mediastinum should be minimized. Administration of intravenous fluids may improve cardiac output and improve V/Q matching by increasing perfusion pressure to the lungs. Application of continuous positive airway pressure (CPAP) with 100% O_2 to the non-dependent lung will reduce intrapulmonary shunt and improve oxygenation during SLV. If hypoxemia persists despite these maneuvers, the operative lung should be re-inflated with 100% oxygen. Although nitric oxide might be expected to increase pulmonary blood flow to the ventilated lung and improve oxygenation, two studies in adults failed to show benefit from nitric oxide during SLV [80, 81].

Some degree of hypoxemia is expected during SLV. In a study of 52 children without CHD undergoing SLV during VATS, a decrease in SpO_2 occurred in 40% of patients in whom a bronchial blocker was used [82]. The bronchial blockers used did not have lumens for administration of CPAP/ O_2. Forty percent of patients in this study also had $PaCO_2$ values >50 mmHg, although the clinical significance of hypercarbia was not documented. In another study of 12 pediatric patients in whom VATS was performed for closure of patent ductus arteriosus, CO_2 insufflation and hypercarbia ($PaCO_2$ 50–70 mmHg) were not associated with circulatory impairment [83]. In fact, the authors reported that hypercarbia was associated with increased cardiac output and central venous and arterial O_2 tension in these patients. The specific mechanism of these effects of hypercarbia, e.g., changes in Qp:Qs, were not described.

Changes in lung function in children with CHD

Ventilation may be impaired in children with increased pulmonary blood flow due to left-to-right shunts. Both decreased lung compliance and increased airway resistance have been demonstrated in these children. Two studies in infants and young children with CHD found strong correlation between echocardiographic evidence of pulmonary artery engorgement and decreased lung compliance [84, 85]. A study of neonatal patients undergoing thoracotomy for Blalock-Taussig (BT) shunt placement or repair of coarctation of the aorta [86] determined that lung compliance decreased and airway resistance significantly increased after surgery. The return to baseline pulmonary function was prolonged after BT shunt placement when compared with coarctation repair, suggesting that an increase in pulmonary blood flow worsens pulmonary mechanics [86]. Some infants develop substantial increases in total lung resistance following heart surgery, the severity of which can be predictive of postoperative respiratory failure [87]. Acute increases in pulmonary artery pressure also produce significant changes in lung mechanics. One study demonstrated that airway resistance increases 43% and compliance decreases 11% during periods of acute pulmonary hypertension [88]. In this study, lung biopsy specimens from patients with the greatest increase in pulmonary artery pressure had increased bronchial smooth muscle mass, suggesting that the same local mediators that affect increases in pulmonary arterial pressure also may cause bronchospasm. Changes in lung mechanics correlate better with the magnitude of pulmonary vascular engorgement than with pulmonary artery hypertension. During cardiac catheterization, the degree of increased pulmonary blood flow is proportionate to increases in respiratory resistance among infants who are mechanically ventilated [89]. Infants with CHD and pulmonary overcirculation have reduced dynamic compliance and increased respiratory resistance that often improves following surgery [90].

Extrinsic compression of larger airways by the heart and vascular structures can also affect lung function in children with CHD. Both left and right mainstem bronchial compression have been described from enlarged pulmonary arteries. An enlarged left atrium can compress the left mainstem bronchus, and bronchial compression can occur from extrinsic compression by a right ventricle-to-pulmonary artery conduit [91].

Table 23.7 Summary of strategies for SLV in infants and young children

Strategy for OLV	Appropriate Age	Advantages	Disadvantages
Endobronchial intubation	<5 years	• Easy to perform • No special blocker or tube required • Can be performed blindly, with fiberoptic assistance or under fluoroscopy • Good quality isolation • Technique of choice in young children with a difficult airway	• Difficult to change to two-lung ventilation • ETT can become occluded with blood and/or secretions • Easy to occlude right upper lobe bronchus with right-sided endobronchial intubation • Inability to suction nonventilated lung or apply CPAP
Bronchial blocker	All age groups	• High quality of isolation • Rapidly change from OLV to two-lung ventilation • Appropriate for all ages depending on size and type of blocker • Intra or extraluminal use • Appropriate for children with a tracheostomy • Can be used in combination with a supraglottic airway	• Can be technically challenging to position • CPAP to nonventilated lung may be ineffective • Can be easily dislodged as a result of surgical manipulation
Univent tube	>8 years	• High quality of isolation • May be more positionally stable than a bronchial blocker • Easy to change from OLV to two-lung ventilation	• Appropriate for children ≥8 years of age • Smaller ventilating lumen relative to patient size may lead to increased resistance
Double lumen tube	>8 years	• Usually straight forward to position • High quality of isolation • Positionally stable • Easy to change from OLV to two-lung ventilation • Can suction and apply CPAP to nonventilated lung	• Appropriate for children ≥8 years of age • Potentially increased rates of glottic or tracheal injury • Not appropriate in most children with a difficult airway

CPAP, continuous positive airway pressure; ETT, endotracheal tube; OLV, one lung ventilation.

Changes in lung function from CPB

Pulmonary dysfunction is common after cardiac surgery [92]. Children with increased pulmonary blood flow due to left-to-right shunting may develop up to a three-fold increase in lung water in the immediate post-operative period, the degree of which appears to be related to the presence of pulmonary hypertension [93, 94]. In addition, both quantitative and qualitative differences in surfactant have been described in children after CPB [95]. Others have found that the most common adverse pulmonary effect of CPB is the development of atelectasis, reported to be as high as 82% among children undergoing CPB [96]. Both noncardiogenic pulmonary edema and acute bronchospasm have also been reported following CPB in children and adults, [97, 98] although the incidence of these complications in children is unknown. Some authors found correlation between the duration of CPB and the severity of lung injury while others found only minor changes in pulmonary mechanics related to CPB [90, 99–101]. These differences may be related to improvements in CPB management over the past decade. A study of over 100 infants undergoing heart surgery found no correlation between the duration of CPB, the duration of aortic cross clamp, the use of deep hypothermic circulatory arrest, and pulmonary outcomes [102].

Cardiopulmonary interactions

Positive intrathoracic pressure typically has adverse hemodynamic effects on the right ventricle and variable hemodynamic effects on the left ventricle in patients with normal cardiac anatomy and function. Intrathoracic pressure is transmitted to the thin-walled, compressible superior and inferior venae cavae, reducing venous blood return to the right atrium and leading to a decrease in right ventricular filling [103]. In addition, right ventricular output will decrease if pulmonary vascular resistance (PVR) increases from hyperinflation of the lungs. With acute rises in PVR, the right ventricle may become dilated, resulting in decreased left ventricular filling as the intraventricular septum is displaced to the left [104].

PVR is affected by mechanical factors, chemical factors, and local humoral factors. PVR is optimal when the resting lung volume is at functional residual capacity (FRC) and becomes elevated when lung volumes are above or below FRC. As lung volume decreases below FRC extra-alveolar (large) blood vessels are compressed. In addition, atelectasis develops when lung volume decreases, leading to hypoxic pulmonary vasoconstriction with associated elevation in PVR. When lung volumes exceed FRC, alveolar distension causes compression of smaller arterioles and

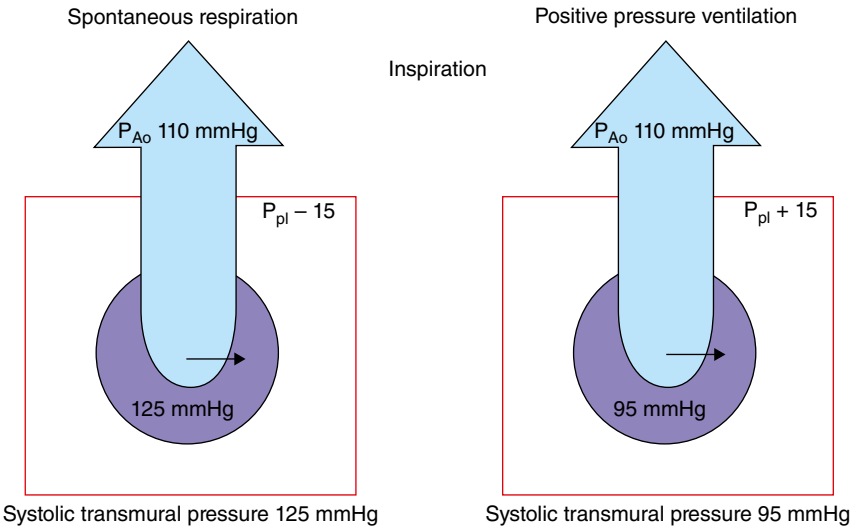

Figure 23.7 The effect of positive pressure ventilation on systemic ventricular transmural pressure. P_{Ao}, aortic pressure; P_{pl}, pleural pressure.

capillaries, also resulting in an increase in PVR [105] (Figure 23.2). Both oxygen tension and pH have significant effects on PVR [106], with alveolar hypoxemia and acidemia causing an increase in PVR; alkalemia causes a reduction in PVR. Local pH has the greatest effect on pulmonary vascular tone, and PVR is reduced by producing either respiratory or metabolic alkalemia. Finally, lung expansion from positive pressure ventilation causes a local release of prostaglandins, leading to pulmonary vasodilation. This may explain the decrease in PVR associated with the onset of hyperventilation that occurs before CO_2 is reduced [106].

Changes in pleural pressure also affect left ventricular function. Ventricular output is affected by changes in afterload of the ventricle from transmitted intrathoracic pressure to the ventricular wall. The left ventricle lies within the thoracic cavity whereas most of the systemic arterial tree lies outside the thoracic cavity. Therefore, changes in pleural pressure affect the left ventricle and not the systemic vasculature. Afterload is affected by the ventricular transmural pressure i.e., the intracavitary pressure minus the pleural pressure. During spontaneous ventilation, negative intrapleural pressure is transmitted to the ventricular wall. During systole, the ventricle must overcome systemic vascular resistance and pleural pressure; therefore, afterload is increased when negative pleural pressure develops as occurs during spontaneous ventilation. With positive pressure ventilation, systemic vascular resistance is unchanged, but afterload to the ventricle is reduced because positive intrapleural pressure reduces ventricular transmural pressure [107–109] (Figure 23.7).

Mechanical ventilation for children with CHD

Changes in pleural pressure during inspiration have a variety of hemodynamic effects on patients with cardiac and/or pulmonary disease. In healthy individuals, spontaneous inspiration augments venous return and increases right ventricular output while increasing left ventricular afterload and decreasing left ventricular output. The net effect on total cardiac output is minor, and the conversion to positive pressure ventilation will have minimal effects on cardiac output. However, in hypovolemic patients cardiac output decreases from positive pressure ventilation because the decrease in right ventricular preload produces the predominant hemodynamic effect.

In patients with significant right heart dysfunction, mechanical ventilation parameters should be selected that will minimize intrathoracic pressure, maintain lung volume at FRC, avoid hypoxemia, and optimize pH in order to minimize PVR. Intrathoracic pressure should be minimized by avoiding excess positive end-expiratory pressure (PEEP) and excessively large tidal volumes. Again, it should be emphasized that lung volumes *below FRC* will also lead to an increase in PVR. Thus, PEEP should be titrated to achieve physiologic FRC throughout the operative case. Pressure volume loops can be used to optimize pulmonary mechanics (Figure 23.8). Hyperventilation is the traditional maneuver performed to reduce PVR because the associated hypocarbia produces alkalemia. However, both metabolic and respiratory alkalosis reduce pulmonary vascular resistance [106, 110]. Local tissue pH is the most significant factor affecting tone in pulmonary vessels. Because hyperventilation requires an increase in minute ventilation, greater intrathoracic pressure must be used which may reduce right ventricular preload. Creating a metabolic alkalosis through the administration of sodium bicarbonate will produce the same beneficial effect on reducing PVR without interfering with right ventricular filling. Inhaled nitric oxide or high concentrations of inhaled oxygen may further reduce PVR in patients with pulmonary hypertension and will improve right heart output.

Acute increases in PVR often produce profound systemic hypotension because left ventricular filling is significantly impaired from both a reduction in preload (right heart output) and a leftward shift of the intraventricular septum as the right heart dilates. Diastolic hypotension reduces coronary

AL Grawany

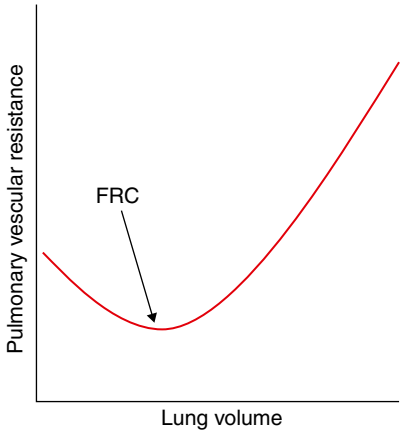

Figure 23.8 Relationship of lung volume to pulmonary vascular resistance. FRC, functional residual capacity.

perfusion to a stressed myocardium which may rapidly result in cardiovascular collapse.

Positive pressure ventilation improves cardiac output among patients with left ventricular systolic failure [111, 112]. As the left ventricle fails and begins to dilate, left atrial pressure is increased, leading to pulmonary venous congestion and decreased lung compliance. Work of breathing is increased and greater negative pressure is generated during spontaneous ventilation, which, in turn, increases left ventricular afterload. Positive pressure ventilation may decrease the work of breathing and thereby decrease oxygen consumption. In addition, positive intrathoracic pressure will reduce ventricular afterload, enhancing cardiac output. However, patients with diastolic ventricular dysfunction will have small stroke volumes as their stiff, hypertrophied myocardium does not adequately relax. The reduction in preload from positive pressure ventilation produces the predominant effect on cardiac output. Studies on patients with tetralogy of Fallot, who commonly have right ventricular diastolic dysfunction, show that cardiac output increases with negative pressure ventilation [113].

Patients with non-pulsatile pulmonary blood flow (e.g., following bidirectional cavopulmonary anastomoses and Fontan procedures) show the most dramatic interactions between alterations in intrathoracic pressure, pulmonary blood flow, and cardiac output. Because they lack pulsatile flow in their pulmonary arteries, positive intrathoracic pressure interferes with pulmonary blood flow in these patients. Likewise, elevations in PVR reduce pulmonary blood flow. Reductions of pulmonary blood flow impair ventricular filling and reduce cardiac output. Maintenance of physiologic FRC and use of small tidal volumes is critical in these patients. PEEP is commonly avoided in Glenn and Fontan patients in order to diminish intrathoracic pressure. However, atelectasis and lung volumes below FRC will increase PVR and these changes can be minimized through the use of PEEP. Delivering the appropriate amount of PEEP during mechanical ventilation of patients with single ventricle physiology is warranted.

Negative pressure ventilation produces a significant improvement in stroke volume and pulmonary blood flow over that of conventional positive pressure ventilation [114]. High-frequency jet ventilation effectively reduces $PaCO_2$ at a lower mean airway pressures than conventional mechanical ventilation and has been shown to improve cardiac output when compared to conventional ventilation in postoperative Fontan patients [115].

In patients with lung disease associated with collapsed or fluid filled alveoli (atelectasis, pulmonary edema, pneumonia, ARDS) gas exchange improves when FRC is re-established through the use of PEEP. The application of PEEP has variable cardiovascular effects depending on lung compliance. Even high levels of PEEP have limited effect on cardiac output when lung compliance is reduced, because the higher airway pressures are not transmitted to the heart and pulmonary vasculature [116]. Some congenital heart defects such as tetralogy of Fallot with absent pulmonary valve are associated with small and large airway compression from engorged pulmonary arteries. These patients develop airway collapse during exhalation and typically manifest hyperinflation of some lung segments and atelectasis in other areas [117]. Such children benefit from a ventilatory strategy that increases exhalation time, i.e., a slower ventilatory rate. Optimal levels of PEEP can be determined by pressure-volume and flow-volume loops (Figure 23.8). Similarly, patients with left-sided obstructive lesions such as mitral valve stenosis, hypertrophic/obstructive cardiomyopathy, and/or aortic stenosis are at risk for the development of significant pulmonary edema secondary to left atrial hypertension. Increased left atrial pressure can limit pulmonary venous drainage, prompting hydrostatic extrusion of fluid into the pulmonary interstitium and air spaces. While ventilatory strategies may not completely relieve the left-sided obstruction, patients will benefit both from the restoration of FRC through the use of PEEP and from the reduction in left ventricular afterload with carefully titrated positive pressure ventilation.

Lung management during CPB

Studies performed in animal models and adult patients have compared use of continuous mechanical ventilation, intermittent sigh breaths, and CPAP during CPB. Most studies show improvement in postoperative gas exchange with CPAP; however, this difference appears to be short-lived [118, 119]. No such studies have been performed in children. Because closing capacity is higher in infants, maintaining airway patency through the application of CPAP would theoretically be beneficial. Lung inflation from CPAP, however, may interfere with adequate surgical access to the heart and complete lung collapse is usually required. An FiO_2 of 0.21 versus 1.0 has the theoretical benefit of diminishing absorption atelectasis during CPB, although this also has not been studied in children. Before weaning from CPB and after confirmation of the absence of air in the left atrium and ventricle, vital capacity breaths should be administered in order to re-establish patency of collapsed airways and alveoli [120] and to mobilize retained secretions. The tracheal tube should be suctioned prior to weaning from CPB to assure patency of the tracheal tube and large airways, but care must be taken in order to avoid tracheal mucosal injury producing hemorrhage in a fully anticoagulated patient. Inhaled beta-2 agonists are often administered before weaning from CPB in order to decrease airway reactivity; however, the efficacy of this practice has not been proven.

Volume control vs. pressure control ventilation

Volume-limited (volume control) ventilation delivers a relatively constant tidal volume despite changes in total pulmonary compliance. During volume-controlled ventilation the peak inspiratory pressure varies and is dependent on the set tidal volume, PEEP, gas flow rate, gas flow resistance, and respiratory system compliance. The presence of high inflation pressures signals decreased pulmonary compliance or conductance (e.g., offset of neuromuscular blockade, bronchospasm) or obstruction of the breathing circuit (e.g., occluded ETT). Disadvantages of volume-limited ventilation include the potential to produce very high inflating pressures and increase the risk of barotrauma. With proper monitoring of inspiratory pressure, including the use of appropriate limits and alarms, changes in the patient's pulmonary mechanics can be observed and the risk of barotrauma minimized. Because of technical difficulties in accurately delivering very small tidal volumes (e.g., <100 cc), volume-limited ventilators have been primarily used in patients over 10 kg body weight. More recently, however, ventilators have been introduced that may safely be used in a volume-limited mode for smaller patients, i.e., with a low incidence of hypoventilation as well as volutrauma [121, 122].

In the neonate and infant, anesthesia ventilators that are pressure-limited and time-cycled are commonly used. These ventilators offer the advantages of avoiding excessive inflating pressures and barotrauma. However, a decrease in the compliance or conductance of the patient's respiratory system, ventilator circuit, or tracheal tube will cause a reduction in delivered tidal volume. An increase in compliance, conversely, will result in an increased tidal volume and the risk of volutrauma. Pressure limited or pressure control ventilation (PCV) is frequently applied to infants and children receiving mechanical ventilatory support in which severe pulmonary pathology dictates the need for rapid respiratory rates or high inflating pressures. Advantages of this mode of ventilation include limiting the peak inflating pressure delivered by the ventilator, thereby limiting the trans-alveolar pressure and ventilator-induced lung injury [123]. The decelerating flow used during PCV is thought to improve the distribution of gas flow to the lungs [124]. When compared with volume control ventilation there is a more rapid improvement in lung compliance and oxygenation with PCV [125]. Older anesthesia ventilators may not deliver small tidal volumes accurately because of the proportionately large compression volume loss in the ventilator and circuit [126]. Therefore, setting an anesthesia ventilator in pressure control mode will deliver more consistent ventilation to infants when the anesthesia machine cannot compensate for compression volume loss in the entire circuit [122]. Modern anesthesia ventilators are capable of delivering accurate tidal volumes down to 20 mL.

Monitoring ventilation

Ventilation is the tidal exchange of gas between lungs and the atmosphere and is reflected in the concentration of CO_2 in arterial blood ($PaCO_2$). In the operating room, the most common non-invasive method of measuring CO_2 is capnography, which closely reflects changes in $PaCO_2$ among patients without lung or heart disease. Capnography is less accurate in infants when there is a leak around the ETT and when CO_2 is measured at the Y piece due to fresh gas washout of the small volume of gas sampled [127]. Another measurement of alveolar ventilation is the measurement of exhaled tidal volumes (V_T). Exhaled V_T is usually measured by a spirometer located at the end of the expiratory limb. This measurement overestimate actual V_T because it reflects the patient's exhaled V_T as well as the compression volume in the breathing circuit. However, modern anesthesia ventilators subtract the compression volume and provide a V_T measurement that is accurate unless there is a large leak in the circuit. A leak around the ETT will produce an underestimate the actual exhaled gas volume. As stated earlier in the chapter, the use of cuffed endotracheal tubes allows safer, more accurate delivery and assessment of mechanical ventilation in infants. Because end-tidal CO_2 may significantly underestimate arterial CO_2 due to dead space ventilation, particularly in patients with reduced pulmonary blood flow, blood gases should be measured frequently in order to assure adequate ventilation and to monitor changes in acid-base status.

Anesthesia ventilators

When using volume-controlled ventilation, the goal of modern ventilator designs is to deliver a volume to the patient that is as close as possible to the volume set to be delivered. To achieve this goal, the ventilator must be able to compensate for both the compliance of the breathing system and the influence of fresh gas flow on tidal volume, independent of changes in lung compliance. Modern bellows ventilators (e.g., Aestiva®, Avance®, and Aisys® from GE Healthcare, Madison, WI) utilize a flow sensor at the inspiratory limb to control the volume delivered by the ventilator. The ventilator output is controlled by the flow sensor such that the set volume is delivered to the breathing circuit independent of changes in fresh gas flow or the compliance of the system between the ventilator and the flow sensor. Piston anesthesia ventilators (e.g., Fabius GS®, Apollo® and Perseus® A500 from Draeger Medical, Telford, PA) measure the compliance of the breathing system during the pre-use checkout. The compliance measurement is then used to determine how much additional volume must be added to each breath to deliver the set volume to the patient. The influence of fresh gas on delivered volume is eliminated in the piston design by altering the configuration of the circle system and including a valve that prevents fresh gas from entering the patient circuit during mechanical inspiration. In addition, the exhaled volume measurement is corrected using the circuit compliance measurement.

Newer generation anesthesia ventilators that compensate for breathing circuit compliance and for fresh gas flow are able to deliver small tidal volumes accurately under conditions of normal and low lung compliance during volume-controlled ventilation. Anesthesiologists should be aware that long, compliant circuits reduce the efficiency of ventilator performance, and increasing the circuit compliance by extending a collapsible circuit will reduce tidal volume delivery [129]. When providing ventilation for an infant with poor lung compliance, using a fixed length circuit with smaller hoses that are less compliant will optimize the anesthesia

AL Grawany

ventilator performance. Also, dead space ventilation can be reduced by eliminating the Y-piece and using a low-dead space heat and moisture exchanger that contains a gas sampling port. Despite significant improvements in anesthesia ventilator technology for smaller infants, an "ICU-type" ventilator may deliver better performance in terms of intended tidal volumes and ventilating pressures in small infants with poor lung compliance. These ventilators are capable of higher working gas flows, have lower dead space, and precisely control of all ventilatory parameters through advanced microprocessor designs. Assistance from a respiratory therapist may be advised in this situation because of the lack of familiarity with this equipment for most anesthesiologists.

Operating room to ICU transition

Depending upon the type and length of procedure, the patient's age and size, and any intraoperative complications, many patients will require continued mechanical ventilatory support in the postoperative period. When transitioning from the operating room to the intensive care unit, respiratory management should continue to focus upon the maintenance of FRC. This "open lung" strategy is designed to minimize PVR, optimize left ventricular afterload, and reduce any ongoing lung injury following the same principles described earlier in this chapter. Adjustment of PEEP based on flow-volume loops and the post-operative chest radiograph are traditionally tools in used to optimize the "open lung" strategy. Many ICU ventilator models allow for the use of novel forms of ventilatory management to attain and maintain physiologic FRC.

First described in adults in 1987 [130], airway pressure release ventilation (APRV) is a form of inverse-ratio ventilation generally used during spontaneous breathing. In this form of ventilation, patients spend the majority of the mechanical respiratory cycle at the set peak pressure (P_{Hi}), allowing for continual recruitment of alveoli. Spontaneous respirations oscillate around this P_{Hi} and patient effort is supplemented by "release breaths" in which the ventilator pressure is allowed to drop to a low pressure (P_{Low}). The mode is time-cycled and designed to provide sufficient time in the exhalatory phase to allow ~70% reduction of the lung volume [131]. While the continuous air-space recruitment of this mode is attractive, data in pediatric patients are mixed. At least one randomized, controlled study required early termination due to increased mortality in patients supported with APRV [132]. Moreover, the cardio-pulmonary interactions of APRV are, to date, inadequately described in the literature.

Another common form of non-conventional, high-pressure ventilation, high-frequency oscillatory ventilation (HFOV), is used in pediatric intensive care units in patients with refractory hypoxemia. Multiple recent trials and meta-analyses have shown no significant reduction in mortality, length of stay, or duration of mechanical ventilation with the use of HFOV compared with conventional ventilation [133–135]. Accordingly, many ICU providers will opt to continue conventional ventilation and utilize high PEEP levels up to 12–14 cm H_2O to maintain alveolar recruitment rather than initiate HFOV in postoperative cardiac patients.

Application of relatively high levels of PEEP to maintain alveolar patency is especially important following cardiac surgery in infants and children. In addition to the impact of cardio-pulmonary interactions on postoperative care, developments such as pulmonary hemorrhage, pulmonary edema, and/or mechanical airway compression related to swelling of the heart and adjacent structures may all necessitate higher PEEP settings. Should lung compliance be noted to decline in the OR, or if intraoperative events predict the evolution of poor lung compliance, consideration should be given to delaying sternal closure after completion of the operative course. Leaving the chest open for 24–48 hours may reduce mechanical compression of the heart and lungs and mitigates chest wall restriction of the circulation and the respiratory system. If lung compliance is very poor following surgery, extra-corporeal membrane oxygenation (ECMO) may be considered to allow lung recovery while minimizing airway pressure and its effects on ventricular function.

Specialized problems

Hypoxic gas mixture and inspired CO_2

Infants and children with single ventricle physiology and excess pulmonary blood flow (e.g., those with hypoplastic left heart syndrome) may benefit from a ventilatory strategy designed to increase PVR and diminish pulmonary blood flow. Hypoxic gas mixtures (i.e., $FiO_2 < 0.21$) or inhaled CO_2 have been used to accomplish this. Among neonatal patients with single ventricle physiology, 3% inhaled carbon dioxide improves cerebral oxygen saturation, mean arterial pressure, and oxygen delivery when compared with 17% inspired oxygen [128, 136]. However, both of these therapies are rarely applied today because of the added difficulty and risk of safely providing stable mechanical ventilation with adequate oxygenation. Infants with elevated Qp:Qs ratios are more safely managed via agents designed to reduce systemic vascular resistance (e.g., milrinone, clevidipine, sodium nitroprusside) or through surgical reduction in Qp (i.e., partial clipping of the aortopulmonary shunt).

Nitric oxide

Nitric oxide (iNO) is an endothelium-derived smooth muscle relaxant that has been used in neonates with persistent pulmonary hypertension [137, 138] and in infants and children with pulmonary hypertension related to congenital heart disease [139, 140]. iNO has also been used in adult and pediatric patients with severe hypoxemic respiratory failure due to acute lung injury [141–145]. Inhaled NO selectively reduces PVR and may decrease intrapulmonary shunting. As a result, oxygenation is improved in patients with acute lung injury due to increased perfusion of relatively well-ventilated lung units and resultant improvement in V/Q matching. Pulmonary vascular resistance and oxygenation are improved to a similar extent by doses between 10 and 60 ppm in children with acute lung injury [146]. In one study, infants with pulmonary hypertension after cardiac surgery had a decrease in pulmonary artery pressures and a 30% increase in oxygenation from the use of as little as 3 to 5 ppm of iNO with no further benefit from increasing iNO to as high as 80 ppm [147]. However, other studies have failed to show sustained improvements in PVR, oxygenation, or

outcome with the use of iNO [148, 149]. Despite a lack of high quality evidence demonstrating outcome improvements, iNO has become a mainstay of intraoperative and postoperative therapy in congenital heart disease, particularly in two-ventricle patients with known pulmonary hypertension receiving chronic vasodilators, single ventricle patients with increased PVR, those with left ventricular assist devices, who often have elevated PVR, and cardiac transplant patients with elevated PVR [150–153].

Tracheostomy in congenital heart disease

Upper and lower airway anomalies are common in infants and children with CHD. Chronic lung disease occurs in premature infants with CHD a well as those with long-standing pulmonary edema, and may result in the need for prolonged mechanical ventilation following cardiac surgery. Tracheomalacia due to vascular rings often require months to improve after reparative surgery. CHD patients may suffer perioperative neurological insults and require long term mechanical ventilation for airway protection or due to airway obstruction. In these patients tracheostomy may provide a stable airway, allow for a reduction in the need for sedation, and improve the ability for infants and children to move and interact with their surroundings. This, in turn, can lead to better physical rehabilitation, more beneficial neurodevelopmental interventions, and better facilitation of discharge to chronic care units or to home. Criteria for tracheostomy vary between institutions and generally are more conservative than for adult indications. However, mechanical ventilation for greater than 30 days and/or failure of multiple ventilation weaning attempts, with limited prospects for improvement in the near future, are common indications.

An analysis of the Society of Thoracic Surgeons' Database cases from 2000 to 2014 found that of 211,408 cardiac operations, 648 (0.31%) underwent postoperative tracheostomy [154]. The median age at tracheostomy was 2.5 months, and prematurity (26%), genetic abnormalities (46%), and preoperative mechanical ventilation (43%) were common risk factors. Postoperative adverse events after the cardiac operation were also commonly associated factors, including cardiac arrest in 20%, the use of ECMO in 13%, phrenic or laryngeal nerve injury in 18%, and neurological injury in 8%. Postoperative cardiac mortality in patients with tracheostomy was 25%. The incidence of tracheostomy increased from 0.11% in early years of the study to a peak of 0.76% in 2012. The primary diagnosis and surgical procedures in patients undergoing tracheostomy are displayed in Table 23.8. Higher volume centers (>350 cardiac surgeries annually) had a 50% lower postoperative tracheostomy rate than lower volume centers (0.34% vs. 0.61%). In a Pediatric Health Information System Database study of 5,721 hypoplastic left heart syndrome patients, 2.2% underwent postoperative tracheostomy [155]. In a separate study of the same database, 2.8% of orthotopic heart transplant patients underwent postoperative tracheostomy [156]. Tracheostomy was not associated with an increased incidence of mediastinitis.

Table 23.8 Most common primary diagnoses and procedures for patients requiring tracheostomy after operation for congenital heart disease, January 2010 to June 2014

Diagnoses and procedures	n (%)[a]	Mortality, n (%)[b]
Primary diagnosis		
Hypoplastic left heart syndrome	62 (9.6)	25 (44)
Other single-ventricle lesions	50 (7.7)	13 (26)
Atrioventricular septal defect, complete	44 (6.8)	8 (19)
Ventricular septal defect, type 2	29 (4.5)	2 (7)
Patent ductus arteriosus	25 (3.9)	6 (24)
Pulmonary atresia, ventricular septal defect	20 (3.1)	6 (32)
Tetralogy of Fallot, absence of pulmonary valve	20 (3.1)	6 (33)
Truncus arteriosus	19 (2.9)	3 (17)
Coarctation of aorta	17 (2.6)	1 (7)
Tetralogy of Fallot	14 (2.2)	2 (14)
Primary procedure		
Norwood procedure	47 (7.3)	15 (33)
Pulmonary artery banding	33 (5.1)	7 (23)
Atrial septal defect creation/enlargement	30 (4.6)	5 (17)

[b] Data are represented as absolute counts with percentages of patients with each underlying diagnosis or primary procedure.

Placement of tracheostomy tubes

Tracheostomy tube (TT) designs have advanced significantly in recent years, and there are many varieties of TT that feature cuffs that can be air filled or water-filled and can be custom-made based on the patient's unique anatomy, i.e., long-segment tracheal stenosis. Multidisciplinary preoperative planning with the otolaryngology and ICU teams is important to ensure that the anesthesiologist is familiar with the TT being placed. Standard surgical and ICU protocols for TT placement include the type of incision and "stay" sutures as well as plans for postoperative sedation and first tracheostomy change by otolaryngology team; reduced variation in post-TT care promotes risk reduction during the postoperative course [157]. The operative plan needs to be well understood and communicated before the surgery. The surgical and anesthesia team should discuss plans for electrocautery - lower inspired oxygen concentrations reduce the risk of intraoperative airway fire. Important aspects of anesthetic care during TT placement also include management of the large air leak that will occur when the trachea is incised. Meticulous attention to withdrawal of the indwelling ETT to prevent inadvertent extubation during insertion of the TT is

AL Grawany

important. Other potential complications that may occur during TT placement include pulmonary overcirculation due to use of a high FiO_2 as well as the risk of a pulmonary hypertension crisis due to inadequate ventilation and/or light anesthesia. Rapid confirmation of correct TT placement in the trachea with capnography, lung auscultation, and the measurement of adequate tidal volumes are crucial. When transferring the patient to the ICU, the plans for managing the airway should the TT become dislodged should be clearly communicated.

Cardiac surgery in patients with pre-existing tracheostomy

Use of a TT during cardiac surgery with median sternotomy presents incremental risk due to lack of access to the airway for suctioning and TT replacement in the event that the TT becomes dislodged. In addition, airway secretions from the TT site may contaminate the chest. In most cases, after induction of anesthesia, the patient's trachea is intubated from above via the oral or nasal route. The TT is carefully removed as the trans-laryngeal ETT is advanced. The tracheal stoma must be completely sealed. An otolaryngologic surgeon can assist with packing the stoma with petrolatum or iodoform gauze and suturing the stoma closed in some cases. A clear adhesive dressing is then placed to prevent any air leak. Plans are made to replace the TT, usually at bedside in the ICU, several days after surgery by the otolaryngology team.

Summary

Neonates, infants, and children with CHD present numerous challenges to the anesthesiologist. These patients commonly have increased myocardial oxygen consumption (e.g., left-to-right shunts, valvar stenosis) and/or decreased myocardial oxygen supply (e.g., cyanosis). CPB has adverse effects on heart and lung function. Less than optimal airway management, oxygenation and/or ventilation can lead to further impairment of oxygen delivery to the heart and other organs with associated injury or death. Patients undergoing thoracic surgery may require single lung ventilation in order to optimize surgical conditions. Accordingly, the pediatric cardiovascular anesthesiologist must have advanced knowledge and expertise in managing the airway and ventilation during cardiothoracic surgery.

Introduction

Today's medical environment is marked by financial constraints. There is increasing pressure to optimize not only medical care but also resource utilization. This notion has also affected the way we approach the treatment of children requiring surgery for congenital heart disease (CHD). For example, reducing intensive care unit (ICU) and hospital length of stay (LOS) without compromising patient's safety translates into much-needed cost savings.

Although the overarching goal of providing efficient and safe care has not changed, not only the terminology but also the approach to achieving this goal has seen a significant evolution. The following chapter will focus on perioperative management, including early tracheal extubation, adequate postoperative pain control, rapid mobilization, and hospital discharge.

Background and history

The focus on not only improving surgical techniques but also on providing efficient care to patients undergoing cardiac surgery was introduced in the mid-1980s. Diagnosis-related groups were implemented nationally into Medicare reimbursement in the United States in 1983. To slow down the rapidly increasing costs of providing medical care, this reimbursement model incentivized efficient resource use, and a shorter length of ICU and hospital stay was suddenly linked to financial benefits for the hospitals. At the same time, in congenital heart surgery (CHS), extubation at the end of the surgical procedure was almost a necessity, as reliable mechanical ventilators and sedatives with minimal side-effects for small patients were not widely available.

In 1980, Barash et al. published their experience with *early extubation* in 197 patients aged less than 3 years including neonates; of them, 61% were successfully extubated in the operating room (OR) [1]. The authors noted that "in this era of cost containment, any technique that allows maximal use of resources without jeopardizing patient safety is welcome." The concept of the day of admission surgery, early-extubation, -mobilization, and -hospital discharge became popular and eventually routine practice in adults undergoing cardiac surgery in the late 1990s. This was especially true when crowded ICUs slowed the expansion of cardiac surgery programs attempting to gain a share of the increasing number of coronary revascularizations being performed [2]. In 1994, Engelman

AL Grawany

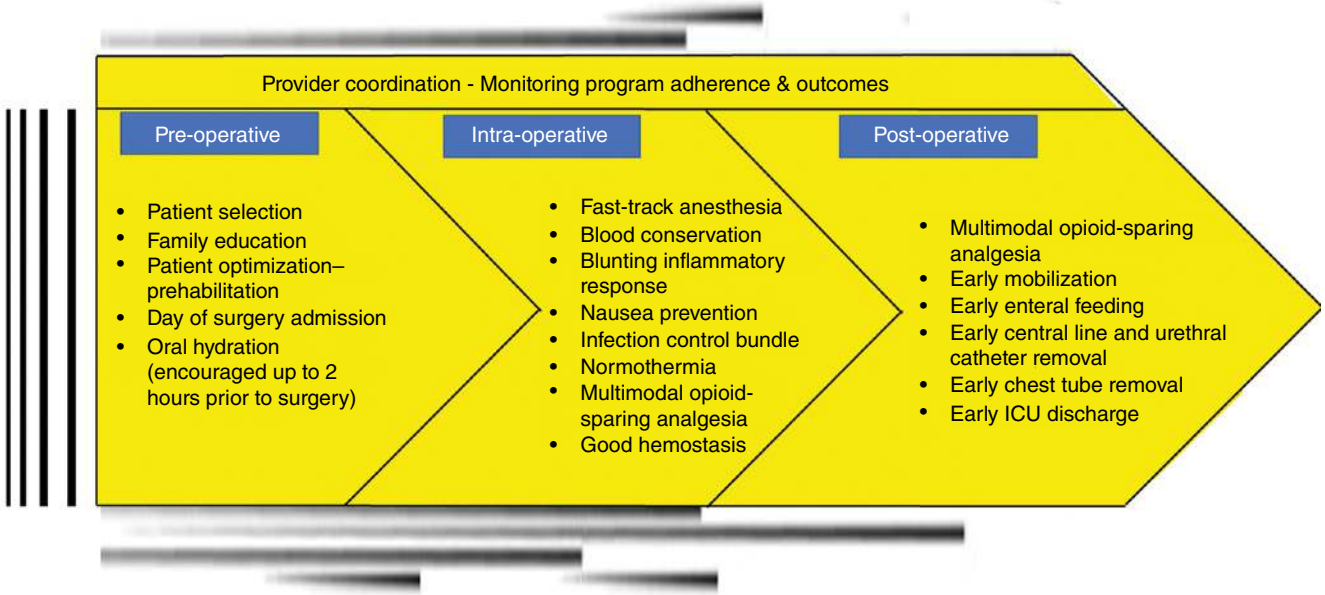

Figure 24.1 Enhanced recovery after pediatric cardiac surgery pathway.

et al. first coined the term "fast-track" in their paper, describing a complete care plan for patients undergoing cardiac surgery, which was associated with reduced hospital LOS [3].

In the field of CHS, surgical techniques developed rapidly and palliation and repair of CHD in even younger and previously inoperable children became feasible. Reports about favorable effects of high-dose opioid-based anesthesia emerged in the early 1990s, promising to reduce stress response, morbidity, and mortality [4, 5]. Administering high doses of opioids subsequently became the standard anesthetic technique in children undergoing increasingly complex CHS. This opioid-based anesthetic technique, however, necessitated prolonged postoperative mechanical ventilation (MV), and early tracheal extubation was no longer an option. Subsequently, shorter-acting drugs and anesthetic agents with less pronounced hemodynamic effects were introduced and the benefit and need of a high-dose opioid-based anesthetic were challenged [6, 7]. More recently, bundled care payment models have been implemented for specific procedures, and healthcare providers are once more encouraged to efficiently manage costs. At the same time, not meeting quality of care measures is linked to financial penalties.

Many of these past and recent changes have led hospital administrators, as well as individual healthcare providers, to re-think and investigate established, yet often inefficient, patient management strategies.

Enhanced recovery after pediatric cardiac surgery

In line with these efforts, the term "enhanced recovery after surgery" or ERAS, originally coined by Henrik Kehlet for colorectal surgery in 1997 [8], was adopted by many surgical specialties, including cardiac and pediatric cardiac surgery [9]. This patient management strategy, paraphrased by the acronym ERACS (enhanced recovery after cardiac surgery), focuses on a patient-centered, evidence-based, multidisciplinary approach to cardiac, including pediatric cardiac, surgery. ERACS strategy includes many if not most of the elements of fast-tracking children and adults undergoing surgery for CHD, that is, multidisciplinary approach, day of admission surgery, normothermia at the end of the procedure, multimodal pain management strategy, early -extubation, -mobilization, -enteral feeding, -ICU and –hospital discharge (Figure 24.1). The goals are also very similar, i.e., providing efficient, patient-centered patient care, that would help accelerate functional recovery and minimize surgical stress, thereby reducing the LOS, improving patient outcomes, optimizing resource use, and reducing associated costs. It further emphasizes routine monitoring and reporting of quality metrics and patient outcomes, aimed at continuously improving the operational aspects of this approach. The American Association for Thoracic Surgery published a consensus document on enhanced recovery after pediatric cardiac surgery [10]. Key strategies that were identified for successfully implementing and maintaining an ERACS pathway include a multi-disciplinary approach, appropriate patient selection, staff and patient/family education, protocol- and guideline-driven practice. The task force concluded that ERACS does not increase morbidity and mortality after pediatric cardiac surgery. Patient and family satisfaction with perioperative care may be improved. Roy and colleagues described their initial experience after introducing ERACS to their CHS program [11]. Compared to a matched historical control group, ERACS implementation resulted in a slightly reduced time on mechanical ventilation and LOS in ICU, although, no difference in hospital LOS was noted.

Feasibility of fast-tracking in congenital heart surgery

The multidisciplinary approach behind fast-tracking CHS patients typically includes an anesthetic technique that facilitates early tracheal extubation. Early extubation is not

consistently defined, and the term is frequently used when the endotracheal tube is removed within 6 hours after surgery [12, 13], but spans from immediate extubation in the OR up to 24 hours after surgery [10].

The feasibility and safety of extubating children immediately or soon after complex CHS had already been demonstrated in the early days of CHS, mostly out of necessity [1]. Schuller et al. reported their experience with early extubation in 1984 [14]. In 209 consecutive children undergoing complex open-heart surgery, 88% of those older than 12 months were extubated in the OR. In the same year, Heard et al. published an article on early extubation following CHS in 220 patients; of whom 147 (67%) were extubated in the OR or within 6 hours of entering the ICU [15]. None of the patients required reintubation. This was accomplished even though many of the anesthetic agents used at that time are obsolete in today's practice.

Despite the increasing popularity of a high-opioid anesthetic technique following these early reports, individual centers continued to pursue an early extubation strategy. The published reports and the recent changes in healthcare practice including ERAS pathways encouraged many institutions to adopt fast-tracking for at least some of their patients. At the time of this writing, the feasibility of fast-tracking including early extubation in children undergoing CHS has been demonstrated for most patients undergoing CHS. This includes neonates and young children [16, 17], complex surgeries [18, 19], children with single-ventricle physiology [20, 21], patients with significant co-morbidities, [22] and even in pediatric heart transplantation [23]. In a recent multicenter international survey spanning 144 pediatric cardiac surgery centers in 29 countries, extubation in the OR at the conclusion of surgery was practiced by 76% of the responding anesthesiologists, mostly for lower surgical risk procedures [24]. Table 24.1 summarizes the current literature on the feasibility of fast-tracking and early extubation in pediatric patients undergoing CHS.

KEY POINTS: FEASIBILITY OF FAST-TRACKING IN CHS

- Fast-tracking is a multidisciplinary patient management strategy aiming for efficient resource use.
- Early extubation is part of fast-tracking and is typically defined as removal of the endotracheal tube within 6 hours of surgery.
- The feasibility of fast-tracking has been shown historically out of necessity and in contemporary patient cohorts.
- Inclusion/exclusion criteria vary significantly between different centers.

Patient selection

When it comes to planning fast-tracking including early extubation for a specific patient or case, it seems prudent to understand the current evidence and have some guidance regarding who is a good candidate for such an approach. Some preoperative factors are almost universally viewed as contraindications for early extubation after CHS. For example, very few patients who have an endotracheal tube in place before the procedure will be good candidates for such a strategy. However, in many institutions, this practice is further limited to selected patients and is based on the anesthesiologist's or surgeon's preferences. While some centers consider early extubation only above a certain age and for simple procedures, others expand such a strategy to the majority of their patients. In many, if not all, of the published reports, specific exclusion criteria were applied, and it is not clear if patients who were not included could have been extubated early as well. As a matter of fact, there are reports showing successful early extubation in even the most complex procedures. Therefore, when interpreting study findings, it is important to notice not only the study design, inclusion and exclusion criteria, but also if extubation was attempted or deferred. A simple association between perioperative parameters and early extubation alone, without the specifics of extubation attempt, will not yield reliable data beyond individual practice or preferences.

The most consistent findings associated with deferred extubation are higher procedure complexity, younger age, longer aortic cross-clamp and cardiopulmonary bypass (CPB) times, and high-dose inotrope use [30, 35–42]. This has also been confirmed by prospective studies. Kin et al. found higher procedure complexity classified with the risk adjustment for congenital heart surgery (RACHS) score [43], surgery involving aortic cross-clamping, young age, and trisomy 21 to be independent predictors of the decision to not attempt extubation at the end of the procedure [32]. Very few patients in that series failed extubation once attempted. At first glance, these findings seem to classify selection criteria in a very simplified scheme. All listed factors are known preoperatively, and the findings seem to indicate that intraoperative factors such as bleeding, cardiac dysfunction requiring high inotropic support, generalized edema, etc., many of which are frequently encountered, are not significantly contributing to predicting early extubation. However, procedure complexity seems to capture many of these factors. Complex surgeries are frequently associated with longer aortic cross-clamp and CPB times, more pronounced inflammatory response, and associated findings such as a higher incidence of bleeding, generalized edema, and higher inotropic requirements, which prohibit early removal of the endotracheal tube all by themselves [29, 44, 45]. In a prospective observational study, Garg et al. [34] collected information on OR extubation and reasons for deferring extubation to a later time point in 1,000 pediatric patients undergoing surgery for CHD within an 8-month time period. Overall, 87.1% of patients were extubated in the OR, resulting in significantly shorter ICU LOS compared to a historical control group. Factors associated with deferred extubation included poor oxygenation, open sternum, ongoing bleeding, high inotrope use, and other reasons necessitating further observation in the ICU.

Aside from complex procedures, young age is one of the most frequently listed reasons for not considering early extubation [32]. In retrospective analyses, young age is consistently associated with not being fast-tracked. Davis et al., for example, assessed factors associated with early extubation following CHS. Children older than 6 months were much more likely to be extubated early compared with younger patients [29]. Winch et al. [46] found that

Table 24.1 Publications on fast-tracking in children undergoing congenital heart surgery

Reference	Study type	Patients enrolled	RACHS category	Findings
Barash et al. [1]	R	197	1–3	• 61% extubated in OR, 11% shortly after ICU arrival, 4% reintubation • Longer CPB time associated with not extubating • Fewer pulmonary complications in early extubation group
Schuller et al. [14]	R	209	1–5	• 80% extubated in OR, 2.4% reintubation • Younger age, PAH, and severe preoperative heart failure, associated with not extubating in OR
Heard et al. [15]	R	220 (1 day–16 years)	1–3	• 67% extubated in OR or within 6 hours after ICU arrival, no reintubation • Fewer pulmonary complications with early extubation • Longer CPB time associated with prolonged MV
Laussen et al. [25]	R	102	1 (ASD only)	• 38% extubated in OR • OR extubation safe • Shorter hospital LOS, and lower costs associated with early extubation
Heinle et al. [17]	R	56 (<90 days)	1–6	• 50% extubated in OR or within 3 hours in ICU • 3 patients required reintubation • Patients extubated early had shorter ICU/hospital LOS, reduced costs
Vricella et al. [26]	R	201	1–3	• 87% extubated in OR, 94% within 4 hours after surgery, 2.6% required reintubation • Fast-tracking in surgery for CHD is feasible and safe
Lofland [27]	P/O	50	3 (bi–Glenn, Fontan only)	• All patients extubated either in OR or within 1 hour postoperatively • Pain-free spontaneous ventilation resulted in superior hemodynamics
Neirotti et al. [19]	R	901	1–3	• 73% extubated in OR, 2.5% reintubation • Younger age, lower weight were risk factors for deferring OR extubation • Simplified postoperative care and increased patient and family satisfaction
Kloth and Baum [28]	R	102 (>2 months)	1–6	• 47% extubated in OR or on ICU arrival, no reintubation • Only RACHS 1–3 extubated early • Mild respiratory acidosis immediately following early extubation well tolerated • Young age, low weight, long CPB time, DHCA, high inotrope use, PAH, are among the factors why extubation was not attempted
Davis et al. [29]	R	219 (≤36 months)	1–6	• 47% extubated within 24 hours • Age >6 months, no PAH, no CHF, gestational age >36 weeks, associated with early extubation • Intraoperative factors less important, except for the cross-clamp time
Vida et al. [22]	R	100 (median age 2.5 years)	2 (VSD + PAH only)	• 65% extubated in OR, overall 90% extubated within 6 hours after surgery, two patients extubated early required reintubation • Trisomy 21 and longer CPB time are risk factors for postoperative complications and prolonged MV • PAH is not a contraindication for early extubation • Degree of PAH not associated with the incidence of postoperative complications, ICU and hospital LOS • Decreased ICU and hospital stay, reduced costs, lower in-hospital mortality with early extubation

(*Continued*)

Table 24.1 (Continued)

Reference	Study type	Patients enrolled	RACHS category	Findings
Mittnacht et al. [30]	R	224 (>1 month, <18 years)	1–4	• 79% in OR, no reintubation for respiratory reasons • Younger age, longer CPB time, and high inotrope use associated with not extubating in OR
Morales et al. [21]	R	112	3 (Fontan only)	• 34% extubated in OR, no reintubation • Lower inotrope use, shorter ICU and hospital LOS, and decreased costs with early extubation
Preisman et al. [31]	P/R/O	50 (OR extubation)/50 (control)	1–3	• No difference in mortality, morbidity, reintubation • Shorter ICU and hospital LOS in OR extubation group
Kin et al. [32]	P/O	Site 1: 275 (2 weeks–18 years, median 18 months) Site 2: 49 (median 25 months)	1–3	• Site 1:89% extubated in OR (three patients required reintubation for respiratory reasons) • Site 2: 65% extubated in OR (no reintubation) • All patients with cross-clamp and RACHS-1 extubated in OR • RACHS, trisomy 21, age, independent predictors of OR extubation
Hamilton et al. [33]	R	50 (OR extubation)/50 (control)	1–3	• Lower inotrope use, and shorter hospital LOS in early extubation (OR) group • More reintubations in early extubation but statistically not significant
Garg et al. [34]	P/O	1,000 (1 day–18 years)		87% extubated in OR, shorter ICU stay, and lower resource use
Harris et al. [35]	R	613, including neonates		71% extubated in OR, 89% within 24 hours including neonates
Varghese et al. [18]	R	148, neonates		30.4% extubated in OR,
Varghese et al. [20]	R	23, stage 1 palliation		5 patients extubated in OR, no difference in outcomes
Shinkawa et al. [36]	R	909, including neonates		64.9% extubated in OR, decreased ICU LOS and costs, no difference in reintubation rate, longer OR turnover
Fukunishi et al. [37]	R	359 (1 month–18 years)		83% extubated in OR, lower RACHS-1 score resulted in higher extubation rate
Wu et al. [38]	R	2,060 (<18 years)		65% extubated in OR, 16.1% within 6 hours, reintubation rate 2.0%

R, retrospective; P, prospective; O, observational; ICU, intensive care unit; OR, operating room; RACHS, Risk Adjusted Congenital Heart Surgery Score; LOS, length of stay; CPB, cardiopulmonary bypass; PAH, pulmonary arterial hypertension; MV, mechanical ventilation.

children younger than 3 months were less likely to be extubated early. However, extubation practice varies significantly and even neonates have been extubated successfully immediately after CHS [17]. Age also needs to be assessed in the context of the planned procedure. Certain more complex procedures may be performed later in life, while a simple procedure in an infant may pose a much smaller risk for not qualifying for early extubation. The fact that age alone is not a good selection criterion for fast-tracking is also supported by the published literature. Kin et al. [32], for example, found that the relationship between age and attempted OR extubation was inconsistent and not linear. Beyond the age of 2 years, however, age did not impact the likelihood of OR extubation. Similarly, in Garg's study [34] representing a large number of patients and a high overall extubation rate (87.1%), OR extubation was accomplished in 40% of neonates, 69.7% of 1–3-month-olds, 85.5% of 3 months–1-year-olds, and leveled off thereafter. In general, these data indicate that successful extubation in the OR can be accomplished more reliably in children older

AL Grawany

than 2–3 months of age. Younger infants and neonates need not be excluded from such a strategy; however, the incidence of encountering contraindications to early extubation at the end of the procedure or soon after in the ICU is typically much higher at this very young age.

Chromosomal abnormalities also account for patients not being considered for early extubation. While not a contraindication *per se*, patients with a genetic variation known to be associated with difficult airway instrumentation, or an increased risk of airway obstruction (e.g., trisomy 21), must be evaluated carefully before attempting early extubation. This is even more of a concern following a long CPB time, which is frequently associated with generalized edema possibly involving the upper airway.

Pre-existing or worsening of pulmonary arterial hypertension (PAH) deserves particular attention. Many practitioners would not attempt early extubation in patients with pre-existing PAH. However, this practice has been challenged, and there are reports of successful extubation following CHS even in patients with significant PAH [22]. In a retrospective analysis of factors associated with early extubation, PAH was not found to be an independent predictor of OR extubation [30], and preoperative PAH did not predict patients who were not extubated in the OR in a similar prospective study [32]. In the latter study, however, significant PAH following CPB was the most common reason for deferring extubation at the end of the procedure. While there is no question why PAH increases the risk for many adverse perioperative events [47–50], it is important to recognize that merely using the current definition of PAH (right-sided pressures ≥20 mmHg) [51] does not accurately reflect such risks in children with CHD [52]. It is often difficult to predict the degree of PAH following surgical repair and, even more importantly, right ventricular failure merely by preoperative right-sided pressures. Assessment of pulmonary vascular resistance (PVR), reactivity to pulmonary vasodilators, as well as the relationship between right-sided pressures and systemic arterial pressure is typically included in the evaluation of PAH in children undergoing CHS [53]. Following weaning off CPB, patients can be reassessed, and even in the setting of pre-existing PAH, patients can often be extubated as long as the right ventricular function is adequate, and no inhalational pulmonary vasodilators are required.

The likelihood of early extubation following CHS can be better predicted by combining several of the risk factors. Kin et al. developed a risk score model based on factors found to be independently associated with extubation in the OR following surgery [32]. All patients undergoing CPB surgery without aortic cross-clamp and simple procedures (RACHS 1, for example, secundum atrial septal defect) were extubated in the OR. Higher RACHS scores and the addition of trisomy 21 as an additional risk factor increased the chance of deferring extubation. Similarly, Davis et al. found age <6 months, prematurity, congestive heart failure, and pulmonary hypertension to be associated with the chance of failing extubation within 24 hours after surgery. Adding individual factors increased the chance of failing early extubation [29]. Factors associated with early extubation in individual studies can be found in Table 24.1.

Implementation and maintaining fast-tracking

The cumulative experience of fast-tracking patients undergoing pediatric cardiac surgery clearly highlights the multi-disciplinary approach required for the successful implementation of such a strategy. Many institutions where fast-tracking has been practiced successfully have started with low complexity cases and older children, and eventually adopted this approach to a broader patient population [54]. With the rebranding of fast-tracking and adoption of ERACS protocols, more data will likely emerge on implementing and maintaining this strategy in pediatric cardiac surgery also. Roy et al. [11] described their initial experience with introducing an enhanced recovery after CHS program at their institution. Key elements for implementation included an initial assessment of the evidence based ERACS interventions in pediatric CHS, multidisciplinary consensus building and development of institutional ERACS guidelines, as well as monthly sharing of outcome data for continuous process improvement. Despite this, the authors comment on the suboptimal adherence to ERACS guidelines.

The Pediatric Heart Network Collaborative Learning Study used collaborative learning principles to implement early extubation guidelines across four active study sites and five control sites [55]. Overall compliance with early extubation guideline adoption was high. An increase in early extubation rates, from 11.7% before to 66.9% after guideline implementation, were seen for patients undergoing tetralogy of Fallot (TOF) repair. No change was noted for coarctation of aorta repair. There was no increase in the reintubation rate during the study period. Although all active sites reported a significant decrease in time to extubation, significant variability between sites was noted (i.e., magnitude of change: –73.3% to –99.2%) [56]. Following this initial rollout, the investigators assessed if this initiative also impacted extubation practice in patients not targeted in the initial trial; "spillover" [57]. One year after the initial practice guideline was implemented, one of the four active study sites also noted a significantly higher extubation rate in patients undergoing ventricular septal defect repair. No change was seen in patients undergoing higher complexity surgeries. The same group of investigators also looked at the sustainability of the observed change in early extubation rate in patients undergoing TOF [58]. One year after initial study completion, the early extubation rate declined from 67% to 30%, and the median time to first extubation attempt increased from 4.5 to 13.5 hours. Only one out of four hospitals maintained the extubation rate achieved during the initial study. Sustaining and even expanding an early extubation practice, without doubt, require continuous work from all stakeholders involved, including transparency and reporting of outcomes and resource use.

KEY POINTS: PATIENT SELECTION FOR EARLY EXTUBATION

- Preoperative factors can be used to help stratify patients who are good candidates for early extubation.

- Many of the traditionally taught "contraindications" for early extubation have been successfully challenged.
- The ultimate decision to extubate can only be made after the surgical procedure if extubation criteria are fulfilled.

Anesthesia technique

Although certain predictors can help select patients who are good candidates for early extubation even preoperatively, the ultimate decision to attempt extubation will always be deferred to the end of the procedure or ICU. For the purpose of fast-tracking and, in particular, early extubation, an ideal anesthetic would allow early extubation and at the same time provide stable hemodynamics, adequate analgesia, and sufficient blunting of the stress response. In the early days of CHS, the use of potent inhalational anesthetics allowed for early extubation at the end of, or within a few hours after surgery. However, a mainly inhalational anesthetic-based technique is not always tolerated and can be associated with significant side effects at higher concentrations. An opioid-based anesthetic provides stable hemodynamics and superior suppression of stress response, but typically requires prolonged MV. The addition of a neuraxial anesthetic is advocated by some practitioners and will be discussed in more detail later in this chapter. There are concerns, however, about adequate evidence regarding the safety of a neuraxial technique in the cardiac surgery setting.

Made possible in large part by the introduction of improved and new anesthetic agents such as modern inhalational anesthetics, short-acting opioids, hypnotics, and sedatives with favorable pharmacodynamics and pharmacokinetic profiles, all the above-mentioned goals can be accomplished, and the side-effects of each individual technique minimized. Such a balanced anesthetic consisting of an inhalation-based technique supplemented with a short-acting opioid is the basis of most of the modern anesthetic techniques aiming for fast-tracking CHS patients and will be discussed in more detail here.

Patients who qualify for fast-tracking are often admitted on the day of surgery, and frequently intravenous (IV) access has not yet been established. Therefore, an inhalational induction technique with sevoflurane is typically chosen for induction and is well tolerated in most patients. If true contraindications to an inhalational induction technique apply, IV access should be established, and ketamine or etomidate can be used as induction agents. With a true inhalation-based fast-tracking technique, the inhalational agent is administered throughout the case, including on CPB. The CPB machine must therefore be equipped with a vaporizer. Alternatively, a continuous infusion of IV agents with hypnotic properties can be used during CPB. As a short-acting hypnotic with favorable pharmacokinetic and pharmacodynamics properties, propofol is frequently used during CPB for patients who are fast-tracked [59]. If, however, a decrease in systemic vascular resistance (SVR) must be avoided, a high-dose opioid technique or the use of ketamine should be considered. Ketamine administered as a continuous infusion maintains stable hemodynamics in most CHS patients.

Regarding IV opioid use, shorter-acting opioids such as fentanyl are preferred. Early extubation can still be accomplished as long as the cumulative dose is limited, and larger repetitive doses avoided toward the end of the procedure. Frequently, not more than 5–10 μg/kg fentanyl is given for the whole case [25, 28, 30, 31], which is significantly less than the doses used for a high-dose opioid technique. Remifentanil is an ultra-short-acting opioid that is metabolized by non-specific esterases in plasma and tissues and minimally affected by CPB [60]. The use of remifentanil allows conduction of a high-dose opioid anesthetic with the benefits of reducing stress response, but with a fast recovery facilitating early extubation [61–63]. The challenge is to provide adequate analgesia after an infusion of remifentanil is discontinued due to its rapid elimination. A neuraxial technique, non-opioid analgesics, and dexmedetomidine can be helpful for this purpose.

Dexmedetomidine is a sedative agent that confers sedation by selectively binding to central α_2 adrenoceptors. Respiratory indices and upper airway patency are maintained during dexmedetomidine sedation in children [64–67]. In addition to sedative and analgesic-sparing effects, dexmedetomidine use has also been reported to reduce stress response in patients undergoing cardiac surgery [68]. Additional favorable properties supporting dexmedetomidine's role in the fast-tracking setting are the reduced incidence of emergence delirium after inhalational anesthesia in children [69–71] and its possible role in reducing the incidence and even treatment of arrhythmias [72]. Additionally, emerging data mostly from in vitro studies show potential neuroprotective effects [73, 74]. Because of these favorable properties, dexmedetomidine is even used throughout the case by some practitioners and allows the reduction of opioid requirements for fast-tracking purposes. Undesirable hemodynamic effects of dexmedetomidine such as bradycardia, hypotension, hypertension, decrease in cardiac output [75], as well as an increase in PVR, especially with high doses or fast bolus administration, have all been described. These side effects, however, are highly dose- and age-dependent. Typically, dexmedetomidine is well tolerated in older children [76]; however, little data are available regarding safe doses in infants and particularly in neonates. There are data showing that dexmedetomidine clearance in neonates and infants is reduced [77–80], and accumulating drug levels causing bradycardic side effects may occur. In a recent pharmacokinetics and safety trial in neonates undergoing cardiac surgery, clearance was significantly reduced; however, dose adjustments resulted in a low incidence and severity of adverse events noted [81].

It must also be noted that at this point dexmedetomidine is still approved only by the US Food and Drug Administration (FDA) for use in adults for ICU sedation up to 24 hours. In clinical practice, however, dexmedetomidine has been widely used in children even for prolonged periods of time [82]. A Pediatric Postmarketing Pharmacovigilance and Drug Utilization Review can be found on the FDA web page [83].

In a Pediatric Heart Network-sponsored multicenter Collaborative Learning Study, the change of anesthesia practice was compared before and after early extubation study guideline implementation [84]. Clinical practice guideline implementation aimed at early extubation in patients

AL Grawany

following repair of coarctation of the aorta or TOF was accompanied by a significant decrease in opioid and midazolam use, no change in intraoperative median volatile anesthetic use, and intraoperative dexmedetomidine administration was an independent predictor of early extubation.

In summary, fast-tracking and early extubation are facilitated by modern anesthetic agents combined with strategies to provide good analgesia without significant respiratory depression.

KEY POINTS: ANESTHESIA TECHNIQUE

- A balanced, inhalational anesthetic-based technique is usually chosen for fast-tracking.
- Opioid use is limited, and short-acting opioids are preferred.
- Non-opioid analgesics and opioid-sparing drugs such as dexmedetomidine are used to reduce opioid use.
- Neuraxial techniques can supplement pain management, but their use is controversial.
- Regional anesthesia techniques, particularly thoracic fascial plane blocks are increasingly being used to help reduce opioid use.

Surgery and CPB considerations

Surgical and CPB techniques contribute significantly to the ability to fast-track patients and have an impact on anesthetic management. Aside from the quality of the surgical repair, it is increasingly recognized that outcomes can be improved by reducing the inflammatory response [85] and limiting surgical trauma [86]. For example, avoiding or limiting prolonged periods of deep hypothermia [87] and circulatory arrest [88] reduces CPB duration and associated complications such as cardiac dysfunction, coagulopathy, and transfusion requirements [89]. Limiting the inflammatory response results in less generalized edema and improves pulmonary function [90–92], all important components to successfully fast-tracking CHS patients. Minimally invasive surgical techniques [93–95], hybrid procedures [96], or alternate surgical access for selected CHD [97] can further contribute to limiting surgical trauma.

Significant changes have also been made to CPB and perfusion techniques. These improvements often benefit patients who are considered for fast-tracking and include miniaturized CPB circuits [98–100], retrograde autologous priming [101], beating heart surgery techniques [102], less cooling [103–105], pulsatile CPB [106], and selective perfusion strategies [107]. Modified ultrafiltration (MUF) is also frequently part of a fast-tracking protocol and has been shown to decrease edema and improve pulmonary and cardiac function [108–110]. Immediate effects on hematocrit and coagulation also help fast-tracking [111]. Many of these techniques are controversial and not universally practiced, however, and the safety and possible outcome benefits are still being evaluated. Nevertheless, many of the currently ongoing changes to the practice of CHS promise to be beneficial to fast-tracking.

KEY POINTS: SURGERY AND CPB CONSIDERATIONS

- Surgical and CPB techniques contribute significantly to fast-tracking.
- Measures to reduce inflammatory response are key to the ability to fast-track.
- Selective perfusion techniques avoid prolonged periods of circulatory arrest and profound cooling.

Failed extubation and prolonged mechanical ventilation

It must be noted that selection criteria for patients who are good candidates for fast-tracking and early extubation are not necessarily the same as the factors associated with extubation success and/or prolonged MV. Selection criteria that were discussed earlier can help guide physicians in planning an anesthetic, and based on prior studies, carefully selected patients will fulfill extubation criteria in most cases. However, assessment of extubation criteria and the decision to remove the endotracheal tube can only be made at the end of the procedure or in the ICU immediately prior to the planned extubation. Extubation success is only obvious once the patient can sustain spontaneous ventilation without significant respiratory support. And if a patient fails extubation or extubation was never attempted and requires prolonged ventilatory support, certain factors have been found to be associated with prolonged MV. These considerations will be discussed in more detail here.

If early extubation was planned but not attempted, the anesthesiologist together with the surgeon will have made this decision based on subjective as well as objective observations and findings. In general, extubation criteria have been defined, are relatively consistent between practitioners, often follow specialty society guidelines and recommendations, and are not different in the CHS setting. However, the reasons for deciding to proceed with attempting extubation may vary greatly between institutions. In a prospective observational study, almost all patients presenting for CHS who did not require mechanical support preoperatively were considered as candidates for extubation at the end of the surgery [19]. The authors further assessed the factors that made the practitioners decide not to attempt extubation immediately following surgery. Significant pulmonary hypertension following CPB, hypoxemia, bleeding/coagulopathy, airway compromise (edema), insufficient respiratory effort, hypothermia, and open chest were listed by the practitioners as the main reasons for diverting from the original plan to remove the endotracheal tube at the end of the procedure. Preisman et al. listed hemodynamic instability, open chest, hypoxemia, hyperlactatemia, inadequate urine output, and higher transfusion requirements as reasons why patients were excluded from planned early extubation [31], while Kloth et al. [28] listed young age, low weight, significant co-morbidity, preoperative MV, high inotropic support, ongoing bleeding, airway concerns, significant PAH, and nitric oxide use.

Once the endotracheal tube is removed, extubation success is relatively high in most studies. Extubation failure is often defined as reintubation within 96 hours after extubation [112, 113]. Reintubation rates reported in patients following fast-track CHS do not differ from those in children who were not fast-tracked, or from any other major surgery setting, and typically do not exceed 4% in the majority of published studies [19, 21, 26, 30, 114]. A review of the literature and meta-analysis confirmed these findings, and reintubation rates did not differ between patients who were extubated early vs. late [13]. In neonates and very young infants, however, extubation failure and reintubation may be higher [17, 115]. Higher surgical risk procedures were also associated with an increased incidence of reintubation [54]. In the Pediatric Cardiac Critical Care Consortium clinical registry, extubation failure defined as reintubation less than 72 hours after the first planned extubation was found in 11% of patients, the majority (61%) within 24 hours [116]. Extubation failure ranged from 5 to 22% between various centers, and in a secondary analysis [117], the staffing model and percentage of nursing staff with critical care certification were associated with lower odds of extubation failure.

Reasons for reintubation and factors associated with failed extubation have been listed by several investigators. Harrison et al. performed a retrospective chart review and analyzed independent predictors of reintubation within 24 hours after extubation in children aged 3 years or younger undergoing CHS [45]. Reintubation was required in 22 out of 219 surgeries, and trisomy 21, surgery with deep hypothermic circulatory arrest, and pulmonary hypertension as the strongest predictor were independently associated with failed extubation. Gupta et al. [113] evaluated extubation failure in infants undergoing the Norwood operation. Pulmonary complications, cardiac dysfunction, diaphragmatic paralysis, and airway-related complications were the most common reasons why patients required reintubation. Almost identical causes of extubation failure were found in patients undergoing repair for TOF[112]. Another study evaluating extubation success following CHS found lung mechanics and associated abnormalities of respiratory function, such as increased work of breathing, as the main cause for failing extubation [118]. Other factors frequently identified as reasons why patients fail extubation are neurologic complications, cardiovascular insufficiency, inotrope score, poor oxygenation, and respiratory acidosis [119, 120]. When evaluating reintubation rates, it must be recognized that reintubation may be required for reasons other than not sustaining spontaneous ventilation. This is not a failure of an early extubation strategy *per se*. These patients would have been successfully extubated but required reintubations for other reasons, such as return to the OR for surgical intervention, sepsis, or pneumonia, and thus, in the context of fast-tracking, reported reintubation rates must be interpreted accordingly.

The decision to continue MV in patients following surgery for a few hours or until the next day is often based on institutional preferences. Prolonged MV, however, often defined as MV beyond the third postoperative day, is usually secondary to a more complicated postoperative course. A prospective observational study found factors associated with prolonged MV to be inconsistent and heterogeneous and included pulmonary hypertensive events, delayed sternal closure, peritoneal dialysis, pulmonary complications, low cardiac output syndrome, neurological events, nitric oxide use, and tracheomalacia [44]. In a retrospective study, independent risk factors of prolonged MV were surgical complexity assessed with the RACHS score, nosocomial pneumonia, low cardiac output syndrome, postoperative positive fluid balance, and extubation failure [121]. Phrenic nerve injury, pleural effusions, pulmonary hypertension, and other airway complications are typical pulmonary complications that require prolonged MV [122]. Trisomy 21 is also frequently associated with a more complicated postoperative course, including prolonged MV [123].

Box 24.1 summarizes common reasons for deferring planned extubation, early extubation failure, and prolonged MV following CHS.

Box 24.1: Common reasons for deferring early extubation, extubation failure, and prolonged mechanical ventilation in patients undergoing congenital heart surgery

Common reasons for deferring planned early extubation

- Preoperative mechanical ventilation
- Pulmonary hypertension (pre-and post-CPB)
- Pulmonary hypertension requiring nitric oxide
- Insufficient respiratory effort
- Airway compromise, generalized edema
- Hypoxemia
- Hemodynamic instability (high inotrope use, hyperlactatemia, open chest, extracorporeal membrane oxygenation (ECMO), hemodynamically significant arrhythmia)
- Ongoing coagulopathy, increased transfusion requirements
- Long CPB, aortic cross-clamp time, deep hypothermic circulatory arrest (DHCA)
- Young age, low weight
- Hypothermia
- Inadequate urine output
- Chromosomal abnormalities (e.g., trisomy 21).

Common reasons for failed early reintubation within 96 hours after extubation

- Pulmonary hypertension
- Cardiovascular instability
- Ongoing coagulopathy
- Pulmonary: insufficient respiratory effort, increased work of breathing, hypoxemia
- History of trisomy 21
- Phrenic nerve paralysis
- Pleural effusion
- Other complications requiring surgical intervention

Reasons for prolonged mechanical ventilation (>72 hours) following CHS

- Pulmonary hypertension (particularly nitric oxide use)
- Pulmonary complications, pneumonia, phrenic nerve injury, tracheomalacia
- Neurologic complications
- Hemodynamic instability, low cardiac output syndrome, low urine output requiring dialysis
- Open sternum

CPB, cardiopulmonary bypass; ECMO, extracorporeal membrane oxygenation; DHCA, deep hypothermic circulatory arrest.

AL Grawany

KEY POINTS: FAILED EXTUBATION AND PROLONGED MV

- Deferring planned extubation to a later time point is different from failed extubation.
- Extubation criteria do not differ from patients who are not fast-tracked.
- Reintubation rates in fast-tracked and conservatively managed children are comparable.
- Prolonged MV beyond the third postoperative day is unrelated to fast-tracking, and associated factors comprise a wide spectrum of complications associated with CHS.

Benefits of fast-tracking

The benefits of fast-tracking were noticed even in the early days of CHS when extubation at the end of a procedure was done more out of necessity than by choice. In 1979, Barash et al. noted fewer complications from MV, earlier patient mobilization, increased patient and parent satisfaction, and optimal resource use with possible cost benefits [1]. Further reports on early extubation in pediatric cardiac patients followed, and the increasing experience with this approach led to recognizing and reporting possible benefits in this patient population. Many of the initially reported benefits are still valid, and even though modern ventilator technology has significantly improved, avoiding prolonged periods of MV is usually preferred. Patients without MV typically require less sedation, which often leads to lower inotropic (hemodynamic) support, more rapid patient mobilization, decreased ICU and hospital LOS, and possibly decreased costs [19, 31, 33]. Aside from cost savings, a prolonged hospital stay can increase the risk of hospital-acquired complications such as infections. The risk of hospital-acquired infections cannot be underestimated and is one of the main reasons why fast-tracking has been adopted, particularly in some of the developing countries with a higher surgical wound infection rate. Additionally, early extubation allows earlier mobilization and verbal communication between the child, parents, and hospital staff involved. Consequently, patient and parent satisfaction are increased in children who are extubated in the OR, or soon after ICU arrival. A large meta-analysis on early extubation in CHS even found lower in-hospital mortality, as well as a trend toward shorter ICU and hospital LOS, lower costs, and fewer respiratory complications in patients who were extubated early; however, it is not clear if selection bias can partially explain these findings [13]. Benefits found with early extubation are listed in Table 24.1 and Box 24.2.

Certain types of CHS patients may benefit more than others from fast-tracking, and in particular from early extubation and spontaneous ventilation. In patients with single-ventricle physiology undergoing bi-directional Glenn or Fontan procedure, early extubation and spontaneous ventilation have been associated with improved hemodynamics [21, 27, 124, 125]. Other reported benefits include lower inotropic support, earlier chest tube removal, and shorter ICU LOS [126, 127]. Lower intrathoracic pressure associated with spontaneous ventilation increases central venous blood return, which becomes the driving force of pulmonary blood flow across the pulmonary vascular bed and thus for maintaining left ventricular preload and cardiac output [128, 129]. In a study of 50 patients undergoing either bidirectional Glenn or Fontan operation who were extubated either in the OR or within 1 hour postoperatively, decreased pulmonary artery pressure and increased cardiac index were recorded following extubation [27]. Morales et al. [21] found mean pulmonary artery and atrial pressure to be lower and mean arterial blood pressure to be higher in patients who were extubated soon after surgery. In patients who were extubated in the OR, less inotropic support was required, the time to chest tube removal was shorter, and ICU/hospital stay and costs were reduced. In particular, for patients who have undergone a bidirectional Glenn surgery, mild hypercapnia frequently seen following early extubation should increase blood flow to the superior vena cava (SVC) and pulmonary circulation from cerebral vasodilation [130–132]. Hoskote et al. investigated the systemic and pulmonary hemodynamic effects of different CO_2 tensions in patients following bidirectional Glenn anastomosis in a prospective trial [133]. Mild hypercarbia ($PaCO_2$ up to 55 mmHg) resulted in improved systemic oxygenation, increased systemic (Qp) and pulmonary (Qp) blood flow (Qp/Qs unchanged), increased cerebral blood flow, and decreased SVR. PVR remained unchanged in this study. In another retrospective study in children following right heart bypass surgery, early extubation and spontaneous ventilation resulted in decreased PVR, lower mean pulmonary artery pressure, and fewer pulmonary complications such as pneumonia and atelectasis [128]. Despite the findings showing that mild permissive hypercapnia may be beneficial or at least well tolerated in patients following bidirectional Glenn and Fontan procedures, there remains widespread concern and controversy about the safety of fast-tracking and early extubation in this patient population, particularly as the age of bidirectional Glenn patients continues to decrease and is often 2–3 months [134]. Kawaguchi and colleagues examined the impact of an institutional policy change on early

Box 24.2: Benefits associated with fast-tracking and early extubation

- Fewer ventilator-associated complications:
  - Accidental extubation
  - Laryngotracheal trauma
  - Mucous plugging of the endotracheal tube
  - The pulmonary hypertensive crisis from endotracheal suctioning
  - Barotrauma from positive pressure ventilation
  - Ventilator-associated pulmonary infections and atelectasis
- Reduced requirements for sedatives/analgesics
- Greater hemodynamic stability
  - Beneficial effects of spontaneous ventilation in stage 2 & 3 single-ventricle palliation
  - Lower inotrope use
- More rapid patient mobilization
  - Earlier ICU discharge
  - Decreased hospital length of stay
- Reduced costs
- Greater parent and patient satisfaction

extubation in patients undergoing Fontan palliation [135]. The policy change was associated with an impressive reduction in pediatric intensive care unit length of stay (PICU LOS) (average 4.1 days; 95% CI −1.2 to −6.9). Fluid balance did not differ, and although the rate of reintubation was statistically not different, hemodynamic instability was the main reason for reintubation prior to policy change and bleeding and respiratory etiology listed most commonly in the time period after.

Cost containment in healthcare has become more important than ever before and centers caring for children with CHD are not exempt from this. The strongest predictors of costs for patients undergoing cardiac surgery are usually intensive care and hospital LOS, OR time, and postoperative complications. Any technique resulting in earlier patient discharge without compromising patient's safety should therefore result in cost savings. While many studies on patients undergoing CHS have shown a decrease in ICU and hospital LOS, as well as cost savings from shorter time on MV [13, 17, 21, 22, 136], overall cost benefits from fast-tracking and early extubation, are not easily evaluated. Most studies reporting on cost savings acknowledge difficulties in comparing historical control groups with contemporary patient care. Results from randomized studies in adult cardiac surgery, however, clearly demonstrated cost benefits from fast-tracking patients [137–139]. Most of those studies conclude that fast-tracking results in shorter ICU and hospital LOS, and decreases in resource use, all of which led to decreased costs. While it may be difficult to compare costs between different institutions and patient populations, it is quite likely that at least some of these findings can be extended to CHS. Heinle et al. [17], for example, found significant cost reductions in patients who were extubated early due to shorter ICU/hospital LOS. Vida et al. showed that patients who were extubated early had significantly shorter ICU and hospital stays, and every additional day spent on the ICU increased overall costs of the procedure by 10% [22]. In patients undergoing atrial septal defect (ASD) repair, for example, Laussen et al. found similar ICU charges regardless of the time of extubation; however, combined ICU and OR charges were reduced mainly because of avoidance of postoperative MV [25].

Most of these reports on cost savings are based on retrospective analyses and are not from randomized, contemporary matched patient populations. When comparing costs using a historic control group, additional factors such as the experience of the surgeon, inflation, and increased costs due to new technologies must be considered and these factors are almost impossible to accurately account for. Lawrence et al. [140] compared their single-institution experience of implementing fast-tracking with outcomes from a large contemporary nationwide database for the same time periods. When fast-tracking including early extubation (the goal was to extubate at the end of the procedure in the OR) was fully implemented, the median hospital LOS at their institution decreased by 1 day compared with the earlier time period, while nationally LOS remained unchanged. This translated into significant cost savings (33 and 35% for ASD and ventricular septal defects, respectively), whereas an increase in costs was noted nationally for the repair of both congenital heart defects in the same time period. A multiple regression analysis confirmed the decrease in both LOS and costs to be significantly greater at their institution compared with the nationwide database. Hospital mortality and 2-week readmission rates remained unchanged and were not different from the national rates. This is particularly important, as an increase in postoperative complications associated with fast-tracking and early extubation would outweigh the potential cost-saving benefits. Similarly, any significant increase in turnover times in the OR could easily jeopardize cost savings.

Holowachuk et al. [141] performed a cost savings analysis after the implementation of an early extubation strategy for eight Society of Thoracic Surgeons (STS) benchmark operations at their institutions. Costs were compared to a large contemporary STS database cohort. Early extubation was associated with a mean cost savings of US$ 12,976 (range US$ 11,934–$14,059) per procedure; the majority of which were related to direct costs savings, i.e., resource utilization.

In the Pediatric Heart Network, Collaborative Learning Study, researchers also examined if the implementation of an early extubation clinical practice guideline in patients undergoing TOF and coarctation of aorta led to cost savings [142]. The change in total hospital costs adjusted for geographic region and inflation was evaluated both before and after guideline implementation and the change was compared between study and control sites. There was an overall 27% decrease in hospital costs (interquartile range, −41.5 to −13.2%) in patients undergoing TOF repair at the active sites and costs were unchanged at the control sites. Most cost savings were related to clinical services, including mechanical ventilation and respiratory services, pharmacy, and blood gas-related costs. No change in costs was noted for patients undergoing coarctation of aorta repair. Although these results are in line with prior findings, this study also highlights that conclusion about potential cost savings cannot be easily generalized across the whole spectrum of CHS, and all institutions.

Early extubation is only one element in the multidisciplinary approach to fast-tracking CHS patients. A meta-analysis of randomized, controlled trials on fast-tracking in patients undergoing coronary artery bypass grafting (CABG) showed that standardized perioperative care including an early extubation protocol and not just early extubation *per se* was essential in reducing ICU and hospital LOS [143]. Avoiding postoperative complications such as bleeding, arrhythmias, cardiogenic shock, and renal failure is essential.

KEY POINTS: BENEFITS OF FAST-TRACKING

- Many of the benefits associated with fast-tracking are related to earlier patient mobilization, and shorter ICU and hospital LOS.
- Reducing hospital-acquired infections by reducing LOS is one of the main reasons for implementing fast-tracking, particularly in developing countries.
- There are increasing data supporting the proposition that fast-tracking reduces costs.

Concerns and safety of fast-tracking

While fast-tracking and early extubation can certainly be accomplished in children undergoing CHS, the debate continues as to whether such an approach is safe and whether it offers benefits over a traditional approach [144–146]. The individual patient's response to CPB is unpredictable. The release of inflammatory mediators, the severity of lung injury, and changes in PVR are among many of the factors frequently cited in the discussion regarding early extubation. It must be noted, though, that improvements in the CPB technique help reduce the inflammatory response. Additionally, modern anesthetic agents, including short-acting opioids, allow for adequate blunting of inflammatory mediator release without compromising an early extubation strategy. Concerns about the lack of data from randomized prospective studies show clear benefits of fast-tracking and early extubation add further to the controversy. Some of the controversies come from the poorly defined definition of fast-tracking and early extubation. Early extubation is typically part of a fast-tracking approach to patient care with defined goals. However, this does not imply compromising patient safety, which has been clearly demonstrated in adult cardiac surgery where fast-tracking is almost uniformly practiced. Early extubation should be viewed as reducing unnecessary time on MV, rather than removing the endotracheal tube regardless of the underlying patient's condition. Commonly acknowledged extubation criteria, including adequate lung mechanics and oxygenation, and hemodynamic stability also apply to patients who are considered candidates for fast-tracking and early extubation. This is regardless of whether the endotracheal tube is removed at the end of the procedure in the OR, or after a certain time in the ICU. For example, low cardiac output and decreased left ventricular function following CPB are usually considered contraindications for early extubation. MV decreases oxygen consumption and workload of the heart and is considered beneficial by many practitioners in this setting. If responsive to low inotropic support, however, mild cardiac dysfunction does not need to be an absolute contraindication for early extubation and many of these children can be fast-tracked.

At this point, there is good evidence from multiple retrospective [17, 19, 26, 30] as well as prospective observational studies that fast-tracking can be accomplished safely even in CHS [34]. Preisman et al. randomly allocated 100 consecutive children (aged 1 month–15 years) presenting for CHS to anesthetic management aiming for fast-tracking and OR extubation or to a traditional approach with elective postoperative prolonged MV [31]. There was no significant difference in mortality, reintubation rate, reoperation for bleeding, infection, and other miscellaneous complications. The authors do acknowledge, though, that the study was not adequately powered to conclusively comment on the safety of fast-tracking, something that could only be accomplished with a large multicenter study. A meta-analysis of available studies on early extubation concluded that early extubation is associated with lower ICU and hospital LOS without increased morbidity or mortality [13].

Another measure of the safety of early extubation in CHS is the reintubation rate. As mentioned earlier, reintubation rates reported in the literature are low and they do not differ from those in fast-tracked patients. Mild respiratory acidosis is frequently encountered in children who have been extubated early. This is typically well-tolerated, normalizes within a few hours, and reintubation for respiratory depression is rarely necessary [21, 25, 26, 28, 30, 39, 114]. In case of mild airway obstruction or diminished respiratory effort, non-invasive respiratory support such as nasal continuous positive airway pressure (CPAP) can be advantageous for a few hours following extubation. The use of CPAP preserves the advantages of spontaneous ventilation and helps avoid reintubation.

Additionally, hospital readmission rates and mortality need to be considered when assessing the safety of fast-tracking CHS patients. Laurence et al. found no significant change in hospital mortality, and 2-week readmission rates were unchanged after implementing fast-tracking at their institution and were not different from the reported national rates [140].

KEY POINTS: CONCERNS AND SAFETY OF FAST-TRACKING

- Published data on fast-tracking support the safety of this strategy in CHS as well.
- Reintubation and readmission rates are similar to non-fast-tracked patients.
- Side-effects of early extubation, such as mild hypercapnia, are usually transient and well-tolerated.

Postoperative considerations

The multidisciplinary approach required for the success of fast-tracking CHS patients is particularly important in the postoperative arena, and the individual roles of all team members cannot be overemphasized. In general, standard postoperative considerations also apply to CHS patients who are fast-tracked and include adequate pain control and sedation without compromising respiratory parameters. Adequate pain control without compromising respiratory effort shortly after surgery is key to the success of an early extubation strategy. This is typically accomplished with multi-modal pain management and by limiting opioid use. The American Association for Thoracic Surgery consensus document on enhanced recovery after pediatric cardiac surgery also emphasizes the increasing role of opioid-sparing strategies [10]. Pain management strategies recommended include patient and family education, non-opioid analgesics, regional anesthesia, all a class IIa recommendation, as well as neuraxial techniques (IIb).

Intravenously administered opioids have been the mainstay of any pain regimen following surgery, including patients who are fast-tracked. Intravenous acetaminophen has analgesic as well as antipyretic effects [147]. It is currently FDA-approved for use in children older than 2 years [148], but off-label use in younger children is almost

ubiquitously practiced. Acetaminophen use for pain control seems attractive for fast-tracking as it does not cause respiratory depression, hemodynamic instability, platelet dysfunction, or potential kidney injury. However, there is currently limited experience with parenteral application in the pediatric cardiac surgery setting in the United States [149]. Although not usually associated with serious hemodynamic effects, mild hypotension, that is, mean arterial pressure decrease 15% from baseline, was seen in 5% of critically ill children with cardiac disease [150]. Hepatic injury is a known serious side effect, and pediatric dosing and contraindications should be carefully considered. Systemic clearance in neonates and young infants is significantly reduced. Dose reductions of 33% (age, 1 month to <2 years), and 50% in neonates up to 28 days, are recommended by the drug manufacturer. Other IV non-steroidal anti-inflammatory drugs (NSAIDs), such as ketorolac and indomethacin, have been linked to side effects such as gastrointestinal bleeding, bronchospasm, and kidney injury, which is why their use is somewhat restricted in the cardiac surgery setting. In a small prospective study in children undergoing CHS, the use of ketorolac was not found associated with adverse events [151]. Similarly, in a retrospective study in 67 patients undergoing CHS, the use of NSAIDs including acetaminophen and ketorolac was associated with lower pain scores and morphine requirements, and no increase in renal dysfunction and bleeding was noted [152]. A large systemic review found inconclusive data to support or reject the use of ketorolac for postoperative pain in children [153]. Despite the acknowledged knowledge gap regarding the safety of ketorolac in pediatric cardiac surgery [154], ketorolac is frequently used in a multi-modal opioid-sparing pain management regimen. The use of dexmedetomidine in CHS has been discussed earlier. As part of a fast-tracking strategy, it can help lower opioid use also in the postoperative period. In a large systemic review including five randomized controlled and nine observational studies and a total of 2,229 patients, dexmedetomidine was associated with lower requirements of postoperative fentanyl and morphine [155]. Dexmedetomidine is also frequently used for sedation in children following CHS [156–159]. It allows for sedation without significant respiratory depression and appears to be safe for use even beyond 24 hours; however, conclusive data from large randomized controlled studies are still lacking [160].

In the setting of fast-tracking, it is particularly important to differentiate between emergence delirium or agitation and inadequate pain control, particularly in infants and small children. The presence of parental support cannot be underestimated also for sedation and pain management purposes. Early extubation and mobilization allow for early parental engagement.

Neuraxial techniques

The addition of neuraxial techniques for pain management is advocated by some practitioners, while others vehemently oppose any neuraxial manipulation in patients undergoing CHS with CPB and full heparinization [161, 162]. Concerns persist about the safety of neuraxial manipulation in patients who are subsequently fully heparinized. Nevertheless, there is evidence that a neuraxial technique can be used safely and may offer benefits in the cardiac surgery setting. Epidural (including caudal) as well as intrathecal, single-shot, and continuous catheter techniques are used. While a thorough review of the individual techniques would go beyond the scope of this text and has been presented in detail elsewhere [163, 164], each individual technique will be discussed in relation to benefits, concerns, and evidence regarding safety and outcome in the pediatric cardiac surgery setting. The use of neuraxial anesthesia in CHS studies is presented in Table 24.2. As data on the safety in patients undergoing CHS are limited, references from large prospective studies in the adult cardiac population providing further insight into the matter are also included in the following sections.

Single-shot neuraxial techniques

Single-shot caudal techniques offer the advantage of simplicity and avoidance of manipulating a catheter in the epidural space. However, for procedures at the thoracic level, large volumes and higher doses of local anesthetics would be required to reach an adequate level from a caudal approach [168, 178]. Even then, the analgesic effect from a single shot local anesthetic would not last far into the postoperative period. Consequently, single-shot caudal techniques include or are often limited to the administration of an opioid; most commonly, preservative-free morphine. Morphine administered via the caudal space exhibits its peak analgesic effect within 4–7 hours [179] and its duration of action has been reported up to 24 hours [166, 180]. Typically, up to 100 μg/kg of preservative morphine is administered into the caudal space, with dose adjustments in the very young. Hydromorphone has also been tested, resulting in good pain control, and lower rates of opioid-related side effects have been suggested; however, data are very sparse at this point [181, 182]. The analgesic effect of a single-shot caudal is somewhat less predictable than a single-shot intrathecal technique. This is probably due to septations in the caudal epidural space, and a higher failure rate mostly from inadvertent subcutaneous rather than epidural injection [183]. In a prospective randomized controlled study in 50 children undergoing CHS, the caudal epidural was compared to intravenous analgesia [177]. The hemodynamic response to surgery was less pronounced and pain scores were lower in the caudal group. A large systematic review of caudal anesthesia in CHS patients identified a total number of 2,159 patients from 17 studies [184]. There was significant heterogeneity with regard to intervention and study population. Lower pain scores and a possible reduction in stress response were noted in some studies; although, the overall data were inconclusive to make firm recommendations for or against caudal anesthesia use. In older children, a single-shot subarachnoid (intrathecal) injection of preservative-free morphine (5–10 μg/kg) can easily be accomplished. Typically, 5 –10 mcg/kg of intrathecal morphine is administered, and higher doses (up to 30 mcg/kg have been reported) are associated with a higher incidence of respiratory depression [185, 186]. The use of intrathecal local anesthetics in children undergoing cardiac surgery, including high spinal anesthesia, has been described [167]. Hypotension is less frequently observed than adult spinal anesthesia [169];

AL Grawany

Table 24.2 Publications on neuraxial anesthesia in children undergoing congenital heart surgery

Reference	Study type	Patients enrolled	Neuraxial	Findings
Shayevitz et al. [165]	R	27/27	• Lumbar epidural catheter morphine infusion, vs. • IV opioid	• Shorter time to extubation, shorter ICU LOS, and earlier enteral feeding in the epidural group
Rosen & Rosen [166]	P/R	32 (2–12 years)	• Caudal morphine (75 μg/kg)	• Lower pain scores and less supplemental IV morphine in the caudal group
Hammer et al. [167]	R	25/25	• Single-shot intrathecal morphine (7–10 μg/kg) + tetracaine, vs. • Epidural catheter bupivacaine + hydromorphone (7–8 μg/kg)	• 100% extubation in OR in both groups, no reintubation • Patients with single-shot required more sedative/analgesics
Peterson et al. [114]	R	220	• Single-shot epidural, intrathecal, and epidural catheter techniques	• 89% extubated in OR, eight reintubations • Less adverse effects with thoracic epidural
Rojas-Perez et al. [168]	P/R	15/15	• Caudal (bupivacaine + morphine) + GA, vs. • GA alone	• Shorter time to extubation in caudal group • Less intraoperative fentanyl requirement in caudal group
Finkel et al. [169]	P	30 (7 months–13 years)	• Intrathecal tetracaine + morphine	• Good hemodynamic stability with spinal anesthesia • 100% extubation in OR
Suominen et al. [170]	P/R/observer-blinded	35/36	• Intrathecal morphine (20 μg/kg) + GA, vs. GA alone	• Time to first IV narcotic dose longer, and total dose of IV morphine lower in intrathecal group • No difference in time to extubation and ICU LOS
Humphreys et al. [171]	P/R	30/30 (<2 years)	• Intrathecal catheter (24–48 hours) morphine (20 μg/kg) and bupivacaine + GA, vs. • GA alone	• Spinal anesthesia resulted in lower plasma norepinephrine, epinephrine, and lactate levels
Hammer et al. [172]	P/R	20/20	• Single-shot intrathecal morphine (7 μg/kg) + GA, vs. GA alone	• Lower pain scores in intrathecal group • No difference in adverse events
Leyvi et al. [173]	R	46/71	• Single-shot caudal (bupivacaine + 70–110 μg/kg morphine), vs. • GA alone	• No difference in ICU/hospital LOS and pain score • Shorter time to extubation and reduced time on mechanical ventilation in caudal group
Stuth et al. [174]	P/R/observer-blinded	64 (2–55 months) Stage 2 and 3 single-ventricle palliation	• Caudal group (100 μg/kg + bupivacaine), vs. • Control (placebo caudal) + postoperative IV morphine	• In extubated children, caudal morphine delayed the need for rescue morphine in stage 3 palliation only • No significant difference in overall morphine requirements between active and placebo group
El-Morsy et al. [175]	P/R/observer-blinded	60 (1–24 months)	• Thoracic epidural, vs. • Paravertebral catheter	• Comparable analgesia, pulmonary function, plasma cortisol levels • Higher failure rate and more complications in the epidural group
Nasr et al. [176]	P/R/observer-blinded	20/20	• Caudal bupivacaine + dexmedetomidine (0.5 μg/kg), vs.	• Serum cortisol levels lower in the dexmedetomidine group
Samantaray et al. [177]			• Caudal bupivacaine + fentanyl (1 μg/kg)	• Lower pain scores in dexmedetomidine group

R, retrospective; P, prospective; O, observational; GA, general anesthesia; ICU, intensive care unit; OR, operating room; LOS, length of stay.

however, the duration of the block for pain management is usually inferior to an epidural continuous technique and is thus very infrequently practiced.

In general, epidurally and intrathecally administered opioids have been shown to provide excellent analgesia [167, 187], blunt the stress response to surgery and CPB [188–190], improve pulmonary function [191], and reduce time on MV [122, 168, 173].

In addition to the already discussed use of local anesthetics and opioids, α_2-receptor agonists such as clonidine [192–194], and more recently dexmedetomidine [176, 195], ketamine [196, 197], and magnesium [198–201], have all been added to minimize side-effects from neuraxially administered opioids, such as respiratory depression, and to prolong analgesic effects. A systematic review of the current literature identified 20 randomized trials where clonidine had been added to local anesthetic for caudal regional anesthesia [202]. The addition of clonidine resulted in superior long-lasting pain control and fewer patients requiring rescue analgesics, with no significant difference in complications. A similar review with ketamine added to caudal local anesthetics produced similar findings; however, the authors also indicated

that the available data do not allow for conclusions regarding potential neurotoxic effects [203]. To date, the experience in the United States with these additives remains limited and they are not routinely used. Even though single-shot techniques may provide somewhat inferior pain control when compared with a thoracic epidural catheter technique, they are quite popular among many practitioners as single-shot techniques require less time and the potential risks associated with an indwelling catheter are avoided [204].

Catheter-based neuraxial techniques

Epidural catheter insertion for pain management in children undergoing CHS has been described. Similar to single-shot neuraxial techniques, however, there are concerns about the safety in the cardiac surgery setting. Consequently, while individual centers routinely use epidural catheters and report good outcomes in the CHS setting, others object to epidural catheter manipulation in this patient population. Regardless of this ongoing controversy, lumbar epidural, caudal epidural, thoracic epidural, paravertebral, and even subarachnoid catheter insertion [171] have been reported in children undergoing cardiac surgery [114]. Compared with single-shot neuraxial or IV analgesia, epidural catheter techniques promise superior analgesia [172]. Peterson et al., for example, compared caudal epidural, lumbar epidural, thoracic epidural, and intrathecal blocks using a combination of morphine or hydromorphone and local anesthetic [114]. The majority of patients were extubated in the OR, and the use of a thoracic epidural catheter technique provided superior pain control with overall fewer adverse events compared with other neuraxial techniques. It seems logical that injection at the thoracic level results in better analgesia for cardiac surgery, and catheter manipulation is minimized. Additionally, local anesthetic administration at the thoracic level provides the additional advantage of the sympathetic blockade and superior blunting of stress response otherwise not achieved by lower epidural single-shot opioid-only based techniques. The insertion of an epidural catheter at the lumbar or caudal level and advancement of the catheter cranially in order to achieve adequate blockade at the thoracic level are also being practiced [165, 205–209]. While this technique seems to offer the advantage of not manipulating a needle in the thoracic epidural space, the epidural canal is heavily vascularized and the risk of advancing a catheter over a longer distance may actually carry a higher risk of injuring an epidural vein compared with the thoracic approach. Also, the correct positioning of the catheter tip at the thoracic level is not always achieved without fluoroscopy and may explain why catheters placed in the thoracic region seem to provide superior pain control with fewer side effects. While there may be real and potential benefits to neuraxial catheter-based analgesia compared with an IV analgesic regimen, the logistics associated with epidural catheter insertion and management are significantly more complex. Unlike adults, children usually do not tolerate awake catheter insertion. Day-of-admission surgery is routinely performed in the United States and is part of fast-tracking CHS patients, preventing catheter insertion well ahead of surgery and systemic heparinization. Additionally, catheter removal in patients with ongoing coagulopathy after surgery is problematic. Even in patients with normal hemostasis, patient discharge from the ICU may be delayed for safe removal and subsequent observation. For many practitioners who oppose neuraxial and, in particular, catheter-based techniques in patients with subsequent full heparinization, the risks outweigh the potential benefits.

Potential benefits of neuraxial techniques

Some of the benefits have already been mentioned in the previous section and many are related to superior pain control and consequently reduction in systemically administered analgesic and sedation requirements. Several studies in patients undergoing CHS compared an IV pain medication regimen with a combined IV and neuraxial technique. Hammer et al. [167] performed a prospective, randomized trial in children undergoing CHS, assessing the effects of adding single-shot subarachnoid tetracaine and morphine to an inhalational/remifentanil anesthetic. The analgesic effects of subarachnoid morphine were long-lasting and 8- and 24-hour pain scores and fentanyl requirements in the postoperative period were significantly lower in the spinal group compared with IV fentanyl only. Similarly, Rojas-Perez et al. also found reduced fentanyl requirements in children undergoing cardiac surgery with caudal morphine and bupivacaine [168]. Suominen et al. [144] examined the effects of a single-shot subarachnoid morphine (20 μg/kg) bolus in children undergoing CHS. In this prospective, randomized, and observer-blinded study, intrathecal morphine was associated with superior pain control following surgery as evidenced by a longer time to first bolus administration and lower total IV morphine requirements. The IV drug-sparing effects were observed for 12 hours after surgery. Interestingly, intrathecal morphine was not significantly associated with earlier extubation and shorter time in the ICU, which is frequently shown with epidural anesthesia. Another prospective study in children undergoing stage 2 and 3 palliations for single-ventricle CHD compared a primarily caudal technique with an IV drug regimen [145]. Both parents and the postoperative care team were blinded to the analgesic regimen. The use of caudal morphine significantly delayed the need for postoperative rescue morphine only in stage 3 patients. Surprisingly, overall IV morphine requirements did not differ between the groups. Most studies in adult cardiac surgery confirm superior pain control with neuraxial anesthesia added to a general anesthetic [210–212].

Despite these findings, critics will rightfully say that adequate pain control can also be achieved with IV analgesic drug administration. What seems more important than actual pain control, however, is how the IV drug sparing effect translates into other outcome measures. For example, multiple studies report earlier extubation and less time on MV with neuraxial analgesia [168, 211–217], and associated benefits such as reduction in respiratory complications have been discussed in detail earlier in the chapter. Findings of earlier recovery of intestinal function with neuraxial anesthesia [218] may also translate to the CHS setting, particularly if patients are mobilized earlier and enteral feeding can be commenced. Additional information can be gained from the adult literature. A large meta-analysis that included 1,178 patients from 15 randomized trials examining the

effects of thoracic epidural anesthesia in CBP surgery found decreased pulmonary complications, dysrhythmias, and time to extubation [219]. While improved postoperative pulmonary function is also reported by several other adult studies [217, 220, 221], the largest prospective randomized trial to date was unable to demonstrate a benefit of neuraxial anesthesia in preventing pulmonary complications or mortality [222]. A meta-analysis by the same author, however, included 31 randomized controlled trials with a total of 3,047 patients, comparing outcomes in adult patients undergoing cardiac surgery with either general anesthesia alone or in combination with thoracic epidural anesthesia [223]. This analysis confirmed a risk reduction for respiratory complications and supraventricular arrhythmias. Another large (1,543 patients) retrospective propensity score-matched study, found intrathecal morphine to be associated with fewer pulmonary complications compared to intravenous analgesia [224].

The effect on ICU and hospital LOS is controversial, with some studies suggesting reduced LOS with a neuraxial technique [225], while others did not observe a difference [212, 215, 216, 226–228]. A large prospective observational study in adult cardiac surgery patients compared general anesthesia supplemented with a thoracic epidural technique with general anesthesia alone. The addition of thoracic epidural anesthesia resulted in a shorter time on MV and fewer postoperative complications, such as delirium, pneumonia, acute renal failure, and myocardial function, resulting in shorter ICU LOS as well as reduced cost [225].

Additional benefits of neuraxial anesthesia include blunting of the inflammatory response to surgery and CPB. In children undergoing CHS, plasma norepinephrine and epinephrine concentrations [171] and 24-hour urinary cortisol excretion [229] were reduced with intrathecal drug administration. Additional benefits reported are less inotropic support requirements and greater hemodynamic stability [230], fewer arrhythmias [212, 217, 231], and improved ventricular function [232]. Data on biomarkers of myocardial injury in adult cardiac surgery were reduced in some studies [233], while others did not observe any difference when an epidural catheter was used [234]. Lee et al. [235] found that a total spinal with subarachnoid bupivacaine before induction of general anesthesia in adult cardiac surgery patients resulted in less β-receptor dysfunction in response to CPB, lower catecholamine levels, a higher cardiac index, and a lower PVR index in the post-CPB period. In adults undergoing cardiac surgery, the thoracic epidural blockade has also been shown to enhance coronary perfusion [236–239]; however, it is unclear if all these findings from the adult literature on neuraxial anesthesia can be transferred to children undergoing CHS.

Overall, the majority of studies in children as well as adults suggest that there are benefits in adding a neuraxial technique to the anesthetic regimen in patients undergoing cardiac surgery. Benefits supported by best evidence include superior pain control, less time on MV, and possibly fewer arrhythmias. With these and many of the additional benefits in mind, adding a neuraxial technique to the anesthetic regimen seems to be suited to facilitate fast-tracking CHS patients.

Risks and complications of neuraxial techniques

Many of the typical side effects of neuraxial anesthetics are not specific to cardiac surgery. Hemodynamic side-effects such as hypotension and bradycardia typically seen with neuraxially administered local anesthetics in adults are less pronounced in children [240]. Nausea and vomiting occur less frequently and prevention with commonly used drugs such as serotonin 5-HT3 receptor antagonists or a combination of drugs should be considered if very early extubation is planned [241]. Pruritus occurs in a very high percentage of cases, especially following intrathecal opioid administration. Diphenhydramine is a popular first-line choice for treatment. Its effectiveness for pruritus related to neuraxial opioids is limited, however, and small amounts of naloxone [242] or even mild sedation, for example, with dexmedetomidine [243] or small amounts of propofol [244] are often more effective choices. Mild respiratory depression is common with neuraxial opioid administration. Mild hypercarbia and respiratory acidosis are frequently seen, especially following early extubation; however, this is usually very well tolerated and rarely requires reintubation. Close observation in a monitored unit is recommended for 24 hours after neuraxial morphine administration, which is rarely a problem in children undergoing CHS. CPAP can be applied nasally or via facemask to support respiratory efforts. Urinary retention is not a problem in this patient population as almost all cardiac patients, including children, have a urethral catheter inserted. Ideally, all neuraxially administered drugs should be labeled for neuraxial use by the manufacturer. Particular attention should be paid to avoid drugs with added preservatives, some of which have been found to be neurotoxic when injected via the neuraxial route [245]. Few drugs are approved specifically for neuraxial administration; however, off-label use is common.

The most feared complication of a neuraxial regional anesthetic technique is an epidural hematoma. This is of particular concern in patients eventually undergoing full heparinization for CPB. Unlike in adults, the preoperative insertion of an epidural catheter in an awake child is rarely possible. Typically, neuraxial techniques are performed in the anesthetized child, prohibiting patient feedback during needle and catheter manipulation as well as injection. In order to perform a neuraxial technique safely, common considerations for neuraxial anesthetics must be followed, and careful attention to the most recent guidelines on neuraxial anesthesia in the setting of anticoagulant and antiplatelet agents is of paramount importance. Guidelines are published and regularly updated by the American Society of Regional Anesthesia (ASRA) [246]. Currently, the recommended time interval between neuraxial manipulation and full heparinization is 60 minutes. In practice, heparin is often administered earlier. For example, Weiner et al. [247] reviewed the medical records of 714 children who underwent CHS and who had either single-shot caudal or intrathecal morphine as part of their anesthetic regimen (no catheter insertion). There were no cases of symptomatic spinal or epidural hematomas. Further analysis showed that the time interval between full heparinization and neuraxial technique was less than 1 hour in 466 patients. Specifically, 299 patients were heparinized less than

45 minutes following neuraxial technique, including 270 caudal and 29 spinal morphine administrations; in 86 patients, heparin was given less than 30 minutes after the neuraxial technique. While this case series is too small to draw conclusions about the safe timing of single-shot neuraxial anesthesia and consequent heparinization, it provides further support that as long as the coagulation system is intact neuraxial manipulation can be performed safely. To date, there has only been one case of epidural hematoma reported in pediatric patients undergoing CHS. Rosen et al. reported a case of an adolescent who developed an epidural hematoma 2 days after surgery and epidural catheter placement. With the catheter still *in situ*, IV heparin was started for prosthetic valve thromboprophylaxis, and alteplase was administered additionally for management of a thrombosed central venous line [248]. The same group reviewed 750 records of children (52% infants) undergoing CHS who also had an epidural catheter placed as part of their anesthetic regimen and did not find any further neurologic complications [39].

While under-reporting may occur, the actual number of cases performed in clinical practice also far outweighs published case numbers. Given the very low incidence of this serious complication, it would require well-designed prospective studies with thousands of patients for an accurate risk calculation. To better assess current practice and the risk of neuraxial anesthesia in children, a multicenter database was created [249]. The Pediatric Regional Anesthesia Network database (PRAN) is a large multicenter registry collecting data on regional blocks performed at the participating institutions. The latest report from that database included over 104,393 blocks placed in children of all age groups, including 18,065 continuous catheters placed [250]. The majority of blocks (93.7%) were placed with the patient under general anesthesia. No permanent neurological complications were noted, and the risk of transient neurological deficits was calculated as 2.4:10,000 (95% CI, 1.6 to 3.6:10,000), with no difference between peripheral and neuraxial blocks. There were no cases of epidural hematomas seen with neuraxial catheters; one epidural hematoma was reported with a paravertebral catheter, and one epidural abscess was documented. From the same registry, Suresh et al. [251] focused on the safety of caudal blocks in children. Of the 18,650 children included, the estimated incidence of complications was estimated to be 1.9% (95% CI, 1.7–2.1%). Although this incidence seems relatively high, it must be noted that complications included the reporting of block failure, and otherwise were defined as blood aspiration, intravascular test dose injection, dural puncture, seizure, cardiac arrest, sacral pain, or neurological symptoms. No cases of permanent sequelae from complications were noted. Two additional large-scale reviews are also worth mentioning, even though they did not specifically target cardiac surgery cases. Participating centers in France submitted data on regional anesthesia in children over a 1-year period [252]. Data on 31,132 regional anesthetics were collected and analyzed. The overall complication rate was 0.12%; most were minor, and none resulted in permanent neurological damage. In Britain, data on epidural catheter analgesia in children were collected over a 5-year period [253]. A total of 10,633 catheter insertions in children were reported. Serious complications occurred in five children (1/2,000) resulting in permanent damage in one child; low severity events were more frequent (1/189). Insertion of epidural catheters in neonates was associated with a higher risk.

Additional information can be gained from publications in adult patients undergoing cardiac surgery [254]. Chakravarthy et al. [255] presented an audit of 2,113 cardiac surgery thoracic epidural anesthesia cases over a 13-year period with no permanent neurologic deficits, a 0.9% dural puncture rate, and 0.2% transient neurologic deficits. Jack et al. published their experience of thoracic epidural catheter placement in 2,837 patients undergoing cardiac surgery [256]. No epidural hematoma was seen in this series. Similar results were reported by Royse et al. [257], who reviewed 874 cardiac surgery cases involving epidural anesthesia over a 7-year period with no complications attributable to epidural catheter use. Pastor et al. [258] reported 714 uneventful cases in patients undergoing CABG surgery over a 7-year period. Overall, there are only very few cases of epidural hematomas associated with epidural anesthesia reported in adult cardiac surgery [259]. The vast majorities of studies are reassuring and confirm the safety of neuraxial anesthesia in adult cardiac surgery [260–264].

Several attempts have also been made to statistically estimate the actual and presumed risk of an epidural hematoma in patients undergoing cardiac surgery. A widely quoted estimation of the risk of epidural hematoma with thoracic epidural anesthesia in patients undergoing cardiac surgery is 1 in 12,000, with 95% confidence intervals (CI) of 1:2,100 to 1:68,000, and 1 in 1,000 with 99% confidence [265]. A risk assessment in cardiac surgery including source data up to 2012 found the risk of catheter-related epidural hematoma estimated to be 1 in 5,493 (95% CI: 1/970–1/31,114), which is similar to the risk of catheter-related epidural hematoma in the general surgery population (1 in 6,628; 95% CI: 1/1,170–1/37,552) [266]. Intrathecal risks from a different older source of risk assessment are quoted as 1 in 3,610 and 1 in 2,400, respectively [267].

In reviewing neurological complications associated with neuraxial anesthesia beyond the CHS setting, very few cases of epidural hematomas associated with neuraxial anesthesia have been reported. Not all of them are related to neuraxial manipulation [268] and even spontaneous epidural hematomas without the use of anticoagulants occur [269–271]. A report of four cases of permanent neurological injury in children undergoing general surgery cases did not reveal a common denominator [271].

In summary, available data on the safety of neuraxial anesthesia in patients undergoing CHS suggest that these techniques can be performed with minimal risk as long as current guidelines are followed. Additionally, when planning for neuraxial anesthesia, medico-legal concerns should also be considered in some CHS with the known inherent risk of spinal cord injury (i.e., coarctation of aorta repair) [272].

Regional blocks

Regional blocks have seen an increase in popularity including in pediatric cardiac surgery. As part of a multimodal pain management regimen suggested benefits include the ability to provide analgesia with fewer side effects. In the American

Association for Thoracic Surgery document on enhanced recovery after pediatric cardiac surgery [273], peripheral regional anesthesia achieves a class IIa recommendation as an effective opioid-sparing modality in CHS. Neuraxial anesthesia is also recognized to help reduce opioid use in the perioperative period (class of recommendation IIb). However, avoiding any neuraxial manipulation make regional blocks a potentially safer option compared to epidural or spinal anesthesia techniques, especially with systemic heparinization required for cardiopulmonary bypass. It must be noted though, that at the point of this writing high-quality data from large, randomized trials regarding the safety of regional blocks in CHS are still missing.

Various regional techniques have been described, including interpleural infusion of local anesthetics [274, 275], and subcutaneous wound infiltration techniques [276]. However, the ultrasound-guided fascial plane blocks that have recently seen a significant increase in use will be presented in the following paragraphs. Blocks can be administered prior to surgical incision, or after surgery, and single-shot as well as catheter based techniques have been described.

The administration of local anesthetic at the sternum bilaterally in each intercostal space prior to sternotomy closure is typically referred to as *parasternal blocks* or *intercostal nerve block (ICNB)* and can easily be performed by the surgeon in the field. Chaudhary et al. conducted a double-blind randomized trial in 30 children undergoing CHS, comparing 0.08 mL/kg/space of 0.5% ropivacaine with 0.9% saline injected in five parasternal spaces on each side before skin closure [277]. They reported no complications, improved pain scores, less postoperative opioid requirement, and shorter time to endotracheal extubation. Although local anesthetic can also be deposited in each intercostal space ultrasound-guided after the closure of the sternotomy wound, fascial plane blocks are typically preferred [278]. These fascial plane blocks target the anterior cutaneous branches of the intercostal nerves 2–6 at the sternum. The fascial plane between the transverse thoracic muscle and internal intercostal muscles also referred to as *Transverse Thoracic Muscle Plane Block* (TTPB) (Figure 24.2), or more superficially the plane between the intercostal muscles and pectoralis major muscle (*Pecto-Intercostal Fascial Block, PIFB*) are targeted (Figure 24.3). These blocks are similar to a parasternal block with regards to the analgesic effect; however, require fewer injections due to the local anesthetic spread in a fascial plane rather than a single intercostal space. In a prospective, double-blind study 100 children undergoing sternotomy were randomized to TTPB using 0.2% ropivacaine versus normal saline [279]. Postoperative pain scores up to 24 hours, intraoperative fentanyl use, and postoperative rescue fentanyl requirements were lower in the ropivacaine group. These findings were confirmed in a similar prospective, randomized, double-blind study in 80 children aged 2–12 years undergoing cardiac surgery [280]. Care must be taken to avoid puncture and inadvertent injection of local anesthetic into the vascular bundle underneath the ribs, and the internal mammary artery, the latter of which descends along the chest wall in the same fascial plane used for the transversus thoracis muscle plane block (TTPB).

Paravertebral blocks [281, 282], as well as catheters [283], have also been used in children and CHS. El-Morsy et al. [284] performed a prospective randomized study comparing thoracic epidural with paravertebral catheter placement in 60 children (age 1–24 months) undergoing CHS. Analgesia, serum cortisol level, and pulmonary function parameters were comparable; however, failure rate and complications were more frequent in the epidural group. In a review of the literature and meta-analysis of epidural vs. paravertebral catheter insertion in adult patients undergoing thoracotomy, Davies et al. also found fewer side-effects such as nausea, vomiting, and hypotension associated with a paravertebral technique [175]. Data from 100 children undergoing CHS with a paravertebral block were reviewed and matched with a historical control group [285]. Pain scores, fentanyl use, and time to first rescue

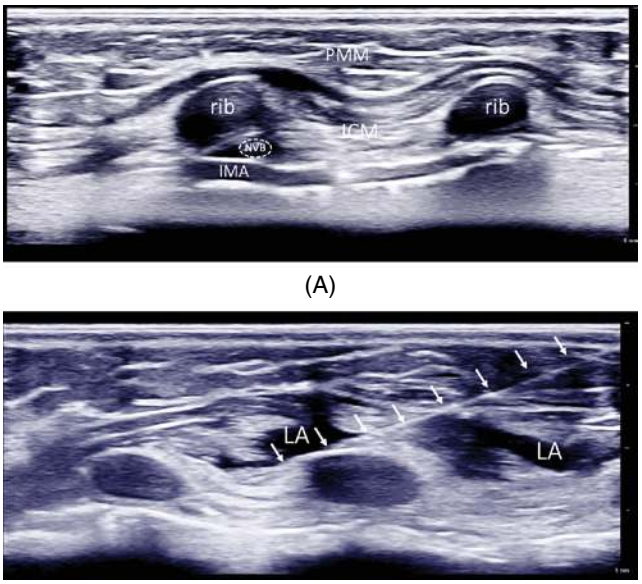

Figure 24.3 Ultrasound image of a Pecto-*Intercostal Fascial Block (PIFB)* in a 2-year-old patient. (A) PMM, pectoralis major muscle; ICM, intercostal muscle; IMA, internal mammary artery; NVB, neurovascular bundle. (B) Arrows indicate needle; LA, local anesthetic.

analgesic were all lower in the paravertebral block group. Limited information is available regarding the risk of developing a hematoma in anticoagulated patients after a paravertebral block. It has therefore been recommended to follow the same guidelines used for neuraxial blockade [246].

Recently, the *Erector Spinae Plane Block (ESPB)* has been the subject of a number of publications for thoracotomy and chest wall surgery, and as a bilateral block for sternotomy procedures [278] (Figures 24.4 and 24.5). The presumed mechanism includes diffusion of local anesthetic into the paravertebral space (posterior paravertebral pathway), as well as anterior spread reaching the lateral cutaneous nerve branches (lateral pathway) [286]. In a prospective, but not blinded study, 80 children were randomized to ultrasound-guided bilateral ESPB with 0.2% ropivacaine and a control group [287]. Postoperative pain scores were significantly lower in the block group up to 10 hours postoperatively. In another prospective, randomized, and double-blinded study using bilateral ESPB catheters in 50 children undergoing sternotomy, patients were randomized and received programmed intermittent boluses of 0.2% ropivacaine versus normal saline [288]. Postoperative pain scores and 48 hours cumulative morphine requirements were significantly lower in the ropivacaine group.

The *Serratus Anterior Plane Block (SAPB)* is another ultrasound-guided fascial plane block; however, its effect is limited to the lateral chest wall, that is, lateral cutaneous nerve, and does not reach the terminal nerve endings near the sternum (Figure 24.6). In CHS, indications for a SAPB may include a lateral incision for surgical closure of a persistent ductus arteriosus, coarctation of aorta, or any lateral chest wall approach to cardiac surgery [289–292]. In a prospective, randomized, single-blind study in 108 children undergoing CHS via a thoracotomy approach comparing ICNB, SAPB, and pectoral nerve block (PECS II), pain scores were similar in the three groups, with higher rescue fentanyl requirements in the ICNB [293]. Despite obvious limitations, the use of SAPB has been described for sternotomy in a small case series [294].

It must also be noted, that despite the promising results and most studies showing opioid-sparing effects, superficial plane blocks are best suited as part of a multimodal regimen, and rarely provide adequate analgesia when used alone. A systemic review including 14 randomized trials and 605 patients found regional anesthesia to help reduce pain up to 24 hours after cardiac surgery [295]. The effective reduction in pain was equivalent to 2.1–2.9 on a scale from 0–10. No significant effect on nausea and vomiting, and major morbidity and mortality were noticed. For single-shot techniques and administered after surgery, the analgesic effect typically lasts no longer than 12 hours, and this time can obviously be extended with catheter-based techniques. Deeper structures, referred pain, positional pain, chest tube insertion and pleural pain, are frequent sources of post-cardiac surgery pain. Often pain significantly subsides when chest tubes are removed in the postoperative course, demonstrating the limitation of regional blocks to the incision site. Chest tube pain can be somewhat mitigated by direct local anesthetic infiltration of the insertion sites, or a *Rectus Sheath Block (RSB)* has been described for that purpose [296].

Other risks and limitations include the laterality of a regional block necessitating bilateral blocks for midline procedures, also possibly increasing the risk for local anesthetic toxicity. Reassuring data come from several studies, including a study in 27 children undergoing cardiac surgery with and without cardiopulmonary bypass. The use of bilateral ESPB catheters in these children did not lead to signs of clinical local anesthetic toxicity, and plasma lidocaine levels were below toxic thresholds in both groups [297]. Although regional blocks and in particular ultrasound-guided fascial plane blocks are considered a safer choice when compared to neuraxial techniques, for deeper blocks such as the ESPB, and blocks administered in areas with high vascularity, the current recommendations are to apply neuraxial guidelines [246].

The reader is referred to several excellent reviews for a more detailed discussion of neuraxial and regional anesthesia techniques [278, 298].

KEY POINTS: NEURAXIAL AND REGIONAL TECHNIQUES

- Multimodal pain management strategies include IV, as well as regional or even neuraxial techniques.
- Regional techniques and in particular ultrasound-guided fascial plane blocks are increasingly used as part of a multimodal pain management strategy.
- Neuraxial manipulation with subsequent systemic heparinization for CPB is controversial.
- There are increasing data showing that neuraxial techniques can be used safely in CHS.
- The benefits of neuraxial anesthesia beyond superior pain control are increasingly recognized.
- For deeper fascial plane blocks neuraxial guidelines should be applied.

Conclusions

Fast-tracking patients undergoing CHS has become a viable alternative to a more traditional approach of prolonged postoperative sedation and MV in CHS. Modern anesthetics allow early extubation and adequate pain control without compromising patient safety. In eligible patients, fast-tracking can offer benefits. The overall success of fast-tracking CHS patients requires careful patient selection, recognizing contraindications, and most importantly embracing the fact that this is a multidisciplinary approach that involves all specialties involved in CHS patient's care [299]. Each individual component is equally important for the success of implementing and maintaining fast-tracking in a CHS program.

The American Association for Thoracic Surgery Congenital Cardiac Surgery Working Group 2021 consensus document on a comprehensive perioperative approach to enhanced recovery after pediatric cardiac surgery. J Thorac Cardiovasc Surg 2021;162(3):931–54. Online ahead of print.PMID: 34059337. The American Association for Thoracic Surgery published a consensus document on enhanced recovery after pediatric cardiac surgery. Key strategies that were identified for successfully implementing and maintaining an enhanced recovery pathway include a multi-disciplinary approach, appropriate patient selection, staff and patient/family education, protocol, and guideline-driven practice. The task force concludes that enhanced recovery protocols do not increase morbidity and mortality after pediatric cardiac surgery. Patient and family satisfaction with perioperative care may be improved.

The Pediatric Heart Network Collaborative Learning Study used collaborative learning principles to implement early extubation guidelines across 4 active study sites and five control sites. Overall compliance with early extubation guideline adoption was high, and an increase in early extubation rates, from 11.7% before to 66.9% at the active sites, were seen for patients undergoing tetralogy of Fallot repair after guideline implementation. No change was noted for coarctation of aorta repair. There was no increase in the reintubation rate during the study period.

126 Ono M, Georgiev S, Burri M, et al. Early extubation improves outcome following extracardiac total cavopulmonary connection. Interact Cardiovasc Thorac Surg 2019;29(1):85–92. In patients with single-ventricle physiology undergoing bi-directional Glenn or Fontan procedure, early extubation and spontaneous ventilation have been associated with improved hemodynamics. This paper reports additional benefits including lower inotropic support, earlier chest tube removal, and shorter ICU LOS. Lower intrathoracic pressure associated with spontaneous ventilation increases central venous blood return, which becomes the driving force of pulmonary blood flow across the pulmonary vascular bed and thus for maintaining left ventricular preload and cardiac output.

135 Kawaguchi A, Liu Q, Coquet S, et al. Impact and challenges of a policy change to early track extubation in the operating room for Fontan. Pediatr Cardiol 2016;37:1127–36. An examination of the impact of an institutional policy change to early extubation in patients undergoing Fontan palliation. The policy change was associated with an impressive reduction in ICU LOS (average 4.1 days; 95% CI −1.2 to −6.9). Fluid balance did not differ, and although the rate of reintubation was statistically not different, hemodynamic

instability was the main reason for reintubation prior to policy change, and bleeding and respiratory etiology listed most commonly in the time period after.

Epidemiology

Although one of the most severe of adverse events related to anesthesia, cardiac arrest (CA) in the perioperative setting occurs infrequently, with rates of anesthesia-related CA during pediatric anesthesia in the general population reported between 0.14 and 0.8% of anesthetics [2–4]. Significant variability in anesthesia-related CA rates exists across the pediatric age and illness category spectrum; yet, there is clear evidence to support higher risks of periprocedural CA for patients with underlying CHD [5]. Children with CHD frequently undergo diagnostic and interventional procedures that require sedation or general anesthesia with over 45,000 noncardiac [6] and over 25,000 cardiac [7] surgical procedures performed every year across North America. In spite of these yearly procedural volumes for the CHD population, our understanding of the epidemiology and outcomes after anesthesia-related CA remains limited to historical reports from CA registries and single-center case series [6, 8, 9]. Clear limitations exist with volunteer registry reporting, including potential underreporting of events, which limits our understanding of true incidence as well as the risks associated with anesthesia during pediatric cardiac surgery, cardiac catheterizations, and noncardiac procedures in the CHD population.

Over the last three decades, several single and multicenter retrospective cross-sectional efforts have provided a basic foundation for our understanding of the incidence and potential risk factors associated with anesthesia-related CA in the CHD population. The Pediatric Perioperative Cardiac Arrest (POCA) registry, formed in 1994 to study the etiology and outcomes after perioperative CA in anesthetized children, has published two reports that focused on anesthesia-related CA which spanned the first 10 years of this registry [2, 8]. Of 373 cases of anesthesia-related CA reported to the registry between 1994 and 2005, 34%

(n = 127; acquired conditions included cardiomyopathy, pulmonary hypertension, arrhythmias, status-post heart transplantation) were in children with congenital and/or acquired heart disease, of which 92% were in children with the American Society of Anesthesiologists (ASA) physical status III–V compared to 62% in children without heart disease. Of note, 47% of all CAs in children with CHD and acquired lesions occurred at the age of 6 months or younger, and 70% occurred in children aged ≤2 years. A slight majority of CAs occurred in the general operating room (OR) setting (54%) as compared to the cardiac OR (33%), cardiac catheterization laboratory (17%), and other imaging suites (3%). Again, younger age (<6 months old) was more commonly seen in the cardiac OR CA population (76%) as compared to general OR (38%) or catheterization laboratory (35%) [8]. In children with heart disease, those with single ventricle composed 19% of CAs, closely followed by patients with left-to-right shunts (e.g. VSD, PDA, AV canal, combined lesions; 18%), left-sided obstructive lesions (e.g. aortic stenosis, coarctation of the aorta; 16%), acquired conditions (13%), Tetralogy of Fallot (12%), Truncus arteriosus (5%), and miscellaneous conditions (e.g. pulmonary hypertension, status-post heart transplant, arrhythmias; 18%). Overall mortality in the heart disease CA population was 33%, with the highest mortality in left-sided obstructive lesions and cardiomyopathy. Resuscitation details available for 68 patients with congenital and/or acquired heart disease revealed few instances of the use of extracorporeal cardiopulmonary resuscitation (E-CPR; n = 3), which would suggest lack of availability of this resource in many centers in the 1990s and early 2000s. Current evidence suggests that patients with underlying cardiac disease are the highest utilizers of E-CPR [10], with an epidemiologic report of CA in the cardiac intensive care unit (CICU) from the Pediatric Cardiac Critical Care Consortium (PC^4) reporting 27.2% of all CAs occurring in participating CICUs undergoing E-CPR [11].

Amongst single-center reports, Boston Children's Hospital has maintained an extensive registry of CHD patients anesthetized in cardiac operating room and catheterization laboratories with reported frequencies of 0.79% (during cardiac surgery) and 0.96% (during cardiac catheterizations) [4, 12]. Within the cardiac catheterization laboratory, recent efforts to evaluate outcomes after risk adjustment have led to the inclusion of CA as a part of a larger group of severe adverse events (AEs) [13, 14]. These efforts have confirmed the findings by Odegard et al. that CA occurs infrequently during pediatric diagnostic and interventional catheterizations (0.8-1.6%). Furthermore, in an analysis of the American Heart Association (AHA)'s Get With the Guidelines-Resuscitation registry of in-hospital cardiac arrest (IHCA) across 33 pediatric hospitals between 2005 and 2016, Lasa et al. described results of CA occurring in the cardiac catheterization laboratory by evaluating survival to hospital discharge and favorable neurologic outcomes [15]. Of 19,957 pediatric IHCA events, only 203 index CAs were reported to the registry as occurring within the cardiac catheterization laboratory. The survival to discharge rate for the overall cohort was 69% (141/203), of which the majority (69%) of deaths were observed in children <1 year of age.

KEY POINTS: EPIDEMIOLOGY OF CARDIAC ARREST IN CHD

- Cardiac arrest (CA) that occurs in the periprocedural arena related to anesthesia is an infrequent event occurring in 0.14–0.80% of anesthetics.
- Children with underlying congenital and/or acquired heart disease are at a higher risk for CA with rates ranging from 0.8 to 1.0%, although limited by single center and/or historical registry data sources.
- Within the CHD population, patients who are younger and/or with single ventricle anatomy/physiology are at the highest risk for periprocedural anesthesia-related cardiac arrest.

Overview of current CPR guidelines

Since serving as a co-sponsor for the inaugural gathering of resuscitation researchers and healthcare providers at the Conference on Standards and Guidelines for Cardiopulmonary Resuscitation and Emergency Care in 1966, the AHA has continued to publish guidelines on the performance of CPR for both adult and pediatric patient populations. From 2015, the process of 5-year updates was transitioned to an online format to allow significant changes in the science to be reviewed in an expedited manner and then incorporated directly into the guidelines if deemed appropriate.

AHA has released the latest 2020 guidelines with 491 updated recommendations for adult, pediatric and neonatal life support. For the purpose of the pediatric advanced life support guidelines, pediatric patients are infants, children, and adolescents up to 18 years of age, excluding newborns. Infant guidelines apply to infants younger than 1 year of age. Child guidelines apply to children from approximately 1 year of age until puberty. For those with signs of puberty and beyond, adult basic life support guidelines should be followed. Although pediatric IHCA outcomes have improved steadily since 2004, similar gains are not being seen in out-of-hospital cardiac arrest (OHCA). Much of the variation in survival rates is thought to be due to the strength of the chains of survival, the critical actions that must occur in rapid succession to maximize the chance of survival from CA (see Figure 25.1) [16]. A separate OHCA chain of survival has been created to distinguish the differences between OHCA and IHCA. In both the chains, a sixth link has been added to stress the importance of recovery [16].

The major new and updated recommendations in 2020 can be seen in Table 25.1 [16]. Rapid recognition of CA, immediate initiation of high-quality chest compressions, and delivery of effective ventilations are critical to improve outcomes from CA. The 2020 AHA recommendations for high-quality CPR can be seen in Table 25.2 [16]. New changes to ventilation rates include increases in recommended respiratory rates to 20–30 breaths/min for infants and children with an advanced airway during CPR or for those requiring rescue breathing with a pulse. The Pediatric Cardiac Arrest Algorithm as updated in the AHA 2020 Guidelines is also available in Figure 25.2 [16].

Table 25.1 Key CPR guidelines recommendations and differences noted between 2010 and 2020 publications

Guidelines/recommendations	2010	2020
Assisted ventilation rate: rescue breathing – in conditions where there is a palpable pulse but inadequate breathing.	Rate of 12–20 (One breath every 3–5 seconds)	Rate of 20–30 breaths/min (One breath every 3–5 seconds)
Ventilation rate during CPR with an advanced airway	10 breaths/min (one breath every 6 seconds)	20–30 breaths/min accounting for age and clinical conditions.
Endo-tracheal tubes (ETT)	Both cuffed and uncuffed ETTs are acceptable for intubating infants and children.	It is reasonable to choose cuffed ETTs over uncuffed ETTs for intubating infants and children.
Cricoid pressure during intubation	Insufficient evidence to recommend	Routine use is not recommended.
Epinephrine administration	Reasonable to administer epinephrine in pediatric cardiac arrest	Reasonable to administer the initial dose within 5 minutes from the start of chest compressions.
Invasive blood pressure monitoring to assess CPR quality	Reasonable for providers to use diastolic blood pressure to assess CPR quality (>25 mmHg in infants, >30 mmHg in children)	Reasonable for rescuers to use diastolic blood pressure to guide CPR quality.
Detecting and treating seizures after ROSC	It is recommended to treat clinical seizures following cardiac arrest	When resources are available, continuous EEG monitoring is recommended for the detection of seizures following cardiac arrest in patients with persistent encephalopathy.
Evaluation and support for cardiac arrest survivors		Rehabilitation services are recommended for survivors. Ongoing neurological evaluation for at least the first year after cardiac arrest.

Table 25.2 Current CPR guidelines recommendations for all age groups

CPR guidelines	Infant	Children	Adult
Chest compression rate (per minute)	100–120	100–120	100–120
Depth of compression	One-third of AP diameter of chest (4 cm/1.5 in.)	One-third of AP diameter of chest (5 cm/2 in.)	At least 5 cm but not more than 6 cm (Once children have reached puberty)
Chest recoil	Allow the chest to recoil completely, after each compression		
Rhythm check	Lasting no more than 10 seconds, approximately every 2 minutes		
Respiratory rate with no advanced airway	Compression to ventilation ratio – single rescuer 30 : 2, two rescuers 15 : 2.		Compression to ventilation ratio – 30 : 2.
Respiratory rate with advanced airway	Reasonable to target respiratory rate of 1 breath every 2–3 seconds (20–30 breaths/min)		Provide breath every 2–3 seconds

Source: Data from Topjian et al. [16].

CPR techniques

For infants, single rescuers should compress the sternum with two fingers or two thumbs placed just below the intermammary line. For two rescuers, the two-thumb encircling hands technique is recommended. If the rescuer cannot physically encircle the victim's chest, the chest can be compressed with two fingers. If the rescuer is unable to achieve the guideline-recommended depth, it may be reasonable to use the heel of one hand. For children, it may be reasonable to use either a one- or two-hand technique to perform chest compressions.

Advanced airway interventions during CPR

For OHCA, studies show similar rates of survival to discharge when comparing advanced airway interventions such as supraglottic airway or endotracheal tube with bag-mask ventilation. Similarly, early placement of an invasive airway after IHCA was also not associated with improvement in survival to hospital discharge [17]. For IHCA there is insufficient evidence as of now to make any recommendation about advanced airway management [18].

Drug administration during CPR

The new guidelines emphasize administration of epinephrine within 5 minutes from the start of chest compressions with repetition every 3–5 minutes until the return of spontaneous circulation (ROSC) is achieved. For shock refractory ventricular fibrillation (VF)/pulseless ventricular tachycardia (pVT), either amiodarone or lidocaine can be used. Routine use of sodium bicarbonate and calcium is not supported by the current data unless their administration is indicated in specific circumstances such as electrolyte imbalances and certain drug toxicities. Table 25.3 lists pharmacologic therapy, indications, and precautions for resuscitation.

Management of ventricular fibrillation and/or pulseless ventricular fibrillation

Defibrillation is the definitive treatment of VF/pVT. An initial dose of 2 Joules per kilogram (J/kg) is recommended followed by an increase in the subsequent dose to 4 J/kg for the second shock. For subsequent shocks, higher energy levels may be considered but not to exceed 10 J/kg or the maximum dose for adults.

Pediatric resuscitation in patients with suspected or confirmed COVID-19 infection

Resuscitation in this population carries an added risk to healthcare workers as the chest compressions, positive pressure ventilation, and establishment of an advanced airway generate aerosols that can remain suspended in the air with a half-life of ~1 hour. These aerosols can be inhaled by those nearby. To mitigate the risk of exposure to healthcare workers, emphasis should be placed on donning personal protective equipment (PPE) before entering the operation room/scene and limiting personnel in the room to only those essential for patient care. If an advanced airway is considered, pause chest compressions for intubation and use the intubator with the highest likelihood of first-pass success. Intubate patients with a cuffed tube and connect the endotracheal (ET) tube to a ventilator with a high-efficiency particulate air (HEPA) filter when available [20]. Protection against inhalation of the aerosolized virus with N95 mask or equivalent, eye protection, gown, and double gloving is important for suspected or confirmed COVID-19 infection.

KEY POINTS: CPR GUIDELINES

- High-quality cardiopulmonary resuscitation (CPR) is the foundation of resuscitation including the provision of adequate chest compression rate and depth, minimizing interruptions in CPR, allowing full chest recoil between compressions, and avoiding excessive ventilation.
- New changes to ventilation rates include increases in recommended respiratory rates to 20–30 breaths/min for infants and children with an advanced airway during CPR or for those requiring rescue breathing with a pulse.

AL Grawany

Pediatric cardiac arrest algorithm

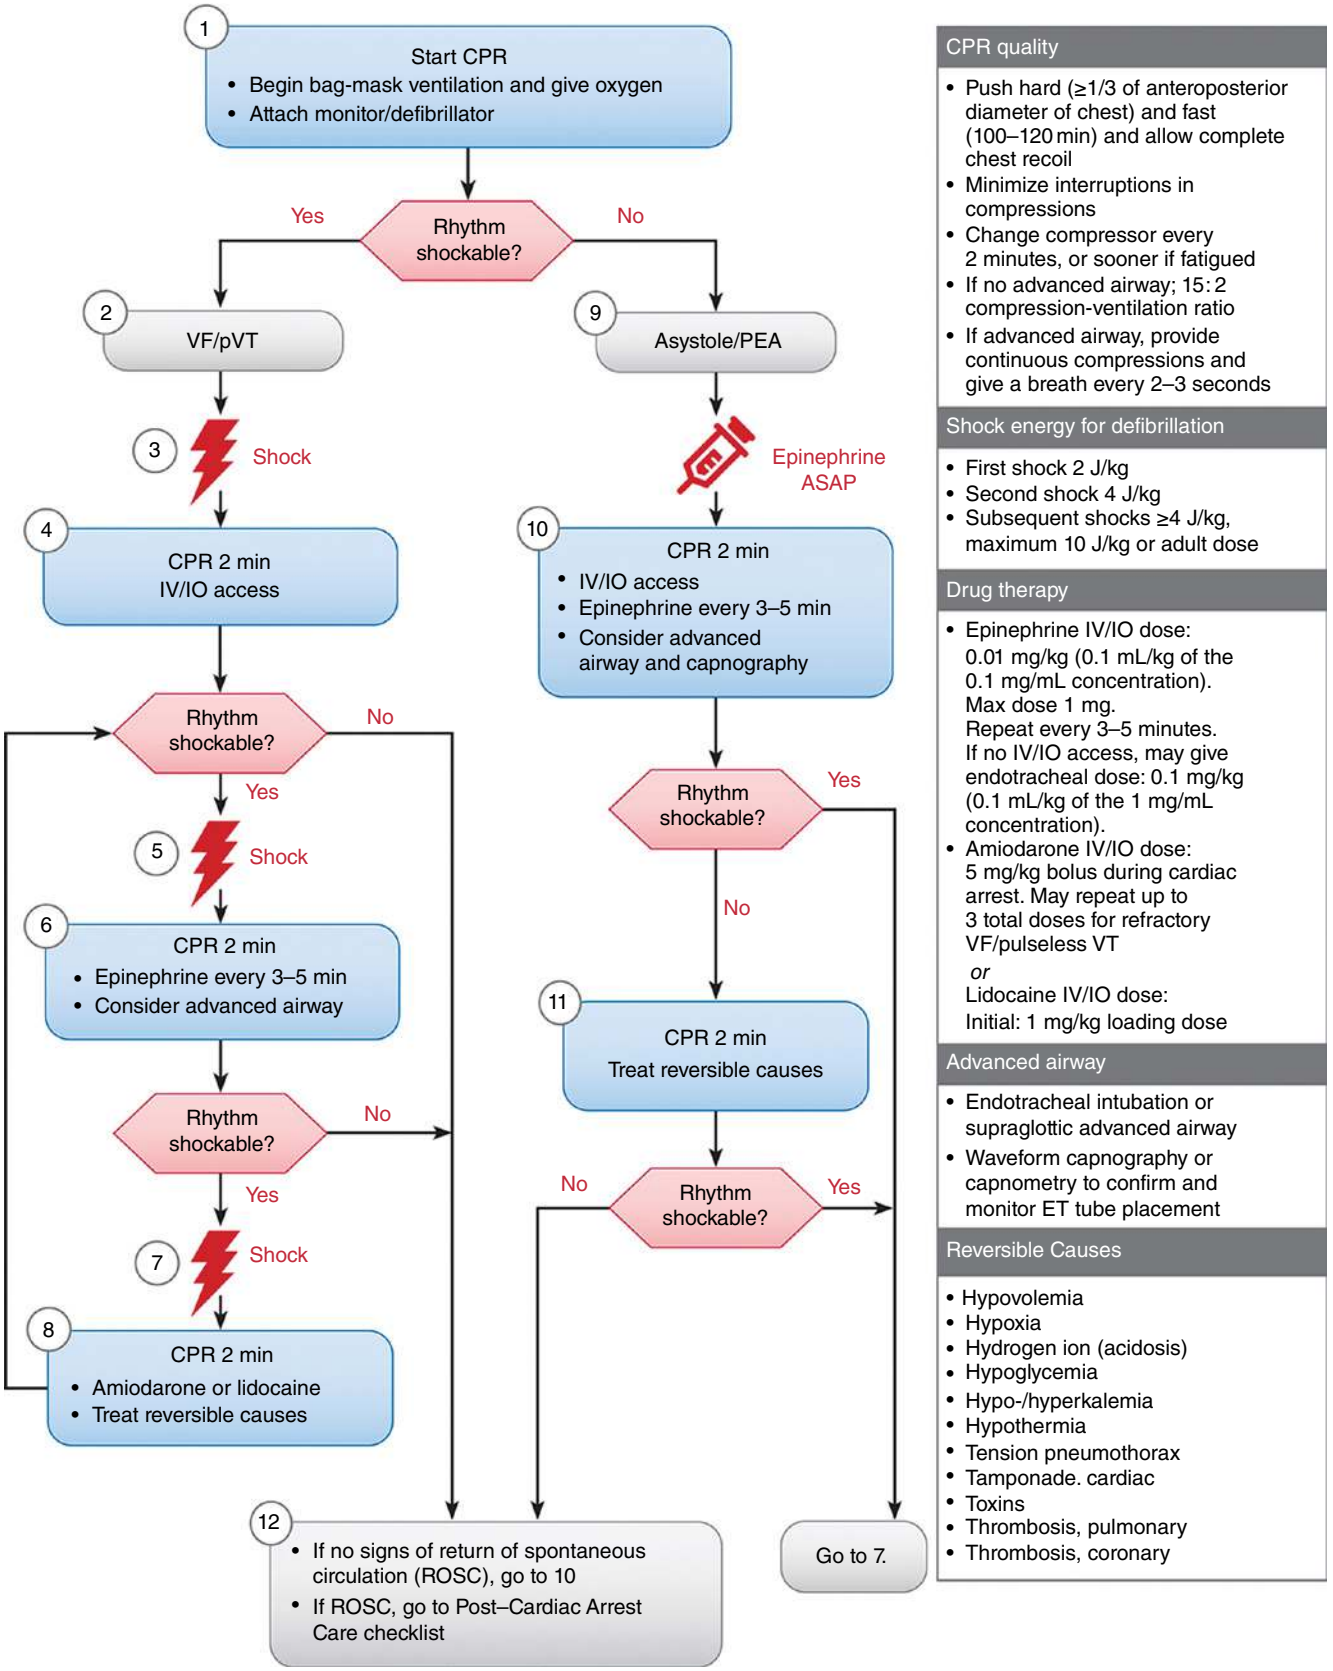

Figure 25.2 Pediatric cardiac arrest algorithm as updated in the American Heart Association 2020 guidelines. (Source: Topjian et al. [16]. Reproduced with permission from Wolters Kluwer Health, Inc.)

Table 25.3 Pharmacology: typical doses and indications

Medication	Dose	Indications	Cautions/precautions
Adenosine	Initial dose: 100 μg/kg (0.1 mg/kg; maximum single dose: 6 mg) rapid IV push; second dose can be double the first dose (i.e. give 200 μg/kg [0.2 mg/kg] for second dose, maximum 12 mg)	Atrioventricular node–dependent SVT	Adenosine will not effectively terminate atrioventricular node–independent tachycardias, such as atrial flutter, ectopic atrial tachycardia, or atrial fibrillation. Should not be administered for wide QRS complex tachycardia unless it is clear that the underlying rhythm is not atrial fibrillation or atrial flutter with associated antegrade accessory pathway conduction Expert consultation should be obtained before the administration of adenosine as a diagnostic and potentially therapeutic intervention for stable patients who have wide QRS complex tachycardia
Amiodarone	For VF/pulseless VT, in absence of known or suspected long-QT syndrome: Initial dose: 5.0 mg/kg IV/IO bolus. Maximum single dose: 300 mg; can repeat to a total of three doses; total: 15 mg/kg/24 hours; in adolescents, maximum 2.2 g/24 hours For perfusing atrial or ventricular arrhythmias: Give loading dose of 5 mg/kg over 30–60 minutes[a] Maximum single dose: 300 mg; can repeat to a maximum of three doses Total: 15 mg/kg/24 hours; in adolescents, maximum 2.2 g/24 hours If the patient is hemodynamically unstable or receiving other medications that lower heart rate, consider lower dose and slower infusion	Shock-refractory cardiac arrest (VF/pulseless VT); atrial and ventricular arrhythmias; JET	Use lower dose and/or slower infusion if the patient is hemodynamically unstable or receiving other medications that lower heart rate; can cause hypotension; can prolong QT interval: 1. Obtain expert consultation before administering, if known or suspected long-QT syndrome. 2. Routine administration in combination with procainamide or digoxin is not recommended without expert consultation
Atropine	For symptomatic bradycardia: 20 μg/kg (0.02 mg/kg); minimum single dose: 0.5 mg; maximum single dose: 500 μg (0.5 mg) For emergent preintubation bradycardia prophylaxis: 20 μg/kg (0.02 mg/kg) Intubation: No minimum dose; maximum single dose 500 μg (0.5 mg)	Vagal-mediated bradycardia; primary atrioventricular block; emergent intubation bradycardia prophylaxis	Loss of constrictive pupillary reflex to light
Calcium chloride (10% = 100 mg/mL = 27.2 mg/mL elemental calcium)	10–20 mg/kg; maximum single dose: 2 g	Hypocalcemia	Precipitates with sodium bicarbonate; rapid IV administration can cause hypotension, bradycardia, or asystole (particularly if the patient is receiving digoxin)
Calcium gluconate (10% = 100 mg/mL = 9 mg/mL elemental calcium)	50–100 mg/kg; maximum single dose: 3 g	Hypocalcemia	Precipitates with sodium bicarbonate; rapid IV administration can cause hypotension, bradycardia, or asystole (particularly if the patient is receiving digoxin)
Dexmedetomidine	0.5–1 μg/kg bolus; infusion 0.25–1 μg/kg/hour; titrate to effect	For sedation and mild analgesia	If at risk for heart block or symptomatic bradycardia, pacing capability should be available; can cause hypotension or bradycardia
Dobutamine	2–20 μg/kg/min	Myocardial systolic dysfunction (i.e. as inotrope and/or vasodilator)	Titrate to effect; can produce hypotension or tachyarrhythmias

AL Grawany

Table 25.3 (Continued)

Medication	Dose	Indications	Cautions/precautions
Dopamine	2–20 μg/kg/min; if ≥20 μg/kg/min is required, consider using an alternative adrenergic agent	Systolic dysfunction; postoperative LCOS	Titrate to effect; can produce vasoconstriction and hypertension or tachyarrhythmias; increases myocardial oxygen consumption
Epinephrine	For pulseless cardiac arrest: Bolus: 10 μg/kg (0.01 mg/kg, or 0.1 mL/kg of 0.1 mg/mL) concentration during cardiac arrest; maximum dose: 1 mg For symptomatic bradycardia: Bolus: 10 μg/kg (0.01 mg/kg, or 0.1 mL/kg of 0.1 mg/mL) concentration; maximum dose: 1 mg For treatment of hypotension or persistent bradycardia with a pulse in the patient with an at-risk myocardiurnt: Give low dose via central administration 1 μg/kg (0.001 mg/kg); continuous infusion: 0.01–0.2 μg/kg/min[b]	Cardiac arrest; symptomatic bradycardia; systolic dysfunction; postoperative LCOS	Significant vasoconstriction at higher doses; increases myocardial oxygen consumption
Esmolol	Bolus: 100–500 μg/kg (0.1–0.5 mg/kg) over 1–2 minutes Infusion: 50–500 μg/kg/min	SVT; hypertension	Can cause bradycardia, hypotension, and/or hypoglycemia
Etomidate	Bolus: 0.2–0.4 mg/kg, over 30–60 seconds; maximum dose: 20 mg	Procedural sedation	Can cause apnea and adrenal suppression
Fentanyl	Bolus: 1–5 μg/kg continuous infusion for neonates and young infants: 0.5–5 μg/kg/hour Continuous infusion for older infants and children: 1–3 μg/kg/min	Analgesia	Can cause apnea and chest wall rigidity in the naive patient
Furosemide	1 mg/kg; starting dose of up to 10 mg to naive patient	Diuresis	Can cause hypokalemia, hypochloremic metabolic acidosis, or hypotension if preload dependent
Heparin	Presumed shunt occlusion: 50–100 U/kg; anticoagulation before ECLS cannulation: 100 U/kg	Presumed shunt occlusion; ECLS cannulation	Can cause bleeding
Hydrocortisone	1–2 mg/kg; maximum dose: 100 mg	LCOS not responsive to inotropic agents	Can cause hyperglycemia and/or hypokalemia
Isoproterenol	0.05–2 μg/kg/min	Post–cardiac transplantation; long QT with torsade des pointes; primary atrioventricular block	Can cause hypotension, tachycardia, and increased myocardial oxygen consumption
Ketamine	0.5–2 mg/kg	Procedural sedation	Can cause apnea and increased respiratory secretions; myocardial depressant at high doses
Levosimendan	Bolus: 12 μg/kg; infusion: 0.1 μg/kg/min	LCOS	
Lidocaine	Bolus: 1 mg/kg. may repeat Infusion: 20–50 μg/kg/min (repeat bolus dose if infusion initiated >15 minutes after initial bolus dose)	VF/pulseless VT cardiac arrest; ventricular arrhythmias	Monitor QTc and lidocaine levels; can cause seizures at high levels
Magnesium sulfate	Pulseless VT with torsade des pointes; bolus: 25–50 mg/kg; maximum dose: 2 g VT with pulses: 25–50 mg/kg over 10–20 minutes; maximum dose: 2 g	VF/pulseless VT arrest with torsade des pointes; hypomagnesemia	Can cause hypotension with rapid administration
Midazolam	0.05–0.2 mg/kg	Sedation	Can cause apnea or hypotension
Milrinone	Bolus: 50 μg/kg, administered over 10–60 minutes Maintenance infusion: 0.25–1.0 μg/kg/min	LCOS	Hypotension

(*Continued*)

Table 25.3 (Continued)

Medication	Dose	Indications	Cautions/precautions
Nitric oxide	Up to 40 ppm	Increased pulmonary vascular reactivity; pulmonary hypertension ± crisis	Methemoglobinemia
Norepinephrine	Infusion: 0.025–0.3 μg/kg/min	LCOS with low SVR; clinically significant vasodilation	Vasoconstriction; increases myocardial oxygen consumption
Oxygen	FiO_2 = 21–100%	Alveolar desaturation	Pulmonary overcirculation with an unrestrictive aortopulmonary shunt
Phenylephrine	Bolus: 5–20 μg/kg; (0.005–0.020 mg/kg) Infusion: 0.1–0.5 μg/kg/min	Cyanotic spell in unrepaired tetralogy of Fallot; symptomatic hypotension because of low SVR; shunt obstruction; coronary hypoperfusion	Can cause vasoconstriction or hypertension
Propofol	Bolus: 1–3 mg/kg Infusion: 50–100 μg/kg/min	Sedation, amnesia	Hypotension; contraindicated in children with mitochondrial disease and not approved in children for prolonged sedation
Procainamide	Bolus: 15 mg/kg over 30–60 minutes; maximum dose: 100 mg Infusion: 20–60 μg/kg/min	JET; SVT; atrial fibrillation	Monitor ECG and procainamide and NAPA levels; can prolong QT interval: 1. Obtain expert consultation before administering, if known or suspected long QT; 2. Routine administration in combination with amiodarone is not recommended without expert consultation
Prostaglandin E_1	To establish ductal patency: 0.05–0.1 μg/kg/min, IV/IO infusion To maintain ductal patency: 0.01–0.05 to 0.01–0.02 μg/kg/min IV/IO infusion	Maintain patency of ductus arteriosus	Apnea; fever and hypotension
Sodium bicarbonate	Bolus: 1–2 mEq/kg slow IV push; dose adjusted to severity of base deficit; use 4.2% (0.5 mEq/L) concentration for neonates	Metabolic acidosis	Precipitates with calcium
Vasopressin	Infusion: 0.0005–0.01 U/kg/min	LCOS with low SVR; vasodilatory shock; diabetes insipidus	Hypertension and increased afterload; fluid retention
Verapamil	Bolus: 0.1–0.2 mg/kg Do not administer to infants <12 months of age without expert consultation	SVT	Hypotension; have calcium available; not to be administered to infants (can cause apnea, bradycardia, and hypotension); avoid in patients with WPW

Source: Marino et al. [19]. Reproduced with permission from Wolters Kluwer Health, Inc.

ECLS indicates extracorporeal life support; FiO_2, fractional inspired oxygen; IO, intraosseous; IV, intravenous; JET, junctional ectopic tachycardia; LCOS, low cardiac output syndrome; NAPA, *N*-acetylprocainamide; SVR, systemic vascular resistance; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia; and WPW, Wolff-Parkinson-White syndrome.

[a] The time range for the administration of the loading dose of amiodarone for the child with a perfusing rhythm is slightly longer (i.e. 30–60 minutes) than the pediatric advanced life support (PALS) 2015 recommended time for administration (i.e. 20–60 minutes). The reason for this slight difference is that the child with cardiac disease is likely to be or is at risk for hemodynamic compromise.

[b] For treatment of hypotension or persistent bradycardia with a pulse in the patient with an at-risk myocardium, give low dose via central administration 1 μg/kg (0.001 mg/kg), which is one-tenth the standard recommended resuscitation dose for symptomatic bradycardia in PALS 2015.

Phases of cardiac arrest

Regardless of the location in which a CA occurs, the provision of high-quality CPR is highly dependent on rapid, coordinated, team-based actions that extend throughout the spectrum of care both before, during, and after hypoxic-ischemic arrest states (no flow/low flow). The likelihood of ROSC, survival to hospital discharge, and neurologic survival are all improved when patients receive high-quality CPR [16]. Measures of high-quality CPR include the provision of chest compressions with appropriate depth, rate, and recoil; minimal interruptions in chest compressions (high chest compression fraction); appropriate ventilation and monitoring of adequacy of ventilation; and reversal of treatable causes. Resuscitation science has historically focused on these elements of CPR including logistics and management

AL Grawany

of chest compressions, assisted ventilation, defibrillation for shockable rhythms, and pharmaceutical reanimation measures. However, recent efforts by the international resuscitation community have extended this focus to include prearrest and postarrest care in light of the reports demonstrating a plateau in survival outcomes for IHCA and OHCA in the pediatric population [21]. Subgroup analyses for outcomes data surrounding anesthesia-related CA for patients with CHD are limited although care processes across the CA spectrum should not be limited by patient or hospital-level factors [19].

In order to emphasize the importance of the elements of pre-/intra-/post-arrest care, the 2020 AHA Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care report highlighted the importance of each element of care along the CA spectrum by utilizing the Chains of Survival model (see Figure 25.1).

Prevention of CA in the in-patient and/or peri-anesthetic setting has traditionally been limited to anticipatory management of known high-risk populations such as those with single-ventricle CHD before/after Stage 1 repair, suprasystemic pulmonary hypertension, left-ventricular outflow tract obstruction, and Williams syndrome [5, 22]. Recent quality improvement efforts by the PC4 have involved national implementation of a CA prevention bundle which identified high-risk populations; standardized anticipatory care plan discussions twice a day; and provided ready access to resuscitation medications, sedation for noxious stimulation, and post-arrest debriefing tools. Applying this methodology to the periprocedural environment presents challenges surrounding the predominantly nonmodifiable patient and procedure-based factors that are presenting constant threats during operations and cardiac catheterizations. Ultimately, highly successful specialized teams with specific equipment, knowledge, and resources can rapidly respond to clinical decompensation events in the CHD population with precision and quality.

The 2020 updated algorithm and recommendations for the provision of high-quality CPR are summarized in Figure 25.2. Pediatric CPR is uncommon and thus very challenging to maintain excellent team skills, even in larger tertiary care children's hospitals. Increasingly, high-fidelity chest compression and ventilation data have become available to provide real-time guidance to care teams providing CPR. These CPR feedback devices, when paired with invasive arterial blood pressure and end-tidal CO_2 monitoring, are shifting the paradigm away from provider-focused CPR training, to one that is patient physiology and hemodynamically focused [23]. Measuring these physiological parameters, which are often available to the anesthesiologist during surgical and/or catheterization procedures, can be used to trend CPR quality, guide therapies during CPR, and gauge likely outcomes like ROC. In retrospective fashion, these data also are available in aggregate to guide quality improvement and resuscitation science efforts.

Cardiopulmonary resuscitation that is prolonged and/or resistant to conventional CPR techniques may warrant rescue with mechanical circulatory support should the resources and expertise be available. E-CPR is defined as the deployment and cannulation onto veno-arterial extracorporeal membrane oxygenation (VA ECMO) during active conventional CPR. In the pediatric population, this resource-intense therapy is highly dependent on the complex choreography of resuscitation teams and surgical staff (general/cardiothoracic surgeons) and often utilized in patients with underlying CHD [10]. Historically, E-CPR began as a specific rescue modality after post-cardiotomy cardiac arrest/cardiogenic shock in the pediatric CHD population [24, 25]. It has since evolved beyond the postoperative CHD population to include multiple populations of critically ill children including those with acute fulminant myocarditis, acute decompensated heart failure, and sepsis[10]. Activation of E-CPR teams in the peri-procedural arena may be less cumbersome than CAs occurring in other inpatient or outpatient settings; yet, excellent communication, multidisciplinary training, and resource allocation for perfusion/priming teams are crucial for effective E-CPR in the current era [26].

Post-cardiac arrest care

Achieving ROSC with the resolution of no-flow or low-flow hemodynamic states has historically been the goal of providers during the high-stress environment of a CA. However, since 2008, the international resuscitation community has recognized the role of ischemia-reperfusion injury in the evolution of the disease state known as postcardiac arrest syndrome (PCAS) [27]. Also recognized in the pediatric population, PCAS is composed of several key pathophysiologic components: post-CA brain injury, post-CA myocardial dysfunction, systemic ischemia-reperfusion response, and persistent precipitating pathophysiology [28]. Although a review of the unique pathophysiology of each phase is beyond the scope of this chapter, it is crucial for the cardiac anesthesiologist to consider the post-return of circulation (ROC) management of the patient with CHD who has suffered a CA as a crucial and equally important time period as active CPR. Figure 25.3 (reproduced with permission from Topjian et al. [19]) provides a standardized approach to help clinicians monitor for ongoing secondary organ injury while also providing them with therapeutic options to address the known pathophysiologic derangements, ultimately providing the best opportunity to mitigate brain and other organ injury post-arrest. Excellent overviews of postarrest stabilization can be found in the AHA guidelines [29], and a more recent AHA Scientific Statement [19].

Neurologic monitoring and targeted neuroprotective management

The central nervous system is especially sensitive to hypoxic insult and reperfusion injury, and even with expeditious initiation of CPR, ischemic neuronal cell death rapidly occurs. Furthermore, there is a clear time-weighted burden; with prolonged low-flow states, irreversible injury is inevitable, and beyond 10–20 minutes, the likelihood of neurologically intact survival is low [30]. Neurologic management after CA, therefore, is focused on identifying actionable lesions, reducing cerebral metabolic demand, and optimizing both global and cerebral oxygen delivery.

Postarrest neurologic prognostication is challenged by conflicting evidence and lack of specific biomarkers with high predictive value. Diagnostic neuronal injury patterns

Components of Post–Cardiac Arrest Care	Check
Oxygenation and ventilation	
Measure oxygenation and target normoxemia 94%-99% (or child's normal/appropriate oxygen saturation).	☐
Measure and target $Paco_2$ appropriate to the patient's underlying condition and limit exposure to severe hypercapnia or hypocapnia.	☐
Hemodynamic monitoring	
Set specific hemodynamic goals during post–cardiac arrest care and review daily.	☐
Monitor with cardiac telemetry.	☐
Monitor arterial blood pressure.	☐
Monitor serum lactate, urine output, and central venous oxygen saturation to help guide therapies.	☐
Use parenteral fluid bolus with or without inotropes or vasopressors to maintain a systolic blood pressure greater than the fifth percentile for age and sex.	☐
Targeted temperature management (TTM)	
Measure and continuously monitor core temperature.	☐
Prevent and treat fever immediately after arrest and during rewarming.	☐
If patient is comatose apply TTM (32°C–34°C) followed by (36°C–37.5°C) or only TTM (36°C–37.5°C).	☐
Prevent shivering.	☐
Monitor blood pressure and treat hypotension during rewarming.	☐
Neuromonitoring	
If patient has encephalopathy and resources are available, monitor with continuous electroencephalogram.	☐
Treat seizures.	☐
Consider early brain imaging to diagnose treatable causes of cardiac arrest.	☐
Electrolytes and glucose	
Measure blood glucose and avoid hypoglycemia.	☐
Maintain electrolytes within normal ranges to avoid possible life-threatening arrhythmias.	☐
Sedation	
Treat with sedatives and anxiolytics.	☐
Prognosis	
Always consider multiple modalities (clinical and other) over any single predictive factor.	☐
Remember that assessments may be modified by TTM or induced hypothermia.	☐
Consider electroencephalogram in conjunction with other factors within the first 7 days after cardiac arrest.	☐
Consider neuroimaging such as magnetic resonance imaging during the first 7 days.	☐

Figure 25.3 Post-cardiac arrest care checklist. Source: Topjian et al. [16]. Reproduced with permission from Wolters Kluwer Health, Inc.

may take time to develop, highlighting the general recommendation to avoid neuroimaging for the first 72 hours post-arrest. However, it is sometimes reasonable to pursue early neuroimaging to characterize the extent of injury, and screen for pathology amenable to medical or surgical intervention, such as space-occupying hemorrhage or cerebral edema indicating possible intracranial hypertension. In neonates with open fontanelle, this can be initially performed with cranial ultrasound, but in most children, the initial modality of choice will be head computed tomography (CT). It should be noted that while certain findings (e.g., loss of grey-white differentiation, sulcal effacement, and reversal sign) are unambiguously associated with poor outcome [31], the negative predictive value of a normal scan for survival is only

AL Grawany

68% [32]. Ultimately, the most informative prognostic data is obtained from brain magnetic resonance imaging (MRI), which can detect the extent and location of injury patterns, specifically the watershed ischemia/infarct that correlates with poor outcomes [33]. The anesthesiologist will often be called upon to transport and provide supportive care to these patients for imaging studies as well as for potentially urgent/emergent neurosurgical intervention; hence, it is essential to understand the principles of neuroprotective management.

Neurologic monitoring is often imprecise and nonspecific, but it can afford the clinician useful data upon which to direct therapy. Electroencephalography (EEG), typically a continuous protocol with video monitoring, has become standard of care in the postarrest phase of intensive care unit (ICU) management. Since as many as half of therapeutically cooled post-arrest patients will have seizures, most of which are subclinical/nonconvulsive [34], EEG serves an essential ongoing surveillance function. As seizures impose a substantial metabolic burden on an already vulnerable brain and are independently associated with mortality, it is critical to identify and treat them to mitigate secondary injury. Near-infrared spectroscopy (NIRS) may be used to assess the adequacy of regional blood flow by providing trend data on brain tissue oxygen saturation, a surrogate for oxygen extraction. Monitoring indicators of flow, as opposed to pressure, is crucial after brain injury. Animal data from an experimental swine model has shown that the autoregulatory capacity of the cerebral vasculature, as assessed by NIRS-derived indices, can be significantly altered following CA [35]. While various cerebral oxygenation saturation threshold targets have been proposed, unique caveats exist in the interpretation of NIRS values in children with CHD [36], as they must be considered in the context of the expected appropriate systemic arterial saturation unique to their specific underlying or palliated physiology (i.e. single ventricle anatomy with systemic to pulmonary artery shunts, cavopulmonary anastomoses, or mixing lesions, among others). Similar to the above is the selection of targets for oxygenation and ventilation, which must often be individualized to cardiac physiology. While hypoxemia is clearly detrimental, hyperoxia may also be deleterious in patients at risk for pulmonary overcirculation with an attendant decline in systemic and brain perfusion. Additionally, despite the cerebral vasodilatory effects of hypercapnia, normocapnia should be the default ventilation target for most patients [28].

In addition to diagnosing and treating nonconvulsive status epilepticus, and optimizing cerebral oxygen delivery, postarrest care is also focused on reducing cerebral metabolic demand through targeted temperature management. Fever/hyperthermia is commonly observed after CA, and aggressive control of fever and maintenance of normothermia with pharmacologic and/or mechanical measures is indicated. While improved seizure control has been shown with therapeutic hypothermia [37], there is equipoise on the superiority of directed therapeutic hypothermia on outcomes, with conflicting evidence from a recent large trial [38]. At present, the best evidence for comatose patients suggests either 5 days of strict normothermia, or alternatively, a 48-hour period of 32–34 °C hypothermia, followed by 72 hours of normothermia [39].

Management of postarrest myocardial dysfunction

Like the brain, the myocardium is vulnerable to ischemia-reperfusion injury, and both the precipitating CA as well as the therapies used during resuscitation can lead to significant ongoing ventricular systolic and diastolic dysfunction [40]. While catecholamines serve a critical role in augmenting coronary perfusion pressure, thereby directly improving the success of resuscitation, their vasopressor effects impose an increased afterload and can lead to myocardial oxygen supply:demand mismatch. Accordingly, excessive attention to inappropriately chosen blood pressure targets may not only lead to excessive or inappropriate resuscitation but also perpetuate ongoing myocardial dysfunction. Advanced hemodynamic monitoring technologies allow the clinician to measure and trend in real-time more relevant physiologic data on global and regional blood flow, essential to optimal post-arrest care. While the choice of inotropic, vasopressor, or vasodilator agent is often institution- and provider-dependent, the most appropriate selection can and should be made based on objective and serial hemodynamic assessments. Using such modalities as NIRS, various invasive continuous cardiac output devices [41] and emerging integrative oxygen delivery platforms with predictive analytics [42] can facilitate a more individualized approach and provide early identification of response to therapy and of patients at risk for deterioration (See Chapter 21 for additional discussion of hemodynamic support and monitoring).

Despite appropriate and timely goal-directed and physiologically driven medical hemodynamic support, some patients postarrest will evidence severe and persistent ventricular dysfunction. In this population, veno-arterial extracorporeal membrane oxygenation (ECMO), either as a bridge to recovery or to more durable long-term mechanical circulatory support (MCS) such as ventricular assist device (VAD) can be considered. The selection criteria, indications, technical/surgical aspects, and management of the various devices are beyond the scope of this chapter though they are addressed elsewhere in this textbook (See Chapter 37 for a detailed discussion of mechanical support). For a complete discussion of pediatric MCS, the reader is referred to two excellent recent reviews [43, 44]. Some fundamentals, however, warrant mention. First, and germane to the care of patients with CHD, is an understanding of the unique anatomic or physiologic features imposed by the underlying lesion that have implications on cannulation approach, type of device, and degree of support required (i.e. single or biventricular anatomy, among others) [45]. Second, the provision of such resource-intensive rescue modalities must be reserved for patients with both a reversible cause of arrest and a reasonable probability of favorable neurologic recovery. As mentioned above, this is often a difficult or impossible assessment to make acutely, but there are instances where such support would clearly be futile. Finally, these therapies require significant multidisciplinary, institutional expertise to achieve excellent outcomes [46].

Management of acute kidney injury

The kidneys are also vulnerable to ischemia during different arrest states. Acute kidney injury (AKI), defined and staged by the Kidney Disease: Improving Global Outcomes

(KDIGO) criteria based on creatinine and urine output parameters [47], can manifest following successful resuscitation and is independently associated with mortality [48]. Since early diagnosis may improve outcomes, the identification of predictive biomarkers is an area of active investigation. Urinary neutrophil gelatinase-associated lipocalin (NGAL) has been shown in post-cardiopulmonary bypass patients to predict the development of AKI in children and precede creatinine elevation [49], which may be unreliable during dynamic changes in renal function. This and other biomarkers may serve a similar diagnostic or prognostic role after pediatric cardiac arrest, but no conclusive evidence exists currently. There is no specific treatment for AKI; therapies are largely supportive and are aimed at maintaining overall cardiac output and adequate renal perfusion, avoiding fluid overload, and minimizing further secondary renal insult from nephrotoxic drugs. Continuous renal replacement therapy (CRRT) can be initiated whenever the solute and water excretion or acid-base balance functions of the kidneys become insufficient. The presence of an extracorporeal circuit such as ECMO often allows the hemofilter to be placed as an in-line shunt, facilitating immediate therapy when clinically indicated [50]; however, most other patients will require placement of a short-term hemodialysis catheter. Once initiated, the patient's metabolic status can be tightly controlled, and optimal fluid balance targeted precisely.

Outcomes, prognosis, and follow-up after cardiac arrest

Several large cohort studies of pediatric CA have examined survival as well as midterm neurodevelopmental outcomes in survivors [11, 21, 51]. In general, cardiac surgical patients fare better than medical patients, and those with biventricular anatomy have better outcomes than those with single ventricle anatomy. Amongst pediatric survivors of IHCA following cardiac surgery, 5-year survival has been reported as high as 66%, however, with demonstrably worse neurologic outcomes than age- and surgical risk-matched controls. This study also found a linear correlation between both time-to-CPR initiation and total CPR duration and outcome [52].

Irreversible injury to the myocardium and kidneys can be managed with mechanical support or dialysis, respectively, and ultimately transplantation if not otherwise contraindicated. Children who suffer catastrophic brain injury following CA, conversely, cannot be salvaged in a similar manner for obvious reasons. Families of these children rightly wish for frank and evidence-informed prognostication to assist them in making difficult decisions around the maintenance or cessation of life-sustaining therapies. While neuroimaging has notable shortcomings in this regard, there is emerging interest in identifying serum brain-specific biomarkers that may predict the outcome. Serum neuron-specific enolase (NSE), S100b, and myelin basic protein (MBP) are specific to neurons, astrocytes, and myelin, respectively, and have been shown to correlate with mortality and functional neurologic outcome as assessed by the Pediatric Cerebral Performance Category scale [53, 54]. While these markers are not in widespread clinical practice, they may provide clinicians predictive data to guide discussions with families as well as to identify at-risk patients whose clinical assessment may be obfuscated by neuroactive medication, critical illness, or equivocal imaging findings.

Survivors of pediatric cardiac arrest clearly are at risk of severe, permanent, and debilitating adverse neurodevelopmental outcomes. As such, many will need ongoing intensive neurorehabilitation care, and ultimately be rendered technology-dependent. There are both immediate peri-arrest and long-term ethical considerations that this raises, and the defensible choice is not always congruent with the wishes of the family or even the entirety of the medical team. The complex medical and legal factors implicit in this will not be discussed here, but all providers of care to these children must be cognizant of this and strive to treat them and their families with compassion.

KEY POINTS: POST CARDIAC ARREST CARE

- Post-CA syndrome, which results from ischemia-reperfusion injury during CPR, is characterized by brain injury, myocardial dysfunction, and renal insufficiency. It may influence mortality from arrest and must be managed as expertly as CPR itself.
- Neuroprotective care after CPR should include diagnosis and management of seizures, optimization of cerebral oxygen delivery, and reduction of cerebral metabolic demand.
- Treatment of myocardial dysfunction should be individualized via advanced physiologic and hemodynamic monitoring to avoid myocardial oxygen supply: demand mismatch.
- Outcomes from resuscitation are better in children after cardiac surgery versus medical admission, and children with biventricular hearts compared to single ventricle anatomy.

Cardiopulmonary resuscitation for the congenital heart disease patient

While CPR outcomes have improved in recent years, it remains true that conventional CPR techniques have not advanced to provide more than half of normal cardiac output during an arrest [55]. Therefore, CPR avoidance via astute pre-arrest management represents the best strategy for care of infants and children with CHD. However, cardiac patients are more prone to arrest [56, 57], and the pathogenesis of their events may be greatly influenced by their individual anatomy and physiology. Three functional conditions that limit the effectiveness of conventional CPR in cardiac patients are (i) limitation to stroke volume (for example, with atrioventricular valve regurgitation, left ventricular outflow tract obstruction, or low ventricular diastolic volume with restrictive myocardial physiology), (ii) limitation of pulmonary blood flow and oxygenation (with pulmonary valve/pulmonary arterial stenosis or pulmonary artery hypertension, or cavo-pulmonary connection wherein superior vena cava flow is reduced), and (iii) limitation of arterial perfusion to

cerebral or coronary vasculature (e.g. semilunar valve regurgitation or aorto-pulmonary runoff, and/or low "diastolic" blood pressure (BP) during chest compression relaxation with poor coronary perfusion pressure) [58]. The response of heart patients to pharmacological interventions such as epinephrine may also vary by lesion, the degree of heart failure, or preoperative or postoperative condition.

Once an arrest has occurred, emphasis upon the performance of high-quality CPR – to include the provision of adequate chest compression rate and depth, minimization of interruptions in CPR, allowance for full chest recoil between compressions, and avoidance of excessive ventilation - is paramount, just as in the noncardiac population [59]. Use of adjunctive CPR techniques that ameliorate physiologic difficulties with CPR in the cardiac population, such as interposed abdominal compression CPR (IAC-CPR), may be considered [see sections below]. Those failing to achieve sustained ROSC in specialized cardiac ICU environments should be placed on extracorporeal life support if the arrest etiology is potentially reversible or as a bridge to alternate therapy (usually durable mechanical circulatory support or heart transplantation).

Some lesion-specific measures for arrest avoidance are mentioned in the sections below as well as considerations unique to the performance of CPR in that population.

Left-heart lesions

Mitral valve disease

Isolated mitral stenosis is uncommon in children and most often occurs in combination with additional left-sided obstructive lesions or Shone's complex (aortic coarctation, subaortic and/or aortic stenosis, and supra-mitral ring or a dysplastic, parachute mitral valve) [60]. The poorly developed mitral valve may also be regurgitant. Whether through stenosis or regurgitation, high left atrial pressures may be present resulting in pulmonary edema, pulmonary venous hypertension, and reactive pulmonary artery hypertension (PAH). Over time, muscularization of pulmonary veins may progress causing pulmonary vascular resistance (PVR) to rise, further exacerbating PAH. Management of these patients prior to surgical intervention should entail avoidance of fluid overload, especially in the setting of left ventricle (LV) systolic or diastolic dysfunction, eschewing rapid administration of large volume boluses that might worsen left atrial hypertension (with mitral stenosis) or distend the mitral annulus and LV, worsening mitral regurgitation or elevating LV end-diastolic pressure. Postoperatively, left atrial pressure should be monitored in addition to central venous pressure (CVP) to provide insight into hemodynamic derangements. Low left atrial pressure either represents hypovolemia (with low CVP) or elevated PVR (with high CVP). High left atrial pressure may indicate volume overload (with high CVP), residual mitral disease, or ventricular dysfunction irrespective of etiology. Withdrawal of several milliliters of blood in neonates may temporarily relieve left atrial hypertension from volume overload. Low cardiac output must be avoided using inotropic support and afterload reduction. Milrinone (an inotrope, vasodilator, and lusitrope) and mechanical ventilation with positive pressure (which lowers LV afterload) may both be useful.

Resuscitation of patients with mitral valve stenosis should proceed according to standard algorithms, although blood flows could be compromised by the limitation of preload to the left heart during chest compressions. High PVR and left atrial hypertension limit pulmonary blood flow (PBF), and mitral stenosis limits inflow to the LV. CPR patients with mitral regurgitation suffer from the inefficiency of regurgitant flow across the mitral valve that reduces cardiac output with each chest compression. Lack of response to early resuscitative efforts should prompt consideration of extracorporeal support.

Aortic valve disease

Aortic stenosis may be seen in isolation or as part of the aforementioned Shone's complex. Left ventricular hypoplasia may also be present in more severe forms of this constellation, along with associated endocardial fibroelastosis indicative of subendocardial ischemia. These patients are at risk for left atrial hypertension (from poor ventricular compliance) and pulmonary edema formation. Assessment of the adequacy of left-sided structures for two-ventricle circulation becomes paramount. Intracardiac exploration of the mitral valve (opening <8 mm and an abnormal subvalvular apparatus) may suggest the need for single ventricle palliation [61] and the use of echocardiographic mitral and aortic Z-scores [62] aid surgical decision-making. Those who are likely to support a biventricular circulation may undergo either percutaneous balloon aortic valvuloplasty or surgical valvuloplasty, often with significant improvement in cardiac function [63]. Newborns with critical aortic stenosis require prostaglandin to maintain ductal patency for blood flow to the systemic circulation. They commonly present with LV dysfunction, with either a hypertrophied or dilated LV. These patients may remain unstable after their procedure and require inotropic support and/or afterload reduction. Prostaglandin should be weaned off and adequacy of circulation assessed.

Children with aortic valve regurgitation suffer from volume loading of the ventricle, which results in remodeling and progressive LV dilation and dysfunction. The occurrence of low diastolic BP may cause coronary insufficiency and myocardial ischemia, which further compromise LV function. Aortic valve repair or replacement becomes necessary with increasing severity of symptoms and LV dilation.

As with all cardiac patients who require resuscitation, high-quality CPR is the mainstay of therapy. However, patients with aortic stenosis face the challenge of reduced stroke volume with chest compressions owing to obstruction to LV outflow. This compromise in cardiac output may worsen coronary perfusion to a hypertrophied myocardium resulting in ischemia. Moreover, a hypertrophied LV with poor compliance will fill poorly during CPR, which will also reduce stroke volume and cardiac output. Thus, the aortic stenosis population may contend with both poor filling and poor output during resuscitation. Not surprisingly, aortic stenosis has been found in adults to be a strong independent predictor of mortality and poor outcome after IHCA [64]. Patients with aortic insufficiency may experience limited cardiac output from chest compressions due to regurgitation of flow back into the LV. Low "diastolic" BP during chest

recoil may also compromise coronary perfusion pressure. E-CPR may be necessary if conventional techniques prove inadequate.

Right-heart lesions

Patients with right ventricular (RV) outflow obstruction (for example, tetralogy of Fallot, double outlet RV with pulmonic stenosis, or pulmonic stenosis) and/or small right-sided structures typically have varying degrees of pressure overload and resultant RV hypertrophy, which may necessitate outflow tract intervention. Ventriculotomy and muscle resection may affect systolic and diastolic ventricular performance, while postoperative pulmonary insufficiency (made worse by elevation in post-bypass PVR) may represent an acute volume load. RV workload may also be increased by elimination of lower resistance outlets for flow, such as the closure of ventricular septal defects or tricuspid valve repairs which limit regurgitation. In this setting, RV function may be further harmed by positive pressure ventilation with elevated mean airway pressure, resulting in increased RV afterload. Loss of sinus rhythm with atrioventricular dyssynchrony may compromise the atrial contribution to ventricular filling and cause low cardiac output.

Once RV diastolic function deteriorates sufficiently, the RV may almost serve as a passive conduit in which there is persistent diastolic prograde flow into the pulmonary artery with atrial contraction. This is termed restrictive RV physiology. Systemic venous pressure becomes elevated with the increase in RV end-diastolic pressure, which can lead to capillary leak, pleural and peritoneal fluid accumulation, renal insufficiency from abdominal compartment syndrome, and later feeding intolerance and chylous effusions. Drainage of the pleural compartment may avoid counterproductive increases in ventilator settings, and peritoneal catheter placement may avoid impairment of inferior vena cava flow. Having a peritoneal catheter in place could also facilitate dialysis with beneficial inflammatory mediator removal [65]. It is important to recognize that poor RV compliance may diminish RV preload and thus LV preload. An atrial level right-to-left shunt may ameliorate the situation by preserving LV preload and systemic output at the expense of systemic arterial saturation.

Treatment of the failing RV should be directed toward ventilator management that minimizes PVR, thus avoiding the extremes of hyperinflation and atelectasis, along with consideration of use of inhaled nitric oxide and early extubation (latter may be good for RV output, but this must be balanced against the potentially detrimental effects of respiratory distress and loss of airway patency). Secondly, the maintenance of adequate intravascular volume for RV filling is necessary. Third, the maintenance of AV synchrony is paramount, and this may entail atrial or AV sequential pacing or dysrhythmia management. Fourth, judicious use of inotropic support (such as low-dose epinephrine and vasopressin) to preserve systolic and diastolic BP may be warranted. Titration of milrinone should be considered if blood pressures are sufficient. Lastly, heart rate control to optimize diastolic filling time should be considered. This may entail the use of adequate sedation and analgesia (i.e. dexmedetomidine) and early use of low dose esmolol infusion in patients not requiring ß-agonist support.

Resuscitation of children with right-sided outflow obstruction may be complicated by the limitation of PBF, resulting in poor LV preload and poor cardiac output. Even the repaired RV outflow tract may be compromised by chest compressions; hence, correct hand position on the lower half of the sternum should be utilized [59]. Patients with significant RV diastolic dysfunction may require fluid during CPR to achieve adequate ventricular filling, and full chest recoil should be employed to refill the thoracic compartment and right heart during CPR diastole. In the future, adjunctive measures to improve venous return to the right heart, such as IAC-CPR or perhaps the impedance threshold device, may prove beneficial (see section below).

Total anomalous pulmonary venous connection

Total anomalous pulmonary venous connection (TAPVC) routes pulmonary venous blood to the right atrium resulting in dilated right-sided chambers and small left-sided structures. Whether supracardiac, cardiac, mixed-type, or infracardiac, there is always some degree of obstruction experienced to venous return in comparison to normal pulmonary venous architecture. Severe obstruction may present in the newborn period and may be difficult to distinguish from neonatal pulmonary disease. Therefore, newborns on ECMO should be carefully evaluated for TAPVC. Presentation with pulmonary venous congestion, interstitial edema, and elevated RV pressure is a characteristic that may be associated with labile pulmonary hypertension. Preoperative management is complicated by the fact that prostaglandin for ductal patency and pulmonary vasodilators given to enhance oxygenation may worsen pulmonary edema. Surgical intervention is indicated, though the postoperative period may be difficult due to the small size and poor compliance of the chronically underfilled LV, presence of pulmonary hypertension, and respiratory failure. Pulmonary vasodilators in the form of oxygen, inhaled nitric oxide, and milrinone may be helpful postoperatively. Deterioration late in the convalescent period should warrant investigation for recrudescent pulmonary hypertension.

TAPVC patients who experience arrest should be treated for reversible causes of elevated PVR (e.g., arrhythmia, unintended interruption of vasodilator therapy, acidosis, hypoxia, hypercarbia, agitation) as well as common postoperative complications such as cardiac tamponade, accidental extubation, and others. High-quality CPR may not generate adequate pulmonary blood flow due to high PVR, which may further compromise LV filling and cardiac output. Use of 100% oxygen, inhaled nitric oxide, and volume for LV preload is warranted. Despite these interventions, ECPR may be required.

Single ventricle lesions

Single ventricle physiology is characterized by the complete mixing of systemic and pulmonary venous return resulting in equal pulmonary and systemic arterial saturations. Total ventricular output (the sum of pulmonary blood flow, systemic blood flow, and atrioventricular regurgitant volume) is divided between parallel pulmonary and systemic circuits based upon relative pulmonary (PVR) and systemic (SVR) resistances. This inherently inefficient situation represents a

AL Grawany

significant burden for the volume-loaded single ventricle, and surgery in the newborn period is often required for palliation. The goals of initial (Stage 1) palliation are as follows: (i) to open the atrial septum to allow egress of blood from the pulmonary venous atrium, (ii) to create an unobstructed path for systemic output, and (iii) to establish a stable, controlled source of pulmonary blood flow (either a modified Blalock-Taussig-Thomas (BTT) shunt or an RV to pulmonary artery "Sano" shunt).

Postoperative management after Stage 1 palliation is directed toward assurance of adequate oxygen delivery and cardiac output. This is assessed via estimates of the systemic venous oxygen saturation (using cerebral near-infrared spectroscopy as a surrogate for superior vena cava saturation) and the arteriovenous saturation difference (using arterial pulse oximetry), and tracking of serum lactates. Clinical assessment of patient heart rate, BP, perfusion, urine output, and feeding tolerance, when applicable, are also critical. The ratio of pulmonary to systemic blood flow (which is subject to inaccuracies related to the estimation of pulmonary venous oxygen saturation) may also be determined to understand the balance between parallel circulations, with a goal ratio slightly below or near unity. Low cardiac output may manifest with decreased arterial saturation. As oxygen delivery worsens, an increased sympathetic tone may preserve systolic BP, and arterial runoff may preserve the ability to palpate pulses. However, low diastolic BP, high intracardiac filling pressures, and higher HR will lower coronary perfusion pressure and diastolic filling time and together may result in coronary ischemia. In the setting of low cardiac output, one must also be suspicious of residual lesions, particularly residual aortic obstruction or compromised coronary artery anatomy. These may be evaluated expeditiously by echocardiography and ECG. Hemodynamic compromise may often be reversed through manipulation of preload (volume or blood transfusion), inotropic support, mechanical ventilation (change in PVR), and titration of oxygen to optimize near-infrared spectroscopy, or sedation/analgesia and afterload reduction (change in SVR).

It is known that arrest rates are high in the SV population due to the volume load on the single RV (especially if there is significant AV valve regurgitation), the imbalance between pulmonary and systemic blood flows, and the risk of shunt thrombosis [19] [66]. Survival may be influenced by anatomic variant (Hypoplastic left heart syndrome (HLHS), TAPVC, and pulmonary atresia/intact ventricular septum with RV-dependent coronary circulation), significant semilunar or atrioventricular valve regurgitation, decreased single ventricle function, and comorbidities including prematurity and genetic syndromes [19] [67]. High-quality conventional CPR is recommended in cardiac arrest, but this raises intrathoracic pressure during the compression cycle and may limit PBF. Low "diastolic" pressure during chest decompression may also reduce the driving pressure for PBF in the case of the modified BTT shunt, and low SVR may limit PBF in the Sano population. Thus, both groups may experience poor blood oxygenation as CPR progresses, with low systemic oxygen content. Hypoxemia coupled with poor coronary perfusion pressure from low diastolic BP and high filling pressures results in coronary ischemia. Not surprisingly, prolonged CPR is associated with worsened outcomes [68]. Shunt or stent compression during CPR is also possible [69] [70]. Change in hand position to the lower 25% of the sternum [71], hemodynamically targeted CPR to maintain diastolic BP above a designated threshold [72], or adjunctive interventions such as sternal reopening (early after surgery) or interposed abdominal compression may be considered. E-CPR activation should be undertaken early. Once the decision is made to initiate extracorporeal circulatory support, repeated doses of epinephrine and vasopressin should be limited due to their persistent afterload effects upon a weakened myocardium.

Superior cavo-pulmonary connection (bidirectional Glenn, or stage 2 palliation)

At approximately 3–6 months, the second stage of single ventricle palliation is undertaken which involves anastomosis of the superior vena cava (SVC) to the pulmonary artery. Postoperatively, these patients benefit hemodynamically from early extubation because of the negative intrathoracic pressure generated by spontaneous respiration. This augments cerebral venous return to the SVC, effective pulmonary blood flow, preload to the systemic ventricle and cardiac output. For those who require mechanical ventilation, hypoventilation with mild hypercapnia will decrease cerebral vascular resistance and augment cerebral blood flow more than hyperventilation and alkalosis augment PBF. Thus, hyperventilation impairs oxygenation despite a decrease in transpulmonary gradient [73] [74]. Patients who manifest desaturation after the superior cavo-pulmonary anastomosis should be evaluated for anatomic causes of reduced PBF such as veno-venous collaterals from the SVC to the pulmonary veins or inferior vena cava, pulmonary artery stenosis, or pulmonary arteriovenous malformations. Thought should also be given to the presence of ventricular dysfunction, atrioventricular valve regurgitation, arrhythmia with loss of atrioventricular synchrony, and pulmonary issues such as hemi-diaphragmatic paralysis and atelectasis/infiltrate. Prior to the arrest, and in the presence of preserved lung function, one may consider a paracorporeal support system with atrial and aortic cannulation, and use of a centrifugal pump [75].

The response to conventional CPR in superior cavo-pulmonary connection cardiac arrest is poor [19]. This may related to the diminution of cerebral blood flow that occurs with chest compressions and raised intrathoracic pressure (creating risk for neurologic injury), as well as the decrease in PBF that results downstream from the cerebral vasculature. Reduced PBF leads to a reduction in systemic ventricular preload and cardiac output. Atrio-ventricular valve regurgitation or semilunar valve regurgitation may worsen cardiac output as well. Chest recoil during CPR becomes critical to allow for venous inflow to the lungs. The use of a CPR adjunct such as IAC-CPR may hold future benefits through augmentation of cerebral blood flow, though this theory is untested at the present time. Results from ECPR in this population are challenged by difficulties with the site of venous cannulation to effectively decompress the heart and the Glenn circuit. If PVR remains low, it may be possible to support cardiac output via the inferior vena cava and aortic cannulation, while allowing superior vena cava flow to continue through the lungs for oxygenation.

Complete superior-inferior cavo-pulmonary connection (Fontan, stage 3 palliation)

This operation is typically accomplished between 2 and 4 years of age, with baffling of all systemic venous return to the pulmonary arteries. This requires passive flow through the lungs of all systemic ventricular preload. Thus, cardiac output is highly dependent upon low PVR and adequate ventricular function. Accordingly, Fontan patients benefit hemodynamically from early extubation postoperatively, but if mechanical ventilation is required, mean airway pressures should be minimized. Fenestration of the Fontan circuit (i.e. connection between the Fontan conduit and the atrium) may maintain ventricular preload at the expense of arterial saturation in the setting of elevated PVR. Non-fenestrated patients with high PVR will appear highly saturated with evidence of poor perfusion and low output. Use of vasopressin preferentially for BP augmentation (due to its greater effect upon SVR than PVR), and for early postoperative venoconstriction to reduce the formation of effusions has been adopted in some centers [76].

Survival from CA in Fontan patients mirrors that in superior cavo-pulmonary connection patients. Evaluation of the Society of Thoracic Surgeons database revealed a Fontan arrest mortality rate of 41.2% [77]. Resuscitative efforts are challenged by the fact that chest compressions reduce PBF, and limit oxygenation and preload to the systemic ventricle. Elevations in SVC pressure limit cerebral blood flow, again making chest recoil important to resuscitation physiology. Early institution of ECPR as a potential bridge to mechanical circulatory support or heart transplantation may provide a useful salvage pathway. Tables 25.4 and 25.5 display the resuscitation profiles at the three stages of single ventricle surgical palliation, and the effect of respiratory manipulations on circulatory parameters at the three stages of palliation.

Anomalous coronary syndromes

Anomalous aortic origin of a coronary artery (AAOCA) is a rare congenital abnormality of the origin or course of an aberrant coronary artery, with both arising from the same aortic sinus of Valsalva, via either a single or dual ostia. The anomalous vessel can be either the right or left coronary, and exists on a wide spectrum, taking intraarterial, intramural, or intraconal/intraseptal courses. Disease severity seems to relate in part to this anatomic coursing, with intraarterial variants posing the most risk. AAOCA is the second leading cause of sudden cardiac death (SCD) in young athletes and has a prevalence range estimated between 0.1 and 1% of the population by large angiography database studies, and with a 3 : 1 male predominance [78]. As this disease is often clinically silent with the first presentation being sudden arrest during exercise, the initial arrest often occurs out of the hospital. While the genetic basis of AAOCA is not elucidated, there may be a familial inheritance, with clusters of sudden cardiac arrest (SCA) occurring in first-degree relatives [79].

The mechanism of ischemia and SCD is hypothetical but thought to be due to ostial stenosis, vasospasm, and intramural compression between the great vessels, as well as a proarrhythmogenic process, either induced by ischemia or via a secondary mechanism triggering lethal arrhythmias. The AAOLCA variant, where the LCA takes its origin from the right sinus, seems to be a higher-risk lesion, with a 6% 20-year mortality risk amongst children and young adults [80].

Table 25.4 Resuscitation profiles for the structurally normal heart and those who have undergone single-ventricle palliation

Physiology	Circulation description	Circulation of blood	Chest compressions	Chest recoil	Positive-pressure ventilation
Structurally normal heart	Two-ventricle series circulation without heart disease	Systemic veins – lungs – pulmonary veins – body	1. RV compression results in PBF 2. LV compression results in SBF	Increases the transthoracic gradient from the systemic veins to the RA, increasing RV filling	Decreases the transthoracic gradient from the systemic veins to the RA, decreasing RV filling
Stage 1 Norwood or shunted physiology	Single-ventricle parallel circulation with shunt-dependent PBF	Systemic veins – single ventricle – lungs (via shunt) or body	Single-ventricle compression results in PBF (shunt ± PVR) and SBF (SVR)	Increases filling to the preload-dependent single ventricle	Decreases filling to the preload-dependent single ventricle
Bidirectional Glenn and hemi-Fontan	Single-ventricle parallel circulation with PBF dependent on multiple arteriolar vascular beds	IVC – single ventricle – body/brain – SVC – lungs – pulmonary veins – body	Single-ventricle compression results in SBF	1. Predominantly fills the RA from the IVC 2. SVC flow dependent on cerebral vascular resistance and PVR	Decreases filling to the single ventricle by impeding SVC flow and IVC filling
Fontan	Single-ventricle series circulation	Systemic veins – lungs – pulmonary veins – body	Single-ventricle compression results in SBF	1. Predominantly fills the PAs with IVC blood flow (PVR) 2. SVC flow dependent on cerebral vascular resistance and PVR	Decreases filling to the single ventricle by impeding both SVC and IVC flow

Source: Marino et al. [19]. Reproduced with permission from Wolters Kluwer Health, Inc.

IVC indicates inferior vena cava; LV, left ventricle; PA, pulmonary artery; PBF, pulmonary blood flow; PVR, pulmonary vascular resistance; RA, right atrium; RV, right ventricle; SBF, systemic blood flow; SVC, superior vena cava; and SVR, systemic vascular resistance.

Measured parameters in multiple studies are shown. Stage 0: Uncorrected/unpalliated ductal-dependent parallel pulmonary and systemic circulations. Maintenance of ductal patency is necessary for systemic perfusion, and prostaglandin E_1 is indicated. No human experimental data exist for measures such as hyperoxic or hypocapnic alveolar gas strategies that tend to reduce pulmonary vascular resistance, and such strategies should generally be avoided without significant monitoring of systemic oxygen delivery. The greatest improvement in systemic oxygenation occurs with the induction of hypercapnic ventilation. Stage 1: After surgical palliation of parallel circulation with relief of arch obstruction and limitation of pulmonary blood flow with a systemic-to-pulmonary artery shunt. Hypercapnia can improve cerebral more than systemic oxygen delivery. Stage 2: After superior cavopulmonary anastomosis. The cerebral and pulmonary circulations are in series, and hypercapnia can improve systemic arterial oxygen saturation and systemic oxygen delivery by increasing cerebral blood flow, superior vena cava flow, and therefore pulmonary blood flow. Stage 3: After superior and inferior cavopulmonary anastomoses (post-Fontan). No systematic data exist for alveolar gas manipulation. See references for details.

AVO_2D, arteriovenous oxygen saturation difference; CBF, cerebral blood flow; lactate, lactate or metabolic acid change; Q_p/Q_s, pulmonary/systemic blood flow ratio; rSO_2C, cerebral oxygen saturation by near-infrared spectroscopy; rSO_2S, somatic oxygen saturation by near-infrared spectroscopy; Sa_{O2}, arterial oxygen saturation; SvO_2, systemic venous saturation; TPG, transpulmonary pressure gradient; VO_2, oxygen consumption.

There are several large institutional and national registries of AAOCA patients, and the American Association for Thoracic Surgery (AATS) published evidence-based consensus management guidelines in 2017 [81]. Typically, referral occurs following an episode of exertional chest pain, with ischemic findings on electrocardiogram. Initial diagnosis is made by echocardiography, with characteristic color flow Doppler pattern, but ultimately cardiac CT with coronary angiography is confirmatory. Surgical intervention is offered to patients with certain risk profiles, namely those with a history of survived arrest, syncope in the setting of ventricular arrhythmia, anginal chest pain, or positive inducible ischemia with provocative stress testing. Asymptomatic patients with intra-arterial AAOLCA are always offered surgery due to the elevated risk of death with that variant. Asymptomatic patients with intra-arterial AAORCA who wish to participate in sports were historically referred for surgery, but current AHA/ACC guidelines now recommend they can safely participate with close follow-up after initial evaluation [82].

The surgical options depend on the type of lesion, and a full discussion is beyond the scope of this chapter, but includes coronary artery unroofing, pulmonary artery translocation, and direct coronary procedures such as reimplantation or osteoplasty [81]. Percutaneous coronary intervention and surgical bypass grafting play little to no role in the management of children and adolescents. Patients will require close lifetime surveillance, and even the following surgery remains at an increased risk of recurrent SCD [83]. If return to competitive athletics is considered, all patients with AAOCA should have an immediately available automated external defibrillator during these activities, as the most prevalent inciting event is malignant ventricular arrhythmia.

An anomalous left coronary artery from the pulmonary artery (ALCAPA) is a rare anomaly, affecting approximately 0.5% of children with CHD or around 1 in 300,000 live births. The embryology and clinicopathologic basis were first described in 1933 by Bland, White, and Garland, after whom the syndrome is sometimes named [84]. ALCAPA results from abnormal conotruncal septation, with anomalous development of the left coronary system, and can lead to chronic myocardial ischemia and early onset cardiomyopathy. Mortality is nearly 90% by age 1 year if left untreated, although there are rare case reports of individuals diagnosed in adulthood [85]. The mechanism of ischemia is multifactorial and dependent on which subtype is present. In the classic infant type, there is insufficient collateral coronary circulation, and severe early ischemia develops following the closure of the ductus arteriosus with a reduction in pulmonary vascular resistance and pulmonary artery pressure. These infants often present with failure to thrive from neonatal onset ischemic heart failure, or sudden death from lethal ventricular arrhythmias [86]. Much rarer is the adult type,

wherein an extensive intracoronary collateral circulation develops from a dominant right coronary artery system. These patients may remain clinically silent for decades, although with ongoing subclinical ischemia and fibrosis, eventually developing anginal symptoms, mitral regurgitation, and decompensated left ventricular heart failure [85], although diagnosis is sometimes made at autopsy [87]. The sentinel event in some adults is ventricular tachycardia (VT) or ventricular fibrillation (VF) with exertion, highlighting the ischemic mechanism in this lesion. Surgical management is indicated in all patients and involves coronary revascularization with the closure of the left main orifice and coronary bypass grafting, or the Takeuchi procedure [88]. Additionally, the placement of an internal defibrillator-cardioverters should be considered if provocative testing in the electrophysiology lab shows inducible ventricular dysrhythmias.

There are reports of successful resuscitation with ROSC in adult patients subsequently diagnosed with ALCAPA [89]. These authors comment on the unfavorable coronary anatomy in this disease as it relates to CPR. Specifically, aortic diastolic blood pressure is lowest during the recoil/non-compression phase of CPR and is much closer to right atrial and coronary sinus pressure, and left coronary perfusion is retrograde from the RCA into the PA via the left coronary system. This anatomy places a significant portion of the myocardium at risk for malperfusion during conventional CPR. Also, as the inciting event is often a shockable malignant ventricular arrhythmia, immediate application of a defibrillator is essential. This has even been reported in successful bystander CPR of individuals presenting with out-of-hospital cardiac arrest, subsequently found to have ALCAPA [90] (See Chapter 3 for further discussion of anomalous coronary artery lesions).

Mechanical circulatory support

MCS for those with advanced heart failure is increasingly used as either a bridge to a decision, heart transplantation, or destination therapy. The devices employed for such support differ by mechanism; thus, some are pulsatile in nature (e.g. Berlin Excor®), while some provide the continuous flow (e.g. Heartmate II® and Heartware®). The differences in flow determine aspects of the physical exam which are used to assess circulatory adequacy. Palpation of pulses commonly relied upon in the setting of native heart function may be untrustworthy or frankly absent in MCS patients who have a continuous flow device supporting the LV. Pulse oximetry may be inaccurate as well. Instead, the assessment of mean arterial pressure should be attempted using either non-invasive BP or automated BP devices. A mean arterial BP >50 mmHg is typically deemed acceptable to sustain organ perfusion. Evaluation of extremity perfusion may also yield important information on circulatory adequacy. It is noteworthy that mechanical device function is influenced by preload and afterload. So, for example, PAH may decrease preload to an LV assist device, as would hypovolemia or pulmonary embolism. Increased afterload, in the form of systemic hypertension, may worsen cardiac output. Conversely, hypotension from septic shock or routine sedation may not be tolerated as devices have little ability to augment their output in the setting of lower SVR.

The two most common causes of pre-arrest VAD failure are disconnection of the device from power or the driver, and failure of the driveline (the tube that passes through the skin to connect the pump to the external controller and power source). Therefore, in larger children on a continuous flow device, unresponsiveness or hypotension should prompt immediate assessment of all connections to power and examination of the power source itself. If connections are secure and batteries are charged, the use of an alternate controller should be considered. Thereafter, other causes of poor flow must be considered, such as RV dysfunction, cannula malposition, thrombosis, arrhythmia, etc. Inotropes can be used to treat RV dysfunction, just as anti-arrhythmics and even cardioversion can be employed. In the case of the Berlin Excor VAD, the most commonly used device in children, a palpable peripheral pulse is expected due to the pneumatically driven pulsatility of the machine. Examination of device membrane movement should be performed, and if lacking, driveline and power connections should be checked. A hand pump can be used to provide flow from the Berlin Excor VAD while airway management is undertaken. Other patient-related factors which may adversely affect circulation such as tension pneumothorax, pericardial tamponade, and PAH must also be considered [91].

Resuscitation of the continuous flow MCS patient who is deemed to have poor systemic perfusion after initial patient and VAD assessment should be managed according to standard resuscitation guidelines, to include chest compressions. Similarly, if the Berlin Excor patient does not have a palpable pulse with the use of the hand pump, chest compressions should be promptly started (see Table 25.6). Administration of medications and defibrillation should proceed according to conventional Pediatric Advanced Life Support recommendations [91].

The underlying disease states

In addition to specific concerns in the various anatomic categories of CHD, there is a wide spectrum of other diseases and syndromes with the propensity for CA. The unique pathophysiology of some of these diseases can influence both the efficacy of CPR and dictate unique considerations during an arrest. In this section, we will review some distinct resuscitation features in Williams-Beuren syndrome, anomalous coronary syndromes, arrhythmias, cardiomyopathies, and pulmonary hypertension.

Table 25.6 Resuscitation management by device type

Flow profile	Continuous	Pulsatile
Common devices	Heartmate II, Heartware	Berlin Excor
ECG for rhythm	Yes	Yes
Pulse present	Only if good native contractility	Yes
NIBP feasible	Only if good native contractility	Yes
CPR chest compressions/ meds	Yes	Yes
Defibrillation	Yes	Yes
Hand pump available	No	Yes

AL Grawany

Williams-Beuren syndrome

First described in 1961, Williams syndrome (WS) is a genetic disease caused by a microdeletion of region q11.23 on chromosome 7. Amongst the gene deletions typically present, it is the hemizygosity for the elastin gene that leads to the classic connective-tissue abnormalities and resultant arteriopathy that characterizes this syndrome. Most significantly, this manifests as supravalvular aortic stenosis (SVAS) as well as diffuse coronary stenosis, but biventricular outflow tract obstruction can also be present and adds to the risk profile. Importantly, while the typical phenotype is generally seen in older children, this disease may be occult in infants. Cases of recurrent unexplained cardiac arrests in young infants [92], rapidly progressive ischemic cardiomyopathy precipitating unprovoked CA [93], and sudden death during induction of anesthesia [94] have all been reported.

The mechanism of ischemia is multifactorial, but fundamentally, elastin loss creates inefficient hydrodynamics with widened pulse pressure, systolic hypertension, and diastolic hypotension. In addition, progressive intima-media hyperplasia leads to obstructive aortic lesions near the sinotubular junction, reduced diastolic coronary perfusion, and intrinsic coronary insufficiency from aneurysmal dilatation; all these factors place the myocardium at risk for ischemia, worsened by omnipresent left ventricular hypertrophy [95]. Tachycardia, inadequate preload, and reduction in systemic vascular resistance (SVR) will all accelerate this pathophysiology, and the rapid fall in cardiac output and diastolic coronary flow serves to perpetuate the ongoing ischemic process

Diagnosis is often pursued when unexplained ischemic electrocardiogram findings and hemodynamic instability manifest in a young child, with echocardiographic findings of high left ventricular outflow tract (LVOT) pressure gradient by spectral Doppler. Hemodyamic catheterization and angiography confirm the cardiac lesions, and genetic testing is diagnostic. Perioperative management of these children centers on maintaining adequate preload, avoiding tachycardia, and preventing sustained reduction in SVR. Despite caution and proper planning, CAs can occur and should be treated with pure vasopressor agents, rapid-acting beta-blockers such as esmolol if tachycardic, and judicious volume loading. Resuscitation can be refractory to standard measures; however, even requiring ECMO as a rescue maneuver until definitive diagnoses can be made, and corrective cardiac surgery is undertaken [94]. It should also be noted that delayed sudden death has been reported remote from procedural or anesthetic care, thought in retrospect to be secondary to malignant arrhythmia [96]. It is for this reason that many centers will admit children with confirmed WS even following routine procedures for overnight observation. See Chapters 8 and 27 for further discussion of Williams-Beuren Syndrome.

Arrhythmias

Appropriate management of ventricular arrhythmias with cardioversion, defibrillation, and pharmacotherapy is a vital component of standard Advanced Cardiac Life Support (ACLS) and Pediatric Advanced Life Support (PALS) algorithms. However, there are specific arrhythmogenic conditions that both predispose patients to cardiac arrest and yet may be exacerbated or perpetuated by standard therapies used during resuscitation.

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is a genetic disorder of cardiac calcium metabolism, caused by mutations in the RyR2 gene, among others[97]. It is a rare disorder with protean symptoms; universally present however is inducible rapid VT in children and young adults in response to catecholamines such as epinephrine. Presentation is generally unexpected syncope, convulsions, or sudden death, and the diagnosis is often elusive. Of note, this catecholamine trigger can be either *exogenous*, such as during vigorous exercise or stress, or *endogenous* as in the treatment of the ensuing arrest with epinephrine. The latter scenario can be vexing to caregivers, as the VT will be refractory to epinephrine boluses, and in fact, maintained and worsened by it. The diagnosis is suggested in previously well patients following a cardiac arrest after physical activity, whose ECG shows ventricular extrasystoles made more frequent with epinephrine, or characteristic bidirectional VT [98]. Even predominantly alpha-adrenergic vasopressor drugs such as norepinephrine used to treat post-arrest vasoplegia, can trigger a CPVT storm due to their beta-adrenergic effects [99]. Initial management should focus on the suppression of catecholamine drive with opioids and anesthetics. More directed treatment is beta blockers such as nadolol, antiarrhythmic therapy with flecainide, and ultimately placement of an ICD. Denervation procedures such as cardiac sympathectomy have also been employed with some success [100].

Another genetic disorder that can manifest malignant arrhythmias in response to stress or catecholamine trigger is the long QT syndrome (LQTS). There is a spectrum of different syndromes causing cardiac channelopathies, resulting in prolongation of the QT interval, with a predilection to the development of torsades-de-pointes and ventricular fibrillation. These congenital or hereditary variants of LQTS include Romano-Ward syndrome (RWS), Jervell and Lange-Nielson syndrome (JLNS), Timothy syndrome, Anderson-Tawil syndrome, among others, all of which have distinct associated genetic bases and clinical features [101]. There are also acquired types of LQTS, commonly drug-induced, but also related to profound electrolyte derangements, myocardial infarction, hypothyroidism; of note, these acquired risk factors also exacerbate the risk of cardiac events in patients with congenital LQTS. In some patients with CHD experiencing first episode syncope or arrest, the diagnosis of LQTS may be obfuscated by QTc-prolonging medications given in the perioperative setting as well as pre-existing right bundle branch block (RBBB), which can mask the prolonged QT interval [102]. Of particular concern for anesthesiologists caring for these patients are the numerous potential triggers that occur in the perioperative setting, many related to dynamic autonomic tone and reduced repolarization reserve. In addition to adequate analgesia, avoidance of hypothermia, and maintenance of cardioprotective electrolyte levels, attention must be paid to careful selection of anesthetic agents and other medications, as an exhaustive list has been implicated as triggers [103]. While propofol is generally thought to be safe, inhalational agents like sevoflurane can prolong the QTc, although they are commonly used without incident [104]. Finally, some consideration must be given to whether the

LQTS is drug-induced, in which case chemical pacing with isoproterenol may overdrive or suppress the VT, and congenital LQTS in which catecholamines will cause further sympathetic stimulation and exacerbate the ventricular arrhythmia. If any doubt exists, short-acting titratable beta blockade with esmolol may be a safer option [105]. See Chapter 22 for further discussion of arrhythmias and their treatment.

Cardiomyopathies and myocarditis

The cardiac anesthesiologist often is called to care for children with cardiomyopathies or presumed myocarditis and for imaging studies, cardiac catheterizations, and both cardiac and noncardiac surgery. These are often fragile patients, with limited cardiac reserve, and the potential for sudden cardiac arrest is omnipresent. Findings of increasing ectopy burden or declining systemic perfusion may signal acute decompensated heart failure with low cardiac output and a pre-arrest state. Patients with dilated cardiomyopathy (DCM) already suffer from poor systolic function with reduced left ventricular ejection and diminished myocardial perfusion, often making successful resuscitation from cardiac arrest unlikely. Attempts to reduce oxygen consumption, reduce LV afterload, and improve myocardial contractility with inotropes should be initiated early in the clinical course. In those with hypertrophic and restrictive phenotypes, inotropic support can be deleterious as it increases myocardial oxygen demand and often induces tachycardia, further reducing diastolic filling time. Inotropes can also be arrhythmogenic in both myocarditis and some cardiomyopathies [19]. Clinicians should recognize that the timely institution of ECMO, as a semi-elective procedure, may be lifesaving [11, 106]. As some types of cardiomyopathies and myocarditis may be reversible (i.e. if dysrhythmia-induced or infectious), ECMO can be considered as a bridge-to-recovery therapy in these contexts or as an interval step toward durable mechanical support for irreversible disease. Similarly, ablation of sympathetic tone and reduction in preload, as can occur with induction of anesthesia and initiation of mechanical ventilation, can precipitate arrest in these patients. Patients in this vulnerable category are often best served by the preemptive mobilization of ECMO resources and personnel prior to such maneuvers ("wet pump" on stand-by). As with many special scenarios, vigilance and prevention are preferable to salvage resuscitative efforts that may well be futile.

Pulmonary hypertension

Pulmonary hypertension (PH) is a significant cause of mortality in patients with CHD, specifically after cardiac surgery. In biventricular anatomy, it is defined as mean pulmonary artery pressure (mPAP) greater than 25 mmHg with indexed pulmonary vascular resistance (PVRI) of greater than 3 Wood units. In single ventricle patients, the definition can be modified to include a transpulmonary pressure gradient (TPG) of greater than 6 mmHg even with PAP below threshold values. PH from CHD can be broadly categorized into *pre-capillary* processes wherein increased pulmonary blood flow occurs from left-to-right shunt lesions (systemic to pulmonary shunts, ventricular septal defect, atrioventricular canal, etc.), or *post-capillary* elevations in PAP from left heart disease (intrinsic left ventricular dysfunction, severe left-sided AV valve stenosis, cor triatriatum, etc.). In addition to CHD, a wide array of other noncardiac processes can lead to the development of PH, including severe interstitial or alveolar lung disease, intrinsic pulmonary arterial vascular disease, thromboembolism, and others. Modern categorization systems such as those from the World Symposium on Pulmonary Hypertension [107] and, more applicable to pediatric disease, the Panama Classification from the Pulmonary Vascular Research Institute Pediatric Task Force [108], reflect this heterogeneity.

Chronic management of PH is beyond the scope of this chapter, but it is discussed elsewhere in this textbook and reviewed in recent guidelines from the AHA and American Thoracic Society [109]. In brief, therapeutics are broadly vasodilators and/or antiproliferatives, with vasodilators directed at either the endothelin, nitric oxide, or prostacyclin pathways. Many severely affected patients will be on combination therapy regimens with an endothelin receptor antagonist (Bosentan, Ambrisentan), a phosphodiesterase-5 inhibitor (Sildenafil, Tadalafil), and a synthetic prostacyclin analog (Epoprostenol, Treprostanil, Iloprost). It is critical to continue all maintenance medications throughout the perioperative period, as abrupt discontinuation, substitution, or dose reduction can be the precipitating factor in a deleterious and possibly fatal increase in PA pressure [110, 111].

The most feared sequelae of PH is the development of a PH crisis, which has a complex and dynamic pathophysiology. The highly muscularized and "reactive" pulmonary vascular bed in PH is vulnerable to many factors that can trigger this acute PVRI rise. Among them, pain, bronchospasm, acidosis, hypoxia, and hypercarbia [112] have been well-studied, and can commonly occur in the perioperative setting. As with many high-risk scenarios in congenital cardiac anesthesia, risk stratification and avoidance are preferable, highlighting the importance of careful planning. Once initiated, the process is rapidly progressive and can be quite challenging to rescue prior to cardiac arrest. These episodes are characterized by acute elevations in pulmonary vascular resistance index (PVRI) and pulmonary artery pressure (PAP), which ultimately precipitate right ventricular failure. The elevated RV afterload, coupled with decreased coronary perfusion from systemic hypotension, leads to myocardial ischemia. Subsequently, a multifactorial reduction in cardiac output occurs, as pulmonary blood flow and therefore LV preload fall, exacerbated by restricted filling from a shifting interventricular septum, and worsened by progressive ischemia. Abortive maneuvers to reverse this vicious cycle include inhaled pulmonary vasodilators, and systemic vasoconstrictors such as vasopressin to increase SVR and restore coronary perfusion.

There are unique features of a PH crisis that can render conventional CPR infective at restoring ROSC, specifically the challenge in generating sufficient pulmonary blood flow to fill the LV and produce systemic cardiac output. When cardiac arrest occurs in the context of a PH crisis outcomes are quite poor, with adult data suggesting a 6% survival [113]. Interestingly, however, a recent single-center study in pediatric in-hospital arrest found a 67% survival amongst those with

ECPR, extracorporeal life support to support failed cardiopulmonary resuscitation; MBTS, modified Blalock-Taussig shunt; SVC, superior vena cava.

[a] General principles for efficient use of extracorporeal life support (ECLS) to support cardiopulmonary resuscitation include the following (i) Venoarterial ECLS should be used in all cases, (ii) Knowledge of venous anatomy and previously occluded vessels is critical for successful and timely deployment of ECLS, (iii) Central (transthoracic) cannulation may be considered in patients who have undergone a recent sternotomy, (iv) Peripheral (percutaneous) cannulation may be preferred for patients without recent sternotomy, and (v) ECLS cannulas should be large enough to provide complete cardiac output (cardiac index >2.5 L/min/m^2). If extracorporeal membrane oxygenation flow is limited by inadequate venous drainage, secondary drainage sites should be considered.

echocardiographic evidence of PH, similar to the rate in children without PH in the study. Notably, there was a more than twofold higher use of inhaled nitric oxide in the PH cohort, highlighting the crucial importance of specific therapies directed at the underlying cause of the arrest [114]. Ventilation should be carefully managed; while acute hyperventilation may reduce unfavorable hypercarbia and acidosis, it may also increase mean airway pressures and end-expiratory lung volumes, reducing RV filling through harmful cardiopulmonary interactions. In addition to standard resuscitative drugs, pulmonary vasodilator therapy, by either inhalational or intravenous routes, may be beneficial during the arrest. Ultimately, timely cannulation onto ECLS as a bridge to recovery or transplant should be considered if CPR is ineffective at restoring circulation. In this group of patients, once stabilized the creation of a restrictive atrial communication via septostomy in the catheterization lab can allow a right-to-left shunt to preserve cardiac output and systemic oxygen delivery, even in the absence of pulmonary blood flow. This may allow separation from ECMO, albeit with often marked hypoxemia; under investigation currently are devices that allow individualized flow regulation through the atrial shunt [115]. See Chapter 33 for further discussion of PH.

Open-sternum CPR

In the operative cardiac surgery patient, the postoperative patient with the open sternum, or the E-CPR patient who will undergo central ECMO cannulation, open cardiac massage is necessary to maintain as much cardiac output as possible while the surgeon cannulates the aorta and right atrium. Where possible the surgical assistant should perform an open cardiac massage while the primary surgeon prepares to cannulate. An arterial catheter is usually present and should guide the force of open cardiac massage. Additional resuscitative measures, that is, drugs and defibrillation, should be pursued while preparations for cannulation are occurring. Distraction from the resuscitation, with ineffective cardiac compressions because of cannulation preparation, or one surgeon attempting to perform both open cardiac massage and cannulate, should not occur. An organized, role-based approach to CPR will reduce the period of no-flow/low-flow until ECMO or emergent CPB is established. This complex situation is particularly amenable to team simulation training. (See below). Cannulation strategies for ECPR according to physiology and stage of palliation are displayed in Table 25.7 and mechanical device support strategies are displayed in Figure 25.4. See Chapter 37 for further discussion of ECMO in CHD.

Adjunctive CPR techniques for the CHD patient

Interposed abdominal compression CPR

As mentioned above, chest compressions during conventional CPR may impede venous return to either the right heart or pulmonary arteries, and in the setting of cavopulmonary anastomoses, may limit cerebral blood flow. In addition, low diastolic BP during CPR, whether exacerbated by aortopulmonary shunts or pre-arrest hypotension, may compromise coronary perfusion pressure. One CPR adjunct that may influence both of these conditions is IAC-CPR.

IAC-CPR is a technique in which force is applied to the abdomen during the recoil phase of chest compressions. It

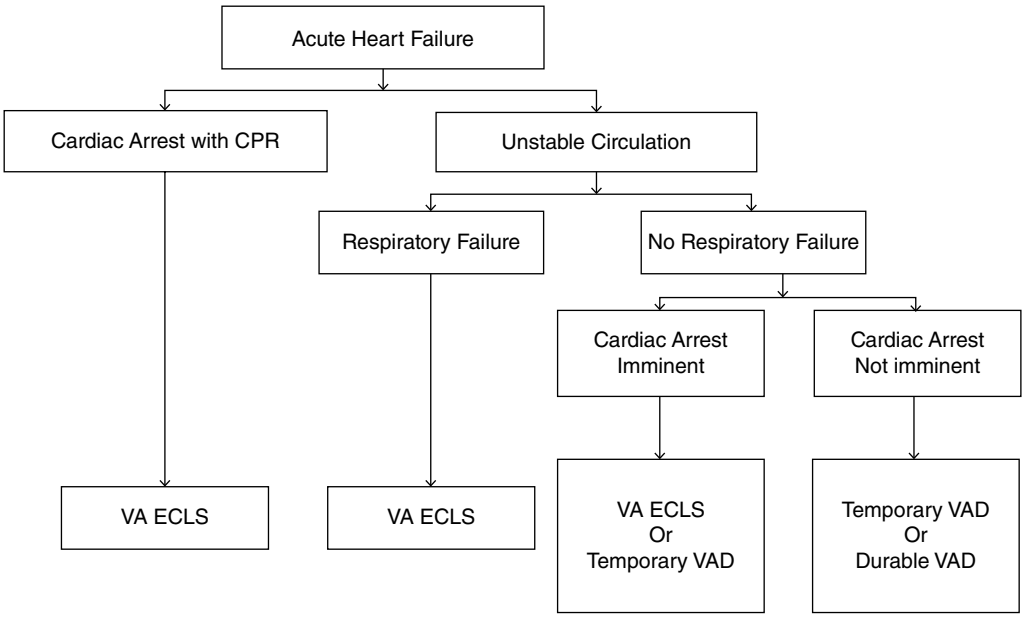

Figure 25.4 Mechanical circulatory support device strategy in rapidly deteriorating children with heart disease.[4,8,35,81,144,271–276,283,298,302,303,312,325–327,331,386,650,659] Choice of ventricular assist device (VAD) depends on patient size and need for left ventricular or biventricular support. Examples of temporary VADs include centrifugal pump extracorporeal life support (ECLS) without oxygenator, Impella, and Tandem Heart. Examples of durable VADs include Berlin Heart EXCOR, Thoratec paracorporeal VAD, HeartMate, HeartWare, and total artificial heart/SynCardia. CPR indicates cardiopulmonary resuscitation; and VA ECLS, venoarterial ECLS.

includes all elements of conventional CPR, thereby serving as an adjunct to traditional resuscitation. IAC-CPR works by external force transmission through the abdomen to the aorta. This leads to an increase in aortic diastolic pressure and enhanced retrograde flow to the coronary arteries and prograde flow to the brain. Hemodynamic effects are similar to intra-aortic balloon counterpulsation or external counterpulsation [116]. IAC-CPR also results in hydrostatic compression of intra-abdominal veins, which advance blood into the thoracic compartment during the relaxation phase of chest compressions. This refilling of the intrathoracic blood pool improves cardiac output with subsequent chest compressions. Finally, IAC-CPR augmentation of baseline venous pressure coupled with maintenance of an adequate arteriovenous gradient overcomes capillary closing pressure and thereby improves vital organ perfusion [117].

IAC-CPR has been evaluated in both animals and human adults. In a swine ventricular fibrillation model, animals receiving IAC-CPR as opposed to conventional CPR during arrest demonstrated greater systolic and diastolic BP, coronary perfusion pressure, and end-tidal CO_2 (as a surrogate measure of cardiac output). Return of spontaneous circulation (ROSC) was greater in the IAC-CPR cohort, and neurologic examinations in survivors who received IAC-CPR were superior to those who underwent conventional CPR [118].

Human studies on IAC-CPR have yielded similar benefits. Data from four randomized clinical trials of IAC-CPR have shown improved resuscitation rates and survival for patients experiencing IHCA [119]. Formal meta-analysis of randomized clinical trials of IAC-CPR versus conventional CPR revealed improvement in the rate of ROSC by 10.7% ($p = 0.006$) and a trend toward increased hospital discharge with the intact neurologic function of 8.7% ($p = 0.06$). When meta-analysis was limited to in-hospital trials ($n = 279$), ROSC was 52% with IAC-CPR versus 26% with conventional CPR ($p < 0.0001$). This suggests that only four patients would need to be treated with IAC-CPR to achieve ROSC in one additional patient. IAC-CPR has been recommended as an acceptable alternative to conventional CPR for in-hospital resuscitation (Class IIb recommendation per AHA guidelines) [120]. However, as yet, no published pediatric data upon which to base recommendations exist. Resuscitation registry information comparing judicious use of IAC-CPR and conventional CPR within the same patient at the discretion of the resuscitation team (including arterial waveforms, other monitor data, and outcomes) is being gathered.

In theory, IAC-CPR could be beneficial in CHD patients who are dependent upon passive flow to the lungs, those who experience limitation of PBF through pulmonary obstruction or PAH, and those with elevated ventricular filling pressures. The technique's ability to raise diastolic BP could augment cerebral blood flow and coronary perfusion pressure. This effect upon diastolic BP is thought to be critical to the achievement of ROSC in both adults and children. Paradis et al. found that adults who do not generate >16 mmHg diastolic BP during resuscitation do not experience ROSC [121]. Similarly, Berg et al. showed that the attainment of a threshold diastolic BP of 25 mmHg in children <1 year and 30 mmHg in those >1 year raised the probability of ROSC [72]. Preliminary mathematical modeling of single ventricle anatomy (personal communication) suggests that IAC-CPR raises overall cardiac output during CPR, including cerebral blood flow, and does not augment PBF in single-ventricle patients at the expense of systemic perfusion. That IAC-CPR could compromise cerebral blood flow through increased venous pressures seems unlikely given the

aforementioned animal findings, and the recently determined correlation of diastolic BP with cerebral blood flow during CPR microsphere experiments in pigs [122].

Head-up CPR

CPR is typically performed with the patient in the supine position. However, some information in animal models of arrest has demonstrated that elevation of the head during CPR may have a beneficial effect upon intracranial pressure, cerebral perfusion pressure, and brain blood flow [123]. With the head up (usually around 30°) gravity helps to drain venous blood from the brain back to the heart, leading to greater intracardiac filling between chest compressions and lower intracranial pressure. This, in turn, lowers impedance to forward cerebral blood flow with subsequent chest compressions. These benefits have only been seen when using an impedance threshold device and/or active compression-decompression device [see below] to generate more negative intra-thoracic pressure and greater cardiac output, and they have not been uniformly validated [124]. Clinical studies, especially in pediatrics, have yet to be conducted.

Intrathoracic pressure regulation: active compression decompression CPR and the impedance threshold device

The ability to use the thorax as a compartment that fills and empties into the systemic circulation is referred to as the thoracic pump mechanism of CPR. This mechanism can be augmented to increase cardiac output through the manipulation of intrathoracic pressures. Reduction of intrathoracic pressure during CPR diastole encourages inflow to the thoracic cavity, and chest compressions which raise intrathoracic pressure to expel blood to arterial vessels. Active compression-decompression CPR (ACD-CPR) uses a suction device to repetitively pull up and push down on the chest. The upward suction enhances chest recoil, creating greater negative intrathoracic pressure. This results in augmentation of venous return to the heart and lungs and preload to the LV; it also lowers intracranial pressure and increases coronary and cerebral perfusion pressure. ACD CPR can be combined with the use of an impedance threshold device (ITD). The ITD works by transiently impeding airflow into the lungs during chest wall recoil (but not during positive pressure ventilation). This also creates negative intrathoracic pressure which pulls more venous return to the heart to augment cardiac output. Both these devices have been tested in animals and humans, with the combination demonstrating a survival benefit relative to conventional CPR, prompting Food and Drug Administration (FDA) approval [125]. Though studies of young animals have been conducted with ACD-CPR plus the ITD, clinical investigation in children has not been accomplished to date.

CPR coaching

Emphasis on the performance of high-quality CPR has prompted a recent investigation into the advisability of having a trained CPR coach present during resuscitation. Cheng et al. randomized CPR teams from four United States and Canadian centers to have a trained CPR coach vs. no CPR coach. CPR coaches were made responsible for providing real-time verbal feedback regarding CPR performance to compressors, and caregivers had access to real-time CPR quality data from the defibrillator. CPR coaching resulted in absolute improvements in mean chest compression depth compliance, mean chest compression fraction, and mean pre-, post-, and perishock pause duration [126]. Kessler et al. then reviewed videotape from the simulated pediatric arrests in the Cheng study and performed a secondary analysis. CPR-coached teams demonstrated improved verbalization before pauses, decreased pause duration, shorter pauses with intubation, and better task coordination than their counterparts [127]. Shorter pause duration is associated with higher rates of ROSC and survival to discharge [128], and current guidelines recommend limiting interruptions in chest compressions to <10 seconds due to adverse effects upon coronary perfusion pressure [59]. Though the studies to date on this subject have all utilized simulated scenarios, the notion that a coaching intervention can significantly improve team choreography, and perhaps CPR quality, is important. The effect upon real outcomes awaits investigation.

KEY POINTS: ADJUNCTIVE CPR TECHNIQUES IN CHD

- CPR avoidance via astute pre-arrest management represents the best strategy for the care of infants and children with CHD.
- Once an arrest has occurred, the tenets of high-quality conventional CPR apply directly to the population with CHD, even as some heart defects and conditions may limit CPR effectiveness.
- E-CPR should be considered early in the course of resuscitation that has failed to achieve ROSC to obtain optimal outcomes.
- Adjunctive CPR techniques, such as IAC-CPR and CPR coaching, have theoretical benefits but require clinical validation in the pediatric cardiac population.

Simulation/education

The education of patient caregivers is a key determinant of survival after CA. The current evidence supports that adherence to the guidelines during CPR improves patient survival. Unfortunately, in both simulated and real CAs, providers often fail to deliver the right depth, rate, and recoil of chest compressions [129, 130]. The current certification training programs from the AHA provide varying rates of skill acquisition. Poor skill performance of providers is seen even after 3 months of learning activity. Increasing the frequency of training may improve the efficacy of training, protect against skill deterioration, enhance performance during patient care, and improve patient outcomes.

In addressing this issue, the AHA's Resuscitation Quality Improvement (RQI) program utilizes a spaced training design, where CPR skills are practiced at least every 3 months. In contrast with high-dose, low-frequency training,

low-dose, high-frequency booster training is effective in improving retention[131]. Studies have shown that short-duration just-in-time CPR training is more effective when performed monthly than quarterly [132, 133]. In pediatric residents, a short deliberate practice-based training session was found effective in achieving mastery learning, and it was maintained in 90% of learners two months after training [134]. Training the learners in a variant of deliberate practice, called rapid cycle deliberate practice, has been associated with improved performance and shorter training times, along with a decrease in decay compared to a standard simulation approach [135–137].

Team training

Team training has been a component of AHA's resuscitation education since 2005. It is directed toward optimizing teamwork, communication, leadership, and other aspects of crisis resource management. IHCA is usually treated by a team of health care professionals. Code teams exposed to composite resuscitation team training are more likely to adhere to resuscitation guidelines [138]. The introduction of a CPR coach, a team member whose primary responsibility is to provide real-time coaching and feedback on chest compression (CC) performance during cardiac arrest can improve the quality of CC during a simulated cardiopulmonary arrest when a CPR feedback device is in use [126].

With advances in technology and web-based connectivity, there is an increasing focus on the use of new platforms and strategies for healthcare provider education. New gaming environments are available, which facilitate CPR skill training, retention, teamwork, and situational awareness [139, 140]. Screen-based education delivery provides the advantage of consistency, the lack of a need for an instructor, lower cost, and flexibility with time and space for learning. With the increasing presence of medical professionals in social media, the incorporation of social media into educational frameworks provides opportunities for increased connectivity, engagement of learners in knowledge creation and dissemination, and reaching learners with varying learning styles through different modalities.

Introduction

Left-to-right shunt lesions are the most common congenital heart defects, accounting for approximately 50% of all lesions. They are defined by a communication between the systemic and pulmonary circulations that allows shunting of well-oxygenated (systemic) blood to the less-oxygenated (pulmonary) circuit. This definition applies whether the associated structures are located on the left or right side anatomically. For instance, a child with a ventricular septal defect (VSD) and L-transposition of the great arteries (ventricular inversion) will shunt blood from the right-sided systemic ventricle to the subpulmonic, lower pressure left-sided ventricle. The degree of shunting through a left-to-right shunt lesion may be limited by the size of the defect or the resistance to blood flow on either side. For example, shunting between high-pressure systems like the ventricles through a large VSD is dependent on the ratio of pulmonary vascular resistance (PVR) to systemic vascular resistance (SVR). In contrast, left-to-right shunting through a large atrial septal defect (ASD) occurs primarily during atrial contraction and is dependent on the relative diastolic compliances of both right and left ventricles into which the atria eject. Hemoglobin concentration is another contributing factor to the amount of left-to-right shunting. Elevated blood viscosity, which rises with increasing hemoglobin concentration, increases both PVR and SVR. The net effect is a reduction in left-to-right shunting. The physiologic decline in hemoglobin concentration in the first 3 months of life is thought to have a substantial role in the normal fall of PVR after birth and may contribute to the exacerbation of symptoms related to left-to-right shunting.

All left-to-right shunts produce a volume burden on the cardiovascular system, the effects of which vary according to the location of the shunt. Chamber dilation and hypertrophy, be it left, right, atrial, or ventricular, occur in structures that are involved in the pathway of the shunted volume (Figure 26.1). Shunting at the atrial level, such as through an ASD, results in an increased volume load in both atria and the right ventricle. Shunting through a VSD results in an increased volume load in both ventricles and the left atrium.

Shunting at the level of the great arteries results in an increased pulmonary artery blood flow, which increases pulmonary venous return to the left atrium. The extra shunt

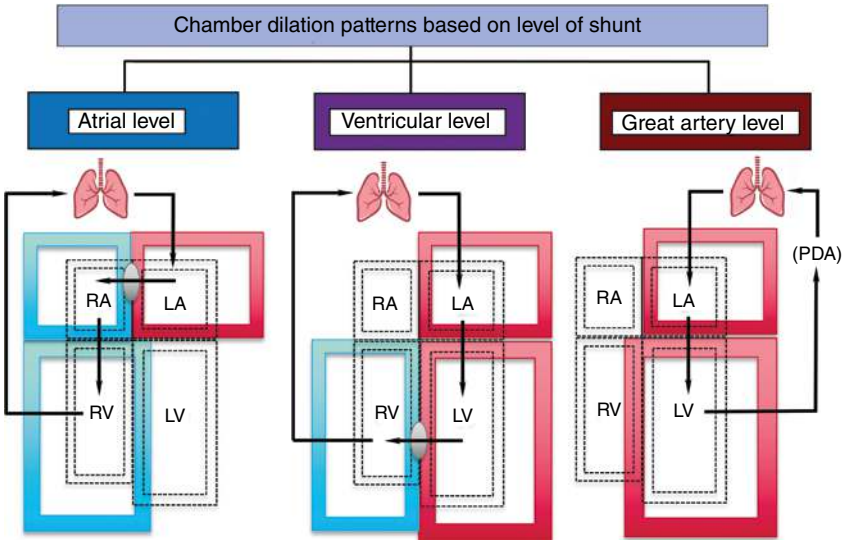

Figure 26.1 Schematic diagram of heart chamber dilation patterns based on level of the shunt. Black arrows represent the flow pathway of left-to-right shunted blood. Dashed lines represent normal chamber size. Red or blue boxes represent chamber dilation. Abbreviations: LA, left atrium; LV, left ventricle; PDA, patent ductus arteriosus. RA, right atrium; RV, right ventricle.

volume dilates the left atrium and leads to increased left ventricular end-diastolic volume and left ventricular stroke work by the Frank-Starling mechanism. The left ventricle also gradually dilates and hypertrophies, producing increased left ventricular end-diastolic pressure followed by increased left atrial pressure. Shunting at the level of the great arteries also produces a decrease in diastolic blood pressure from runoff of blood into the low-pressure pulmonary circuit after the closure of the aortic valve. Low diastolic pressures decrease coronary perfusion, potentially creating ischemia from decreased myocardial oxygen delivery in the setting of increased oxygen demand from the hypertrophied ventricle. The final result is pulmonary edema from pulmonary venous congestion and left heart failure. While the right atrium and ventricle are spared the volume loading is seen in the left-sided chambers, as PVR increases over time, there is an increased pressure burden on the right ventricle and eventual right heart failure.

Prolonged exposure of the pulmonary vasculature to increased flow and pressure results in a fixed increase in PVR. When PVR exceeds the SVR, the direction of the shunt can reverse and result in chronic cyanosis and erythrocytosis. Shunt reversal is more likely and occurs sooner with large defects distal to the tricuspid valve, but can be seen with any form of long-standing left-to-right shunt. When the elevated PVR causing right-to-left shunting becomes irreversible, this is known as Eisenmenger syndrome.

Figure 26.2 presents a schematic summary representation of the pathophysiology of the left-to-right shunting lesions and the factors that influence the degree of shunting at each level. Note that the four principal outcomes of RV failure, pulmonary edema, LV failure, and Eisenmenger physiology are possible with a long-standing shunt at any level. For example, although shunting at the atrial level does not create a direct volume burden on the left ventricle, if it eventually produces pulmonary hypertension to a degree that right ventricle (RV) pressure exceeds left ventricle (LV) pressure, the ventricular septum will shift leftward and impair LV function.

The normal compensatory mechanisms that maintain systemic cardiac output and myocardial performance in the patient with a left-to-right shunt include the Frank-Starling mechanism, the sympathetic nervous system, and hypertrophy of the myocardium. Manifestations of these compensatory mechanisms include sweating and tachycardia. Infants are also often tachypneic because of decreased lung compliance associated with increased pulmonary blood flow. Tachypnea impairs feeding, and growth failure develops from both decreased caloric intake and increased caloric utilization. Although significant left-to-right shunts can induce heart failure, infants rarely manifest peripheral edema or jugular venous distension like adults. The most consistent sign of right-sided failure in an infant is hepatomegaly.

Anesthetic management for left-to-right shunt lesions should be individualized to the patient, but certain generalities do exist. Premedication with intravenous or oral drugs such as midazolam (0.05–0.1 mg/kg IV or 0.75–1.0 mg/kg PO) can be safely administered for the purpose of decreasing anxiety and providing more controlled induction of anesthesia [1]. Standard American Society of Anesthesiologists (ASA) monitors, along with the use of invasive arterial and central venous pressure monitoring and careful attention to urine output are recommended for all cases involving cardiopulmonary bypass (CBP). Transesophageal echocardiography (TEE), cerebral oximetry, and cerebral blood flow monitoring are also useful monitoring adjuncts (see Chapters 14 and 15 for a more detailed discussion). Rarely, patients will present with severe, poorly controlled congestive heart failure (CHF) and be intolerant to the myocardial depressant effects of inhalational anesthetics. For this group of patients, intravenous (IV) anesthesia is preferred, with common agents including fentanyl, midazolam, and dexmedetomidine [2–5]. In most situations, however, inhalation induction with sevoflurane is a viable option when IV access is not initially available.

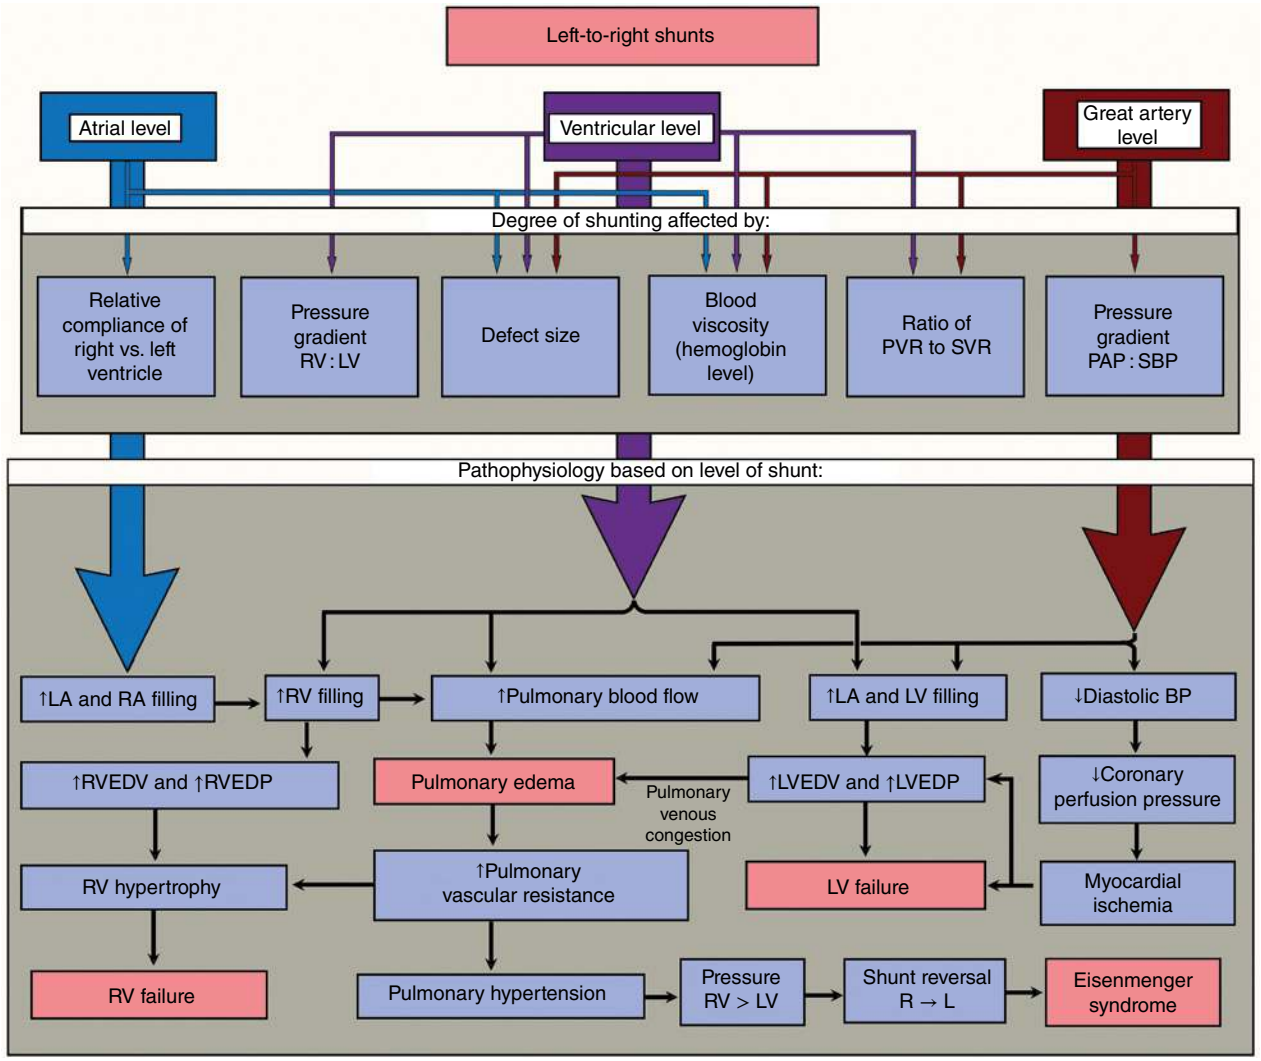

Figure 26.2 Pathophysiology of left-to-right shunting lesions. The flow diagram depicts factors that affect left-to-right shunting at the atrial, ventricular, and great artery levels and the pathophysiology produced by these shunts. A large shunt at any level can result in RV failure, LV failure, and pulmonary edema. Increased pulmonary blood flow leads to pulmonary hypertension and eventually Eisenmenger syndrome, characterized by irreversible right-to-left shunting. Abbreviations: BP, blood pressure; LA, left atrium; LVEDP, left ventricular end-diastolic pressure; LVEDV, left ventricular end-diastolic volume; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance; R, right; L, left. See text for detailed discussion. RA, right atrium; RV, right ventricle; LV, left ventricle; RVEDP, right ventricular end-diastolic pressure; RVEDV, right ventricular end-diastolic volume; SBP, systemic blood pressure; SVR, systemic vascular resistance.

Additional anesthetic issues include avoidance of air bubbles in IV lines to prevent paradoxical emboli. The anesthesiologist must also be cognizant of the pulmonary vasodilatory effect of oxygen and hypocarbia and manipulate ventilation in order to balance the PVR and SVR. Such measures generally include minimizing the fraction of inspired oxygen (FiO_2) and avoiding hyperventilation (maintaining the pressure of carbon dioxide ($PaCO_2$) between 40 and 50 mmHg).

Patent ductus arteriosus

Incidence, anatomy, and natural history

Isolated persistent patent ductus arteriosus (PDA) occurs in approximately 1 in 2,500 to 1 in 5,000 live births. The incidence is higher for premature births and PDA is two to three times more common in females than in males [6]. PDA is also found as part of other complex CHDs and is usually the source for pulmonary or systemic blood flow in patients with a functional single ventricle before palliative repair.

The ductus arteriosus is a vascular communication between the descending aorta and pulmonary artery. Embryologically, it arises from the distal portion of one of the sixth paired aortic arches [7]. It most commonly originates from the aorta, just distal to the left subclavian artery, and attaches to the left pulmonary artery (Figure 26.3) [8].

The ductus arteriosus is an essential component in normal fetal circulation; it becomes functionally closed within 10–15 hours after birth and permanently closes by thrombosis, intimal proliferation, and fibrosis in the first 2–3 weeks. Functional closure is initiated by several mechanisms

AL Grawany

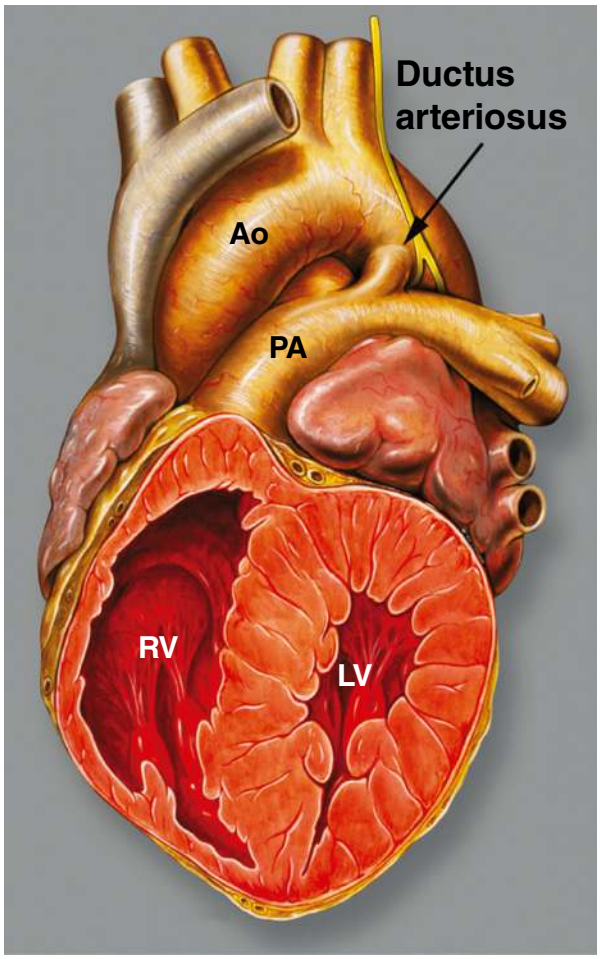

Figure 26.3 Patent ductus arteriosus. Ao, aorta; LV, left ventricle; P, pulmonary artery; RV, right ventricle. The yellow structure is the recurrent laryngeal nerve. (Source: Patrick J. Lynch, Medical Illustrator; C. Carl Jaffe, MD, Cardiologist / Wikimedia Commons / CC BY 2.5. https://en.wikipedia.org/wiki/File:Heart_patent_ductus_arteriosus.jpg.)

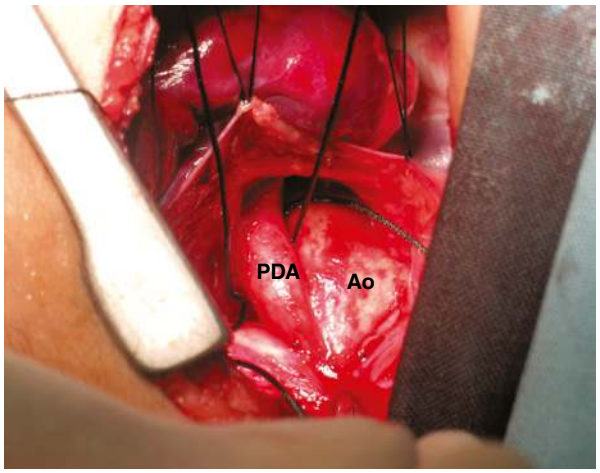
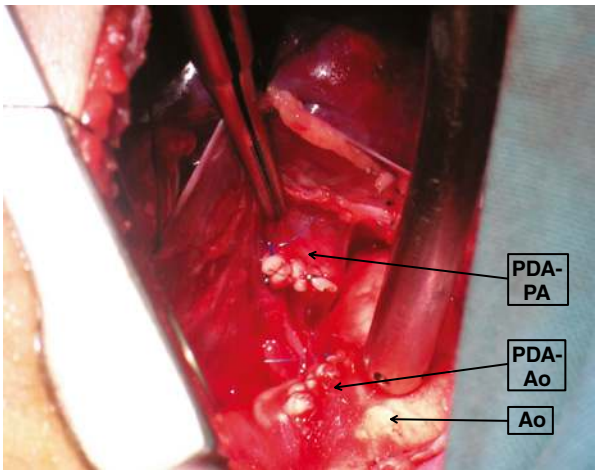
including aeration of the lungs, removal of prostaglandins produced in the placenta, increased arterial PO_2, and release of vasoactive substances (bradykinins, thromboxanes, and endogenous catecholamines) [6, 7, 9, 10].



The consequences of a PDA left untreated depend on many factors. A small PDA may be hemodynamically insignificant and unrecognized. The larger the PDA and left-to-right shunt, the more likely the progression to CHF, pulmonary hypertension, and if chronic and/or extreme, reversal of the shunt. In premature infants, PDA may result in increased morbidity from associated respiratory distress syndrome, necrotizing enterocolitis, and intracranial hemorrhage.

Pathophysiology



As a PDA represents a shunt at the level of the great vessels, the degree of left-to-right shunting depends on the dimensions of the PDA, the ratio of PVR and SVR, the ratio of PA pressure to systemic blood pressure, and blood viscosity as determined by the hemoglobin level. Ductal dimensions of importance include diameter and length. Larger diameters and shorter lengths produce less resistance, with the potential to allow greater flow. In patients with large PDAs, the diastolic runoff into the pulmonary artery results in lowered aortic diastolic pressure, which may increase the risk of myocardial ischemia, especially in the presence of anemia or lowered SVR.

Surgical and transcatheter approaches and outcomes

In premature newborns, the initial management of PDA is typically pharmacological closure using cyclo-oxygenase inhibitors such as ibuprofen, indomethacin, or acetaminophen [11, 12]. Cyclo-oxygenase inhibitors reduce the synthesis of prostaglandins, which would otherwise act to keep the PDA. Surgical treatment is usually reserved for patients who fail medical therapy. Surgical options include posterolateral thoracotomy with ligation or division of the PDA [13] (Figure 26.4), video-assisted thoracoscopic surgery (VATS), and robotically assisted total endoscopic closure [14]. These

(A)

(B)

Figure 26.4 Surgical ligation of a patent ductus arteriosus (PDA) via thoracotomy. (A) The PDA has been dissected and secured with ligatures, (B) Divided and oversewn PDA. Abbreviations: Ao, aorta; PDA-Ao, aortic end of PDA; PDA-PA, pulmonary artery end of PDA. (Source: Reproduced with permission from CTSNet.org.)

approaches have mortality approaching 0% and minimum morbidity; however, mortality rates in premature neonates are slightly higher. Complications of surgical treatment include bleeding, chylothorax, vocal cord paralysis (injury to the recurrent laryngeal nerve), pneumothorax, atelectasis, recurrence of patency, and inadvertent ligation of the pulmonary artery or descending aorta. Advantages of VATS compared to thoracotomy include decreased pain, decreased hospital cost (secondary to decreased hospital stay), and avoidance of post-thoracotomy syndrome (rib fusion, chest wall deformities, scoliosis, and compromise of pulmonary function). Disadvantages of VATS include intraoperative oxygen desaturation and hypercarbia, as well as higher morbidity during the surgical learning curve [15–17]. The use of robotic assistance achieves similar outcomes but with longer surgical times because of increased complexity [14, 18].

While surgical techniques are still employed, PDA closure is now most commonly accomplished in the cardiac catheterization laboratory. Techniques include the use of a variety of devices, including coils, vascular plugs, and umbrella-type occluders. Risks of transcatheter approaches include arrhythmias, embolization of the device, and incomplete closure [19–23]. However, these methods are considered safe, efficacious, and cost-effective when compared to surgical closure [24, 25]. Historically, there have been size limitations for use in small infants, but newer devices may allow for transcatheter closure in patients less than 1 kg with favorable anatomy [18–23]. See Chapters 19 and 34 for further discussion of transcatheter PDA occlusion.

Anesthetic considerations

The anesthetic management for PDA ligation depends on factors such as the patient's clinical condition, prematurity, coexisting disease, body weight, and surgical technique. Large volume venous access (which may be a 22- or 24-gauge IV in a premature infant) and forced air-warming devices are recommended. Pulse oximetry of both upper and lower extremities will assist in detecting inadvertent ligation of the descending aorta. For patients with coexisting disease, intra-arterial pressure monitoring provides a method of assessing arterial blood gases, electrolytes, hematocrit, and acid-base status. Whether by cuff or arterial line, blood pressure should be monitored in both an upper and lower extremity and observed carefully before and after ductal occlusion. Proper ductal occlusion will typically be accompanied by an increase in diastolic blood pressure consistent with the elimination of pulmonary runoff. Significantly decreased or absent blood pressure in the lower extremity indicates aortic rather than ductal occlusion. A gradient between the systolic pressure in the upper and lower extremities indicates the creation of aortic coarctation.

Although inhaled anesthetics can be safely used for many patients undergoing PDA ligation, neonates are prone to hemodynamic instability with exposure to inhaled anesthetics and benefit from an intravenous anesthetic technique using opioids such as fentanyl and possibly a benzodiazepine along with muscle relaxation.

Neonatal PDA ligation is often performed in the newborn intensive care unit (ICU) to avoid the additional risks of transport, need for ventilator changes, and hypothermic exposure. High spinal anesthesia, caudal and thoracic epidural techniques have all been described as safe and producing faster recovery [26, 27].

Lung isolation improves surgical exposure, especially through VATS surgical techniques, but it may require ventilation with 100% inspired oxygen to maintain acceptable oxygenation. Prior to lung isolation, FiO_2 should be minimized and hypocarbia avoided in order to maintain pulmonary vascular tone and to limit the degree of left-to-right shunting. This technique is usually unnecessary for small infants, with either gentle retraction and packing in the case of open thoracotomy or gentle CO_2 insufflation with retraction for VATS, being sufficient.

Infants having thoracotomy or VATS often require postoperative mechanical ventilation, especially if they are premature. Older patients or patients undergoing transcatheter closure are often extubated at the conclusion of the case [17–27].

KEY POINTS: PATENT DUCTUS ARTERIOSUS

- PDA is a relatively common congenital heart defect and is associated with prematurity.
- Pathophysiology depends on the degree of shunting, which is greatest with a short ductus of large diameter.
- Surgical closure may involve an open, thoracoscopic, or transcatheter technique.
- Choice of anesthetic is unlimited in older, less symptomatic patients but often restricted to the opioid technique in premature infants.
- Monitoring perfusion above and below the ductus is critical in recognizing inadvertent ligation of the aorta.
- Immediate postoperative extubation is an option for healthy patients and/or transcatheter techniques, but postoperative mechanical ventilation is required for most neonates and infants.

Aortopulmonary window

Incidence, anatomy, and natural history

Aortopulmonary window (APW), also known as aortopulmonary (or aorticopulmonary) fistula, fenestration, or septal defect is a rare anomaly comprising approximately 0.1–0.6% of all congenital heart defects [28–30]. A total of 50–80% of patients with APW have associated defects including PDA (72%), a right pulmonary artery from the aorta (32%), anomalous origin of a coronary artery from the pulmonary artery (23%), VSD (20%), agenesis of the ductus arteriosus (20%), and other lesions [28, 31]. Embryologically, APW is thought to originate from nonfusion or malalignment of the aortopulmonary and truncal septi, or complete absence of the aortopulmonary septum [28, 32].

The basic anatomical defect in APW consists of a communication between the aorta and the pulmonary artery. Type I APW is a proximal defect located just above the sinus of Valsalva, a few millimeters above the semilunar valve. Type

AL Grawany

II is a distal APW located in the uppermost portion of the ascending aorta. Type III is a total defect involving the majority of the ascending aorta. Type IV or intermediate defects, which are neither proximal nor distal, are also designated in this system; these defects are noted for being conducive to device closure because of adequate superior and inferior rims (Figure 26.5) [33].

Uncorrected APW results in a reported 40% mortality in the first year of life, with a substantial proportion of survivors succumbing to CHF later in childhood [32].

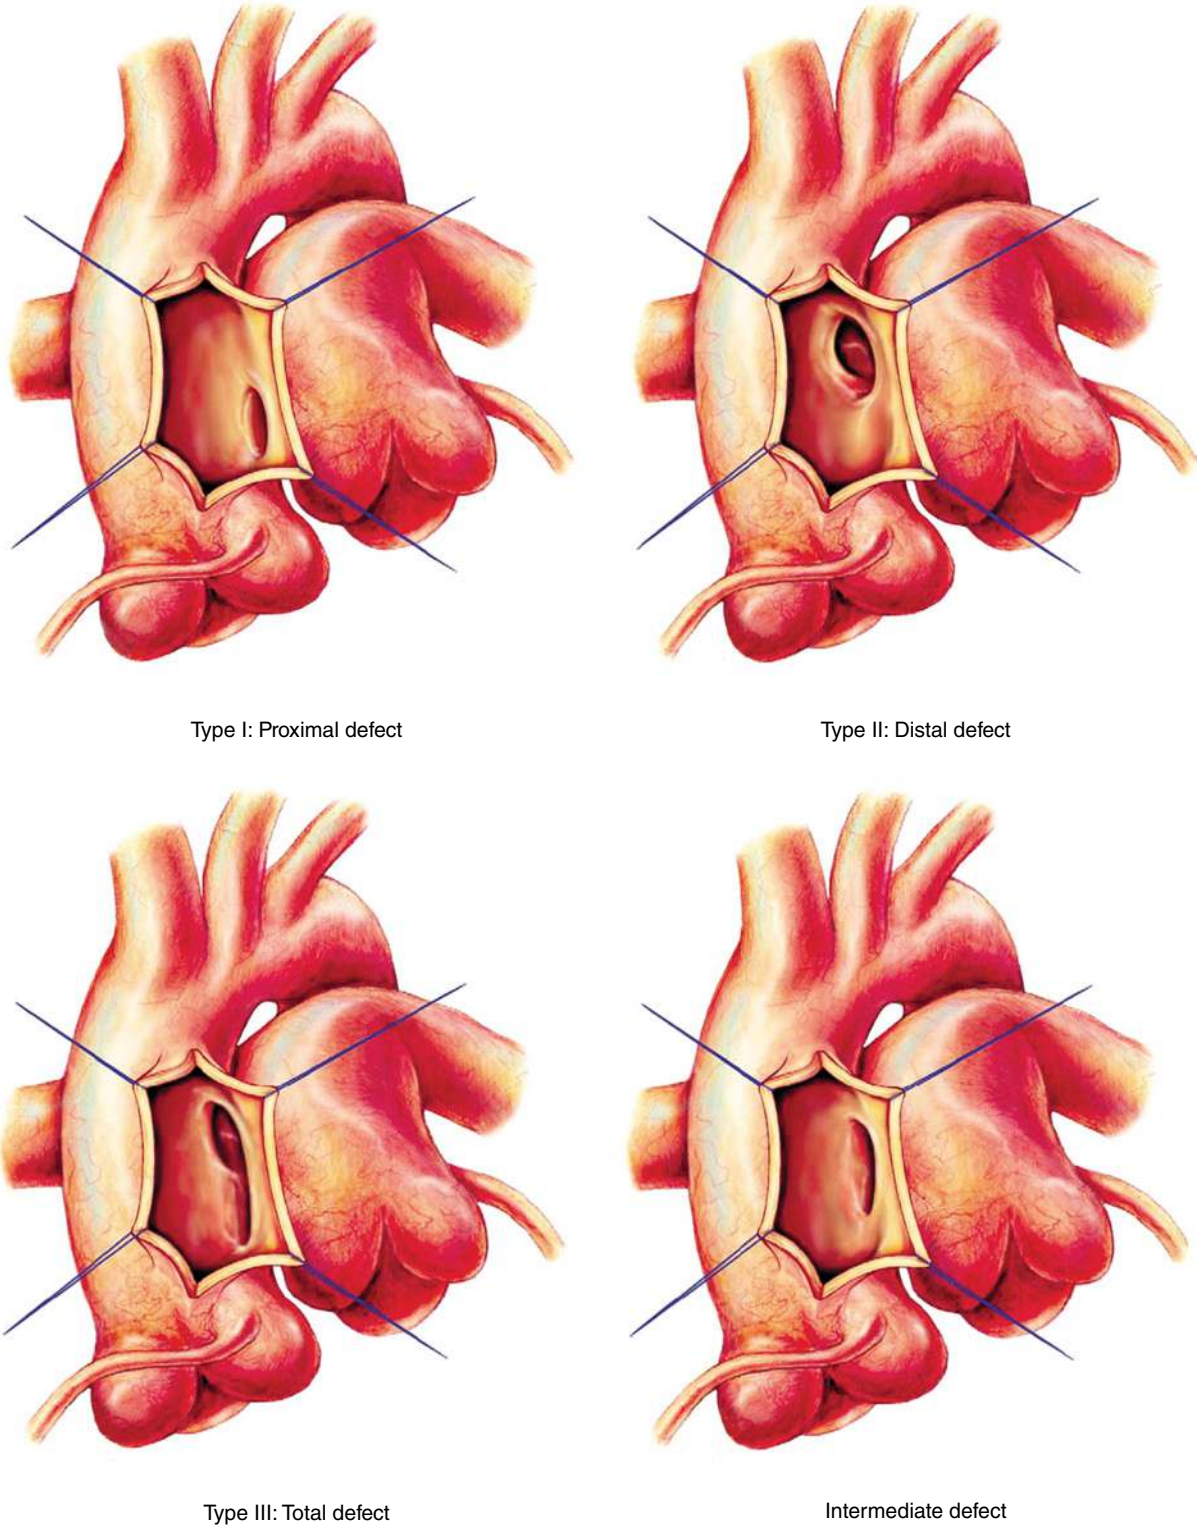


Figure 26.5 Classification of aortopulmonary window variants (see text for explanation). (Source: Backer [33]. Reproduced with permission of Elsevier.)

Pathophysiology

The pressure gradient between the aorta and pulmonary artery will produce significant left-to-right shunting depending on the size of the defect and the relative resistances of the pulmonary and systemic vascular beds. A defect such as an APW is considered "restrictive" when it is small enough that there is a size-related flow limitation across the defect indicated by a significant pressure gradient from one side to the other. Flow across a "non-restrictive" APW is not limited by size; any pressure gradient across the defect is related only to the relative resistances of the pulmonary and systemic vascular beds. Coexisting cardiac anomalies may alter the pathophysiology. Pulmonary hypertension can develop as early as 12 days of age [34].

Surgical and transcatheter approaches and outcomes

A variety of techniques have been described for repair of APW, including ligation and/or division with or without cardiopulmonary bypass, transaortic patch closure, complete separation, and reconstruction of both the aorta and pulmonary artery, and transcatheter closure [33, 35–37]. The repair is usually performed via median sternotomy with the use of cardiopulmonary bypass. Surgical repair of the aortic defect can be accomplished using a pulmonary artery flap with subsequent repair of the pulmonary artery with a pericardial patch [38, 39]. A Gore-Tex® cardiovascular patch can also be used to close the defect [33] (Figure 26.6). Care must be taken to explore and repair associated anomalies of the pulmonary and coronary arteries and to repair coexisting cardiac abnormalities. Deep hypothermia and circulatory arrest may be required for the repair of large APW involving the proximal ascending aorta in neonates.

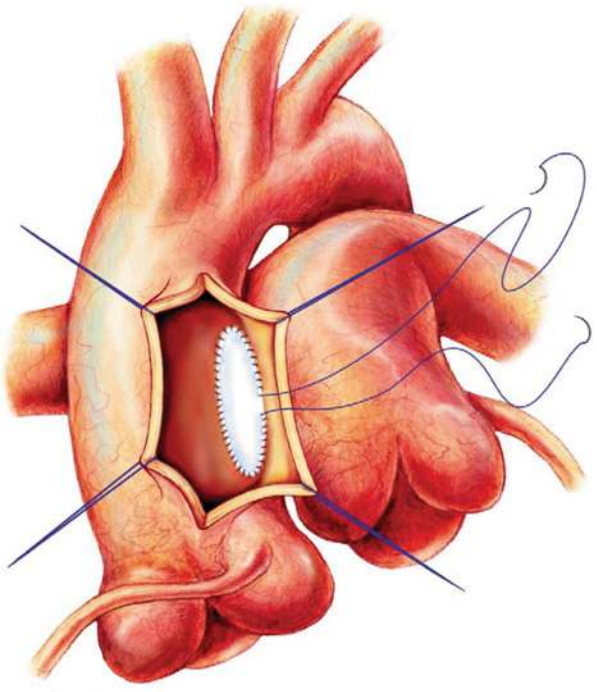

Figure 26.6 Patch closure of type III aortopulmonary window (APW) total defect. Aortic cross-clamp and cardiopulmonary bypass cannulas not shown (Source: Backer [33]. Reproduced with permission of Elsevier.)

Actuarial survival after repair of APW is between 80 and 100%, with the most significant risk factor in the modern era being the presence of associated cardiac defects. Simply repaired APW lesions have a mortality approaching zero [28]. Transcatheter closure of APW is typically accomplished with an umbrella-type occluding device [36, 37, 40–42]. Although transcatheter closure has generally been reserved for patients with restrictive defects, device closure has been reported in selected non-restrictive defects as well [43].

Anesthetic considerations

The anesthetic management of APW is similar to that of truncus arteriosus. Younger patients may have considerable diastolic runoff from low PVR. Prior to cardiopulmonary bypass, efforts should focus on maintaining pulmonary vascular tone. This can be accomplished by lowering the minute ventilation and restricting the FiO_2 to maintain a moderate hypercarbic respiratory acidosis and an oxygen saturation level of 80–85%. In these cases, surgical snaring of the pulmonary artery prior to bypass may also be helpful. In contrast, patients undergoing later repair are likely to present with elevated PVR, and anesthetic management should include avoiding further increases in PVR.

Regardless of PVR at presentation, all patients with APW are at risk to develop perioperative pulmonary hypertension. The administration of inhaled nitric oxide, as well as other maneuvers described above, may be necessary to lower PVR. Patients exhibiting signs of pulmonary hypertension should initially be maintained under deep sedation with or without neuromuscular blockade during the immediate postoperative periods (see Chapter 33).

KEY POINTS: AORTOPULMONARY WINDOW

- APW is a rare lesion with a pathophysiology and management scheme that varies with the size and location of the defect.
- Surgical and transcatheter approaches have been used; deep hypothermic bypass and circulatory arrest may be required.
- High pulmonary blood flow and diastolic runoff into the pulmonary circulation should be mitigated by maintaining PVR through a lower oxygen saturation and moderate hypercarbia.
- Pulmonary hypertension precautions should be observed in all patients with APW.

Atrial septal defects

Incidence

Atrial septal defects (ASDs) make up approximately 5–10% of all CHDs with the secundum ASD comprising nearly 80% of all ASDs. Isolated ASDs are more common in females than males by a factor of 2:1 [9]. A probe-patent foramen ovale is

AL Grawany

found in approximately 30% of otherwise normal adult hearts [44]. When associated with other CHDs, an ASD may be a life-saving communication allowing mixing of blood between the pulmonary and systemic circulations. Examples include total anomalous pulmonary venous return, tricuspid atresia, and transposition of the great arteries (TGA). In such cases, an ASD may be iatrogenically created as a palliative measure, often on an urgent or emergent basis (e.g. balloon atrial septostomy).

Anatomy

The right and left atria are normally divided by the fusion of two septa: the septum primum and the septum secundum. The septum primum develops during the fourth week of gestation and the septum secundum during the fifth week [7]. The septum primum originates posteriorly and advances across the atrial midline. The opening it leaves by incompletely advancing to the endocardial cushion is the ostium primum, which later closes. A second opening, the ostium secundum, forms in the central portion of the septum primum. The septum secundum originates anteriorly and to the right of the septum primum and advances over the ostium secundum. Although traditionally the septum secundum has been described in terms similar to those of the septum primum in its formation and composition, it is instead to a large extent composed of an infolding of the superior margin of the atrium rather than an advancing wall of tissue [45]. It eventually develops a central opening called the foramen ovale. The septum primum forms the valve of the foramen ovale on the left atrial side [7, 46]. Figure 26.7 illustrates the process of embryologic development of the atrial septum. Errors in this process form the basis for the five different types of ASDs: secundum, primum, sinus venosus, coronary sinus, and patent foramen ovale (PFO) (Figure 26.8) [48].

Secundum ASD

The secundum ASD is contained within the area bordered by the limbus of the fossa ovalis [49]. It results from abnormal reabsorption of the septum primum or defective formation or shortening of the septum secundum. Combinations of these abnormalities may contribute to large defects.

Primum ASD

The primum ASD results from abnormalities in the formation of the septum primum. It is frequently associated with atrioventricular canal (AVC) defects, especially partial atrioventricular canal (PAVCs) that include a cleft in the anterior leaflet of the left atrioventricular valve. AVC defects are due to abnormalities in the fusion of the endocardial cushions.

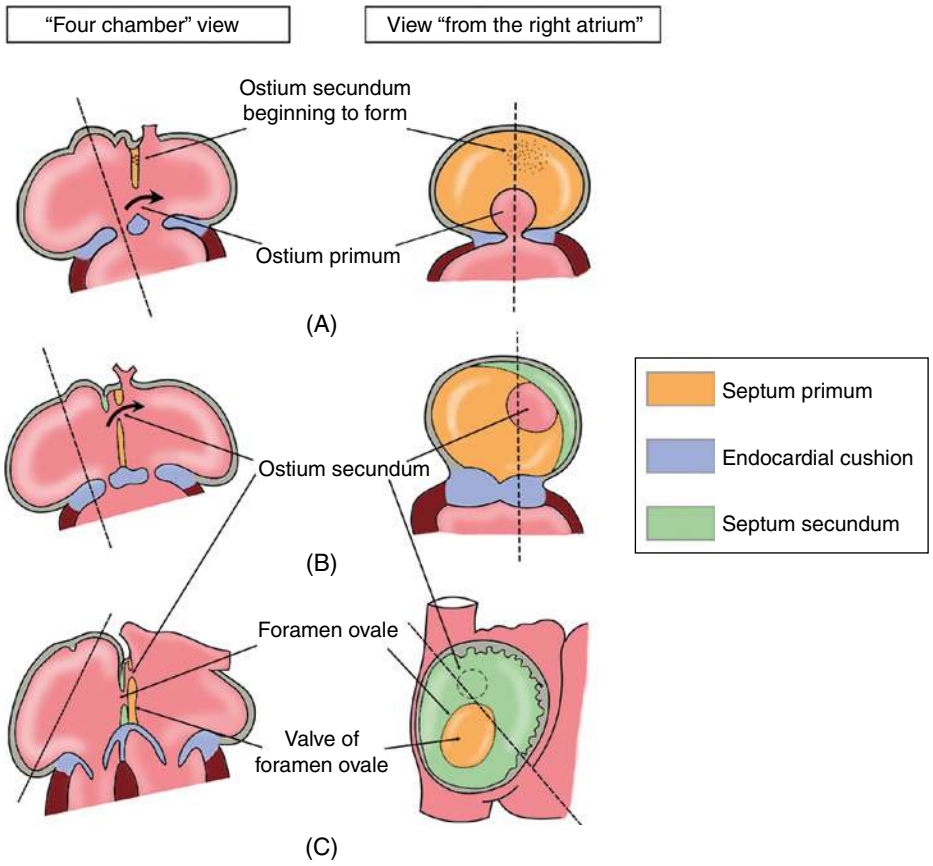

Figure 26.7 Embryologic development of the interatrial septum. The left column is a long axis cross-section similar to that of an echocardiographic four-chamber view. The right column is the view from the right atrium with the right atrial free wall removed, looking at the right side of the developing atrial septum. (A) 29 days gestation. (B) 37 days gestation. (C) Birth. (Source: Adapted from Radiologykey.com.)

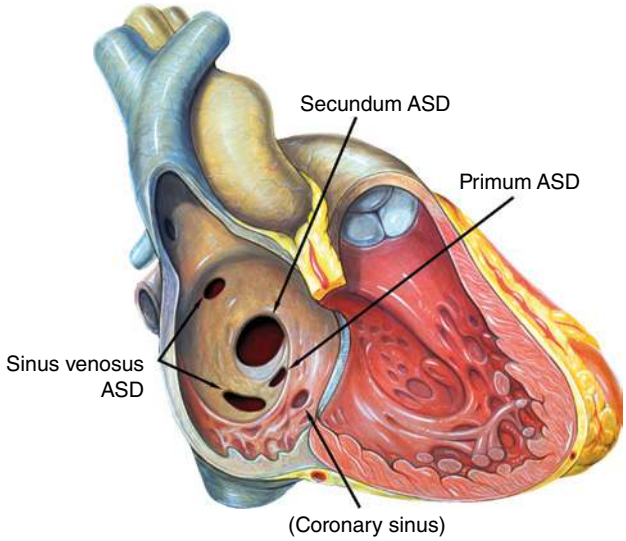

Figure 26.8 Types of atrial septal defects. Coronary sinus ASDs are not typically visible from the right atrium, as they result from unroofing of the coronary sinus as it courses along the posterior wall of the left atrium. Also not shown is the patent foramen ovale (PFO), which is usually covered by the remnant of the septum primum. (Source: Conti et al. [179]. Reproduced with permission of Elsevier.)

Sinus venosus ASD

Sinus venosus defects result from abnormal development of the septum secundum or the sinus venosus (the primitive venous collecting chamber). The most common type is located near the superior vena cava (SVC) orifice and is associated with partial anomalous pulmonary venous return involving the right upper and middle pulmonary veins. Defects near the orifice of the inferior vena cava (IVC) also exist and may involve partial anomalous pulmonary venous return of the right lower pulmonary vein.

Coronary sinus ASD

Coronary sinus ASD, also called an unroofed coronary sinus, results from an absence in the wall between the coronary sinus and the left atrium. This allows blood from the left atrium to drain into the right atrium via the coronary sinus. Persistent left SVC is also associated with this defect [49].

Patent foramen ovale

PFO results from failure of fusion of the septum primum to the limbus of the septum secundum. Patency of the foramen ovale is normal during fetal life and allows right-to-left shunting of blood in order to bypass the lungs in fetal circulation. Following birth, PVR decreases and SVR increases. Subsequent higher pressure in the left atrium causes the septum primum to close over the foramen ovale, but it may not completely fuse to the septum secundum.

Natural history

Isolated ASDs are usually asymptomatic during infancy and childhood despite the increased volume load on the right ventricle. CHF usually occurs after the second or third decade of life due to chronic right ventricular volume overload. Pulmonary hypertension can occur in up to 13% of unoperated patients younger than 10 years of age; however, progression to Eisenmenger syndrome is unusual [9]. The risk of arrhythmia is increased with increasing shunt volume and atrial dilation. Patients with a Qp : Qs of 2 : 1 or less have an 11% incidence of atrial arrhythmia, compared to 38% in those with Qp : Qs of 3 : 1 or greater [50]. An ASD is sometimes discovered during a neurological work-up for transient ischemic attacks or strokes from paradoxical emboli [49].

Pathophysiology

The amount of left-to-right shunting at the atrial level is dependent on two factors: the size of the defect and the relative compliance of the right and left ventricles. Shunting occurs primarily during diastole and produces a volume burden on the cardiovascular system that is proportionate to the degree of shunting.

Surgical and transcatheter approaches and outcomes

Surgical repair of an ASD is usually recommended between the ages of 3 and 5 years [51]. Spontaneous closure of small secundum type ASDs occurs in up to 87% of infants in the first year of life [9], and controversy exists regarding the closure of small ASDs that are asymptomatic. Conventional surgical treatment involves median sternotomy with the use of CPB to perform a primary repair or patch closure, with surgical mortality approaching 0% [9, 52]. Primum ASD repairs typically require patch closure as well as repair of the coexisting mitral valve cleft (Figure 26.9). Sinus venosus defects are usually repaired using a patch to close the ASD and baffle the anomalous pulmonary veins to the left atrium. The SVC may need to be translocated and anastomosed to the right atrial appendage to avoid baffle obstruction (Warden procedure). Many centers now favor partial sternotomy approaches because of the improved cosmetic result with similar morbidity and mortality to complete sternotomy [53–55]. Robotically assisted totally endoscopic ASD repair with remote access perfusion (using femoral cannulation) has been described in adults [56]. With conventional repair, postoperative dysrhythmias are reported in 23% of patients, and as many as 2% of patients may need a pacemaker following surgery [9].

Increased use of transcatheter ASD closure in the cardiac catheterization laboratory has dramatically reduced the number of operative repairs. While the several FDA-approved devices that have been utilized differ in detail, the typical design consists of a catheter-deployed expandable "double umbrella" type occluder, with a right and left atrial side (Figure 26.9) [57]. Nonsurgical transcatheter closure of PFO without an occluding device has also been described, using either radio frequency ablation or suture closure [58, 59]. Transcatheter ASD closure is usually performed under general anesthesia with the use of TEE to guide placement. However, intracardiac echocardiography using intravascular two-dimensional imaging may eliminate the need for TEE and reduce the need for general anesthesia [60]. Transcatheter closure is safe, associated with decreased hospital stay, lack of

AL Grawany

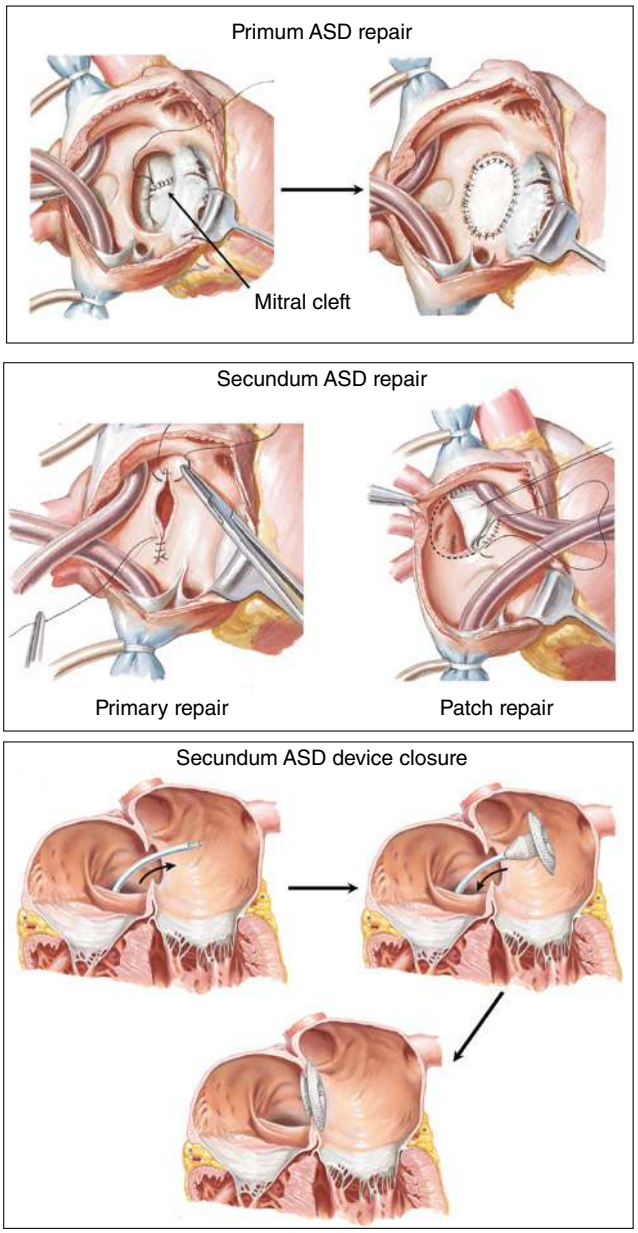

Figure 26.9 Surgical repair of primum (top) and secundum (middle) atrial septal defect (ASD), and device closure of secundum ASD (bottom). A primum ASD requires closure of the mitral valve cleft (top left), followed by patch closure of the ASD (top right). A secundum ASD may be repaired by direct suture closure (middle left) or by patch closure (middle right). Secundum ASD closure device is delivered via catheter across the ASD, wherein the left atrial side of the device is opened. The device is then pulled back against the ASD, where the right atrial side is opened and the device is deployed from the catheter. (Source: Conti et al. [47]. Reproduced with permission of Elsevier.)

a surgical scar, avoidance of CPB, and reduced anesthetic requirements. Limitations to transcatheter closure of ASD include patient size (introducer sheaths may be too large for smaller patients), type of ASD (usually limited to PFO or secundum), and the requirement for an adequate tissue rim to which the device can attach [61]. Occasionally, pre-procedure transthoracic echocardiography does not provide complete information about septal tissue rim size or other requirements for device closure, and backup surgical repair can be arranged during the same anesthetic if the TEE examination reveals contraindications to a transcatheter procedure.

Anesthetic considerations

Patients with an isolated ASD are generally asymptomatic and do not have pulmonary hypertension. Therefore, the induction of anesthesia can be safely accomplished with either inhalation or intravenous techniques. Whenever possible, patients should have an intraoperative TEE performed prior to incision, because transthoracic echocardiographic studies are sometimes unable to exclude the possibility of a partial anomalous pulmonary venous return due to difficulty in visualizing all four pulmonary veins. During surgery, TEE can be helpful to assess the de-airing of the left heart and adequacy of the repair. Most patients have a good myocardial function and do not require inotropic support perioperatively. Maintenance of anesthesia typically consists of a combination of inhaled and intravenous agents. Adjunct regional techniques are favored by some and may facilitate early extubation [62–65]. Tracheal extubation in the operating room (OR) has been shown to decrease patient charges without compromising patient care when compared to extubation in the ICU [66, 67]. Whatever technique is chosen, the primary goals for the uncomplicated ASD patient should include preparation for early extubation either in the OR or within the first 4 hours postoperatively.

KEY POINTS: ATRIAL SEPTAL DEFECT

- ASDs are a common congenital heart lesion and may be important in maintaining adequate intracardiac mixing in association with other life-threatening heart defects.
- Untreated ASDs may be asymptomatic until CHF, atrial arrhythmias, or strokes from paradoxical emboli occur, generally after the second or third decade of life.
- Anesthesia for isolated ASD closure is generally well tolerated and early extubation is an important goal.
- Transcatheter techniques for ASD closure have dramatically reduced the number of operative repairs.

Ventricular septal defects

Incidence

VSD is the most common CHD, occurring in 50% of all children with congenital heart disease and in 20% as an isolated lesion. The reported incidence ranges from 1.56 to 53.2/1,000 live births [68]. VSD is associated with a variety of inherited conditions, including trisomy 13, 18, and 21 as well as VACTERL (vertebral, anal, cardiac, tracheoesophageal fistula, renal, and limb anomalies) association and CHARGE (coloboma, heart defects, atresia choanal, retarded growth and development, and genital hypoplasia, and ear anomalies/deafness) syndrome [69].

Anatomy

Embryologically, the primitive left ventricle is formed from the ventricular portion of the bulbus cordis and the primitive right ventricle is formed from the proximal portion at approximately 23–25 days gestation. Disruption of ventricular septation at a given point during primary morphogenesis is responsible for four different types of VSD: type I: subarterial; type II: perimembranous; type III: inlet; and type IV: muscular (Figure 26.10) [69, 70]. Each of these types has various synonyms, making VSD nomenclature somewhat complex. A thorough understanding of the anatomy of the normal ventricular septum is helpful in making sense of the various types and subtypes of VSDs. In this way, VSDs may be understood as those within the muscular portion of the ventricular septum (type IV) and those that exist at its margins near the tricuspid and pulmonary valves (types I–III).

Type I: subarterial VSD

The subarterial (also called *juxtaarterial, subpulmonary, supracristal, conal*, or *infundibular*) VSD is located just beneath the pulmonary valve, within the outlet septum, above the crista supraventricularis. The crista supraventricularis defines the inferior margin of the smooth-walled muscular tube of tissue connecting the right ventricle to the pulmonary artery known as the *infundibulum* or *conus arteriosus*. As a result of the location of this defect, a Venturi effect may be produced by the jet of blood flowing through the VSD causing the right or noncoronary aortic cusp of the aortic valve to prolapse toward the defect, producing aortic insufficiency [68]. This type of lesion is more common among VSDs found in the Asian population, occurring in about 30% of all VSDs versus in about 5% of the non-Asian population [71].

Type II: perimembranous VSD

The perimembranous (also called *paramembranous* or *conoventricular*) VSD is a communication adjacent to a portion of the membranous septum and the fibrous trigone of the heart, where the aortic, mitral, and tricuspid valves are in fibrous continuity. These infracristal defects (below the crista supraventricularis) are the most common VSD subtype, accounting for approximately 80% of VSDs.

Type III: inlet VSD

Inlet VSDs (also called *canal type*) are located in the posterior region of the septum beneath the septal leaflet of the tricuspid valve. These defects account for approximately 10% of VSDs.

Type IV: muscular VSD

Muscular VSDs are located anywhere within the muscular portion of the interventricular septum. These defects can be multiple and represent approximately 2–7% of VSDs.

Natural history

Patients presenting with VSD may be asymptomatic or may exhibit signs and symptoms of CHF in varying degrees. The rate and extent of progression of symptomatology depend on the patient's age, size of the defect, and the degree of left-to-right shunting. Infants who have non-restrictive VSDs typically develop symptoms of CHF by 3 months of age because of the physiologic decline in PVR that occurs during early postnatal life. If left untreated, 15% of patients with large VSDs develop pulmonary hypertension that will progress to the development of pulmonary vascular obstructive disease, shunt reversal, and cyanosis

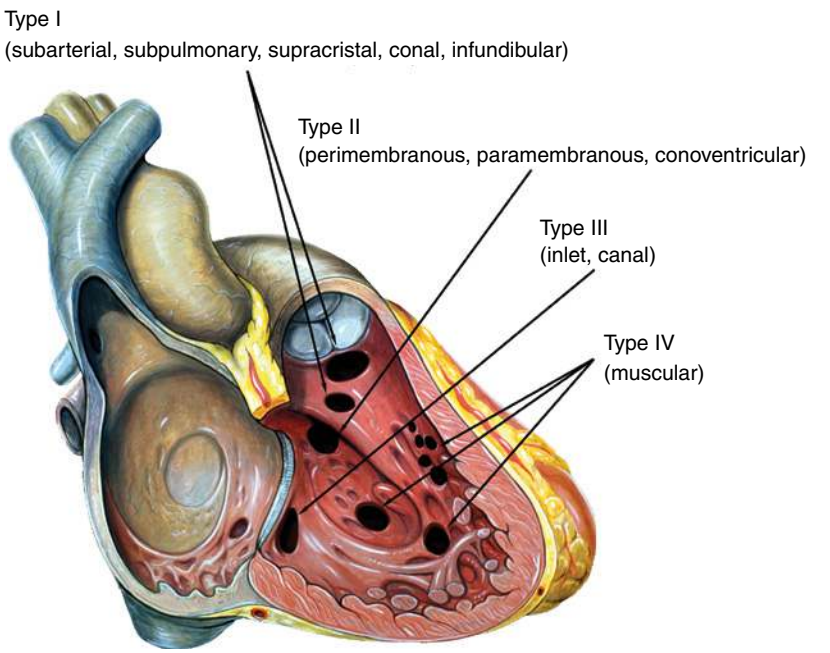

Figure 26.10 Types of the ventricular septal defect. (Source: Patrick J. Lynch, Medical Illustrator; C. Carl Jaffe, MD, Cardiologist / Wikimedia Commons / CC BY 2.5. https://commons.wikimedia.org/wiki/File:Heart_right_vsd.jpg.)

AL Grawany

(Eisenmenger syndrome) by the age of 20 years [72]. The irreversible changes that lead to Eisenmenger syndrome may develop by age 2 years; therefore it is important to close large non-restrictive VSDs within the first 2 years of life. However, these large defects often decrease in size over the first year, becoming restrictive and relatively asymptomatic, allowing avoidance of surgery through careful surveillance in some cases [73]. Spontaneous closure of small perimembranous and muscular VSDs occurs in as many as 50% of patients [72, 74, 75], and such patients are typically asymptomatic.

Pathophysiology

Isolated VSDs produce left-to-right shunting at the ventricular level, predominantly during systole. In contrast to ASDs, in which ventricular dilation is isolated to the right ventricle, the volume load induced by shunting through a VSD affects both ventricles. A VSD may be restrictive or non-restrictive, depending on size. A clear definition of a non-restrictive defect is elusive. The presence of a pressure gradient across the defect is inadequate because a gradient generally exists even in non-restrictive lesions related to the relative resistances of the pulmonary and systemic vascular beds. Proposed definitions involve the cross-sectional ratio of the defect to the aortic orifice, defect size versus body surface area, or shunt flow velocity [6].

In addition to the pathophysiology associated with left-to-right shunting, VSDs may be associated with secondary structural cardiac anomalies not related to the shunt and resultant volume loading. An example is the aortic valve prolapse often associated with VSDs near the aortic valve, resulting in aortic insufficiency. Another is the phenomenon of a "double-chambered right ventricle", which occurs with some frequency in the setting of a VSD. In this lesion, mid-cavity obstruction by hypertrophied muscle bands creates a high-pressure proximal chamber and a low-pressure distal chamber within the right ventricle. These lesions are also often associated with discrete subaortic stenosis [76].

Surgical and transcatheter approaches and outcomes

Surgical repair of VSD is usually by patch closure and occasionally by primary closure using CPB via median sternotomy. Perimembranous and inlet VSDs are most commonly repaired via a right atriotomy, which may require detachment of the septal leaflet of the tricuspid valve for exposure [77] (Figure 26.11). Subarterial VSDs are most commonly repaired via the transpulmonary approach. Midmuscular VSDs are most commonly repaired via right atriotomy, and anterior or apical muscular VSD may be approached using right ventriculotomy. However, the use of a right ventriculotomy carries the risks of conduction disturbances and ventricular dysfunction later in life. Symptomatic patients with lesions that are not approachable via right atriotomy may be treated with pulmonary artery banding until the patient is larger, allowing transatrial repair. Pulmonary artery banding is also utilized for multiple muscular VSDs and in patients that are high-risk candidates for CPB. Partial median sternotomies, as well as small right anterolateral thoracotomies, are advocated by some because of improved cosmetic results [78, 79]. Total thoracoscopic repair has also been described [80].

Timing for surgical repair varies depending on age at presentation and severity of signs and symptoms. Patients younger than 6 months of age are repaired if they manifest uncontrollable CHF and failure to thrive. Patients between 6 and 24 months of age undergo repair to treat CHF symptoms or pulmonary hypertension. Patients older than 24 months undergo repair if the Qp : Qs is greater than 2:1. Among patients with subarterial VSD, the presence of aortic insufficiency is an indication for surgical repair to prevent further progression of the valvular insufficiency [81, 82]. A defect

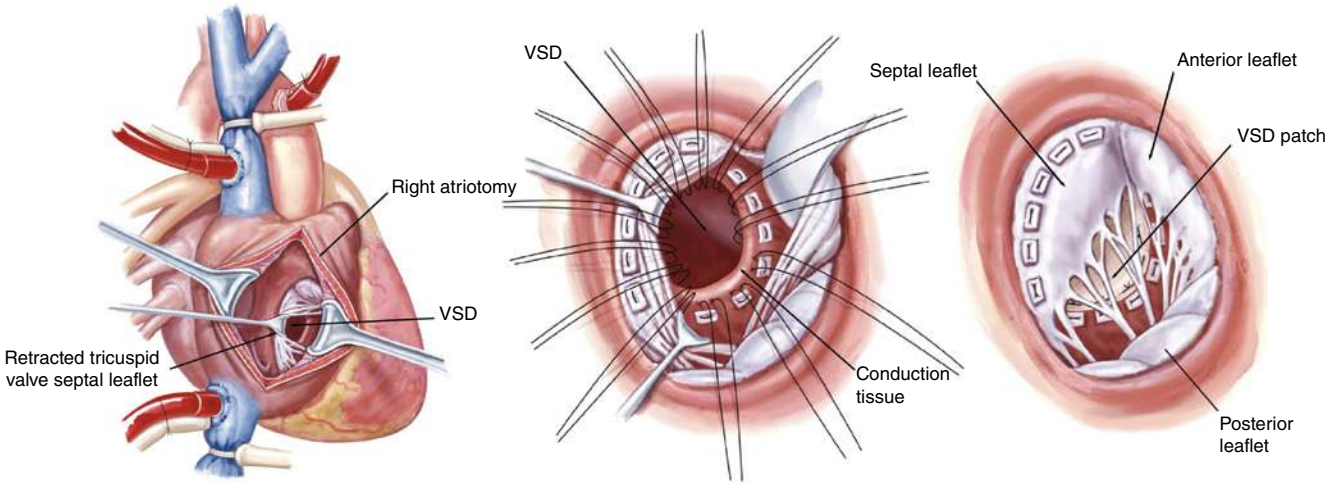

Figure 26.11 Surgical repair of perimembranous ventricular septal defect (VSD). This technique, typically done through a right atriotomy, is similar to that for inlet VSD. Note exposure requires retraction or detachment of the septal leaflet of the tricuspid valve (Source: Conti et al. [47]. Reproduced with permission of Elsevier.)

size of greater than 5 mm is repaired to avoid progression to aortic cusp prolapse and aortic insufficiency, and defects less than 5 mm can be managed conservatively [83]. Finally, even small, otherwise asymptomatic VSDs are usually repaired because of the low risk of infective endocarditis.

Mortality for uncomplicated VSD in older patients is less than 1–2% [84]. Mortality for VSD repair in infants during the first year of life is less than 5% [85].

Transcatheter closure of VSDs has been performed successfully since at least the late 1980s [86–90]. Indications for use of these devices include all types of muscular VSDs, including apical and multiple, as well as perimembranous VSDs. Transcatheter closure is typically performed in the catheterization laboratory via percutaneous access. However, "hybrid" techniques involving a sternotomy to place a device either by direct visualization on CPB or in a beating heart using perventricular transcatheter placement have also been described [91]. The major limitation in the application of percutaneous transcatheter techniques is related to the size of the sheaths necessary for device delivery, precluding use in infancy. Complications of device closure include the need for blood transfusion, tricuspid valve regurgitation, and device embolization [86, 87]. Heart block is a particular concern following device closure of perimembranous VSDs, sometimes occurring years after placement [92–94].

Anesthetic considerations

Anesthetic management for patients with VSD is similar to that of ASD. Pulmonary hypertension may develop early, especially in patients with trisomy 21, and preoperative chest radiograph revealing decreased pulmonary vascular markings is indicative of pulmonary hypertension [95–99]. Such patients may respond to the use of inhaled nitric oxide prior to the termination of CPB and/or in the postoperative period. Right heart failure with decreased cardiac output may result if pulmonary hypertension is not controlled, and it may require the use of dopamine, milrinone, dobutamine, or isoproterenol.

Conduction disturbances may be transient or permanent. Atrioventricular heart block, formerly reported to occur in up to 10% of patients post-VSD repair, is now a rare complication occurring in less than 1% of patients after VSD closure [100]. If heart block develops, treatment with atrioventricular synchronous pacing using temporary pacing wires is indicated. Junctional ectopic tachycardia is sometimes observed in patients younger than 1 year after surgery for lesions that involve VSD repair, most commonly after tetralogy of Fallot correction. Treatment includes cooling to 35 °C, increasing anesthetic depth, paralysis, procainamide, esmolol, or amiodarone [101].

Intraoperative use of TEE will allow recognition of residual VSDs and intracardiac air, as well as provide an assessment of ventricular volume and function. Small muscular VSDs often become apparent after the closure of larger VSDs. Frequently these smaller defects, especially if near the apex, may not be amenable to surgical repair or worth the risk of returning to CPB.

Patients with uncomplicated VSDs are good candidates for extubation in the OR or early after arrival in the ICU.

KEY POINTS: VENTRICULAR SEPTAL DEFECT

- VSDs are the most common congenital heart defects.
- Both ventricles are affected by left-to-right shunting through a VSD.
- The pulmonary vascular tone should be maintained in those patients with pulmonary overcirculation prior to repair.
- Be prepared to treat arrhythmias, including heart block and junctional ectopic tachycardia, especially after repair.
- Patients with uncomplicated VSDs should be considered for early extubation.

Atrioventricular canal

Incidence

Four to 5% of CHDs involve defects of the atrioventricular septum, and AVC defects occur in 0.19 in 1,000 live births [99, 102]. AVC is associated with multiple syndromes and occurs in approximately 20% of persons with trisomy 21. It accounts for 15% of congenital heart defects in persons with Noonan syndrome and nearly 50% in persons with Ellis–van Creveld syndrome [103].

Anatomy

Atrioventricular canal defects result from failure of the endocardial cushions to fuse during the fifth week of fetal development [7]. AVC consists of three basic defects: (i) an ostium primum defect resulting in interatrial communication, (ii) abnormal atrioventricular valves, and (iii) an inlet VSD resulting in an interventricular communication. Three types of AVC exist: (i) partial, (ii) transitional, and (iii) complete [104].

Partial AVC

The PAVC defect consists of an ostium primum ASD and a cleft in the anterior leaflet of the mitral valve, usually resulting in some degree of insufficiency [96]. The tricuspid valve is often abnormal as well, and no VSD or other interventricular communication exists.

Transitional AVC

The transitional (also called *intermediate*) atrioventricular canal (TAVC) defect consists of an ostium primum ASD, abnormal atrioventricular valves that form two separate orifices, and a VSD, often restrictive, just below the atrioventricular valves [104]. Like the PAVC defect, the left atrioventricular valve is usually associated with a cleft and has some degree of insufficiency.

Complete AVC

The complete atrioventricular canal (CAVC) defect consists of an ostium primum ASD and a non-restrictive VSD just below a common atrioventricular valve that bridges both the right and

AL Grawany

left sides of the heart to create a single valve orifice [105]. The left atrioventricular portion of the valve usually contains a cleft that is insufficient. Three classifications of CAVC defects exist based on the chordal attachments of the anterior bridging leaflet of the common atrioventricular valve and are commonly referred to as Rastelli types A, B, and C [104, 105] (Figure 26.12).

In Rastelli type A CAVC, which is the most common type, the anterior bridging leaflet is divided at the septum into right and left components and attached to the crest of the ventricular septum by thin chordae tendinae. Rastelli type B CAVC is rare and is characterized by anomalous papillary muscle attachment from the right side of the ventricular septum to the left side of the anterior bridging leaflet. Rastelli type C CAVC is defined by an anterior leaflet that lacks any ventricular septal attachments and "floats" above the septum [104]. The Rastelli type C defect may be associated with other major cardiac or extracardiac anomalies such as tetralogy of Fallot or trisomy 21 [49].

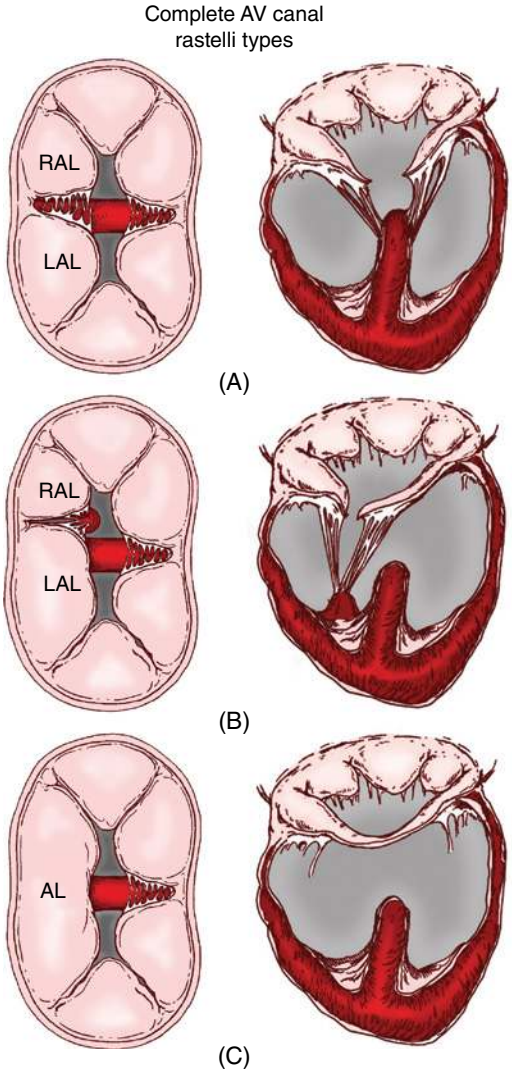

Figure 26.12 Complete atrioventricular canal defects: Rastelli types A, B, and C. LAL, left anterior leaflet; RAL, right anterior leaflet. (Sources: Jacobs et al. [104]. Reproduced with permission of Elsevier; Munoz et al. [105]. Reproduced with permission of Springer Nature.)

Other variants of AVC also exist, including right or left ventricular dominant types in which the common atrioventricular valve opens predominantly into one of the ventricles ("unbalanced" AVC). If one ventricle is hypoplastic the physiology produced by such lesions is similar to other single ventricle lesions (see Chapter 30 for a detailed presentation). Many lesions occur in association with AVC, including PDA, Tetralogy of Fallot, coarctation of the aorta, subaortic stenosis, left SVC, asplenia, and polysplenia syndromes [105].

Natural history

As with other left-to-right shunts, pulmonary hypertension may develop by 1 year of age and eventually lead to Eisenmenger syndrome [106]. The severity of CHF and symptoms will depend on the degree of left-to-right shunting and the severity of atrioventricular valve regurgitation. Among the forms of AVC, PAVC is the least symptomatic, CAVC the most, and TAVC intermediate. Patients with untreated PAVC may do well through childhood but have an increased likelihood of developing CHF in adulthood, especially as atrial dysrhythmias develop [49]. The presence of moderate to severe atrioventricular valve regurgitation leads to earlier development of CHF and higher morbidity and mortality if untreated. Those patients with PAVC presenting with CHF in the first year of life should be suspected of having additional lesions, most commonly left-sided obstructive lesions [107]. Patients with CAVC develop CHF, failure-to-thrive, and frequent respiratory infections in the first year of life. During this same interval, 12% of these children will develop irreversible pulmonary hypertension. Those with trisomy 21 develop pulmonary hypertension earlier and with increased severity as compared to other children; however, this has not manifested as a risk factor in surgical repair or long-term outcome [96–98, 108–110].

Pathophysiology

A left-to-right shunt may occur at the atrial, ventricular, and atrioventricular valvar level, depending on the type of AVC present. This shunting, in addition to atrioventricular valve regurgitation, results in volume overload of both the atria and ventricles. Volume overload soon develops into CHF and may result in pulmonary hypertension as the ratio of pulmonary to systemic blood flow increases.

Surgical approaches and outcomes

Surgical repair of PAVC is usually performed at age 2–5 years unless there are signs of CHF or other lesions that necessitate earlier repair. Patients with TAVC may be relatively asymptomatic and may tolerate surgical repair at an older age.

Primary complete surgical repair for patients with CAVC is performed between 1 and 6 months of age because it is safe, controls CHF, prevents the development of fixed pulmonary hypertension, and reduces annular dilation (a cause of atrioventricular valvar regurgitation) [107, 111, 112].

Surgical techniques vary, but generally consist of a right atriotomy with patch closure of the ASD, cleft closure in the anterior leaflet of the left atrioventricular valve, and closure of the VSD with a patch or, in the case of the TAVC,

pledgetted sutures [49, 111]. A one- or two-patch technique can be used. The one-patch technique consists of a single patch closure of both the ASD and VSD (Figure 26.13) [113, 114]. Staged repair with initial pulmonary artery banding is reserved for cases of severe respiratory illness, sepsis, or anatomy not suitable for biventricular repair. The presence of associated cardiac anomalies such as Tetralogy of Fallot, double outlet right ventricle (DORV), left-sided obstructive lesions, and unbalanced AVC (with a hypoplastic ventricle) further complicates the repair and results in higher mortality, especially in patients with a hypoplastic ventricle [115, 116].

Mortality for the repair of PAVC is less than 5%, and the mortality for the complete repair of CAVC is between 2.5 and 10.5% [112, 117–119]. The presence of preoperative pulmonary hypertension and increasing size of the VSD is

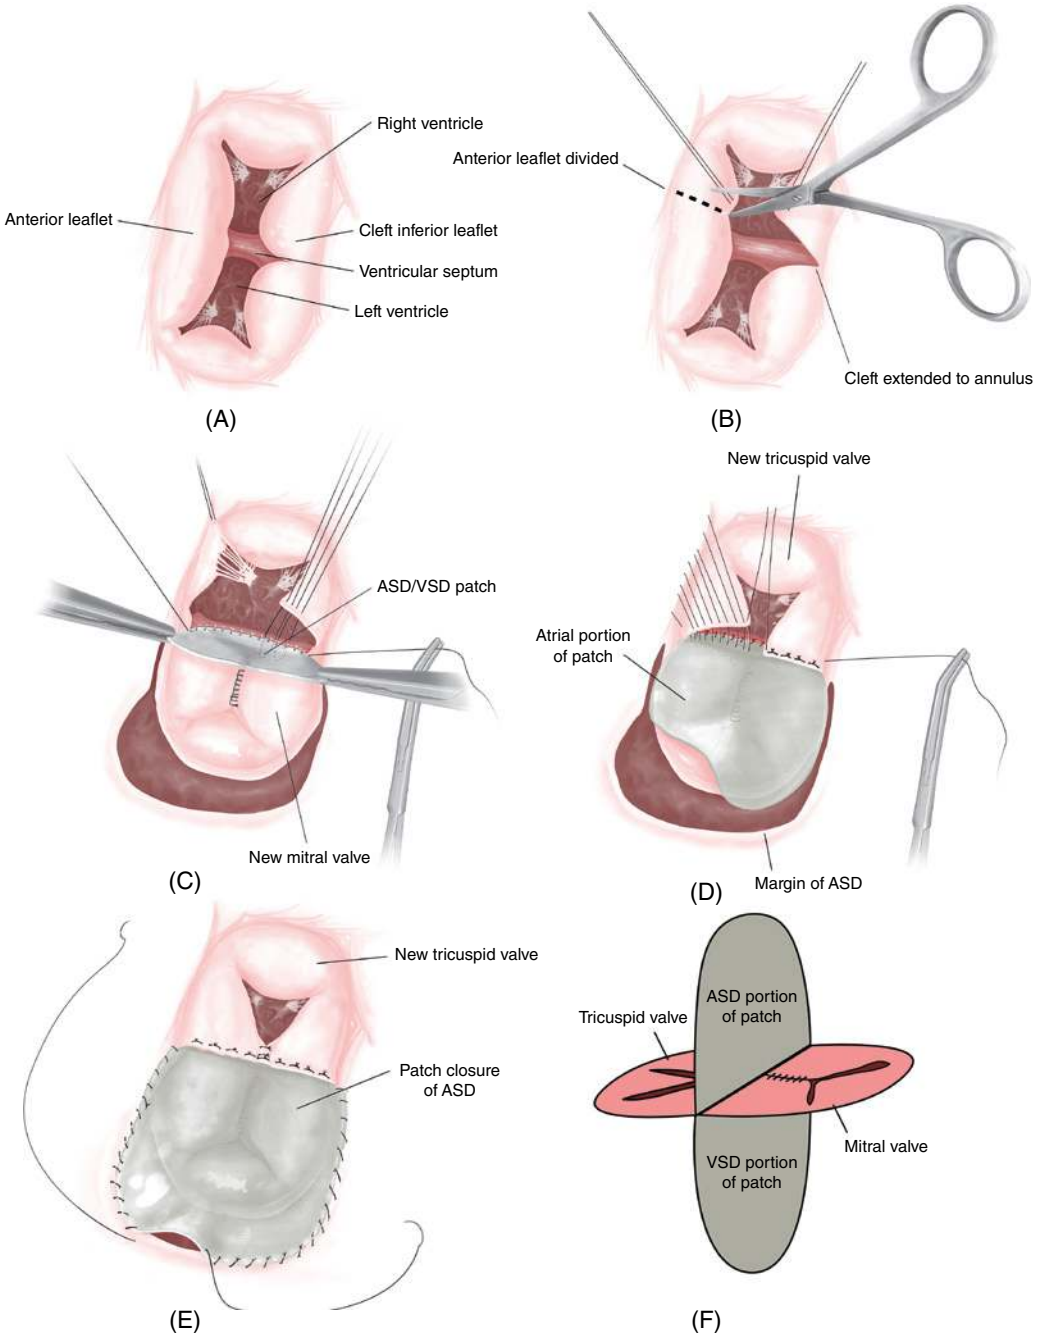

Figure 26.13 One-patch repair of a complete atrioventricular canal (AVC) defect. (A) The defect is exposed. (B) The anterior and posterior common valve leaflets are divided to separate the mitral and tricuspid sections. (C) The VSD is closed using the inferior portion of the patch. The mitral valve is rendered bicuspid by the closure of the anterior and posterior common leaflets on the mitral side, which had been natively separate, to create a functional mitral valve after being anchored to the patch. (D) The tricuspid valve leaflets are anchored to the mid-portion of the patch. (E) The superior portion of the patch is used to close the atrial septal defect. AL Grawany

associated with higher morbidity and mortality among patients undergoing complete repair of CAVC [49, 117].

Anesthetic considerations

Anesthetic management of AVC defects depends primarily on the degree of left-to-right shunting and the presence and severity of pulmonary vascular hypertension. As with other septal defects, balancing the ratio of PVR to SVR and thereby limiting the amount of pulmonary overcirculation is paramount to successful management, and is usually accomplished by manipulations in FiO_2 and ventilation (see above). TEE is very helpful in detecting residual intracardiac shunts, assessing atrioventricular valvar function, and determining ventricular function and volume following repair.

Surgical placement of left atrial and pulmonary arterial pressure lines may be used to guide the management of inotropes, use of inhaled nitric oxide, and volume replacement. Persistent elevation and acute increases in pulmonary arterial pressure contribute to right heart failure and increased mortality [117]. Pulmonary hypertension develops commonly in these patients and is treated with hyperventilation, 100% oxygen, systemic alkalinization, opioids, and inhaled nitric oxide. Increasing the pH is more effective than lowering the $PaCO_2$ in controlling pulmonary pressures and may be accomplished by the administration of sodium bicarbonate [120]. Sildenafil has also been effective in this setting [121].

Most patients require inotropic support upon weaning from CPB, and those with residual atrioventricular valve regurgitation and/or VSD benefit from the use of milrinone or other afterload reduction. Hypotensive patients who have elevated left atrial pressures should be evaluated for the presence of severe residual left atrioventricular valve regurgitation or stenosis, residual VSD, left ventricular outflow tract obstruction, or left ventricular dysfunction. Intraoperative TEE is essential for the initial diagnosis of these conditions, and re-initiation of CPB and repair may be necessary.

CAVC repair is associated with conduction abnormalities, especially atrioventricular and sinoatrial nodal dysfunction resulting in complete heart block. In this situation, atrioventricular sequential pacing is necessary to minimize atrioventricular valve regurgitation and to improve cardiac output [105].

KEY POINTS: ATRIOVENTRICULAR CANAL

- AVC is associated with trisomy 21, Noonan syndrome, and Ellis–van Creveld syndrome
- AVC may be partial, transitional, or complete
- Measures to maintain pulmonary vascular tone are necessary to avoid pulmonary overcirculation prior to repair
- Following bypass, pulmonary hypertension is common and therapy may include inhaled nitric oxide, hyperventilation, 100% oxygen, systemic alkalinization, deep sedation, and neuromuscular blockade
- Inotropic support is often needed post-bypass
- Residual defects and cardiac function are evaluated by TEE post-repair
- Dysrhythmias, including complete heart block, are common and temporary pacing may be required

Double outlet right ventricle

Incidence

DORV comprises approximately 1–1.5% of all patients with congenital heart disease with an incidence estimated at 1/10,000 live births [122]. Although DORV can occur with an intact ventricular septum, this is extremely rare [123]; almost all patients with DORV also have a VSD.

Anatomy

DORV is a type of ventriculoarterial connection in which both great vessels arise either entirely or predominantly from the right ventricle. This definition is intended to simplify what is in fact a complex spectrum of defects ranging from morphology that mimics tetralogy of Fallot to that which resembles transposition of the great vessels. Embryologically, DORV is a bulboventricular malformation that results from failure of proper alignment of the conotruncus with the ventricular septum [122].

Characterization of the anatomy of DORV is crucial in understanding the physiologic consequences as well in determining the surgical approach for palliation or correction. Complete characterization of the anatomy will include (i) the relationship of the VSD to the great arteries, (ii) the relationship of the great arteries with respect to one another, (iii) the morphology of the ventricles and their outflow tracts, and (iv) the presence of associated anomalies [123]. Four different anatomic types of DORV are defined on the basis of the relationship of the VSD to the great arteries: (i) subaortic VSD, (ii) subpulmonary VSD, (iii) doubly committed VSD, and (iv) noncommitted VSD [124, 125] (Figure 26.14).

DORV with subaortic VSD

These lesions represent approximately 51–56% of DORV [123, 126] and are characterized by a VSD located beneath the aortic valve. The great vessels may be normally related or transposed. When this defect is associated with pulmonary stenosis, the resulting physiology is similar to that of tetralogy of Fallot [122].

DORV with subpulmonary VSD

DORV with subpulmonary VSD represents approximately 30% of DORV [126, 127]. Pulmonary stenosis is rare, but subaortic or aortic arch obstructions are common. The VSD is typically non-restrictive. This lesion often occurs in the form of the *Taussig–Bing* type, with D-malposition of the great arteries in the absence of pulmonary stenosis [122]. The resulting physiology is similar to that of transposition of the great arteries.

DORV with doubly committed VSD

Three to 10% of patients with DORV have a doubly committed VSD [126–128]. The doubly committed VSD results from hypoplasia of the conal septum and variable degrees of override of the VSD by both great arteries [122].

DORV with noncommitted VSD

Twelve to 17% of patients with DORV have a noncommitted VSD [123, 126], and the VSD is an apical

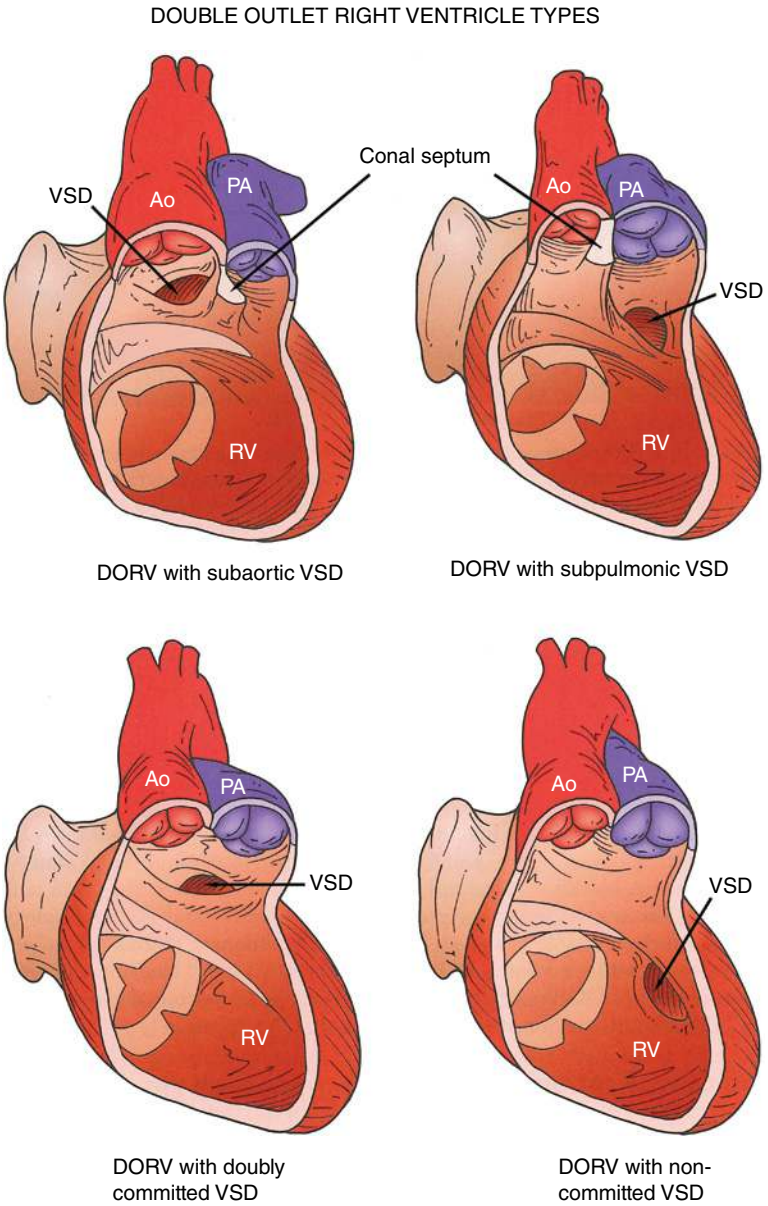

Figure 26.14 Anatomic sub-types of double outlet right ventricle (DORV), as determined by the position of the ventricular septal defect. Ao, aorta; PA, pulmonary artery; RV, right ventricle; VSD, ventricular septal defect. (Source: Ungerleider et al. [125]. Reproduced with permission of Elsevier.)

muscular or membranous-inlet type. The VSD is remote from the great arteries and is frequently associated with AVC defects [122].

Natural history and pathophysiology

The natural history and pathophysiology of DORV are dependent on the specific anatomy of the lesion and relative amounts of pulmonary versus aortic blood flow as well as the degree of mixing of pulmonary and systemic venous blood. Consideration of these variables serves to simplify the pathophysiology of DORV into three basic subtypes: VSD, Tetralogy of Fallot, and transposition of the great arteries [129].

DORV with a doubly committed or subaortic VSD without pulmonary stenosis produces physiology similar to that of a VSD. Because VSDs in this setting are usually non-restrictive, the degree of left-to-right shunting will generally depend on the relative ratio of PVR to SVR.

DORV associated with pulmonary stenosis resembles the physiology of tetralogy of Fallot with varying degrees of cyanosis depending on the severity of pulmonic stenosis. These patients have right-to-left shunting across the VSD and may have hypercyanotic spells, erythrocytosis, and failure to thrive. Although there is a fixed component of obstruction, pulmonary blood flow may vary due to alterations in PVR. Pulmonary stenosis is present in approximately 50% of patients with DORV [122].

DORV with a subpulmonary VSD without pulmonary stenosis usually produces physiology similar to transposition of the great arteries. Streaming of pulmonary venous blood to

the pulmonary artery and systemic venous blood toward the aorta results in variable degrees of mixing of oxygenated and deoxygenated blood. Patients can present early with both cyanosis and CHF followed by the development of pulmonary vascular occlusive disease if left untreated.

DORV may be associated with other anomalies that further affect pathophysiology, such as multiple VSDs, AVC defects, PDA, aortic arch obstruction, interrupted aortic arch, subaortic stenosis, hypoplastic ventricle, or mitral valve abnormalities [126–132].

Surgical approaches and outcomes

The surgical approach to DORV varies depending on the type of DORV and the associated anomalies, and the preoperative delineation of anatomy is crucial to determine the operative strategy. However, echocardiography, angiography, and magnetic resonance imaging may still result in incomplete information due to the complexity and anatomic variations of this lesion [131, 133]. Three-dimensional reconstruction using computed tomography and 3D printing can delineate complex anatomy and facilitate surgical planning (Figure 26.15) [134, 135]. Depending on the lesion, four surgical treatment options generally exist: (i) palliative procedures such as Blalock–Taussig shunts, coarctation repairs, and pulmonary artery banding; (ii) intraventricular repair with a baffle from the left ventricle to the aorta [125, 136] (Figure 26.16); (iii) intraventricular baffle from the left ventricle to the pulmonary artery followed by the arterial switch; and (iv) bidirectional cavopulmonary shunt staged to the Fontan procedure (univentricular heart repair) [126–132].

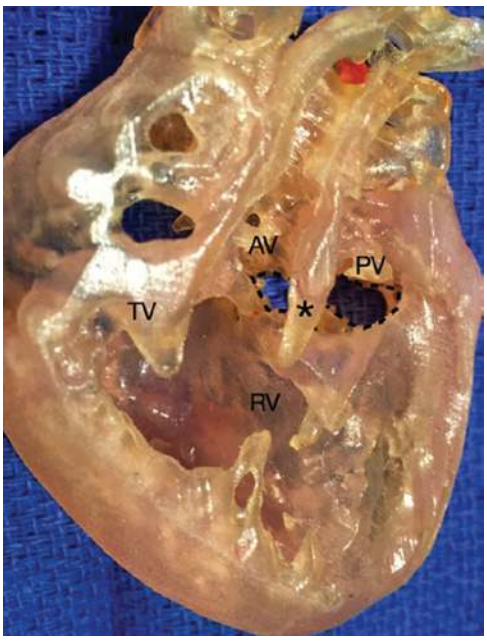

Figure 26.15 A coronal plane three-dimensional flexible polyjet-printed model of a heart with the right ventricle free wall removed. This model is from a heart with a double outlet right ventricle and doubly committed ventricular septal defect, which is outlined by the black dashed line. (Source: Bahtla et al. [134]. Reproduced with permission of John Wiley & Sons.)

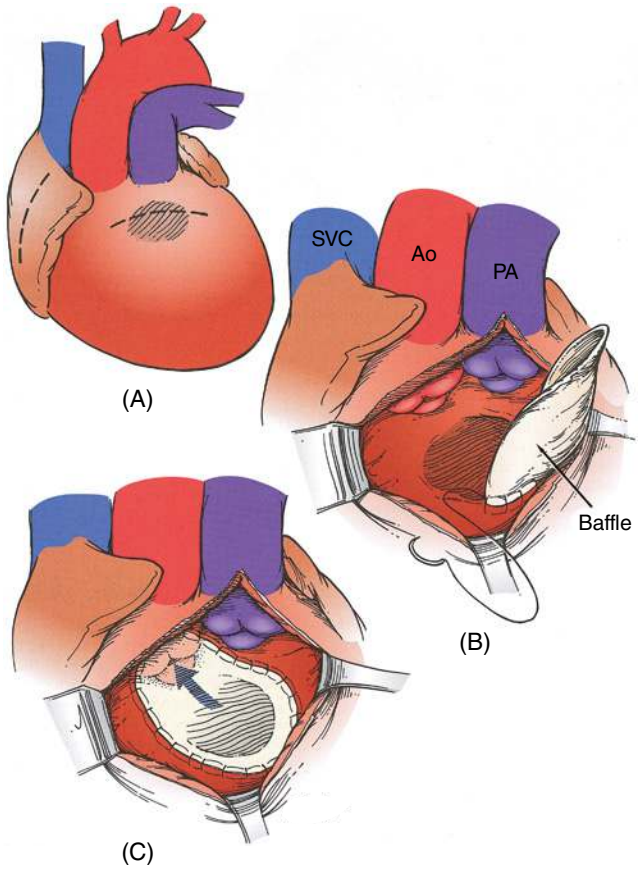

Figure 26.16 Surgical repair of double outlet right ventricle without pulmonary stenosis. (A) The approach can be either by right atriotomy or ventriculotomy (dashed lines). (B and C) A baffle is used to close the ventricular septal defect and direct blood from the left ventricle to the aorta without obstructing flow from the right ventricle to the pulmonary artery. (Source: Ungerleider et al. [125]. Reproduced with permission of Elsevier.)

The overall early mortality for the repair of DORV is approximately 9% [126, 127, 132]. Ten-year survival is 81–86% [126, 127]. Significant risk factors for early mortality include congenital mitral valve anomalies, side-by-side great arteries, multiple VSDs, and age at operation <1 month [126–130]. Among patients with complex anatomy, Fontan palliation may be the procedure of choice as it has been associated with lower early mortality in this group compared to biventricular repair [126].

Anesthetic considerations

Anesthetic management varies greatly depending on the specific type of DORV and associated anomalies. Management of palliative procedures, such as the modified Blalock–Taussig shunt, is reviewed in Chapter 28. Patients with pulmonary stenosis who present with physiology similar to tetralogy of Fallot should be managed to minimize right-to-left shunting (see Chapter 28). Patients with subpulmonary VSD without pulmonary stenosis who have physiology similar to TGA should be managed as such (see Chapter 29). Subaortic and noncommitted VSDs without

pulmonary stenosis produce physiology similar to that of a VSD and should be managed as described earlier in this chapter. Patients with complex DORV and other associated anomalies that proceed through the single ventricle staged palliation to the Fontan procedure are reviewed in Chapter 30. In all patients with DORV, regardless of specific anatomy, intracardiac shunting must be balanced with manipulation of PVR and SVR to optimize systemic cardiac output and oxygen delivery.

Arrhythmias are common, especially with repairs involving baffling and enlargement of the VSD. Ventricular tachyarrhythmias and complete heart block can occur in as many as 9% of patients postoperatively and may require permanent pacing [123, 126, 127]. Frequently, repair of DORV is complex and requires periods of circulatory arrest. Patients may have residual VSDs, valvar insufficiency, outflow tract obstruction, or ventricular dysfunction. Postoperative TEE and left atrial pressure monitoring are helpful in determining the diagnosis and guiding management.

KEY POINTS: DOUBLE OUTLET RIGHT VENTRICLE

- The four anatomic sub-types of DORV depend on the location of the VSD: subaortic, subpulmonary, doubly committed, and noncommitted
- DORV with a doubly committed or noncommitted VSD is managed as a VSD
- DORV associated with pulmonary stenosis is managed similarly to tetralogy of Fallot
- DORV with subpulmonary VSD without pulmonary stenosis is managed similarly to transposition of the great vessels
- Some patients require single ventricle staging to a Fontan
- Postoperative arrhythmias are common
- Inotropic support is often needed, especially after long bypass intervals

Truncus arteriosus

Incidence

Truncus arteriosus is an uncommon congenital heart defect representing less than 3% of all congenital heart defects [137–139]. Deletion of chromosome 22q11 is present in approximately 11–35% of patients with truncus arteriosus, and this chromosomal abnormality is associated with DiGeorge and velocardiofacial syndromes. Patients with these syndromes also have noncardiac anomalies such as aplasia or hypoplasia of the thymus and/or parathyroid glands, which can lead to T-cell deficiency and/or hypocalcemia. Patients may also have palatal abnormalities, speech and learning disabilities, neuropsychological disorders, and craniofacial dysmorphia [140–142]. As many as 77% of patients with 22q11 deletion are immunocompromised [142].

Anatomy

Truncus arteriosus is defined by the presence of a single great artery arising from the base of the heart that supplies the coronary, pulmonary, and systemic circulations. Embryologically, this defect results from the failure of the truncus arteriosus to divide into the aorta and pulmonary artery.

Truncus arteriosus has historically been classified by two main systems. The first and most widely used classification system was described by Collett and Edwards in 1949 and the second by Van Praagh and Van Praagh in 1965 [143, 144]. The Collett and Edwards classification is based on the embryologic arrested development of the pulmonary arteries from the sixth aortic arches and is categorized into four different subtypes. For the purpose of this chapter, the Collett and Edwards system will be used (Figure 26.17) [143, 144].

Type I truncus arteriosus

Type I truncus arteriosus accounts for 70% of truncus arteriosus lesions. It is defined by the origin of the main pulmonary artery from the truncus dividing into left and right pulmonary arteries.

Type II truncus arteriosus

Type II truncus arteriosus accounts for 30% and is defined by the separate origin of the left and right pulmonary arteries from the posterior surface of the truncus, with the branch pulmonary arteries arising very close to one another.

Type III truncus arteriosus

Type III truncus arteriosus is also characterized by separate origin of the left and right pulmonary arteries, but in this

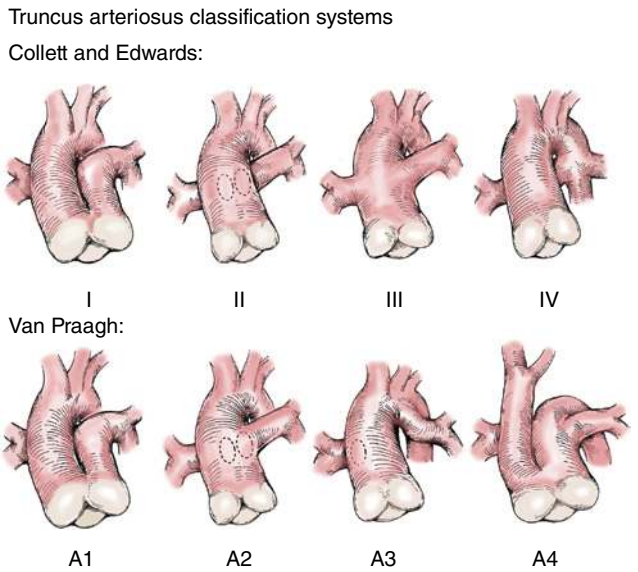

Figure 26.17 Major classification systems for truncus arteriosus. The "A" in the Van Praagh system indicates the presence of a ventricular septal defect (rare cases of the intact ventricular septum are designated with a "B"). The Collett and Edwards system is used for the purposes of this chapter. (Source: Jacobs et al. [104]. Reproduced with permission of Elsevier.)

AL Grawany

case, the arteries arise from the lateral aspects of the truncus and are widely separated. This type accounts for approximately 1% of cases.

Type IV truncus arteriosus

Type IV is included for historical purposes but has been rejected as a true form of truncus arteriosus. It is now defined as a form of pulmonary atresia and VSD and is sometimes called "pseudotruncus." There is a complete absence of the pulmonary arteries in this defect, with bronchial and collateral arteries of the descending aorta providing the blood supply to the lungs.

Truncus arteriosus is most commonly associated with a VSD but can occur with an intact ventricular septum. The truncal valve may be dysplastic and may have an abnormal number of leaflets, varying between two and six [144]. Truncal valve insufficiency is estimated to occur in 25–50% of patients; varying degrees of truncal valve stenosis may also occur [144]. Anomalies of the coronary arteries may also exist. Additionally, truncus arteriosus is associated with other cardiac anomalies such as aortic arch obstruction, ASDs (62%), right aortic arch (21–36%), aortic arch interruption (11–19%), PDA (18%), aberrant subclavian artery (4–10%), absence of one pulmonary artery (10%), and persistent left SVC (4–9%) [137, 139].

Natural history

If left untreated, the early CHF and increased pulmonary blood flow associated with truncus arteriosus lead to the rapid development of pulmonary vascular occlusive disease in infancy. Patients without surgical treatment have a 74–100% mortality in the first year of life [133, 136, 137]. Surgical repair in patients older than 2 years is contraindicated when pulmonary vascular resistance (PVR) is greater than eight Wood units or when Eisenmenger syndrome is present [137].

Pathophysiology

Truncus arteriosus by definition has a common arterial trunk that provides blood flow to the coronary, pulmonary, and systemic arteries. As PVR falls in the early neonatal period, pulmonary blood flow progressively increases and results in CHF. A variable degree of mixing of the systemic and pulmonary venous blood occurs at the ventricular level through the VSD. The large runoff provided by the pulmonary arteries results in low diastolic pressures, which may be worsened by the presence of truncal valve insufficiency. Low diastolic pressures in the face of increased myocardial work and increased ventricular pressures place the patient at risk of developing myocardial ischemia from coronary steal.

Surgical and transcatheter approaches and outcomes

Definitive surgical repair is usually recommended in the neonatal period, although some centers time surgery on an individual basis, performing repair between 2 and 3 months of age [137–139, 145]. Early repair is indicated due to the rapid development of pulmonary hypertension and high mortality rate in patients in the first year of life if left untreated. Palliative surgery involving pulmonary artery banding has largely been abandoned except for those very few patients who are not suitable candidates for definitive repair [139]. Definitive surgical repair involves removal of the pulmonary arteries from the truncal root and closing the resulting defect either primarily or with a patch. The VSD is usually closed with a patch via a transatrial or transventricular approach. A right ventricle to pulmonary artery connection is provided by a valved homograft (Figure 26.18) [146]. Though direct anastomosis of the pulmonary artery with the right ventricle has been described, it may distort the pulmonary arterial architecture [147]. If high right ventricular

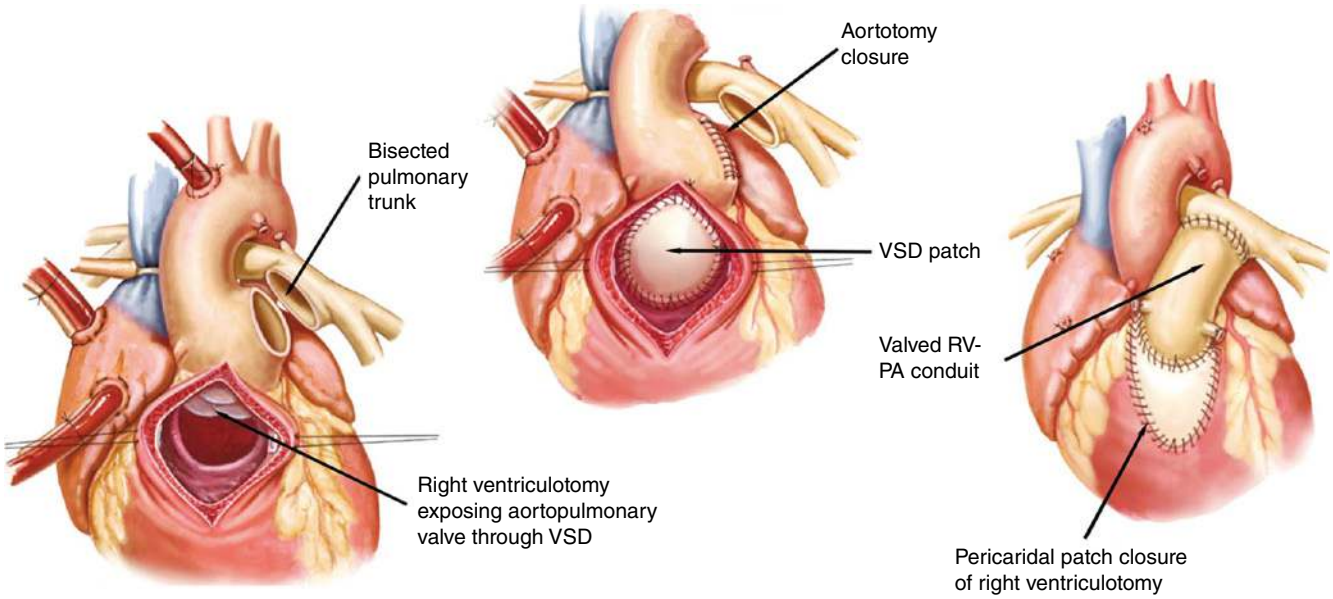

Figure 26.18 Surgical repair of a type I truncus arteriosus. A right ventriculotomy allows patching of the ventricular septal defect and placement of a valved conduit from the right ventricle to the bisected pulmonary artery trunk. (Source: Conti et al. [47]. Reproduced with permission of Elsevier.)

pressures are anticipated, a small ASD may be created as a "pop-off" for right-to-left shunting in order to improve cardiac output at the expense of arterial oxygen saturation [137, 138, 145, 148]. This ASD creation can be closed at a later date by a transcatheter technique in the cardiac catheterization laboratory. Moderate to severe truncal valve regurgitation is repaired by valvuloplasty, "double-homograft" technique with coronary reimplantation, or mechanical valve implantation [137, 149, 150]. Valve repair has been successful even in neonates and avoids or delays serial truncal valve replacements [150]. Over time, the right ventricular to pulmonary artery conduit may become stenotic and/or regurgitant. This may necessitate repair or replacement either surgically or via percutaneous techniques using a transcatheter pulmonary valve [151]. Much of the long-term pathophysiology after repair of truncus arteriosus is related to truncal valve dysfunction, particularly insufficiency. This contributes to the diminished physical health status of many of these patients in the second decade of life and beyond and may influence anesthetic management for later cardiac or non-cardiac surgery [152]. Early mortality after repair of truncus arteriosus is 5–18% [137, 138, 145, 148], and mortality rates are higher in infants who weigh less than 3 kg or have other cardiac anomalies [138, 148, 153].

Anesthetic considerations

Anesthetic management is dependent on the patient's anatomy and age at presentation. Depending on the severity of CHF, the patient may require preoperative inotropic support, and the induction of anesthesia should be accomplished with drugs that maintain SVR and preserve myocardial function. Ketamine or etomidate, often combined with fentanyl and/or midazolam, may be used to safely attain this goal. If an inhalational induction with sevoflurane is chosen, it should be performed with careful titration and extreme caution. Muscle relaxation may be achieved with any choice of a nondepolarizing neuromuscular blocking agent. Maintenance of anesthesia often includes high-dose fentanyl. Efforts to balance PVR and SVR to make the ratio of Qp : Qs approach 1:1 are essential. Care must be taken to avoid hyperventilation and excessive oxygenation, which lower PVR and may exacerbate pulmonary overcirculation and decrease diastolic blood pressure. Patients with truncal valve insufficiency combined with excessive pulmonary blood runoff will be particularly susceptible to myocardial ischemia, and it may be necessary for the surgeon to temporarily place a vessel snare around the pulmonary artery to limit pulmonary blood flow and increase diastolic blood pressure in the prebypass period. Occasionally this myocardial ischemia is heralded by ventricular fibrillation prior to bypass, and the anesthetic and surgical teams must be alert to this possibility and be prepared to intervene with external or internal defibrillation, open or closed cardiac massage, or emergent institution of bypass. Preoperative placement of external adhesive defibrillator pads is advisable. Those patients presenting late in infancy who have developed significant pulmonary hypertension from long-standing pulmonary overcirculation may require increased FiO_2 to maintain oxygen saturations between 80 and 90%. Unless ruled out by a chromosomal evaluation, patients with truncus arteriosus should be assumed to have DiGeorge syndrome and given irradiated blood products due to the high incidence of associated T-cell deficiencies. An absent or hypoplastic thymus is often evident upon sternotomy. Upon weaning from CPB, most patients require inotropic support, afterload reduction, ventricular volume assessment, and efforts to minimize pulmonary arterial pressures in order to improve right heart function.

Pulmonary hypertension is commonly present after cardiopulmonary bypass. These patients have signs of right heart failure with high central venous pressures, desaturation, tachycardia, hypotension, acidosis, and oliguria. Management includes hyperventilation, 100% oxygen, correction of acidosis, and inhaled nitric oxide as needed. These patients are usually kept heavily sedated for at least 24 hours postoperatively to minimize early pulmonary hypertensive crises. Signs similar to right ventricular dysfunction may also occur from residual VSDs or truncal valve stenosis or regurgitation. VSD closure or right ventricular incision may produce complete right bundle branch block, complete heart block (3–5%), junctional ectopic tachycardia, atrial tachycardias, or atrioventricular block in the postoperative period [82]. After bypass, many patients benefit from calcium infusions because of the hypocalcemia associated with DiGeorge syndrome and citrate binding of ionized calcium from the administration of blood products.

KEY POINTS: TRUNCUS ARTERIOSUS

- TA is associated with DiGeorge and velocardiofacial syndromes.
- Subtypes are defined by the relationship of the pulmonary arteries to the truncus.
- The presence of DiGeorge syndrome may necessitate calcium infusions and irradiated blood products.
- Pulmonary overcirculation requires maintenance of PVR pre-bypass and pulmonary hypertension precautions post-bypass.
- Myocardial ischemia may occur due to coronary steal as PVR decreases in the first weeks of life.
- Inotropic support is often necessary perioperatively.

Partial and total anomalous pulmonary venous return

Incidence

Both partial anomalous pulmonary venous return (PAPVR) and total anomalous pulmonary venous return (TAPVR) are rare cardiac lesions. Since PAPVR is often asymptomatic, its true incidence is unclear, but it has been reported as an incidental finding on autopsy in approximately 0.6% of the general population [154]. TAPVR represents less than 5% of congenital heart lesions [155–157].

Both PAPVR and TAPVR can be associated with other cardiac lesions. PAPVR is most commonly associated with sinus venosus type ASDs. Congenital mitral stenosis, DORV, VSD, tetralogy of Fallot, coarctation of the aorta, and PDA have all been described with PAPVR [156]. Nearly 33% of patients

AL Grawany

with TAPVR have other cardiac anomalies, such as CAVC, hypoplastic left heart syndrome or other single ventricle lesions, PDA, and transposition of the great arteries. Abnormalities of the atrial and visceral situs with heterotaxy syndrome, asplenia, and polysplenia are also common among patients with TAPVR [156]. Scimitar syndrome consists of either partial or complete anomalous drainage of the right pulmonary veins to the IVC, dextrocardia, and hypoplasia of the right lung. In these patients, the descending vertical vein resembles a scimitar, or Turkish sword, on a frontal chest radiograph [156].

Anatomy

Partial anomalous pulmonary venous return (PAPVR) is an anomaly in which some, but not all, of the pulmonary veins, connect to the right atrium or to one or more of its venous tributaries. In TAPVR, all of the pulmonary veins connect anomalously to the right atrium. Although these lesions are sometimes referred to as anomalous pulmonary venous *connections*, the use of the term *return* recognizes the fact that the pulmonary veins may be connected normally to the left atrium, but have an ASD anatomically configured to cause an abnormal return to the right atrium [154]. In either case, the pathophysiology is that of a left-to-right shunt.

The stage in embryologic development during which errors occur determines the various anatomic subtypes of abnormal pulmonary venous return. At 27–30 days of gestation, the pulmonary veins are derived from the splanchnic plexus that communicates with the cardinal and umbilicovitelline system of veins. Anomalous drainage to the left common cardinal system results in pulmonary venous connections to the coronary sinus or left innominate vein. Drainage to the right common cardinal system results in pulmonary venous connections to the SVC and/or the azygous vein. Drainage to the umbilicovitelline system results in pulmonary venous connection to the portal vein, ductus venous, or IVC. Early atresia of the common pulmonary vein, while primitive pulmonary–systemic venous connections are still present, results in TAPVR. If only the right or left portion of the common pulmonary vein becomes atretic, the persistence of the primitive pulmonary venous–systemic venous connection on that side leads to PAPVR [156].

Partial anomalous pulmonary venous return

Multiple types of PAPVR exist. The most common is the connection of the right pulmonary veins to the right SVC or right atrium which represents approximately 74% of patients. The next most common type is the connection of the right pulmonary veins to the IVC. The least common type is the connection of the left pulmonary veins to the left innominate vein or to the coronary sinus [156].

Total anomalous pulmonary venous return

Four different types of TAPVR exist based on the location of the anomalous connection: supracardiac, cardiac, infracardiac, and mixed (Figure 26.19) [158, 159]. A "stretched PFO" (70–80%) or true ASD (20–30%) is usually present in TAPVR.

Supracardiac TAPVR

Supracardiac connection comprises approximately 55% of cases of TAPVR. In this type, pulmonary venous drainage is to the SVC. In the most common form of this lesion, the two pulmonary veins from each lung converge posteriorly to the left atrium. A vertical vein then arises from the left side of the confluence and usually passes anterior to the left pulmonary artery and the left mainstem bronchus to drain into the left innominate vein, which then drains to the SVC. Pulmonary venous obstruction is unusual but may occur as a result of either intrinsic narrowing or extrinsic compression of the vertical vein. Although anomalous connection can occur to the SVC via a right-sided vertical vein, this is much less common [156]. A stretched PFO or ASD is present to allow left heart filling; although this constitutes a right-to-left shunt, cyanosis is often mild due to the greater degree of left-to-right shunting.

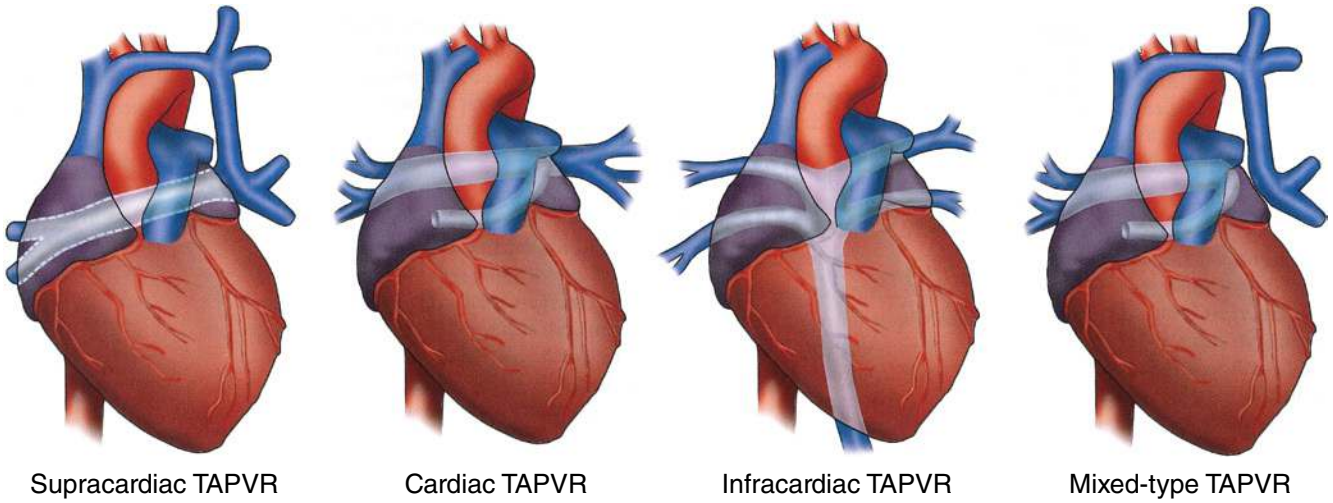

Figure 26.19 Four major subtypes of total anomalous pulmonary venous return (TAPVR) (see text for further explanation). (Source: Yuh et al. [158]. Reproduced with permission of McGraw Hill.)

Cardiac TAPVR

The cardiac type of TAPVR accounts for approximately 30% of cases. The pulmonary veins in this type drain into the coronary sinus or right atrium. Obstruction to the pulmonary veins was reported in 22% of patients in a series of TAPVR to the coronary sinus [160]. The coronary sinus is often "unroofed" prior to its drainage into the right atrium, allowing some pulmonary venous drainage into the left atrium; an ASD is usually present.

Infracardiac TAPVR

Infracardiac TAPVR comprises approximately 13% of cases and is commonly referred to as infradiaphragmatic TAPVR [156]. This type of connection usually involves a confluence of pulmonary veins from both lungs posterior to the left atrium. A descending vein then courses anterior to the esophagus through the diaphragm at the esophageal hiatus [161]. In 70–80% of patients, the descending vein then joins the portal venous system at either the splenic or the confluence of the splenic and superior mesenteric veins [161]. Nearly all patients with infracardiac TAPVR have obstructed pulmonary veins. This obstruction, which may be either intrinsic or extrinsic, can occur at any location along the pulmonary venous pathway. A stretched PFO or ASD is present in essentially all of these patients.

Mixed TAPVR

Mixed type TAPVR makes up approximately 2% of cases. This type of TAPVR consists of anomalous connections at two or more levels. The most common connection involves the left pulmonary veins draining into the left innominate vein and the right pulmonary veins draining to the right atrium or the coronary sinus [156]. Pulmonary venous obstruction has also been observed in these types of connections. A stretched PFO or ASD is usually present in this lesion.

Natural history and pathophysiology

Partial anomalous pulmonary venous return

PAPVR results in a variable amount of left-to-right shunting that depends on several factors: the number of anomalously draining veins as a percentage of the total pulmonary venous return, the pulmonary lobes or segments from which the anomalous veins originate, the relative resistances of the normally and anomalously drained pulmonary vascular beds, and the compliance of the receiving chambers. The left-to-right shunt leads to increased pulmonary blood flow and enlargement of the right atrium and ventricle as well as dilation of the pulmonary artery [156]. Most patients with an isolated single vein PAPVR and intact atrial septum are asymptomatic and have a normal life expectancy even if left untreated. Those patients with greater than 50% of the pulmonary veins draining anomalously or those with an associated ASD usually remain relatively asymptomatic until the third to fourth decades of life, when progressive symptoms of dyspnea, recurrent bronchitis, hemoptysis, chest pain, and palpitations with supraventricular arrhythmias can occur. These patients may also present with right heart failure or with pulmonary hypertension and cor pulmonale [156].

Total anomalous pulmonary venous return

The natural history and pathophysiology of TAPVR depend largely on whether or not pulmonary venous return is obstructed. In the presence of obstructed pulmonary veins, pulmonary venous hypertension exists with associated pulmonary edema. It is commonly confused with intrinsic lung disease when a chest radiograph reveals bilateral infiltrates in the absence of cardiomegaly. Occasionally neonates with hypoxemic respiratory failure placed on extracorporeal membrane oxygenation are subsequently diagnosed with obstructed TAPVR. Pulmonary arteriolar vasoconstriction occurs as a compensatory mechanism to minimize pulmonary edema. As PVR increases, the right ventricular systolic and end-diastolic pressures increase resulting in increased right atrial pressure and right-to-left shunting at the atrial level. Progressive systemic hypoxemia ensues with metabolic acidosis and multisystem organ failure. Left untreated, death occurs in the first few months of life [156].

In unobstructed TAPVR, the left-to-right shunt of pulmonary venous blood results in right atrial and ventricular enlargement with pulmonary overcirculation and subsequent right heart failure. The presence or absence of restrictive interatrial communication is another major determinant in the pathophysiology of TAPVR; 70–80% of infants have only a PFO, which restricts filling of the left atrium and ventricle. This causes tremendous pulmonary overcirculation, right-sided dilation, and minimal left-sided filling, which results in decreased size of the left atrium and ventricle. The abnormal displacement of the interventricular septum along with chronic underfilling of the left ventricle leads to decreased systemic cardiac output. Symptomatic CHF usually develops in the second month of life and may be partially or totally relieved by transvenous balloon atrial septostomy. Patients with a nonrestrictive interatrial communication, generally consisting of a secundum type ASD, have a large left-to-right shunt with increased pulmonary blood flow, but if left untreated may not develop signs of right heart failure or pulmonary hypertension until the third or fourth decade of life [156, 162].

Surgical approaches and outcomes

The timing of surgical repair of PAPVR is dependent in part on symptomatology. Patients with a single anomalous pulmonary vein with an intact atrial septum may never require surgical treatment. Surgical therapy is generally reserved for those patients with (i) hemodynamically significant left-to-right shunting with Qp : Qs greater than 2:1; (ii) patients with recurrent pulmonary infections, especially those associated with Scimitar syndrome; (iii) patients having surgical repair of other major cardiac lesions; and (iv) patients with anomalous connections which affect surrounding structures by compression or obstruction [156]. Surgical technique for repair of PAPVR varies depending on the specific anatomy present. The repair can consist of a direct anastomosis of the anomalous veins to the left atrium, or more commonly an

AL Grawany

indirect communication may be developed utilizing a patch to baffle the anomalous veins to the left atrium while closing the ASD with the same patch. In configurations where the SVC is at risk for obstruction, it may be transected above the anomalous pulmonary veins and translocated to the right atrial appendage (Warden procedure). In cases of PAPVR in which there is a dual connection to the right and left atrium, which often presents as a connection to the right atrium via a vertical vein and to the left atrium as a "dormant" pulmonary vein, the anomalous connection (e.g. vertical vein) can be occluded via transcatheter techniques [163].

Obstructed TAPVR should be corrected emergently at the time of diagnosis [164]. Patients with unobstructed TAPVR with restrictive interatrial communications are urgently palliated with blade and/or balloon atrial septostomies. These patients (and those with unobstructed TAPVR and nonrestrictive interatrial communications) can be medically managed for elective surgical repair, usually in the first year of life.

Techniques for surgical repair of TAPVR depend on the specific anatomy involved. In some cases, a period of deep hypothermic circulatory arrest may be necessary. Surgical repair generally includes incision and enlargement of the anomalous pulmonary venous confluence and direct anastomosis with the left atrium [165]. Occasionally, a patch is needed to baffle the veins to the left atrium, particularly with cardiac-type defects with drainage to the coronary sinus. So-called "sutureless" techniques are intended to reduce the risk of acquired pulmonary vein stenosis by using marsupialization of pericardium or pleura to create the atrial anastomosis [166, 167]. Examples of surgical techniques employed based on TAPVR type are illustrated in Figure 26.20 [168].

Operative mortality for the repair of asymptomatic PAPVR approaches zero [169], and in older symptomatic patients has been reported as less than 6% [170]. Operative mortality for patients with TAPVR is somewhat higher, between 7 and 9% [171–173]. Risk factors for operative mortality in TAPVR include heterotaxy syndrome and single ventricle [171, 174].

Anesthetic considerations

Intraoperative considerations for patients with PAPVR are similar to the management of ASD. Minimizing pulmonary blood flow by control of ventilation and consideration for early extubation following repair should be the primary goals.

The prebypass management of the patient with obstructed TAPVR generally includes maximizing PaO_2 with ventilatory support which may include significant levels of positive end-expiratory pressure (PEEP), inspiratory pressures, and FiO_2, avoiding metabolic acidosis, and maintaining hemodynamic stability with the use of inotropic medications as necessary. Pre-bypass inhaled nitric oxide is contraindicated because the pulmonary arteriolar dilation and increased pulmonary blood flow in the face of a fixed distal anatomic obstruction will worsen pulmonary mechanics and often paradoxically worsen hypoxemia. TEE should be employed with caution due to the risk of further compression and obstruction to pulmonary veins even in the presence of nonobstructed TAPVR. Perioperative monitoring of central venous, left atrial, and pulmonary arterial pressures is helpful.

After bypass, inhaled nitric oxide should be used empirically in the case of obstructed TAPVR and should be readily

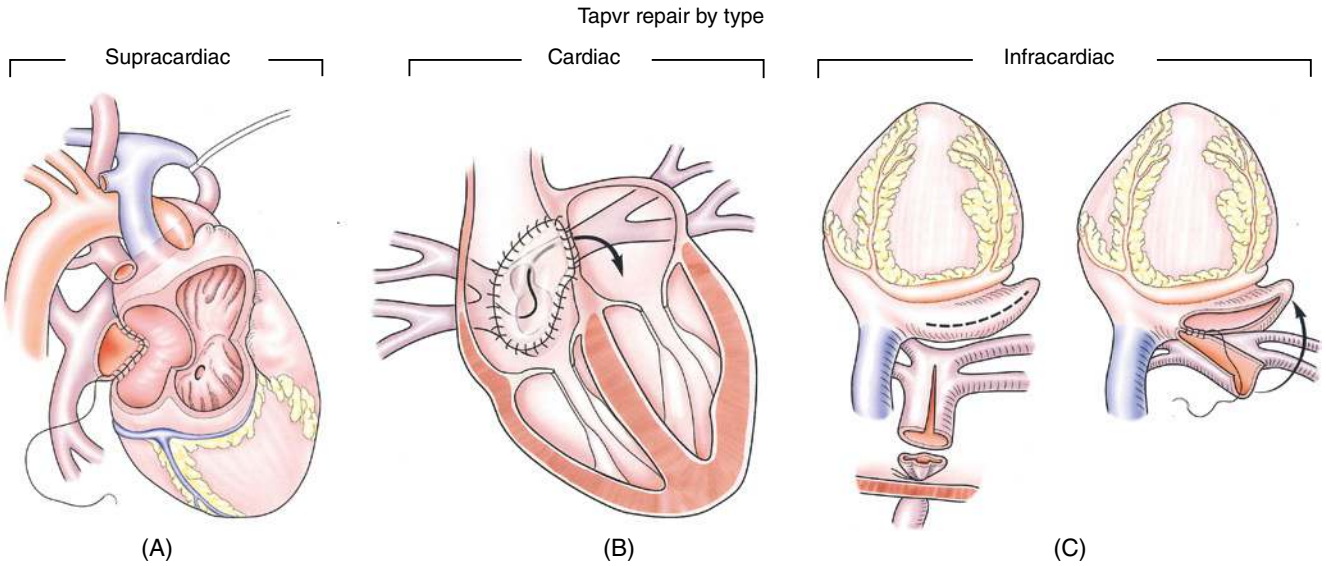

Figure 26.20 Examples of surgical techniques for the repair of total anomalous pulmonary venous return (TAPVR). (A) Supracardiac TAPVR: a transverse right atriotomy is extended across the atrial septum at the level of the atrial septal defect (ASD) and through the posterior aspect of the left atrium. The common pulmonary vein is anastomosed to the posterior wall of the left atrium and the supracardiac connection is ligated. The ASD and right atriotomy are then closed. (B) Cardiac TAPVR: The ASD is enlarged, with unroofing of the coronary sinus into the left atrium. An ASD patch is then used to channel pulmonary venous return to the left atrium. (C) Infracardiac TAPVR: With the heart rotated superiorly, the vertical vein is ligated at the level of the diaphragm. The common pulmonary vein and the posterior wall of the left atrium are incised and anastomosed. The ASD may be closed through an atriotomy. (Source: Gardner and Spray [168]. Reproduced with permission of Taylor & Francis.)

available in unobstructed TAPVR. Perioperative pulmonary hypertension occurs in as many as 50% of patients and is a major risk factor for early mortality [175, 176]. Pulmonary hypertensive crises may be avoided by employing hyperventilation, use of 100% oxygen, systemic alkalinization, sedation, paralysis, and inhaled nitric oxide. Sildenafil, magnesium sulfate, and prostaglandin E1 have been used in some patients to treat severe pulmonary hypertension [177]. Paradoxical pulmonary hypertension with systemic hypotension has been reported from the postoperative use of inhaled nitric oxide in patients with preoperative atrial obstruction and a poorly compliant and dysfunctional left ventricle. This paradoxical pulmonary hypertension is thought to be due to acute increases in pulmonary blood flow and resultant excessive preload to the noncompliant left side [178].

Pulmonary function may be compromised after bypass as a result of two pulmonary insults: (i) preoperative pulmonary edema secondary to pulmonary venous obstruction and (ii) the inflammatory response from cardiopulmonary bypass. Pulmonary compliance is decreased, and a large arterial-to-alveolar gradient develops. Pulmonary gas distribution may be optimized with the use of pressure control ventilation and altering PEEP to improve lung compliance.

Following repair, left atrial filling pressures may be elevated due to the small size and low compliance of the left atrium and ventricle. Accepting low blood pressures while weaning from CPB will help avoid overdistending the "unprepared" left side. Pulmonary artery pressures are frequently equal to or sometimes exceed, systemic pressures immediately after weaning from bypass. If the right ventricle is functioning adequately, this situation is often well tolerated for short periods as the PVR decreases in the first hour after bypass. Careful fluid management, optimization of heart rate and rhythm, and inotropic support will improve cardiac output. Temporary cardiac pacing may also be helpful. Perioperative dysrhythmias, especially supraventricular tachycardias, occur in as many as 20% of patients. If tolerated, an inovasodilator like milrinone will decrease left ventricular work and improve cardiac output. It is important to recognize that the Frank-Starling curve is very flat in the small, noncompliant LV, and administration of even small amounts of fluid may cause the left ventricle to become overdistended and fail.

KEY POINTS: PAPVR AND TAPVR

- PAPVR is often asymptomatic but may be associated with heart failure.
- PAPVR is managed similar to an ASD.
- TAPVR exists in four subtypes based on the anomalous connection: supracardiac, cardiac, infracardiac, and mixed.
- The pathophysiology of TAPVR is dependent on the presence and degree of pulmonary venous obstruction and the size of the interatrial communication.
- Obstructed TAPVR patients are particularly cyanotic and require 100% oxygen and significant ventilatory support pre bypass; inhaled nitric oxide (iNO) should be avoided.
- All TAPVR patients are at risk for post-bypass pulmonary hypertension, especially obstructed patients, and iNO should be available.
- TEE may cause or worsen the pulmonary venous obstruction.
- The chronically underfilled left ventricle may respond poorly to overloading after repair.

Introduction

Left-sided obstructive lesions of the heart can occur at various anatomic levels and with varying degrees of severity, ranging from a bicuspid aortic valve with minimal hemodynamic compromise to aortic atresia and hypoplastic left heart syndrome (HLHS) with profound hemodynamic derangements. Imbalances in systemic blood flow may occur due to a circumscribed obstruction at a single level, such as in hypertrophic cardiomyopathy; coarctation of the aorta; interrupted aortic arch; and subvalvular, valvular, or supravalvular aortic stenosis, or from obstructions at multiple levels, such as seen in patients with Shone's complex. Depending on the specific type of left-sided obstruction, the child may also be at risk for pulmonary hypertension and/or impaired coronary perfusion during anesthetic care. A clear understanding of the level and degree of the obstruction is therefore important for optimal anesthetic management.

Aortic valve stenosis

Incidence, anatomy, and natural history

A normal aortic valve has three leaflets and occupies an area of around 2 cm^2/m^2 of body surface area. Although by some estimates, isolated congenital valvular aortic stenosis occurs in only approximately 2 per 10,000 births [1], it is associated with other cardiac lesions in more than 5% of children suffering from congenital heart disease (CHD) and presents with three to four times higher prevalence in males [2]. Valvular aortic stenosis may be associated with aortic coarctation and/or hypoplasia of the ascending and transverse arch, due to decreased antegrade blood flow in the fetus, which prevents adequate development of these structures. Aortic stenosis (AS) has been described as part of Hunter's, Hurler's, and Turner's syndromes. Structural variations from the customary tricuspid contour of the aortic valve are common and result in a bicuspid or monocuspid appearance

AL Grawany

of the valvular apparatus, whose formation starts during weeks 5–7 of embryonic development [3, 4]. The diseased valve leaflets are gelatinously or myxomatously malformed, and the commissures are often partially fused, leaving a diminished aortic orifice, which can be located eccentrically. Left ventricular myocardial hypertrophy is commonly observed, but non-hypertrophied left ventricular dilation has also been reported [5]. The age of diagnosis, clinical presentation, treatment modality, and timing of intervention depend not only on the degree of valvular obstruction but also on concomitant cardiac lesions and left ventricular size and function. Only a small minority (approximately 2%) of asymptomatic patients will develop aortic valve dysfunction by adolescence, and progression of the lesion is usually slow [6, 7]. Conversely, neonates with ductal-dependent critical AS may present in shock, requiring aggressive resuscitation and emergent intervention.

Pathophysiology

The diagnosis is typically made using transthoracic echocardiography (TTE), which provides comprehensive information regarding valve anatomy, annular size, aortic root diameter, and ventricular function (Table 27.1) [8, 9]. Continuous-wave mean Doppler gradients adequately predict the peak-to-peak transvalvular gradient as measured during cardiac catheterization, whereas peak instantaneous Doppler gradients slightly overestimate the transvalvular gradient [10, 11]. However, correcting the peak Doppler gradient for pressure recovery, a phenomenon describing the kinetic energy being transformed back to pressure energy as the velocity decreases distal to the stenosis, significantly improves agreement with subsequently measured catheter gradients [12]. Depressed left ventricular function, however, can lead to a misleadingly low gradient.

In the most severe form of critical AS, presenting in the neonatal period, systemic blood flow and coronary perfusion can often be dependent on retrograde blood flow via a patent ductus arteriosus (PDA). After spontaneous ductal closure, the affected neonates frequently present with symptoms of significant congestive heart failure, metabolic acidosis, and mitral valve insufficiency, quickly progressing to cardiogenic shock. Aggressive hemodynamic, respiratory, and metabolic resuscitation as well as immediate treatment with prostaglandin E_1 are essential to re-establish adequate systemic perfusion. In infants with a less dramatic presentation, left ventricular stroke volume is often maintained for extended periods of time. Normal ventricular wall tension is maintained by concentric ventricular hypertrophy; however, increased left ventricular systolic and end-diastolic pressures can result in impaired subendocardial perfusion and ischemia. In severe cases, this malperfusion leads to the replacement of the myocardium with a fibrous tissue, termed endocardial fibroelastosis, further impairing ventricular performance and diminishing survival [13–15].

Table 27.1 Grading of aortic stenosis severity

Severity	Mild	Moderate	Severe
Mean echo pressure gradient [mmHg]	<20	20–40	>40
Peak transvalvular velocity V_{max} [m/s]	2.0–2.9	3.0–3.9	>4.0
Indexed aortic valve area [cm^2/m^2]	>0.85	0.60–0.85	<0.6
Velocity ratio	>0.50	0.25–0.50	<0.25

Surgical and transcatheter approaches and outcomes

Treatment options and timing for intervention depend on the acuity of the clinical presentation and the concomitant cardiac abnormalities, as valvular aortic stenosis can cover a wide anatomical and pathophysiological spectrum. Patients with mild AS can be followed conservatively, and if aortic valve repairs or replacements are performed, outcomes are generally excellent [16], especially if achieved without patches [17]. Neonates suffering from critical AS, on the other hand, require immediate intervention. In this population, important consideration is given to the size and adequacy of the left ventricle to tolerate a one- or two-ventricle repair [18]. In order to predict a successful outcome with either biventricular or univentricular palliation (the latter is discussed in Chapter 30) in neonates with critical AS, several scoring systems have been developed (Table 27.2) [19]. Unfortunately, a recent single-center, retrospective study in 68 neonates did not find any of the binary score cutoffs to be predictive of successful biventricular *vs*. univentricular repair. In particular, the Rhodes and Discriminant scores

Table 27.2 Predictive scores for successful biventricular repair of critical aortic stenosis

Scoring System	Formula	Severe
Rhodes	14 (BSA + 0.943 (indexed aortic root) + 4.78 (long-axis ratio) + 0.157 (indexed mitral valve area) – 12.03	≥0.35
CHSS 1	30.55 (inverse of age at study entry [d]–1) – 6.20 (aortic root z-score) – 12.14 (echocardiographic grade of EFE) – 23.33 (logarithm of ascending aortic [mm]) – 28.30 (presence of moderate or severe tricuspid regurgitation) – 0.70 (LV long-axis length *z* score) – 86.47	<0
Discriminant	10.98 (body surface area) – 0.56 (aortic annulus z-score) – 5.89 (left ventricular to heart long-axis ratio) – 0.79 (grade 2 or 3 EFE) – 6.78	≥–0.65
CHSS 2	Multivariable regression equation using BSA, mitral valve *z* score, indexed heart long axis, minimum LVOT diameter, mid-aortic arch indexed	<0
2 V	[(Mitral valve annulus in 4Ch/aortic valve annulus in PSLA)/(Left ventricular length 4Ch/Right ventricular length 4Ch) + main pulmonary artery diameter]/BSA	≤16.2

BSA, body surface area; CHSS, Congenital Heart Surgeons' Society; LV, left ventricular; LVOT, left ventricular outflow tract; 4Ch, four-chamber; PSLA, parasternal long axis; BiV: biventricular; EFE: endocardial fibroelastosis; 2 V, two-ventricle.

predicted the need for a univentricular approach in most patients who successfully maintained biventricular circulation after neonatal aortic valve intervention.

Given an adequate left ventricular size, the majority of pediatric cardiac centers currently favor percutaneous balloon valvuloplasty as the first treatment option for severe, ductal-dependent congenital AS. Using a retrograde approach, the balloon sheath is most commonly advanced from the femoral, umbilical, or carotid arteries. However, femoral vascular complications are not uncommon using this technique [20]. An alternative, antegrade approach can be used, in which the balloon is usually inserted from the femoral or umbilical veins, via the foramen ovale, into the left atrium and ventricle. If left ventricular function is adequate, administration of a bolus of adenosine (0.3–0.5 mg/kg), rapid right ventricular overdrive pacing (rate of 220–240/min), or an infusion of esmolol (200 μg/kg bolus followed by titrated infusion) during balloon dilation prevents forceful ventricular contraction against the balloon-occluded left ventricular outflow tract (LVOT) and ejection of the balloon from the aortic position with potential injury to the valve apparatus. In order to avoid post-interventional aortic valve insufficiency, the selected balloon size usually should not exceed the diameter of the aortic root. Using these techniques, severe aortic valve insufficiency can be avoided in greater than 80% of patients immediately after intervention, and the 5-year mortality typically remains below 20% [20–24]. If the left ventricle is of borderline size, significant aortic insufficiency would disqualify patients from single-ventricle palliation. See Chapter 34 for further discussion of percutaneous balloon aortic valvuloplasty.

Surgical options include primary surgical valvotomy, valvular repair, or replacement and depend on severity of the lesion and patient age. Advantages of an open approach include direct inspection and commissurotomy of the valve and the ability to address concomitant cardiac lesions such as PDA, ventricular septal defect (VSD), or aortic coarctation during the same procedure. However, the need for cardiopulmonary bypass (CPB) can increase morbidity for the patient. Historical case series using this approach have demonstrated an operative mortality of 0–18%, 5-year survival of 60–100%, aortic valve competency in greater than 95% of patients, and a 10-year freedom from reintervention of greater than 70% following surgical valvuloplasty [22, 25–28].

The Ross procedure, an aortic valve replacement with a pulmonary autograft combined with placement of a homograft in the pulmonary position, was introduced by Donald Ross in 1967 (Figure 27.1) [30]. The autograft can also be supported on the outside by a tube graft [31]. It can also be combined with enlargement of the LVOT, which is termed as the Ross–Konno procedure [29]. These procedures can be performed in neonates and infants, but have demonstrated better outcomes when performed in childhood or adolescence. Compared with prosthetic valve replacement, the Ross procedure uses autologous tissue and avoids the need for chronic anticoagulation. Long-term outcomes have been favorable, with greater than 75% freedom from reoperation up to 10 years postoperatively [32–35]. Allograft or prosthetic valve replacement is usually reserved for adolescent patients after completion of much of their somatic growth, if they are candidates for chronic anticoagulation.

More recently, reconstruction of the aortic valve with pericardial tissue has been described by Ozaki and colleagues [36] (Figure 27.2). The diseased aortic leaflets are excised and replaced with three pieces of glutaraldehyde-treated autologous pericardium trimmed to the size of the original leaflets, which are then attached to each annulus. Initial long and medium-term results in adults and children have been encouraging [37–39]. Table 27.3 presents the outcomes after aortic valve surgery in children.

During the past two decades, transcatheter aortic valve replacement (TAVR) has evolved from compassionate use in high-risk inoperable patients to an alternative modality to surgical valve replacement, even in lower risk patients [41]. A recent review in adult patients suggested a trend toward favoring a transcatheter over the surgical approach for aortic valve replacement, with a concomitant decline of in-hospital mortality for TAVR. TAVR has also been utilized in pediatric patients down to 4 years of age who were suboptimal surgical candidates; however, data on valve longevity is not yet available [42].

Experimental treatment options for critical AS or aortic atresia have included fetal transcatheter valvuloplasty [43]. The rationale for intervention, despite the risks for both mother and fetus, is to avoid single-ventricle palliation by preventing the natural progression of severe AS to HLHS. The treatment assumes that alleviating the restricted blood flow across the aortic valve will lead to improved growth and function of the left ventricle, thereby allowing a postnatal biventricular repair. However, fetal interventions for AS remain highly controversial and long-term outcomes are unclear [44, 45]. See Chapter 19 for further discussion of emerging treatment options.

Anesthetic considerations

Neonates with critical AS can present with significant metabolic derangement and hemodynamic instability. Anesthetic management is directed toward meeting the increased oxygen requirement of the hypertrophied left ventricular myocardium and optimizing cardiac output. Physiologic goals include maintenance of preload, afterload, and contractility. A normal or, to some extent, decreased heart rate is preferred. Bradycardia, however, is not well tolerated in neonates, whose cardiac output is heart rate-dependent given their fixed stroke volume, even without AS. Anesthetics that decrease systemic vascular resistance and/or increase heart rate must be used with caution to avoid myocardial ischemia and rapid deterioration of the patient's status. Vasoconstrictors such as phenylephrine can be used in this clinical scenario. Dysrhythmias are not uncommon during cardiac catheterization and should be treated aggressively.

Inotropic support with a medication such as epinephrine may be required if myocardial function becomes depressed, but must be used with caution given its ability to increase heart rate and myocardial oxygen requirement. In unstable patients, a high-dose opioid technique will facilitate both balloon valvuloplasty and surgical valvotomy. Occasionally, extracorporeal membrane oxygenation backup is arranged for selected high-risk patients.

KEY POINTS: VALVULAR AS

- Neonates may present in shock and require aggressive resuscitation prior to intervention.
- Transcatheter valvuloplasty is usually the treatment of choice in the neonate with severe or critical AS and adequate left ventricular size, with the major technical risk being overaggressive dilatation with resultant aortic valve insufficiency.
- Complications during balloon angiography include profound myocardial depression, bradycardia, asystole, and ventricular fibrillation.
- Anesthetic management with an opioid-based technique often facilitates maintenance of preload, afterload, contractility, and a low-normal heart rate; significant bradycardia should be avoided in the neonate.

Subvalvular AS

Incidence, anatomy, and natural history

Subvalvular AS (subAS) is a fixed obstruction occurring within the LVOT and accounts for approximately 1% of patients with CHD. Patients with subAS usually become symptomatic after infancy, with a higher male predilection of 2:1 to 3:1 [46]. Most commonly, the anatomic correlate of the LVOT obstruction is either a thin, discrete membrane of endocardial or fibrous tissue or a fibromuscular ridge emanating from the crest of the interventricular septum. Less common manifestations include a circumferential, fibromuscular ring that originates from the anterior mitral valve leaflet and a diffuse, tunnel-like fibromuscular obstruction. Other rare causes of subAS include anomalous attachments of mitral valve leaflets or mitral chordae. A variety of congenital heart lesions may exist in association with subAS and

include bicuspid valves, AS, VSD, and aortic coarctation (Table 27.4). SubAS can occasionally present in infancy as part of Shone's complex or following the surgical closure of a VSD, but more commonly, the diagnosis is not made before the end of the first year of life and severity usually increases with age.

Table 27.4 Concurrent congenital anomalies in patients with subvalvular aortic stenosis

Lesions	Percentage of patients
Bicuspid valves	40
Aortic stenosis	28
Ventricular septal defect	24
Coarctation of aorta	12
Patent ductus arteriosus	12
Atrial septal defect	4

Pathophysiology

Patients usually present with complaints of orthopnea, dyspnea on exertion, or exertional angina and syncope. A systolic ejection murmur is present, most notable in the left, second, and third parasternal spaces, and a carotid artery thrill can be palpated in a significant number of patients. The diagnosis is confirmed by color Doppler echocardiography, which allows assessment of the degree of stenosis, biventricular enlargement and function, and concomitant mitral and aortic regurgitation. Cardiac catheterization is usually only needed to assess patients with serial obstructions or a tunnel-like stenosis. As the severity of subAS increases with age, progression of the LVOT obstruction may eventually lead to left ventricular diastolic dysfunction and pulmonary venous hypertension. Moreover, abnormal blood flow across the aortic valve can lead to thickening of the valve leaflets, causing valvular AS, left ventricular hypertrophy, damage to the aortic valve, and subsequent aortic insufficiency with progressive regurgitation. A higher LVOT gradient at diagnosis is an independent predictor for these adverse outcomes.

Surgical and transcatheter approaches and outcomes

Currently, surgery is favored as an early intervention for LVOT peak pressure gradients exceeding 40 mmHg and consists of fibromuscular resection with or without myectomy through an aortotomy (Figure 27.3), but timing remains controversial. A study comparing early and late surgery in 83 patients with subAS found that the LVOT gradient was successfully reduced in both groups, but that the late surgery group had a much higher recurrence rate at 5 and 10 years (28 and 57%, respectively) compared with the early surgery group (6 and 0%, respectively) [47]. Failure to intervene early also increases the risk of developing aortic regurgitation, which does not necessarily improve following subaortic resection. Transcutaneous balloon dilation is usually ineffective due to only temporary relief of the stenosis. Surgical complications include newly developed or worsened aortic insufficiency and postoperative atrioventricular heart block. In patients with tunnel-type subAS, an aortoventriculoplasty (Konno procedure) may be required or in the presence of aortic insufficiency, an aortic root replacement with a prosthetic valve or a Ross–Konno procedure is now favored. The Konno operation is still favored in patients with very small aortic annulus and involves an aortic incision above the aortic commissures and extended to the annulus and carried through the left and right ventricular outflow tracts, placement of a mechanical or bioprosthetic stented aortic valve, followed by

AL Grawany

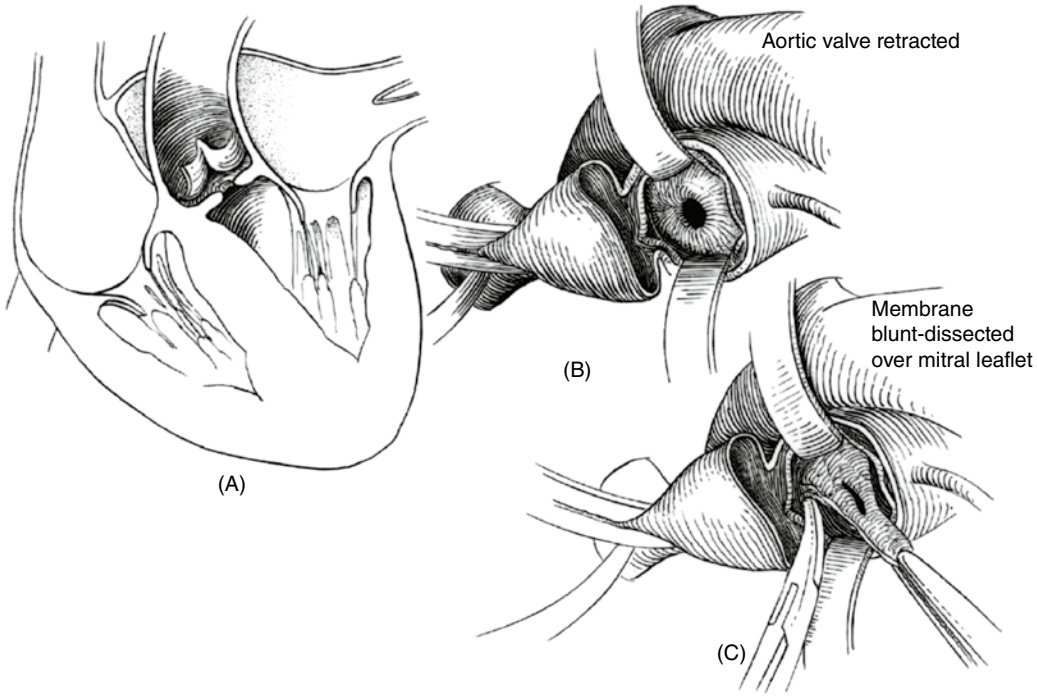

Figure 27.3 Surgical repair of subaortic stenosis. (Source: Adapted from Tworetzky et al. [43].)

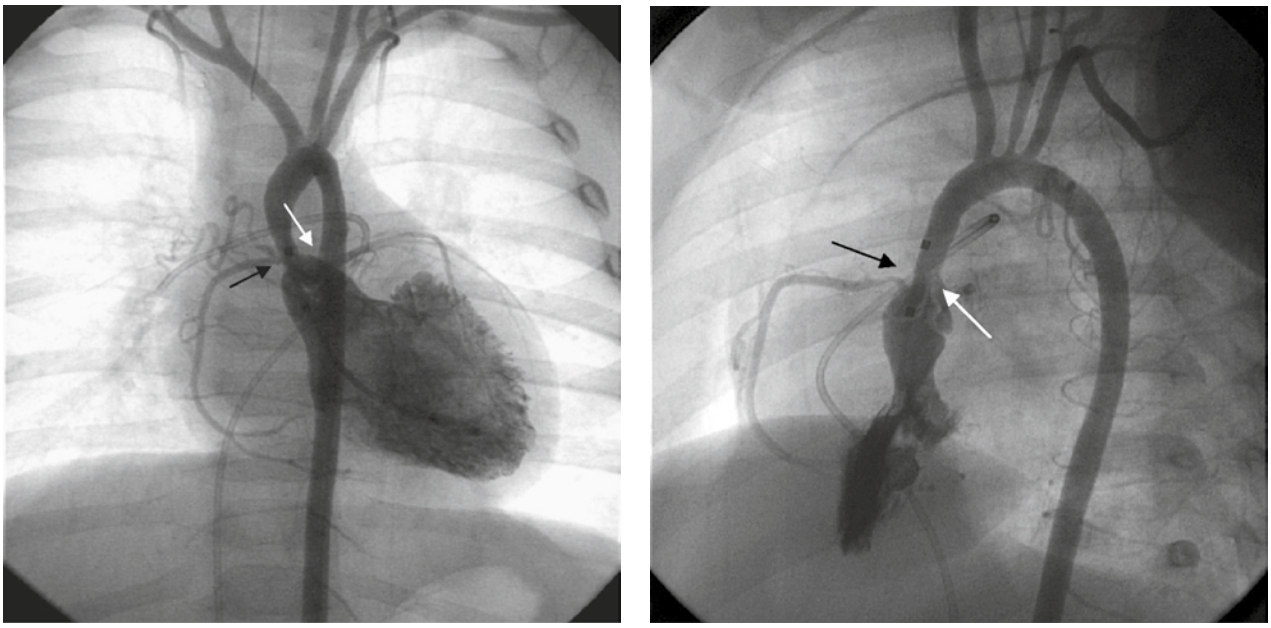
closure with a pericardial or synthetic patch. Compared with the Konno operation, the Ross–Konno procedure requires less of an incision into the interventricular septum, limits right ventricular outflow tract distortion and potential injury to the conduction system (see also section on Shone's Complex later in this chapter). The operation involves harvesting the pulmonary valvular autograft, resection of the diseased aortic valve with coronary button mobilization, implantation of the pulmonary autograft and neoaortic reconstruction with coronary button anastomoses, followed by implantation of a pulmonary homograft into the right ventricular outflow tract. The use of an autograft provides growth potential and freedom from anticoagulation regimens [29].

Anesthetic considerations

Anesthetic management of subvalvular stenosis aims at maintaining the oxygen requirements of the myocardium and other end organs. Accordingly, the goal is to decrease myocardial oxygen demand and preserve both preload and afterload while maintaining or allowing a slightly decreased heart rate. In this regard, the anesthetic management of the patient with subAS is very similar to that for valvular AS.



KEY POINTS: SUBVALVULAR AS

- Subvalvular AS usually consists of a discrete membrane in the LVOT presenting after infancy, but can also be seen as part of multi-level left-sided obstruction in patients with Shone's complex.
- Early surgical membrane resection with or without myectomy is favored over transcatheter approaches for an LVOT pressure gradient >40 mmHg.
- Hemodynamic goals during anesthetic management are similar to AS, maintaining preload and afterload, and allowing a slightly decreased heart rate.

Supravalvular AS

Incidence, anatomy, and natural history

Congenital supravalvular AS is the least common fixed obstruction of the LVOT, accounting for less than 0.05% of CHD. However, caused by abnormalities in the elastin gene (ELN), supravalvular AS occurs in up to two-thirds of patients with Williams–Beuren syndrome, also known as Williams syndrome, and as part of familial supravalvular AS [48–51]. The outflow tract obstruction frequently arises as a concentric narrowing of the ascending aorta at the superior margin of the sinuses of Valsalva, creating a typical hourglass deformity of the aorta [52]. Other manifestations include a diffuse narrowing along the entire ascending aorta or a fibrous semicircular membrane at the sinotubular junction. Supravalvular AS is a progressive disease, usually diagnosed after infancy, but may present earlier in life in patients with Williams syndrome. Coronary artery involvement, which is common in children with Williams syndrome, may include a reduction of the left coronary artery ostial size, ostial obstruction by fusion of the aortic cusp to the supravalvular ridge, or diffuse narrowing of the left coronary artery (Figure 27.4). In cases of mild supravalvular

(A) (B)

Figure 27.4 Representative angiogram of a patient with Williams syndrome, demonstrating supravalvular aortic stenosis (black arrow) and left coronary artery ostial stenosis (white arrow). (A) Anteroposterior view. (B) Lateral view. Peak systolic gradient during catheterization was 70 mmHg. (Source: Robert Beekman, MD. Reproduced with permission.)

AS, one case series found spontaneous improvement in the obstruction with time in 16% of patients and complete resolution in another 12% [53].

Pathophysiology

The underlying mechanism for supravalvular AS in Williams syndrome is an elastin arteriopathy, leading to a lack of elastic tissue in the walls of large arteries, increased amounts of collagen, and hypertrophy of smooth muscle cells [54]. Accordingly, pulmonary artery stenosis is also observed in over 30% of these patients, which can lead to biventricular hypertrophy [50]. Supravalvular AS may also be associated with a bicuspid aortic valve and aortic valvular stenosis in up to 50% of patients [55]. Concentric left ventricular hypertrophy can lead to myocardial ischemia, which is exacerbated by concomitant coronary artery stenosis. The risk of sudden death may only be slightly raised in patients with sporadic supravalvular AS, but is significantly increased in patients suffering from Williams syndrome, compared with the general population [56, 57]. A low-pitched, crescendo–decrescendo, systolic murmur is commonly heard at the base of the heart, radiating to the right carotid artery. The diagnosis of supravalvular AS is routinely made using two-dimensional echocardiography, and Doppler echocardiography can be utilized to determine the pressure gradient across the ascending aorta. Electrocardiograms usually show left ventricular hypertrophy with special attention given to potential ischemic ECG changes. Patients with Williams syndrome, occurring in approximately 1 in 20,000 live births, are easily recognized due to their characteristic facial dysmorphisms; common features include a wide mouth with full lips, micrognathia, dental malocclusion, widely spaced teeth, a short nose with a flat nasal bridge, and a long philtrum. They may also suffer from arterial hypertension, hypercalcemia with nephrolithiasis, esotropia, a hoarse voice, joint hyperelasticity, and sensorineural hearing loss. Although patients often exhibit cognitive impairment, they commonly have a characteristic desire for conversation and company with a lack of social inhibition [50, 58]. The suspected diagnosis of Williams syndrome can be verified even in neonates who do not yet exhibit the characteristic features, using genetic testing for karyotype and the fluorescent in situ hybridization (FISH) test for the 7q11.23 elastin gene deletion [54]. See Chapter 8 for futher discussion of Williams Syndrome.

Surgical and transcatheter approaches and outcomes

Infants with a peak pressure gradient of less than 20 mmHg across the supravalvular stenosis often remain stable and do not require intervention; however, a peak instantaneous pressure gradient of greater than 75 mmHg is usually an indication for surgical intervention [40]. Surgical techniques for repair of supravalvular stenosis include patch aortoplasty with one (Figure 27.5) or multiple patches [59, 60], complete excision of the stenotic ring with end-to-end anastomosis, or the Ross or Ross–Konno procedures [55, 61]. Significant coronary ostial obstruction may be relieved by a patch enlargement of the coronary os, excision of the obstructing aortic leaflet, or coronary artery bypass grafting [62]. Concomitant pulmonary artery stenosis in many patients with Williams syndrome is frequently addressed by balloon dilation of the right ventricular outflow tract stenosis prior to surgical repair of the LVOT obstruction.

Anesthetic considerations

Supravalvular AS shares many of the pathophysiological characteristics and anesthetic management requirements of valvular and subvalvular stenosis. However, due to the potential combination of supravalvular AS, left ventricular hypertrophy, right ventricular outflow tract obstruction, and coronary artery disease, patients with Williams syndrome can be at significantly increased risk for anesthesia-related complications. Accordingly, several reports have described perioperative fatalities in these patients, ranging from events during anesthesia induction or intubation to postoperative complications [56, 63–67]. The majority of these reported events seemed to be caused by myocardial ischemia. Maintaining afterload at slightly elevated levels is therefore paramount to preserve coronary perfusion pressure. Volatile anesthetics must be used with caution due to their myocardial depressive and vasodilatory effects. Intramuscular premedication with ketamine may facilitate the establishment of intravenous access, and high-dose opioid techniques may accomplish the anesthetic goals. However, significant increases in heart rate, which can occur following administration of ketamine or vagolytic agents, are not well tolerated and need to be treated aggressively. Also, arrhythmias, such as those caused by catheter manipulation during cardiac catheterizations, are frequently poorly tolerated. It must be emphasized that the coronary arteries are frequently significantly involved, being partially obstructed or "hooded" from the abnormal surrounding connective tissue in the aorta, and the degree of coronary obstruction often does not correlate with the severity of the supravalvular AS. Other anesthetic complications, such as difficult mask ventilation or difficult tracheal intubation, may arise due to the concomitant facial deformities in this syndrome. Moreover, the potential development of abnormal skeletal muscle tissue with lipid deposits may lead to an increased sensitivity to muscle relaxants, thus warranting close monitoring of neuromuscular blockade [68]. Additional sources of perioperative morbidity include their predisposition to renal insufficiency and arterial hypertension, which need to be appropriately addressed in the anesthetic plan. Preoperative risk assessment is difficult, because adequacy of coronary blood flow is difficult to verify and the more reliably quantifiable degree of supraaortic stenosis does not necessarily correlate with the degree of coronary abnormalities. In particularly, for critical patients,

extracorporeal membrane oxygenation (ECMO) or CPB backup may be advised as cardiopulmonary rescuscitation can be challenging in these patients.

KEY POINTS: SUPRAVALVULAR AS

- Supravalvular AS occurs in two-thirds of patients with Williams syndrome and can be accompanied by coronary and ostial stenoses, substantially increasing the risk of coronary events and sudden death.
- Maintain preload and afterload at high-normal levels to preserve coronary perfusion pressure, and maintain heart rate and contractility at low-normal levels.
- Avoid anesthetic techniques that produce significant decreases in preload and afterload, e.g., high doses of volatile anesthetics and/or propofol.
- Tachycardia is not well tolerated in patients with significant coronary stenosis and must be treated aggressively.

Hypertrophic cardiomyopathy

Incidence, anatomy, and natural history

Hypertrophic cardiomyopathy (HCM) is a cardiac disorder with significant heterogeneity of etiology, anatomic findings, and clinical presentation; in adults, it occurs with an estimated prevalence of 1:500 [69, 70]. This disease is diagnosed less commonly in children, but when identified, it carries a significant risk for adverse outcomes, with an overall survival of 97% at 5 years and 94% at 10 years [71]. Over the past decade, the increased availability of genetic and metabolic testing has improved the ability to identify the underlying etiology of HCM. While in both adults and children, the most common cause of HCM is a mutation in sarcomeric genes, in the pediatric population, the etiology is more heterogeneous and non-sarcomeric causes represent up to 35% of cases of HCM [72] (Table 27.5).

In one single-center pediatric study, an affected family member, positive HCM gene panel mutation, metabolic disease, or genetic syndrome were identified in over 80% of patients with HCM. [61] Children presenting with HCM at less than 1 year of age carry a worse prognosis, and an inherited error of metabolism or malformation syndrome (e.g., RASopathies) is likely present [72, 73]. Genetics evaluation and testing is now recommended in all children diagnosed with HCM [71].

The characteristic gross morphologic feature in HCM is a hypertrophied and non-dilated left ventricle, and the absence of other disease processes capable of causing this degree of hypertrophy (e.g., AS). There is significant heterogeneity with regard to the location and degree of cardiac hypertrophy, and in fact, even first-degree relatives with familial HCM often exhibit different patterns of hypertrophy [74, 75]. Myocardial hypertrophy may occur in the anterior, posterior, and/or basal regions of the ventricular septum, and in the ventricular free wall. The hemodynamic severity is dependent on the particular region where hypertrophy is most prominent: significant hypertrophy of the anterior region of the ventricular septum compared with the posterior septum more commonly causes subaortic outflow obstruction [76]. Echocardiography is extremely helpful in determining the extent, location, and severity of the disease. Quantitative echocardiographic findings in patients with HCM include increased left ventricular wall thickness, decreased left ventricular end-diastolic cavity size, and increased left ventricular fractional shortening [77]. Other important findings include the presence and severity of LVOT obstruction, systolic anterior motion of the mitral valve, and mitral regurgitation [78]. Cardiac Magnetic Resonance Imaging (CMR) is also commonly used for diagnosis, risk prediction, and presurgical planning. This imaging modality provides extremely accurate information regarding LV wall thickness, ventricular chamber sizes, and the degree of myocardial fibrosis which has been shown to be a marker for increased risk for ventricular tachyarrhythmias and heart failure progression [79].

The natural history of this disease is dependent on multiple factors, including the underlying etiology, age at presentation, clinical signs and symptoms, and the presence of other co-morbidities. Most patients with HCM, and neonates in particular, often remain asymptomatic for a long period of time. Many patients are not diagnosed until they present with symptoms of congestive heart failure, cardiac rhythm disturbances, or syncope or following a near-death cardiac event [70]. HCM has become the leading cause of sudden cardiac death in young athletes [74, 75]. Even when the diagnosis is

AL Grawany

made prior to a catastrophic event, the clinical course of the disease is inconsistent and dependent on whether the HCM is obstructive or non-obstructive. If obstructive, more than 25% of infants will develop symptoms of congestive heart failure manifested by feeding intolerance or failure to thrive [80].

Pathophysiology

Hypertrophic cardiomyopathy is most commonly caused by mutations in genes encoding proteins of the myocardial sarcomere, and in fact over 50 mutations causing the disease have been identified, making it one of the most widespread genetic diseases of the myocardium. Depending on the specific mutation, abnormalities in the protein may lead to ineffective contraction of the sarcomere and the development of myocyte hypertrophy [70]. The histology of the left ventricle is remarkable for disarray of the hypertrophied cardiac muscle cells, myocardial scarring and fibrosis, and thickened walls in small intramural coronary arteries causing luminal narrowing [76, 81]. Although fiber disarray is present even in normal hearts, the extent to which this happens in the heart with HCM is significantly increased [82]. A minority of patients may progress to a secondary phase characterized by wall thinning in areas of previous hypertrophy, enlargement of cavity size, and impairment of ventricular function, a phenomenon likely related to myocardial ischemia and necrosis [76].

Hypertrophic cardiomyopathy also presents in infancy without sarcomeric protein gene mutations, such as in infants of insulin-dependent diabetic mothers, children with malformation syndromes such as Noonan syndrome, or in patients with glycogen storage diseases such as Pompe disease. In Noonan syndrome, a genetic disorder commonly associated with congenital cardiac disease, approximately 15–20% of children have HCM, with less favorable outcomes than children with non-syndromic HCM [80, 83]. Pompe disease represents a glycogen storage disease type II (GSD-II) which is a rare autosomal recessive disorder occurring in 1 out of 40,000 live births, in which lysosomal glycogen accumulates in both cardiac and skeletal muscle due to a deficiency of acid α-glucosidase [84, 85]. Children presenting with the infantile form of this disease exhibit severe HCM, and, if untreated, often die in the first year of life from respiratory or cardiac complications. Therapy with long-term intravenous recombinant α-glucosidase often leads to significant resolution of the cardiac hypertrophy and skeletal muscle weakness [86] Infants presenting for surgery prior to therapy with recombinant human α-glucosidase are at a high risk for anesthetic complications [87]. In a retrospective review, 6% of patients with infantile-onset Pompe disease receiving anesthetics developed an arrhythmia or cardiac arrest soon after induction of anesthesia [88]. Two-thirds of these events were attributed to the use of sevoflurane or propofol.

The most common finding in patients with HCM is a hyperdynamic left ventricle with abnormal diastolic relaxation and compliance; LVOT obstruction is present in no more than 25% of patients [89] (Figure 27.6). The degree of outflow tract obstruction is a dynamic process and may be reduced or abolished by decreasing myocardial contractility, increasing preload, or increasing afterload. Conversely, the dynamic obstruction is increased during periods of increased ventricular contractility or sympathetic stimulation, as for instance, with exercise. The outflow tract gradient is felt to be caused in part by anterior movement of the mitral valve toward the ventricular septum during early systole, and more likely to occur in the setting of a hypertrophied anterior septum [89]. Anterior movement of the mitral valve may interfere with optimal valve closure, causing mitral regurgitation, occurring more commonly in the setting of LVOT obstruction. The combination of severe left ventricular hypertrophy, LVOT obstruction, and abnormalities of the intramural coronary arteries all place these patients at an increased risk of myocardial ischemia and ventricular arrhythmias.

Surgical and transcatheter approaches and outcomes

Treatment modalities for HCM include medical therapy, surgical therapy, the use of pacing and/or implantable cardioverter-defibrillators, and cardiac transplantation. Aggressiveness of therapy in any given patient depends on the risk factors for morbidity and mortality. Identified risk factors for patients with HCM include family history of sudden death or syncope, extreme septal hypertrophy, and LVOT obstruction [90, 91]. Asymptomatic patients with HCM may not require any therapy. When medical therapy is initiated, it usually consists of either a β-blocker or calcium-channel blocker, and can be guided by treadmill exercise testing or patient symptoms [70]. Another treatment option is dual-chamber pacing, which has been used as an alternative to surgery with mixed results. Although pacing has been shown to be of benefit in some patients, randomized controlled trials showing long-term improvement in outcomes are lacking. For patients with HCM that have had a sudden cardiac death event and/or sustained ventricular tachycardia/ventricular fibrillation, placement of an implantable cardioverter-defibrillator is indicated [79].

Indications for surgical intervention include a left ventricular outflow gradient >60 mmHg, significant symptoms such as dyspnea, angina, or syncope unresponsive to medical therapy, and an increase in mitral regurgitation [92]. Septal myectomy is an effective treatment in both pediatric and adult patients [76, 78]. In pediatric patients with HCM undergoing septal myectomy at the Mayo Clinic over a 28-year period, there were no early deaths and survival rates at 5 and 10 years were 97 and 95%, respectively. Late follow-up was remarkable for 96% of patients remaining in New York Heart Association (NYHA) functional class I or II [91]. The surgical approach is commonly transaortic, and often technically challenging in smaller children. Transesophageal echocardiography (TEE) can be used to aid in the assessment of intracardiac anatomy before resection and of the adequacy of resection following myectomy. Despite an excellent surgical result with minimal residual left ventricular outflow gradient, these children remain at risk for cardiac arrhythmias and sudden death [91]. Patients with congestive heart failure, myocardial ischemia, and/or life-threatening arrhythmias, despite optimal medical and surgical therapies, may be considered for cardiac transplantation.

Anesthetic considerations

Patients with HCM are at a significant risk for cardiac complications during anesthesia and surgery. A recent retrospective study looking at the incidence of complications in children with HCM undergoing general anesthesia at a tertiary care pediatric center demonstrated a 0.6% mortality rate; minor complications were seen in 12% of patients [92]. One adult study was remarkable for 40% of patients experiencing at least one perioperative adverse cardiac event, and predictors of adverse outcome included major surgery and duration of surgery [93]. To avoid hemodynamic instability, anesthetic management should be tailored toward maintaining preload and afterload, decreasing myocardial contractility, and avoiding tachycardia. Maintenance of normovolemia prior to induction is vital, and the placement of an intravenous catheter and administration of intravenous fluids prior to surgery may be beneficial. While halothane meets many of the hemodynamic goals and has been well tolerated in such cases, it is no longer available [94]. Sevoflurane and desflurane, on the other hand, may cause significant increase in heart rate and reduction in systemic vascular resistance and should be used with caution. The use of an intravenous access for anesthetic induction allows for careful titration of anesthetic agents and for rapid treatment of hypotension and/or cardiac arrhythmias. High-dose opioid anesthesia provides stable hemodynamics and maintenance of a normal to low heart rate. Remifentanil, a short-acting potent opioid administered by continuous infusion, may be an excellent choice when extubation of the trachea following surgery is planned. For patients not already on β-blocker therapy, esmolol can be used in the perioperative period to control heart rate and reduce cardiac contractility.

Depending on the procedure and severity of HCM, arterial vascular access and central venous access may be indicated. Patients with a critical LVOT gradient may benefit from pre-induction placement of an arterial line for close monitoring of systemic blood pressure during anesthetic induction. However, one must carefully judge whether the increased anxiety and pain caused by the procedure might precipitate an adverse event. During placement of a central venous line the patient must be closely monitored for the occurrence of an atrial dysrhythmia. Rapid treatment of dysrhythmias is important, as hemodynamics may deteriorate swiftly. Central venous pressure may be significantly elevated in patients with HCM due to the hypertrophied noncompliant ventricle.

KEY POINTS: HYPERTROPHIC CARDIOMYOPATHY

- Hypertrophic cardiomyopathy is a heterogeneous condition caused by multiple factors including mutations in genes encoding sarcomeric proteins, metabolic and mitochondrial disorders, and RASopathies such as Noonan and Costello syndrome.
- Characteristic anatomic features include a hypertrophied left ventricle with hyperdynamic systolic function and abnormal diastolic relaxation.
- Hypertrophic cardiomyopathy currently is the leading cause of sudden death in young athletes.
- Anesthetic considerations include maintaining preload at high-normal levels, decreasing myocardial contractility, and avoiding tachycardia.

Coarctation of the aorta

Incidence, anatomy, and natural history

Coarctation of the aorta denotes a narrowing of the aortic lumen and is most often located just distal to the opening of the left subclavian artery at the point of insertion of the ductus arteriosus (Figure 27.7). Although usually presenting as a discrete narrowing, the coarctation can also be a long-segment stenosis or be associated with hypoplasia of the transverse aortic arch. Up to 8% of patients with CHD have an aortic coarctation, which is more prevalent in males than females by a 1.5:1 ratio [2, 94]. The etiology of the coarctation is a folding of the medial tissue of the aortic wall; the obstructing shelf is often composed of circumferential ductal tissue, and with ductal closure contraction of this tissue leads to aortic coarctation. Both proximal and distal transverse arch hypoplasia is common and defined as less than 60% or 50% respectively of the diameter of the ascending aorta [95]. When the coarctation is severe with limited anterograde flow from the transverse arch, blood flow to the distal aorta may be entirely dependent on a PDA. If the coarctation segment remains uncorrected for a prolonged period of time, collateral blood flow will develop, thus allowing for adequate perfusion distal to the aortic obstruction. Other congenital cardiac anomalies are present in about one-half of patients with aortic coarctation and include ventricular septal and atrioventricular canal defects, valvular AS, and subvalvular AS.

If untreated, the natural history of aortic coarctation is primarily related to the severity of the obstruction. Over 90% of untreated patients with coarctation of the aorta die by the

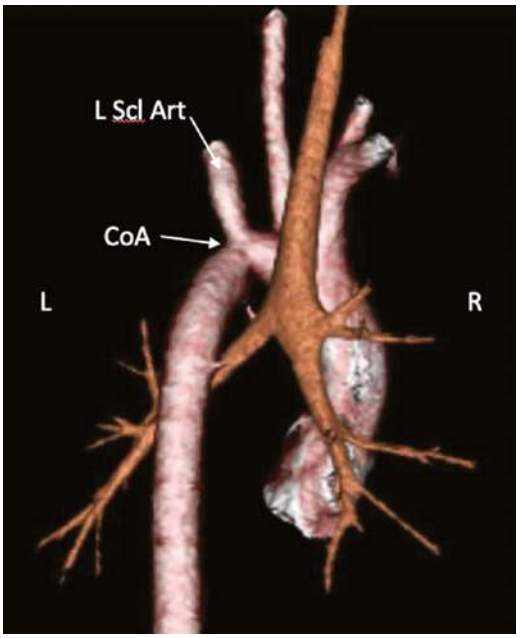

Figure 27.7 Posterior-anterior computed tomography imaging of an infant with an aortic coarctation located just distal to the left subclavian artery. L, patient's left side; R, patient's right side; CoA, coarctation; L Scl Art, left subclavian artery. (Source: Courtesy of Michael Taylor, MD.)

age of 50 [96]. Even with surgical repair, patients with aortic coarctation demonstrate an increased predilection for hypertension, coronary artery disease, stroke, heart failure, and ruptured aortic and cerebral aneurysms. Over 50% of patients have arterial hypertension at long-term follow-up, which is not necessarily related to the presence of a recurrent stenosis [97]. Patients who have undergone aortic coarctation repair during infancy without residual stenosis also exhibit abnormal left ventricular diastolic function and aortic elasticity as adults [98].

Pathophysiology

The neonate with a severe coarctation generally presents during the first few weeks of life with congestive heart failure, left ventricular systolic dysfunction, and, in some cases, cardiogenic shock. The closure of the ductus arteriosus causes an acute increase in left ventricular afterload, elevation of left ventricular end-diastolic pressure, reduction in stroke volume, pulmonary venous congestion, and pulmonary artery hypertension [2]. The infant with a less severe coarctation may exhibit tachypnea and failure to thrive. Still, the asymptomatic child with an unrecognized coarctation is at an increased risk for developing systemic hypertension proximal to the coarctation and subsequent left ventricular failure.

The diagnostic feature of aortic coarctation is a systolic blood pressure difference between the upper and lower extremities. TTE [99] using a suprasternal long-axis view typically shows a localized narrowing ("posterior shelf") just distal to the left subclavian artery, and Doppler analysis aids in assessing the severity of the coarctation. Evaluating the heart for other associated lesions is important. Magnetic resonance imaging (MRI) and computed tomography (CT) angiography with three-dimensional reconstruction are other modalities used to image the aortic arch, and are more commonly utilized in older children and adults where imaging by TTE is often suboptimal. A study comparing CT angiography with TTE for diagnosis of coarctation demonstrated that CT angiography was the more sensitive test (100% vs. 87.5%) [100]. Drawbacks to these modalities include the use of ionizing radiation with CT angiography and the necessity for anesthesia or sedation for MRI in younger children.

Surgical and transcatheter approaches and outcomes

Therapeutic options for aortic coarctation include surgery, balloon dilation, and placement of endovascular stents. However, there continues to be significant debate regarding the optimal long-term treatment strategy. At the present time, neonates and infants are thought to have a superior outcome with surgical repair, while older patients may benefit from balloon dilatation with or without stenting as the initial therapy [101]. A retrospective study comparing balloon angioplasty and surgery as the initial therapy for neonatal coarctation showed that over 80% of patients undergoing balloon angioplasty subsequently required surgery or repeat balloon dilation, while less than 20% of patients undergoing surgery required reintervention [102]. Another study comparing outcomes in children undergoing balloon angioplasty for native coarctation found that the incidence of restenosis and aneurysm formation was significantly increased in children <1 year of age [101]. The options for surgical repair include a subclavian flap aortoplasty, a resection of the narrowed portion of the aorta with a traditional end-to-end anastomosis, extended end-to-end or end-to-side reconstruction (aortic arch advancement technique), or an interposition tube graft (Figure 27.8). The aortic arch advancement technique is used when significant transverse arch hypoplasia is present and requires proximal extension of the anastomosis onto the underside of the transverse arch up to the level of the innominate artery [103] This operation can be performed through a left thoracotomy approach or median sternotomy with cardiopulmonary bypass (CPB). Indications for a median sternotomy and CPB include significant transverse hypoplasia and the need for repair of a concomitant cardiac lesion such as a ventricular septal defect. Repair through a left thoracotomy requires placement of a cross-clamp just distal to the innominate artery, placing the patient at risk for cerebral hypoperfusion. Some controversy exists regarding the degree of transverse arch hypoplasia necessitating a median sternotomy approach. A recent single-center retrospective study concluded that median sternotomy should be considered for patients with distal transverse arch z-scores lower than −2.8 and proximal transverse arch z-scores lower than -4.1, and that with the left thoracotomy approach there was a low mortality rate, reintervention rate, and incidence of hypertension [104]. Other perioperative complications from surgical repair of coarctation include recurrent laryngeal nerve or phrenic nerve injury, chylothorax, bleeding, and rarely paraplegia (0.4%) [105].

Restenosis after surgical repair of aortic coarctation is not uncommon, with an incidence that varies widely depending

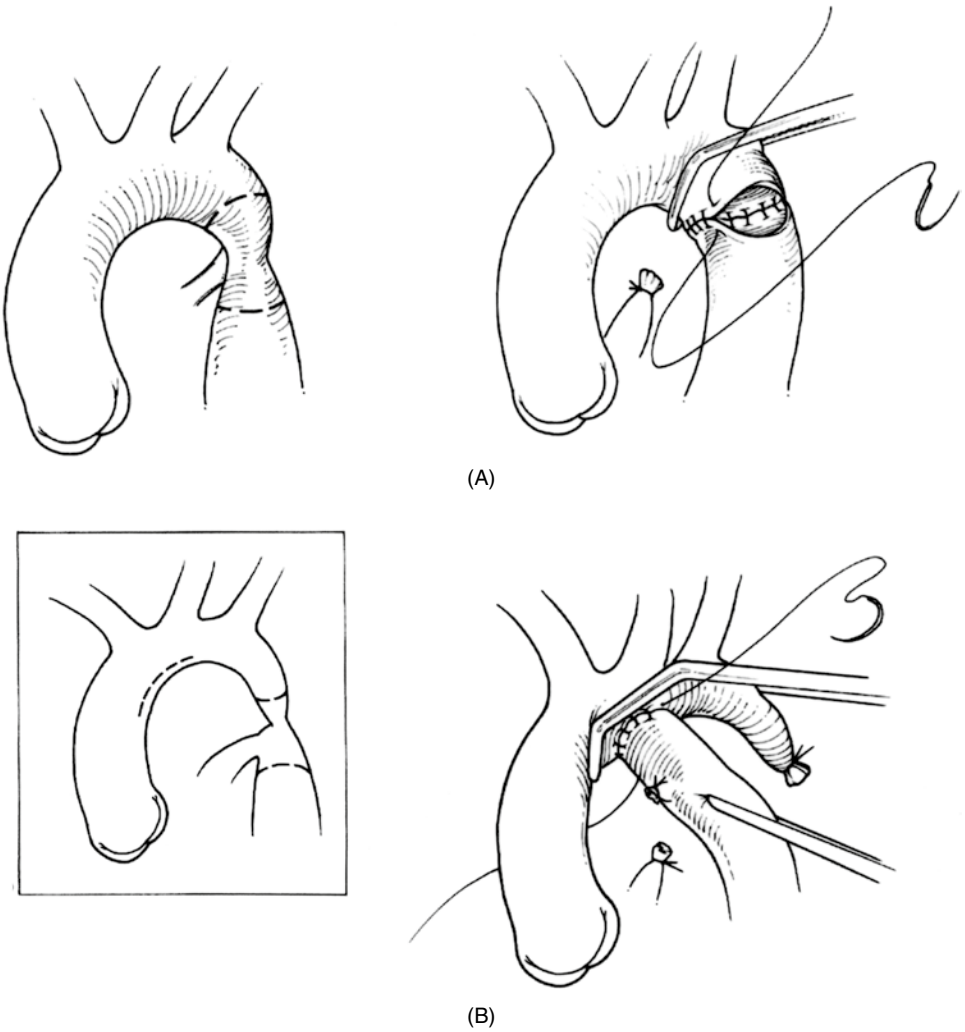

Figure 27.8 Two surgical approaches for repair of coarctation of the aorta. (A) Resection of coarctation with end-to-end anastomosis. (B) End-to-side, or aortic arch advancement technique. (Source: Chang et al. [59]. Reproduced with permission from Wolters Kluwer Health, Inc.)

on the surgical technique, age of patient at time of repair, definition of recurrence, and length of follow-up [106]. A study examining long-term complications in a cohort of patients up to 27 years after repair found a restenosis rate of 11%, with restenosis defined as a systolic brachial–ankle blood pressure difference of greater than 20 mmHg [97]. Earlier studies showed a higher incidence of recoarctation if the operation was performed in the first 3 years of life; the recurrence rate was <3% if performed afterward [107]. A more recent study utilizing MRI in adults that had undergone aortic coarctation repair during childhood found recoarctation and local aneurysm formation in 48 and 21% of patients, respectively [108]. Current surgical techniques emphasizing aggressive excision of ductal tissue and the use of an extended end-to-end anastomosis in the setting of arch hypoplasia may lead to a lower incidence of restenosis. Because of the significant prevalence of hypertension and other long-term sequelae following coarcation repair, many centers aggressively treat even mild recurrent stenosis in the interventional catheterization suite.

The use of balloon angioplasty for initial treatment of discrete aortic coarctation in children frequently provides excellent immediate hemodynamic results [99, 101, 109]. Reluctance to use this approach in some centers is related to concerns about restenosis and aneurysm formation, which occur in 10–20% and 5–10% of patients, respectively [100]. Approximately 25% of children undergoing an initial balloon angioplasty will require a reintervention within 2 years [99, 101]. Balloon angioplasty is generally accepted as the first-line therapy for restenosis following surgical repair of aortic coarctation, providing excellent immediate and long-term results [106, 110, 111]. In approximately 80% of cases, the residual systolic pressure gradient can be reduced to less than 20 mmHg. Repeat balloon angioplasty or surgery is required in about 25% of these patients due to restenosis [106]. Complications related to balloon angioplasty include femoral artery thrombosis, aortic rupture, and stroke. The risk of femoral artery injury is greater in the smaller child. An increased mortality risk has been reported for patients undergoing angioplasty for recurrent coarcation versus native coarctation [110].

Balloon-expandable endovascular stents provide an effective therapy for the treatment of native or recurrent coarctations occurring after surgery or balloon angioplasty

AL Grawany

Note the multiple arterial collaterals (white arrows). (B) Angiogram after stent placement. The systolic gradient was reduced from 30 to 3 mmHg following stent placement. (Source: Robert Beekman, MD. Reproduced with permission.)

[112–115] (Figure 27.9). In a study including 565 procedures from multiple institutions, 97.9% of patients had a successful reduction in the coarctation gradient at the time of the procedure [112]. Stents have been successfully used to treat patients with both discrete coarctation and transverse arch hypoplasia. Intermediate follow-up in patients receiving stents shows that the incidence of restenosis is reduced compared to balloon angioplasty [113–115]. Stents allow for future redilation to a larger size to accommodate the growth of the child. This therapy is limited by the need for a large sheath (8–9 Fr) in the femoral artery, and is thus not utilized in some centers until a child reaches a certain size. Endovascular stents have been placed in smaller children using the carotid artery, thus requiring a surgical procedure to place a sheath in this vessel. Complications related to stent placement include aneurysm formation, aortic dissection, stent migration, balloon rupture, femoral artery injury, and stroke, and may occur in as many as 15% of patients [116]. The use of covered stents, currently investigational in the United States, may decrease the risk of arterial wall injury, particularly in older patients with increased aortic fragility. In a recent single-center study, 56 patients (11–56 years of age) were treated with covered stents for complex coarctation of the aorta with a decrease in the systolic gradient from a mean of approximately 50 to around 5 mmHg [117]. Complications included one patient who was found to have an aortic dissection, which was treated conservatively, and one death during the postoperative period felt to be related to pre-existing left ventricular dysfunction. Redilation of the stent due to a subsequent increase in the gradient was required in four patients.

Anesthetic considerations

The medical management of infants with severe coarctation consists of inotropic support and diuretics. In infants younger than 1 month, intravenous prostaglandin is utilized to reopen the ductus arteriosus. Intubation may be necessary to decrease the work of breathing and reduce left ventricular demand. Metabolic acidosis should be corrected to improve left ventricular function.

The anesthetic management of the patient presenting for surgical repair of coarctation of the aorta should include a right-sided upper extremity arterial catheter in addition to the usual anesthetic monitors. The placement of the right intra-arterial catheter ensures that blood pressure will be monitored during the phase of the operation when the aorta, left carotid artery, and left subclavian artery may be clamped or compressed. The use of cerebral near-infrared spectroscopy (NIRS) for continuous monitoring of bi-hemispheric cerebral oxygenation allows the anesthesiologist to identify cerebral hypoperfusion related to aortic cross-clamp position or inadequate cardiac output [118]. Central venous access may be indicated for initiation of inotropic support.

Induction of anesthesia can be accomplished by either intravenous or inhalational anesthesia; however, in the child with significant ventricular dysfunction, an opioid-based induction may be preferable. The surgical repair is usually performed through a left thoracotomy, and lung retraction can impact ventilation. Single lung ventilation, especially in larger children, can facilitate access to the aorta. (See Chapter 23 for further discussion of single lung ventilation). Close monitoring of arterial blood gases for adequacy of ventilation is vital. Inadequate ventilation causing severe acidosis in a critically ill

neonate can worsen cardiac function and lead to cardiac arrest. There have been reports that infants with a core temperature greater than 38 °C are at an increased risk for spinal cord ischemia. Many centers choose to allow the child to cool to about 34–35 °C in order to protect against this complication [119]. The application of the aortic cross-clamp usually causes upper body hypertension. This increase in arterial blood pressure is important for maintenance of blood flow to the lower body and spinal cord which is reliant on collateral flow that can vary depending on the anatomy of collateral blood vessels and arterial pressure. Some authors advocate for mainting upper extremity blood pressures of 100–120 mmHg in infants and 160–200 in older patients during this clamp period [120]. It is possible that the failing ventricle may be unable to maintain an appropriate cardiac output after cross-clamp placement due to the sudden increase in afterload, in which case an inotropic agent may need to be administered [121]. If myocardial function is adequate, volatile anesthetics can be used to reduce the arterial pressure during aortic cross-clamp. When aortic coarcation repair is performed in older children and adults, some centers advocate for placement of a lower extremity arterial line and maintenance of a mean arterial pressure >45 mmHg. If this pressure cannot be maintained the use of left heart bypass may be indicated. Prior to completion of the vascular anastomosis, the dose of volatile anesthetic is usually reduced and fluid boluses may be administered in anticipation of systemic hypotension following release of the aortic cross-clamp.

The early postoperative period is often complicated by the onset of hypertension, which may be exacerbated in the setting of poor pain control. Greater than one-half of patients who undergo repair of a coarctation experience significant increases in blood pressure for up to 2 weeks [122]. It has been postulated that the increase in blood pressure may be secondary to stimulation of the sympathetic system distal to the anastomotic site, with subsequent increases in plasma renin activity. Untreated hypertension can result in mesenteric arteritis [123]. Hypertension in the acute perioperative period is usually treated with infusions of sodium nitroprusside, nicardipine, or esmolol. Some centers utilize continuous epidural analgesia for control of pain following coarctation repair. Purported benefits of this technique compared with intravenous opioid therapy include better pain and blood pressure control and improved respiratory mechanics. Others avoid epidural analgesia because of the potential for confusion as to etiology in the rare instance of paraplegia after coarctation repair.

KEY POINTS: COARCTATION OF THE AORTA

- Coarctation of the aorta is commonly located immediately distal to the takeoff of the left subclavian artery and may be accompanied by hypoplasia of the transverse aortic arch.
- Neonates with aortic coarctation may present with congestive heart failure due to left ventricular dysfunction and may require inotropic support and mechanical ventilation prior to surgical repair.
- Maintaining myocardial contractility and a higher blood pressure during the aortic repair is important to provide perfusion to the spinal cord and subdiaphragmatic viscera. In older patients invasive monitoring of lower extremity blood pressure may be indicated.
- Patients with a history of repaired aortic coarctation are at an increased risk for systemic hypertension, left ventricular systolic and/or diastolic dysfunction, and coronary artery disease.

Interrupted or hypoplastic aortic arch

Incidence, anatomy, and natural history

An interrupted aortic arch (IAA) exists in about 1% of patients with congenital malformations of the heart. The interruption may be divided into three anatomical variants: type A, which is characterized by a location just distal to the left subclavian artery (25% of IAA); type B, located in the space between the left subclavian artery and the left common carotid artery (70% of IAA); and type C, between the innominate and left common carotid arteries (5% of IAA) [123, 124] (Figure 27.10). The majority of patients with a type B IAA have DiGeorge syndrome (chromosome 22q11.2 deletion) [125]. Common features in the infant with DiGeorge syndrome include hypocalcemia, an absent thymus, and anomalies of the ears, face, and palate.

All types of IAA have a high incidence of associated congenital cardiac anomalies. A VSD is most prevalent and present in greater than 90% of type B interruptions and more than 50% of type A interruptions [126]. The VSD is usually posteriorly malaligned, leading to posterior deviation of the conal septum into the LVOT. Other concomitant cardiac defects include bicuspid aortic valve, truncus arteriosus, transposition of the great arteries, and double outlet right ventricle [127]. LVOT obstruction occurs in as many as 57% of patients with IAA, and is more commonly associated with type B interruption and anomalous right subclavian artery (Table 27.6) [128, 129].

In children born with IAA, the prognosis for survival without surgical intervention is poor, with as many as 90% of patients dying within the first year of life [130]. Those who survive past the first year develop a collateral circulation that allows for adequate lower-body perfusion despite the aortic interruption [131]. Even with surgical intervention during infancy, many children will require subsequent procedures later in life and should be closely followed by a congenital cardiologist [132]. The most common indications for surgical- or catheter-based interventions following IAA repair are aortic arch obstruction and LVOT obstruction [133].

Pathophysiology

Neonates suffering from IAA often remain asymptomatic initially after birth, but over the course of a few days or weeks, they can become precipitously ill following closure of the ductus arteriosus. As the duct constricts, blood flow to the lower body becomes compromised, drastically increasing the risk of shock. Congestive heart failure may develop as a greater proportion of blood flow is directed to the

pulmonary circulation. Rapid diagnosis accompanied by initiation of prostaglandin therapy, treatment of metabolic acidosis, and respiratory and/or myocardial support may be lifesaving. Fetal echocardiography has led to improvements in early diagnosis and a reduction in the number of neonates presenting with circulatory collapse. Unlike the neonate with severe coarctation of the aorta, differential oxygen saturations between the right upper and lower extremities may not be present due to mixing of blood through a VSD.

The diagnosis of IAA can usually be established with TTE, and cardiac catheterization is usually not indicated. MRI and CT angiography have also been used to delineate complex arch anatomy. Careful evaluation for additional cardiac anomalies, including the presence of LVOT obstruction, is important.

Surgical and transcatheter approaches and outcomes

Surgical strategies for treatment have varied. A two-stage approach involving initial repair of the aortic arch through a left thoracotomy accompanied by pulmonary artery banding allows for palliation without the use of CPB. This approach provides only limited exposure of the proximal aorta and does not allow the surgeon to address other coexisting lesions such as LVOT obstruction. A primary one-stage repair using a midline sternotomy and CPB is now favored. This approach provides optimal exposure for aortic arch repair, and the ability to close the VSD and address other associated lesions. One multicenter study suggested that surgical approaches other than direct anastomosis with patch augmentation of the IAA may increase the risk for future aortic arch reintervention [23]. However, a subsequent study reported that 100% of patients required no arch reintervention at 5 years after direct anastomosis without patch augmentation when the descending thoracic aorta was circumferentially mobilized, ductal tissue aggressively excised, and a wide anastomosis made between the descending aorta and the posterior aspect of the distal ascending aorta [134]

In the setting of IAA with VSD and severe LVOT obstruction, an alternative surgical plan may be indicated. Alternative surgical strategies in the setting of severe LVOT obstruction include the Yasui procedure, which combines the interrupted arch repair with a Damus-Kaye-Stansel (DKS) [135]. A VSD patch baffle is utilized to connect the left ventricle to the DKS root and a right ventricle to pulmonary artery conduit is placed to provide pulmonary blood flow (Figure 27.11) [136]. This operation can be performed as the primary repair during the neonatal period or as a staged procedure in which a Norwood operation is the initial surgery. Another alternative strategy is to perform the Ross-Konno procedure as the initial procedure or as subsequent operation for relief of LVOT obstruction.

Until the last decade, major aortic arch surgery required the use of deep hypothermia with circulatory arrest, which may adversely impact long-term neurodevelopmental outcomes [137]. Many centers now use antegrade cerebral (ACP) and myocardial perfusion during arch repair providing continuous delivery of oxygen to the brain and minimizing myocardial ischemic time (see Chapter 11). Over the next decade, studies should elucidate whether these techniques improve survival and reduce long-term morbidities.

Interrupted aortic arch continues to be associated with significant mortality during the perioperative period and subsequent long-term follow-up. A study reporting outcomes from 33 institutions between 1987 and 1997 found an overall survival of 60% at 21 years after initiation of study [132]. One-third of patients in this study required one or more subsequent arch and/or LVOT procedures. Other studies found an overall perioperative mortality rate for procedures done since 1990 of 12%, compared with an overall mortality rate of 42% prior to 1985 [138]. One-month survival of >92% following IAA repair has been reported at a number of centers [128, 134]. Risk factors reported to be associated with increased mortality include low birth weight, type B IAA, other major associated cardiac anomalies, DiGeorge syndrome, LVOT obstruction, and an episode of circulatory collapse prior to repair [23, 127, 134]. Several studies have questioned whether LVOT obstruction is a risk factor for increased operative mortality [130, 134].

Preoperative aortic root size has been shown to predict the need for reintervention for postoperative LVOT obstruction after single-stage repair of IAA with VSD. In a single-center study of 70 patients with IAA and VSD, 23% of patients required a reintervention for LVOT obstruction with a median time to reintervention of 1.2 years [133]. Subaortic resections were performed via a surgical approach, while aortic valve stenosis was treated with aortic balloon valvuloplasty. A recent publication recommended that in neonates with a preoperative aortic valve annulus diameter less than the patient's weight in kilograms, the risk of LVOT obstruction after standard repair is high and some type of LVOT bypass procedure should be considered [139].

Anesthetic considerations

Intravenous access will have been established in the neonate with IAA scheduled for surgery. Induction of general anesthesia is usually accomplished with an opioid and benzodiazepine in combination with a non-depolarizing muscle relaxant. Inhaled anesthetic agents can be safely used as long as blood pressure is closely monitored and maintained. Management of ventilation following anesthetic induction and intubation is aimed toward optimizing systemic cardiac output. The use of a low inspired FiO_2 and avoidance of hyperventilation reduces pulmonary overcirculation. The use of cerebral NIRS can help guide anesthetic management during this period.

The optimal position for placement of the arterial catheter requires careful consideration in the infant with IAA. The right subclavian artery may originate in an anomalous fashion from the descending aorta, especially in a type B IAA with associated subvalvular AS [140]. In one study, 15 of 49 patients with type B IAA had a coexisting anomalous right subclavian artery [128]. In some cases, the left subclavian artery may be utilized during the surgical repair. The use of an umbilical artery catheter is ideal in this setting. In the absence of an anomalous right subclavian artery, some centers prefer to have both a right upper extremity and lower body (UAC or femoral) arterial line. The right upper extremity arterial line allows for monitoring of arterial pressure to help guide flow rate during regional cerebral perfusion (See Chapter 11 for detailed discussion). Central venous access is indicated for the infusion of inotropic agents and monitoring of intracardiac pressures. This can be accomplished by either

AL Grawany

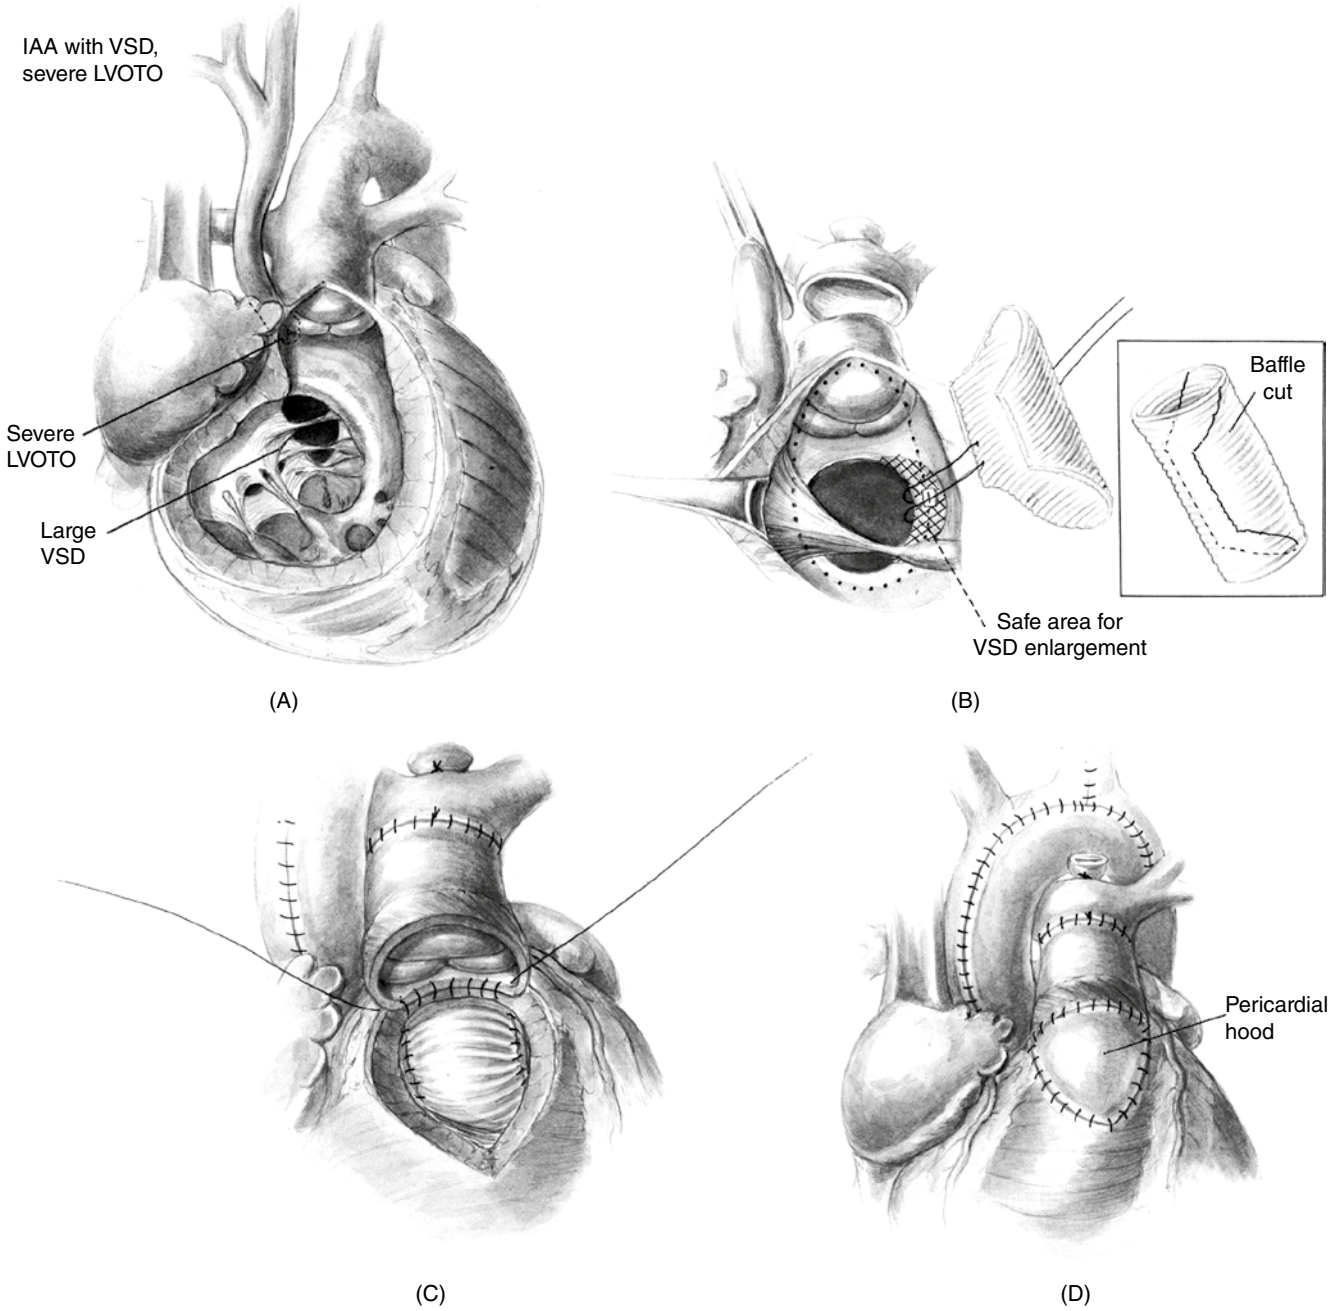

Figure 27.11 Yasui operation. (A) This depicts a cutaway of the anatomy of a patient with type B interrupted aortic arch with severe left ventricular outflow tract obstruction (IAA/LVOTO). Commonly, these patients have aberrant origin of the right subclavian artery from the descending aorta. The left ventricular outflow tract obstruction is both muscular (subvalvular) as well as due to a hypoplastic aortic annulus and ascending aorta. A standard biventricular repair of interrupted aortic arch with VSD, consisting of VSD closure and repair of the arch, could result in significant postrepair left ventricular outflow tract obstruction. Although these patients can be managed with a neonatal Ross-Konno procedure and arch repair, a Yasui operation is a useful alternative. IAA = interrupted aortic arch; LVOTO = left ventricular outflow tract obstruction; VSD = ventricular septal defect. (B) A Hemashield (Boston Scientific, Natick, MA) Dacron graft (usually 10 or 12 mm) is opened longitudinally and trimmed as shown in the inset. This is used to baffle the left ventricular outflow through the VSD to the pulmonary artery. At least half of the circumference of the graft is used to insure a generous unobstructed pathway through the VSD to the pulmonary valve. The superior tip of the baffle is typically at the most anterior portion of the right ventriculotomy and the inferior tip of the baffle is oriented just near the papillary muscle of Lancisi. A continuous 5/0 polypropylene suture is used for the majority of the baffle, keeping well on the right ventricular side of the VSD to avoid the area of the conduction tissue. The portion along the septal leaflet of the tricuspid valve is typically closed with interrupted pledgeted 5/0 polypropylene sutures with the pledgets on the atrial side of the tricuspid valve. This more easily can be done through the right atriotomy. VSD = ventricular septal defect. (C) The superior edge of the right ventriculotomy is sewn to the posterior wall of the proximal homograft with continuous 5/0 polypropylene incorporating the leading edge of the VSD patch into a portion of this anastomosis for hemostasis and security. (D) Right ventricular to homograft continuity is established with a roof of autologous pericardium using contin- uous 5/0 polypropylene to complete the repair. percutaneous catheterization or placement of intracardiac lines by the surgeon prior to separating from CPB. Echocardiography using a pediatric TEE probe can effectively guide inotropic and fluid management, determine the adequacy of VSD closure, and assess the LVOT for any evidence of obstruction. Two intravenous catheters should be placed, as significant blood loss may occur following separation from CPB. The use of deep hypothermia places the infant at higher risk for significant bleeding after CPB; red blood cells, platelets, and cryoprecipate should be available. In the case of the infant with DiGeorge syndrome, the use of irradiated blood is necessary to avoid graft-versus-host reactions [141].

Separation from CPB usually requires inotropic support and close monitoring of serum calcium levels. The infant with DiGeorge syndrome is prone to hypocalcemia and may benefit from a calcium infusion. Once the hemodynamics are stabilized and the bleeding is controlled, sternal closure may be attempted. Inotropic support, fluid management, and ventilation may need to be adjusted at this time. The patient should be closely monitored for pulmonary hypertension following repair and, if present, may benefit from inhaled nitric oxide. Should sternal closure result in unacceptable instability due to a reduction in cardiac output or pulmonary function, a polytetrafluoroethylene patch may be placed over the open chest for subsequent closure in 1–3 days.

KEY POINTS: INTERRUPTED OR HYPOPLASTIC AORTIC ARCH

- 70% are type B (L common carotid-subclavian artery; 90% VSD), 25% type A (distal to L subclavian artery; 50% VSD), 5% type C (innominate-left common carotid)
- Another important associated cardiac finding in the child with an interrupted arch includes LVOT obstruction.
- Neonates with an IAA or severely hypoplastic aortic arch are dependent on patency of the ductus arteriosus for blood flow to major abdominal organs and the lower extremities.
- IAA should be considered a chronic disease for which future interventions on the aortic arch and/or LVOT are common.
- Management of ventilation prior to CPB includes the use of a low inspired FiO_2 and avoidance of hyperventilation to increase pulmonary vascular resistance.

Shone's anomaly

Incidence, anatomy, and natural history

Shone's anomaly (or Shone's complex) consists of a supravalvular mitral ring, parachute deformity of the mitral valve, subvalvular AS, and coarctation of the aorta, and was first described by Shone and colleagues in 1963. This complex of lesions causes multi-level left heart obstruction and is variable in regard to the presence and severity of each lesion [142, 143]. In 30 consecutive patients with Shone's anomaly, 73% had a supravalvular mitral ring, 87% had a parachute mitral valve, 87% had subvalvular AS, and 97% had coarctation of the aorta. Additional lesions also present in these patients were a bicuspid aortic valve (61%) and a VSD (67%) [142]. Hypoplasia of the left ventricle is generally not considered a component of Shone's complex. The parachute mitral valve describes a mitral valve deformity where two mitral valve leaflets are supported by only one papillary muscle and the chordae are usually shortened and thickened [144] (Figure 27.12). Because the mitral leaflets are pulled together in proximity, the mitral valve can become stenotic. The supravalvular ring is a ridge of connective tissue arranged circumferentially on the atrial side of the mitral leaflets. Although this ring does not cause severe obstruction in the majority of cases, fibrous tissue can obtrude into the mitral inflow tract, causing obstruction. Although not classically considered part of Shone's anomaly, "typical" congenital mitral stenosis with a small annular size has been noted in 25–50% of patients with Shone's anomaly in two published series [145, 146]. Subvalvular AS is caused by either a discrete membranous thickening in the outflow tract or a more complex long-segment "tunnel" stenosis. The coarctation is usually located in the descending aorta in proximity to the left subclavian artery.

Cor triatriatum must also be considered in the setting of left-sided obstructive disease. The anomaly is characterized by the pulmonary venous return entering an accessory left-sided chamber that connects with the left atrium through a slender passageway (Figure 27.13). The left atrial appendage and fossa ovalis are always distal to the obstructing membrane. In contrast, a supramitral stenosing ring, when present as part of Shone's complex, leaves the left atrial appendage in connection with the upper portion of the left atrium and proximal to the stenosing formation [147].

The natural history of Shone's anomaly is highly variable and dependent on the severity of the left-sided obstructive lesions and the degree to which the obstructive lesions can be relieved. In particular, the degree of involvement of the left ventricular inflow tract is the major factor, which determines long-term outcome. In a recent study of 45 children with Shone's anomaly, the cumulative survival rate was 70% at 15 years following mitral valve repair, and risk factors for reoperation and mortality included the severity and type of mitral valve abnormalities, LVOT lesions, and pulmonary hypertension [148]. In another large retrospective single-center study which followed 121 patients with Shone's syndrome and a biventricular circulation, the transplant-free survival was 86% [139]. These children required multiple surgical and catheter-based interventions but showed significant left heart growth over the study period.

Pathophysiology

Patient symptoms depend on the anatomic location of the most critical areas of obstruction. As many as two-thirds of patients with Shone's anomaly may present in the neonatal period with an aortic coarctation [146]. Assessment of the hemodynamic significance of lesions causing obstruction of the mitral valve or subaortic region can be very challenging in the context of a ductal-dependent systemic circulation. After the repair of aortic coarctation, these infants are followed closely for signs of congestive heart failure often

AL Grawany

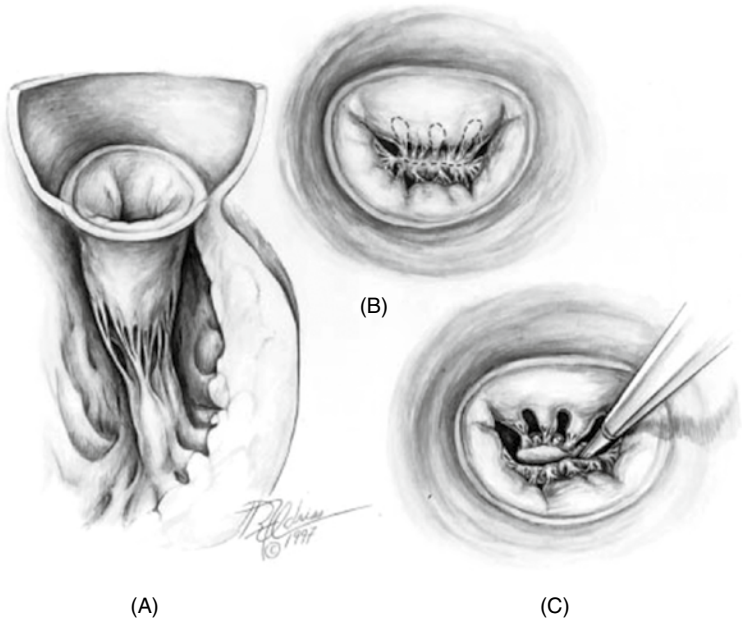

Figure 27.12 Cut-away atrioventricular view (A) and left atrial views (B, C) of a stenotic parachute mitral valve. (A) A single papillary muscle or fused papillary muscles usually arise from the posterior left ventricular wall. (B) The dotted lines show the areas of proposed leaflet fenestrations and papillary muscle incision to open the ven- tricular inlet. (C) Leaflet fenestrations are accomplished to maximize unrestricted blood flow into the left ventricle during diastole while preserving enough valvular tissue for effective coaptation during systole. The fused papillary muscle is being incised to facilitate valvular mobility. (Source: Zias et al. [144]. Reproduced with permission from Elsevier.)

related to mitral valve abnormalities. Subvalvular AS is rarely significant in the neonatal period but can rapidly progress during infancy [47]. Those patients with a high degree of subvalvular AS will develop left ventricular hypertrophy.

Echocardiography and cardiac catheterization with angiography are the primary diagnostic modalities for detecting and defining the extent of the Shone's anomaly [149]. The presence of markedly elevated pulmonary vascular resistance at cardiac catheterization increases perioperative risk and worsens long-term outcome. It is extremely important to be aware of all levels of obstruction, because the intraoperative repair of one obstruction may often reveal other less critical stenoses that continue to impede blood flow. Failure to recognize all levels of obstruction leads to increased perioperative risk for the patient.

Surgical and transcatheter approaches and outcomes

The intracardiac surgical repair generally consists of resection of the supravalvular mitral ring, fenestration of the mitral valve tensor apparatus, repair or replacement of the mitral valve, and resection of any encroaching muscular tissue in the LVOT. When aortic arch obstruction is present, surgical repair of this lesion may be necessary during the neonatal period. Early mitral valve repair is advocated whenever possible, allowing for continued annular growth and avoidance of anticoagulation, and should occur before pulmonary hypertension develops [146]. When subvalvular AS is caused by a discrete membranous lesion, resection is performed through a transaortic approach and accompanied by ventricular septal myectomy, which is felt to reduce the incidence of recurrence [150]. A long-segment "tunnel" type of subvalvular AS is commonly corrected with an aortoventriculoplasty (Konno procedure) [151] (Figure 27.14). The Konno operation is used to augment the left ventricular outflow tract and enlarge the aortic annulus and requires placement of a prosthetic aortic valve or a pulmonary autograft (Ross-Konno) [152] (Figure 27.15). The modified Konno operation is performed when the aortic annulus is normal in size and placement of a prosthetic valve in the aortic position is not necessary [153, 154]. Intraoperative TEE is important for anatomic assessment before CPB and then following surgical repair. Surgical and long-term outcomes for Shone's anomaly depend on the age of

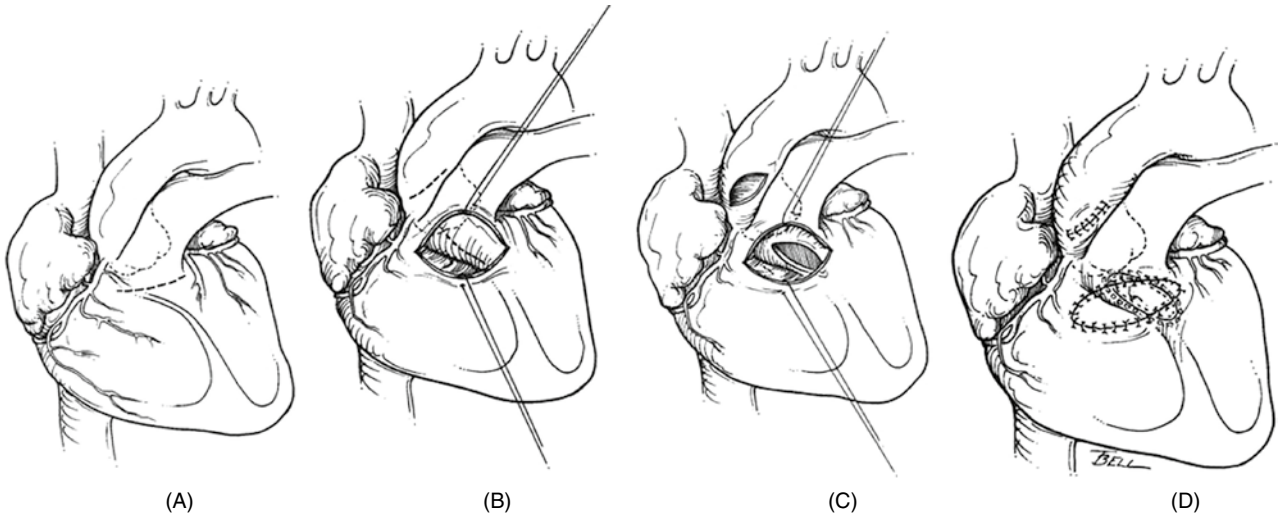

Figure 27.14 The modified Konno operation. (A, B) Incisions are made in the ascending aorta (to assess outflow and protect aortic valve), infundibulum, and conal septum. (C, D) The outflow is enlarged with a polytetrafluoroethylene patch, and the infundibulotomy is also closed with a patch. (Source: Takahashi & Hanzawa [151]. Reproduced with permission from Springer Nature.)

presentation, severity of mitral valve disease, need for multiple surgical procedures, and presence of pulmonary hypertension [142, 145, 146]. Despite an initially satisfactory mitral valve repair, approximately one-half of children with Shone's anomaly will require a subsequent repair or mitral valve replacement [148].

Diagnostic cardiac catheterization is often indicated in patients with Shone's anomaly to better assess the relative hemodynamic significance of multi-level left-sided obstructive lesions and the degree of pulmonary hypertension. Catheter-based interventions may also be indicated to address primary or recurrent aortic arch obstruction.

Anesthetic considerations

The medical management of patients with Shone's complex depends on the location of the most critical stenosis. Neonates with coarctation of the aorta will require prostaglandins to maintain patency of the ductus arteriosus and appropriate ventilatory strategies aimed at reducing pulmonary overcirculation. Children with dynamic LVOT obstruction may require β-blockers to improve intracavitary laminar blood flow. Congestive heart failure is usually treated with diuretics and may require inotropic support. The presence of pulmonary hypertension before or after surgery for relief of a left sided obstructive lesion may require a phosphodiesterase inhibitor (such as milrinone) and nitric oxide [155, 156]. In the presence of a significant left-sided obstructive lesion, the effects of nitric oxide can be variable, and this drug should be used with caution.

The anesthetic management of the patient with Shone's anomaly requires an appreciation of all levels of stenosis and knowledge of the location of the dominant lesion. A patient with predominantly mitral stenosis requires sufficient preload to maintain left atrial pressure, and a normal to slow heart rate to optimize ventricular filling during diastole. In the patient primarily suffering from subvalvular AS and left ventricular hypertrophy, arterial pressure needs to be maintained for optimal myocardial perfusion. An anesthetic plan carefully tailored to meet these hemodynamic goals is vital for optimal outcome.

KEY POINTS: SHONE'S ANOMALY

- Shone's anomaly consists of multiple left-sided obstructive lesions, including a supravalvular mitral ring, parachute deformity of the mitral valve, subaortic stenosis, and coarctation of the aorta.
- The presence of multiple levels of obstruction can make assessment of the degree of obstruction at each level extremely challenging.
- Important principles of anesthetic management include maintaining sufficient preload, a normal to slow heart rate to optimize ventricular filling, and maintaining arterial blood pressure to assure optimal myocardial perfusion.

Mitral stenosis

Incidence, anatomy, and natural history

Mitral stenosis is most often observed as a component of a complex left-sided malformation syndrome, i.e., Shone's anomaly. Isolated congenital mitral valve stenosis is a rare lesion, occurring in well less than 1% of infants with CHD and a normal-sized left ventricle [157]. The anatomical complexity of the mitral valve and its supporting apparatus, the papillary muscles and chordae tendineae, have led to several complicated schemata to describe abnormalities of the mitral valve [157–159]. One functional classification of mitral stenosis anatomy divides this lesion into type A, with a normal papillary muscle, which includes commissural fusion, a

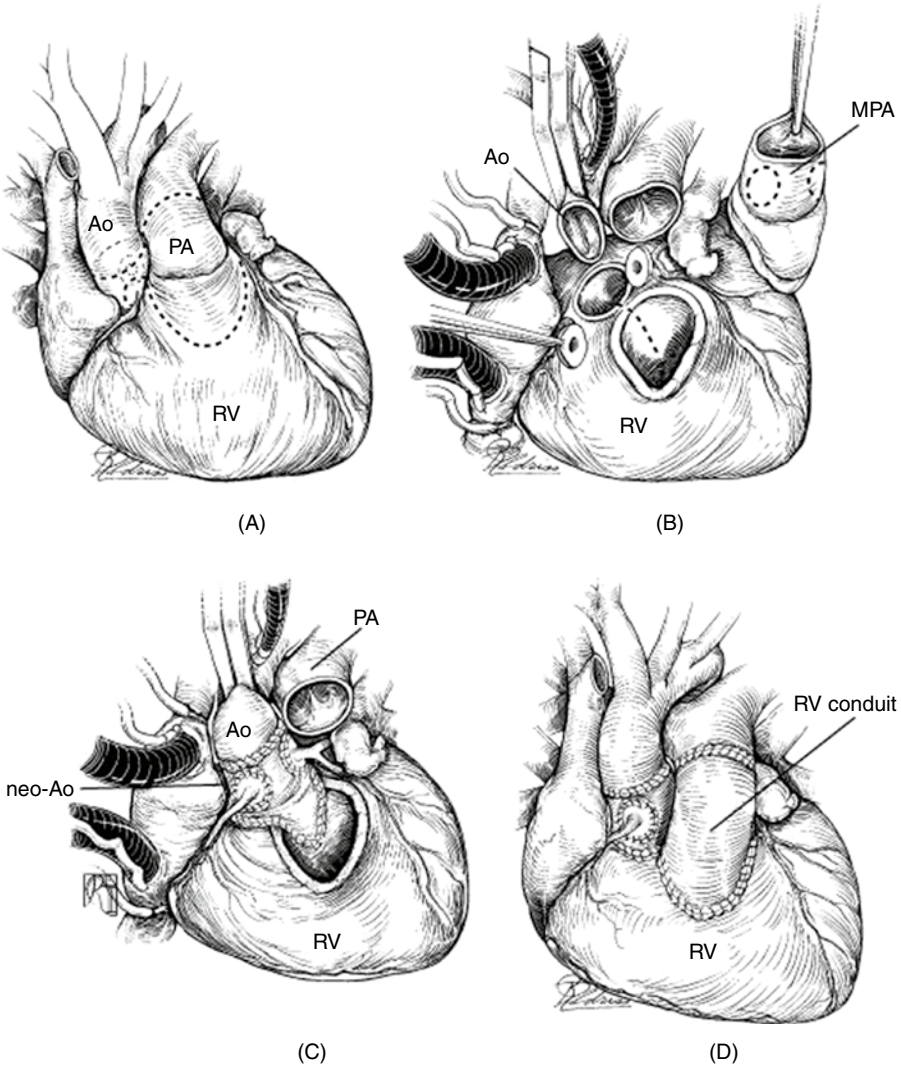

Figure 27.15 Ross-Konno operation. (A) Intended incision and excision boundaries en route to the Ross-Konno Procedure. (B) After aortic cross-clamping, antegrade and retrograde cardioplegic arrest, aortic resection, coronary mobilization, and main pulmonary artery harvest, the inter ventricular incision is noted by the dotted line. The pulmonary autograft was harvested, with an extra portion of right ventricle to be used for the ventriculoseptoplasty part of this operation. (C) The neoaortic left ventricular outflow recontruction is shown using the pulmonary autograft extension into the interventricular septum ("apron extension"). (D) The completed Ross-Konno procedure is shown after separation from cardiopulmonary bypasss. Ao, aorta, aortic; MPA, main pulmonary artery; PA, pulmonary artery; RV right ventricle. valvular or supravalvular ring, or an obstructive left superior vena cava, and type B, which consists of an abnormal papillary muscle producing a parachute, or a hammock mitral valve. [159]. The natural history of mitral valve stenosis is dependent on the severity of the stenosis and the feasibility of repair or replacement.

Pathophysiology

Depending on the degree of mitral stenosis, a progressive elevation in left atrial pressure can lead to pulmonary venous and then pulmonary arterial hypertension. This can result in interstitial pulmonary edema, "cardiac asthma," frequent respiratory infections, tachypnea, poor feeding and poor growth. Significant pulmonary hypertension will be accompanied by elevated right ventricular pressures, right ventricular hypertrophy, and potentially diminished function. Left-sided cardiac output will be restricted by diminution of blood flow into the left ventricle. A resultant tachycardia shortens diastolic filling time and can severely depress systemic cardiac output. Hypovolemia reduces left ventricular end-diastolic volume and pressure, worsening the functional mitral stenosis. In patients with elevated pulmonary artery pressure and resistance, maneuvers to reduce PVR may paradoxically worsen the obstructive pulmonary symptoms by promoting increased pulmonary blood flow in the face of a fixed downstream obstruction. A frequently dilated left atrium predisposes to atrial arrhythmias such as atrial flutter, atrial fibrillation, or atrial tachycardia.

Anatomical diagnosis of mitral stenosis is often based solely on echocardiographic findings. Three-dimensional echocardiography is particularly useful in defining the morphological complexity of the diseased mitral valve and its use is increasingly widespread [160, 161]. Decisions about

intervening are made on the basis of increasing clinical symptomatology, such as frequent respiratory infections and failure to thrive despite optimal medical management.

Surgical and transcatheter approaches and outcomes

When surgery is indicated, most congenital heart surgeons adopt a conservative approach, repairing the stenotic valve whenever possible [162]. There are a number of techniques employed, including resection of a supravalvular ring, commissurotomy, division or reconstruction of the papillary muscles, and reconstruction of the chordae tendineae [159, 162]. The main goal of surgery is to reduce the mitral stenosis without producing mitral regurgitation; the surgeon will often perform a test of the repair with the aorta cross-clamped by rapidly instilling saline solution through the repaired valve to produce a normal end-diastolic volume. Retention of this volume in the left ventricle signifies lack of significant mitral regurgitation. After separation from bypass, TEE is critical in assessing the adequacy of repair and the need for returning on bypass to improve the surgical result. Because of the potential morbidity from anticoagulation and the need for future replacement as a child grows, mitral valve replacement is performed only as a last resort in young children, when attempts at repair have failed. However, when a mitral valve repair cannot be successfully performed in these patients, a supra-annular mitral valve replacement may be necessary in infants because of the small size of the annulus. Surgical outcomes are dependent on the specific abnormality and the feasibility of repair. The need for mitral valve replacement increases the risk of both short- and long-term complications. In some cases, interventional catheter approaches have been successfully used to dilate a stenotic mitral valve [163].

Anesthetic considerations

Hemodynamic goals in mitral stenosis include maintaining a low-normal heart rate to enhance diastolic filling time for the left ventricle and maintaining preload to minimize the functional stenosis across the valve. Preserving ventricular contractility and afterload are important goals of any technique. Maintaining normal sinus rhythm is critical; therefore, prompt recognition and treatment of atrial dysrhythmias are important. With severe mitral stenosis, the patient will have significant pulmonary hypertension and care must be taken not to induce a pulmonary hypertensive crisis, e.g., due to a large catecholamine surge secondary to inadequate anesthetic depth. On the other hand, acutely lowering PVR with excessive FiO_2 and hyperventilation will promote excessive pulmonary blood flow, often leading to worsening pulmonary function due to the fixed downstream obstruction at the level of the mitral valve.

During surgical repair, the left side of the heart will by necessity be opened, and there is the potential for retention of significant air in the heart during weaning from bypass. Accordingly, prolonged cardiac de-airing maneuvers, assisted by TEE, may be required. Some surgeons will insufflate CO_2 into the surgical field to improve the dissolution of any gas retained in the left side of the heart [164].

After bypass, a left atrial and possibly a pulmonary artery catheter may be placed by the surgeon. It is important to realize that pulmonary artery pressures may not be immediately reduced, and treatment with adequate depth of anesthesia and analgesia, milrinone, nitric oxide, high FiO_2, and mild hyperventilation may be required for hours or days. Left atrial pressure should decrease with successful mitral valve repair in the face of normal left ventricular function. TEE is crucial to assess the immediate results of the surgical repair.

Cor triatriatum

Cor triatriatum is a rare anomaly seen in about 0.1% of patients with CHD, consisting of a membrane or diaphragm in the left atrium, functionally dividing it into two chambers, where the pulmonary veins enter superior to the membrane [165] (Figure 27.13). Blood flows from the upper to the lower left atrial chamber through one or more orifices, and the patient's symptoms and presentation depend on the degree of restriction of blood flow through these orifices, and can range from completely asymptomatic to severely restricted blood flow. This may result in severe left atrial hypertension, pulmonary venous and arterial hypertension, and low cardiac output, similar to that seen in severe mitral stenosis. Pulmonary symptoms such as wheezing are prominent and may be the only presenting complaint [166]. Most patients present in the first year of life, and 24–80% have associated cardiac anomalies such as anomalous pulmonary venous drainage, left superior vena cava, or HLHS. The surgical approach consists of resecting the membrane in the left atrium and repairing associated defects. Anesthetic considerations are identical to those for the patient with mitral stenosis.

KEY POINTS: MITRAL STENOSIS/COR TRIATRIATUM

- Hemodynamic goals include slow-normal heart rate, and maintenance of normal sinus rhythm and adequate preload and afterload.
- Severe obstruction from these lesions can result in significant left atrial hypertension, and pulmonary venous and arterial hypertension, which may need to be managed with inhaled nitric oxide after surgical repair.
- In the face of severe obstruction pre-bypass, nitric oxide and other maneuvers to decrease PVR can worsen the problems because they do not address the anatomic obstruction.

Introduction

Right-sided obstructive congenital heart disease (CHD) is extremely variable in presentation – both in severity and clinical signs and symptoms. In some cases, severe cyanosis and/or congestive heart failure (CHF) is immediately apparent in a neonate, whereas in other cases, a teenager or adult may present with mild complaints of fatigue or reduced exercise ability. Variations in the extent of malformations in the right heart and great vessels dictate the severity and timing of presentation. All right-sided obstructive diseases can cause right-to-left shunting of blood flow.

Obstruction to blood flow in the right heart can result from malformations at a single anatomical area, such as the right atrioventricular (AV) valve, or multiple structural sites, as found in the tetralogy of Fallot (TOF). Failure of tissue formation and coordinated growth leads to poor development of valvar structures and incomplete septation of the right heart from the left. Impairment of normal hemodynamic blood pressures and flows from structural anomalies adds further malformations such as chamber dilation or hypertrophy as well as abnormal blood vessel growth and formation.

Right-to-left shunting is present in patients who manifest cyanotic right-sided obstructive heart disease. Examples include deoxygenated blood passing to the left heart via a patent foramen ovale (PFO) or atrial septal defect (ASD) as might be found with severe Ebstein anomaly (EA) or a ventricular septal defect (VSD) in TOF. Those patients who do not present with neonatal cyanosis may manifest periodic cyanosis from variations in shunt direction, depending on the relative pressures between the right and left chambers of the heart. When right heart pressures are higher than left, the right-sided hypertension can be partially relieved by the right-to-left blood flow when septal defects are present. With severely restrictive septal defects, inadequate relief of right-sided hypertension manifests with CHF.

The degree of neonatal systemic hypoxemia that accompanies right-sided obstruction is also dependent on the patency

AL Grawany

of the ductus arteriosus. Pulmonary blood flow (PBF) in the presence of severe obstructions of the right heart, such as with critical pulmonary stenosis (PS) or pulmonary atresia (PA), might be entirely dependent on a patent ductus arteriosus (PDA). Affected neonates can rapidly show signs of increasing hypoxemia, such as respiratory distress and deepening cyanosis when the ductus arteriosus begins to close shortly after birth unless the ductal patency is stabilized with exogenous prostaglandin E_1 (PGE_1).

Congenital malformations that impede blood flow through the right heart can occur at a single critical anatomical area or a combination of areas. These include the right AV valve, the outflow tract of the right ventricle (RV), the pulmonary valve (PV), and the main pulmonary artery (MPA) and/or branch pulmonary arteries (BPAs). Commonly, congenital malformations affect several of these critical areas simultaneously, such as in TOF. Malformations can occur directly as a result of aberrant movement of tissues during development or indirectly as a result of impaired flow hemodynamics due to misaligned structural anatomy. Often the resultant congenital heart deformity is a combination of both processes.

The physiology of right-sided obstructive defects and the changes that occur with palliative or reparative intervention in the context of perioperative anesthetic care and planning for such patients are described in this chapter for:

- EA
- TOF
- PS with intact ventricular septum (PS/IVS)
- PA with intact ventricular septum (PA/IVS)
- PA and VSD with major aortopulmonary collateral arteries (MAPCAs).

Other right-sided obstructions such as those that result in a single functional ventricle (e.g. tricuspid atresia) are covered elsewhere in this book. See Chapter 30.

Ebstein anomaly

Incidence, anatomy, and natural history

Although EA occurs in only 0.3–0.7% of CHD, it is the most common congenital malformation of the tricuspid valve (TV) [1]. The incidence is approximately 1/10,000 live births [2]. EA was first described by Ebstein in 1866 [3] from necropsy findings. Clinical diagnosis was not achieved until 1949 [4] because the clinical presentation of more severe cases with diminished PBF and cyanosis resembled TOF, and partial competence of the malformed TV often was enough to prevent signs of CHF until late in evolution of the disease [5]. EA is characterized by a malformed TV and RV [6] (Table 28.1). With advent of cardiac catheterization and echocardiography, cardiologists were much more able to diagnose EA with certainty.

The highly varied range of dysplastic characteristics of EA causes extreme variations in clinical presentation from the neonate to the adult [7–9] (Figures 28.1–28.2, Table 28.1). The septal and posterior leaflets vary in the apical displacement of their attachments, and in approximately one third of cases the septal and/or posterior leaflets may remain adherent to the ventricular myocardium due to a failure of delamination. The anterior leaflet is attached at the functional annulus in a position superior to the other leaflets, but it is morphologically abnormal. Large with apparent redundant tissue, the leaflet frequently appears sail-shaped, often with fenestrations, and with abnormal RV attachments at the boundary of the inlet and trabecular areas. The anterior leaflet and/or the shortened chordae/dysplastic papillary muscles can restrict blood flow from the atrium/atrialized RV to the trabecular RV. Slits or perforations in the abnormally fixed anterior leaflet can be a significant obstruction. The shortened chordae extend from dysplastic papillary muscles. The trabecular RV is small, and sometimes very small, lacking an inlet chamber. Trabecular RV myocardial function can be normal or impaired with thin walls. An interatrial shunt is almost invariably present as over one third will have an ASD and most of the remainder will have a PFO.

Table 28.1 Characteristics of the malformed tricuspid valve and right ventricle in Ebstein anomaly

- The septal and posterior leaflets of the tricuspid valve fail to separate from the underlying myocardium
- The functional annulus of the tricuspid valve is displaced toward the apex; the septal leaflet is most displaced followed by lesser displacement of the posterior leaflet and least displacement of the anterior leaflet.
- The anterior leaflet is large with redundant tissue, often with fenestrations, and is tethered.
- A portion of the right ventricle located below the right coronary sulcus and above the functional but displaced annulus (the "atrialized" right ventricle) is dilated with an often thin and dysplastic freewall.
- There is dilation of the atrioventricular junction, the location of the true tricuspid valve annulus.

The line formed at the site of the distally displaced tricuspid leaflets serves as a functional TV ring and is the boundary between the trabecular and atrialized portions of the RV (Figure 28.3). Above this line of the distally displaced TV leaflets, the inlet portion of the anatomical RV serves as part of the RA. The atrialized portion of the RV is often thin and dilated with an abnormal ventricular electrical conduction pattern. Extreme thinning of the atrialized or inlet RV wall causes it to exhibit paradoxical movement with ventricular systole and dilation with RA contraction. The RA is dilated and sometimes massively dilated. The dilation of the atrialized RV creates an abnormal position for the interventricular septum, compromising left ventricular (LV) geometry and reducing the size of the LV chamber. There is increased fibrosis in both ventricles.

On prenatal ultrasound screening, the most severe forms of EA present with hydrops fetalis characterized by a massively enlarged heart and pulmonary hypoplasia. Lesser affected infants will have a neonatal course dependent on the severity of the EA defects, ranging from asymptomatic to cyanosis of varying degrees. Cyanotic neonates with severe obstruction will show signs of CHF that could lead to death. In general, cyanotic neonates with EA require intervention for survival. For lesser affected infants, the clinical presentation ranges from asymptomatic to progressive CHF depending on the degree of apical displacement of the TV. Diagnosis

is sometimes delayed until symptoms present in older children or young adults, and less commonly in middle age or later. Generally, exercise tolerance is minimally impaired in the mildly affected unless the foramen ovale is not patent. Adults who present with CHF from long-term effects of tricuspid regurgitation (TR) have a poor prognosis without definitive intervention. Severity cyanosis in children and young adults with EA is associated with a poor prognosis. Even milder forms of EA that present in late childhood, adolescence, or young adulthood often result in death from CHF in the second and third decades of life without surgical intervention. For those asymptomatic individuals who have not developed CHF, up to 20% may die of atrial and ventricular arrhythmias, sometimes as a sudden death. Paradoxical emboli, abscess formation, and less commonly endocarditis contribute to later fatalities [10].

Pathophysiology

The TR of EA and the degree of downward displacement of the TV variably impair adequate development of the heart. Diminished flow through the RV *in utero* may play a role in the development of right ventricular outflow tract obstruction (RVOTO), PS, and even PA. Significant TR places a volume load on the RV that results in a largely dilated RV that impairs LV function. Severe TR produces a massively ballooned RA. As pulmonary vascular resistance (PVR) decreases and stabilizes to near adult values, forward flow in the neonatal right heart can cause EA signs to improve [11, 12]. A cyanotic neonate with an unrestrictive ASD may eventually become acyanotic with acceptable cardiac output (CO). However, an infant with a restrictive ASD can have a low CO due to LV impairment from malposition of the interventricular septum with paradoxical motion.

The distortion of atrial and ventricular chambers with EA is associated with arrhythmias that can further impair function and be life-threatening. As many as 25–30% of individuals will have atrial flutter, atrial fibrillation and paroxysmal supraventricular tachycardia. Other electrophysiological abnormalities are also frequently present [1] (Table 28.2).

Familial genetically inherited forms of EA are sometimes associated with LV noncompaction cardiomyopathy. In fact, the type of CHD most associated with this myopathy is EA. This combination is associated with mutations in the B-myosin heavy chain gene MYH7. Although autosomal dominant, gene penetrance is variable as some individuals do not have cardiac abnormalities [13]. Characteristics of LV noncompaction include prominent trabeculations with deep intratrabecular recesses that give the LV a spongy appearance on cardiac ultrasonography. Added risks of CHF, arrhythmias, thromboemboli, and sudden cardiac death occur with this combination [14]. Recent genetic analyses of patients with EA suggest multiple genetic associations with genes involved with myocardial development or function other than MYH7 including NKX2-5, TTN, MYH6 as well as a number of various single nucleotide alterations, genetic locus deletions/duplications and copy number variants [15] not infrequently associated with cardiomyopathies.

Table 28.2 Major electrophysiologic abnormalities in Ebstein anomaly

- Intra-atrial conduction disturbance: right atrial P-wave abnormalities, PR prolongation
- Atrioventricular nodal conduction: PR interval prolongation
- Infranodal conduction
  - Intra-His or infra-His conduction abnormalities
  - Right bundle branch block
  - Bizarre *second* QRS attached to preceding normal QRS
- Type B Wolff–Parkinson–White pre-excitation
- Supraventricular tachycardia
- Atrial fibrillation or flutter
- Arrhythmogenic atrialized right ventricle
- Deep Q waves in Leads V_{1-4} and in inferior leads

Progressive right heart failure resulting from TR, an inadequately sized RV pumping chamber, and other right-sided obstruction combined with the EA TV are sometimes indications for surgery in the infant or child. Otherwise, moderate CHF can be treated with diuretic therapy, perhaps combined with digoxin. Medical therapy and perhaps catheter ablation can be used to control some types of arrhythmias. However, if deterioration of the TV and RV appears progressive, long-term outcome will be improved with earlier surgical intervention [16].

Surgical and transcatheter approaches and outcomes

The timing of intervention for EA is determined by the degree of apical displacement of the functional TV, the competency of the TV, the presence of PA or circular shunting, and the age of the patient (Figure 28.4). Depending on the size of the trabecular RV, patients may undergo two ventricle repair or be palliated with one-and-one-half (1.5) or single ventricle surgical pathways. Timing of intervention in neonates also takes into account potential RVOTO and allowance for PVR to resolve to near adult pressures. Only the most severely compromised infants are generally considered for cardiac transplantation [11] such as those with poor biventricular function and/or uncontrollable arrhythmias. Decision-making for the type of surgical repair or palliation depends first on the age of the patient and secondly on two key elements: the TV morphology and the size of the trabeculated RV (Figure 28.5). A number of infants with adequate trabecular RVs have successfully undergone two ventricular repairs.

In 1958 after studying EA heart specimens, Hunter and Lillehei [17] suggested a potential repair for the TV but advances in valvuloplasty ultimately led to the first successful EA TV repair in 1963 [18]. From 1972 onward, further refinements in valvuloplasty by Danielson et al. [19] and others have improved survival for patients with EA (Table 28.3).

Techniques for valvuloplasty of the EA TV have evolved for nearly 60 years. A technique introduced in 1972 altered the anterior leaflet of the TV such that it would approximate

Table 28.3 Developments in the treatment of Ebstein anomaly

- Valvuloplasty techniques
  - Improved TV coaptation, decreasing TR
  - Relocation of the TV to the true, and often remodeled annulus
  - Centralized flow in the remodeled TV with less impedance
  - Delamination of valve tissue attached to RV wall or septum
  - Use of the cone technique for those valves with suitable TV tissue
  - Stabilization of the true TV annulus with rings and partial rings
- Improvements in functional RV morphology by employing plication techniques to the atrialized RV
- Advances in electrophysiological ablation technology with improved success in ablating accessory conduction pathways

the ventricular septum or the small, malformed septal leaflet during systole. Coaptation of the TV was facilitated by plicating the TV annulus at the apical boundary of the atrialized RV to reduce annulus diameter [19]. Further modifications for mobilizing and fixing the anterior and posterior leaflets at the true tricuspid annulus while utilizing a valve ring ensued [9]. Some infants with adequately sized RVs have done well with an aggressive two-ventricle repair that included reconstruction of a monocuspid TV from the anterior leaflet with or without translocation of the leaflets to the true annulus, ventriculorrhaphy, reduction atrioplasty, subtotal closure of the ASD, and repair of other associated defects [20]. Others have focused on a bicuspid TV repair without repositioning the valve to the true annulus [21].

Building on a previous technique, da Silva et al. [22] developed a method known as the cone reconstruction that enhances available valve tissue by surgically delaminating leaflets attached to the RV wall and septum. The cone reconstruction of the TV for EA began to be developed in 1989 and has evolved to become a successful option for patients with adequate available valvar tissue and trabecular RV chambers. The TV leaflets are mobilized and reattached to the true TV annulus. The anterior and posterior leaflets are sutured together into a cone shape, incorporating the septal leaflet into the cone when possible. The atrialized RV is longitudinally plicated. Flexible annuloplasty rings (partial rings for children to allow for growth) are sometimes used to add stability to the dilated TV annulus [23] (Figure 28.6). Although cone reconstruction has been successful

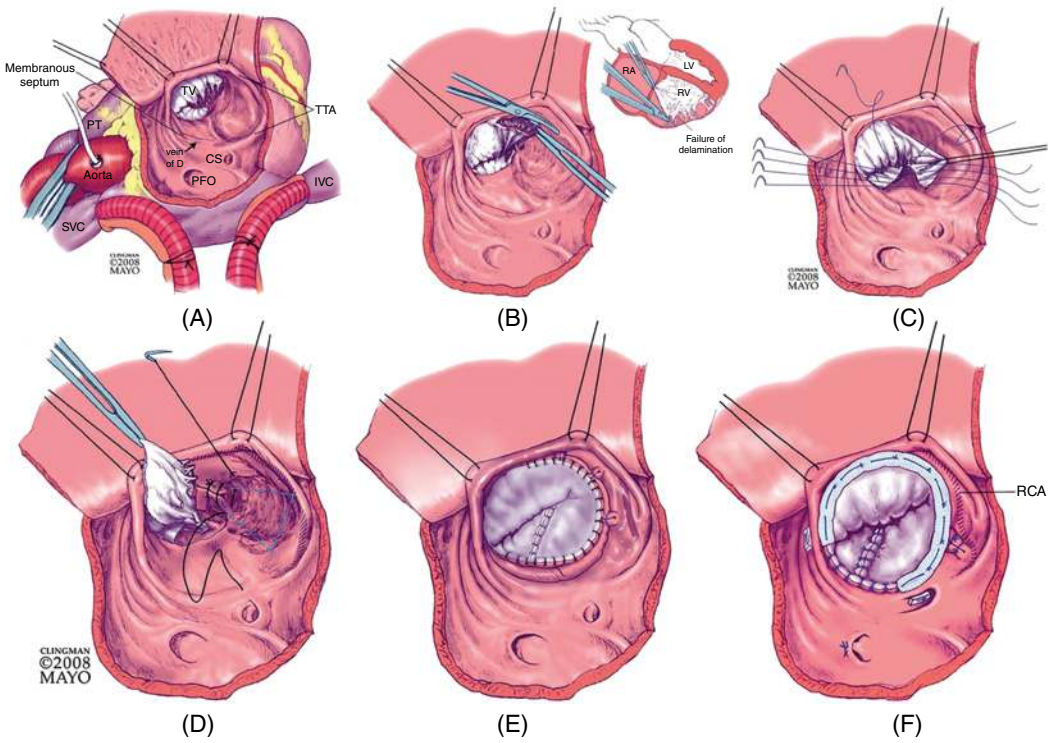

Figure 28.6 Key components of the cone repair. (A) Standard aortic and bicaval cannulation. Right atriotomy is parallel to the atrioventricular (AV) groove. Anatomic examination of the tricuspid valve (TV) and the atrialized right ventricle (RV). Membranous septum and AV node are marked by small vein (vein of D). (B) Delamination of the TV. First incision is made at 12 o'clock in the anterior leaflet a few millimetres away from the true annulus. Surgical delamination is the division of the fibrous and muscular attachments between the body of the leaflet(s) and the free wall of the RV. Delamination must continue to all attachments between the AV groove and the leading edge of the leaflets (close to the RV apex) while keeping the attachments at the leading edge of the leaflet intact. (C) Rotation of leaflet tissue. Following mobilization of all leaflet tissue, the inferior leaflet, or most medial aspect of the anterior leaflet, is rotated clockwise to meet the mobilized septal leaflet. These leaflets are approximated with suture. At completion, the neo-TV orifice should be composed of 360° of leaflet tissue. Prior to reattachment, the atrialized RV is examined to determine need for RV plication. (D) RV plication. Internal triangular plication of portions of the atrialized RV reduces tension on the repair, reduces size of the TV annulus, and eliminates noncontractile RV. Plication is started close to the RV apex and proceeds to the AV groove. Care must be taken to avoid injury to the right coronary artery. (E) Attachment of neo-TV to the true annulus. The septal leaflet is reattached to the ventricular septum (just caudal/ventricular side of the true annulus). (F) Repair can be reinforced with either a felt band (in younger children) or an annuloplasty band (older children and adults). CS, coronary sinus; IVC, inferior vena cava; LV, left ventricle; PFO, patent foramen ovale; RA, right atrium; RCA, right coronary artery; SVC, superior vena cava; TTA, true tricuspid annulus. Figure 28.7 Tricuspid valve (TV) leaflet augmentations for the cone repair. Leaflet augmentation can be accomplished with either autologous pericardium or CorMatrix membrane to increase the height of the anterior TV leaflet (A) or to increase the TV diameter at the annulus (B). When there is a linear attachment of the leading edge of the anterior TV leaflet to the right ventricular endocardium, autologous neochordae can be fabricated with surgical fenestrations (C). (Source: Dearani et al. [29]. Reproduced with permission of Elsevier.)

in neonates [24, 25] and small infants [26], valve rings are not an option for these small patients. When tissue is found to be insufficient, leaflets can be augmented with patch material [27, 28] (Figure 28.7). The cone operation improves coaptation of the TV leaflets and allows for centralized flow.

Utilization of a semi-functional RV by combining RV output to the MPA from the inferior vena cava (IVC) with a bidirectional Glenn (BDG) anastomosis in a 1.5 ventricular repair can be beneficial. Compared to patients converted to single ventricle physiology, 1.5 ventricular pulsatile flow to the pulmonary arterial tree might reduce MAPCA development while inclusion of hepatic venous flow to the pulmonary arterial tree might reduce formation of pulmonary arteriovenous malformations. Even a hypoplastic RV may increase CO with increased cardiac demand beyond what could occur with a Fontan circulation. The BDG can be used to reduce RV preload to hypoplastic EA RVs or those with moderate degrees of TV stenosis, allowing for closure of a coexisting ASD or PFO.

In some cases of severe EA, there may be no identifiable TV leaflet tissue available for reconstruction. In the absence of available leaflet tissue combined with a severely dilated dysfunctional RV and secondary LV compression, a fenestrated RV exclusion procedure with a systemic-to-pulmonary arterial shunt may be the best option for an infant [30]. The modified Starnes procedure is accomplished by placing a patch with a 5 mm fenestration at the level of the true tricuspid annulus while allowing the coronary sinus to remain on the RA side of the patch. The fenestration allows for thebesian venous drainage from the excluded RV to the RA. If there is pulmonary arterial insufficiency, the RV to pulmonary connection is interrupted. As with all single ventricle palliations, an unrestricted atrial communication is ensured. Later, the infant or child may advance to a BDG or Fontan palliation. A limited follow-up for 12 patients has shown that the RV involutes sufficiently to allow improved geometry and function of the single LV [31]. The Sano RV exclusion technique [32] for EA is similar but employs an RV to pulmonary artery conduit rather than a systemic-to-pulmonary shunt to provide PBF. The advantage of the modified Starnes procedure over the Sano RV exclusion technique is that the already reduced functional RV myocardium is less compromised without the ventriculotomy required for the RV to pulmonary artery conduit.

Complications of the cone procedure are similar to other TV repairs for EA. Inadvertent tricuspid stenosis or suture dehiscence are possible. Sutures too near the AV node can cause third-degree heart block. Distortion caused by plication of the atrialized RV and TV annulus can impair right coronary artery blood flow. Outcomes are compromised when neonatal EA is associated with RVOTO, PA, small pulmonary arteries, or any congenital disease that causes LV dysfunction.

Rhythm disturbances can occur at any time with EA. Temporary pacing wires should be placed on the RA and RV near the conclusion of surgery as postoperative pacing could be necessary. Generally, teenaged and adult patients who do not require postoperative pacemakers have fewer rhythm disturbances on follow up [33]. Wolff-Parkinson-white accessory pathways, often near the orifice of the TV, are present in 10–20% of EA.

Outcome studies are limited for the cone reconstruction. A follow-up of 52 patients ranging in age from 0.25 to 49 years (mean 18.5 ± 13.8 years) showed that the cone repair maintained its integrity and there was an increase in RV function relative to body surface area indexing. Two of the 52 died postoperatively in-hospital and one was lost to follow up resulting in a statistical survival of 86.2 ± 8%f at 7 years. Of the followed 49, four underwent TV revision (3, 4, 5, and 10 years postoperatively), one received a pacemaker for intermittent episodes of complete AV block 1 year after surgery, three had atrial arrhythmias (one successfully ablated and the other two medically controlled). Eleven had Wolff-Parkinson-White syndrome and had the anomalous bundle surgically sectioned; ten were successful and one had repeated ablations, developed TR, and then underwent TV revision 5 years postoperatively [34].

A single institution review of 151 EA patients with a mean age of 28 years (56 patients less than 18 years of age) who underwent either cone reconstruction (n = 38, age 31 ± 19 years), conventional repairs (n = 94, age 26 ± 18 years), or TV replacement (n = 19, age 36 ± 21 years) presented mid-term follow up comparisons for cone repair, conventional repairs, and TV replacement. Cardiopulmonary bypass (CPB) times as well as aortic cross clamp times were longer for cone repairs than either conventional repairs or TV replacement. Cone repair was more successful than conventional repairs at mid-term follow up (8 years) with moderate or less TR (p = 0.031) and a reduced incidence of post-repair severe TR that did not reach clinical significance. Of note, most of the cone repairs were performed more recently than many of the conventional repairs [35].

AL Grawany

In the largest series to date from the Mayo Clinic [28], 235 consecutive cone repairs for patients with EA and a median age of 15 years (range 6 months to 73 years) showed only one early death of a 50-year-old from low CO syndrome related to endocarditis from pacemaker leads. Extracorporeal membrane oxygenation (ECMO) was needed for the one adult early mortality patient and for 5 pediatric patients with severe preoperative RV dysfunction and dilation. Cone repair was the primary correction in 80% and a re-repair in 12%. Early reoperation for recurrent TR occurred in 5.9% (7 children and 7 adults). TV replacement was ultimately required for 6/7 adults, but 6/7 children had a successful reoperation. Of those requiring reoperation, 11 of the 14 were in the first third of the series, suggesting a learning curve for a successful cone repair. Supplemental techniques were used in many, including the BDG anastomosis in approximately 20% (41 children and 5 adults), annuloplasty bands, leaflet augmentation, and use of neochordae.

In general, TV replacement is reserved for irreparable TV and RV anatomy as reoperation and repeat cardiotomy for TV replacements will likely be necessary for the patient's lifetime. In addition, options for prosthetic valves are limited or non-available for small infants and children. Some teenaged or adult patients with late diagnoses might have incurred TV leaflet damage from turbulent blood flow or endocarditis that preclude successful repair, and TV replacement may be the best option. For select patients such as the elderly, TV replacement might be considered if advantages of lessened CPB time outweigh the longer time needed for TV repair. Bioprosthetic valves are preferable in the tricuspid position due to their lower thrombogenicity over mechanical valves. When placing the prosthetic TV, care is exercised in avoiding the conduction system on the septal side and the right coronary artery on the anterior and inferior sides of the implanted TV as well as avoiding the right ventricular outflow tract (RVOT) and impingement of the valve struts on the AV node. Similar considerations will apply to future development of percutaneous TV replacement.

Older children and adults with preoperative paroxysmal atrial fibrillation or atrial flutter might be candidates for a modified right-sided maze procedure or cavotricuspid isthmus ablation using either radiofrequency or cryoablation [23] (Figure 28.8). Those with continuous atrial fibrillation may do better with a biatrial maze [36].

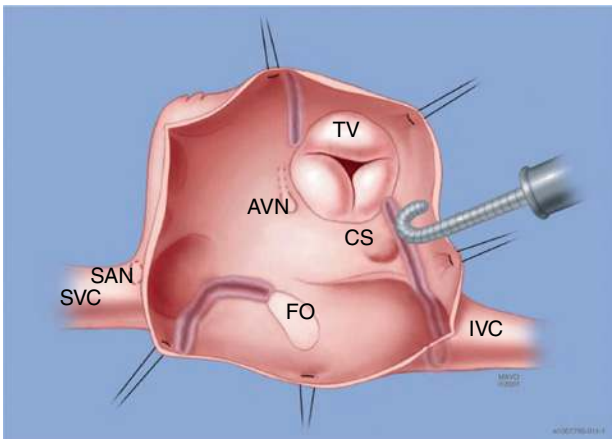

Figure 28.8 Cryoablation for atrial flutter/fibrillation in Ebstein anomaly. Anesthetic considerations

Preoperative

For neonatal presentation of EA, signs of right heart failure and systemic hypoxemia are most critical. Dyspnea, cyanosis, and hepatomegaly suggest that the infant should be supported such that demands on CO and oxygen consumption are minimized. The most severely affected infants benefit from intubation, mechanical ventilation, paralysis, and sedation to reduce work of breathing and demands on CO. Oxygen, inhaled nitric oxide (iNO, if pulmonary hypertension is suspected), inotropic support, and possibly PGE_1 may increase oxygen delivery. For the less affected infant, signs of fatigue with feeding, feeding intolerance, irritability, diaphoresis, dyspnea, and episodic cyanosis with distress suggest a poorly functioning heart. Oxygen, milrinone, and possible PGE_1 may be beneficial prior to anesthesia. Some neonates will manifest a gradual improvement in right heart forward flow and a reduction in right-to-left shunting and cyanosis as TR declines. Neonatal surgical intervention, when possible, is delayed until PVR has declined significantly.

For the toddler, older child, adolescent, or even young adult, functional symptoms of dyspnea with exertion, excessive fatigue with daily activities or as compared to peers, and certainly signs of cyanosis as well as the trends in symptomatology in recent months give some insight into the severity of EA. In the older child and young adult, syncope, chest pain, and palpitations should be investigated for the presence of arrhythmias.

Physical examination often reveals a soft, high-pitched systolic murmur, sometimes accompanied by triple or even quadruple heart sounds. A mid-diastolic murmur is sometimes found at the left sternal border and apical areas and has a soft, scratchy sound. A persistently split-second heart sound due to delayed emptying of the RV is usually present and varies little with respiration. Pediatric patients with myocardial failure are diaphoretic, tachypneic, and irritable. Chest auscultation can be notable for rales if LV function is impaired by a dilated RV. Abdominal examination often reveals hepatomegaly on palpation. Moderate to severe cardiomegaly is found on the chest radiograph, and pulmonary vascularity is reduced. The silhouette of the heart is globular due to the enlarged RA. In fact, the electrocardiogram (ECG) usually shows an increased duration for the P-wave suggesting right atrial enlargement, an increased PR interval, and not unusually a complete or incomplete right bundle branch block. In at least 10–15% of patients, the pre-excitation patterns of Wolff-Parkinson-White syndrome are present. An echocardiogram is usually diagnostic for EA, showing a large TV orifice with apical displacement of the septal leaflet [29] (Figure 28.9). Cardiac catheterization is seldom useful, even for the most commonly associated defects, and place the patient at risk for development of tachyarrhythmias. Magnetic resonance imaging (MRI) can be valuable in estimation of the size of the functional RV and accurately

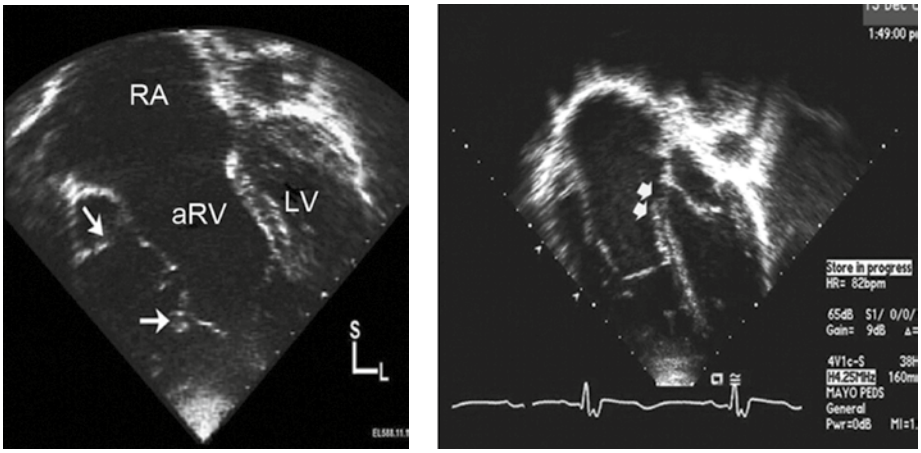

Figure 28.9 Preoperative four-chamber view echocardiogram evaluation for potential cone repair. (A) Multiple attachments between the anterior leaflet and the RV free wall from base to apex (arrows). (B) The undelaminated septal leaflet (arrows) suggests that this leaflet tissue can be recovered increasing the chances for a successful repair. aRV, atrialized right ventricle; LV, left ventricle; RA, right atrium. (Source: Dearani et al. [29]. Reproduced with permission of Elsevier.)

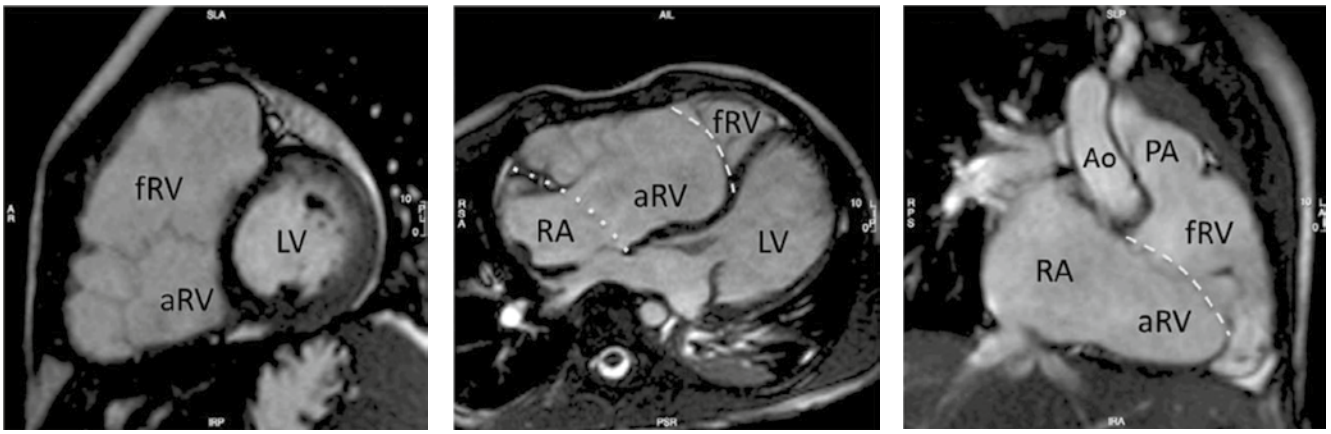

Figure 28.10 Cardiac magnetic resonance imaging of Ebstein anomaly. (A) Short-axis plan at mid-ventricular level. (B) Four-chamber view. (C) Right ventricular inflow-outflow view. The atrioventricular junction (dotted line) and the functional tricuspid valve orifice (dashed line) define the basal and apical boundaries (respectively) of the atrialized right ventricle (aRV). The functional right ventricle (fRV) lies between the dashed line and the pulmonary valve. The anatomic RV includes both the aRV and fRV. The tricuspid valve functional orifice is rotated apically and superiorly towards the RV outflow tract. Ao, aorta; LV, left ventricle; PA, pulmonary artery; RA, right atrium. (Source: Holst et al. [23]. Reproduced with permission of Mayo Foundation for Medical Education and Research.)

measuring the displacement of the TV leaflets (Figure 28.10). Though both MRI and echocardiography are useful in detecting associated defects, echocardiography may underestimate the degree of TR but is more effective in detecting small shunts from associated defects than MRI [37].

Hypoxemic neonates should be managed with interventions aimed to decrease and avoid increasing PVR. For the mechanically ventilated neonate, adequate tidal volumes and minute ventilation must be achieved with minimum airway pressures. Those infants with marginal heart function may benefit from iNO by reducing PVR and enhancing right heart to pulmonary artery flow. In addition, functional and anatomical obstructive components to PBF may be further defined by the addition of iNO as poor right heart function is anticipated to improve with iNO while anatomical obstructions in the RVOT, PV, and PAs will remain. In the first couple weeks after birth, pulmonary arterial blood flow may require augmentation with a PDA maintained with PGE_1. However, too much flow through a large PDA can result in cardiac failure and loss of systemic and pulmonary perfusion with a phenomenon known as "circular shunt" [38] (Figure 28.11). Circular shunt results when generous flow to the pulmonary arterial system from the aorta via the PDA follows a retrograde path of least resistance when the PV and TV are incompetent and there is an interatrial communication. Sequentially, flow proceeds from the PDA, BPA, MPA, PV, RV, RA, ASD or PFO, LA, LV, and finally the aorta. Perfusion of the pulmonary capillary bed is diminished and

AL Grawany

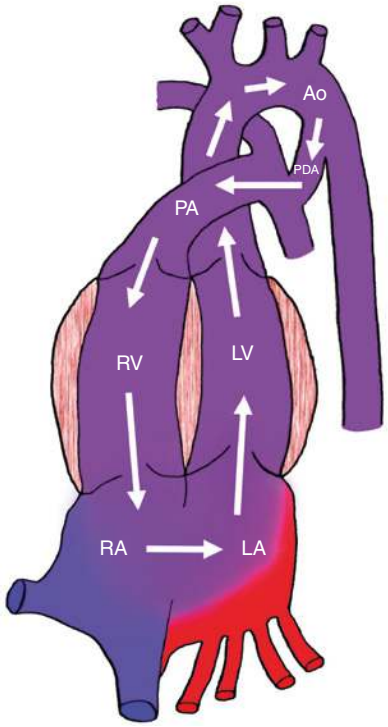

Figure 28.11 Circular shunt: aortic blood enters the lower pressure pulmonary artery (PA) via the patent ductus arteriosus (PDA). Pulmonary insufficiency allows blood to continue retrograde into the right ventricle (RV), right atrium (RA), left atrium (LA), left ventricle (LV), and then again to the aorta (Ao). (Source: Schmitz et al. [38]. Reproduced with permission of John Wiley & Sons.)

CO to the vital organs is reduced. PGE_1 should be discontinued so that the PDA becomes smaller and more resistant to flow, reducing the circular shunt and high output failure [12].

Most neonates and young infants may not require anxiolytic premedication. Older infants, those who have developed stranger anxiety (approximately 9 months of age), and children often benefit from anxiolytic administration of midazolam. Midazolam may be given orally (0.5–0.75 mg/kg up to 15–20 mg) or intravenously (IV) (0.1–0.15 mg/kg up to 2–4 mg). Anxiolysis can be helpful in reducing or avoiding decreases in PBF that can result with crying or breath-holding during application of the mask anesthetic. In some cases, a sleeping child who has received dexmedetomidine can be safely transported and undergo a safe anesthetic induction, but this technique requires planning. Loading with 0.5 to 1.0 μg/kg IV over 10 minutes is often sufficient but requires monitored attention for potential bradycardia. For patients who do not yet have IV access and are to undergo a mask anesthetic induction or merely have a non-stimulating procedure (such as a sedated transthoracic echocardiogram), intranasal dexmedetomidine is administered with a nasal atomizer (2–3 μg/kg, 100 μg/mL) often results in adequate sedation. The time required for mean onset of sufficient sedation is 10–24 minutes for 3 μg/kg [39]. Reducing ambient light and background noise while ensuring that the child is warm and comfortable facilitates the sedative effect. Relative contraindications for dexmedetomidine include poor CO, hypovolemia, bradycardia or risk for bradycardia, AV nodal block, or medications that delay AV conduction or increase vagal tone [40].

Intraoperative

An inhalational induction with nitrous oxide and sevoflurane is appropriate for infants and children with mild to moderate EA. Inhalational induction is slowed by interatrial left-to-right shunting as well as by decreased CO. Ketamine (1–4 mg/kg) or propofol (1–2 mg/kg) are IV induction alternatives for mild to moderate disease. For those with severe EA, hemodynamic stability is maintained in a euvolemic patient in most instances with IV ketamine (1–4 mg/kg) or etomidate (0.2–0.3 mg/kg) without inducing detrimental myocardial depression or afterload reduction.

Sufficient right heart preload must be maintained to maximize the EA right heart forward flow. As the anesthetic progresses, increases in vascular compliance are accommodated with replacement of intravascular volume, such as 5% albumin, crystalloid solutions, or in the anemic patient, packed red blood cells (PRBC). Muscle relaxants are selected based on the anticipated duration of the procedure and the occasional need for a modified rapid-sequence induction. Rocuronium offers quick action for induction and intubation (0.6–1.2 mg/kg) as well as subsequent maintenance of muscle relaxation (0.1–0.2 mg/kg every 20–30 minutes). Pancuronium is another option with a longer duration of action (0.06–0.1 mg/kg for induction and approximately 0.01–0.02 mg/kg for redosing). Both muscle relaxants induce ganglionic blockade and vagolysis, effecting a higher baseline heart rate. For CPB cases, opioid-based anesthetics combined with modest levels of potent inhalation agents such as sevoflurane or isoflurane are common. The relative balance of opioids and inhalation anesthetic is based on the patient's ability to tolerate the myocardial depressant effects of higher ranges of inhaled halogenated agents and the plan for early versus delayed liberation from mechanical ventilation. For patients that will remain intubated with mechanical ventilation after arrival to the intensive care unit (ICU), fentanyl 10–15 μg/kg and 0.5–1.0 minimum alveolar concentrations (MAC) of halogenated agent may be used prior to CPB with a total fentanyl of perhaps 20–30 μg/kg combined with a morphine infusion of 30–35 μg/kg/hour started at the time of incision. If extubation in the operating room is anticipated, total fentanyl administration is approximately 10–20 μg/kg and halogenated agents are utilized at higher MAC as tolerated. A morphine infusion of 25 μg/kg/hour is started by the time of incision. For infants beyond the neonatal period, sedation with dexmedetomidine at 0.5 μg/kg/hour is added for sedation management in the postoperative period whether extubated in the operating room or later in the ICU. Plasmin–binding inhibitor antifibrinolytic drugs such as epsilon-aminocaproic acid or tranexamic acid infused during surgery and in the immediate postoperative period can reduce overall blood loss.

Monitoring for rhythm changes, especially tachyarrhythmias in EA, can be accomplished with a five-lead ECG and monitoring capable of displaying multiple tracings to facilitate identification of the arrhythmia. ST monitoring is helpful in identifying EA post-repair right coronary artery compromise which may be identified by ST elevation in leads II, III,

or AVF or reciprocal depression in I or AVL. Sometimes, temporary AV pacing may be necessary when complete heart block, junctional rhythms, or sinus node dysfunction present after removal of the aortic cross clamp in order to achieve hemodynamic function sufficient to separate from CPB. Depending upon the etiology of the rhythm disturbance, temporary pacing could be needed for a brief period after cessation of CPB, several hours, several days, or until a permanent pacemaker is placed. Other useful monitoring includes near-infrared spectroscopy (NIRS) for monitoring brain and somatic oxygenation, especially during the nonpulsatile flow of CPB. Near the end of CPB, intraoperative transesophageal echocardiography (TEE) is used to assess clearance of air bubbles in the systemic heart chambers, reconstructed TV function, ventricular contractility, and residual shunts in the immediate post-CPB period. Transcranial Doppler (TCD) flow velocity is not commonly utilized due to the technical difficulty in maintaining its positioning on the patient, but it has the ability to follow changes in cerebral blood flow velocities in unilateral or bilateral anterior and/or middle cerebral arteries during surgery. The TCD can also be used to detect gaseous or particulate emboli that enter the cerebral circulation.

Patients with good biventricular function and mild TR can be candidates for immediate extubation at the end of surgery provided that the rhythm is normal sinus or stable in a paced mode and there are no concerns for postoperative surgical bleeding. Inhaled halogenated anesthetics are utilized primarily after CPB, and muscle relaxant and opioids employed sparingly. After the sternum is closed, reversal of muscle relaxation and initiation of pressure-supported ventilation can begin. Adjunctive IV acetaminophen can be used to decrease opioid requirements at the end of surgery. Additional opioids can be titrated to the respiratory rate as surgical stimulation decreases and inhaled halogenated agents are weaned. Local analgesia administered by the surgery team decreases narcotic requirements at the end of the case. Dexmedetomidine sedation (0.3–0.5 μg/kg/hour) and morphine infusion (25 μg/kg/hour for extubated patients and 30–35 μg/kg/hour for mechanically ventilated patients) are continued upon transfer of the extubated patient to the ICU.

High risk patients, such as those who presented with severely dilated right hearts and compressed LVs, are not candidates for extubation in the OR. In addition to higher needs for inotropic support, such patients are at high risk for lethal ventricular arrhythmias in the post-repair period, especially if they have undergone RV plication. Antiarrhythmic medications such as lidocaine and amiodarone need to remain readily available. Patients who manifest runs of ventricular tachycardia or other ventricular arrhythmias should be placed on amiodarone (3–5 mg/kg over 30 minutes, then 2 mg/kg/day, maximum 20 mg/kg/day or 2.1 g/day) or lidocaine (20–50 μg/kg/min) infusions in the early postoperative period. Prophylactic amiodarone infusions may be considered for patients who present with severe right heart cardiomegaly. Right heart forward flow can be augmented with infusions of milrinone (0.2–0.5 μg/kg/min) and low-dose epinephrine 0.02–0.04 μg/kg/min. Preload to the right heart must be fastidiously maintained for a poorly functioning RV. In cases with elevated pulmonary vascular resistance, iNO can be instituted. Leaving the sternum open in highest risk patients facilitates access for ECMO in the case of cardiovascular collapse due to arrythmias, low cardiac output, or pulmonary hypertension.

Postoperative

In the ICU, continuous monitoring of the heart rhythm and arterial blood pressure is essential. Intravascular volume expansion options need to be readily available. Often, there may be post-CPB papillary muscle dysfunction, possibly of ischemic etiology. Early ICU echocardiography can show poor coaptation of the TV leaflets, but as the papillary muscle bundle dysfunction resolves, later echocardiographic examinations can show improving TV leaflet coaptation.

Pain is controlled with morphine infusions of 25–30 μg/kg/hour for extubated opioid-naïve patients and 30–40 μg/kg/hour for mechanically ventilated opioid-naïve patients. Dexmedetomidine 0.3–0.5 μg/kg/hour is used for sedation rather than relying on narcotic infusions for sedation. For the patients with poorly functioning RVs, gradual recovery from sedation is appropriate to allow for recovery of myocardial function prior to increased CO demands of the fully awake patient. Morphine boluses (20 μg/kg) can be added for breakthrough pain, and dexmedetomidine boluses of 0.5 μg/kg over 10 minutes or lorazepam (0.05–0.1 mg/kg IV every 6 hours) can be added for periodic needs of additional sedation, especially for patients who remain intubated and mechanically ventilated.

Rhythm disturbances are common in the early post-repair periods and in some instances extend as a late complication. Operative recovery can be complicated by supraventricular tachycardia, AV block (intermittent or persistent), and junctional rhythm. Temporary pacing enhances CO for patients with AV block or junctional rhythm in the early postoperative period. A return of normal sinus rhythm can result as myocardial edema resolves and cardiac conduction pathways recover. Ventricular arrhythmias and the risk for sudden death is greatest in the first month after repair with those patients who had perioperative ventricular tachycardia or ventricular fibrillation being at enhanced risk [41]. High-risk patients who have had intermittent ventricular arrhythmias during their early ICU recovery and were treated with IV lidocaine or amiodarone infusions might benefit from continuing oral amiodarone for several months after surgery.

KEY POINTS: EBSTEIN ANOMALY

- Gradually, cyanosis and PBF will improve in symptomatic neonates as PVR decreases.
- Depending on the potential for functional remodelling and relocation of the TV to the true annulus and the adequacy of RV morphology, EA may be remedied by a biventricular repair for less severe forms or palliated with a 1.5 or single-ventricle physiology for more severely affected individuals.
- Patients with extreme cardiomegaly or perioperative ventricular arrhythmias should receive prophylactic antiarrhythmic treatment, such as amiodarone.
- Patients with poorly functioning RVs are dependent upon high filling pressures to maintain adequate CO.

AL Grawany

Tetralogy of Fallot

Incidence, anatomy, and natural history

TOF is the most common cyanotic congenital heart disease with an estimated incidence of 1 in 2,500–3,000 live births [2]. Although reports of this abnormality can be dated back to 1671, it was Etienne Fallot in 1888 who reported the four cardinal distinguishing features and proposed clinicopathophysiologic correlations derived from extensive clinical and postmortem studies. This "blue malady or cardiac cyanosis" as Fallot referred it, was named "tetralogy of Fallot" in 1924 by Maude Abbott [42].

The first surgical treatment for TOF occurred in 1945, when the first Blalock-Taussig shunt (BTS) was performed. The tetrad of TOF consists of (Figure 28.12):

1. RVOT obstruction
2. A large unrestrictive VSD
3. Overriding aorta
4. RV hypertrophy

One embryologic theory states that TOF results from uneven conotruncal spiral septation leading to a smaller MPA and a larger aorta. Another theory, van Praagh's, suggests that the TOF stems from one abnormality – the underdevelopment of the subpulmonary infundibulum (infundibulum means "funnel" in latin). The hypoplastic infundibulum, in turn, affects the surrounding structures as follows: (i) the conoseptum is deviated anterior and leftward contributing to obstruction to flow, (ii) the aorta is shifted rightward over the ventricular septum facing the VSD and facilitates flow of the ejected RV blood into the systemic circulation, (iii) a VSD results from the malaligned conoseptal tissue failing to join the remainder of the ventricular septum, and (iv) postnatal RV muscle hypertrophy develops from cumulative work against the higher pressure load imposed by a stenotic outflow tract and systemic pressure transmitted across the VSD. The phenotype of TOF with PS varies from patient to patient. Although no two TOF cardiac anatomies are the same, physiologically they follow similar guiding precepts for management. Of note, the normal RV of a newborn infant has similar thickness to the LV because of exposure to systemic pressures. As normal cardiac development progresses, the RV becomes thinner relative to the LV as a result of their markedly different afterloads.

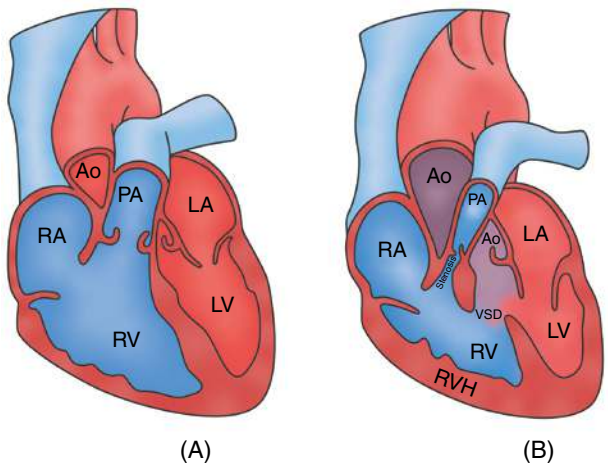

Figure 28.12 Schematic illustration of tetralogy of Fallot. (A) Normal heart. (B) Tetralogy of Fallot demonstrating right ventricle infundibular stenosis (Stenosis), ventricular septal defect (VSD), overriding aorta (Ao), and right ventricular hypertrophy (RVH). LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle. (Source: Michael L. Schmitz, MD.)

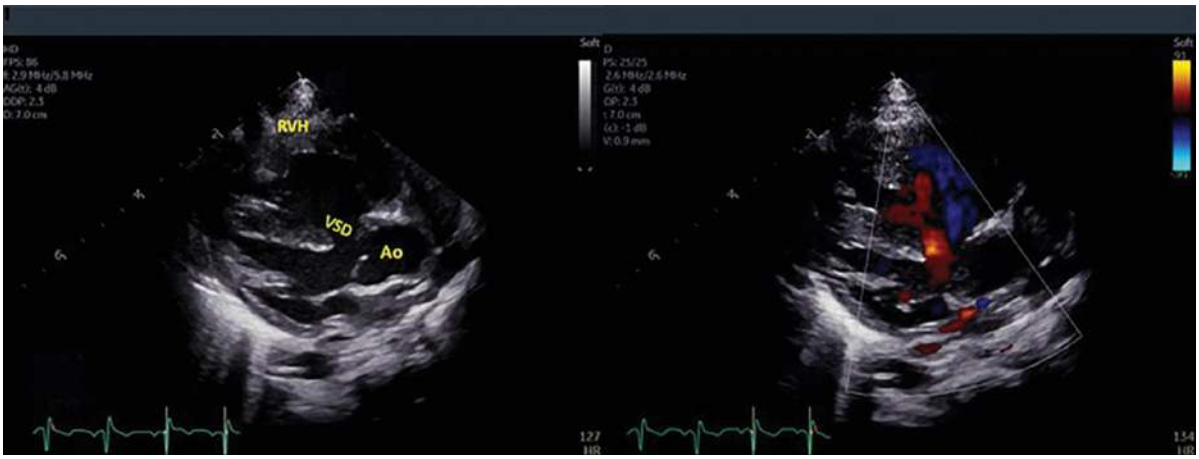
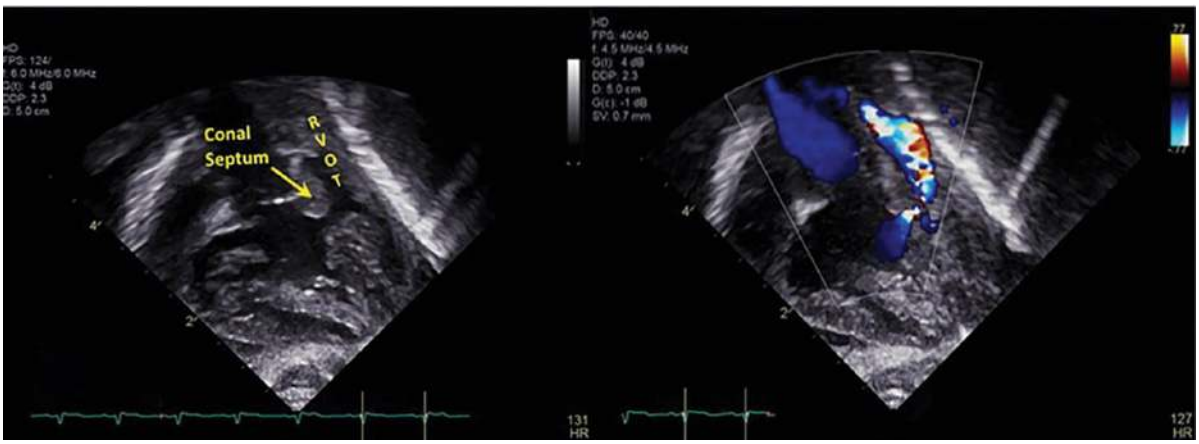


In TOF, the RVOTO often occurs at several levels and has fixed and dynamic components. The fixed obstructions occur at the valvar and supravalvar levels. At the valvar level, the pulmonary annulus is frequently hypoplastic with a bicuspid valve that contains dysplastic leaflets. At the supravalvar level, hypoplasia of the MPA can be localized at the sinotubular ridge or be diffuse and extend into the BPAs. The RVOTO dynamic component comes from the hypertrophied subvalvar muscle bundles. The hypertrophy develops over time in response to the increased pressure load. This dynamic component is thought to play a major role during hypercyanotic episodes associated with TOF. The VSD is usually large and unrestrictive. The bundle of His courses at the posteroinferior edge of the defect, near the anteroseptal leaflet of the tricuspid valve, and can be inadvertently injured during VSD closure [43, 44] (Figures 28.12–28.14).

Other cardiac anomalies associated with TOF are found in about 40% of patients, and they have implications for the optimal surgical repair strategy [44–56] (Table 28.4). Also, anatomical variations influence surgical conduct, e.g. degree of aortic override and location of conoseptum determine the patch size to close the VSD and baffle the LV flow to the aorta [57].



Unique TOF variants include TOF with PA/VSD/MAPCAS (7%) and TOF with absent PV (5%) [58, 59]:

- In TOF with PA/VSD/MAPCAS, total lack of blood throughput leads to severe underdevelopment of the MPA and peripheral pulmonary artery branches such that the MPA may be completely absent, and the BPAs are hypoplastic, non-confluent or even non-existent. MAPCAs often develop to supply blood flow to the lungs. The lungs often show aberrant arborization, unless that side is supplied by a PDA. Some lung lobes have blood supply via BPAs, MAPCAs or both. The surgical approach to this variant varies significantly from that of classic TOF and is described later in this chapter.
- In TOF with absent PV, the PV is ring-like with valve cusp remnants which lead to both stenosis and free pulmonary insufficiency (PI). The MPA, BPAs, and distant peripheral pulmonary arteries are massively dilated, causing compression of the associated airway. The ductus is often absent. Significant tracheobronchial malacia, often with compression, is characteristic of this condition. In severe cases, the newborn presents in respiratory distress and often requires endotracheal intubation with high levels of positive end-expiratory pressure (PEEP) to improve airway patency and decrease air trapping. Prone positioning can also be useful in respiratory management. During surgical repair, the TEE probe has been known to compress the large airways and worsen obstruction. Postoperatively, many patients require long-term ventilatory management due to persistent tracheobronchomalacia and lung disease.

Typically, TOF presents as an isolated lesion, although in 15–30% of patients TOF can present with other abnormalities

AL Grawany

Table 28.4 Cardiac anomalies associated with tetralogy of Fallot and their implications

	Description	Frequency	Surgical Significance	Other Considerations
Coronary artery anomalies	Anomalous and variant coronary artery anatomy can limit options for RVOT patch placement	4.3% anomalous coronary artery (usually the LAD), 6% have a variant infundibular artery originating from RCA crossing the RVOT (Total 10.3%)	Presence of coronary artery over RVOT limits options for RVOT patch and may require RV to PA conduit placement	Direct visual inspection prior to RVOT incision. TTE is usually an adequate primary survey. CT scan can be definitive.
Pulmonary Valve	Frequently bicuspid with thickened leaflets tethered to the pulmonary artery wall	Over 50% are bicuspid	Pulmonary surgical valvotomy for relief of stenosis	Usually, valve will re-stenose after balloon valvuloplasty
Multiple VSDs	Can occur in multiple locations, generally in the muscular septum	5–14%	Suture placement can damage the conduction system. When multiple VSDs are present some may be missed, leading to repeat CPB run to close hemodynamically significant VSDs.	Residual VSDs can result in continued postoperative pulmonary overcirculation. Most muscular VSDs close spontaneously.
Discontinuous Pulmonary Arteries	The proximal LPA near the site of ductal insertion is a frequent location for stenosis. The LPA has ductal tissue that, once regressed, can lead to stenosis or discontinuity of LPA.		Restoration of continuity and/or augmentation of the branch pulmonary arteries is required.	
ASD/PFO	Potential for postoperative atrial level shunting if not closed surgically	Almost always PFO or ASD is present	Often a small opening is left if anticipating postoperative RV dysfunction.	Occasionally included as the pentalogy of Fallot
Right Aortic Arch	Often present with associated abnormal branching of head and neck vessels	25%	Placement of palliative shunts depend on spatial location of aortic branches to pulmonary artery	
Others	• Partial or total anomalous pulmonary venous return • Persistent LSVC • AV septal defect • PDA • Interrupted IVC • Anomalous aortic origin of the coronary artery • Aberrant origin of the right or left pulmonary artery		All might require modifications to the surgical repair, such as an additional venous drainage cannula for a LSVC	

ASD, atrial septal defect; AV, atrioventricular; CPB, cardiopulmonary bypass; IVC, inferior vena cava; LAD, left anterior descending artery; LSVC, left superior vena cava; PA, pulmonary artery; PDA, patent ductus arteriosus; PFO, patent foramen ovale; RCA, right coronary artery; RV, right ventricle; RVOT, right ventricular outflow tract; TTE, transthoracic echocardiogram; VSD, ventriculoseptal defect.

or as part of a syndrome [60–62]. The most common include the 22q11 microdeletion-associated syndromes called DiGeorge, velocardiofacial syndrome, and conotruncal anomaly face syndrome. Other conditions include trisomy 21 and VACTERL association, among others [60–71] (Table 28.5). There is a mild association of familial inheritance of TOF. Other genetic bases for TOF have been linked to mutations on NKX2-5, JAG1, chromosome 20p12, chromosome 5q35, the GATA4 gene on chromosome 8p23, ZFPM2, TBX1, and GATA6 [72].

The natural course of uncorrected TOF reveals about 50% mortality in the first 5–10 years of life. Prolonged survival is enabled by the persistence of pulmonary flow via the PDA and /or collaterals, and by compensatory hypoxic mechanisms such as erythrocythemia. Uncorrected, it is rare for survival beyond the 4th decade of life. The morbidity and mortality are secondary to chronic hypoxemic ramifications such as thromboembolism, brain abscesses and endocarditis [73].

Modern operative mortality is low with an overall rate of less than 2% in developed countries [74], and less than 4% in low-to-middle income countries [75]. A report analyzing the only collaborative database of congenital heart surgery in

Table 28.5 Syndromes associated with tetralogy of Fallot

*Nearly 1 of 4 of patients with syndromic TOF undergo palliation prior to full repair

Syndrome	Frequency	Associated findings
22q11.2 microdeletion, also known as DiGeorge syndrome, velocardiofacial syndrome and others	7.4–10.5% of all TOF patients or 40–47.8% of the syndromic TOF patients	• 1 per 6000 live births • Variable phenotype • Conotruncal defect (TOF, PA/VSD, IAA, truncus arteriosus) • Immunodeficiency • Neonatal hypocalcemia • Facial and velopharyngeal anomalies • Psychiatric abnormalities
Trisomies: 21, 18, 13	• Trisomies account for 5–7% of all TOF patients • Trisomy 21 is the most common (5.2–5.8% of all TOF patients). • Trisomy 21 was 29–42% of the syndromic TOF patients • Trisomy 18 was 0.8% of the syndromic TOF patients • Trisomy 13 was 0.2% of the syndromic TOF patients	Trisomy 21 • 1 per 700 live births • Cardiac anomalies–the most common is AVC defect • Developmental delay • Congenital hypothyroidism • Hearing loss • Hypotonia Trisomy 18 • 1 per 6,000–8,000 live births • Cardiac anomalies • Respiratory insufficiency • Horseshoe kidney • GI–omphalocele, TEF • CNS–cerebellar hypoplasia, corpus callosum agenesis, spina bifida • Others–micrognathia, microphthalmia, coloboma. Trisomy 13 • 1.9 per 10,000 live births • Cardiac anomalies • Respiratory insufficiency • Renal anomalies • GI- dysphagia • CNS – holoprosencephaly, arhinencephaly, microcephaly, spina bifida • Others–Orofacial clefts, microphthalmia, coloboma
VACTERL association	2.6% of the syndromic TOF patients	• 1 per 10,000–40,000 live births • Vertebral defects • Anal atresia • Cardiac anomalies • Tracheoesophageal fistula, esophageal atresia • Radial and renal dysplasia • Limb abnormalities
CHARGE Syndrome	0.9% of all TOF patients	• 1 per 10,000–100,000 live births • Coloboma • Heart defects • Choanal atresia • Retardation of growth • Genital hypoplasia • Ear anomalies/ deafness
Alagille Syndrome	0.4–1.3% of all TOF patients	• 1 per 30,000 live births • Cardiac defects • Hepatic (bile duct paucity) • Renal anomalies • Skeletal (butterfly vertebrae) • Ophthalmologic findings • Facial abnormalities
Holt-Oram syndrome	0.2% of the syndromic TOF patients	• 0.7–1 per 100,000 births • Congenital heart defects • Upper limb anomalies

AVC, atrioventricular canal; CNS, central nervous system; GI, gastrointestinal; IAA, interrupted aortic arch; PA, pulmonary atresia; TEF, tracheoesophageal fistula; TOF, tetralogy of Fallot; VSD, ventriculoseptal defect.

AL Grawany

low-to-middle income countries found that over half of the children undergoing primary TOF repair were over 1 year of age. Interestingly, age at primary repair was not a risk factor for mortality. Poor nutritional status and hypoxemia were associated with increased infection rates and mortality [75]. Athanasiadis et al. found that syndromic patients with TOF had an all-cause mortality rate of 9.8% [62]. Long-term survival 40 years after TOF repair has been quoted to be over 70% with late mortality from ventricular fibrillation and heart failure [76].

Pathophysiology

Patients with TOF manifest a wide spectrum of clinical presentations depending on the severity of RVOTO and degree of right-to-left shunting of venous blood into the systemic circulation. The unrestrictive VSD allows a near equalization of RV and LV pressures. Shunting direction will be determined by the balance of systemic vascular resistance (SVR) and RVOTO. Most patients are initially asymptomatic and acyanotic – the "pink tets." Some of them have near-normal sized pulmonary valvar and supravalvar areas with minimal RVOTO. As PVR drops, the increasing left-to-right shunting through the unrestrictive VSD leads to pulmonary overcirculation and even CHF. Cyanosis eventually presents at about 6–12 months when infundibular muscles become hypertrophied and RVOTO increases over time. In contrast, some babies present with severe cyanosis shortly after birth and need immediate medical management for stabilization of PBF while preparing for surgical intervention. In these patients, the main obstruction is usually at the level of the PV.

A number of patients develop acute hypercyanotic events or "tet spells," a sudden and profound hypoxemic event that can result in loss of consciousness, stroke, or death. Typically, hypercyanotic episodes occur in association to periods of increased sympathetic activity such as crying, pain and fright. Other predisposing conditions include dehydration, acidosis, and fever – events which decrease SVR and promote right-to-left shunting with resulting arterial desaturation. Additionally, it is postulated that infundibular muscle spasms with acute worsening of RVOTO lead to right-to-left shunting and drastic PBF reduction. The resulting acidosis and hypoxemia decrease SVR, furthering the right-to-left shunting. Prompt aggressive treatment to halt the vicious cycle, reverse the shunt, and restore pulmonary flow is imperative. Treatment for hypercyanotic episodes is described later in the chapter. During these events, awake patients often hyperventilate, likely to mitigate the hypoxia and acidosis. Squatting behavior during the spell is also observed in older children. Squatting increases SVR from compression of the iliac arteries, increasing RV preload with enhanced venous return generated by elevating intraabdominal pressure and compressing veins in the leg musculature. The result of squatting is reduced right-to-left intracardiac shunting and increased PBF.

Progression of infundibular and RV hypertrophy from exposure to high pressure loads results in anatomical changes that complicate the perioperative course and contribute to postoperative RV dysfunction: (i) the RV becomes less compliant with abnormal diastolic relaxation, requiring high filling pressures for adequate CO, (ii) the hypertrophied RV and muscle bands increase surgical complexity, (iii) the increased RV muscle mass may reduce the myocardial protection of cardioplegia, a reduction in protection that in some instances is compounded by abnormal coronary artery distributions, and (iv) muscle resection or division is often required to relieve the RVOTO.

Presently, complete surgical correction is commonly performed in early infancy for most patients. Early repair is thought to prevent the development of RV hypertrophy, minimize the effects of cyanosis and polycythemia, allow improved pulmonary vascular development via greater PBF, and avoid the occurrence of hypercyanotic episodes.

Fetal ultrasonography can diagnose TOF prenatally. After birth, most neonates with TOF are acyanotic and present with non-specific physical examination findings. Auscultation shows a crescendo–decrescendo systolic murmur best heard at the left upper sternal border prompting further investigation. Clubbing is not a feature at this stage; it only becomes apparent after prolonged periods of chronic hypoxemia. Ductal closure will uncover cyanosis in those with severe PS and ductal-dependent PBF. The ECG reveals persistent RV hypertrophy and right axis deviation beyond the neonatal period. The chest radiograph shows a "boot-shaped" cardiac silhouette, resulting from the RV hypertrophy displacing the apex upwards and the hypoplastic MPA creating a concave upper left heart border. Transthoracic echocardiography is effective at establishing the TOF diagnosis and demonstrating related important features: (i) extent and anatomical characteristics of RVOTO, (ii) VSD size, number and locations, (iii) coronary artery distribution, (iv) additional cardiac abnormalities including ASD and aortic arch-sidedness, and (v) biventricular function.

Most children are diagnosed during infancy in countries with routine access to modern medicine. In regions of the world with limited access to care, it is common to see children with uncorrected TOF present at much older ages with advanced pathology.

Surgical and transcatheter approaches and outcomes

Initial stabilization and planning for intervention

All infants born with TOF eventually require intervention as hypoxemia develops. Most patients can be monitored until meeting indications for surgery that occurs when the oxygen saturation declines below 75–80% or with the advent of hypercyanotic episodes. If delaying surgery is necessary, patients manifesting hypercyanotic episodes can sometimes be temporized with propranolol.

For patients with significant cyanosis who have contraindications to surgery, a palliative balloon dilation and/or stenting of the PDA or RVOT can be performed in the cardiac catheterization laboratory [77]. Surgical palliation via a modified BTS (mBTS) is also an option for patients who are deemed too high risk or have unfavorable anatomy to undergo early primary repair. A palliative shunt allows time for optimization of surgical conditions including time for corporal growth; complete repair is facilitated when performed on a larger-sized heart and infant. This two-stage repair (palliative systemic-to-pulmonary artery shunt

followed by later full repair) comes with the risks associated with an additional thoracic surgery as well as risks of loss of shunt patency, imbalance of PBF to systemic blood flow ratio (Qp:Qs), and distortion of pulmonary arterial anatomy.

Factors influencing the surgical approach and timing are based on the patient's symptomatology, cardiac anatomy, concomitant risk factors, the center's capability and preferences, and contraindications to early complete repair. Elective complete repair in the neonate is currently performed in some centers. The smaller anatomy makes the operation more challenging; many use a ventriculotomy to facilitate surgical exposure as opposed to a transatrial or transpulmonary approach. Additionally, the neonate's immature organ systems are subject to the negative effects of CPB. Other concerns of neonatal full repair are associated with increased longitudinal morbidity [78, 79]. For elective cases, some centers prefer the staged approach while other centers favor elective complete primary repair between 3 and 6 months of age [78]. Current survival rates after complete repair of TOF are over 98%. Although the optimal TOF repair strategy is unclear, the preservation of the PV and supporting structures while reducing RVOTO are key determinants for reducing long-term morbidity. Morales et al. have proposed a surgical decision algorithm with the goal of preserving the RV and infundibulum [80, 81] (Figure 28.15). Results for this approach appear promising [81, 82].

Surgical and transcatheter palliation

Palliation, meaning "lessening the intensity of disease," comes from the late Latin word "palliatus," meaning to cloak or to mask. A palliative intervention does not offer correction but rather a relief for a condition, generally only temporary. For TOF, the first operative procedure was palliative, the classic BTS by Blalock in 1945, an end-to-side anastomosis of the subclavian artery to the right pulmonary artery branch, to provide a source of pulmonary flow. The anastomosis is usually performed on the side ipsilateral to the innominate artery. Direct anastomotic aorto-pulmonary shunts, such as the now nearly obsolete Potts and Waterston shunts, are difficult to take down due to their anatomical locations. The mBTS is the most commonly used systemic-to-pulmonary shunt (Figure 28.16). It consists of prosthetic graft placed between the innominate artery or the subclavian artery and the ipsilateral BPA. When anatomy is unfavorable for a mBTS, a central shunt, comprising a graft placed between the ascending aorta and the MPA, may be placed. In TOF, the shunt augments PBF until complete primary repair can be achieved. The mBTS allows early palliation without sacrificing the subclavian artery. Resistance from the graft diameter (usually 3.5–4 mm) and length regulates PBF. The locations of the mBTS and central shunts allow exposure and maneuverability during subsequent repairs. A right-sided mBTS is most common due to more favorable surgical exposure during take down and less risk of phrenic nerve injury compared to a left-sided mBTS. Although mBTS was traditionally done via a thoracotomy, many centers are performing mBTS via median sternotomy. This approach also facilitates patch augmentation of narrowed BPAs with bypass support. A downside of a mBTS is that the shunt can frequently lead to stenosis and distortion of the BPA [44].

Patients who are unsuitable candidates for surgical palliative shunts, often small and critically ill neonates or infants, can undergo the less invasive transcatheter palliative interventions such as pulmonary balloon valvuloplasty and stent placement in the RVOT or PDA to maintain PBF. Candidates for ductal stenting have an anatomically suitable ductus as well as an additional source of PBF. Pulmonary balloon valvuloplasty alone seldom produces long-lasting improvement, as the dilated RVOT often returns to its original stenotic state. Cutting balloons or primary stent implants are associated with longer-lasting improvement in relief of obstruction. Application of stents should be done in consultation with the cardiac surgeons as the stents impact the operative conduct of the full repair [52, 83, 84]. See Chapters 19 and 34 for further discussion of RVOT and PDA stenting.

Surgical repair

Preoperative knowledge of pertinent anatomic TOF details is important for surgical planning and successful repair, including size and nature of RVOTO at the subvalvular, valvular, and supravalvular levels, coronary artery distribution, type and number of VSDs, and any other associated cardiac anomalies.

The first successful full repair of TOF was performed on a 10-year-old boy by Walton Lillehei in 1954. In the early era of TOF repair, the goals of surgery were relief of RVOTO and VSD closure via ventriculotomy while preserving RV function. In the 1960s, full repair was reserved for children 4–6 years of age because surgical mortality was too high for younger patients. Later, use of deep hypothermic circulatory arrest improved survival and opened the door for full primary repair during infancy.

Early repair has hemodynamic and anatomic advantages for the developing heart. Although some centers offer neonatal elective full repair, most centers prefer to perform elective full primary repair between 3 and 6 months of age and prior to 12 months for those with a palliative shunt. The increased duration of longitudinal postoperative follow-up reveals that adults with repaired TOF exhibit medical and surgical sequelae such as impaired exercise capacity, atrial and ventricular arrhythmias, RV and LV dysfunction, cardiac failure, and sudden death. The pathophysiology of these late complications appears related to the effect of extensive ventriculotomy, coronary artery compromise and PV destruction. Findings from outcomes have led to changes in the surgical approach by emphasizing the preservation of the RVOT apparatus, sparing PV injury, minimizing ventriculotomy incisions, and reducing residual VSDs. Hence, transatrial and transpulmonary approaches with valve-sparing techniques are emphasized with only selective use of transannular patches (Figure 28.17). The surgical approach is via median sternotomy with CPB-assist. The thymus size is noted prior to subtotal excision due to association to 22q11.2 microdeletion syndromes with TOF.

Upon cardiac exposure, the coronary artery distribution is assessed. After CPB commencement and cardioplegia, the RVOT is examined through a right atriotomy via the TV, and the PV annulus is sized with calibrated dilators. Muscle bundles are divided as needed. A PV commissurotomy can be performed transatrially if exposure is adequate; otherwise, it can be accessed via a transpulmonary approach by a longitudinal incision in the MPA. If preservation of the PV is not feasible, a right ventriculotomy with placement of transannular patch will be done to augment the RVOT size. The VSD is closed using a patch, avoiding the AV node or bundle of His that passes adjacent to the VSD margin. The atrial level shunt is closed if present. If postoperative RV dysfunction is expected, a small atrial communication ("pop-off") is left to allow LV filling and preload with a degree of right-to-left shunting. Patch augmentation of BPA stenosis is performed as needed. In some patients, a RV-to-pulmonary artery conduit may be necessary to avoid injuring a coronary artery crossing the RVOT (Figure 28.18). TEE is used after separation of CPB to assess for adequacy of repair, residual shunts and defects, and ventricular function. An RV:LV pressure ratio greater than 0.7 usually indicates inadequate relief of RVOT obstruction, with the caveat that early post-CPB pressure measurements do not always correlate to later measurements and might prompt unnecessary revisions. If residual shunts are suspected, a comparison of PaO_2 from simultaneous blood gas measurements taken from the superior vena cava and the MPA can be helpful. Temporary atrial and ventricular pacing wires are placed prophylactically for the management of postoperative arrhythmias such as heart block and junctional ectopic tachycardia (JET) following TOF repair.

Long-term surgical complications

Most patients with repaired TOF will live to adulthood; however, many will require reintervention before 30 years of age to address residual disease. The most common sequela is PI. Other sequelae include BPA stenosis, residual VSDs, and RVOT aneurysmal dilation. Chronic PI leads to RV volume overload, RV dilation and dysfunction, and ventricular arrhythmias. Eventually, these sequalae affect the LV and cause biventricular dysfunction and heart failure. Monitoring

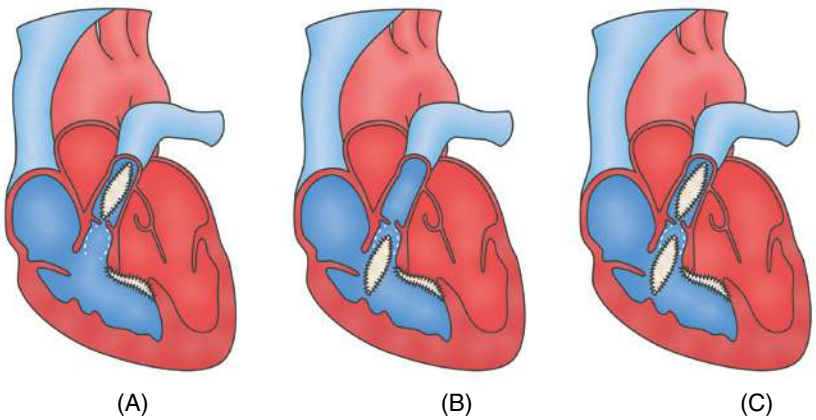

Figure 28.17 Surgically repaired hearts with tetralogy of Fallot, showing resection of right ventricular outflow tract (RVOT) muscle (dashed lines), patch closure of the ventricular septal defect (VSD), and patch arterioplasty: (A) supravalvular main pulmonary patch arterioplasty, RVOT muscle resection, VSD patch; (B) RVOT patch, RVOT muscle resection, VSD patch; (C) supravalvular main pulmonary patch arterioplasty, RVOT patch, RVOT muscle resection, VSD patch. (Source: Michael L. Schmitz, MD.)

for symptomatology and progression of RV dilation is essential. An increasingly used monitoring modality is cardiac MRI for the longitudinal evaluation of volumetric ventricular measurement, PI fraction quantification, and RV functional status [85]. Ideally, a PV replacement is performed prior to irreversible RV dysfunction from the effects of PI but as late as possible to allow placement of an adult-sized valve to decrease the number of re-interventions needed in a patient's lifetime. Bioprosthetic valves deteriorate over time, and most patients will require another replacement within a decade. For symptomatic patients, PV replacement is indicated. For asymptomatic patients, the timing and indications for PV replacement is unclear. Professional organizations have published criteria to guide these decisions [86].

Transcatheter pulmonary valve implantation

Multiple PV interventions are needed over the lifetime of the TOF patient. The most common late re-intervention in the patient with repaired TOF is PV replacement. Nonsurgical options for PV replacement are currently available as transcatheter valve implants for patients with dysfunctional RV-to-pulmonary artery conduits, such as the Medtronic Melody valve (Medtronic, Inc., Minneapolis, MN), a stent-mounted bovine jugular valve and the Edwards SAPIEN XT valve (Edwards Lifesciences Corporation, Irvine, CA), a stent-mounted bovine pericardial valve. Pre-stenting a RV-to-pulmonary artery conduit to prepare a landing zone for the PV to anchor is often necessary (Figure 28.19). Transcutaneous valves for the native RVOT without a circumferential conduit are under development. Knowledge of coronary artery location is necessary to avoid coronary artery compression during and after valve implantation. Other than coronary artery compression, complications include stent fracture, RV-to-pulmonary artery conduit tear, device dislodgement and infective endocarditis. This field continues to grow, and more transcutaneous device options will become available [87]. See Chapter 34 for additional discussion of transcatheter PV implantation.

Anesthetic considerations

Initial assessment and planning

Hypoxemia becomes progressive over time as PBF diminishes concordant to the increasing obstruction by the RVOT. Some patients experience hypercyanotic episodes when the oxygen saturation acutely drop to 20–30% or less. Since systolic pressure in the RV reflects the pressure in the LV and aorta, a decrease in systemic arterial pressure (as may occur with peripheral vasodilatation caused by anesthetic agents and sedative drugs, or prolonged fasting) results in decreased RV pressure and PBF. An increase in LV pressures, as induced by vasoactive agents and volume administration, can reverse shunting of blood from the RV into the LV and promote PBF. Close monitoring of blood pressure changes from anesthetic interventions can provide early physiological guidance for optimizing PBF and preventing hypercyanotic episodes.

Preoperative assessment should include the history of hypercyanotic episodes in patients who are not palliated or repaired. Patients with severe cyanosis present with failure to thrive and polycythemia unless they are anemic. Polycythemia actually enhances the "blueness" during hypercyanotic episodes due to higher levels of deoxygenated hemoglobin. Patients with stable and mild cyanosis often have had generous weight gain from frequent feedings given to prevent agitation and worsened cyanosis. Anticipation, early recognition, and management of potential hypercyanotic episodes are essential for avoiding cardiovascular collapse.

Preoperatively, the following factors are considered for preventing hypercyanotic episodes:

- Minimize patient agitation to reduce tachycardia, increased infundibular tone and increased oxygen consumption. Keep the patient at ease by avoiding irritating events; use premedication in a monitored setting and comfort the infant as needed (e.g., judicious use of sugar drops or a pacifier may mitigate hunger).
- Minimize dehydration by avoiding prolonged fasting. Offer clear fluids up to 1–2 hours prior to anesthesia induction or administer IV fluids if IV access is present.
- Beta blocker therapy should be continued as prescribed.

Even under anesthesia, increased stimulation can incite infundibular spasm that enhances right-to-left shunting, precipitating a hypercyanotic episode. Anesthetic induction and

times of surgical manipulation are especially vulnerable periods for occurrence of a hypercyanotic episode. Infants with unrepaired TOF may present for anesthetic care for non-cardiac interventions such as cardiac catheterizations, MRI, and CT, or for surgical procedures that cannot be delayed until cardiac palliation or repair (Table 28.6).

Management of hypercyanotic episodes

The primary goal is to improve PBF so that the hypoxemia can be reversed. PBF is increased by reducing acute RVOT obstruction promoted by the infundibular spasms, enhancing RV preload, and reversing right-to-left intracardiac shunting by increasing SVR relative to RV pressure. The

Table 28.6 Overview of considerations and recommendations for the anesthetic management of patients with unrepaired tetralogy of Fallot (TOF), acyanotic or cyanotic, for non-cardiac surgery

Anesthesia considerations and recommendations for patients with unrepaired TOF undergoing non-cardiac surgery	
Acyanotic, "Pink Tets," at risk for pulmonary overcirculation	**Cyanotic, "Blue Tets," at risk for hypercyanotic spells**
Hemodynamic goal: Maintain Qp:Qs near 1:1 1. Avoid increased left to right shunt and worsening of pulmonary overcirculation. 2. Maintain awareness that the shunt can reverse in situations of increased PVR (hypoxia, hypercarbia, acidosis, hypothermia)	**Hemodynamic goal**: Preserve PBF and avoid hypercyanotic episodes 1. Avoid tachycardia, dehydration 2. Maintain adequate preload to counteract stiff RV and decrease RVOTO 3. Maintain SVR to minimize right to left shunt & promote PBF 4. Avoid sudden catecholamine release, maintain appropriate anesthetic depth
FiO_2 restrictions- Avoid unnecessary hyperoxia as it increases PBF	**FiO_2 restrictions**- None
PREOPERATIVE 1. Premedicate as needed for anxiolysis. 2. Avoid prolonged fasting. Patients may be on diuretics for CHF.	**PREOPERATIVE** 1. Premedicate as needed for anxiolysis to avoid hypercyanotic episodes prior to induction 2. Avoid unnecessary fasting to maintain preload.
INTRAOPERATIVE **Monitors/Lines** 1. Standard ASA monitors with 5-lead ECG 2. De-air all lines to avoid paradoxical embolism. 3. +/– invasive arterial line or central line as warranted by extent of surgery and anticipated hemodynamic perturbations.	**INTRAOPERATIVE** **Monitors/Lines** 1. Standard ASA monitors with 5-lead ECG 2. De-air all lines to avoid paradoxical embolism. 3. +/– invasive arterial line or central line as warranted by extent of surgery and anticipated hemodynamic perturbations.
Anesthesia induction 1. Inhalation induction, sevoflurane +/– nitrous oxide, +/–IM ketamine and rocuronium as needed 2. Place IV after induction. 3. If IV → ketamine (1–2 mg/kg) +/– fentanyl (1–2 mcg/kg) +/– sevoflurane. Intubate after paralysis. **SBE prophylaxis as indicated	**Anesthesia induction** 1. Inhalation induction sevoflurane +/– nitrous oxide, +/–IM ketamine and rocuronium as needed 2. Place IV after induction. 3. If IV → ketamine (1–2 mg/kg) +/– fentanyl (1–2 mcg/kg) +/– sevoflurane. Intubate after paralysis. **SBE prophylaxis as indicated
Anesthesia maintenance 1. Inhaled anesthetic agent (sevoflurane). Titrate dexmedetomidine. 2. Volume replacement to maintain euvolemia. Used blood products as needed to compensate for surgical blood loss, maintain organ perfusion and optimize hemostasis	**Anesthesia maintenance** 1. Inhaled anesthetic agent, sevoflurane. Titrate dexmedetomidine. 2. Volume replacement often needed to maintain preload, with higher filling pressures for a stiff RV. Used blood products as needed to compensate for surgical blood loss, maintain organ perfusion and optimize hemostasis.
Anesthesia emergence 1. If extubation planned, optimize pain control with adjuvant acetaminophen, regional block or local anesthetic infiltration. Titrate dexmedetomidine to adequate sedative effect. 2. If postoperative mechanical ventilation planned, prepare for sedation for transport to ICU.	**Anesthesia emergence** 1. If extubation planned, optimize pain control with adjuvant acetaminophen, regional block or local anesthetic infiltration. Titrate dexmedetomidine to adequate sedative effect. 2. If postoperative mechanical ventilation planned, prepare for sedation for transport to ICU.
Postoperative care 1. ICU or stepdown ICU if extubated 2. ICU care if mechanically ventilated	**Postoperative care** 1. ICU or stepdown ICU care if extubated 2. ICU care if mechanically ventilated

ASA, American Society of Anesthesiologists; CHF, congestive heart failure; ECG, electrocardiogram; IM, intramuscular; IV, intravenous; PBF, pulmonary blood flow; PVR, pulmonary vascular resistance; Qp, pulmonary blood flow; Qs, systemic blood flow; TOF, tetralogy of Fallot; RV, right ventricle; RVOTO, right ventricle outflow tract obstruction; SBE, subacute bacterial endocarditis; SVR, systemic vascular resistance.

AL Grawany

Table 28.7 Treatment for a "tet spell" or hypercyanotic episode for patients with tetralogy of Fallot

- Increase RV preload – dilate the right ventricular outflow tract and improve cardiac output
  - Give IV fluids
  - Apply knee-chest position or abdominal compression
  - Directly compress aorta via open chest
- Increase SVR – Reverse right to left shunt
  - Administer phenylephrine 5–10 mcg/kg IV
  - Apply knee-chest position or abdominal compression
  - Directly compress aorta via open chest
- Decrease infundibular spasm via negative inotropic effects
  - Administer sedatives
  - Administer beta-blocker drugs (e.g., esmolol 50 mcg/kg, and then titrate to effect)
  - Increase depth of anesthesia; if inhaled agent, use sevoflurane
- Decrease pulmonary vascular resistance by reducing hypoxic pulmonary vasoconstriction
  - Increase inhaled oxygen
- Avoid tachycardia – increase diastolic filling time and improve right ventricular preload
  - Administer sedatives
  - Administer beta-blocker drugs

RV, right ventricle; IV, intravenous; SVR, systemic vascular resistance; ECMO, extracorporeal membrane oxygenation; CPB, cardiopulmonary bypass.

objectives are to increase afterload to the left heart, reduce RV infundibular spasm, and augment RV preload (Table 28.7).

If the patient remains cyanotic despite these measures, ECMO should be considered as a lifesaving therapy. Sternotomy with manual compression of the aorta can be used to temporarily increase SVR and reverse right-to-left shunting while rapidly instituting CPB.

Perioperative anesthetic management for surgical palliation

Most neonates or infants needing surgical palliation are critically ill and dependent on PGE_1 infusion to maintain ductal patency for augmenting PBF and managing hypoxemia. Some other infants become symptomatic shortly after discharge from the hospital as they develop cyanosis and fail to thrive. Anesthetic goals are to maintain PBF by limiting right-to-left intracardiac shunting and preserving adequate SVR. Induction of anesthesia can be successful with ketamine and/or fentanyl with an inhaled agent for maintenance. General anesthesia and potent inhaled agents have been demonstrated to depress ventricular function [88, 89]. Rivenes et al. showed that both sevoflurane and isoflurane have a dose-dependent, albeit not statistically significant, decrease in CO and shortening fraction at 1 and 1.5 MAC. Isoflurane led to larger dose-dependent increases in heart rate and decreases in SVR index compared to sevoflurane; thus, sevoflurane would be the better choice [90]. IV fluids and phenylephrine are useful to increase SVR. Inotropic drugs can increase heart rate and contractility and worsen infundibular spasms. In the absence of reliable IV access, inhalational induction with sevoflurane, and intramuscular ketamine and rocuronium as needed can provide adequate conditions for IV access and tracheal intubation. Central venous access is obtained for the infusion of fluids and vasoactive agents. An arterial line is placed for close hemodynamic monitoring and blood gas sampling. If placing a radial arterial line, it is recommended on the contralateral side of the anticipated mBTS, so that blood pressure assessment is unbiased by the run-off from the ipsilateral innominate artery or by possible stenosis at the anastomotic site.

Although mBTS was traditionally done via a thoracotomy, the mBTS is now often performed via median sternotomy [47]. Median sternotomy permits exposure for conversion to a central shunt, institution of CPB in the event of severe hemodynamic instability or need to patch augment the BPAs, inspection of the coronary anatomy, division of the PDA while confirming adequacy of the shunt flow, and avoidance of a separate incision site after full repair. Median sternotomy also avoids the lung retraction required for exposure with thoracotomy. Heparin at 100 units/kg is given prior to shunt placement. Hypoxemia and hemodynamic instability can occur during the partial clamping for the graft anastomosis and is managed with vasoactive support, fluids, and ventilatory adjustment. Once the shunt is open, oxygen saturation acutely improves while blood pressure decreases. A widened pulse pressure gradient results due to low diastolic pressure secondary to blood run-off to the lungs; insufficient diastolic blood pressure can compromise coronary perfusion. Management with normoventilation, low FiO_2, volume, and vasopressors can temporize this problem. If a mBTS was done via a right thoracotomy and a PDA was present, the excessive diastolic run-off may continue until the PDA closes. PGE_1 infusion is discontinued when alternative PBF is established. A shunt flow approaching Qp:Qs of 1:1 under normal physiological conditions of normocarbia while breathing spontaneously in room air is ideal, resulting in an SpO_2 of 80–85% in the absence of parenchymal lung disease. Intraoperatively, simulating normal physiological conditions as closely as possible is important for accurate clinical assessment of Qp:Qs. If the ductus is still open, the additional PBF must be considered in Qp:Qs. Otherwise, saturations too high or too low would indicate an imbalanced Qp:Qs. Lower than expected saturations, after ruling out reversible ventilatory impairments such as atelectasis or endobronchial intubation, may indicate that the shunt is inadequate. Some surgeons prefer the larger diameter shunts if physiologically tolerated to accommodate patient growth and associated increased PBF needs prior to the full repair. Platelet transfusions are avoided whenever possible due to an increased risk of shunt thrombosis.

Postoperative care for surgical palliation

In the ICU, the patient is supported with mechanical ventilation for the next 12–24 hours for stabilization, monitoring and management of ongoing physiologic changes. Potential complications include unilateral or bilateral pulmonary edema or hemorrhage from increased PBF. Also, low systemic diastolic blood pressure can compromise coronary artery flow during diastole, causing myocardial ischemia. Shunt thrombosis is always a potential risk, and heparin infusion at 6–10 units/kg/hour is commenced to maintain

shunt patency after the risk of surgical bleeding subsides. A shunt murmur, reflecting presence of shunt blood flow, can be easily auscultated by pausing ventilation and placing the stethoscope at the end of the endotracheal tube; the murmur is transmitted via the endotracheal tube because the shunt is near the bronchus. Antiplatelet therapy is initiated with aspirin when enteral intake is started and continued until the time of complete repair. Other perioperative complications include recurrent laryngeal nerve and phrenic nerve damage and development of chylothorax from thoracic duct injury.

Perioperative anesthetic management for surgical repair

The pre-CPB goal is the promotion of PBF, and post-CPB goals are preservation of ventricular function and CO optimization. Monitors include central venous pressure and invasive arterial blood pressure. Cerebral oximetry is helpful. TEE is recommended post-CPB to assess the surgical repair, but epicardial echocardiography can be used if TEE is not feasible.

Induction of anesthesia for complete repair can be similarly accomplished as for the palliative shunt placement. For patients at a low risk of hypercyanotic episodes, inhalational induction of anesthesia is generally safe. There are several described techniques for maintenance of anesthesia. If immediate extubation in the operating room or early extubation in the ICU (within 6 hours after surgery) is anticipated, then a multimodal low-dose opioid technique is recommended. At the author's institution, a technique of total fentanyl dose of 10–15 μg/kg supplemented with an inhalational agent, dexmedetomidine infusion 0.3–0.5 μg/kg/hour, morphine infusion 20–25 μg/kg/hour, local anesthetic wound infiltration and IV acetaminophen provide for adequate immediate extubation conditions after surgical closure. The extubated patient is transported to the cardiac ICU with continuation of the dexmedetomidine and morphine infusions, as well as a milrinone infusion. A report compared three anesthetic techniques in patients 30 days-old to 3 years-old undergoing TOF, AV canal or ASD repair: fentanyl 10 μg/kg vs. fentanyl 25 μg/kg vs. fentanyl 10 μg/kg plus dexmedetomidine at 1 μg/kg loading dose followed by 0.5 μg/kg/hour infusion, until separation from CPB. Adjuvant isoflurane was used in all three groups. It showed that the stress response, coagulopathy, transfusion requirements and postoperative opioid use were highest in the fentanyl 10 μg/kg group while the stress response was most blunted with the 25 μg/kg fentanyl dose. Adding dexmedetomidine to the low-dose fentanyl group improved stress response blunting and provided better postoperative pain control. No difference in timing for fast track extubation was found amongst all three groups [91]. One institution described using a ketamine infusion and found more hemodynamic stability when compared with isoflurane due to preservation of SVR in the pre-CPB period [92].

Considerations for separation from CPB include:

- *RV dysfunction* can occur especially if a ventriculotomy was performed. Pre-existing RV hypertrophy and diastolic dysfunction may require high filling pressures to maintain CO. Management should target increasing preload, decreasing RV afterload, and adding inotropic support such as milrinone (0.375–0.75 μg/kg/min) and perhaps low dose epinephrine (0.02–0.04 μg/kg/min).
- *A hyperdynamic RVOT* may be observed especially during periods of tachycardia, limiting stroke volume. Management includes decreasing the heart rate with an esmolol infusion in the early postoperative period while maintaining adequate preload.
- *Tachydysrhythmias* occur frequently after complete TOF repairs. A recent review found an overall frequency of 19% in a multi-institutional database of 7749 patients [93]. Surgical repair frequently disrupts the conduction system located in close proximity of the VSD. JET is a narrow complex tachydysrhythmia originating from the AV node and His bundle area; it often develops within 24 hours after repair and has been associated with increased length of stay [94]. JET is characterized by heart rates above 170/min and AV dissociation leading to significant hemodynamic instability. Risk factors include young age, long CPB and aortic cross clamp times, preoperative tachycardia, high inotropic requirements, and surgical intervention near the AV node. Treatment consists of sedation, electrolyte correction, cooling to 34–35 °C, and IV amiodarone [56, 95]. A meta-analysis showed that a prophylactic dexmedetomidine infusion was effective in reducing postoperative JET [96]. Another study showed that dexmedetomidine has increased preventive effects when started preincision [97]. Prophylactic amiodarone has also been reported to reduce the incidence of JET [98]. Heart block is common after separation of CPB. The heart block may be transient due to inflammation around conduction fibers. A temporary pacemaker is helpful while awaiting recovery of normal cardiac conduction. In some patients, recovery is not seen until for 7–10 days; afterward, a permanent pacemaker is considered. Many patients demonstrate right bundle branch block on postoperative ECG, particularly those who underwent ventriculotomy.
- *Coagulopathy and bleeding* after separation of CPB is common after TOF repair. Hemodilution of coagulation factors and platelets, pronounced inflammatory effects of CPB and immature coagulation systems increase the risks for bleeding in small, young patients undergoing early TOF repair. Transfusion of multiple component blood products is almost always required for this patient group. It is not surprising that a recent Society for Thoracic Surgeons (STS) Congenital Heart Surgery database analysis showed a consistent median greater than 99% for intraoperative blood transfusion for all patients 30 days and younger and those aged 31 days to 12 months across 82 centers [99]. The use of antifibrinolytics such as epsilon-aminocaproic acid or tranexamic acid have been shown to reduce post-CPB bleeding and minimize the use of blood products. Aprotinin, a protease inhibitor antifibrinolytic, is no longer available in the US; however, it is available in Europe.
- *Residual VSDs* appear to be common. Small VSDs are usually hemodynamically insignificant and are likely to close spontaneously. If greater than 2–3 mm, excessive PBF will be poorly tolerated and it may be necessary to resume CPB for further VSD closures after quantification of the shunt magnitude by echocardiography and hemodynamic evaluation [100, 101]. Also, some VSDs that were undetected preoperatively due to equalization of ventricular pressures may be now visualized after relief of the RVOT obstruction.

AL Grawany

The degree of additional shunting and hemodynamic significance may indicate a return to CPB.

Indications for returning to CPB include coronary compromise by excessive traction or injury, residual VSDs, residual RVOT obstruction and TR.

An STS database report found that early extubation (within 6 hours after surgery) was performed in 31.5% (478 of 1,519) of children undergoing TOF repair between 2010–2013, in an aggregate of 92 centers [102]. An updated report from 2010–2017 found that 17.15% (705/4126,120 programs) of TOF repair patients were extubated before leaving the operating room [103]. Although early tracheal extubation has associated advantages such as avoidance of positive pressure ventilation and shorter lengths of ICU and hospital stay, patient selection and the implementation of strong strategies for managing postextubation pain, sedation, RV dysfunction, and pulmonary status are essential for successful early extubation and good outcomes. Reintubation after extubation failure is associated with increased morbidity, hospital stay and mortality. A factor that might contribute to extubation failure is delirium, a condition that often is treated with additional sedation and sometimes leading to inadequate ventilation [104, 105].

Postoperative care for surgical repair

After chest closure, the patient is prepared for planned immediate extubation after meeting extubation criteria. Otherwise, the patient remains intubated and ventilated while receiving adequate sedation during transport to the ICU. Regardless of whether the patient continues mechanical ventilation or is extubated, analgesia and adequate sedation can be provided with morphine (20–40 μg/kg/hour) and dexmedetomidine (0.3–0.7 μg/kg/hour) infusions at titrated doses.

KEY POINTS: TETRALOGY OF FALLOT

- Decreases in SVR and catecholamine surges can trigger hypercyanotic episodes. Anesthetic induction and periods of surgical manipulation are especially vulnerable times.
- Hypercyanotic episodes are managed with IV fluids, oxygen, phenylephrine, increased anesthetic depth, and knee-chest positioning or abdominal compression.
- During mBTS placement, hypoxemia and hemodynamic instability often occur during the shunt placement. After shunt opening, hypotension with widened pulse pressure occurs.
- Postoperative ventilation is recommended after mBTS placement due to the risk of pulmonary edema and coronary artery ischemia from diastolic hypotension.
- Coronary arteries crossing the RVOT may preclude the option to use a transannular patch repair. A RV to pulmonary artery conduit is an alternative.
- Patients with RV hypertrophy and diastolic dysfunction require high-filling pressures to maintain adequate CO.
- Following full repair, RV dysfunction, tachydysrhythmias, and bleeding should be anticipated.
- Significant residual VSDs result in poorly tolerated excessive PBF.

Pulmonary stenosis with intact ventricular septum

Incidence, anatomy, and natural history

PS/IVS is a fairly common malformation, consisting of 10% of congenital heart defects [2]. The lesion can be further divided into three groups: valvar, subvalvar, or supravalvar. Valvar PS is the most common [80–90% of reported cases of PS] while subvalvar or supravalvar (including stenosis of the BPAs) varieties are less common [106]. Acuity can range from asymptomatic (mild valvar PS) to requiring urgent intervention (ductal-dependent or "critical" PS).

The stenotic pulmonary valve may be unicuspid, bicuspid, or tricuspid and is dome-shaped or dysplastic with a narrow, central opening. Obstruction to the RVOT may lead to hypertrophy of the infundibulum, eventually leading to diastolic dysfunction as ventricular compliance worsens [107]. Valvar PS is commonly associated with other defects such as Noonan syndrome, ASD, EA, double outlet RV, and transposition of the great arteries [108].

Subvalvar PS can be divided into two further subtypes: infundibular and subinfundibular. Infundibular PS is usually a part of TOF whereas subinfundibular PS occurs within the context of double-chambered RV (DCRV). A DCRV is caused by an anomalous muscle band that runs between the anterior wall to the ventricular septum [109]. These muscle bands divide the RV cavity into a proximal high-pressure chamber and a distal low-pressure chamber that if not surgically corrected, may progressively worsen and lead to DCRV. Supravalvar PS is seen in many disorders such as congenital rubella, Williams, Noonan, Alagille, DiGeorge, and Leopard syndromes [108] (Table 28.8). The stenosis can be localized to the MPA, as well as the bifurcation, and/or the BPAs proper. If the stenosis is located in the MPA, there is usually poststenotic dilation of the MPA and sometimes of the LPA as well.

Pathophysiology

Newborns with critical PS may present with heart failure that results from suprasystemic RV pressure, significant TR and right-to-left shunting via an ASD or PFO. However, most patients have mild to moderate PS and are asymptomatic at birth, developing symptoms gradually. Many patients are initially discovered by the presence of a systolic ejection murmur on routine physical exam. Individuals with mild to moderate PS have been documented to survive well into their 4th decade of life [108]. Symptomatically, patients present with dyspnea, fatigue, and sometimes syncope. Patients with mild PS may have a normal ECG, whereas an ECG in a patient with severe stenosis may show right axis deviation and evidence of RV hypertrophy. Echocardiography with Doppler evaluation can be used to grade peak and mean gradients, location of the stenosis, presence of DCRV, and with the advent of 3D echocardiography, accurately estimate RV volume and ejection [110]. MRI can be used to study anatomy and establish the exact location of the stenosis (supravalvar, valvar, or subvalvar) as well as decrease exposure to ionizing radiation, as with multislice computed tomography (CT) scans. Limiting factors for MRI imaging include

Table 28.8 Common genetic syndromes associated with pulmonary stenosis [108]

Syndrome	Genetic defect	Cardiac features	Non-cardiac features
Noonan	PTPN11, SOS1, aberrant RAS-MAPK-signaling, heterogenous trait	Dysplastic pulmonary valve stenosis, hypertrophic cardiomyopathy	Short stature, hypertelorism, downward eye slant, low set ears
Williams-Beuren	7Q11.23 deletions, autosomal dominant trait	Supravalvular aortic or pulmonary stenosis	Elfin face, short stature, impaired cognition and development, endocrine disorders, genitourinary abnormalities
Leopard	PTPN11, RAF-1, autosomal dominant trait	Electrocardiographic abnormalities, supravalvular or valvular pulmonary stenosis	Lentigines, ocular hypertelorism, abnormal genitalia, retardation of growth, deafness
DiGeorge (velocardiofacial)	22Q11 deletion, autosomal dominant trait	Conotruncal defects such as tetralogy of Fallot, interrupted aortic arch, truncus arteriosus, vascular rings and ASD/VSD	Hypertelorism, low set and posteriorly rotated ears, palatal abnormalities, micrognathia, developmental delay, hypoplastic thymus, hypocalcemia, variety of immunological abnormalities
Alagille	JAG-1, NOTCH-2, dominant trait	Peripheral pulmonary stenosis	Facial dysmorphias (triangular face, wide nasal bridge, deep set eyes), intrahepatic cholestasis, butterfly vertebrae
Keutel	MGP mutations, autosomal recessive trait	Multiple peripheral pulmonary stenoses	Abnormal cartilage calcifications, brachytelephalangy, subnormal IQ, hearing loss
Congenital rubella	–	Peripheral pulmonary stenosis, open ductus Botalli	Congenital cataract/glaucoma, deafness, pigmentary retinopathy

ASD, atrial septal defect; VSD, ventricular septal defect.

incompatibility with pacemakers and requirements for breath holds. Cardiac catheterization is utilized diagnostically to directly measure pressure gradients and evaluate anatomy via angiography but is used primarily for interventional options such as balloon valvuloplasty.

Surgical and transcatheter approaches and outcomes

Transcatheter balloon valvuloplasty is now considered the first-line treatment for PS. The procedure is considered when patients exhibit symptoms, have a PV mean gradient greater than 40 mmHg while sedated, or have clinically significant PS with RV dysfunction on echocardiography [108]. Exceptions include cases involving a hypoplastic annulus, severely dysplastic valve, and other associated congenital cardiac lesions. In these cases, surgery may be the preferred initial option [108]. Percutaneous balloon valvuloplasty can be used serially for PV stenosis that recurs over time and is considered successful when the mean gradient is reduced to less than 30 mmHg. The incidence of PI after balloon valvuloplasty is 80%, but it is usually mild in clinical severity. In the past, postprocedural PI was noted with little concern, but correlations between long-standing PI, RV dilation, and potential decreases in RV function have led some centers to utilize smaller balloons and tolerate some residual PS [107]. Complications, though rare, include transient bradycardia and hypotension with balloon inflation, transient/permanent AV block, tricuspid papillary muscle rupture and MPA rupture. However, with experienced providers, the risk of death/major complications is exceedingly low (0.24%/0.35%, respectively). Beta-blockers may be needed infrequently to reduce contractility in a hyperdynamic RV after valvuloplasty.

If balloon valvuloplasty fails, or if there are more complicated lesions (usually sub- or supravalvar stenosis), surgical repair with CPB may be necessary. For valvar stenosis, open commissurotomy or valvulotomy is usually performed through a vertical incision in the pulmonary trunk. If necessary, a transannular patch of autologous pericardium can be placed. Subvalvar obstruction in the infundibular region can be excised and an MPA patch placed. If valve replacement is required (as in the case of severe postprocedural PI), implantation of a bioprosthetic valve is preferred as the risk of thrombosis in pulmonary mechanical valves is higher than in mechanical valves in the aortic position [108]. Pulmonary homograft or other bioprosthetic valves may be used. Patients with prior valve replacements that have developed stenosis or regurgitation can be candidates for percutaneous valve implantation.

Despite successful pulmonary balloon valvuloplasty, some neonates with critical PS may exhibit cyanosis with ductal closure, and a PGE_1 infusion will need to be reinstated. As RV hypertrophy diminishes and RV compliance improves, PGE_1 may be weaned. If the neonate remains ductal-dependent for PBF after 2–3 weeks, a systemic-to-pulmonary arterial shunt or PDA stent may be required. About 15–20% of neonates with critical PS will eventually need surgical intervention.

Anesthetic considerations

Periprocedural anesthesia for transcatheter pulmonary balloon valvuloplasty

Neonates with critical PS require PGE_1 to maintain adequate PBF and urgently undergo PV transcatheter intervention. Often, these infants are supported prior to the

AL Grawany

procedure with mechanical ventilation and inotropic support. Anesthetic agents may include inhalational agents supplemented with low-dose opioids and muscle relaxants. Procedural stimulation is limited beyond establishment of venous access for catheterization, so anesthetic requirements are minimal. Intraprocedural complications include temporary bradycardia and hypotension during balloon inflation and transient AV block. After sufficient PV dilation, an immediate reduction in the transvalvar gradient is observed with angiographic evidence of increased PBF. At the time of the sudden relief of PV obstruction, filling pressures will require immediate support with the administration of intravascular volume such as 5% albumin in order to maintain forward flow from the hypertrophic, low-compliance RV. After establishing PBF through the PV, PGE_1 is discontinued. The neonate returns to the ICU with mechanical ventilation for adjustments of inotropic support and ventilation.

Older infants and children with PS usually present electively for pulmonary balloon valvuloplasty. Inhalational anesthetic induction followed by establishment of intravenous access is generally well-tolerated. The intraprocedural complications are similar to those above. Maintenance of anesthesia can be accomplished with inhaled anesthetic agents supplemented with low-dose opioids as necessary. After successful pulmonary balloon valvuloplasty, some patients may have transient dynamic RVOTO secondary to infundibular hypertrophy. A beta-blocker such as with an infusion of esmolol can reduce contractility and heart rate. Increasing right heart filling pressures with intravascular volume administration assists in enhancing right heart CO by increasing preload and overcoming RVOTO. After balloon valvuloplasty of severe PS, the sudden enhancement of PBF can result in reperfusion pulmonary edema, requiring adjustments of mechanical ventilation and especially PEEP. In most cases, the intraoperative course is uneventful, and the patient can be extubated at the conclusion of the catheterization procedure. Local anesthetic infiltration of the access sites, titration of dexmedetomidine for post-procedural sedation and acetaminophen analgesia are usually sufficient for a smooth anesthetic emergence and recovery.

Perioperative anesthesia for surgical valvotomy

Preoperative

In the current era of transcatheter interventions, surgical valvotomy is reserved for those patients that have failed the transcatheter approach or have multilevel fixed RVOTO not amenable to transcatheter intervention. Patients are medically optimized prior to surgery, particularly those with PS complicated with CHF.

Intraoperative

Premedication, anesthetic induction, and intubation are tailored to the clinical status of the patient. Anesthetic management prior to CPB is directed towards preservation of ventricular function and optimization of PBF. Anesthetic induction can be accomplished with low-dose fentanyl, with or without ketamine (depending on the presence of dynamic RVOTO), and low levels of anesthetic agent such as sevoflurane. Meticulous titration of inhaled anesthetic agent with sufficient muscle relaxation and opioid infusion is appropriate for anesthetic maintenance. Continuous arterial blood pressure monitoring with central venous access for central venous blood pressure monitoring and drug administration are established prior to surgery. Cerebral and somatic NIRS monitoring for regional tissue oxygenation and TEE for assessment of the RVOT status and cardiac function are useful.

After completion of the surgical valvotomy, a milrinone infusion can be used to facilitate RV relaxation and lower PVR. Generous RV preload will be necessary to accommodate a noncompliant hypertrophic RV. As the patient is weaned from CPB, the sudden increase in PBF can result in reperfusion pulmonary edema. Mechanical ventilation with sufficient PEEP will be required to maintain airway gas exchange. Transient RV dysfunction, especially after a right ventriculotomy approach, may require inotropic support such as with low-dose epinephrine. Excessive inotropy can be detrimental if residual dynamic RVOTO is present. For a hyperdynamic RV, CO may actually be improved with an esmolol infusion by reducing dynamic RVOTO. Commonly, a residual pressure gradient with persist across the RVOT after surgical repair, improving over the first 24 postoperative hours.

Postoperative

If reperfusion pulmonary edema is evident or suspected, patients are best managed with postoperative mechanical ventilation with sufficient PEEP until the pulmonary vasculature has accommodated the increased PBF. Residual infundibular hypertrophy usually resolves over time with removal of the valvar obstruction. Effective postoperative analgesia and sedation are accomplished with opioid and dexmedetomidine infusions as well as IV acetaminophen. Early extubation is reserved for patients with mild PS, an uneventful intraoperative course, adequate ventricular function, and no evidence of reperfusion pulmonary edema.

KEY POINTS: PULMONARY STENOSIS WITH INTACT VENTRICULAR SEPTUM

- Valvar PS is most common at 80–90% of cases, with subvalvular and supravalvular types making up the remaining 10–20%.
- Successful percutaneous balloon valvuloplasty results in a transvalvar gradient of less than 30 mmHg.
- Beta-blockers may be useful in reducing contractility in a hyperdynamic RV after percutaneous balloon valvuloplasty.
- In the immediate period after repair, RV filling pressures must be adequate while avoiding high pulmonary artery pressures; adequate RV preload and pulmonary vasodilators are useful treatments.

Pulmonary atresia with intact ventricular septum

Incidence, anatomy, and natural history

PA/IVS is a rare (accounting for 3% of congenital heart defects) right heart obstructive lesion defined by the presence of an atretic PV and an IVS (absence of a VSD). Males are more likely to have PA/IVS with a male to female ratio of 1.5:1 [111]. Although the etiology of the defect is unknown, there is evidence to suggest that atresia of the PV may be a result of abnormal coronary arterial development [112]. Patients commonly develop TR or coronary fistulas in an effort to help decompress the hypertensive RV [113]. Typically, there is a PFO or secundum ASD that is restrictive in 5–10%. The TV is generally smaller than normal but can range from extremely stenotic to the dilated annulus of EA (5–10%). The RA is dilated proportionately to the degree of TR. The RV is hypertrophic with a reduced cavity. In about 50% of cases, there are endothelial-lined blind channels within the RV myocardium known as sinusoids that may be remnants of vessels providing nutrients to the ventricles prior to the formation of coronary arteries. Sinusoids are in direct communication with the RV cavity and sometimes to the coronary arteries, becoming RV to coronary artery fistulae. Sinusoids may persist due to RV hypertension. In the least affected individuals, RV blood is sent as part of a dual blood supply to small areas of myocardium in tandem with normal aortocoronary flow. But approximately 20% of patients with PA/IVS have an absence of anterograde aortocoronary flow, a finding confirmed with either cardiac catheterization or computed tomography (Figure 28.20). In this circumstance, the coronary bed is perfused with poorly saturated systemic venous blood directly from the RV and the RV myocardium is chronically ischemic. In the most severely affected, aortocoronary connections will be absent and coronary cameral connections with the RV establish an RV-dependent coronary circulation (RVDCC) that supplies the RV myocardium [113].

Sometimes the PV appears intact, but with fused commissures. Most often, there is fibrous tissue at the ventriculoarterial junction. The pulmonary arteries usually have normal branching and can be hypoplastic in about 6% of cases. There is almost always a PDA. The LA is enlarged and hypertrophic. Subaortic stenosis can result from bulging of the ventricular septum into the LV due to RV hypertension.

Without treatment, PA/IVS results in death in 50% of neonates, and in 85% of infants by 6 months of age. Fetuses with small, hypertrophied ventricles often survive to birth, whereas those with dilated RVs and severe TR may die in utero with fetal hydrops. Postnatal death is usually due to hypoxemia which is exacerbated by closure of the ductus arteriosus, and eventual myocardial ischemia and infarction [114].

Pathophysiology

Many fetuses with PA/IVS succumb to intrauterine demise or develop hydrops fetalis from RV failure, but for some surviving neonates who have not developed hydrops fetalis, moderate TR may have allowed the RV pressure to remain low such that sinusoids and coronary fistulae have not developed. Alternatively, if TR is mild or the valve is competent, the neonatal RV will be small and hypertrophic with marked systolic hypertension. This subset, with a competent or nearly competent TV and suprasystemic RV pressure, is at higher risk for coronary artery abnormalities such as coronary cameral connections with the RV, coronary ostial stenosis and atresia, and absent aortocoronary connections. Coronary cameral connections with the RV, or RVDCC, perfuse the RV myocardium with blood at oxygen levels and pressures of the RV. The RVDCC are dependent on

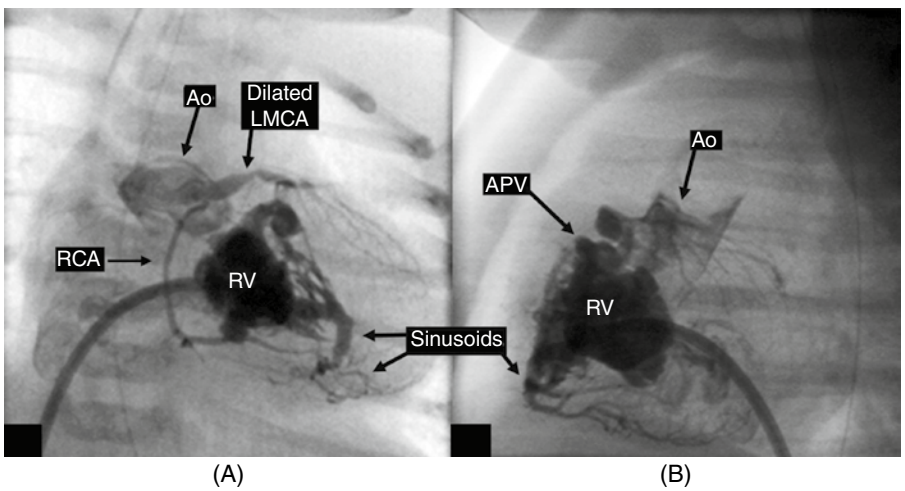

Figure 28.20 Pulmonary atresia with intact ventricular septum in a 1-day-old infant. A National Institutes of Health (NIH) catheter has been placed prograde into the right ventricle (RV) via a hypoplastic tricuspid valve for a contrast hand injection. There is mild tricuspid regurgitation. Numerous coronary sinusoids from the RV cavity to both right coronary artery (RCA) and left coronary artery are demonstrated. Contrast faintly opacifies the aorta (Ao) retrograde through a dilated left main coronary artery (LMCA). (A) Frontal view. (B) Lateral view. RV outflow tract ends at the atretic pulmonary valve (APV). (Source: Schmitz et al. [38]. Reproduced with permission of John Wiley & Sons.)

AL Grawany

RV pressures while in turn, adequate RV pressure generation is reliant on myocardial perfusion/oxygenation by the RVDCC. Patients with RVDCC are at an elevated risk for myocardial ischemia and infarction, particularly if the high-pressure RV becomes decompressed. RV decompression allows diastolic runoff from the aorta through the coronaries into the RV chamber at lower pressures, thereby creating coronary "steal" with resulting myocardial ischemia. RVDCC is present in 9–34% of patients with PA/IVS [115]. In addition, LV hypertrophy and dilation, and possible aortic root dilation may be present due to increased left heart flow across the foramen ovale in utero.

After birth, the PDA remains the sole source of PBF, and early initiation of PGE_1 is key for survival to surgical repair or palliation. An atrial communication is necessary for right-to-left shunting of systemic venous return, mixing on the left side of the heart with oxygenated blood from the pulmonary veins. The newborn with PA/IVS demonstrates functional single ventricle physiology so that the distribution of systemic and PBF is dependent on PVR/SVR ratios. Thus, arterial saturation is principally obtained by three variables: Qp:Qs, systemic venous saturation, and pulmonary venous saturation.

The ECG reveals small RV forces and often a tall P wave, indicative of RA enlargement. The chest radiograph often shows decreased to normal pulmonary vascular markings depending on the amount of ductal flow. The cardiac silhouette is normal unless RA and RV enlargement occur due to severe TR. Echocardiography can define the atrial septum (adequacy of atrial communication), TV (size, function, and morphology), RV (evidence of hypertrophy and functional structure), RVOT (membranous vs muscular PA) and PDA (size and direction of blood flow). While proximal coronary artery anatomy and the presence of coronary cameral connections can be delineated by echocardiography, cardiac catheterization or computed tomography may be necessary to adequately visualize coronary artery abnormalities, with cardiac catheterization being the preferred tool to concurrently provide therapeutic interventions [116].

Surgical and transcatheter approaches and outcomes

In the early 1960s, palliative shunts and closed pulmonary valvotomies were done. However, survival was dismal given that an estimated 2.5% of patients survived to 3 years of age. CPB-assisted RV outflow procedures were combined with systemic-to-pulmonary arterial shunts in the 1970s. Since that time the therapeutic approach has been directed toward the following outcomes: biventricular circulation, single ventricle (including 1.5 ventricle) palliation, or cardiac transplantation, depending on RV size and anatomy (unipartite, bipartite, or tripartite), TV and PV size, subPV stenosis, TR, ventriculocoronary connections, and RVDCC [113] (Figure 28.21).

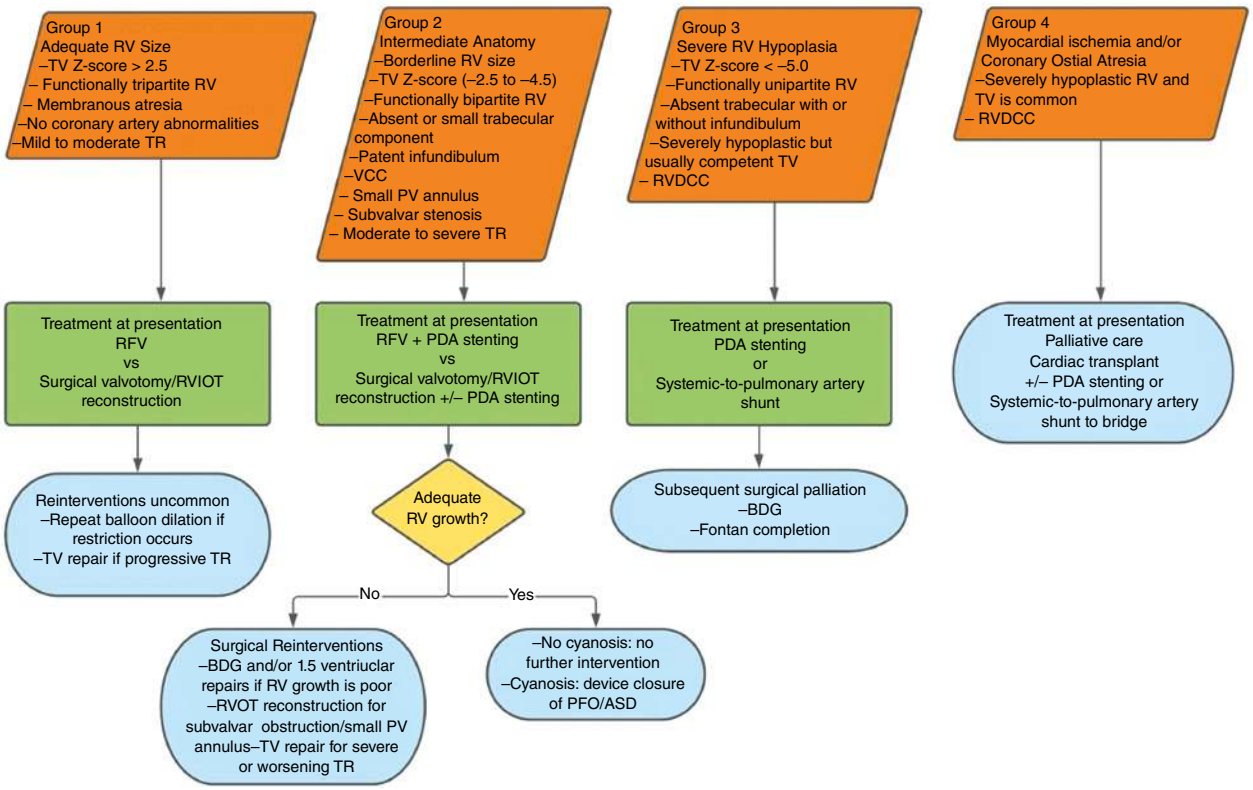

Figure 28.21 Strategies for the management of variants of pulmonary atresia with intact ventricular septums from Chikkabyrappa et al. [113]. ASD, atrial septal defect; BDG, bidirectional Glenn; PDA, patient ductus arteriosus; PFO, patent foramen ovale; PV, pulmonary valve; RFV, radiofrequency valvotomy and balloon dilation; RV, right ventricle; RVDCC, right ventricle-dependent coronary circulation; RVOT, right ventricular outflow tract; TR, tricuspid regurgitation; TV, tricuspid valve; VCC, ventriculocoronary connections. (Source: Michael L. Schmitz, MD.)

Patients with PA/IVS are usually first evaluated via cardiac catheterization with hemodynamic measurements, coronary angiography, and possible intervention. Once the absence of RVDCC is confirmed, decompression of the RV via percutaneous pulmonary valvotomy with radiofrequency ablation, wire or laser and balloon dilation can be undertaken. Other interventions may include balloon atrial septostomy and balloon dilation or stenting the PDA.

Initial neonatal surgical options include:

- RVOT reconstruction with surgical valvotomy
- RVOT reconstruction with surgical valvotomy and PDA stenting
- Systemic-to-pulmonary arterial shunt
- Cardiac transplant or systemic-to-pulmonary arterial shunt as bridge to transplant

After the initial neonatal palliation, the decision about subsequent procedures and a biventricular repair vs. single ventricle palliation depends on similar initial considerations such as RV and TV size and function [113, 117, 118] (Figure 28.21). To evaluate for biventricular repair, oxygen saturations and potential for further RV growth are assessed. Within 6 months after the initial procedure, the systemic-to-pulmonary artery shunt and the ASD can be temporarily occluded in the cardiac catheterization laboratory. If oxygen saturations remain appropriate and the right atrial pressure remains below 12–15 mmHg with adequate CO, the patient may be a candidate for biventricular repair [119].

If biventricular repair is not feasible, the patient proceeds to a BDG. Patients with inadequate RV size retain an open ASD and proceed to Fontan palliation. Those who have intermediate RV size and some degree of RV outflow might proceed to a BDG with ASD closure, resulting in a 1.5 ventricle palliation. If tolerated, a 1.5 ventricle palliation may be preferable to a Fontan circulation as it may lead to a step-down in pressure in the IVC and a step-up in pulmonary artery pressures, avoiding the caval hypertension and potential pulmonary arterial hypotension with a Fontan circulation [118].

Surgical options for PA/IVS with RVDCC are more limited as procedures are limited to those that do not decompress the obstructed RV. Initial options include placement of a systemic-to-pulmonary artery shunt or ductal stent to provide a stable source of PBF with the ultimate goal of single ventricle palliation or cardiac transplant. As mortality exceeds 50% in infancy for patients undergoing single ventricle palliation, cardiac transplant may be a more viable option [115].

As Reddy and Hanley [120] stated more than two decades ago, the goals of initial surgical intervention for neonates with inadequate RV anatomy are to:

- Minimize mortality
- Promote growth of the RV to improve chances for a subsequent two ventricle repair
- Minimize the requirement for later non-definitive surgical intervention

The systemic-to-pulmonary artery shunt can be a non-defining initial palliation with relatively low mortality and for neonates with small RVs without RVDCC and allowing the RV to decompress may allow for RV growth. The systemic-to-pulmonary artery shunt allows time to later estimate the ultimate functional potential of the RV, potential that is often unclear in neonatal PA/IVS.

Anesthetic considerations

Despite the multitude of interventional and surgical options available for PS/IVS and PA/IVS, there are some general considerations for perioperative care [118] (Table 28.9).

Table 28.9 Key considerations in the perioperative management of pulmonary atresia with intact ventricular septum (PA/IVS)

Perioperative period	Key considerations

Preoperative	• Neonates dependent on PGE_1
	  ○ Appropriate physiologic monitoring
	  ○ Stable vascular access
	• Standard preoperative evaluation:
	  ○ ECG
	  ○ TTE
	  ○ Chest X-ray
	  ○ Cardiac catheterization (to evaluate coronary anatomy and identify RVDCC

Intraoperative	• Neonatal palliation
	  ○ Systemic-pulmonary artery shunt
	  ■ Balance Qp:Qs
	  ■ Avoid diastolic blood pressure hypotension
	  ■ Monitor ECG closely for signs of myocardial ischemia
	  ○ RV decompression procedure (valvotomy or transannular patch)
	  ■ Maintain RV preload/filling pressure
	  ■ RV inotropic support
	  – Milrinone
	  – Dobutamine/epinephrine
	  – Nitric oxide to reduce RV afterload
	• 2nd Stage BDCPA or 1.5-ventricle palliation
	  ○ Adequate preload delivery to partially unloaded RV
	  ○ Avoid high PVR
	  ○ Mild hypercarbia post-BDCPA
	  ○ Adequate oxygenation
	• 3rd Stage Fontan circulation
	  ○ Maintain intravascular volume
	  ○ Ensure atrioventricular synchrony (sinus rhythm or AV pacing)
	• RVDCC (10% of PA/IVS patients)
	  ○ Cannot undergo procedure to decompress the obstructed RV
	  ○ Maintain RV pressures and avoid decompression
	  ○ CPB cases: second arterial cannula via the RA used to pressurize the RV
	  ○ Partial CPB flow with mechanical ventilation (reported option)

Postoperative	• Early extubation
	  ○ Negative intrathoracic pressure reduces RV afterload and increases PBF
	  ○ RV inotropic support

BDCPA, bidirectional cavopulmonary anastomosis; CPB, cardiopulmonary bypass; ECG, electrocardiogram; PA, pulmonary artery; PBF, pulmonary blood flow; PGE_1, prostaglandin E_1; PVR, pulmonary vascular resistance; Qp:Qs, pulmonary:systemic blood flow; RV, right ventricle; RVDCC, right ventricular-dependent coronary circulation; TTE, transthoracic echocardiogram.

AL Grawany

Cardiac catheterization laboratory

Postnatal TTE results can help guide anesthetic planning. If RV fistulas are a concern, maintenance of RV preload and systemic diastolic pressure are essential to preserve coronary perfusion pressure [118]. Risks involving cardiac catheterization should be anticipated, including difficulty with obtaining vascular access, injury to large vessels and myocardium, and hemorrhage.

Neonatal palliation

Neonates with PA/IVS may undergo systemic to pulmonary arterial shunt in isolation or combined with pulmonary valvotomy. (Patients with RVDCC will be discussed separately below.) Procedures may be performed with or without CPB via a sternotomy or thoracotomy. Monitoring should include arterial and central venous line access, NIRS, and TEE. Anesthetic induction and maintenance are performed with a combination of opioid, inhaled anesthetic agent and muscle relaxant. Careful consideration should be given to maintaining an appropriate Qp:Qs balance and diastolic BP to provide adequate CO and avoid myocardial ischemia respectively. For any patient with a small hypertrophic, hypertensive RV, RV filling pressures must be maintained such that the RV cavity does not collapse, and thus maintain CO. For patients undergoing RV decompression on CPB, preservation of filling pressures is essential as poor RV preload will compromise CO. This is particularly important in patients undergoing repairs leading to biventricular circulation. Inotropic RV support is often needed as RV dysfunction is commonly present after CPB. Optimizing ventilation pressures and utilizing pulmonary vasodilators with drugs such as milrinone (0.375–0.75 μg/kg/min) help to reduce RV afterload. If pulmonary hypertension was present prior to repair, iNO can be used to aid in pulmonary vasodilation until the vascular bed adjusts to the increased flow. Postoperatively, expedited tracheal extubation and resumption of spontaneous ventilation aid in improving PBF and reducing RV afterload. Narcotic infusions to ensure adequate analgesia will reduce oxygen demands from agitation.

For a few patients who undergo systemic-to-pulmonary artery shunt placement, low CO in the postoperative period could be caused by either unrecognized RVDCC or from a "circular shunt" (described earlier in this chapter). A circular shunt arises in patients who have had both a pulmonary valvotomy and a systemic-to-pulmonary arterial shunt and have significant PI. In this situation, blood ejected from the LV flows through the systemic-to-pulmonary arterial shunt and to the pulmonary circulation. Due to PV incompetence, blood proceeds retrograde along a declining pressure gradient to the RV, and depending on the competence of the TV, into the RA, and then the LA via the interatrial communication. The "steal" of blood from the systemic circulation causes systemic hypoperfusion with resulting metabolic acidosis. Raising the PVR and reducing the SVR may be helpful in improving systemic perfusion, but surgery is often needed to revise the shunt and treat TR.

Single ventricle palliation (including 1.5 ventricle palliation and Fontan procedure)

On initial presentation, infants unable to undergo biventricular repair (primarily those with severe RV/TV hypoplasia and/or RVDCC) instead have stabilization of their PBF by various mechanisms. With borderline RV size, PBF can be enhanced and stabilized by radiofrequency pulmonary valvotomy with PDA stenting, surgical pulmonary valvotomy and RVOT reconstruction with or without PDA stenting, or in the case of severe RV hypoplasia, PDA stenting or systemic-to-pulmonary artery shunt placement [113]. Monitoring is similar to that of neonatal palliation with care to place the arterial line monitoring on the contralateral side of systemic-to-pulmonary shunts utilizing innominate or subclavian arteries. For subsequent establishment of a bidirectional cavopulmonary anastomosis (BDCPA), central venous access is often placed in the right or left internal jugular vein to measure superior cavopulmonary pressure. For initial procedures on infants to stabilize PBF, the induction and maintenance of anesthesia is also similar to PS/IVS and performed via a combination of opioids, inhaled anesthetic agent, and muscle relaxants. For construction of the BDCPA, hyper- or hypocapnia and hypoxia are avoided and low PVR is maintained to provide adequate PBF. Early extubation and postoperative positioning with the upper body elevated 30 degrees can improve facilitate PBF. Intraoperative considerations for 1.5 ventricle palliation are similar to that of the single-ventricle BDCPA with the caveat that the small RV will be very dependent on preload and require inotropic support including milrinone as described above. For a later Fontan procedure, anesthetic goals include early extubation with upper body elevation, maintenance of intravascular volume, adequate sedation and analgesia (e.g., dexmedetomidine and narcotic infusions as described previously) to reduce oxygen demands, and AV synchrony (sinus rhythm or AV pacing) and discussed in detail elsewhere in this volume.

RVDCC

Patients with RVDCC are tenuous from a hemodynamic standpoint and require constant communication with the surgical and perfusion teams for optimal care [118]. For procedures requiring CPB (including those mentioned above), RV pressure can be maintained through a second arterial cannula placed transmurally into the RA and secured with a purse string suture. Alternatively, partial CPB with continued mechanical ventilation can be employed to maintain RA pressure [115]. As mentioned previously, strategies to prevent RV decompression are critical in patients with RVDCC as it may lead to severe ischemia and death if not employed.

KEY POINTS: PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

- Approximately 20% of patients with PA/IVS do not have anterograde aortocoronary flow and have a chronically ischemic myocardium with RVDCC.
- Mortality in untreated infants is 50% by 1 month and 85% by 6 months of age.
- For any patient with a small, hypertrophic, hypertensive RV, filling pressures must be maintained to prevent RV collapse.
- Filling and RV pressure must be maintained for patients with RVDCC at all times to prevent "coronary steal" from the myocardium, even while on CPB.

Pulmonary atresia/ventriculoseptal defect/major aortopulmonary collateral arteries

Incidence, anatomy, and natural history

PA/VSD/MAPCAs or TOF/PA is a rare defect that involves features of TOF (infundibular hypertrophy, large misaligned VSD) with a lack of continuity between the RV and pulmonary trunk and varying levels of pulmonary arterial hypoplasia, thus causing heterogeneity in regards to PBF. The incidence is 0.7 per 10,000 live births for PA/VSD/MAPCAs [121]. The native MPA and BPAs are absent in 20–25% of patients, with significant abnormalities in the remaining 75–80% that do have intrapericardial native BPAs [122]. In the latter group, native BPAs are inevitably hypoplastic to varying degrees, likely due to lack of antegrade flow from the RV and retrograde flow from MAPCAs [123]. Lung parenchyma may be perfused singly by native BPAs or MAPCA flow, or redundantly by both. MAPCAS vary in number, size, and origin with the most common origin being the descending thoracic aorta, but not infrequently involving the innominate, subclavian, internal mammary, and coronary arteries as well, and usually traverse through the posterior mediastinum associating with the major airways and at times the esophagus [123]. Unfortunately, MAPCAs commonly develop stenosis at the point of their origin, causing the area supplied by the MAPCA to become underperfused without an alternate source of PBF. A classification system has been proposed, based on the morphology of the pulmonary arteries and MAPCAs, that can be useful for surgical decisions [124] (Figure 28.22). Of note chromosome 22q11 deletion may be present in >35% of patients with TOF/PA/MAPCAs [125].

Disease progression of TOF/PA is best done by organizing patients into three distinct groups based on PBF, each of which has differing mortality outcomes. The first group has a PDA as the source of PBF, and more than 50% die by 6 months of age and 90% by 1 year. In the second group MAPCAs are present with a PDA as PBF; 50% die by 3–5 years of age and 90% within 10 years. In the third group, multiple and large MAPCAs are present as the only source of PBF. In this group, only mild cyanosis may present on physical exam, without signs of CHF; when left untreated, patients usually live into the third decade, but eventually die from pulmonary vascular disease resulting in Eisenmenger syndrome [126].

Pathophysiology

TOF/PA can be viewed as a mixed lesion with PBF determined by overall TR with highly variable sources of PBF. Approximately 90% of patients have nearly balanced Qp:Qs, with oxygen saturations between 75–90% while the remaining 10% present with either excess (O2 saturation >90%) or decreased (O2 saturation <75%) PBF leading to pulmonary congestion/CHF or metabolic acidosis respectively [123]. It is important to note that MAPCA patency is dynamic as proximal stenosis of the vessels is common and leads to ischemic loss of lung segments.

Fetal and neonatal echocardiography is useful to identify PA and presence of a VSD and MAPCAs; however, virtually all patients require cardiac catheterization and/or CT/MRI angiography to fully delineate the pulmonary artery and collateral artery anatomy and determine the appropriate surgical approach (Table 28.10). MRI or CT with three-dimensional reconstruction of the images is also useful in outlining

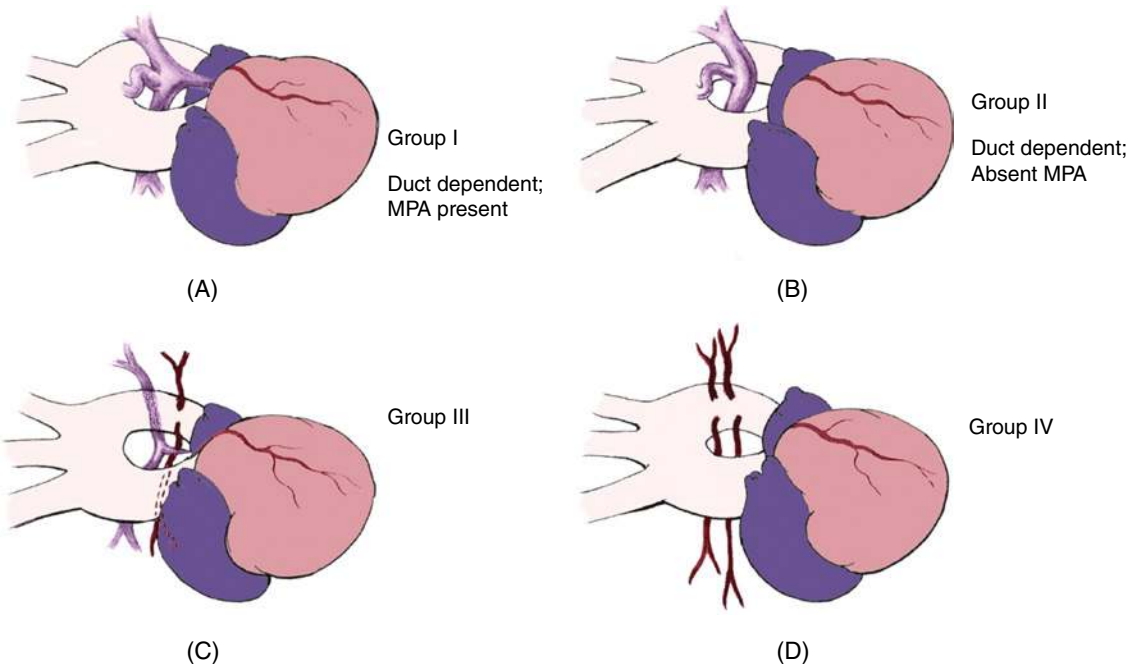

Figure 28.22 Tetralogy of Fallot with pulmonary atresia occurs with much variation depending on the development of the true pulmonary arteries and aortopulmonary collateral arteries. (A) Group I: simple valvular or infundibular atresia. (B) Group II: ductal-dependent branch pulmonary arteries and absence of the main pulmonary artery (MPA). (C) Group III: hypoplastic true pulmonary arteries with major aortopulmonary collateral arteries. (D) Group IV: true pulmonary arteries are absent, and all pulmonary blood supply is from major aortopulmonary collateral arteries. (Source: Jonas [124]. - Age of the patient

complex anatomy (Figure 28.23). Three dimensional CT often is the better option for the fine resolution needed for infants (Figure 28.24).

Surgical and transcatheter approaches and outcomes

Ma et al. [123] note the approach to surgical repair is threefold:

1. Achieve normal physiology and biventricular repair by minimizing TR with preservation and augmentation of the PBF, usually accomplished via early/complete unifocalization if needed. (see later in section for description of unifocalization procedure).
2. Complete biventricular repair with atrial and VSD closure with placement of an RV to pulmonary artery valved conduit in patients with a RV systolic pressure that is 50% or less of the LV systolic pressure: Patients not meeting this pressure ratio receive a central shunt, and intracardiac repair is delayed until a RV/LV pressure ratio of 0.5 is achieved in follow-up cardiac catheterization.
3. Periodic surveillance with indicated studies (CTA/MRI/cardiac catheterization) to assess the adequacy of PBF and decreases in PVR: Post repair, elective balloon angioplasty of recruited MAPCAs and pulmonary arteries as well as embolization of redundant MAPCAs can non-surgically augment PBF (Figure 28.25).

Most patients (85%) are repaired at 3–6 months of age after further maturation of the trachea and secondary airways, decreasing postoperative pulmonary morbidity [127]. The remaining 15% of patients undergo repair in the neonatal period due to the following:

- Unilateral lung perfusion by MAPCAs with contralateral lung perfusion by a PDA: The ductus can close in the neonatal period resulting in loss of ductal-perfused lung. Unifocalization and intracardiac repair is performed with favorable MAPCAs, otherwise a ductal stent or surgical shunt to the ductal-dependent lung is placed. The patient is then repaired later in infancy [128].
- Normally arborized hypoplastic native pulmonary arteries (all lung segments supplied by native BPAs) with redundant blood flow by MAPCAs. MAPCAs are ligated in this situation, and an aortopulmonary anastomosis (Melbourne shunt) can be placed to encourage further pulmonary vascular bed growth [128].

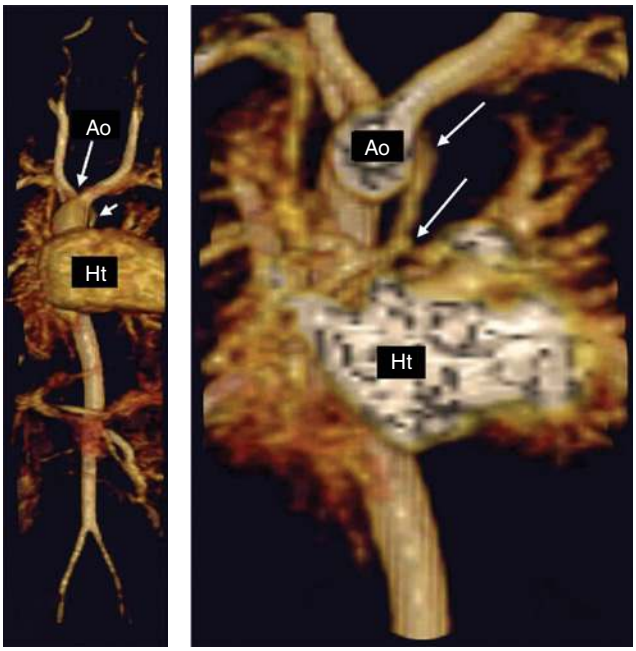

Figure 28.23 Gadolinium-enhanced magnetic resonance angiogram of a 3-day-old, 2.5-kg infant with tetralogy of Fallot, pulmonary atresia, and multiple aortopulmonary collateral arteries. (A) Anterior-posterior view demonstrating a right aortic arch (Ao) and no visible pulmonary artery originating from the heart (Ht). The short arrow shows a large collateral artery originating from the left side of the aortic arch. (B) Same view as the left image, but with the ascending aorta removed. The upper arrow shows the same large collateral artery as seen in the left image descending to supply tiny branch pulmonary arteries (lower arrow). (Source: Schmitz et al. [38]. Reproduced with permission of John Wiley & Sons.)

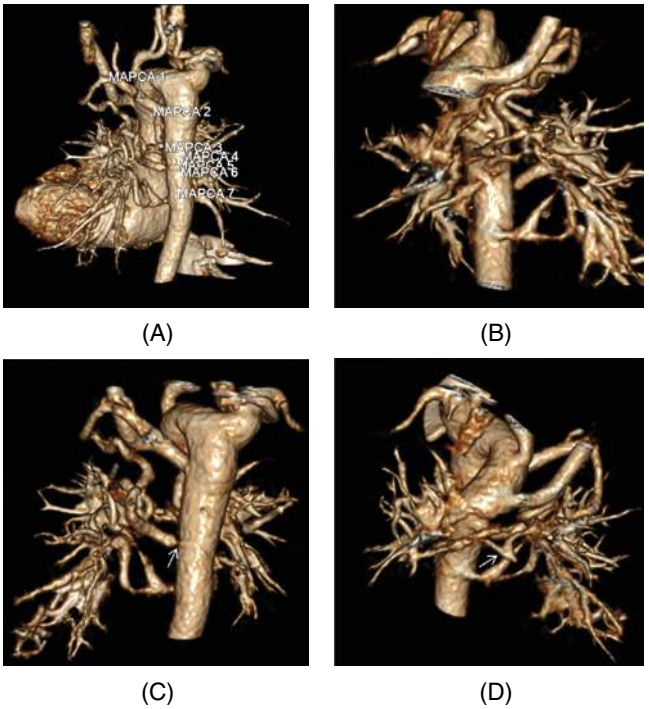

Figure 28.24 Three-dimensional reconstruction of cardiovascular computed tomography scan of a patient with seven major aortopulmonary collateral arteries (MAPCAs). The posterior (A) and anterior (B) views show numerous MAPCAs supplying the lung fields. Proximal stenoses as seen in MAPCA 5 (C, arrow) are common. This patient had severely hypoplastic but confluent native pulmonary arteries (D, arrow).

Ao, aorta; AP, aortopulmonary; MAPCAs, major aortopulmonary collateral arteries; PA, pulmonary artery; PDA, patent ductus arteriosus; PBF, pulmonary blood flow; RV, right ventricle; VSD, ventricular septal defect. (Source: Michael L. Schmitz, MD.)

- Significant pulmonary overcirculation resulting in severe failure to thrive: Unifocalization is usually done in this situation.
- Profound hypoxia (usually due to proximal MAPCA stenoses with or without native BPAs): If patients have significant native BPA tissue, yet proximal stenoses in MAPCAs, surgical palliation may be accomplished via unifocalization. On the other hand, patients with limited native BPA tissue are poor surgical candidates for early complete palliation and future prognosis to obtain biventricular physiology is poor [129].

"Unifocalization" refers to the process of dividing MAPCAs from their aortic origin and anastomosing them directly to the native BPAs or to a homograft or tube graft conduit connecting to the pulmonary arteries [124] (Figure 28.26). As mentioned, unifocalization is usually performed in infancy but occasionally in the neonatal period. Midline sternotomy is the common approach, although thoracotomy (usually on the side of the descending aorta) may be necessary to initially access MAPCAs lying posteriorly or within lung fissures. Previously, multistage procedures were often performed with sequential bilateral thoracotomies

AL Grawany

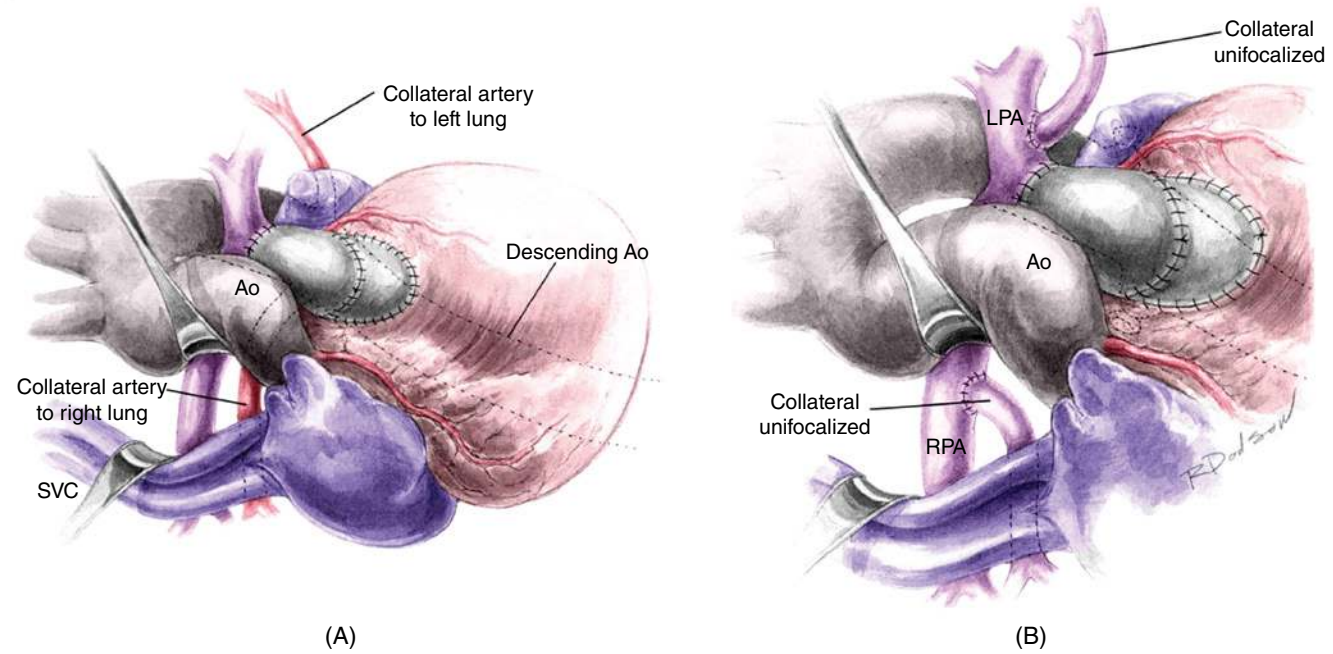

Figure 28.26 Unifocalization of collateral arteries to true pulmonary arteries via a median sternotomy. (A) As the aorta (A0) is retracted to the left, a collateral artery to the right lung is seen posterior to the transverse sinus. (B) One collateral artery has been unifocalized to the true right pulmonary artery (RPA) and another collateral artery has been unifocalized to the left pulmonary artery (LPA). SVC, superior vena cava. (Source: Jonas [124]. Reproduced with permission of Taylor & Francis.)

followed by a midline sternotomy approach that might include intracardiac repair. Single-stage unifocalization with or without an intial thoracotomy, sometimes including intracardiac repair, has shown excellent results [130]. In a review of patients who underwent single-stage midline unifocalization, Mainwaring et al. identified predictors for later need for unifocalization revision. These predictors included increased PBF augmentation with a systemic-to-pulmonary artery shunt, a higher RV:aorta pressure ratio (0.44 ± 0.08 versus 0.33 ± 0.07), or absence of central pulmonary arteries (32.8% versus 13.4%) [129]. Regardless of approach, it is essential to isolate and control all significant MAPCAs with vessel loops prior to going on CPB as systemic and cerebral hypoperfusion can occur despite adequate CPB flow as blood volume is lost into the pulmonary vasculature via open MAPCAs. A single-stage approach is not feasible in all patients (see neonatal repairs above); some require a systemic-to-pulmonary artery shunt or an RV-to-pulmonary artery conduit to allow growth before definitive repair.

Several single-center outcome analyses of surgical repair of TOF/PA have been published in the last decade. While some advocate using MAPCAs for reconstructing the pulmonary blood supply (MAPCA-based PBF), others are against using MAPCAs due to concerns of long-term reliability for PBF as they are prone to proximal stenosis. Therefore, two main management strategies have evolved: (i) to recruit all sources of PBF and focus on early intervention and midline single-stage unifocalization [123] and (ii) to focus on native pulmonary arterial rehabilitation and not utilize MAPCAs. In the second strategy, a central connection via aortopulmonary shunt or RV-pulmonary artery conduit is used to provide antegrade perfusion and hopeful future pulmonary vascular bed growth [130]. Serial balloon dilations and possible stenting are performed in the hopes of achieving appropriate RV/LV pressure ratio and subsequent intracardiac repair.

Of note, some centers have noted good early and late results regarding RV/LV pressure ratio utilizing MAPCA-based PBF [127]. While historical analysis of MAPCA-based circulations has shown poor late outcomes, it has been hypothesized that early intervention in the neonatal period and infancy (versus intervention at older ages) may lead to decreased arterial shear force and potential overcirculation, and thus improved late clinical outcomes [123].

Anesthetic considerations

Preoperative

The anesthetic management is based on the surgical procedure, including a range from shunts and PDA stents to unifocalization via thoracotomy or midline sternotomy. Principles for induction, maintenance and monitoring are similar to those described above for repair/palliation of TOF, however there are unique considerations. Anesthetic management for central systemic-to-pulmonary artery shunts placement, PDA stenting, and RV-to-pulmonary artery conduit placement are discussed earlier. Anesthetic management for single-stage palliation with unifocalization via median sternotomy follows.

Patients with TOF/PA/MAPCAs have variable complexity owing to severity of disease. Preoperative oxygenation, Qp:Qs, and cardiac function can be obtained from cardiac catheterization data [131]. Qp/Qs is largely influenced by MAPCA size and their associated PBF. Large, unobstructed

MAPCAs can result in overcirculation to the point of CHF. On the other hand, tortuous MAPCAs and those with proximal stenoses can result in cyanosis and metabolic acidosis.

Chromosome 22q11 deletion is commonly present and may be associated with hypocalcemia as well as a difficult airway due to a small mouth opening, micrognathia, subglottic stenosis, glottic web, laryngeal paralysis, larygomalacia associated with bronchial malposition, and velopharyngeal and palate defects [131–133]. Basic laboratory data, including complete blood count with differential, basic metabolic panel; coagulation studies; ECG, chest radiograph, imaging as transthoracic echocardiography; CT and MRI results; cardiac catheterization data; and prior anesthetic records are reviewed prior to surgery [134].

Intraoperative

Most patients tolerate a slow, controlled inhalational induction with sevoflurane [90], with FiO_2 adjusted to maintain an oxygen saturation of 75–85% to balance Qp:Qs. Standard monitors are utilized. Those with airway abnormalities should be anticipated, requiring advanced airway devices such as video laryngoscopy. As MAPCA development can be associated with tortuous peripheral vessel development, percutaneous vascular access can be difficult [134] but facilitated with bedside ultrasound guidance for both arterial and venous access.

Administration of anesthetic drugs during repair requires careful consideration. Considerable pulmonary runoff can occur from large MAPCAs; therefore, maintaining adequate systemic perfusion pressure is important to prevent systemic acidosis and hypoxemia from hypoperfused collateral arteries. A total or near-total IV technique with various agents (narcotics, benzodiazepines, dexmedetomidine, neuromuscular blocker) may be preferred to avoid decreases in mean arterial blood pressure (MABP), SVR, and CO that can occur with inhaled anesthetic agents in a dose-dependent fashion. Use of high dose narcotic anesthetic regimens (>50 μg/kg) as the primary anesthetic in congenital cardiac surgery can provide hemodynamic stability.

Dissection and ligation of collaterals is usually done off CPB to minimize total CPB time, provided the patient does not experience extreme hypoxia and metabolic acidosis [134]. This portion of the procedure may be prolonged (4–6 hours). With each MAPCA ligation, PBF is subtracted and redistributed to the systemic circulation, creating desaturation and hemodynamic changes. Careful monitoring of respiratory and hemodynamic parameters is required as large changes in oxygenation, ventilation, systemic perfusion, and cardiac arrhythmias may occur. A TEE probe may be placed, but if the patient is at risk for tracheobronchial compression, TEE should be omitted. Correction of metabolic and respiratory acidosis, maintenance of adequate circulating hemoglobin, and use of low-dose inotropic drugs may be useful during off-CPB dissection to maintain adequate oxygenation and perfusion.

Anesthetic management on CPB is similar to that of TOF (see previous section) with the caveat that residual open MAPCAs can cause hemodynamic instability on CPB due to shunting of arterial blood away from vital organs and loss of blood volume into the pulmonary vasculature. The target MABP is higher than usual for neonatal/infant repairs (60–70 mmHg) to ensure end-organ perfusion. Evidence of adequate end-organ perfusion is estimated by NIRS trends, urine output and ABG analysis. Some centers conduct an intraoperative PBF study to ensure appropriate RV/LV pressure ratios prior to intracardiac repair [135].

After cessation of CPB, reperfusion injury may occur in the lung segments that experienced low perfusion preoperatively which can impact hemostasis and worsen pulmonary compliance due to increased dead space ventilation from tracheobronchioalveolar pulmonary edema and intraparenchymal bleeding [134]. Frequent suction, aggressive pulmonary toilet and maintenance of appropriate PEEP may be useful to improve oxygenation and ventilation. Inotropic drugs as milrinone and epinephrine are commonly used to decrease PVR/improve lusitropy, and enhance CO respectively in a potentially stressed RV. To further reduce PVR, iNO may be necessary to improve oxygenation and CO. Blood loss can be significant secondary to extensive dissection, CPB time, and multiple suture lines. Ready transfusion with blood products to restore coagulation and replace hemoglobin losses is imperative.

Postoperative

Postoperatively, patients remain on mechanical ventilation with inotropic support. Aggressive pain control with opioid infusions and/or regional anesthesia and sedation with benzodiazepine and dexmedetomidine infusions are useful to minimize systemic and pulmonary hypertension. Continued aggressive management of postoperative bleeding is often necessary with prompt transfusion and correction of developing coagulopathies.

KEY POINTS: PULMONARY ATRESIA/ VENTRICULAR SEPTAL DEFECT/MAJOR AORTOPULMONARY COLLATERAL ARTERIES

- Biventricular repair consists of constructing a pulmonary bed using various available sources of PBF, connecting the RV to the new pulmonary bed, and closing the VSD.
- The successful post-biventricular repair requires an RV systolic pressure ≤50% of LV systolic pressure.
- Prepare for major blood loss and replacement.
- Ventilation can be compromised from intrapulmonary and airway bleeding from multiple anastomoses and/or lung reperfusion injury.
- RV dysfunction from increased afterload is treated with adequate preload, inotropic support, and ventilation adjustments/iNO to reduce PVR.

Summary

Right-sided obstructive congenital cardiac lesions comprise a range of heart defects associated with variable clinical manifestations. The pattern and severity of the structural anomalies determine the presentation of the patient on the symptomatology spectrum, from a neonate with cyanosis, CHF and ductal-dependent circulation, to the young adult

AL Grawany

with mild to moderate exercise intolerance. The presence of a septal defect is nearly universal in this group of lesions and confers the potential for right-to-left intracardiac shunt. One lesion, TOF–the archetype of CHD, leads the way for the evolution of multifaceted diagnostic and therapeutic advances while charting the unknown territory of long-term outcomes beyond survival. The optimal perioperative anesthetic management for the patient with a right-sided obstructive congenital heart lesion requires an understanding of the anatomy and pathophysiology of the cardiac lesion, the implications of the proposed surgical maneuvers, and the effects of the anesthetic and ventilatory techniques in dynamic interaction with other factors. Most patients with CHD have limited cardiopulmonary reserve; thereby, anticipation of complications with preparation for prevention and rescue are critical for improved outcomes.

Introduction

Transposition of the great arteries (TGA) refers to a spectrum of conditions of discordant ventriculoarterial (VA) connections. The term TGA is most commonly used to denote concordant atrioventricular (AV) connection and discordant VA connection, where the aorta arises from the morphological right ventricle and the pulmonary artery from the morphological left ventricle. This is the most common anatomic form encountered in clinical practice and is referred to as dextro-TGA, or d-TGA. The term TGA also encompasses the hearts with discordant AV and VA connections known as congenitally corrected TGA (or ccTGA, levo- or l-TGA) and more rarely, other forms of anomalous AV connections.

TGA is the second most common congenital cardiac lesion, which accounts for approximately 6% of all congenital heart defects [1]. It is frequently an isolated lesion with no other associated extracardiac anomalies. Medical and surgical advances in the past four decades have spectacularly improved the outcome for individuals born with these lesions, from what was a universally lethal condition, into one of expected survival with the ability to lead near-normal lives.

Initial attempts at anatomical repair were associated with poor outcome, leading to the development of physiological repair by Mustard and Senning. Today, the arterial switch operation (ASO) is the mainstay of management of these patients, with excellent results. Surgical intervention requires the cardiac anesthesiologist to fully understand the pathophysiology, aims of treatment, surgical procedures, and postoperative consequences to form the perioperative management plan.

This chapter will address two main subcategories of transposition: physiologically uncorrected TGA (referred to as TGA or d-TGA) and congenitally corrected TGA (ccTGA or l-TGA).

KEY POINTS: INTRODUCTION

- TGA refers to a spectrum of conditions of discordant VA connections.
- The two main categories are physiologically uncorrected (d-TGA) and congenitally corrected (ccTGA or l-TGA).
- The outcome of d-TGA is very good, with patients expecting to lead near-normal lives.

Physiologically uncorrected TGA

Incidence

TGA accounts for 5–7% of all congenital heart defects with a prevalence of 0.2 per 1,000 live births [1, 2]. There is a male preponderance of 2–3:1, and sibling recurrence rates of between 0.27 and 1.8% have been noted [3].

AL Grawany

Anatomy

Physiologically uncorrected transposition of the great arteries is the most common anatomic form encountered in clinical practice and is referred to as TGA or d-TGA. In other words, the normal connections of right atrium (RA) to right ventricle (RV) and left atrium (LA) to left ventricle (LV) are preserved, but there is VA discordance: the aorta arises from the RV rather than LV and the pulmonary artery (PA) from the LV (Figure 29.1).

This definition encompasses a spectrum of cardiac anomalies that can be further subdivided into either simple or complex TGA (Figure 29.2). In approximately 50–75% of cases children present with simple TGA in which there is isolated VA (VA) discordance with either a patent foramen ovale (PFO) or patent ductus arteriosus (PDA) or both. This is referred to as TGA with intact ventricular septum (TGA/IVS).

The lesion is considered a complex TGA when it has associated cardiac abnormalities. Complex TGA occurs in 25% of the patients with D-TGA and requires alternative management and operative planning. Cardiac anomalies included in complex TGA are as follows:

- Ventricular septal defect (VSD), 40%
- Left ventricular outflow tract obstruction (LVOTO), 5%
- Double outlet right ventricle and the Taussig–Bing malformation
- Rarer abnormalities, which include TGA with VSD and coarctation of the aorta 5% or TGA with VSD and interrupted aortic arch.

The focus of this chapter will be on the most common and important clinical subsets:

- TGA with intact ventricular septum (TGA/IVS)
- TGA with VSD including the Taussig–Bing malformation
- TGA with LVOTO
- TGA and pulmonary vascular obstructive disease

In the normal heart, the position of the aorta is posterior and to the right of the pulmonary trunk. There is a

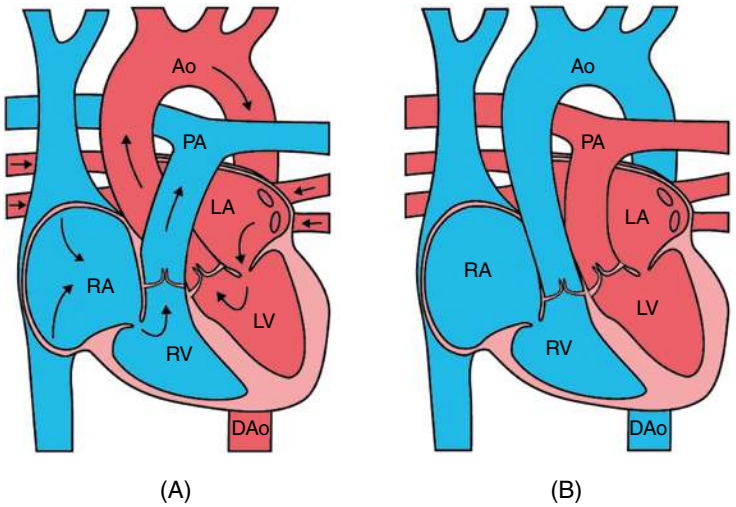

Figure 29.1 Dextro-transposition of the great arteries (d-TGA). (A) Normal anatomy. (B) d-TGA anatomy. Ao, aorta; PA, pulmonary artery; RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle; DAo, descending aorta.

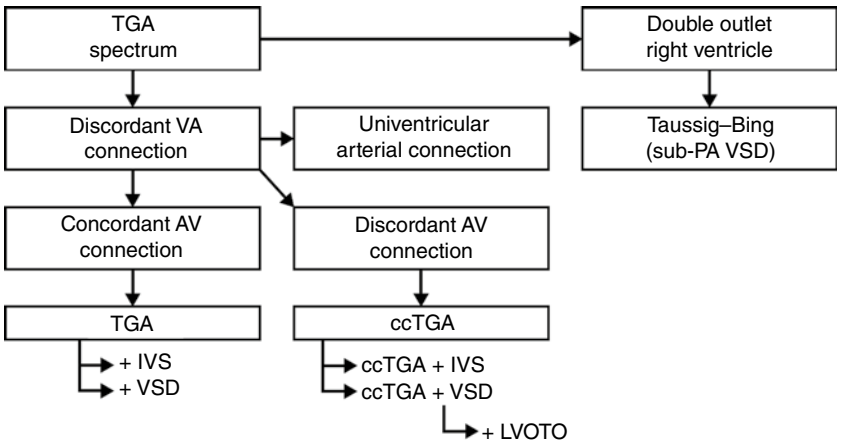

Figure 29.2 The spectrum of discordant ventriculoarterial connections that come under the "umbrella" of the term transposition of the great arteries (TGA). AV, atrioventricular; VA, ventriculoarterial; PA, pulmonary artery; VSD, ventricular septal defect; IVS, intact ventricular septum; ccTGA, congenitally corrected transposition of the great arteries; LVOTO, left ventricular outflow tract obstruction.

subpulmonary muscular infundibulum, and the annulus of the aortic valve is in fibrous continuity with the mitral valve annulus. In the most common manifestation of TGA, a right sided right atrium connects via a right sided tricuspid valve and RV to a right sided and anterior aorta. There is a subaortic muscular infundibulum. On the left, a left-sided atrium connects via the mitral valve and LV to a left-sided and posterior PA. As a result, there is fibrous continuity between the mitral and pulmonary valves, but no fibrous continuity between the tricuspid and aortic valves [4, 5]. This anatomical manifestation is commonly referred to as d- or dextro-TGA with the position of the aorta being anterior and to the right of the pulmonary trunk. However, in strict anatomical terms, d- or dextro-TGA describes patients who have [S,D,D] segmental anatomy, meaning situs solitus [S], d-loop ventricles [D], and d-loop great arteries [D].

Although VSDs are detected in up to 30–40% of patients with TGA using angiography, only about one-third of these are hemodynamically significant [6]. Approximately one-third of the VSDs are perimembranous, and another one-third are outlet VSDs with malalignment. From a surgical perspective, outlet VSDs with malalignment are more difficult to repair. In the presence of a VSD, the aorta is generally smaller than the PA; this discrepancy in size tends to be amplified in the presence of an anterior maligned VSD. Conversely, LVOTO is common when there is posterior deviation of the outlet septum.

The Taussig–Bing anomaly (TBA) represents a complex subset of double outlet right ventricle (DORV) with subpulmonary VSD that behaves as a physiological TGA. It is not theoretically a TGA, as the VA connection is double outlet, however, it is so similar to TGA from a physiological and management perspective that it is included within the TGA subset. In TBA, there is DORV with subpulmonary VSD, side-by-side vessels, and bilateral conus [7]. The aorta originates from the RV, and the PA arises from above the nonrestrictive VSD. It is frequently associated with subaortic right ventricular outflow tract obstruction (RVOTO) because of hypertrophy of the infundibular septum and aortic arch obstruction. Left ventricular oxygenated blood is preferentially streamed into the PA, thereby simulating TGA physiology.

Anatomic LVOTO can be found in approximately one-third of patients with TGA and VSD, but it is rare in TGA/IVS, with an incidence of approximately 0.7%. Anatomic LVOTO can arise at the valvular or subvalvular level and can be caused by several anatomical structures. Valvular obstruction might be secondary to commissural fusion, annular hypoplasia, or leaflet immobility from a hypertrophic tissue [6, 8]. Pulmonary subvalvular obstruction may be attributable to posterior displacement of the conal septum, a subvalvular fibrous membrane, accessory leaflet tissue of the AV valve, or diffuse hypoplasia of the left ventricular outflow tract (LVOT). In TGA/IVS, mechanical LVOTO is uncommon, but 5% patients have functional LVOTO. This occurs due to the presence of a high systemic right ventricular pressure, displacing the interventricular septum into the LV during systole. This is uncommon in neonates as the septal shift required is prevented by their high pulmonary vascular resistance [9]. LVOTO limits pulmonary blood flow and therefore exacerbates the cyanosis in TGA.

Coronary artery anatomy

Coronary artery anatomy is extremely important in d-TGA patients as transfer of the coronary arteries to the neo-aorta without narrowing or distortion is critical to the success of an arterial switch operation (ASO). Mortality from distortion of the newly implanted coronary arteries arises from myocardial ischemia; necrosis of the supplied myocardial segment may cause fatal arrythmias, such as ventricular fibrillation [10]. The critical importance of unrestricted aortocoronary blood flow after ASO was established during the earliest unsuccessful ASOs in the 1950s by William T. Mustard [11, 12]. Initially the ASO was associated with 100% mortality. In 1954, three patients underwent ASO, a 6-week-old child died from aortic suture line bleeding, a 19-day-old died from left coronary artery occlusion, and another 19-day-old died from ventricular fibrillation [13].

In the normal heart, the coronary arteries arise from the aortic sinuses of Valsalva, which face the PA and are located on the anterior portion of the aorta (Figure 29.3). In TGA, the coronary arteries also arise from the aortic sinuses of Valsalva, but the location of the sinuses is posterior [4]. Considerable variability exists in the origin, distribution, and epicardial course of coronary artery anatomy in d-TGA. The Leiden classification (Figure 29.4) system appears most commonly in surgical literature and is used to demonstrate the frequent coronary patterns that exist in TGA [16].

Although all types of coronary anatomy are suitable for the ASO, the less common coronary patterns present potential technical difficulties for an ASO and a moderately increased risk [17]. Single right coronary artery, inverted coronary artery, and coronary arteries with an intramural course have been identified as carrying increased risk [17, 18], but recent studies have shown that with increased surgical experience, coronary artery pattern may not be a risk factor for increased morbidity following the ASO [19, 20].

KEY POINTS: ANATOMY OF D-TGA

- In d-TGA, there is concordant AV connection and discordant VA connection.
- The aorta arises from the morphological RV and the PA from the morphological LV.
- Approximately 75% have simple TGA: isolated VA discordance with a PFO, PDA, or both.
- Complex TGA has VSD, LVOTO, or Taussig–Bing malformation.
- Coronary anatomy has considerable variability in its origins and distribution.

Natural history and pathophysiology

In the normal circulation, blood circulates in series; deoxygenated blood from the systemic circulation enters the right heart and proceeds to the lungs via the PA. Oxygenated blood then returns from the lungs via the pulmonary veins to the LA and is pumped through the LV to the systemic circulation via the aorta. In TGA, there is AV concordance (RA→RV and LA→LV) but VA discordance (LV→PA and RV → aorta) resulting in two parallel circulations (Figure 29.5). Blood flows in a

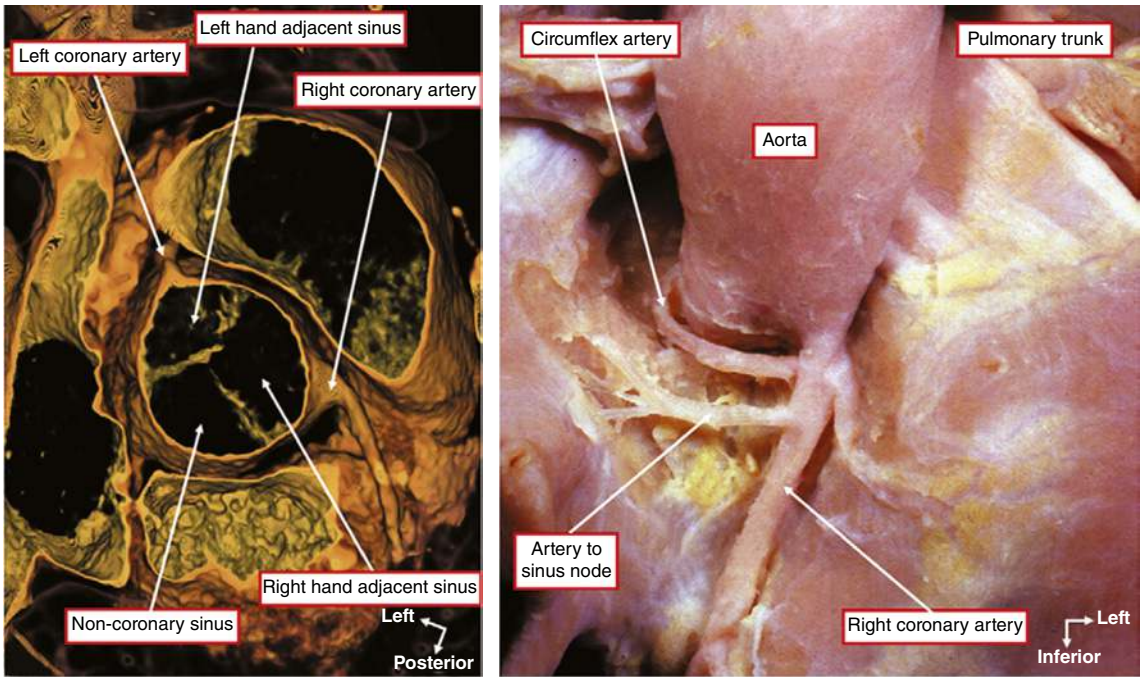

Figure 29.3 Anatomy of normal coronary arteries is well shown by computed tomography. (A) The aortic root as viewed from above. Right and left coronary arteries arise from the aortic valvular sinuses adjacent to the subpulmonary infundibulum, which has been transected to provide this image. (B) Variant in an otherwise normal heart in which the circumflex coronary artery arises from the right coronary artery and then extends through the transverse sinus. (Source: Chiu & Anderson [14]. Reproduced with permission of Elsevier.)

closed circuit on both sides of the heart where deoxygenated blood is recirculated to the body without passing the lungs for oxygenation. Oxygenated blood from the left side of the heart returns back to the lungs via the PA without reaching the body. Without one or more communications that allow for intercirculatory mixing, survival would be impossible. If left untreated, death from hypoxia and congestive heart failure (CHF) will occur in 90% of patients within the first year of life.

Shunting and effective pulmonary and systemic blood flow in TGA

In TGA, the parallel circulations mean that, without shunting, no oxygenated blood would reach the tissues or deoxygenated blood the lungs. Anatomical shunting occurs due to a communication at the level of the cardiac chambers or great vessels allowing blood to move from one circulation to the other. A physiological shunt occurs when blood is recirculated and is considered "surplus" and noneffective. For example, a physiological left to right shunt is all the blood that is recirculated through the pulmonary vascular bed (the LA to the PA avoiding the systemic circulation). Physiological right-to-left shunt occurs through the recirculation of systemic venous blood (RA to the aorta, avoiding the pulmonary circulation). Therefore, in TGA, the majority of the blood flow is physiological shunt (recirculated blood that is ineffective) with a small proportion of blood that travels across the anatomical shunt (in effect, making up the effective blood flow) (Figure 29.6) [21]. The effective blood flow is the flow necessary for survival and comprises blood from the venous system of one circulation that reaches the arterial system of the other.

- **Effective pulmonary blood flow** is the amount of systemic venous blood that reaches the pulmonary arterial bed (e.g., *in TGA, an anatomic R-to-L shunt)*
- **Effective systemic blood flow** is the amount of pulmonary venous blood that reaches the arterial systemic circulation (e.g., *in TGA, an anatomic L-to-R shunt)*

Note: When bidirectional shunting occurs, the anatomic and effective blood flows are not equal. This is because some of the anatomic shunted blood may be redirected back to its original venous side prior to reach the arterial side of the other circulation. [21]

Effective pulmonary blood flow and effective systemic blood flow must be equal or one of the circulations would become deplete. Total pulmonary circulation is the volume of recirculated pulmonary venous blood and effective pulmonary blood flow. Total systemic blood flow is the volume of recirculated systemic blood and effective systemic blood flow. The greater the volume of the effective systemic blood flow relative to the recirculated flow, the greater is the arterial oxygen saturation. In contrast to effective blood flow, total pulmonary blood and total systemic blood flow do not have to be equal. This is most evident in the pulmonary circulation, where the total pulmonary blood flow is 2 to 3 times that of the total systemic blood flow (Qp:Qs 2–3:1). When there is adequate mixing of pulmonary and systemic venous blood, the arterial oxygen saturation is influenced by the Qp:Qs ratio. A high Qp will result in a pulmonary artery saturation that is higher than the aortic oxygen saturation, and systemic hypoxia will not occur. If there is effective mixing but pulmonary blood flow is restricted (due to LVOTO or PAH), the Qp:Qs ratio will drop below 2, significantly lowering the systemic arterial saturation

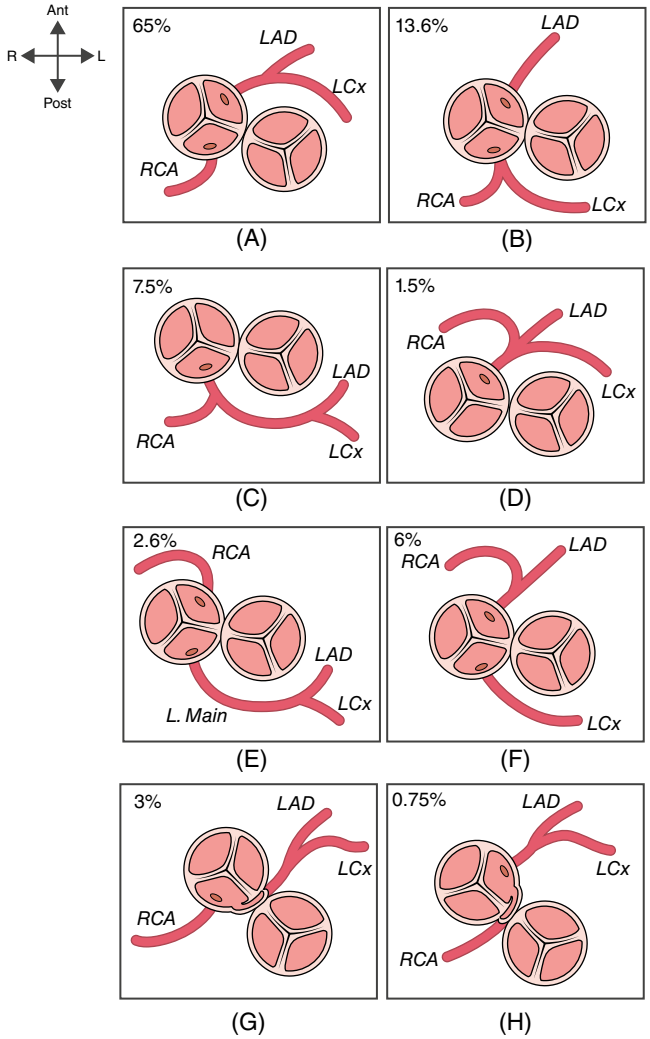

Figure 29.4 The most common patterns of coronary anatomy in patients with D-loop transposition of the great arteries (TGA). and causing severe hypoxia [22]. These concepts are vital in understanding the physiology in TGA circulation.

Intercirculatory mixing

Intercirculatory mixing can occur at one or more intracardiac (PFO/ASD or VSD) or extra-cardiac (PDA or bronchopulmonary collaterals) sites. The degree of intercirculatory mixing is one of the factors that influences hemoglobin oxygen saturation and hence tissue oxygen delivery. In the first few days of life, the degree of cyanosis and the stability of the child will be largely determined based on the degree of mixing that occurs between the two parallel circulations, which in turn will determine the neonate's course, medical management, and surgical timing.

Intercirculatory mixing is dependent on multiple factors in the neonatal period, namely the number, size, and position of the anatomic communications (Table 29.1). Larger, unrestrictive, and multiple communications allow for improved intercirculatory mixing. Although there is significant interplay between these factors, one large communication will allow for better mixing than two or more restrictive ones and a large but unfavorably positioned VSD, namely an anterior muscular VSD, is not conducive to effective mixing. [23]

Physiological factors have a significant impact on mixing, including ventricular compliance, systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR). Balancing the effective pulmonary and systemic blood flows allows for optimal intercirculatory mixing. At the level of the atria, shunting is mainly influenced by the size of the ASD and the pressure variations across it. Mixing here is the most efficient as lower pressures allow for bidirectional flow during the cardiac cycle; for this physiologic reason, balloon atrial septostomy (BAS – see below) is preferred for cyanotic d-TGA patients. Conversely, mixing at a VSD or PDA is usually more restricted as larger pressure gradients exist, typically directing blood in one direction (usually from right to left).

AL Grawany

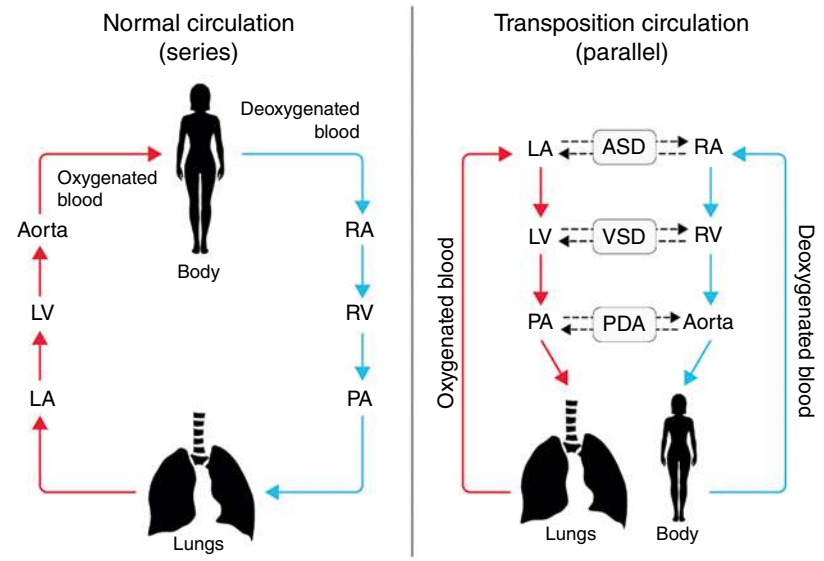

Figure 29.5 Comparison of the normal circulation, which is in series, with that in transposition of the great arteries (TGA), which is in parallel. In the normal circulation (left), deoxygenated blood from the body enters the right-sided circulation before being oxygenated by the lungs and then distributed to the body via the left side of the heart. In the transposition circulation (right), the potential sites of mixing are shown: atrial septal defect (ASD), ventricular septal defect (VSD), and patent ductus arteriosus (PDA). The circulation is in parallel; thus, deoxygenated blood from the body enters the right side of the heart, but because of the anomalous connection, it is recirculated to the body via the aorta. Similarly, the oxygenated blood from the lungs enters the left heart but is recirculated to the lungs via the PA. This condition would be incompatible with life, if there was not any mixing of the oxygenated and deoxygenated blood. RA, right atrium; RV, right ventricle; PA, pulmonary artery.

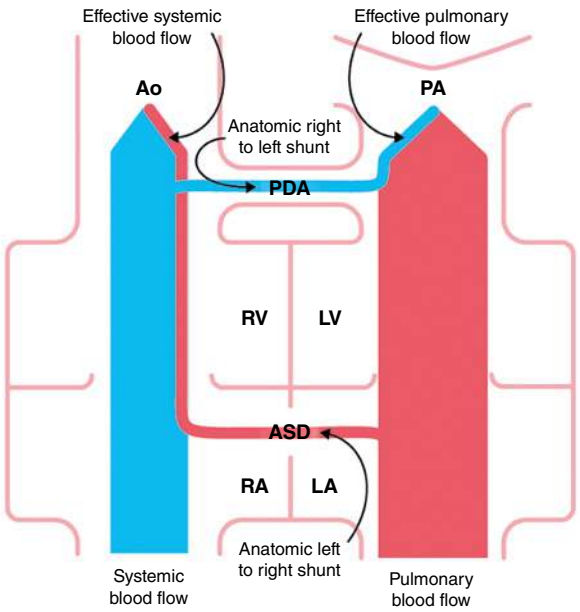

Figure 29.6 Representation of intracardiac shunting in transposition of the great arteries with intact ventricular septum (TGA/IVS), unrestrictive atrial septum, and PDA. The majority of flow is recirculated, RA→aorta and LA →PA, and is therefore, ineffective. A small amount of blood shunts left-to-right via the ASD; this is effective systemic blood flow. Equally, a small amount of blood flows from the aorta to the PA via the PDA, this is effective pulmonary blood flow. The effective systemic and pulmonary blood flows are equal and constitute a small volume of flow that is necessary for life. Typically, the total pulmonary blood flow is 2 to 3 times greater than the total systemic blood flow. AO, aorta; PA, pulmonary artery; ASD, atrial septal defect; LA, left atrium; RA, right atrium; RV, right ventricle; LV, left ventricle; PDA, patent ductus arteriosus.

Table 29.1 Factors influencing intercirculatory mixing in patients with D-TGA

Factor	Effect on mixing
Size	• Mixing improved by larger, unrestrictive communications
Position	• More efficient mixing at the atria due to lower pressure • Poor mixing at anterior muscular VSDs due to unfavorable position
Number	• Greater number of communications increases intercirculatory mixing
Pulmonary blood flow	• High pulmonary flow is associated with maximal mixing

Pulmonary blood flow

The efficiency of mixing is further influenced by total pulmonary blood flow (Qp) [23]. As the patient surpasses the neonatal period, pulmonary blood flow is increasingly important in determining intercirculatory mixing. As PVR continues to drop after the neonatal period, cyanosis tends to improve. This may occur as the decrease in PVR increases pulmonary blood flow, thus increasing mixing. The opposite may also to be true: as pulmonary blood flow is reduced (usually secondary to pulmonary stenosis or pulmonary vascular occlusive disease), a decrease in mixing occurs resulting in a drop in systemic arterial saturation [23, 24]. A reduction in pulmonary blood flow caused by a decrease in overall cardiac output (e.g., hypovolemia, depressed myocardial contractility from volatile anesthetics) will also exacerbate cyanosis.

TGA and pulmonary vascular occlusive disease

Children with TGA are at particular risk of developing pulmonary vascular occlusive disease compared with other congenital heart lesions, especially in TGA with VSD. Pulmonary vascular remodeling caused by an abnormal hemodynamic state [25] (i.e., high pulmonary blood flow) plays a significant role in the development of pulmonary vascular occlusive disease. Multiple other factors believed to contribute to this disease process also exist in these patients: hypoxemia, polycythemia, and high PA pressure [6].

As PVR increases and pulmonary hypertension develops, pulmonary blood flow is reduced, thereby decreasing intercirculatory mixing and worsening systemic hypoxemia. Late diagnosis of TGA may result in severe pulmonary vascular occlusive disease. Once pulmonary hypertension is established, the therapeutic surgical options are reduced, sometimes necessitating palliative rather than curative options.

Flow characteristics and intercirculatory mixing vary depending on the variations in anatomy of the TGA subsets.

TGA with intact ventricular septum

In TGA/IVS, intercirculatory mixing occurs at two main sites: ASD and PDA. In TGA/IVS without additional communications (i.e., no PDA), shunting at the atrium is predominantly dependent on the size and pressure gradients across the atrial communication. During systole blood shunts from the LA to the RA (effective systemic blood flow) due to a raised LAP from the high volume of recirculating pulmonary blood flow. During diastole blood shunts from the RA to the LA (effective pulmonary blood flow) due to reduced ventricular and vascular compliance of the systemic circuit [26]. Respiratory variation also effects shunting across the atrial communication.

When a PDA is also present, flow across the PDA is dependent on the size of the inter-atrial communication and the PVR. With a non-restrictive ASD and a low PVR, blood flows from the aorta to the PA across the PDA (effective pulmonary blood flow) and left to right across the ASD (effective systemic blood flow).

As the PVR increases, shunting across the PDA and ASD becomes bidirectional. A unique clinical scenario occurs when raised PVR results in the PAP exceeding aortic pressure, causing blood to shunt across the PDA from the PA to the descending aorta, creating a reverse differential cyanosis. In this scenario, post ductal saturations (lower limb) will be higher than preductal (right hand). This phenomenon only occurs in TGA with preductal coarctation/interruption or when PVR is elevated (usually due to persistent pulmonary hypertension). A restrictive ASD or small PFO can cause elevated PVR due to raised LAP, resulting in poor mixing and severe cyanosis. The PFO may even close due to the raised LAP – eliminating a source of atrial mixing. Smaller infants with inadequate atrial mixing are at a high risk of preoperative or sudden death at birth due to PFO closure [27]. A BAS may be lifesaving in this setting.

TGA with ventricular septal defect

Although VSDs occur in 40% of patients with TGA, approximately one-third of these are too small and not functionally significant [28]. In TGA with non-restrictive VSDs, mixing at the VSD is usually less efficient than at the atrial level. This is due to larger pressure gradients throughout the cardiac cycle at the level of the ventricles which typically shunt blood in one direction, in this case from right to left (effective pulmonary blood flow). Flow across the PDA is also predominantly effective pulmonary blood flow, with blood shunting from the RV to the aorta to the PA. Effective systemic blood flow originates from blood shunted from left to right across an ASD or PFO. The increased pulmonary blood flow will pass almost entirely through the LV, resulting in a volume-overloaded LV and subsequent heart failure. This increased pulmonary blood flow, particularly in patients with a VSD, significantly increases the risk of developing PAH, as systemic pressures are transmitted to the pulmonary vasculature.

TGA with left ventricular outflow tract obstruction

TGA with LVOTO occurs in approximately 5–10% of patients with TGA and is more commonly associated with a VSD. In TGA with LVOTO and VSD, there is a large anatomical left to right shunt and reduced pulmonary blood flow. Effective pulmonary blood flow is carried via the PDA. Due to a low Qp, LA hypertension and cardiac failure do not occur, but severe systemic hypoxemia is present. Cyanosis after birth is a common clinical feature, the degree of which is dependent on the magnitude of the obstruction.

Dynamic LVOTO can occur in patients with TGA/IVS who do not undergo an early ASO. This happens when the LV pressure drops below the RV pressure in the postnatal period due to a corresponding drop in PVR. High systemic right ventricular pressure displaces the interventricular septum posteriorly into the left ventricular outflow tract during systole. Dynamic LVOTO should be resolved after ASO; however, if left untreated, this obstruction can become fixed over time necessitating alternative surgical strategies.

Fixed LVOTO requires detailed surgical planning with assessment of the degree of LVOTO and adequacy of the pulmonary valve. Selected patients with fixed LVOTO may still proceed to ASO with satisfactory short- and mid-term results [29, 30]. Neo-aortic valve regurgitation remains a concern in long term [29]. If LVOTO is severe and fixed, other surgical options than ASO are advised [29, 30].

TGA with right ventricular outflow tract obstruction

Obstruction to the systemic circulation is an infrequent but important variant of TGA and occurs in approximately 5–10% of cases [31]. Systemic saturations will be variable depending on the degree of RVOTO and significant systemic hypoperfusion may occur due to impedance of systemic blood flow (including absent or diminished femoral pulses) if the PDA becomes restrictive. As mentioned above, a finding of reverse differential cyanosis indicates significant anatomical left-to-right shunting at the PDA and should alert clinical suspicion of coarctation of the aorta. A detailed evaluation of the aortic arch anatomy and of any coarctation and/or aortic arch hypoplasia are important surgical considerations.

KEY POINTS: NATURAL HISTORYAND PATHOPHYSIOLOGY

- In d-TGA the pulmonary and systemic circulations exist in parallel.
- Deoxygenated venous blood recirculates to the body through the right side of the heart, without being oxygenated in the lungs, and oxygenated blood recirculates between the lungs and the left side of the heart.
- Intercirculatory mixing is vital for survival in children with d-TGA.
- Mixing can occur through a PFO, ASD, VSD, or PDA.
- Atrial level mixing is the most effective way to increase oxygenation.
- Without treatment, death from hypoxia and congestive heart failure will occur in 90% of patients within the first year of life.

Clinical presentation and diagnostic features

With the evolution of fetal echocardiography, most diagnoses of TGA are likely to occur antenatally. As a result, a preliminary management plan can be formed aimed at postnatal stabilization before a more definitive surgical correction takes place. Antenatal diagnosis facilitates planned delivery and early administration of prostaglandin preventing the production of lactate and thus improving the neonates' preoperative condition. In addition, it reduces the risk of cerebral damage which has been shown to correlate with high lactates [32]. A detailed echocardiogram is repeated at birth which allows for comprehensive assessment of cardiac anatomy and the associated anatomical defects and to aid preoperative management and surgical planning. The echo must be performed promptly as prolonged duration of severe cyanosis and tissue hypoxia are important factors in determining acidosis, ventricular function, and ultimately multiple organ failure.

Clinical features in TGA are difficult to distinguish from other causes of neonatal cyanosis:

- **Cyanosis**-The degree of cyanosis is determined by the amount of intercirculatory mixing. In infants with mild cyanosis, the lesion may only be detected on the basis of a pulse oximetry screen.

  TGA/IVS: If the ASD is restrictive, limited intercirculatory mixing occurs leading to profound central cyanosis and tachypnea presenting within the first few hours of life. Arterial oxygen saturation will usually range between 50 and 70% unresponsive to oxygen administration.

  TGA LVOTO: Due to reduced pulmonary blood flow from LVOTO or pulmonary obstructive disease, these patients can present with significant cyanosis. Reverse differential cyanosis might be present.

  TGA/VSD: In infants with a large VSD that allows for satisfactory mixing between the two circulations, cyanosis may only be perceived during episodes of crying or agitation. However, signs of congestive heart failure will prevail due to ventricular overload: tachypnea, tachycardia, failure to thrive, a gallop rhythm, and eventually hepatomegaly. Arterial oxygen saturations will range between 75 and 90%.
- **Tachypnea** – Patients will usually have a respiratory rate of over 60 breaths per minute and appear comfortable without other signs of respiratory distress (grunting, nasal flaring, subcoastal, or tracheal recession). Infants with large VSDs may present with severe respiratory distress due to heart failure by three to 4 weeks of age.
- **Heart murmurs** – Heart murmurs are not a consistent finding in patients with TGA. An ejection systolic murmur is associated with left outflow tract obstruction (i.e., PS). A pansystolic murmur may be heard with a small to moderate VSD or PDA.
- **Diminished pulses** – Diminished femoral pulses may be seen in patients who also have coarctation of the aorta or interruption of the aortic arch.

Cardiac catheterization is not routinely performed unless it is in conjunction with BAS, when ECHO cannot establish coronary artery anatomy, or to quantify pulmonary vascular occlusive disease and PVR in the older child. Table 29.2 presents common ECG and chest radiograph findings in the various TGA morphologies.

Table 29.2 ECG and Chest Radiograph (CXR) findings in various D-TGA morphologies

TGA morphology	ECG	CXR
TGA IVS	Essentially normal	"Egg on side"
TGA VSD	Normal or RVH	Narrow superior mediastinal area, cardiomegaly, prominent vascular markings
TGA LVOTO	Normal or biventricular hypertrophy	Cardiomegaly, increased pulmonary vascular markings

Preoperative management

After birth, infants with TGA require early treatment; it is therefore recommended that they are delivered at or close to a tertiary care hospital that provides pediatric cardiology and cardiac surgery facilities [33]. Enabling early stabilization and optimization of these children can reduce cost and transport-related complications [34]. Infants born outside of a tertiary center will need to be stabilized in NICU prior to transfer; some institutions will electively intubate these patients, although there is increasing evidence that rates of complications are higher in intubated neonates [35].

The initial management of newborns with TGA should focus on stabilization, optimization of the mixing of systemic and pulmonary circulations, oxygen delivery, maintenance of adequate systemic perfusion and correction of acidosis. To ensure sufficient mixing between the two parallel circulations, an intravenous infusion of prostaglandin E1 is recommended to maintain patency of the PDA until a comprehensive series of post-natal echocardiograms has

been completed to assess all sites of possible intercirculatory mixing. Prostaglandin infusions should be started at 0.05 mcg/kg/min, higher doses may be necessary to reopen a closed PDA. Prostaglandin may cause fever, platelet dysfunction, hypotension and apnea, particularly with increased doses which may necessitate intubation. If PGE1 does not improve tissue oxygenation, then an urgent balloon atrial septostomy (BAS) should be performed as ductal shunting is often insufficient in the presence of a restrictive ASD.

Transcatheter approaches

A BAS can be performed in a catheterization lab under angiography or in NICU using echocardiography. Occasionally, BAS may be performed at the local hospital by a specialist cardiac retrieval team so that the patient can be stabilized prior to transport to the cardiac center for definitive surgery. Because BAS can be safely performed under echocardiographic guidance, preoperative diagnostic cardiac catheterization should be considered only in selected cases for diagnosis of complex lesions or if institutional experience does not permit performance of atrial septostomy under echocardiographic guidance. Exact coronary artery definition is generally not required by the majority of surgeons as it can be determined in the operating room, and ASO is performed for almost every coronary artery arrangement.

During BAS, a balloon is passed via the umbilical vein or the femoral vein, into the left atrium across the PFO, the balloon is inflated and pulled back briskly across the septum, to tear the inferior aspect of the foramen ovale (Figure 29.7). This is repeated at least once to ensure adequate enlargement of the ASD; echocardiogram is performed to assess the intercirculatory mixing.

Outcomes from balloon atrial septostomy

The introduction of balloon atrial septostomy (BAS) by Rashkind and Miller in 1966 has greatly improved the prognosis of patients with TGA, with 3-month survival increasing from 20 to 85% [37]. The significant improvement in saturations must be weighed against the risk of vascular trauma, arrhythmias, and rare complications such as atrial perforation and avulsion of the inferior vena cava [38]. Mortality of an urgent BAS is around 3%, with increased risk of complications if performed out of hours [39]. Although there is no increased mortality between patients who received a BAS and patients who did not, some studies have shown a strong association between BAS and preoperative stroke in neonates with TGA [39, 40]. Multiple studies have described MRI changes in both white and grey matter locations, including focal ischemic changes and periventricular leukomalacia (PVL) in patients with TGA, with reported prevalence rates of 30% [41]. Although it is possible that this is due to embolic phenomenon from the BAS, there are likely to be multifactorial components, including the degree of hypoxemia and hemodynamic instability. Multiple papers have now refuted the association between BAS and stroke [42, 43].

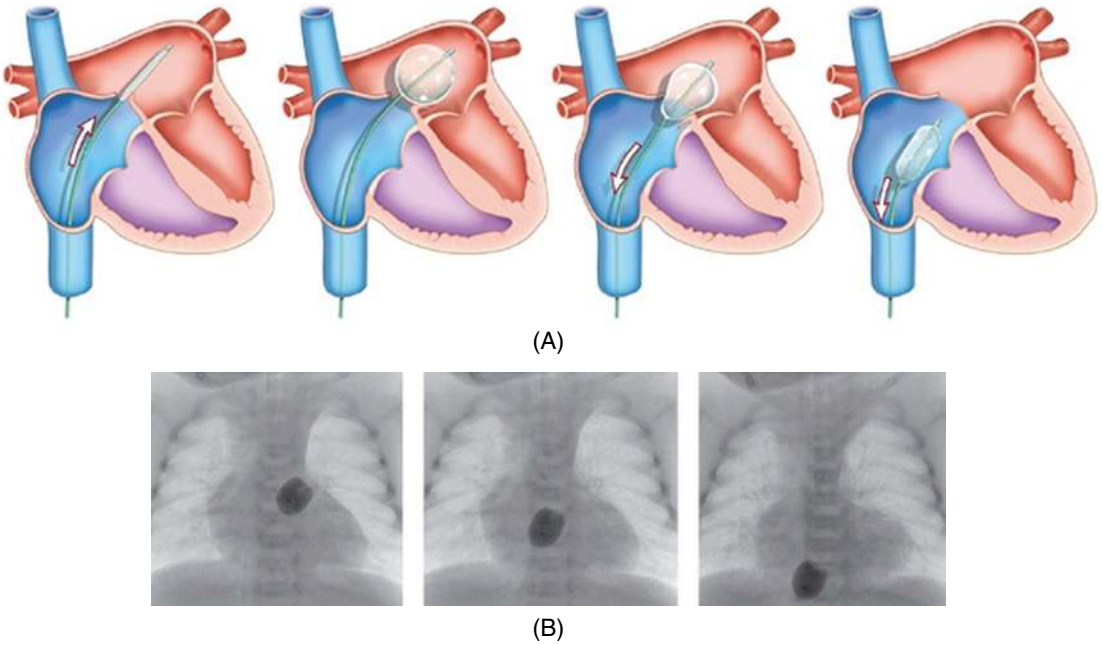

Figure 29.7 Balloon atrial septostomy. (A) Schematic representation of the maneuver. A balloon-tipped catheter is introduced via the inferior vena cava into the right atrium. After passing through the foramen ovale, the balloon is inflated into the left atrium and then pulled across the septum to enlarge the opening. Finally, the balloon is rapidly deflated, and the catheter removed. (B) Angiographic images showing the different steps of the maneuver. (Source: Seguela et al. [36]. AL Grawany

Anesthesia for balloon atrial septostomy

A BAS can be performed in the cardiac catheterization laboratory under angiographic guidance or in the neonatal intensive care unit under echo guidance, with the latter being more common.

The procedure is performed by a pediatric interventional cardiologist, with a neonatologist or an anesthetist present to manage sedation and mechanical ventilation.

A stable airway must be guaranteed, although not all neonates need to be intubated. Our center advocates routine intubation, this permits optimal sedation and analgesia, as well as permitting the use of paralysis to facilitate BAS. Prior to the procedure, an ABG, baseline blood tests, and IV access are required. A unit of red blood cells is essential and ideally crossmatched if time permits. Baseline observations including HR, RR, pre- and post-ductal saturations, BP, blood glucose, and urine output should be documented prior to and throughout the procedure.

Intubated neonates will usually be sedated with a morphine infusion, with additional boluses of fentanyl, ketamine or midazolam given as required. In spontaneous ventilating neonates, small incremental boluses of appropriate sedation should be used, including opioids (morphine or fentanyl), midazolam, and ketamine [44]. Dexmedetomidine is a safe drug in children with congenital heart disease with no significant respiratory depressive effect; thus, it may be useful in this setting [45]. Acetaminophen can be a useful adjunct in these patients.

If a BAS is performed successfully, systemic oxygen saturations should begin to increase immediately; if adequate mixing is seen at the atrial level, then the PGE1 infusion can be gradually discontinued (as long as there are no concerns regarding aortic arch obstruction). The aim is now to ensure hemodynamic stability and optimize preoperative condition. Once the patient is stable, they can be fed, and all further required investigations should be performed.

Associated medical problems (such as respiratory distress, necrotizing enterocolitis (NEC), and intracranial hemorrhage) should be diagnosed and treated appropriately. If the patient is extremely premature or other associated conditions are present, an early ASO should be postponed. If intracranial hemorrhage occurs, surgical repair is usually delayed by 2 weeks. Due to this delay, the left ventricular mass will decrease and will need to be "re-trained" to support a high SVR after the ASO (see below).

A small proportion of patients may remain cyanotic after a BAS, requiring further detailed echocardiography to confirm the ASD is unrestrictive, assess the patency of the PDA, and assess for pulmonary hypertension if present. Incidence of persistent pulmonary hypertension in neonates with TGA is 12.5%, occurring more commonly in patients with TGA /IVS [46]. Multiple treatment strategies have been used with variable success, including sedation, paralysis and hyperventilation, inhaled nitric oxide (NO) [47], sildenafil, bosentan [48], and extracorporeal life support (ECLS) [49]. The prognosis in these patients remains poor [50].

KEY POINTS: PREOPERATIVE MANAGEMENT

- The initial management of newborns with TGA should focus on stabilization and optimization of the mixing of systemic and pulmonary circulations.
- To ensure sufficient intercirculatory mixing, an intravenous infusion of prostaglandin E1 is required to maintain patency of the PDA.
- An urgent balloon atrial septostomy (BAS) may be required to improve intercirculatory mixing in patients with severe hypoxemia.
- A BAS can be performed in the cardiac catheterization laboratory under angiographic guidance or in the neonatal intensive care unit under echo guidance.
- Mortality of an urgent BAS is 3%.

Surgical options

The ASO, first performed successfully in 1975 by Adib Jatene, has become the standard corrective procedure for patients with D-TGA and has revolutionized their survival (Figure 29.8). Mortality has decreased from >90% to <1% in patients with simple TGA and 4% with complex TGA [51]. The ASO has been used as the preferred procedure for patients with D-TGA since the late 1980s and has replaced the earlier atrial switch techniques by Mustard and Senning.

Indication and timing of ASO

Significant uncertainty exists regarding the optimal timing of surgical repair. For ASO to be successful, the LV must have significant myocardial mass to support the systemic circulation. At birth, the LV mass is equal to that of the RV. In TGA/IVS, as the PVR drops postnatally the left ventricle involutes, losing muscle mass and thus becoming unable to support the systemic circulation [52]. Due to this, the majority of ASOs for TGA/IVS are performed within the first 2 weeks of life [53]. In older infants with TGA/IVS, there is a concern that the LV will decondition and therefore fail when exposed to higher systemic pressures after ASO, resulting in low cardiac output syndrome. There is no clear upper age limit for ASO, with most surgeons performing a primary ASO up to 4 weeks of age (Box 29.1). Beyond 4 weeks, a primary ASO becomes controversial, and it is likely that patients will require post-op mechanical circulatory support and a prolonged ICU admission [54]. A study from Lo Rito et al, however, has suggested that primary ASO can be safely performed in TGA/IVS patients who present late with a severely deconditioned LV. They showed no significant differences in early mortality or LV recovery, although an increase in neurological injury was noted, which was thought to be due to the 3- to 5-fold increase in ECMO use [55]. For infants >2 months old, a rapid two stage ASO is recommended. A two-stage ASO involves pulmonary artery banding (+/− an aortopulmonary shunt in cyanotic patients) to "re-train" the left ventricle by inducing LV hypertrophy before performing an ASO within 2 weeks. The PA band must be sufficiently tight to increase pressure in the LV to approximately one-half to two-thirds of the systemic ventricle without compromising pulmonary blood flow.

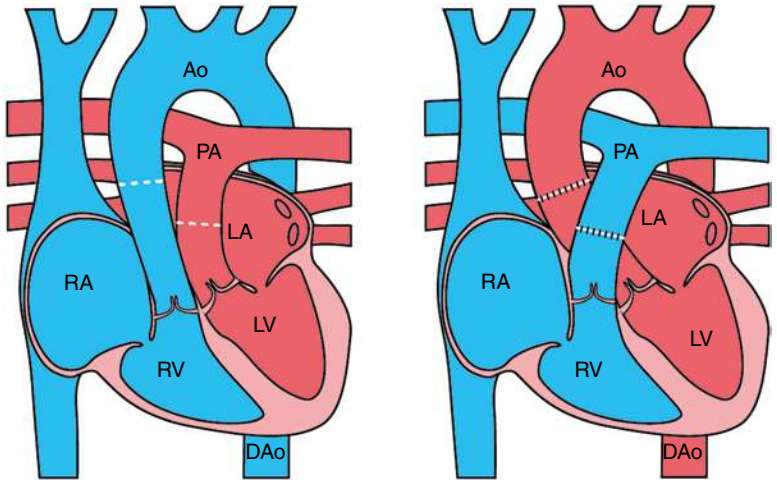

Figure 29.8 The arterial switch operation (ASO). Schematic representation of d-transposition of the great arteries anatomy before (A) and after (B) the ASO. Ao, aorta; PA, pulmonary artery; LA, left atrium; RA, right atrium; RV, right ventricle; LV, left ventricle.

Box 29.1: Indications for LV retraining prior to ASO [56]

- >3 weeks old
- <35 g/m^2
- Banana-shaped IVS (IVS bulges right to left due to low LV pressure)
- Absence of PDA or LVOTO

The majority of the left ventricular mass increase occurs in the first seven days after banding, with the ASO therefore typically performed within a week [57]. Although primary ASOs have better outcomes, a rapid two-stage repair may be unavoidable in patients where a primary ASO would expose the infant to excessive risk. Primary ASO may not be possible due to prematurity, sepsis (e.g., NEC), low birth weight (<1.5 kg) or late presentation.

Timing of surgery may also have an impact on neurodevelopmental outcome with some evidence to suggest that delaying surgery beyond 2 weeks of age is associated with impaired brain growth and slower language development at 18 months of age [58]. This may be due to the effects of prolonged hypoxia on the developing brain, with the risk of PVL increasing with lower arterial oxygenation and longer time to surgical repair [43].

Some evidence supports day 3 of life as the optimal time for an ASO, with increasing morbidity and healthcare cost beyond this timeframe. Currently, in Europe, 30% of ASOs are performed within the first week of life [59], with the majority of ASOs performed on Day 6 or 7 in the United States [60]. Preliminary reports have shown that performing an ASO in the first few hours of life is safe, thus avoiding the need for a BAS and theoretically reducing neurological impacts of prolonged hypoxia. This technique remains very controversial having been carried out in a limited number of cases [61, 62].

In the subsets of patients where the LV is exposed to systemic pressures (such as LVOTO, a large VSD, or PDA), LV mass is maintained after birth, preventing ventricular deconditioning beyond the age of 2–3 weeks. In these patients, there is less urgency to perform the surgery, and it can be done up to 6 weeks of life. In reality, they are usually operated on within the first month, before intractable cardiac failure or pulmonary vascular occlusive disease can occur.

TGA with left ventricular outflow tract obstruction

Surgical intervention in TGA with LVOTO varies with the type of LVOTO obstruction. Dynamic LVOTO obstruction is amenable to ASO as the dynamic nature of the LVOTO will be fully reversed, with no residual LVOT gradient.

Challenging decision-making is required in TGA with mechanical LVOT obstruction. The surgical decision is dependent on the complexity of LVOT obstruction, the size of the pulmonary valve, and the size of the VSD (Figure 29.9). ASO and muscle resection may be possible in certain patients with a normally aligned LVOT where complete or near complete relief of the LVOTO is to be expected. There is an increased risk of reintervention of the LVOT or neo-aortic valve [30]. For complex TGA with severe or fixed LVOTO (due to subvalvular, valvular or multilevel obstruction) and a VSD, an ASO is generally not performed. There are three main surgical options: the Rastelli, the REV and the Nikaidoh procedure (see below).

Aortic arch obstruction (coarctation with hypoplastic arch or interruption) is present in only 5–9% of TGA patients, but it is much more frequent in patients with TBA (more than 50%). Previously a two-stage repair was advocated in these patients that included a primary coarctation reconstruction +/− PA band, followed by an ASO or intracardiac repair months later; however, mortality rates were high. Now a one-stage ASO is usually undertaken [63].

Arterial switch operation

The ASO is performed through a median sternotomy on cardiopulmonary bypass (CPB). Both of the great vessels are transected distal to their respective valves, translocated, and

AL Grawany

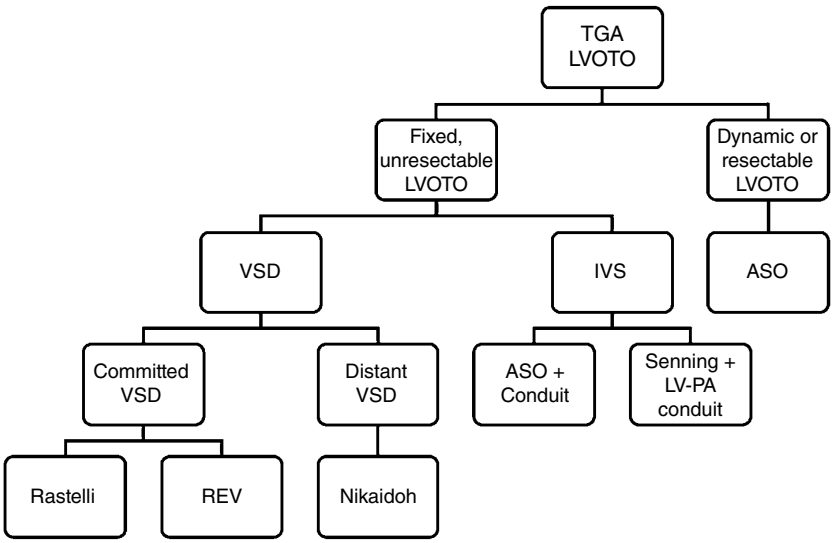

Figure 29.9 Flowchart illustrating anatomical factors determining surgical decision-making in patients with transposition of the great arteries (TGA) with left ventricular outflow tract obstruction (LVOTO). re-attached to the opposite root. This will result in the right ventricle attaching to the pulmonary artery and the left ventricle to the aorta. When CPB is established, the ductus arteriosus is divided, the ascending aorta is clamped, and cardioplegia is administered. The ascending aorta is transected above the commissures and the left and right coronary arteries are excised with 3–4 mm of the surrounding tissue. These aortic explant sites are repaired with a pericardial patch. The main pulmonary artery is transected, and the coronary arteries are reimplanted into the remaining root of the PA which will become the neo-aorta (Figure 29.10). This clarifies why delineating coronary artery anatomy is important prior to surgical repair. The LeCompte maneuver (Figure 29.11) is then performed; this involves the PA being brought anterior to the aorta before it is re-anastomosed to the native aortic root whilst the distal aorta is re-anastomosed to the proximal cuff of the native pulmonary artery (now the neo-aorta). This results in the aorta lying behind the bifurcation of the PA, which reduces the risk of subsequent PA stenosis.

An ASD is usually closed by direct suture, while patients with a VSD require a pericardial patch. In children with TBA, the VSD is closed with a patch placed diagonally to achieve continuity of the LV with the neo-aorta, while the neo-PA remains connected to the RV.

Once the aortic cross-clamp is removed, the myocardium is carefully observed for perfusion, and ECG and LAP are closely monitored. Ischemia of the myocardium is reflected by lack of reactive hyperemia or a rise in LAP, even before the ECG changes become apparent. A rise of LAP above 10 mmHg requires careful re-examination of the myocardium and coronary vessels to ensure adequate coronary flow. During rewarming, the aortic sinus defect is repaired, the anastomosis is completed, and temporary atrial and ventricular pacing wires are placed (Figure 29.12).

Other surgical procedures

Rastelli procedure

The Rastelli procedure is used to anatomically correct TGA with VSD and fixed LVOTO. A right ventriculotomy is performed, and a patch is placed to diagonally direct blood from the LV through the VSD toward the aorta. The PA is ligated at the level of the pulmonary valve, and a valved RV-to-PA conduit is placed [65]. The conduit can be an aortic or pulmonary homograft with a polytetrafluoroethylene graft extension. This achieves the LV to the aorta and the RV to the PA continuity, whilst bypassing the LVOTO (Figure 29.13). It is advantageous as it allows the LV to act as the systemic ventricle. The Rastelli procedure requires a large subaortic VSD, although restrictive VSDs can be enlarged to allow precise patch placement. Enlargement of the VSD has been shown to reduce the risk of developing post-operative LVOTO but may increase the risk of heart block from damage to the conduction pathway [66].

In patients with severe LVOTO, where the pulmonary blood flow is low and inter-arterial mixing is limited, a systemic-to-pulmonary shunt (usually a modified Blalock– Taussig shunt) is inserted in the neonatal period; these children are too young to be considered for a primary Rastelli procedure. This is used to increase pulmonary blood flow until the child has outgrown the BT shunt and a Rastelli operation will then be performed. This usually occurs before two years of age.

Senning and mustard procedures

The first surgical treatments of TGA were the atrial switch operations, performed by Senning and Mustard for the first time in 1958 and 1964, respectively. Senning and Mustard procedures (also known as atrial switch procedures) provide physiological, but not anatomic correction of the TGA. During the Senning procedure, an autologous tissue from the right atrial wall and intra-atrial septum is used to create an

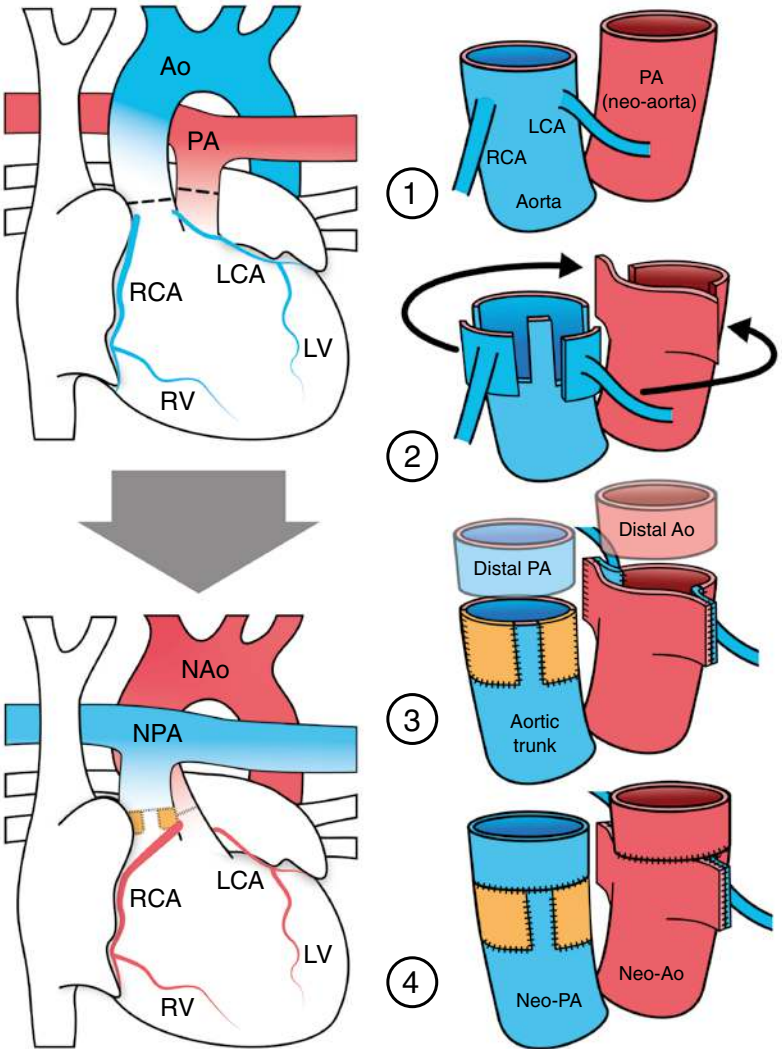

Figure 29.10 Technique for the arterial switch operation. (1) The great arteries are transected above the sinuses of Valsalva. (2) The coronary arteries are excised from the aorta, transposed posteriorly, and reanastomosed to the pulmonary artery trunk: the neo-aorta. (3) The distal aorta is brought behind the pulmonary artery (LeCompte maneuver) and anastomosed to the neoaorta. (4) Completed repair. intracardiac baffle redirecting systemic venous blood via the mitral valve to the LV and pulmonary venous blood via the tricuspid valve to the RV [67]. The Mustard procedure was developed as a modification of the Senning technique, where the interatrial septum is excised to create a large ASD and a baffle, made of either autologous pericardium or a synthetic material, redirects systemic and pulmonary venous blood flow to the LV and RV, respectively (Figures 29.14 and 29.15). Despite the Mustard procedure being a simplified technique, many deem the Senning procedure to be superior due its use of an autologous atrial tissue, thus allowing atrial growth and preserving contractility.

Réparation à l'Etage Ventriculaire (REV) and Nikaidoh procedures

Réparation à l'Etage Ventriculaire (REV) involves radical excision of the outlet septum to enlarge the VSD, then a patch closure to direct the LV flow to the aorta. The PA is transected with the distal end brought anterior to the aorta (LeCompte) and the proximal stump ligated. The distal PA is then augmented with an autologous patch and anastomosed directly to the RV creating RV-PA continuity [69] (Figure 29.16). REV avoids the use of an extra-cardiac prosthetic conduit and reduces the risk of intracardiac tunnel obstruction. It is feasible in patients with anatomic contraindications to the Rastelli operation, and it may reduce the need for re-operation and prevalence of residual pulmonary outflow tract obstruction. Disadvantages are the lifelong implications of pulmonary regurgitation and tension of the pulmonary artery reconstruction leading to early RVOTO [71].

During the Nikaidoh procedure, the aortic root is completely mobilized and translocated posteriorly to overlie the LV. The VSD is closed, and the PA is translocated anteriorly (LeCompte) and anastomosed to the RV using an autologous pericardial patch to reconstruct the RVOT (Figure 29.17). Patients with a hypoplastic right ventricle benefit the most from the Nikaidoh procedure. It creates a more normally

aligned right and left outflow tracts, reducing the risk of recurrent LVOT obstruction and RV-PA compression by the sternum.

Outcomes for ASO

Long-term outcomes after ASO are excellent, with over 95% survival at 25 years after discharge [72]. ASO also provides very good functional status and little limitation in physical activity, with over 95% of patients in NYHA functional class I [51]. These outcomes are particularly favorable in comparison to atrial switch operations, Mustard or Senning, where long-term survival is 80% at 20 years and 75% at 25 years respectively [73]. Despite excellent survival, patients are at risk for morbidity that may require further surgical intervention into adulthood (Table 29.3). Overall freedom from catheter or surgical re-intervention is 75% at 20 years, with re-intervention being significantly more common in the TGA/VSD cohort post ASO [75, 76]. The most common reason for re- intervention post ASO is pulmonary artery stenosis, possibly due to inadequate growth at the neo-pulmonary anastomotic site [76]. Performing ASOs in the neonatal period reduces the need for a PA band, which, alongside the introduction of the LeCompte maneuver, has likely reduced the incidence of PA stenosis, resulting in <5% now requiring reintervention [51, 77, 78].

Coronary artery insufficiency has been a long-held concern after ASO and led to high early hospital mortality when ASO was first introduced. As surgical techniques and experience have improved, early mortality from coronary artery complications has dropped significantly. Coronary artery complications are the primary cause of early mortality with ischemia or ventricular dysfunction most commonly presenting in the first 3 months postoperatively [79]. This is likely due to anatomical kinking, torsion, or external compression, thus reducing coronary perfusion. Long-term outcomes are also dependent on the patency of the coronary arteries, although late deaths due to coronary insufficiency are rare. It is thought that late coronary artery insufficiency is caused by stretching of the coronary arteries as they grow or progressive fibrocellular intimal thickening [80]. This may also predispose to early atherosclerotic disease, which is screened for during long-term follow up. Coronary lesions occur in around 3 to 6.8% of patients, with coronary angiography being the gold standard as lesions are often subclinical [75, 79, 81]. This may be due to collateral circulation, which may mask ischemia on noninvasive screening modalities (ECG, echocardiography, stress tests, etc.) [79].

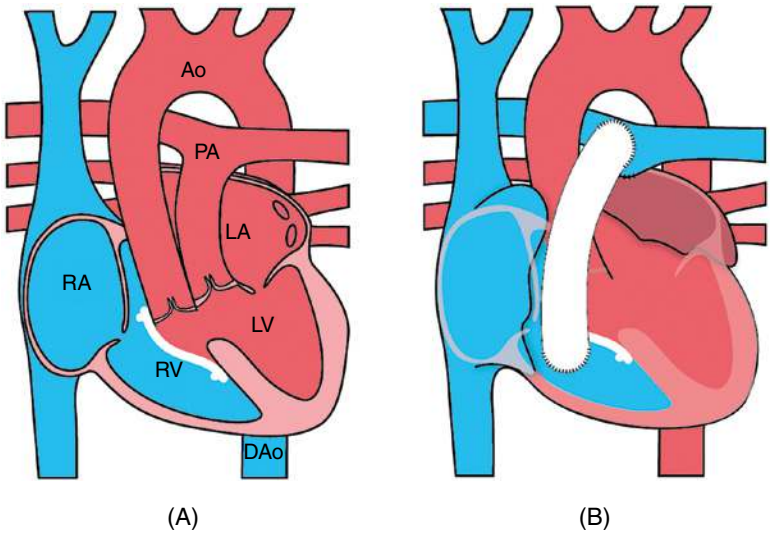

Figure 29.13 Rastelli procedure for repair of transposition of the great arteries with ventricular septal defect (VSD) and left ventricular outflow tract obstruction (LVOTO). Figure 29.15 The Mustard procedure. An intra-atrial baffle diverts blood from both the superior vena cava (SVC) and the inferior vena cava (IVC) across to the mitral valve and left ventricle, which ejects blood to the pulmonary artery. Pulmonary venous blood is returned via the tricuspid valve and RV, which ejects blood into the aorta. The baffle is made from pericardium or a synthetic material. Ao, aorta; RV, right ventricle; LV, left ventricle; DAo, descending aorta.

In the immediate post-op period after ASO, there is a high incidence of chronotropic impairment due to sympathetic denervation, despite this over 96% of patients are in sinus rhythm [51, 79]. Arrythmias present after the immediate post-op period require urgent investigation to rule out coronary artery abnormalities or residual lesions resulting in hemodynamic compromise. Late arrythmias are a relative frequent complication occurring in around 2 to 10% of patients [51, 79, 82, 83].

Neo-aortic valve regurgitation is a frequent finding after ASO as the native pulmonary valve is exposed to systemic pressures. Up to 20% of patients develop some degree of aortic regurgitation, with 5% of patients requiring neo-aortic root or valve reoperation at 20 years, increasing to 8% at 25 years. This demonstrates the significant attrition of the neo-aortic valve over time and the need for ongoing close surveillance of ASO survivors. It is not yet known how well the

AL Grawany

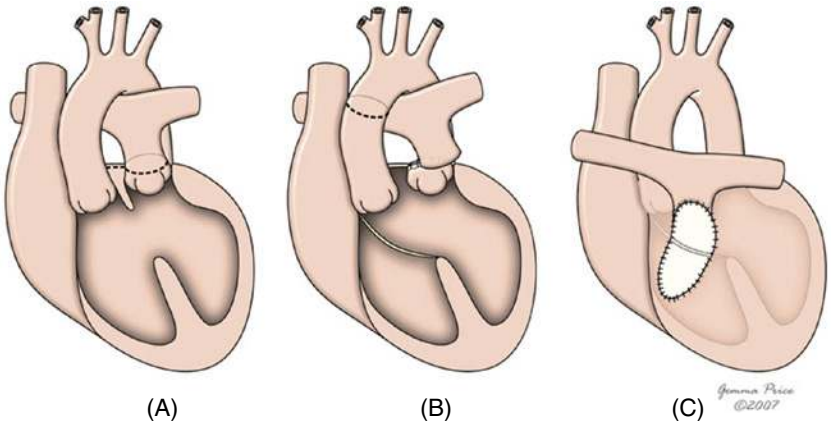

Figure 29.16 This figure shows the innovations of the REV procedure relative to the Rastelli procedure, (A) preoperative anatomy, with resection of the muscular outlet septum (B) and use of LeCompte maneuver (C) which avoids the use of an extacardiac conduit. neo-aortic root will cope with systemic pressure as these patients reach middle age [84, 85].

With increased survival after TGA repair, attention has turned toward quality of life and functional outcomes. There is increasing evidence that neurodevelopmental impairment is more prevalent in children after TGA repair than in the general population [86]. Neurodevelopmental impairment in these children ranges from motor delay, cognitive impairment, poorer academic achievements, speech and language dysfunction and psychosocial impairment. Multiple studies have described MRI changes in both white and grey matter locations, including focal ischemic changes and PVL in patients with TGA, with reported prevalence rates of 30% [41]. However, MRI abnormalities poorly predict adverse neurodevelopmental outcomes in these patients [58]. Poorer neurodevelopmental outcomes are likely to be

Table 29.3 Postoperative sequelae following the arterial switch operation

Postoperative sequalae	Incidence
Supravalvar pulmonary stenosis[a]	~10%
Supravalvar aortic stenosis[a]	<5%
Neoaortic root dilatation	Essentially 100%
Neoaortic regurgitation	~50%[b]
Significant arrythmia	Rare
Asymptomatic coronary occlusion	2–3%
Pulmonary hypertension	Rare
Hypertrophied bronchial collaterals[a]	<5%
Abnormal bronchial collaterals[a]	Unknown
Sudden death	Rare

[a] Requiring intervention.

multifactorial and strongly associated with the infant's prenatal, neonatal, and perioperative course. Risk factors include post-natal diagnosis of TGA, greater degree of hemodynamic instability and hypoxemia, underlying genetic abnormality, inadequate nutrition, complex TGA, prolonged bypass times, peri-operative complications (e.g., NEC), use of DHCA, and need for ECMO [86]. This highlights the importance of fastidious attention to neuroprotection in the perioperative period, with optimal timing of surgery, anesthetic and surgical techniques, and monitoring to improve neurodevelopmental outcomes and quality of life in ASO neonates.

Outcomes for Rastelli

Overall survival after Rastelli operation has improved drastically in the last few decades from 52 to 93% at 20 years [87, 88]. Despite this, the re-intervention rate remains high, with approximately 40% of patients requiring re-intervention for RVOTO at 20 years [88]. The conduits do not grow with the child, become stenosed overtime, and are at a risk of calcification; therefore, serial conduit replacements are inevitable. However, extension of the VSD at the time of operation has nearly eliminated the need for reintervention for LVOTO. Atrial and ventricular arrythmias occur commonly and sudden death from arrythmia is a problematic long-term complication. Although RV and LV failure may also occur, the Rastelli operation protects the RV from chronic regurgitation, unlike the REV and Nikaidoh procedures.

Outcomes for Senning and Mustard procedures

Mustard and Senning procedures have low operative mortality, and overall survival for all patients is approximately 75% after 25 years [73]. Long-term sequelae, however, are common and are largely related to RV failure, arrythmias, and baffle complications. Mustard and Senning procedures were the original mainstay for surgical correction of TGA, but as a result of the morphological RV remaining as the systemic ventricle, they have been largely superseded by the ASO. All adults develop some degree of RV dysfunction, with 10% of adults requiring hospital admission for CHF after 20 years [73, 89]. Common baffle-associated complications include leak, stenosis, and/or intractable atrial arrhythmias [90]. Scarring around the sinus node and intra-atrial baffle sutures results in sick sinus syndrome and atrial flutter, respectively. Sudden, presumed arrhythmogenic death and myocardial failure are the most frequent causes of late death in these patients [91].

KEY POINTS: SURGICAL OPTIONS

- The most common procedure for d-TGA is the ASO; others include the Rastelli procedure and (rarely) the atrial switch.
- Left ventricular mass involutes in d-TGA/IVS as PVR decreases postnatally.
- ASO repair is usually performed in the first 2–3 weeks of life.
- Long-term complications include PA stenosis, coronary artery insufficiency, early atherosclerotic disease, neoaortic regurgitation, and neurodevelopmental impairment.

Anesthetic considerations and perioperative management

It is essential for the anesthesiologist to have a detailed understanding of the pathophysiology of the TGA lesion, other associated anomalies, the overall condition of the child, and any interventions that have been undertaken to stabilize the child.

Preoperative assessment

A thorough and detailed anesthetic pre-op assessment is focused on issues relevant to any neonatal high-risk surgery and pertinent to TGA physiology. Pre-operative optimization and assessment is a multidisciplinary endeavor with the involvement of expert surgeons, cardiologists, anesthetists, and intensivists. Cardiac multidisciplinary conferences to tailor peri-operative care to the patient and discuss surgical planning, surgical timing, pre-operative optimization strategy, and clinical course are best practice.

The pre-operative assessment should focus on:

- Adequacy of intercirculatory mixing
  - PGE/BAS/ASD/number of communications and direction of shunts
- Associated cardiac conditions
  - IAA/Coarctation/VSD/LVOT
- Associated co-morbidities – Congenital/acquired (e.g., NEC/IVH) – does surgery need to be delayed?
- Age of Child
  - >1 month in TGA/IVS – LV mass involutes, may need alternative surgical strategy (PA banding) or back up EMCO
  - >2 months TGA VSD – pulmonary over-circulation leading to PAH

AL Grawany

- Details of TGA type and cardiac anatomy
  - Size of VSD, ventricular function, coronary anatomy, pulmonary valve structure, and function
- Elevated PVR
  - Patients with high PVR may present with inadequate mixing and require urgent surgery with a suboptimal acid–base balance
- Clinical examination – Pre/post ductal saturations, Reverse differential cyanosis
- Cardiorespiratory status and current support
  - Arrhythmias, pulmonary over-circulation, CHF
  - Inotropes, mechanical support, iNO, ventilatory support (high flow nasal cannula, CPAP, mechanical ventilation)
- Pre-operative blood tests – complete blood count/electrolytes/coagulation panel and cross match
- Family rapport, detailed informed consent, and discussion of perioperative course
- Team brief – surgeons/perfusion/scrub/anesthetic team on day of operation to discuss concerns, surgical approach, and perfusion strategy.

Anesthetic goals

Anesthetic goals include:

- Maintain ductal patency in duct-dependent lesions
- Maintenance of stable cardiovascular parameters
  - Maintain HR, sinus rhythm, pre-load, and myocardial contractility to maintain cardiac output (CO) – reduced CO reduces mixed venous oxygen saturation (SVO_2) and therefore decreases arterial saturation
- Avoid increase in PVR relative to SVR
  - An increase in PVR will reduce pulmonary blood flow and hence reduce intercirculatory mixing.
  - In PAH or mild/mod LVOT, ventilatory strategies can be used to reduce PVR, increase pulmonary blood flow, and increase mixing
- Avoid reduction in SVR relative to PVR
  - Decreased SVR increases recirculation of systemic venous blood and decreases arterial saturation

Anesthetic intraoperative management

On arrival in the anesthetic room after pre-op checks are complete and consent form is checked, monitoring is placed – SpO_2 (pre- and post-ductal), ECG, and NIBP. Induction can be intravenous or inhalational and should be tailored to the child. Our institution would use a combination of an opiate, an inhalational agent, and a muscle relaxant. A high-dose opioid technique has many advantages including attenuating the stress response, decreasing post-op morbidity, reducing coagulopathy and transfusion requirements [92, 93]. Fentanyl is the most commonly used opioid for induction in the United Kingdom, with doses ranging from 30–300 ug/kg, usually 10 mcg/kg is required as a minimum prior to incision. It is important to note that inhalational induction may be prolonged in patients with TGA due to high pulmonary re-circulation; it is therefore important to avoid high percentage sevoflurane for induction as myocardial depression may occur rapidly. Pancuronium, if available, at the dose of 0.1 mg/kg can be used for muscle relaxation, which is advantageous due to its long half-life. Pancuronium has vagolytic and sympathomimetic effects, thus inducing tachycardia, which can be blunted with co-administration of fentanyl. A nasal endotracheal tube in inserted, if possible, to aid comfort in the post-operative period.

Once intubated, arterial and central venous access is obtained. Radial arterial access is the preferred location due to the increased incidence of arterial thrombosis in femoral arterial lines, particularly in patients with cyanotic heart disease [94]. A central venous line is also inserted; preferably an internal jugular CVC, but if SVC cannulation is required for VSD closure a femoral central line may be preferable. Central venous pressure measurement is then established.

Once transferred into the operating theatre, core and peripheral temperature probes are placed, and NIRS is applied to the forehead. A urinary catheter is inserted to monitor urine output intraoperatively and throughout the postoperative course. The patient is then positioned appropriately; all lines are checked, secured, and padded prior to draping. A transesophageal echocardiography probe (TEE) is inserted after sufficient fentanyl has been administered to blunt cardiovascular response to the stimulating effect of its insertion. If a neonatal probe is available, then children weighing as little as 2.5 kg are suitable for this transesophageal approach. Epicardial echocardiography is preferred in some centers and is used in children with failed transesophageal placement or if they weigh less than 2.5 kg. The benefit of immediate echocardiography after separating from bypass is indisputable, particularly for the assessment of myocardial function, detection of residual defects, assessment of neo-aortic valve regurgitation, and adequacy of coronary anastomosis. Careful placement of the TEE probe is of paramount importance because of the higher risk of complications in neonates. TEE risks include compression of structures adjacent to the esophagus, predominantly the trachea and LA, leading to ventilatory or hemodynamic compromise respectively. The most frequently occurring risks involve esophageal or oropharyngeal trauma leading to dysphagia or hoarseness post-operatively, with most serious complication of esophageal perforation being extremely rare. A pre-bypass TEE examiniation is often preformed to clarify cardiac anatomy.

KEY POINTS: ANESTHETIC GOALS

- Maintain the PDA with PGE_1 in the duct-dependent circulation.
- Avoid increases in PVR and reductions in SVR to ensure adequate pulmonary blood flow and avoidance of recirculation of pulmonary venous blood.
- Maintain HR, sinus rhythm, pre-load, and myocardial contractility to maintain cardiac output (CO).

Pre-bypass Management

Due to the effects of anesthesia on the parallel systemic and pulmonary circulations, the pre-bypass period requires close attention from the anesthesiologist. PVR should be carefully optimized as an increase in PVR will decrease pulmonary blood flow and reduce intercirculatory mixing. SpO_2 is influenced by

the ratio of PVR to SVR. Arterial saturations usually sit around 75%; further desaturation in this period may relate to issues with ventilation (secretions, endobronchial intubation etc.) or decreased cardiac output. A reduction in cardiac output decreases systemic venous saturation and hence arterial saturation, which can be improved with the administration of a fluid bolus or inotropes. A decrease in SVR results in recirculation of venous blood and decreased arterial saturation, boluses of vasopressors (phenylephrine is used in our institution) can be used to counteract this decrease. If these interventions do not result in an improvement in arterial saturation, FiO_2 can be increased as a short period of high oxygen administration is unlikely to result in acute cardiogenic shock from pulmonary over-circulation.

Bypass

Cannulation for CPB is usually achieved following systemic heparinization using bicaval cannulation in the superior and inferior vena cava, avoiding the need for deep hypothermic circulatory arrest (DHCA). Single venous cannulation of the RA can be used but this requires a brief period of DHCA to repair the septal defects or aortic arch. The ASO is performed prior to the closure of any intracardiac defects as these will act as cardiac vents. The pump is primed with packed red cells and fresh frozen plasma (FFP) and during bypass hematocrit is maintained at ~30% [95]. An adequate mean arterial pressure is essential for ensuring adequate cerebral NIRS. A pH stat technique is preferred for acid-base management as it has been shown to increase cerebral NIRS, suggesting greater cerebral oxygenation during CPB in cyanotic patients with heart disease [96].

Antibiotics

Prophylactic antibiotics are administered 30 minutes prior to skin incision. Specific antibiotics administered are based on local policies and post-natal age.

Attenuating the systemic inflammatory response syndrome

The proinflammatory state as a consequence of cardiac bypass has been postulated to have deleterious consequences to cardiac function, such as low cardiac output syndrome (LCOS) and increased need for pharmacological or mechanical support leading to increased post-operative morbidity and mortality [97]. Corticosteroids are used by many centers to attenuate this inflammatory response while providing myocardial protection, but their use remains controversial, with no large-scale randomized controlled trials (RCTs) to provide clarity. Multiple trials have suggested that corticosteroids provide no significant benefit to justify their use, with some evidence that there is increased morbidity in lower risk groups due to increased risk of infection and prolonged length of stay [97–99]. A recent meta-analysis demonstrated attenuation of the cardiac bypass-induced inflammatory response, greater preservation of renal function, and lower mortality with steroid administration. However, the numbers are limited, and a larger prospective randomized study is still needed to verify the use of prophylactic steroids in pediatric cardiac patients [100]. A recent RCT in adults showed methylprednisolone had no significant effect on mortality or major morbidity after cardiac surgery [101]. Steroids are not routinely used in our center as a means of reducing the proinflammatory state of surgery and CPB. Systemic inflammatory reaction after bypass can also be reduced by a high dose fentanyl technique, heparin-coated bypass circuits, adequate heparinization, and the utilization of modified ultrafiltration (MUF) after bypass [93, 102, 103]. See Chapter 12 for further discussion of the inflammatory response.

Near infrared spectroscopy and neuromonitoring

Minimizing neurological morbidity associated with congenital cardiac surgery has become increasingly important as mortality has fallen dramatically with improvements in pre-natal diagnosis, intensive care treatment, and surgical technique [104]. Brain injury in these patients is a multifactorial process with risk factors from the pre, intra and post-operative period. Mechanisms of pre-operative brain injury include hypoxemia, prolonged time to surgery, and cardiac arrest [105] (Table 29.4). McQuillen et al. reported that balloon atrial septostomy is associated with pre-operative stroke in neonates with TGA although this is controversial, with recent data indicating that there was no association between brain injury and BAS [40, 41]. The Boston group highlighted that CPB is a clear risk factor for intra-operative neurological complications, likely due to hypoxia or ischemia from disturbances in cerebral perfusion [106–108]. This is particularly significant during periods of low flow CPB and deep hypothermic cardiac arrest. Near-infrared spectroscopy (NIRS) is a noninvasive, continuous monitoring of cerebral oxygenation that is not observable from standard monitoring technology [109]. It measures regional oxyhemoglobin saturation (rSO_2), through concentrations of oxyhemoglobin and deoxyhemoglobin, which correlates closely with jugular venous saturations in children [110, 111]. Several studies have demonstrated the benefit of NIRS during CPB and its accuracy in correlating with vital parameters [112]; however, there is limited knowledge on how to manage CPB according to cerebral oximetry values. Although there is some data that intervening to improve low intra-operative NIRS values may decrease the incidence of post-operative neurological adverse outcomes, [113] a randomized control trial is required. Our institution continues to record

Table 29.4 Risk factors for neonatal brain injury in patients with TGA

Preoperative	Intraoperative	Postoperative
Post-natal diagnosis of TGA	Hematocrit <25%	Low arterial PaO_2
Length of time to surgery	Decreased NIRS	Low BP
Low arterial hemoglobin saturation	Prolonged circulatory rrest	NIRS <45% for >3 hours
Cardiac arrest	CBP strategy	Morphologically immature brain
Morphologically immature brain		
Balloon atrial septostomy		

AL Grawany

NIRS trends in the intensive care unit during the initial postoperative period due to on-going risk of brain injury secondary to hypotension and hypoxemia [114]. See Chapter 14 for further discussion of neurological monitoring and outcomes.

Anticoagulation and thromboelastography/thromboelastometry

Management of anticoagulation during CPB is of fundamental importance due to the creation of a procoagulant state resulting in both hemorrhagic and thrombotic complications. Infants with cyanotic heart disease are at a particular risk and experience higher surgical morbidity and mortality compared to older children [115]. This is due to the immaturity of the coagulation system leading to a deficiency of antithrombin, hemodilution of clotting factors, and physiological changes associated with cyanosis [116, 117]. To minimize the risk of thrombosis heparin is administered while on CPB at an initial dose of 300–400 units/kg, ensuring that activated clotting time (ACT) is >350 seconds (or over three times baseline) and maintained throughout bypass. Children require higher doses of heparin than adults due to their ability to metabolize heparin more rapidly as well as their lower levels of antithrombin [118]. Due to relative heparin resistance in these infants, there may be ineffective suppression of thrombin generation [119]. This increases the likelihood of clot formation in the post-bypass period or microthrombi formation during bypass, causing the depletion of clotting factors resulting in a more severe coagulopathy post-bypass. Excessive anticoagulation, on the other hand, may place patients at risk of postoperative bleeding complications, even after its neutralization [120]. ACT is used to monitor the anticoagulant effect of heparin during bypass. It is a measure of whole blood coagulation, but its accuracy is limited by multiple factors that prolong ACT commonly encountered during CPB (hemodilution, hypothermia and impaired platelet function) even when the heparin dose is inadequate.

ACT correlating poorly with heparin effects has led to the use of patient-specific heparin management [121]. Patient-specific heparin management systems use a heparin dose-response test to determine the individualized response to heparin, along with heparin level monitoring. This has been more effective at suppression of thrombin than conventional heparin dosing and measurement, resulting in reduced blood loss and need for transfusion [122, 123].

Protamine sulfate is used to neutralize heparin at the end of bypass, by binding ionically to unfractionated heparin causing dissociation from the heparin–antithrombin complex. Dosing protamine can be problematic; accurate dosing requires knowledge of the circulating heparin concentration. Insufficient neutralization of heparin will increase the risk of postoperative bleeding, while excessive protamine dosing causes a paradoxical anticoagulant effect [124]. This is further complicated by ultrafiltration, as heparin molecules are too large to pass through the filter, leading to increased heparin concentrations [125]. Protamine administration can be associated with adverse effects including catastrophic pulmonary hypertension and histamine related vasodilation; therefore, careful administration is required [126].

Bivalirudin, a direct thrombin inhibitor, is an uncommonly used alternative in maintaining anticoagulation during CPB. Bivalirudin does not require the presence of anti-thrombin to be effective; thus, it can be used successfully in patients with heparin resistance due to antithrombin deficiency, and it has the potential to provide more consistent anticoagulation in neonates [127]. Bivalirudin is also used in patients with heparin-induced thrombocytopenia (HIT) as well as anticoagulation for ECMO or ventricular assist devices [127]. Bivalirudin has multiple drawbacks to its use including no point-of-care test to monitor anticoagulation effect, with limited pediatric studies, and despite its removal from the circulation via ultrafiltration, the lack of a reversal agent raises the concern of increased postoperative blood loss [128].

Hyperfibrinolysis is activated during bypass, and it is one of the major contributing factors leading to post-bypass bleeding [129]. Prophylactic administration of antifibrinolytics including tranexamic acid (TXA), aminocaproic acid (EACA), and aprotinin have been shown to decrease postoperative bleeding and transfusion requirements after pediatric cardiac surgery [130, 131]. Debate exists around the optimal dosing and administration of tranexamic acid, although studies suggest that sustained antifibrinolysis (dosing pre, during, and post-bypass) provides the greatest reduction in blood loss [132]. Although further studies are required to clarify optimum dosing of tranexamic acid, current expert opinion suggests a loading dose of 30 mg/kg followed by a continuous infusion of 10 mg/kg/hour in children <1 year of age [133].

Aprotinin is a serine protease inhibitor that has been shown to decrease bleeding and shorten ICU stays in adults; however, its use is controversial. It was withdrawn from the U.S. market in 2008 due to reports of increased risk of renal failure and mortality in adults undergoing cardiac surgery [134]. To date, there is no data to support similar findings in children. The use of aprotinin in neonates and children remains very controversial due to a lack of well-designed studies and an undefined safety profile; it is prudent to use lysine analogues (TXA and EACA) preferentially.

Thromboelastography and thromboelastometry

Conventional measures of coagulation such as PT, APTT, and ACT reflect the initial phases of coagulation but do not accurately predict post-op bleeding in neonates. Thromboelastography (TEG®) measures whole-blood coagulation profile incorporating interactions between platelets, fibrin polymerization, and fibrinolysis. TEG is therefore considered a better predictor of postoperative bleeding than conventional laboratory measurements, and its use has been found to significantly reduce postoperative bleeding, RBC transfusion, and length of ICU stay [135]. It is important to note TEG use may lead to excessive use of platelets and fibrinogen; therefore, abnormal TEG should be corrected in only the bleeding patient [136]. Its rapid generation of information is advantageous when targeting blood product administration after bypass [137]. Thromboelastometry (ROTEM®) has many similarities with TEG®, and both can assist in diagnosing the cause and aiding decision-making in the treatment of coagulopathy. Chapters 11 and 16 present further discussion of coagulation monitoring during and after bypass.

Separation from bypass

Separation from bypass requires clear communication between the surgeons, anesthesiologists, and perfusionists to ensure the transition occurs smoothly. The child must be adequately re-warmed, ventilation re-established, and the heart de-aired, with good ventricular function and no evidence of arrythmias or ischemia. Inotropes will be required to support the myocardium after bypass and need to be established prior to separation. Our institution favors epinephrine (although dopamine and dobutamine can also be used) with milrinone for its valuable inodilator properties. Milrinone is particularly important in reducing the LV afterload, as the LV will now be required to support the systemic circulation. Poor LV performance is of particular concern in patients undergoing late repair of TGA.

Preceding separation, pacing wires are placed and close inspection of the coronary arteries is required to ensure sufficient coronary patency (and perfusion) with minimal bleeding from the surgical anastomosis and suture lines. Inadequate invasive pressures and ST segment abnormalities can indicate coronary artery occlusion or kinking and require prompt rapid assessment of coronary patency. This may be difficult to visualize with TEE; hence, epicardial echography can be used, or surrogate markers of coronary patency such as regional wall motion abnormalities or mitral regurgitation may be observed. Coronary post-CPB myocardial dysfunction may be due to air in the coronaries, inadequate coronary transfer, poor myocardial protection, or a deconditioned LV. Prolonged ischemia must be avoided, and CPB may need to be resumed to fully assess the coronary arteries and any other precipitating factors to prevent end-organ hypoperfusion. Separation from bypass is often facilitated with low LAP (e.g. 2–5 mmHg) and a gradual reduction in pump flow.

On separation from bypass, blood volume may be required, which can be given by the perfusionist via the aortic cannula. Inotropes should be titrated to optimize cardiac output and organ perfusion whilst ensuring afterload is reduced. Once cardiovascular stability has been achieved, a period of modified ultrafiltration (MUF) can begin. MUF removes inflammatory mediators, which are thought to cause myocardial depression, from the circulation; although the most beneficial mechanism is due to the increase in hematocrit and concentration of clotting factors and pressor agents, which has been shown to significantly decrease bleeding in children after cardiac surgery. All children will require blood and clotting products once bypass has been terminated and protamine administered. Platelets, cryoprepitate, and FFP are available and given in incremental 5–10 mL/kg aliquots to prevent overdistension of the heart. Overdistention can lead to stretching of the newly implanted coronary arteries and subsequent myocardial ischemia. A left atrial pressure (LAP) line is placed prior to separation from bypass, providing valuable information immediately post bypass and can remain in situ in the post-op period to monitor LV dysfunction. A high LAP is a marker of excessive LV preload, which is not well tolerated by the non-compliant LV. Raised LAP also results in PA distension, which may compress the newly implanted coronary arteries, as the PA now sits anterior to the aorta. Fluid must be given cautiously, targeting LAPs of between 8–10 mmHg, with mean arterial pressures of 35–45 mmHg being sufficient to maintain adequate tissue perfusion. In the acute setting, if LAP is excessively high, a small volume of blood can be withdrawn from the central line to avoid precipitating fulminant LV failure.

Pulmonary vascular resistance can be increased due to preoperative exposure to increased pulmonary flow leading to reactive pulmonary vasculature. Inhaled NO should be readily available and instituted with a low threshold. If RV pressures are over two-thirds systemic while on iNO, direct measurement of RV and PA pressures is required to evaluate for potential obstruction across the neo-pulmonary anastomosis.

Chest closure should occur at the end of the operation providing there is hemodynamic stability and minimal bleeding. Rarely ECMO is required for temporary hemodynamic support. In this case, the chest is splinted open with a stent, and the wound covered with a Silastic™ dressing. The goal is to close the chest in the cardiac intensive care unit in the next 24–48 hours once stabilized.

Advances in perioperative care have enabled a drive toward early extubation after surgery for congenital heart disease. Prolonged intubation increases the risk of associated laryngeal trauma, pneumonia, and atelectasis, as well as increasing the unfavorable hemodynamic consequences on right heart function. There is some preliminary data to suggest "fast-track" extubation (within 6 hours) is safe, increases parental satisfaction, and results in reduced length of hospital stay – without an increase in morbidity and mortality [138, 139]. Evidence is limited and large multicenter trials are required to determine whether early extubation should become the standard of care. Patients with high oxygen requirements, ventricular dysfunction, and prolonged bypass times would not be suitable candidates for early extubation. Our institution uses a high dose opioid technique which reduces morbidity and mortality by suppressing the stress response to surgery but prevents early extubation [93].

KEY POINTS: ANESTHETIC MANAGEMENT

- Induction can be inhalational or intravenous.
- Maintenance with balanced opioid/inhalational technique is often preferred for better hemodynamic control.
- Invasive monitoring (arterial line, central venous pressure) is placed after nasotracheal intubation.
- Nasopharyngeal, rectal, and skin temperatures, neuromonitoring, and TEE or epicardial echocardiography probes are employed.
- Antibiotic prophylaxis is administered 30 minutes before skin incision.
- Heparin is administered with an ACT goal of >350 seconds; heparin level measurement systems are often very useful.
- CPB weaning is accomplished after rewarming, intracardiac air is removed, and cardiac function is acceptable, with acceptable rhythm and no signs of ischemia.
- Echocardiography is performed before sternal closure.

AL Grawany

Postoperative management of the arterial switch operation

Postoperatively, patient management takes place on the intensive care unit and is tailored to preoperative condition and the surgery performed. Patients are transferred to intensive care intubated, where sedation is continued. Our priority is to achieve hemodynamic stability and carry out careful observation for potential complications.

Common immediate post-op complications

Bleeding

Bleeding is a common complication in the early post-op period after the ASO, with early post-op hemorrhage an independent risk factor for increased morbidity and mortality after cardiac surgery [120, 140]. Multiple suture lines across great vessels after an ASO increases the risk of surgical bleeding, exacerbating coagulopathy, and hence medical bleeding. Coagulopathy necessitating administration of large volume of blood products (platelets, cryoprecipitate and FFP) can deleteriously affect pulmonary and myocardial function (via overdistention and stretching of the newly implanted coronary arteries). Bleeding is closely monitored in the post-op period with chest drain losses of >4 mL/kg/hour being indicative of significant bleeding. Avoidance of arterial or pulmonary hypertension is also imperative to minimize surgical bleeding from the numerous suture lines.

Left ventricular function and low cardiac output syndrome

Cardiovascular parameters and clinical findings must be closely observed in the intensive care unit post-operatively, with management directed toward ensuring adequate tissue perfusion (Table 29.5). Monitoring is continued from the intra-operative period with particular attention paid to LAP, lactate, SvO_2, and NIRS. MAPs of 40–45 mmHg are usually sufficient in these patients, with filling targeted to a LAP ideally between 5–8 mmHg, with no advantage to tissue perfusion with LAP above 10 mmHg. This is because ventricular diastolic function is poor after the ASO, and volume overload is not tolerated. Overfilling post ASO may lead to cyclical situation, where an already struggling LV dilates and distends (particularly in the context of mitral insufficiency) resulting in stretching or kinking of the coronary arteries, further worsening the myocardial insult and triggering further LV dilatation. Raised LAP can exacerbate this problem, raising PAP that can compress the coronary ostia due to its new anterior position after the LeCompte maneuver. Fluid administration must therefore be cautious, and boluses should be given in aliquots of 5 mL/kg with impact closely monitored. If required, blood can be withdrawn from the arterial or central line to reduce LAP pressure.

Table 29.5 Intensive care unit targets post arterial switch operation

Parameter	Target
MAP	>45 mmHg
LAP	5–8 mmHg
SvO_2	>60%
Lactate	<3 mmol/L
Urine output	>0.5 mL/kg/hour

Box 29.2: Causes of low cardiac output after the arterial switch operation

- Coronary artery insufficiency
- Low cardiac output syndrome
- Untrained LV
- Unprotected myocardium after cardiopulmonary bypass

Myocardial function after an ASO may be impaired for multiple reasons related to coronary insufficiency, inadequately trained left ventricular mass and insufficient intra-operative myocardial protection during bypass (Box 29.2). Low cardiac output after an ASO must always raise the suspicion of coronary insufficiency first. If coronary artery insufficiency is suspected, prompt surgical review with possible intervention and revision is required. Low cardiac output will also be the clinical presentation in patients with primary myocardial dysfunction, most commonly occurring in patients with borderline pre-op LV function or inadequate LV mass. Inotropic support is therefore required while the LV adapts to support the systematic circulation. Nonspecific low cardiac output could be due to LCOS (Low cardiac output syndrome) – a serious yet commonly occurring complication of bypass, with 25% of children with CHD affected after cardiac surgery. LCOS results in insufficient cardiac output to meet systemic oxygen demand, usually occurring 6–18 hours after cross clamp removal. The etiology of LCOS is multifactorial and appears to be related to the inflammatory response to CPB, myocardial reperfusion injury, and ischemia from aortic cross clamping [141]. LCOS contributes to increased morbidity and mortality; therefore, it should be anticipated, with early identification and aggressive treatment of paramount importance. The clinical parameters indicating LCOS (persistently low MAP), poor peripheral perfusion, increasing lactate, and raised LAP), may also be caused by myocardial insufficiency and hence requires urgent investigation with echo.

Arrythmias

Neonates undergoing an ASO will be predisposed to arrythmias in the early post-op period; this is associated with increased mortality after cardiac surgery; therefore, early recognition and management is of paramount importance [142]. The most commonly occurring arrythmias include supraventricular tachycardia (SVT), junctional ectopic tachcardia (JET), or ventricular tachycardia (VT) and may relate to multiple factors: line placement, electrolyte imbalance, inadequate myocardial protection after bypass, LCOS or due to surgical trauma, or inflammation [142]. Arrythmias, especially VT, are frequently indicative of coronary insufficiency, which is more likely with unusual coronary anatomy (single coronary artery, intramural coronary arteries) due to the technically demanding nature of the coronary transfer.

Pulmonary hypertension

Pulmonary hypertension or pulmonary hypertensive crisis may complicate the post-op course, particularly in patients with TGA/IVS; it typically occurs within the first 48 hours

post-op and usually coincides with a decrease in cardiac index [141]. Although the exact mechanism is unknown, it is likely related to ischemia-reperfusion injury post bypass or acute ischemia leading to left ventricular dysfunction, with backward transmission of elevated left ventricular filling pressures to the pulmonary circulation. Patients with D-TGA are prone to increased pulmonary vascular reactivity due to pulmonary over-circulation contributing to the degree of PH. Inhaled NO, increased depth of sedation, hyperventilation, and paralysis are used as treatment strategies to help reduce pulmonary bed reactivity. An echo should be performed to assess the degree of pulmonary hypertension and biventricular dysfunction as well as looking for residual shunts or branch pulmonary stenosis following LeCompte maneuver.

Respiratory support and drains

After return from the operating room the child remains sedated and mechanically ventilated, using lung protective ventilation strategies to avoid barotrauma. Respiratory support is gradually weaned over the first 12–24 hours. Patients will need to remain ventilated beyond this if they are hemodynamically unstable, develop arrythmias or continue to bleed. Patients who return to CICU with an open chest will need to stay ventilated until 24 hours after chest closure, providing they remain stable. Although there is a push in some centers toward early extubation, our center will wait until relative stability has been achieved. This includes:

- Hemodynamic stability – an adequate blood pressure, heart rate and LAP with low inotropic support
- Minimal ventilatory requirements
- A negative fluid balance – a good urine output is usually a positive indicator and is essential to remove excessive fluid from the myocardium, lungs, and other organs
- Chest radiograph without significant lung pathology
- Normalized blood gases
- No signs of sepsis.

Mediastinal drains are closely monitored in the early post-operative period as they are a visible indicator of post-op bleeding. In the first four hours bleeding between 0–4 mL/kg/hour is normal, with chest drain output usually decreasing in the ensuing hours. Bleeding above 4 mL/kg/hour may signify surgical bleeding or uncorrected coagulopathy, requiring directed blood product administration and urgent surgical review. A sudden reduction in previously brisk bleeding associated with hemodynamic instability may indicate cardiac tamponade necessitating urgent action. Chest drains stay in situ until there is minimal drainage, typically around day 3 post-operatively. After chest drain removal, a chest radiograph will be performed to rule out pneumothorax, atelectasis or residual pleural effusions.

Sedation and analgesia

An individualized plan optimizes patient comfort and helps to reduce the stress response whilst minimizing hemodynamic compromise. While insufficient sedation may cause ventilation desynchrony (with deleterious effects on gas exchange) and risks inadvertent removal of tubes, drains or lines; excessive sedation prolongs ICU stay, delays recovery and increases the symptoms of withdrawal. Sedation assessment scores (e.g. COMFORT score) should be measured at regular intervals to ensure sedation and analgesia are optimized and titrated to individual patient need. If possible, high dose and protracted use of sedation should be avoided to minimize the effects of physical dependence and withdrawal. For this reason, short acting drugs are preferred, reviewed regularly and weaned as soon as appropriate.

Our institution commonly uses a combination of opioids (morphine or fentanyl) and alpha agonists (dexmedetomidine or clonidine) delivered via continuous infusion. Occasionally benzodiazepines such as midazolam are used. Dexmedetomidine is particularly useful in this patient cohort due to limited effects on respiratory function, facilitating early or "fast-track" extubation while reducing the need for additional sedation or analgesic agents [45, 143, 144]. Dexmedetomidine has significant cardiovascular benefits as it has been found to be effective in reducing post-operative arrhythmias including SVT, JET, and VT and reduces vasopressor agent dosing for children with catecholamine- refractory cardiogenic shock [145–147]. Although dexmedetomidine has been shown to cause a dose related decrease in heart rate, it has not been found to be clinically significant in infants after congenital heart surgery [148]. Neuromuscular blockade post-operatively may be required in management of JET, LCOS, or a pulmonary hypertensive crisis, although their use should be avoided where possible. Use of neuromuscular blocking agents in critically ill children is associated with increased mortality and high rates of physical and cognitive disability [148].

Renal support

Transient acute kidney injury is common after cardiac surgery and CPB leading to increased morbidity and mortality [149]. Approximately 50% of neonates undergoing ASO have some degree of renal injury, with 10% requiring renal replacement therapy (RRT). Renal failure is multifactorial, predicting which patients will develop acute kidney injury (AKI) or require RRT remains difficult. Furosemide is started 8–12 hours after return from theatre. In our institution, all neonates have a peritoneal dialysis (PD) catheter inserted at the time of surgery. Prophylactic insertion of a PD catheter has shown diminished timescales for achieving negative fluid balance, reduced time to extubation, and lessened ionotropic requirement [150].

Fluids and electrolytes

Due to the risk of volume overload resulting in raised LAP and worsening LV dysfunction, fluid must be given cautiously post-operatively. Fluid boluses should be avoided if possible; if required for volume resuscitation due to bleeding, blood products should be given in 5–10 mL/kg aliquots, paying close attention to the LAP. Maintenance fluid should be administered at 30–50% total fluid requirements in first 24 hours post-op and should not exceed 50–75% until extubation. Electrolytes should be carefully monitored and corrected to ensure Mg++ >1 mmol/L, K+ 4–5 mmol/L and Ca++ >1.2 mmol/L.

Feeding and nutrition

Nasogastric feeds should be started as soon as hemodynamic stability has been achieved. Early feeding can prevent gastric translocation, minimize the loss of lean body mass, and support vital organ function [151]. If enteral feeding is not started within the first 24 hours, parental nutrition should commence. Once extubated, infants with stable respiratory parameters can be fed orally.

Sepsis

Prophylactic antibiotics are started at induction (30 minutes prior to incision) and continued for 24 hours post-operatively, as per local guidance. Patients with an open chest continue on broad spectrum antibiotics until the chest is closed. Targeted measures and clinical bundles should be followed to minimize the risk of post-operative infections such as ventilator-associated pneumonias, line infections, and sternal wound infections.

Congenitally corrected TGA (L-TGA)

Incidence

Congenitally corrected transposition of the great arteries (ccTGA) is an uncommon cardiac defect, accounting for less than 0.5% of all congenital heart disease.

Anatomy

Congenitally corrected transposition of the great arteries (ccTGA), or levo-TGA (L-TGA) is a rare disease characterized by both atrioventricular and ventriculoarterial discordance. ccTGA is also commonly referred to as double discordance or ventricular inversion (due to reversal of ventricular positioning) Consequently, a right-sided RA connects via the mitral valve to a morphological LV to a right-sided PA. The left-sided LA drains via the tricuspid valve into a morphological RV to supply a left-sided aorta (Figures 29.18 and 29.19). ccTGA may present as situs solitus (the morphological left ventricle is located on the right, with a left sided aorta) or situ invertus.

Situs invertus ccTGA is an extremely rare lesion, with this variant accounting for one-third of ccTGA cases/lesions. Situs invertus ccTGA results in an anatomic mirror image of L-TGA and despite anatomical differences, pathophysiology of the disease is the same [153].

During embryological development, looping of the heart is required to ensure correct anatomical arrangement of the four chambers. In ccTGA the primitive heart loops toward the left (levo-bulboventricular) rather than following the usual right-sided looping (dextro-bulboventricular), resulting in abnormal atrioventricular and ventriculoarterial connections. This double discordance results in a series circulation; deoxygenated venous blood returns to the heart and oxygenated pulmonary venous blood is transported to the systemic circulation. Although blood flow is physiological, problems arise due to the intrinsically abnormal tricuspid valve and progressive decline in RV function, as it is poorly adapted to supporting the systemic circulation. In addition to this, >90% of patients have associated cardiac abnormalities, with a broad spectrum of severity.

Associated anatomic features in addition to AV and VA discordance that complicate ccTGA include [154]:

- Perimembranous or malaligned VSD (50–80%)
- Multiple or remote VSDs
- Multilevel LVOTO (50–70%) secondary to pulmonary atresia and subpulmonary or pulmonary stenosis
- Tricupsid valve anomalies (25–90%)
- Straddling or overriding AV valves
- Abnormalities and disturbances of the AV conduction system
- Ventricular hypoplasia
- Coronary anomalies
- Dextrocardia with or without situs abnormalities.

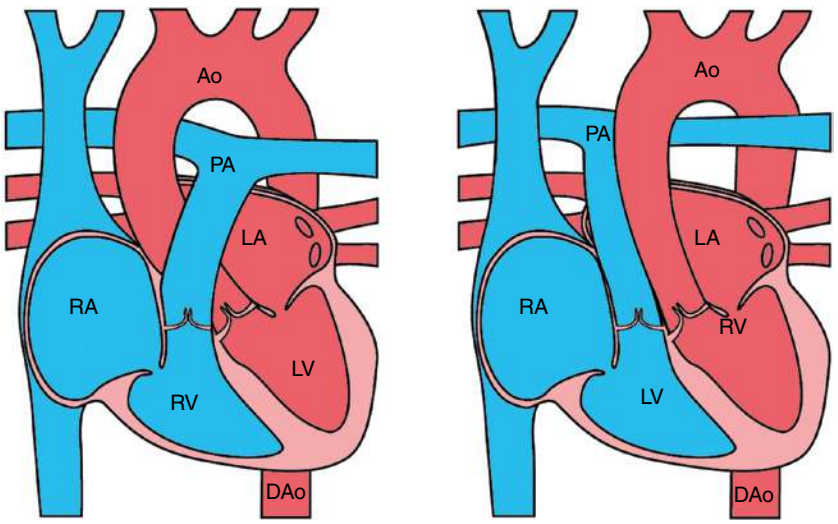

Figure 29.18 Congenitally corrected transposition of the great arteries (ccTGA). (A) Normal anatomy. (B) ccTGA – blood flow in corrected transposition. Ao, aorta; PA, pulmonary artery; LA, left atrium; RA, right atrium; RV, right ventricle; LV, left ventricle; DAo, descending aorta.

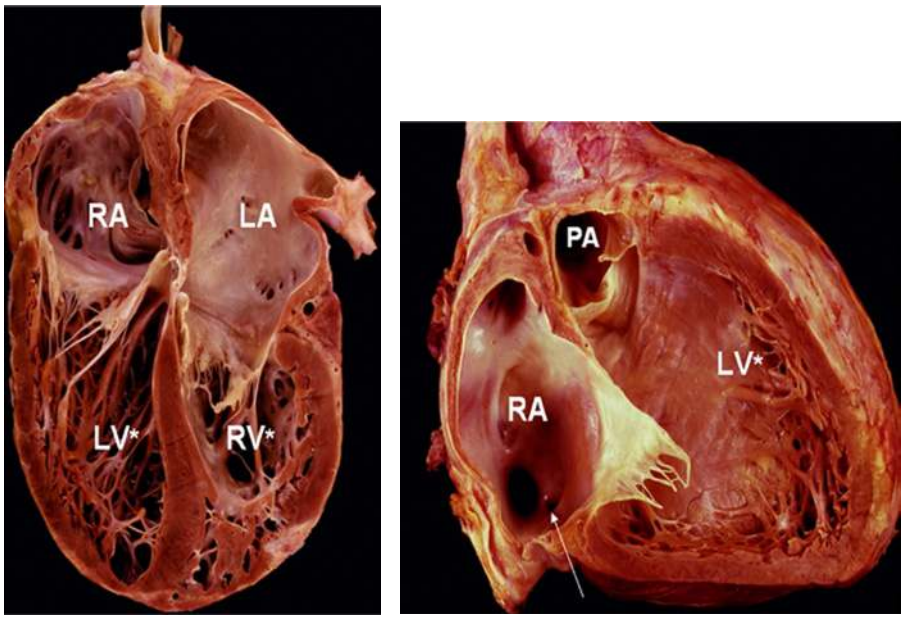

Figure 29.19 Anatomic section of heart from a patient with ccTGA. (A) Four-chamber view with the right AV valve located cephalad to the AV valve. (B) Long-axis view with the arrow pointing to the coronary sinus ostium. Note a relatively thin and indistinct Eustachian ridge separating the CS from the inferior vena cava. AV, atrioventricular; ccTGA, congenitally corrected transposition of the great arteries; CS, coronary sinus; LA, left atrium; LV, morphologic left ventricle; PA, pulmonary artery; RA, right atrium; RV, morphologic right ventricle. (Source: Bottega et al. [152]. Reproduced with permission of Elsevier.)

A VSD is present in approximately 70% of patients and is most commonly the result of malalignment between the atrial septum and the inlet of the ventricular septum, although defects can be found anywhere in the ventricular septum. LVOTO occurs in over 50% of patients and is nearly always associated with a VSD. Subpulmonary/valvular stenosis is the most frequently occurring manifestation of LVOTO and is usually due to posterior deviation of the conal septum or AV valve tissue. Isolated pulmonary valve stenosis is rare. Tricuspid valve abnormalities occur in >90% of patients, although this will result in functional consequences in approximately half of the patients [153]. The valve is described as "Ebstein-like." Posterior and septal leaflets are tethered to the posterior RV wall which tends to limit the long-term functional reliability of the tricuspid valve in the systemic circulation. In contrast to an Ebstein's anomaly, apical displacement of the valve leaflets with ensuing arterialization of the right ventricle is rare.

The AV node position is abnormal and is located between the orifice of the RA appendage and the mitral valve annulus, rather than at the apex of the triangle of Koch. Many patients also have dual AV nodes. As a consequence of the AV node abnormality, disturbances of the AV conduction system are common and thought to be secondary to fibrosis of the junction between the AV node and the AV conduction system [155]. Complete heart block is the most common resulting arrythmia, with a progressive incidence of 2% per year [68].

Coronary anatomy in ccTGA

The coronary artery anatomy in ccTGA is a mirror image of the normal anatomy. The artery originating from the right-sided sinus gives rise to the left anterior descending (LAD) and the circumflex artery, thus being considered the morphological left coronary artery. Originating from the left-sided sinus, following the left AV groove and supplying the right ventricle is the morphological right coronary artery.

KEY POINTS: ASSOCIATED ANOMALIES IN CCTGA

- Common anomalies associated with ccTGA can be summarized as follows:
  - Perimembranous or malaligned VSD (50–80%)
  - Tricuspid valve abnormalities (25–90%)
  - Multilevel LVOTO (50–70%)
  - Dextrocardia (25%) with/without situs inversus
  - Interruption or abnormally situated conduction pathway

Natural history

Isolated ccTGA is a variable lesion, and its natural history is dependent on three main factors: RV function, tricuspid valve function, and the development of arrythmias. The RV is intended to support the low-pressure pulmonary circulation and is poorly adapted at sustaining the systemic load. While patients without associated cardiac lesions are asymptomatic in early life, over the course of a normal lifespan, heart failure is a common long-term complication.

Twenty-five percent of patients with isolated ccTGA develop congestive heart failure (CHF) by the fourth decade, which increases to 67% in patients with associated cardiac lesions [156]. The risk factors of heart failure in ccTGA relate to advancing age, presence of associated cardiac abnormalities, tricuspid regurgitation, significant arrythmias, tricuspid valve surgery, pacemaker implantation and open-heart surgery [156, 157]. The long-term systemic workload of the RV leads to tricuspid regurgitation, resulting in RV volume overload, in turn accelerating ventricular dysfunction and failure [158]. It is also suspected that abnormal perfusion plays a major role in the development of progressive RV dysfunction, due to a single coronary artery supplying the systemic ventricle [159].

Pathophysiology

In ccTGA, the TGA is physiologically corrected, giving rise to a normal series circulation where deoxygenated blood is oxygenated in the lungs prior to entering the systemic circulation. The morphological LV is the pulmonary ventricle and empties deoxygenated blood into the PA; the LA receives oxygenated blood from the pulmonary veins, which enters the aorta via the morphological RV.

This creates a unique pathophysiological condition in which the morphological right ventricle (RV) sustains systemic circulation from birth. As the RV is not designed to withstand systemic pressures over the course of a normal lifespan it must undergo various adaptive mechanisms to support the systemic load, including eccentric hypertrophy, fibrosis, and dilatation of the RV [160]. Right ventricular dysfunction will eventually occur, with heart failure as a common long-term complication. Tricuspid regurgitation is strongly associated with RV dysfunction and CHF; its mechanism is thought to be multifactorial. Due to exposure of the RV to systemic pressure, the ventricular septum bows towards the LV, resulting in a spherical RV shape. This pulls the septal attachments of the TV away from the annulus, resulting in progressive tricuspid regurgitation and exacerbating the volume overload on the systemic and morphologic RV. In addition, the TV is frequently dysplastic (most commonly the Ebstein-type abnormality), with this group more likely to develop significant TR and ventricular dysfunction earlier in life [161]. Late RV dysfunction will be compounded by chronic microvascular ischemia and inadequate perfusion via the single coronary artery supplying the hypertrophied mass of the RV [161].

Clinical presentation and diagnostic features

The majority of patients with ccTGA are diagnosed postnatally. While ccGTA may be detected on prenatal fetal ultrasound, particularly in specialized centers, diagnosis remains challenging, especially when associated defects are not present [162].

Timing of post-natal presentation is dependent on the presence and nature of associated cardiac abnormalities. Isolated ccTGA is very unusual, only occurring in <10% of patients. These patients are initially asymptomatic but may present in adult life with symptoms of tricuspid (systemic) valve regurgitation, conduction disturbances, impaired systemic ventricular function, and CHF [163]. Complete heart block is the most common arrythmia with symptoms of chest pain, fatigue, dyspnea, and poor exercise tolerance. Tricuspid valve regurgitation and impaired systemic ventricular function will present with signs of heart failure, including fatigue, reduced exercise tolerance, dyspnea, and peripheral edema.

The majority of patients have concomitant cardiac abnormalities and will present with signs or symptoms associated with the pathophysiology of these lesions:

- **VSD** – may present with a systolic murmur or signs of heart failure.
- **LVOTO** – Cyanosis may be a presenting feature in patients who have a VSD and severe LVOTO due to decreased pulmonary blood flow and a large pulmonary-to-systemic ventricular shunt.
- **Tricuspid valve abnormality** – may present with signs of right heart failure or respiratory distress, cyanosis or a systolic murmur.

Diagnostic testing

ECG – Q waves present in the right precordial leads, but absent in the left precordial leads are characteristic of ccTGA due to inversed septal depolarization due to ventricular inversion i.e., from right to left. Patients may also present with complete heart block due to disturbances of the AV conduction system. Complete heart block may even be detected antenatally, raising clinical suspicion of ccTGA.

CXR – ccTGA with levocardia may result in prominence of the upper left border of the mediastinum. Presence of mesocardia or dextrocardia may raise clinical suspicion of ccTGA.

Echo – Echocardiography is a reliable method for diagnosis of ccTGA and the presence of associated anomalies. The four-chamber apical view will show the more trabeculated morphological RV on the left and the smoother walled morphological LV on the right.

Cardiac MRI – Cardiac MRI is commonly used to further evaluate these complex lesions and is able to provide detailed information about anatomy as well as quantitative assessment of function and flow. Cardiac catheterization is reserved for assessment of those patients who have pulmonary vascular occlusive disease and is frequently carried out in conjunction with cardiac MRI to give detailed information about PVR.

KEY POINTS: CCTGA

- ccTGA is a rare defect with AV and VA discordance.
- The TGA is physiologically corrected and has normal series circulation where blood is oxygenated in the lungs before entering the systemic circulation.
- The morphological RV is the systemic ventricle.
- There is a high incidence of associated cardiac anomalies, in up to 98% of patients.
- Age at presentation and natural history depend on the combination and severity of associated defects.
- Surgical repair is either physiologic or anatomic.

Surgical options

Surgical treatment options have been available for over 50 years, but optimal surgical management of ccTGA remains controversial. Surgical strategies are divided into "physiological repair" (the morphological RV remains as the systemic ventricle) or "anatomic repair" (creating atrioventricular concordance with the LV and mitral valve acting as the systemic ventricle and AV valve.) The first surgical repairs for ccTGA were "physiologic" and performed by Anderson and Lillehei in 1957. In the past two decades, anatomic repair has been considered a better option despite its more complex nature due to the unfavorable long-term outcomes of physiological repair (50% mortality at 20 years) [164].

The diverse anatomy of this lesion leads to a significant variance in symptoms and timing of presentation requiring a broad range of treatment options (Figure 29.20). Due to its rarity and the lack of robust data on long term outcomes, comparisons of treatment pathways is made difficult, and decision-making for the surgical management of ccTGA is challenging. The choice of surgical approach will depend on the anatomic features, the patient's age at presentation and severity of symptoms. Center and surgeon preference will also have an impact, given that ccTGA is a rare lesion, consequently most surgeons will not have the opportunity to operate on large numbers of patients; the learning curve for such complex operations is an important consideration. Current data suggests that early anatomic repair is the preferred strategy for the majority of children, with prompt LV banding if required. For patients with a balanced anatomy and no evident dysfunction, expectant management is a viable strategy with transition to other pathways if nonintervention fails [165].

There are numerous surgical approaches for anatomic variations involving ccTGA. These can be classified into three categories according to which ventricle is the designated post-repair systemic ventricle:

- Systemic right ventricle
  - Classical (physiologic) repair
  - Isolated tricuspid valve repair/replacement
  - Multisite pacing
- Systemic left ventricle
  - Senning – ASO (double switch procedure)
  - Senning – Rastelli
- Systemic left and right ventricle

Fontan operation

Physiologic repair

Physiologic repair in ccTGA consists of repair of the associated cardiac defects while maintaining the morphological right ventricle as the systemic ventricle. It addresses VSD closure,

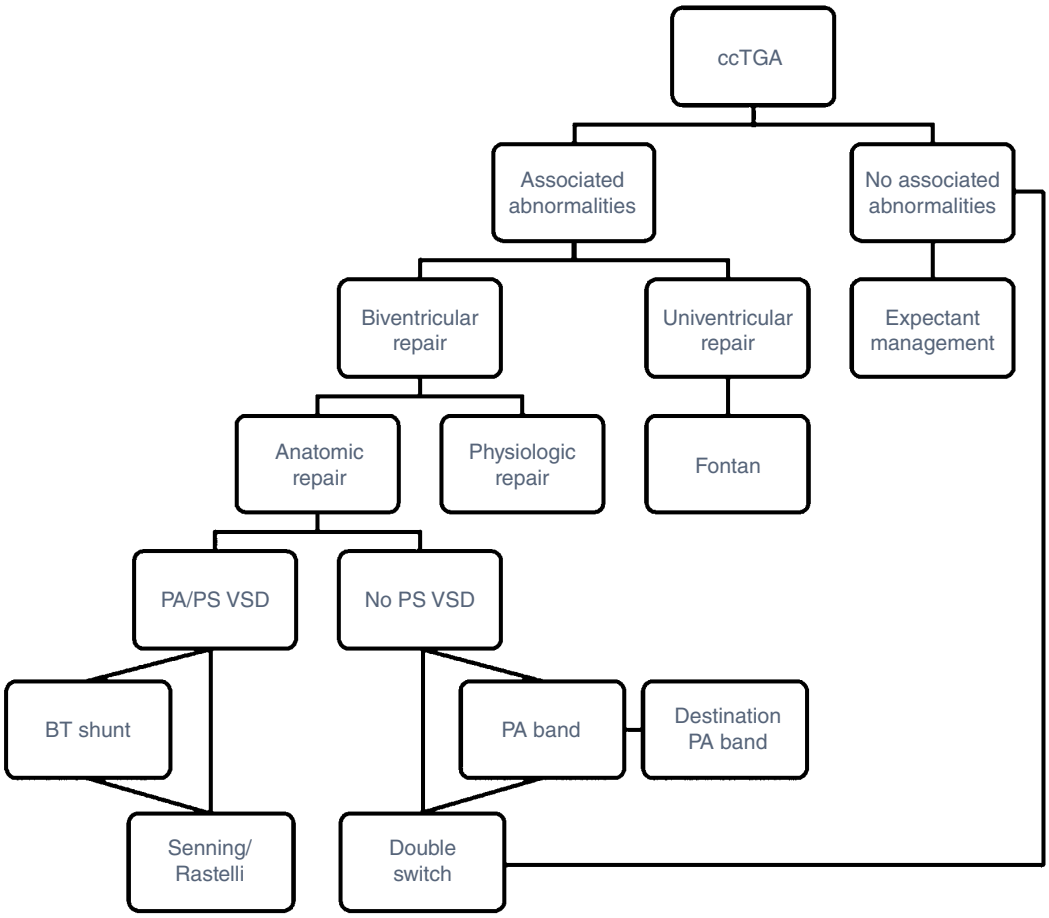

Figure 29.20 Flowchart illustrating anatomical factors determining decision-making in patients with congenitally corrected transposition of the great arteries (ccTGA). PA, pulmonary atresia; PS, pulmonary stenosis; VSD, ventricular septal defect; BT shunt, Blalock-Taussig shunt; PA, pulmonary artery.

AL Grawany

relief of LVOTO, conduit insertion, valvular repair or replacement and pacemaker insertion. Recent data suggests that patients with physiological repair have equivalent short and midterm survival compared to those with anatomic repair [165]. Despite this, physiologic repair appears to be compromised in mid-term outcomes, with progressive RV dysfunction irrespective of TV interventions from 12 years post repair. Overall survival after physiologic repair was 71 vs 80% for anatomic repair at 15 years. In addition to this, interventions to reduce TV regurgitation did not reduce systemic ventricular failure or result in survival benefit [165, 166]. It is noteworthy that these patients also had the highest frequency of transplant among the treatment pathways, indicating that once the systemic ventricle starts to decline there are limited successful treatment options. After physiological repair, close follow-up is required to monitor tricuspid valve function, with early surgical intervention required to repair or replace the TV prior to progressive systemic ventricular failure. Risk factors for poor outcomes include tricuspid valve replacement, preoperative RV dysfunction, complete heart block postoperatively subvalvar PS and "Ebstein-like" abnormity of TV.

Despite these limitations, the physiologic operative approach may still be useful in highly selected cases. Patients with good right ventricular and tricuspid valve function, balanced ventricles, and favorable septation anatomy may be suitable candidates. This is especially the case if a relative contraindication to anatomic repair exists, such as poor mitral valve function, coronary anomalies, small atrium, dextrocardia or inlet VSD features [154].

Anatomic repair

The anatomic repair involves creating AV and VA concordance, ensuring the morphological left ventricle is supplying systemic circulation. Blood is redirected at the atrial level using a Mustard or Senning technique and at the great arteries via the ASO or ventricular level using the Rastelli operation. ASO and Senning procedure (double switch) was first performed in the late 1980s by Imai, Yagihara, Mee, and others [154, 167, 168]. A decade later, Ibawi described an atrial repair in combination with the Rastelli operation for cases of ccTGA with LVOTO and since then, anatomic repairs of both varieties have had a prominent place in the management of ccTGA. Patients will require balanced ventricles and a morphological LV that is capable of maintaining the workload of the systemic circulation. The LV will decondition quickly after birth in patients without pulmonary outflow obstruction or an unrestricted VSD, requiring LV "training." A PA band is placed to increase the afterload of the morphological LV increasing wall thickness [169]. The PA band will also alter the LV/RV pressure ratio, reducing the spherical shape of the RV thus stabilizing tricuspid valve regurgitation [170]. Varying measures are used to ascertain when the LV is ready, it is suggested that a LV-to-RV peak systolic pressure ratio of 0.70 to 0.90 is optimal [171]. Repeat banding may be required to ensure the band is tight enough to adequately train the LV [172]. Periodic assessment by echocardiography, cardiac catheterization, or MRI is used to determine whether adequate training been achieved in advance of anatomic repair. LV training is most successful in younger children, as myocardial response to increased afterload changes from hyperplastic to hypertrophic with increasing age [173].

Patients with a large VSD, LVOTO (subpulmonary or pulmonary stenosis) or pulmonary hypertension expose the morphological LV to systemic pressures from birth, retaining LV mass, and are suitable for primary anatomic repair. An anatomic repair is the preferred approach in patients with good mitral valve function, balanced ventricles and a septatable heart. Patients with poor RV or TV function would also be candidates for this type of repair as physiologic repair in these patients almost always has an unfavorable outcome.

Double switch procedure

The double switch (DS) procedure incorporates an atrial (Mustard or Senning procedure) and an ASO, creating VA and AV concordance. It can be simplified as a three-step procedure.

First, the VSD is closed. Second, the great arteries are switched to their respective ventricles (similar to the ASO performed for D-TGA) and coronaries re-implanted, creating VA concordance. As with the ASO for d-TGA, the identification of coronary anatomy is fundamental to optimal surgical outcome. The mitral valve and the morphological LV become the systemic AV valve and ventricle, and the tricuspid valve and morphological RV become the pulmonary AV valve and ventricle.

Last, the Mustard or Senning part of the operation creates an intracardiac baffle which redirects deoxygenated blood from the RA to the morphological RV via the tricuspid valve, emptying into the neo-pulmonary artery to the lungs. Similarly, the oxygenated blood from the LA is redirected to the LV creating AV concordance. This procedure is appropriate where patients have deteriorating systemic ventricle dysfunction, in the presence of systemic (tricuspid) valve regurgitation. Good LV function and minimal LVOT (pulmonary arterial) obstruction is a prerequisite for this type of surgical repair. Decision-making around surgical timing and patient readiness is complex. Surgical timing is dictated by the severity of CHF symptoms, which is determined by the size of VSD and presence of tricuspid regurgitation (Figure 29.21). The larger the VSD, the more likely that the LV will retain sufficient mass, however, it increases the risk of developing CHF and hence pulmonary hypertension. A PA band can be placed in these patients to minimize pulmonary over-circulation, reducing symptoms of CHF until the child is an adequate weight prior to surgical repair. This is of particular importance due to the technically challenging nature of the operation.

Senning and Rastelli

The combination of the Senning and Rastelli procedures (SR) has been undertaken in patients with ccTGA that have a VSD and significant LVOTO. It involves an atrial level switch (Mustard or Senning procedure) and a Rastelli operation. During the Rastelli operation the VSD is closed with a patch that directs blood to the aorta and a valved conduit is placed between the RV to PA.

Timing of surgery depends on the degree of pulmonary stenosis and cyanosis. Patients with severe pulmonary stenosis or pulmonary atresia require a systemic to pulmonary shunt (e.g. modified BT shunt). The Rastelli procedure can then be performed once the child has outgrown the shunt, which usually happens at around 6 months of age. Patients

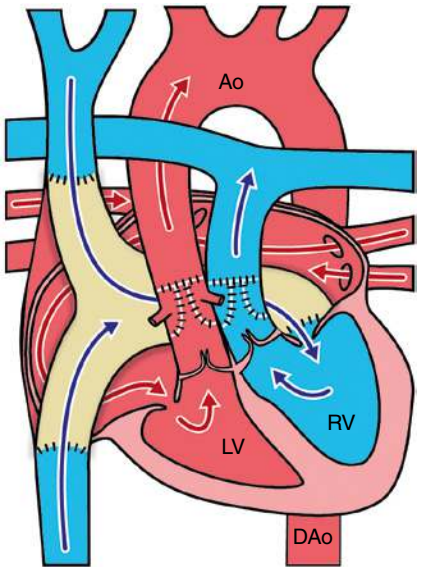

Figure 29.21 "Double switch" operation: Mustard operation with the arterial switch procedure. Ao, aorta; LV, left ventricle; RV, right ventricle; DAo, descending aorta.

with less severe pulmonary stenosis may wait until cyanosis develops but should be performed prior to systemic ventricular failure or tricuspid regurgitation occurs.

Fontan procedure for ccTGA

The use of the Fontan operation as a treatment pathway for ccTGA is controversial. Patients unsuitable for a biventricular repair due to single ventricle physiology (tricuspid atresia) or large VSDs not amenable for septation, are clear candidates for Fontan palliation. However, there is variation in treatment pathways between centers, with patients with Ebstein anomaly, for example, directed to Fontan in some centers and to septation by others. Despite some hesitancy to proceed with a Fontan pathway in potentially septatable, biventricular hearts, there is data to suggest that it compares favorably to physiological biventricular repair [154]. Data regarding the outcome of Fontan vs. other repairs in patients with ccTGA remain limited, but good outcomes in patients with a single ventricle or AV valve support its use in certain patients [165].

Outcomes

From the most current data, anatomic repair offers the best long-term outcomes although it is still unclear which patient cohort will benefit the most (Table 29.6). Early and midterm survival is between 80–85%, with no apparent difference in survival between the DS and SR group [174, 175]. Despite significant early and late interventions, overall survival is approximately 80% at 10 years post anatomic repair [165, 175].

Anatomic repair is based on the principle that long-term outcome is improved when the LV is the systemic ventricle, consequently late LV dysfunction is of particular concern. Late LV dysfunction occurs in approximately 15% of patients after anatomic repair, with a higher risk after the double switch than Rastelli-Senning procedure [175]. This may be due to the increased risk of deterioration of the LV in patients who required LV training [169]. Increased age and the need for pacing are also risk factors for late LV dysfunction, suggesting that early anatomic correction and primary cardiac resynchronization therapy in patients requiring a pacemaker, may reduce the risk of developing late LV failure [176].

Table 29.6 Long-term outcomes after anatomic repair for congenitally corrected transposition of the great arteries

Outcome	Incidence
LV dysfunction	15–20%
Post-op complete heart block	~30%
Neo-aortic valve regurgitation (mild)	70%
Baffle complications	Unknown, 15–50% after d-TGA
Reintervention rate	25%

Conduction abnormalities are common in patients with ccTGA due to abnormal anatomy of the conduction pathway with the risk of complete heart block occurring with a progressive incidence of 2% per year [68]. Post-operative CHB occurs in ~30% of patients, with some data to indicate that it is more common in the DS group especially when VSD closure is required [175, 177]. Centers have been known to advocate for permanent pacemaker lead insertion intraoperatively due to the high risk of heart block associated with ccTGA. Mustard and Senning operations are associated with a significant risk of atrial tachyarrhythmias, which can contribute to LV dysfunction from loss of atrial contraction. Catheter ablation has been used to successfully treat tachyarrhythmias in such patients [178].

Around 70% of patients after DS have at least mild aortic insufficiency (AI). Despite this, mild AI is well tolerated in the majority of patients and does not appear to correlate with morphological LV dysfunction [175]. Previous PA band and use of LeCompte maneuver in side-by-side vessel arrangements may also predispose to AI post-operatively [179].

Despite the Senning procedure being the most commonly used atrial switch technique, there remains no clear data on its long-term advantages over the Mustard technique; both are associated with baffle-complications including stenosis, residual leaks and atrial arrythmias [90]. There is little data on baffle complications after ccTGA; hence, data is inferred from adults after D-TGA repair. One long-term follow-up study showed significant morbidity and mortality after the Mustard procedure for d-TGA and a reintervention rate of nearly 50% [180]. Data in patients with a Senning atrial switch in ccTGA have shown an 11% re-intervention rate for baffle complications. Most baffle complications can now be effectively managed with transcatheter techniques, thus minimizing the need for re-operations [181].

Approximately 25% of patients require some form of reintervention after anatomic repair. Aortic valvular and pulmonary artery interventions were the commonest reinterventions in the double switch group [175]. In the SR group, conduit modifications were the most often required predominantly due to stenosis, calcification, or the need for conduit augmentation [182].

  - Senning and Rastelli
- Systemic LV and RV
  - Fontan operation

Anesthetic considerations and perioperative management

Preoperative assessment

The main perioperative risks in patients with ccTGA are tricuspid valve regurgitation, RV dysfunction, congestive cardiac failure, and rhythm abnormalities, including heart block. The pre-anesthetic visit should focus on identifying and risk-stratifying the presence of these, by carefully assessing the patient in terms of history, examination, review of the clinical notes, laboratory results and review of echocardiography, cardiac MRI, and cardiac catheterization. A detailed understanding of what the cardiac defects are, the presence and degree of LVOTO, and the presence of pulmonary vascular occlusive disease and its response to pulmonary vasodilators is vital. History and examination should focus on elucidating symptoms and signs of CHF, systemic valve regurgitation and the presence of cyanosis. Prior procedures such as pacemaker insertion or PAB placement should be noted. Review of the ECG for rhythm and conduction assessment and echocardiography will establish ventricular mass and function as well as systemic AV valve competency. Ventricular mass of the morphological LV is particularly important mainly to check that the LV mass is adequate to become the systemic ventricle. Occasionally a PAB is placed for that purpose and its outcome has to be reviewed.

Induction and maintenance of anesthesia follow the principles highlighted in the section on pathophysiology of ccTGA above. These children may be compromised with little cardiac reserve, so induction has to be tailored to the specific child and the situation. Invasive intraoperative monitoring (arterial line, central venous pressure, and TEE) is necessary, as well as preparation for anesthesia on CPB, as reviewed earlier. Occasionally, preinduction invasive arterial monitoring is indicated, and ability to institute CPB emergently should be available. In the presence of systemic AV valve regurgitation and systemic RV dysfunction, the aim should be to decrease RV pressure load. Care should be taken to control arterial blood pressure and prevent sudden increases in response to intubation or surgical stimulation. At the end of the procedure, TEE should be used to detect residual defects, assess biventricular and valvular function, and evaluate neo-aortic valve regurgitation.

Postoperative course and complications

These children are not candidates for early extubation and will be admitted to intensive care postoperatively for stabilization; therefore, all the invasive monitoring should remain in situ and sedation established. Intracardiac lines measuring right and left atrial pressures are useful in evaluating RV and LV function for management and inotrope titration. In a small proportion of patients in whom the LV fails to function as the systemic ventricle, ECMO, or ventricular assist device might be required as a bridge to recovery.

Introduction

In the early 1970s, Fontan and Baudet [1] and Kreutzer et al. [2] independently described the operative treatment of tricuspid atresia (TA) that resulted in nearly normal systemic arterial oxygen saturation and normal volume work for the single functional systemic ventricle. This procedure subsequently referred to as the Fontan operation, created a series circulation that requires the single ventricle (SV) to pump fully saturated blood only to the systemic circulation, thereby reducing the pressure and volume work to that of a normal systemic ventricle. Systemic venous drainage passes directly through the pulmonary vascular bed without the benefit of a pumping chamber, and pulmonary vascular resistance (PVR) must be low to maintain the pulmonary circulation and the cardiac output (CO) on which it depends. The principle of the Fontan operation has subsequently been applied to the full spectrum of cardiac lesions with one functional ventricle. Suitable physiology for ultimate palliation with a modification of the Fontan procedure is predicated on appropriately timed and executed staged operations designed for the specific patient's SV physiology. Essentially, all patients with a single functional ventricle now undergo staged palliation, resulting in the completion of the Fontan circuit at 18 months to 4 years of age. The majority undergoes a neonatal palliative procedure, followed by a superior cavopulmonary connection (bidirectional Glenn or hemi-Fontan procedure) at 3–6 months of age in all patients. This chapter will initially present these principles by using hypoplastic left heart syndrome (HLHS) as the most common SV congenital cardiac lesion. Tricuspid atresia and other forms of SV lesions will then be discussed. Finally, the growing recognition of the implications and sequelae of the long-term Fontan circulation, along with management strategies, will be described.

Hypoplastic left heart syndrome

Incidence, anatomy, and natural history

Hypoplastic left heart syndrome (HLHS) represents the fourth most common defect presenting in the neonatal period and accounts for 7.5% of newborns with congenital heart disease (CHD) requiring early therapeutic intervention. Although the incidence of HLHS is 1.4–3.8% of all CHD, it results in 23% of deaths from CHD within the first week of life and 15% within the first month [3]. HLHS has a high heritability component, inherited as a complex trait causing a severe form of valve malformation. Thus, it is important to screen first-degree relatives of HLHS patients [4]. Recent genome sequencing has demonstrated a link between gene defects causing HLHS and those causing cardiomyopathies. Clinically, certain variants associated with these genes could increase the risk of developing myocardial dysfunction in HLHS patients [5].

HLHS is characterized by a single right ventricle (RV) and varying degrees of hypoplasia of the left side of the heart. Most commonly HLHS involves either severe aortic stenosis (AS) or aortic atresia (AA), severe mitral stenosis (MS) or mitral atresia (MA), and a very hypoplastic or rudimentary left ventricle (LV) (Figure 30.1) [6, 7]. Blood returns normally from the pulmonary veins to the left atrium (LA), but obstruction at the mitral and aortic levels means that the majority of flow must be left-to-right across the atrial septum. This causes enlargement and dilation of the right atrium (RA) and RV, which must support the outputs of both the systemic and pulmonary circulations. Blood flows from the pulmonary artery (PA) right-to-left through the patent ductus arteriosus (PDA) to the aorta, thus supplying the systemic arterial circulation. Although there may be some antegrade flow through the aortic valve, perfusion of the brachiocephalic vessels, aortic root, and coronary arteries occurs mainly via retrograde flow from the PDA into the ascending aortic arch – a hallmark of HLHS. Some variations of left heart hypoplasia involving the LV, mitral valve (MV), and aortic valve (AV) may be amenable to two-ventricle surgical repairs and are presented in detail in Chapter 27.

Without intervention, HLHS is uniformly fatal in the first several months of life. As the PDA narrows and closes, diminished blood flow to the systemic circulation and coronary arteries results in a state of circulatory shock resulting in poor perfusion, lactic acidosis, and respiratory failure.

Pathophysiology of HLHS

A parallel circulation exists in HLHS. Both pulmonary and systemic venous blood mix in the RA, and the RV, via the PA, then supplies both the pulmonary circulation (through the branch PAs) and the systemic circulation (through the PDA). Prostaglandin E_1 infusion must be initiated after birth to maintain patency of the ductus arteriosus. Maintenance of a delicate balance between pulmonary (Qp) and systemic (Qs) blood flow is necessary, with the Qp: Qs optimally kept near 1: 1 to maintain adequate perfusion of lungs and body. As pulmonary vascular resistance (PVR) decreases after birth, Qp: Qs increases and may reach 2: 1 or 3: 1. The resultant pulmonary overcirculation at the expense of the systemic circulation generally results in pulmonary interstitial and alveolar edema, tachypnea, and retractions, potentially culminating in respiratory failure. Increases in FiO_2 or hyperventilation will further lower PVR and should be avoided. Even more critical is the "steal" effect, in which blood flow is diverted away from the systemic circulation, compromising flow to both the body and the coronary arteries. Cardiogenic shock can ensue, with poor perfusion and increasing lactic acidosis. Steal of flow from the systemic circulation may also result in mesenteric ischemia and necrotizing enterocolitis. Maneuvers to increase PVR are important treatment strategies if steal is suspected. These strategies can include maintaining FiO_2 at 0.21 and allowing $PaCO_2$ to rise via

AL Grawany

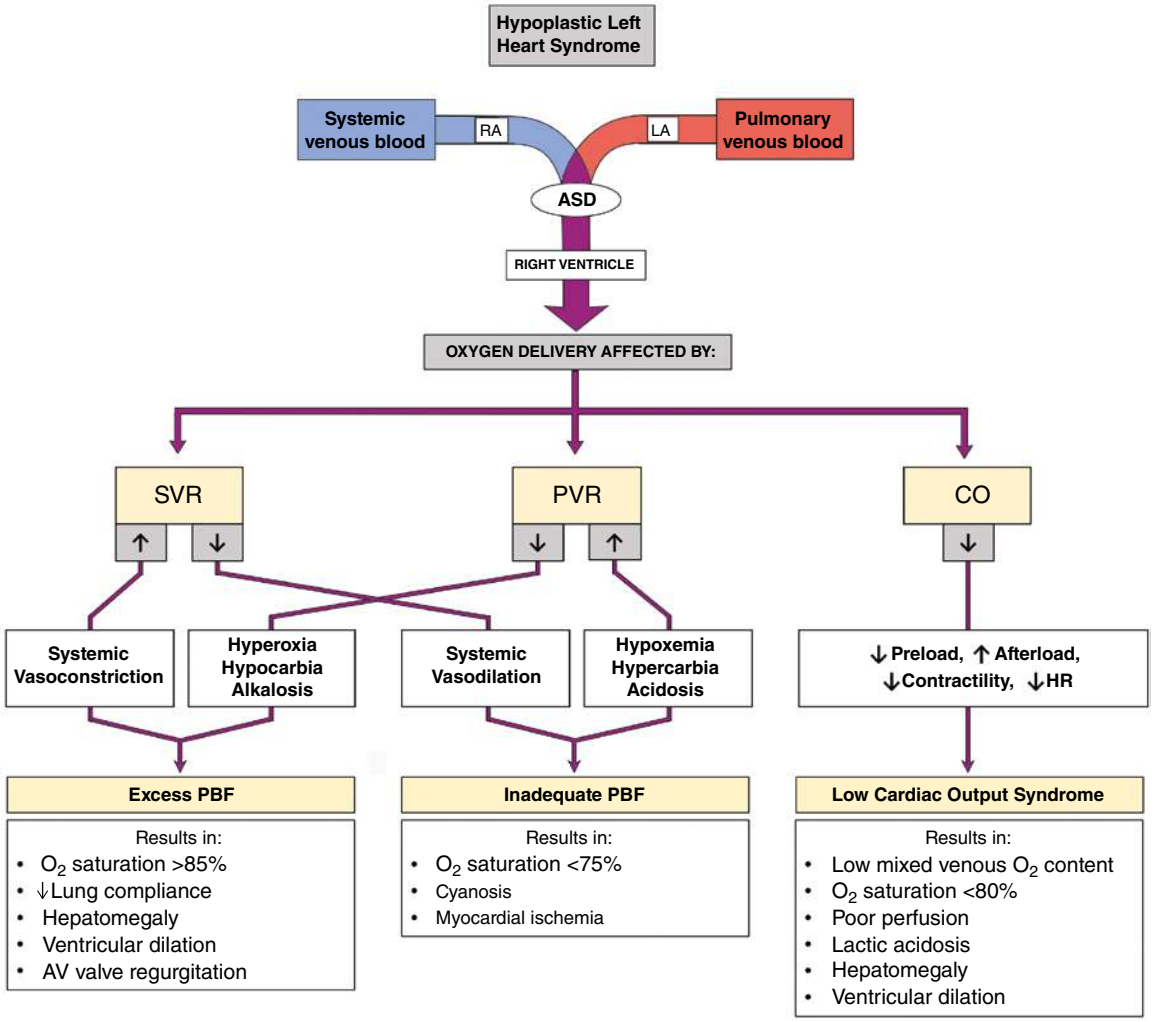

Figure 30.2 Pathophysiology of the functional single systemic ventricle. Optimal oxygen delivery involves maintaining adequate cardiac output while balancing SVR and PVR. spontaneous respiration or by decreasing minute ventilation for mechanically ventilated patients. The former practice of delivering sub-ambient FiO_2 via mechanical ventilation can reduce both systemic and cerebral oxygenation significantly but has been abandoned in favor of maintaining spontaneous respirations preoperatively and early surgical intervention [8]. Should the PDA narrow, Qp: Qs increases and systemic perfusion becomes compromised, leading to a cardiogenic shock.

Anatomic variables can have a major impact on the observed physiology. If the ASD is restrictive or limited to a patent foramen ovale (PFO), resistance to pulmonary venous return may balance pulmonary and systemic resistances, positively impacting Qp: Qs. Infants who lack that restriction, such as those with a large atrial septal defect (ASD) or unrestrictive anomalous pulmonary venous return, tend to exhibit high Qp: Qs. However, infants presenting with an intact atrial septum and no alternative decompressing vein have severely obstructed pulmonary venous return, leading to left atrial hypertension and an extremely low Qp: Qs. These infants exhibit marked hypoxemia and require intervention to enlarge the atrial communication and decompress pulmonary venous return in order to have any chance of survival. This may be accomplished either via *in utero* atrial septostomy or immediately after planned delivery in an adjacent operating room (OR) via an *ex utero* intrapartum treatment (EXIT) procedure [9, 10]. Several other factors, including atrioventricular valve regurgitation (AVVR) and hemoglobin level, can also affect the pathophysiology of HLHS. An overview of SV pathophysiology is presented in Figure 30.2.

In the current era, the majority of HLHS cases are diagnosed *in utero* after an abnormal screening ultrasound at 18–22 weeks' gestation is confirmed by a detailed cardiac examination. Fetal echocardiography can also reveal additional features including limitation of flow across the atrial septum and abnormal pulmonary venous return flow patterns which, if present, can greatly impact risk and survival [10]. In the Single Ventricle Reconstruction Trial (SVRT), a multicenter study of over 500 HLHS patients sponsored in the US and Canada by the Pediatric Heart Network of the US National Heart, Lung, and Blood Institute, 76% of HLHS

patients were diagnosed *in utero* [11]. As noted, fetal catheter interventions may be attempted for some HLHS patients, either to dilate and stent a restrictive atrial septum or to dilate the aortic valve. An analysis from the International Fetal Cardiac Intervention Registry that examined fetuses with HLHS from 13 institutions between 2001 and 2015 demonstrated a 77% success rate with atrial septoplasty and atrial stent placement procedures. However, complications, including 13% fetal demise, were common [9]. Fetal interventions are discussed in detail in Chapter 19.

Although prenatal diagnosis alone has not been demonstrated to improve HLHS survival, late postnatal diagnosis and distance from a cardiac surgical center negatively impact survival, with most mortality occurring before surgical intervention [12]. Therefore, prenatal diagnosis and planned delivery in or near a cardiac surgery center may improve survival. Late diagnosis occurs when the PDA narrows and the infant demonstrates clinical signs of low CO and shock, prompting echocardiographic assessment. Emergent resuscitation of the infant, including immediate initiation of a PGE_1 infusion, is essential for survival. The magnitude and the type of acquired vital organ dysfunction usually correlate with the degree of circulatory instability at the time of diagnosis. Infants who have suffered a profound or protracted shock state can demonstrate a wide spectrum of injury to renal, central nervous system, cardiac, gastrointestinal, or hepatic systems [13–15]. These derangements may necessitate a delay in operative intervention to permit recovery. Because 15–30% of HLHS neonates also have extracardiac anomalies or genetic syndromes such as the CHARGE association or chromosomal abnormalities, a thorough evaluation for these problems should also be performed [3].

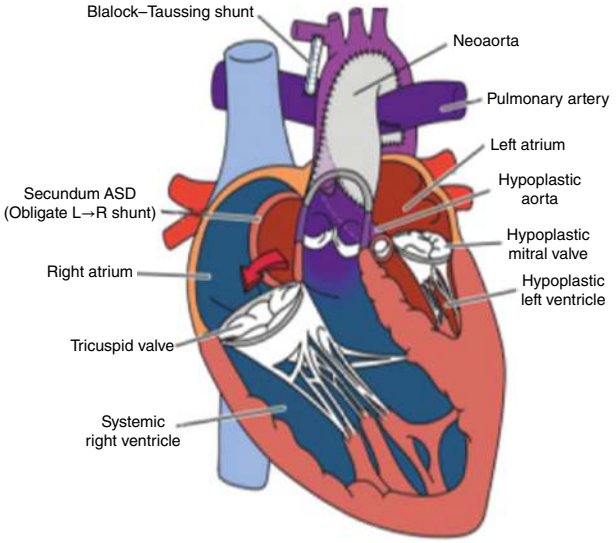

Figure 30.3 Norwood Stage I palliation for hypoplastic left heart syndrome. See text for details. (Source: Berenstain & Spaeth [18]. Reproduced with permission of Cambridge University Press.)

Surgical and transcatheter approaches and outcomes

Stage I palliation

In 1979, Norwood et al. reported a neonatal palliative operation for HLHS that stabilized native HLHS physiology and eliminated ductal dependence. He later described a Fontan palliation as the second stage operation, resulting in the first long-term survivors of HLHS [16]. The Norwood stage I palliation involves reconstruction of the diminutive ascending aorta, usually with a cryopreserved homograft patch, along with the creation of outflow from the systemic RV through the pulmonary valve, which also provides blood flow to the native aortic root and coronary arteries. The pulmonary valve becomes the "neo-aortic valve" (Figure 30.3) [17, 18]. The main PA is transected, and the proximal portion of the PA is incorporated into the aortic repair while the underside of the PA bifurcation is oversewn. In addition, an atrial septectomy is performed to provide unrestricted left-to-right blood flow across the atrial septum. Pulmonary blood flow is then delivered via a polytetrafluoroethylene (PTFE) shunt, either via the creation of a systemic-to-pulmonary shunt from the right innominate or subclavian artery to right PA (also termed modified Blalock–Thomas-Taussig shunt [mBTTS]) or by the creation of an RV–PA shunt (also termed the Sano shunt). It is crucial that the area of the anastomosis between the pulmonary valve and the aortic valve is free of obstruction, as it can affect the already tenuous coronary blood flow. The complete removal of any residual ductal tissue to prevent later coarctation of the aorta is also critical. During aortic arch reconstruction, cardiopulmonary bypass (CPB) techniques must provide a bloodless surgical field. Deep hypothermic circulatory arrest (DHCA) or antegrade regional cerebral perfusion (ACP) may be utilized for this purpose. Preference for a particular approach is largely surgeon and institution dependent. Details of each technique along with short- and long-term outcomes are discussed in Chapter 11.

Systemic-to-pulmonary and RV-to-pulmonary shunts

The systemic-to-pulmonary artery shunt is a 3.0- to 4.0 mm polytetrafluoroethylene (PTFE) graft that provides continuous flow into the PA. Originally described as a modified "Blalock-Taussig" shunt after surgeon Alfred Blalock and cardiologist Helen Taussig, more recently, it has become identified as a modified "Blalock-Thomas-Taussig shunt" to recognize the primary contribution of Vivien Thomas, a surgical technologist, to its successful development and implementation [19, 20]. Shunt flow is inversely proportional to the length of the shunt and the fourth power of its radius. It is directly proportional to the pressure drop across the shunt and therefore influenced by the ratio of PVR and systemic vascular resistance (SVR). Kinking or distortion of either the shunt or PA can occur and interfere with the flow. Because there is continuous "run-off" of flow from the systemic circulation into the PA, these patients remain at risk for steal from the systemic circulation as PVR decreases. This is proposed as the major pathophysiological etiology for the frequent instability observed in the early postoperative period in these patients. In 2003, Sano et al. reported improvement in stage I survival in a small number of patients at one institution when pulmonary blood flow (PBF) was provided by a

AL Grawany

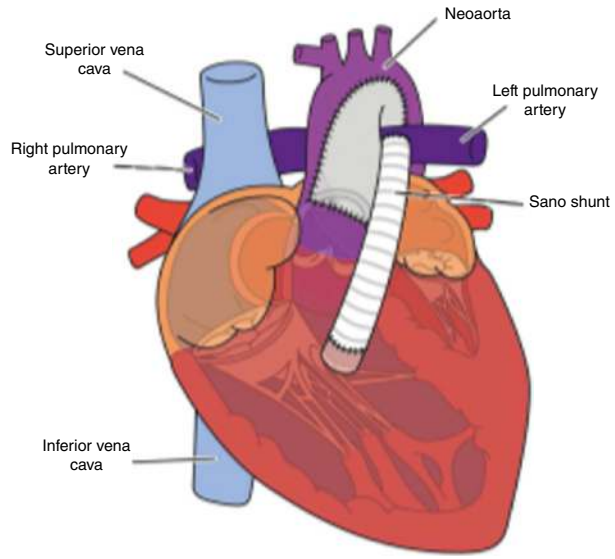

Figure 30.4 Norwood Stage I palliation for hypoplastic left heart syndrome with right ventricle to pulmonary artery shunt (Sano shunt). See text for details. (Source: Berenstain & Spaeth [18]. Reproduced with permission of Cambridge University Press.)

5–6 mm PTFE graft from the RV to the PA, rather than via an mBTTS (Figure 30.4) [18, 21]. Because the RV–PA shunt arises proximal to the neo-aortic valve, there is no flow from the aorta into the PAs during diastole, limiting diastolic run-off and coronary ischemia. The resultant higher diastolic blood pressure has been hypothesized as the physiologic reason for improved survival.

The SVRT was designed to test the hypothesis that stage I survival would improve with the utilization of the RV–PA shunt, with an endpoint of death or transplantation in the first 12 months [7]. In all, 555 infants were randomized to receive either an mBTTS or RV–PA shunt. Approximately 10% of subjects required cross-over from their randomly assigned shunt type to the other shunt type because of anatomic considerations. At 12 months, 36.4% of the mBTTS subjects had died or been transplanted, compared with 26.3% for the RV–PA shunt ($P = 0.010$). However, overall complication rates in the RV–PA shunt group were higher (72 vs. 46 per 100 infants, $P = 0.03$), and the number of infants experiencing one or more complications was also greater with the RV–PA shunt (39 vs. 28%, $P = 0.03$). After 12 months, the hazard ratio for death or transplantation did not differ between the two types of shunts. Follow-up after 6 years demonstrated slightly higher transplant-free survival (5%) but an increased need for catheter re-interventions in the RV-PA shunt patient group; however, there were no statistically significant differences in the hazard ratio for death or transplantation as well as catheter re-interventions [22]. A recent meta-analysis of 32 studies by Cao et al. assessed long-term survival in HLHS with either mBTTS ($n = 1348$) or RV-PA shunt ($n = 1258$). Although the RV-PA shunt group had significantly higher in-hospital survival and inter-stage survival between stage I and II palliation until 2 years post-stage I palliation, no significant differences in long-term outcomes between stage II and stage III palliation were identified [23]. In contemporary practice, the shunt type used depends largely on the surgeon and institutional preference.

In a publication specifically examining the rate and causes of 30-day in-hospital mortality in SVRT subjects, 16% of patients died during the initial hospitalization, with 12% mortality in the first 30 days after Norwood stage I palliation. Although after multivariable analysis shunt type was not identified as a significant risk factor for mortality, the presence of an mBTTS was an independent risk factor for cardiopulmonary resuscitation (CPR). Independent risk factors for both 30-day and total in-hospital mortality included low birth weight, genetic abnormality, post-procedure need for extracorporeal membrane oxygenation (ECMO), and open sternum. Longer duration of DHCA was an independent risk factor for hospital mortality. Independent risk factors for major morbidity (renal failure, sepsis, increased duration of ventilation, and hospital stay) included genetic abnormality, lower center/surgeon volume, open sternum, and additional post-Norwood operations [24].

Inter-stage mortality occurring after the initial hospitalization for stage I palliation and during the 3–6 months prior to Stage II superior cavopulmonary connection (SCPC) has been a persistent issue. The physiology of the HLHS patients remains tenuous after the initial palliation, as a parallel circulation with all systemic and pulmonary output passing through the single systemic ventricle still persists. The Qp: Qs remains labile, and thus, coronary ischemia continues to be a risk. Significant hemodynamic perturbations may easily result from dehydration due to viral gastroenteritis, upper respiratory infections, or micro-aspiration episodes caused by a recurrent laryngeal nerve injury that frequently accompanies stage I palliation. In the SVRT, of 426 subjects discharged from the hospital, 50 died inter-stage (12%) [25]. The inter-stage death rate was greater for mBTTS patients (18%) than for RV–PA shunt patients (6%, $P < 0.001$). Risk factors for inter-stage death included gestational age <37 weeks, Hispanic ethnicity, AA/MA, a greater number of post-Norwood complications, census block poverty level, and moderate to severe AVVR. Ahmed et al. recently developed a validated risk scoring system to predict mortality or transplant in single-ventricle patients during the inter-stage period between stage I and II palliation. Between 2008 and 2015, data from over 2,000 patients from the National Pediatric Cardiology Quality Improvement Collaborative Registry were analyzed to create a weighted scoring system. This novel system, known as the NEONATE score, assessed the following independent risk factors: Norwood type (mBTTS or hybrid vs. Sano shunt), postoperative ECMO, opioids required at discharge, no digoxin required at discharge, arch obstruction, ≥ moderate Tricuspid regurgitation, and extra oxygen plus ≥ moderate tricuspid regurgitation at discharge. During the inter-stage period, the strongest predictor of death or transplant was ≥ moderate tricuspid regurgitation, which worsened if oxygen was required [26]. With a combined 28% mortality observed in the SVRT in the inter-stage period between stages I and II, the challenges of caring for this group of patients are evident. Death after stage II SCPC in the first year of life is less common; the stabilizing effect on the pathophysiology of HLHS (see later) is the most significant factor.

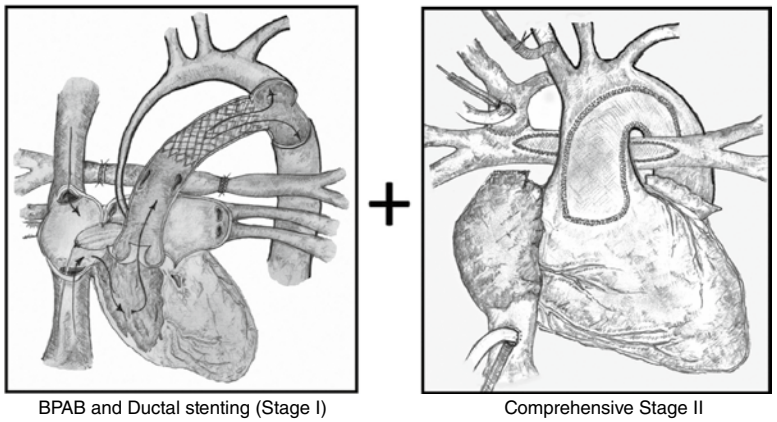

Figure 30.5 Giessen hybrid procedure for HLHS: stage I and stage II. Giessen hybrid procedure consists of bilateral pulmonary artery banding with ductal stenting in the neonatal period and comprehensive stage II procedure in the infancy period. The arrows show the direction of the bloodstream. BPAB, bilateral pulmonary artery banding. (Source: Yörüker & Akintürk [33]. Reproduced with permission of Elsevier.)

Hybrid procedure

Despite continuing improvements in the perioperative management of infants with HLHS, specific populations of patients remain at higher risk and demonstrate a more significant level of morbidity and mortality during and after surgical stage I palliation [27]. Risk factors include birth weight <2.5 kg, prematurity, ascending aortic size <2 mm, MS/AA anatomy, poor RV function, severe tricuspid regurgitation, restrictive atrial septum, obstructed pulmonary venous return, and the presence of additional cardiac or non-cardiac anomalies [28–32]. Continuing advancements in interventional cardiology techniques have facilitated the development of alternative therapeutic strategies for these subpopulations of patients. Due to the utilization of both surgical and interventional catheterization procedures, these interventions are known as "hybrid" procedures. A hybrid procedure is performed in the catheterization laboratory, OR, or "hybrid" procedure suite. It consists of median sternotomy without CPB, surgical placement of bilateral PA bands, and placement of a stent in the PDA by interventional cardiology via access obtained in the main PA (see Figure 30.5) [33–35]. The atrial septum can also be stented if restrictive. Advantages of hybrid procedures include avoiding CPB and/or DHCA in the neonatal period and providing an extended waiting period for infants who require cardiac transplantation or who may be eligible for biventricular repair. The hybrid procedure may also be utilized to delay a planned Norwood operation or as a salvage procedure for patients unsuitable for early Norwood operation [35]. The hybrid procedure is further detailed in Chapter 34. Modifications to the hybrid procedure continue to occur as newer devices become available. One such example is the internal self-expanding flow restrictor, which can be utilized in place of external, surgically placed PA bands, allowing all components of the hybrid procedure to be accomplished in the catheterization laboratory [36].

As with surgically palliated patients, inter-stage mortality continues to be an issue after the hybrid procedure. Close echocardiographic monitoring for tricuspid valve regurgitation and/or RV dysfunction has been advocated, as these can indicate obstruction at the atrial level or through the PDA stent. Re-interventions in the catheterization laboratory are not infrequently required to relieve such obstructions [37]. The most concerning and potentially life-threatening complication involves the development of reverse or pre-ductal coarctation, resulting in diminished coronary and cerebral perfusion. This can occur either secondary to uncovered ductal tissue that remains capable of closure or as a result of ductal stent placement. Once recognized, additional retrograde stent placement is utilized to address proximal aortic arch obstruction [38].

At the age of 3–6 months, aortic reconstruction, along with removal of the PA bands, ductal and atrial stents, repair of the PAs (if necessary), atrial septectomy, and SCPC, is performed. This is known as a "comprehensive stage II procedure" (See Figure 30.5). Patients subsequently progress to Fontan completion via a surgical approach or placement of a covered stent via catheter intervention [33, 39].

While previous small studies demonstrated no significant difference in survival statistics between the hybrid and traditional Norwood stage I palliation [40–43], a 2018 meta-analysis of 14 studies comparing outcomes found that the hybrid group had significantly higher early mortality, reduced 6-month and 1-year transplant-free survival rates, and an increased number of required re-interventions [44]. However, some institutions preferentially perform hybrid procedures with outcomes comparable to those seen with the Norwood procedure [33, 44, 45]. According to the Society of Thoracic Surgeons Congenital Heart Surgery Database, 13 out of 100 institutions performed >50% of stage I palliations as a hybrid rather than Norwood procedure between 2010 and 2012 [46]. With continuing experience and technical modifications, the hybrid procedure may offer the potential for increased survival opportunity with early avoidance of CPB for certain groups including high-risk patients, those awaiting cardiac transplantation, and those with the potential for future biventricular repair [47].

Biventricular repair in borderline HLHS

Given the broad spectrum of pathology observed in HLHS, with LV size ranging from rudimentary to mildly hypoplastic, the best surgical strategy may not always be clear. Patients

AL Grawany

with "borderline HLHS," also known as "hypoplastic left heart complex," or a "borderline LV" often pose particular management challenges, as either single-ventricle palliation or a biventricular repair may be considered [48, 49]. In recent years, strategies to aid in determining which patients may be suitable for biventricular repair have been developed using echocardiographic and cardiac MRI parameters. While the use of these parameters may differ between institutions, mitral and aortic valve Z-scores (Z-score is standard deviation; e.g., a -2 Z score for a valve diameter is 2 standard deviations below normal for weight or body surface area) of between -5 and -2 (excluding atretic valves) are typical. Other critical factors include LV end-diastolic pressure, LV end-diastolic volume index, LV length and volume, and the degree of endocardial fibroelastosis (EFE) [50]. A group of 24 Congenital Heart Surgeons Society institutions studied 320 neonates who underwent either Norwood palliation or biventricular repair, leading to the development of hazard models based on various morphologic and functional characteristics [51].

Due to the high risk associated with the primary neonatal biventricular repair, many institutions choose a period of LV recruitment or staged LV rehabilitation, with initial SV palliation. This relieves obstructions and promotes PBF. Other techniques to stimulate LV growth, such as resection of endocardial fibroelastosis (EFE), mitral and/or aortic valvuloplasty, and ASD restriction, are also performed. Additionally, increasing PBF (via an mBTTS plus SCPC versus an RV-PA shunt) after ventricular septation volume loads the LV and stimulates growth. If these techniques successfully promote adequate LV growth, subsequent takedown of the SV palliation with conversion to a biventricular repair can occur [50, 52].

The success of biventricular conversion or repair is dependent on many factors, including appropriate patient selection and clinical and technical experience. Further evidence comparing long-term outcomes between biventricular conversion versus progression with single-ventricle physiology to Fontan completion is still being gathered [53].

Anesthetic considerations

Preoperative considerations

The diagnosis of HLHS is most frequently made *in utero*. After an initial assessment, immediate treatment in the delivery room for HLHS patients includes initiation of a PGE_1 infusion, placement of umbilical arterial and venous catheters, maintenance of spontaneous ventilation on room air, and transfer to a neonatal or cardiac intensive care unit (ICU). A postnatal transthoracic echocardiogram is performed to confirm the initial diagnosis and provide other crucial anatomic information, including LV size, presence of AVVR, degree of atrial septal restriction, or the presence of anomalous pulmonary venous return. Other less common but important details such as the presence of coronary artery fistulae or sinusoids to the LV should also be assessed. Patients with a restrictive atrial septum may require urgent or emergent intervention, requiring either balloon atrial septostomy or early surgical intervention. Cardiac catheterization is rarely performed for diagnostic purposes, and additional imaging (i.e., computed tomography [CT] or magnetic resonance imaging [MRI]) is seldom required unless anatomic questions remain. Certain anatomic and physiologic features have been identified as risk factors that may affect outcomes (see Table 30.1).

Table 30.1 Preoperative risk factors prior to stage-1 palliation

Mitral stenosis/aortic atresia
Hypoplastic ascending aorta (<2 mm)
Restrictive atrial septum
Obstructed pulmonary venous return
Greater than moderate tricuspid valve regurgitation
Pulmonary valve regurgitation
Age >14 days
Pre-maturity
Low birth weight (<2.5 kg)
Non-cardiac congenital abnormalities
Metabolic acidosis
Chromosomal abnormalities
Inotropic support
Right ventricular dysfunction

The chest radiograph is followed daily to assess the heart size and status of the pulmonary vasculature. Common preoperative laboratory tests include complete blood count, coagulation studies, and blood type and cross-match, along with the measurement of serum electrolytes, blood urea nitrogen, creatinine, and glucose. In a recent evaluation of standard preoperative laboratory testing for pediatric cardiac surgery patients in the US and Canada by the Congenital Cardiac Anesthesia Society Hemostasis Interest Group, 11 of 12 centers surveyed reported routinely obtaining preoperative testing. However, 83% agreed that only a type and screen and complete blood count were necessary. No centers reported changes in management due to preoperative testing, suggesting that preoperative testing requirements are controversial and subject to institutional preferences [54].

Ideally neonatal HLHS patients "self-regulate" their Qp:Qs prior to stage I palliation, spontaneously breathing with a slightly elevated $PaCO_2$. Diuretics are often used preoperatively to limit blood volume recirculating through the lungs. Nasal continuous positive airway pressure (CPAP) may be helpful to provide positive pressure to relieve respiratory distress and elevate the PVR while maintaining spontaneous respiration. Tracheal intubation and mechanical ventilation are reserved for the most severe cases of respiratory insufficiency or for patients with anatomic variants (e.g., restrictive intra-atrial communication) that markedly diminish PBF. Early surgical intervention before severe derangements in Qp:Qs ensue is essential to prevent complications.

Intraoperative considerations

Neonates presenting for stage I reconstruction (i.e., Norwood procedure with mBTTS or Sano shunt) receive an intravenous (IV) induction of anesthesia with meticulous attention to the hemodynamic consequences of the anesthetic agents selected. Phenylpiperidine-based synthetic opioids, such as fentanyl, are generally preferred because they blunt the

endogenous catecholamine response to noxious stimuli at doses that are usually tolerated hemodynamically [55–57]. However, even with these hemodynamically "neutral" agents, larger doses may result in significant cardiovascular changes, such as bradycardia and hypotension. These observations suggest that some endogenous catecholamine release is required in an infant with HLHS to sustain satisfactory hemodynamics. Unfortunately, the threshold narcotic dose that is "sufficient" and not "excessive" varies between patients, necessitating careful titration.

Although clinical research conducted in the early 1990s popularized the view that very high doses of opioid analgesics should be administered perioperatively for stress hormone suppression in neonates undergoing cardiac surgery [58], efforts to duplicate these findings have not confirmed the original results [59]. The latter demonstrated that very high doses of fentanyl did not completely suppress the release of endogenous catecholamines, even in combination with benzodiazepine infusions. Additionally, outcome measures were no different in any of the study groups. Emerging evidence has demonstrated potential benefits of the use of dexmedetomidine in pediatric cardiac surgery, including neuroprotection as well as improved morbidity and mortality [60]. According to data from the Congenital Cardiac Anesthesia Society and Society of Thoracic Surgeons Cardiac Anesthesia Database Collaboration, dexmedetomidine use has steadily increased since 2010 [61]. Strategies vary significantly between institutions, with total intraoperative fentanyl doses ranging between 10–100 μg/kg, and the addition of low-dose volatile anesthetics, benzodiazepines, ketamine, and dexmedetomidine in various combinations described as components of a balanced anesthetic approach to initial palliations for HLHS [62]. Most institutions now utilize fentanyl dosages in the lower range, generally <25 μg/kg.

Management of the airway and ventilation assumes great importance during induction of anesthesia. Given the propensity for most neonates with HLHS to have excessive PBF, the anesthesiologist must take care not to employ ventilatory maneuvers that lower PVR, such as hyperventilation or utilization of high inspired concentrations of oxygen (FiO_2). In an infant with typical HLHS physiology, manual ventilation should be initiated with room air or a low concentration of supplemental oxygen. The extent to which FiO_2 is increased before laryngoscopy should depend upon the magnitude of hemodynamic response to the initiation of controlled ventilation. Infants who demonstrate a significant reduction in systemic arterial pressure despite low FiO_2 may not tolerate prolonged exposure to a higher FiO_2 without deleterious hemodynamic consequences.

Intraoperative monitoring consists of standard cardiovascular, respiratory, and temperature monitors and continuous direct arterial pressure monitoring. An umbilical arterial line, if present, may be used to preserve other arterial access sites for future interventions. Most centers utilize central venous access as well. An umbilical venous catheter positioned in the orifice of the superior vena cava (SVC) at the time of surgery serves as a valuable monitor of mixed venous oxygen saturation, enabling more precise assessment of systemic CO and Qp: Qs [6, 63, 64]. Some institutions may place direct transthoracic atrial lines instead of percutaneous jugular or subclavian central venous pressure catheters due to concern regarding thrombosis in the central thoracic veins in SV patients. However, other institutions have failed to demonstrate the significant risk associated with the use of upper body central venous catheters even in SV patients [65]. Peripherally inserted central catheters (PICCs) are increasingly utilized as well. In a 2020 retrospective review of PICC use in pre-stage II SV patients, only 2 out of 56 patients with PICCs developed detectable thrombus (4%) versus 3 out of 17 patients with central venous catheters (18%) [66]. Most centers utilize cerebral and somatic near-infrared spectroscopy (NIRS) as additional non-invasive monitors which correlate with SvO_2. Cerebral NIRS can be used to guide ACP as it has been shown to detect alterations in CBF in neonates undergoing Norwood stage I palliation [67, 68]. The use of cerebral and somatic NIRS in the immediate postoperative period has also been shown to predict early mortality and to highlight the need for ECMO in HLHS patients [69]. Transesophageal echocardiography (TEE) is often utilized depending on the size of the neonate and institutional preference. Epicardial echocardiography after CPB can also be utilized and is particularly useful to assess AVVR and neo-aortic regurgitation.

Measures to clear airway secretions and assure complete re-expansion of the pulmonary parenchyma are performed in the terminal phases of rewarming on bypass. The magnitude of reduction in the mean systemic arterial pressure that occurs with the opening of the shunt during the terminal phase of CPB can provide qualitative insights into what PVR might be expected in the early post-CPB period. Initial ventilatory support should be adjusted accordingly. It is best to begin with a FiO_2 between 0.6 and 1 and a pattern of ventilation designed to result in low-normal $PaCO_2$, recognizing that further adjustments will be indicated by the individual infant's physiology. Assuming a technically satisfactory repair without unusual risk factors, PVR typically falls within the first few hours after surgery. Until then, some patients may potentially require high levels of supplemental oxygen in the immediate post-CPB period.

While the physiologic goals post-CPB remain identical to those of the preoperative period, the variables affecting the achievement of these goals differ. The pulmonary circulation now resides either at the distal end of a restrictive prosthetic systemic-to-pulmonary shunt or an RV–PA shunt. A variety of subtleties, including technical execution of the shunt, relief of atrial obstruction, and the pre-existing condition of the pulmonary circulation, can render the ultimate physiology unpredictable. When a Sano shunt has been performed, technical issues of graft insertion, proper graft size (particularly in the neonate <2.0 kg), and the ability to delineate the etiology of insufficient PBF at the termination of CPB can introduce additional complexities.

Even with a perfect technical result, the Norwood operation does not reduce the volume or pressure burden on the SV. Supporting and maintaining the physiology of parallel systemic and pulmonary circulations with a Qp: Qs of 1.0 remain the objective throughout the post-CPB period. Postoperatively, the heart has incurred the cost of insults related to CPB, cessation of coronary perfusion, and DHCA, which may contribute to the cardiovascular frailty often exhibited in the early postoperative period. However, in the absence of major deficiencies in myocardial protection or

AL Grawany

persistent anatomic residua, such as significant aortic arch obstruction, coronary compromise, or valvular insufficiency, myocardial dysfunction can usually be addressed with relatively modest doses of inotropic agents and vasodilation. Low dose epinephrine (0.03–0.05 mcg/kg/min) and milrinone (0.25–0.5 mcg/kg/min) are commonly utilized after CPB. Vasopressin infusion may be added as well if necessary. While some clinicians advocate routine use of perioperative milrinone in Norwood procedures, others propose a targeted approach, citing the relatively weak inotropic and lusitropic effects of milrinone compared to its vasodilating properties. There is also conflicting evidence regarding the efficacy of perioperative milrinone in reducing mortality after the Norwood procedure [70–72]. In many neonates and young infants undergoing major cardiac interventions, myocardial performance may deteriorate in the first 6–12 hours postoperatively before it begins to improve. As a result, measures to reduce metabolic demands by providing continuous neuromuscular blockade and opioid infusions may be utilized in the immediate postoperative period. The sternum may be left open, covered by Silastic™ or other synthetic material, and stabilized with a plastic strut. This may improve hemodynamic stability as mediastinal edema is frequent in the first several postoperative days. The potentially deleterious effects of positive pressure ventilation are also mitigated. The open sternum also provides access for postoperative mediastinal exploration for bleeding, or the institution of ECMO. Sternal closure can be accomplished at the bedside 24–72 hours postoperatively.

A variety of ultrafiltration techniques, including conventional, modified, zero-balance, and combination ultrafiltration, may be utilized during and after CPB to improve postoperative hemodynamics. Several studies have demonstrated the beneficial effects of ultrafiltration upon hematocrit, hemodynamics, hemostasis, pulmonary function, and central nervous system recovery [73–78]. Perioperative weight gain is significantly reduced, as are the levels of specific inflammatory mediators. Occasionally, the position of the bypass cannulae or the continuous flux of blood through the modified ultrafiltration (MUF) circuit results in unfavorable hemodynamic changes precluding completion of the ultrafiltration. In 99 consecutive patients undergoing stage I palliation between September 2000 and August 2002, all tolerated the hemodynamic perturbations of MUF [79]. Clinical outcomes, however, have not consistently been improved and no single method of ultrafiltration has proven superior over others [73, 80]. Some institutions routinely place peritoneal dialysis (PD) catheters in the OR, and utilize PD in the early postoperative period for removal of excess interstitial fluid and potentially to remove inflammatory mediators.

Rapid restoration of normal hemostasis is an essential objective in the post-CPB period, particularly as the creation of the neo-aorta in Stage I reconstruction requires substantial arterial suture lines, and cyanotic heart disease is a predictor of postoperative blood loss [81]. Following the completion of MUF and confirmation of satisfactory technical and physiologic repair, heparin effect is reversed with protamine. Despite the theoretical advantages of fresh whole blood, studies have not demonstrated benefit from this strategy relative to the use of reconstituted whole blood [82]. Additionally, fresh whole blood is not available at most institutions. Gruenwald et al. demonstrated that a reconstituted fresh whole blood bypass prime, consisting of packed red blood cells (PRBCs), fresh frozen plasma, and platelets from the same donor, <7 days old, followed by a second such unit given after bypass, reduced bleeding in infants undergoing surgery compared with standard blood component therapy [83]. Should these measures fail to achieve adequate hemostasis despite the elimination of most surgical bleeding sites, laboratory testing (platelet count and function, fibrinogen level, and viscoelastic testing) should be conducted to direct component therapy.

Data specifically examining procoagulant medications in infants undergoing stage I reconstruction are sparse. Antifibrinolytic therapies have demonstrated efficacy in infants and children following heart surgery, but data in neonates continues to be very limited [84–87]. Although aprotinin, a serine protease inhibitor that acts as an antifibrinolytic agent with anti-inflammatory properties, demonstrated effectiveness comparable to other antifibrinolytics in infants and children [88]; this agent was voluntarily removed from the market when it was linked to greater 5-year mortality following coronary bypass grafting [89]. The lysine analogs epsilon aminocaproic acid and tranexamic acid appear to have comparable efficacy [84, 87], and extensive experience implying safety, making them appropriate substitutes for aprotinin [90].

Recombinant activated factor VII (rFVIIa) has been used as rescue therapy in infants and children following cardiac surgery, including neonates undergoing stage I reconstruction when conventional correction of postoperative coagulopathy with blood product transfusions fails to control hemorrhage [91, 92]. While rFVIIa can aid in controlling intractable bleeding, caution is warranted, as a recent retrospective review of 149 infants and children who received rFVIIa during cardiac surgery demonstrated an increased risk of thrombosis compared to control patients (20% vs. 8%) [93]. Another retrospective review of 414 neonates who underwent cardiac surgery found a 22% frequency of thrombosis in patients who received rFVIIa compared to a 6% incidence in patients who did not receive it. In neonates who underwent the Norwood procedure, those who received rFVIIa and developed thrombus had significantly higher mortality and incidence of requiring ECMO [94]. Recombinant factor VIIa may be capable of producing a hypercoagulable state that poses risks to certain surgical repair elements, including prosthetic shunts. Prothrombin complex concentrates (PCCs) may pose a similar thrombotic risk and should be used cautiously in patients undergoing stage I palliation. The 2019 patient blood management guidelines from the Network for the Advancement of Patient Blood Management, Haemostasis, and Thrombosis (NATA) for neonates and children undergoing cardiac surgery recommend against the use of PCCs in pediatric cardiac surgery except in clinical trials due to insufficient efficacy and safety data [95].

Point-of-care viscoelastic tests and transfusion algorithms are increasingly used in pediatric cardiac surgery [95–97]. Cyanotic patients, including those with HLHS, are known to have abnormal thromboelastography parameters compared to normal children, with these coagulation imbalances predisposing to both bleeding and thrombosis [96, 98]. The development of institution-specific, target-population transfusion

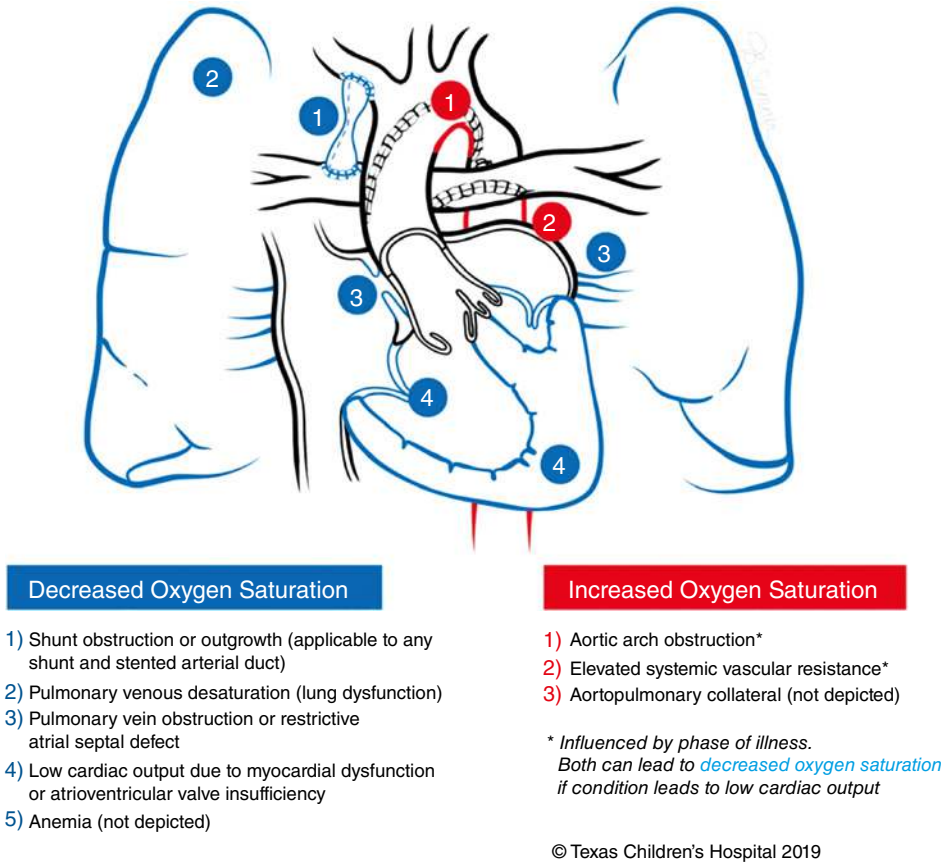

Figure 30.6 Pathophysiology associated with changes in oxygen saturation for shunt-dependent single ventricle heart defects. The figure illustrates differential diagnoses to consider when oxygen saturation thresholds are breached after Norwood palliation with a modified Blalock-Taussig shunt for hypoplastic left heart syndrome. Similar pathophysiologic considerations are applicable to the right ventricle to pulmonary artery shunt, hybrid palliation, and other shunt-dependent single ventricle variants. (Source: Rudd et al. [104]. Reproduced with permission from Texas Children's Hospital. © 2019 Texas Children's Hospital.)

algorithms may lead to reduced intraoperative transfusions and improved outcomes. However, additional data regarding patients undergoing stage I palliation is needed [96, 97, 99]. As PRBC transfusion has been associated with a longer duration of mechanical ventilation and ICU stay in stage I palliation patients [100], the Pediatric Critical Care Transfusion and Anemia Expertise Initiative released recommendations regarding red blood cell transfusion in patients with CHD. These recommendations state transfusions should be avoided "solely based upon hemoglobin, if hemoglobin is >9.0 g/dL in infants undergoing staged palliative procedures with stable hemodynamics" [101]. Further details of coagulation and bleeding management are discussed in Chapter 16.

Postoperative considerations

Excessive hypoxemia represents one of the more commonly encountered problems in the early post-CPB period. Although inadequate Qp:Qs is often the cause, factors that impair systemic oxygen delivery and reduce mixed venous oxygen saturation can also occur [63, 64, 102, 103]. A progressive increase in systemic oxygen saturation is often observed during MUF, likely due to the effect of hemoconcentration and the resulting increased oxygen delivery on mixed venous oxygen saturation. Post-CPB, measures directed at maintaining the hematocrit above 40–45% may alleviate excessive demands placed upon the recovering heart to increase systemic output. The distinction between systemic hypoxemia due to low Qp:Qs, low pulmonary venous oxygen saturation, or low mixed venous oxygen saturation (SvO_2) is crucial as the therapies for each differ. Measures designed to reduce PVR will impose a further volume load on a heart already struggling to provide marginal systemic perfusion. Patients demonstrating low SvO_2 are better served with therapies that promote systemic output, such as inotropic agents or vasodilators (see Figure 30.6) [104].

Similarly, infants with low pulmonary venous oxygen saturation require a strategy of ventilatory support designed to reduce atelectasis and promote gas exchange in impaired alveoli. Although pulmonary vein desaturation is not the most common cause of persistent systemic hypoxemia after stage I palliation, one series found pulmonary vein desaturation in as many as 30% of patients [105]. Unfortunately, this diagnosis is rarely made definitively in the OR or cardiac ICU due to the logistical challenges of blood sampling from the pulmonary veins. Intraoperatively, expectant measures

AL Grawany

directed at expansion of the lungs and maintenance of normal functional residual capacity (FRC) usually suffice to avoid pulmonary vein desaturation.

When systemic hypoxemia is suspected to be due to low Qp: Qs, other manifestations can provide supporting evidence. A trial opening of the systemic-to-pulmonary artery shunt during the latter phases of rewarming on CPB may have failed to demonstrate a significant drop in the mean systemic arterial pressure, and early post-CPB hemodynamics may have revealed a relatively narrow pulse pressure and/or high diastolic pressure. A substantial discrepancy may exist between arterial and end-tidal CO_2 measurements. These suggestive pieces of inferential evidence can be confirmed by aortic Doppler flow analysis or calculation of a Fick ratio using oxygen saturation determinations. Most commonly, diminished PBF may reflect a subtle technical aspect of the arch reconstruction, innominate artery dimension, or shunt placement. However, specific patient subsets can exhibit profound abnormalities in the pulmonary vasculature that result in excessive PVR elevations. Neonates born with HLHS and severe pulmonary venous obstruction due to intact atrial septum without alternative decompressing veins routinely demonstrate extremely high and volatile PVR. Even the typical HLHS anatomic constellation is associated with marked abnormalities in the number and muscularization of the pulmonary vasculature by pathologic examination. Hypotheses attribute these changes to chronic fetal pulmonary venous obstruction [106, 107]. One can speculate that these changes become more extreme in the context of the significant obstruction caused by HLHS with an intact atrial septum. Fetal echocardiography has confirmed alteration in pulmonary venous flow pattern in relation to the magnitude of restriction at the atrial septum [108].

In the context of hypoxemia due to low Qp:Qs, interventions fall into three categories: surgical modification, pulmonary vasodilation measures, and systemic vasoconstriction. In the subgroup of patients expected to have unusually elevated PVR, surgical modifications might entail placement of a larger shunt or placement of a central shunt (PTFE shunt from the aorta to the pulmonary artery). Potential pulmonary vasodilator therapies include the strategies one might employ in any patient demonstrating elevated PVR, such as supplemental oxygen, moderate hyperventilation, normothermia, alkali, and inhaled nitric oxide (iNO) [109–111]. Additionally, the use of higher doses of inotropic infusions or even vasoconstrictors to increase the driving pressure across the shunt may be considered. The latter necessitates careful monitoring to avoid jeopardizing perfusion to other vital organs.

The depressed myocardial function represents another potential problem in the early post-CPB period. Some degree of myocardial dysfunction typically occurs following stage I palliation, as no hemodynamic benefit is achieved that offsets the cost of CPB and an ischemic interval. When this dysfunction becomes more significant than usual, specific causes should be sought. Even in the context of the typical conduct of stage I reconstruction, the presence of AA can make routine myocardial protection measures, such as the infusion of cardioplegia solutions, challenging, and thus inadequate myocardial preservation represents one potential cause for persistent or excessive myocardial depression.

Technical considerations represent the predominant cause of myocardial dysfunction following this complex intervention. One of the most complex aspects of this procedure is the reconstruction of an aortic arch so that the small ascending aorta, which principally serves to provide coronary flow, is not compromised. Problems with retrograde flow to the coronary arteries may not become evident until the cardiac volume is restored in anticipation of terminating CPB. Residual hemodynamic derangement represents another potential cause of myocardial dysfunction. Given that under the best circumstances, the Norwood operation does not provide appreciable hemodynamic benefit, one would expect that a surgical result with newly imposed volume or pressure loads would be poorly tolerated. Examples of such findings include residual aortic arch obstruction, AV valve dysfunction, and/or semilunar valve obstruction or regurgitation.

Metabolic disturbances can also result in significant myocardial dysfunction. A fragile RV struggling to cope with significantly increased volume output demands at systemic pressure is perhaps more susceptible to what might otherwise be modest metabolic disturbances. As such, variables that can impact myocardial performance, such as ionized calcium levels and the presence of lactic acidosis, should be monitored closely and observed for trends. The rapid administration of blood products containing calcium-binding drugs, high levels of potassium, and lactic acid, along with other vasoactive mediators can result in an acute, profound deterioration in cardiac performance in the early postoperative period. When the arterial pH falls below 7.3, myocardial performance may deteriorate and contribute to a further reduction in Qs. The administration of IV bicarbonate, calculated to eliminate the base deficit completely, often exerts a beneficial effect on both myocardial performance and Qs. In addition to the inherent cardiac sensitivity, certain anatomic factors accentuate this vulnerability to metabolic disturbances. Blood carrying the transfused products from the systemic venous circulation enters the RV and is directed immediately to the reconstructed aorta, which has as its first branch the coronary arterial circulation. Thus, constituents of the transfused blood (e.g., citrate, potassium, lactate) infused into the venous circulation arrive at the coronary arteries with greater speed and more concentration than might have occurred had they been dissipated throughout the pulmonary vasculature before entering the aorta. This effect is further accentuated if central venous catheters are employed to infuse the blood product. It is best to utilize either washed packed cells or blood that is <7 days of age.

Arrhythmias most commonly occur as manifestations of the problems described previously. When they occur early in the rewarming process on CPB, coronary insufficiency represents the most common cause, particularly if the arrhythmia is ventricular in origin. Metabolic disturbances produce the same qualitative rhythm changes seen in normal hearts, although the manifestations might be more extreme. Given the predominantly extracardiac nature of the Norwood procedure, acquired heart block rarely follows this operation unless it existed preoperatively. On rare occasions, a patient presents with HLHS and a primary arrhythmia, such as Wolff–Parkinson–White syndrome. A 2021 retrospective review of 120 patients with HLHS after the Norwood procedure demonstrated a 26% incidence of postoperative

arrhythmias. Of these, the majority (32.4%) were ectopic atrial tachycardia [112].

Excessive PBF may complicate the early postoperative period; however, this diagnosis should be entertained cautiously. In many instances, the apparent excess PBF reflects a relative imbalance with respect to significantly diminished systemic CO (Qs). The latter should be specifically excluded and addressed before invoking extreme measures to restrict PBF. Of course, subtle technical differences in the conduct of the operation can result in an anatomic propensity to an excessive Qp: Qs, which can, in turn, jeopardize systemic perfusion. Such patients typically exhibit an extremely wide pulse pressure or low diastolic pressure, reflecting pulmonary "run-off." If myocardial performance otherwise appears robust, specific measures employed to increase PVR are appropriate in this setting. In most patients, this condition dissipates as the infant recovers from surgery. Should the problem persist beyond the first postoperative day, cardiac catheterization should be considered to evaluate the need for further surgical intervention to diminish PBF.

The subset of patients who demonstrate either an inability to separate from CPB or refractory cardiac dysfunction postoperatively may benefit from ECMO utilization as a support strategy. Ungerleider et al. have advocated the routine use of mechanical ventricular assistance in all patients following stage I reconstruction, reporting 89% survival to hospital discharge [113]. According to data from the National Pediatric Cardiology Quality Improvement Initiative database, 66 of 931 (7.1%) HLHS patients required ECMO during admission for stage I palliation. Patients requiring ECMO had a significantly higher risk of death or transplant (18%) compared to those who did not require ECMO (9%) [114]. Risk factors described for post-Norwood ECMO requirement include birth weight <2.5 kg, longer CPB time, peak serum lactate >9 mmol/L, and the vasoactive inotropic score of >27 [115]. An analysis from the Extracorporeal Life Support Organization of 738 HLHS patients requiring ECMO after stage I palliation demonstrated a 31% survival rate. Longer duration of mechanical ventilation before ECMO, longer duration of ECMO support, and ECMO complications such as renal failure or neurologic injury, all increased the risk of mortality [116, 117].

The risk of cardiac arrest in neonates with HLHS remains a concern in stage I postoperatively and the inter-stage period until SCPC is performed [118]. According to the Society of Thoracic Surgeons Congenital Heart Surgery Database, there was a 12.7% incidence of cardiac arrest among stage I palliation patients between 2007 and 2012. CPR in this population is also difficult, with a 62.3% mortality rate compared to 12.5% mortality in patients who did not experience an arrest [119]. The 2020 American Heart Association Pediatric Advanced Life Support guidelines include a specific section regarding the resuscitation of patients with SV physiology [120]. In stage I palliated patients, chest compressions provide both pulmonary and systemic blood flow, while chest recoil increases filling to the SV. Due to the parallel circulation, systemic blood flow will be lower and may have a low oxygen content, leading to coronary ischemia, systemic hypoperfusion, and end-organ damage [118]. Cardiac arrest and resuscitation are discussed in greater detail in Chapter 25.

The European Association for Cardio-Thoracic Surgery (EACTS) and the Association for European Paediatric and Congenital Cardiology (AEPC) recently developed a set of guidelines for managing neonates and infants with HLHS. These guidelines include suggested management for diagnosis, imaging, preoperative assessment, surgical and anesthetic management, and inter-stage monitoring. These recommendations allow practice standardization and identify potential targets for practice improvement at individual institutions [121]

KEY POINTS: HYPOPLASTIC LEFT HEART SYNDROME

- Preoperative stabilization of HLHS requires PGE_1 infusion to maintain ductal patency, along with measures to balance Qp: Qs near 1: 1. Room air ventilation and mild hypercarbia are often required to elevate PVR.
- Stage I palliation involves reconstruction of the hypoplastic aorta, with the pulmonary valve becoming the neo-aortic valve. Coronary perfusion is dependent on a technically sound anastomosis.
- Pulmonary blood flow is supplied by either a systemic-to-pulmonary shunt or an RV-to-pulmonary shunt; mid- and long-term outcomes are equivalent for either shunt type.
- Hybrid palliation involves a non-bypass surgery to place PA bands combined with interventional catheterization to stent the PDA and possibly the ASD; a comprehensive stage II palliation involving aortic arch reconstruction is done at the time of the SCPC.
- Interstage mortality between stage I palliation and SCPC continues to be an issue, currently at about 10–12%.

Tricuspid atresia

Incidence, anatomy, and natural history

TA is a cyanotic congenital heart defect characterized by total agenesis or complete obstruction of the AV valve associated with the morphologic RV. Tricuspid atresia accounts for approximately 1% of all cases of CHD. It is the fourth most common form of cyanotic CHD, following transposition of the great arteries, Tetralogy of Fallot, and HLHS. Its incidence, similar in males and females [122], is 1 per 10,000 individuals [123]. Tricuspid atresia occurs due to the disruption of tricuspid valvulogenesis, a multistep process, and genetic mutations in specific pathways (NFATC1 gene, Wnt/beta-catenin, RASA1, and Ras/ERK cascade) have been proposed to underlie certain cases of TA [124, 125].

Tricuspid atresia results in the absence of the RV inlet and varying deficiency of the trabecular portion of the RV, leaving the RV composed mainly of an infundibular portion and resulting in a functionally single LV (Figure 30.7) [126]. Other anatomic characteristics of TA include the presence of an interatrial defect (either ASD or PFO) and an enlarged left-sided AV valve. A ventricular septal defect (VSD) is nearly

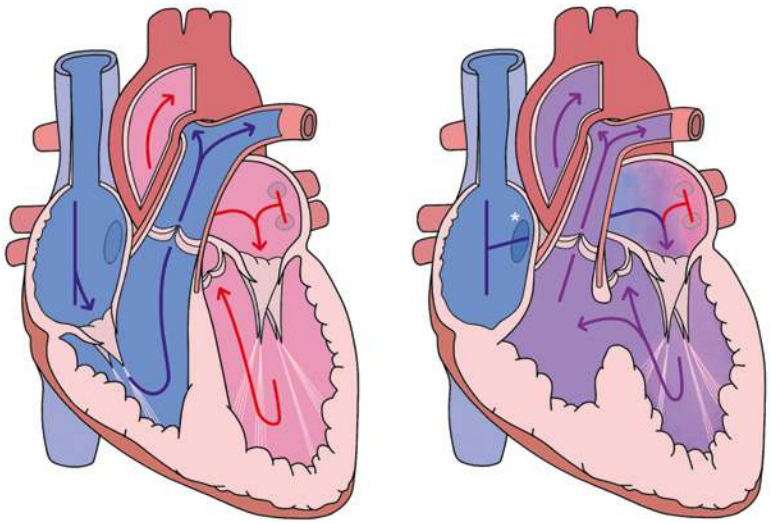

Figure 30.7 Blood flow in tricuspid atresia. (A) Normal cardiac anatomy. (B), Tricuspid atresia. *, patent foramen ovale or atrial septal defect. ASD, atrial septal defect; TA, tricuspid atresia. (Source: Sumal et al. [126] / John Wiley & Sons / CC BY 4.0.)

universally present, and abnormalities such as pulmonary stenosis (PS) may occur as well. In cases where a VSD is not present or pulmonary outflow obstruction is complete, the patient's PBF will rely on the presence of a PDA. The amount of PBF is determined by the degree of pulmonary outflow tract obstruction, the presence and size of a VSD, the relationship of the great arteries, and the presence of a PDA.

The timing and presentation of TA are determined by the degree of PBF, with approximately 50% of patients presenting on the first day of life and 80% by the age of 1 month. Without intervention, TA is associated with 90% mortality by the end of the first year of life [127]. The majority of patients present with cyanosis due to decreased PBF secondary to pulmonary obstruction and/or a small VSD. Patients with increased PBF secondary to shunting across a VSD and unobstructed PBF may initially have minimal cyanosis and progress to develop signs of excessive PBF and congestive heart failure (CHF) as the PVR falls after birth. Patients with less severe PS generally have a milder degree of cyanosis and may not require immediate surgical intervention as they have relatively balanced systemic and pulmonary circulations (see Figure 30.8) [128]. The Fontan procedure was initially applied to patients with TA, and many long-term adult survivors remain from the early Fontan era.

Pathophysiology of TA

Although different classifications have been proposed for TA, the most widely accepted schemes are based upon *the relationship of the great arteries* (Type I, II, or III) and *the degree of pulmonary outflow obstruction* (subclassification a, b, or c) (see Figure 30.9) [129]. Table 30.2 summarizes the anatomic classification, incidence, and pathophysiological features of TA.

Type I: Great artery relationships are normal. This is the most common type of TA, affecting 70–80% of patients. In the absence of a PDA, PBF is primarily dependent upon the size of the VSD and the severity of PS.

- **Type I-A**: Intact ventricular septum with pulmonary atresia (incidence approximately 10%). These patients are dependent on the presence of a PDA for PBF.
- **Type I-B**: Small VSD with PS (most common; 50% incidence). As the PDA closes, these patients will become increasingly cyanotic, related to the size of the VSD and the degree of PS. PGE_1 should be infused in these patients. The VSD may be of adequate size in early infancy, but as the heart grows and CO increases, the size of the VSD may become inadequate, resulting in increased cyanosis.
- **Type I-C**: Large VSD without PS (10% incidence). With a large VSD, PBF will depend on PVR. As PVR falls, the ratio of PBF to systemic blood flow (Qp: Qs) will increase, with hemoglobin-oxygen saturations (SaO_2) appearing near normal and pulmonary overcirculation and signs of congestive heart failure.

Type II: D-transposition of the great arteries exists. Type II affects approximately 25% of patients. Due to the transposed great arteries, the systemic outflow is dependent on the size of the VSD. Therefore, a small or restrictive VSD often results in aortic stenosis, arch hypoplasia, or coarctation of the aorta. Systemic hypoperfusion occurs as the PDA narrows and PGE_1 infusion may be necessary to maintain ductal patency. Obstruction to PBF is unusual in these patients, and they frequently develop pulmonary overcirculation and CHF in the first few weeks of life.

- **Type II-A**: A VSD exists with pulmonary atresia. In this extremely rare variant, the CO passes through the VSD into the aorta, and the patient depends on the PDA to provide PBF.
- **Type II-B**: A VSD is present with pulmonic stenosis (incidence 8%). Pulmonary blood flow is determined by the severity of PS and is often dependent on the PDA to maintain adequate oxygen saturation.
- **Type II-C**: A VSD without PS accounts for about 18% of all TA. Without PS, the relationship between PVR and any restriction to the systemic circulation (such as the size of

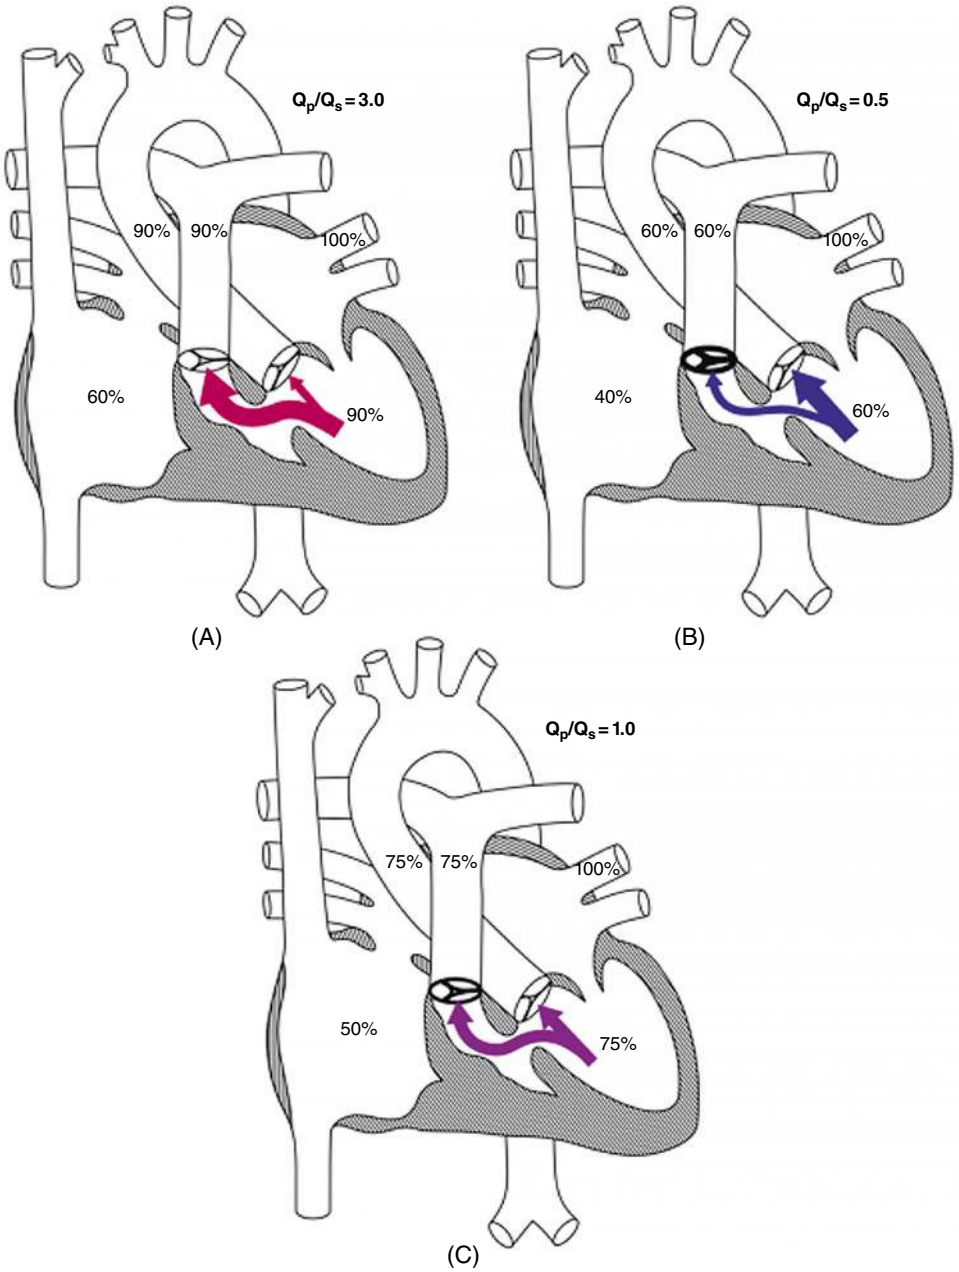

Figure 30.8 Hemodynamics of Type I tricuspid atresia with (A) no pulmonic stenosis (PS); (B) severe PS; and (C) "well-balanced" PS. Qp, pulmonary blood flow; Qs, systemic blood flow. Numbers with percentages are oxyhemoglobin saturation values. (Source: Taggart [128]. Reproduced with permission of John Wiley & Sons.)

the VSD and/or outflow tract obstruction) will determine Qp: Qs.

Type III: Malpositions of the great arteries other than d-transposition. This type is less commonly seen (3–6% of patients) and is used to classify TA with complex associated malformations such as AV septal defect or truncus arteriosus.

- Type III-A is associated with restrictive PBF due to pulmonary or subpulmonary stenosis.
- Type III-B is associated with systemic outflow obstruction due to subaortic stenosis or aortic annulus hypoplasia.

The pathophysiology of TA is determined by the degree of anatomic obstruction to PBF, the PVR, and the patency of the ductus arteriosus. The size of the VSD and the degree of PS (if present) will determine the amount of antegrade PBF that can occur left-to-right via the VSD, from the LV to the RV and the pulmonary arteries. Without communication between the RA and the RV, deoxygenated systemic venous return from the RA must travel to the LA through the ASD or PFO. Systemic arterial desaturation is present in all patients with TA due to the obligatory mixing of all venous returns (systemic, pulmonary, and coronary) in the LA. An unrestricted atrial defect is crucial to allow both venous mixing and adequate CO. If the ASD or PFO is restrictive after birth, an urgent atrial septostomy must be performed to enlarge it. Blood may also enter the PA from the aorta via the PDA.

AL Grawany

L-TGA (subtype 1) is shown (3%). (D) TA with persistent truncus arteriosus. D-TGA, dextro-transposition of the great arteries; L-TGA, levo-transposition of the great arteries; TA, tricuspid atresia. (Source: Taggart [128]. Reproduced with permission of John Wiley & Sons.)

The diagnosis of TA is generally made prenatally with obstetrical screening ultrasound or fetal echocardiography. Postnatal diagnosis is confirmed with history and physical examination, chest radiography, electrocardiogram (ECG), and echocardiography. Chest radiography can differentiate between patients with high or low PBF as those with increased PBF demonstrate cardiomegaly and prominent pulmonary vasculature. In contrast, patients with pulmonary oligemia have a normal-sized heart and concavity in the region of the PA. The ECG demonstrates left axis deviation in the frontal plane. Echocardiography describes the anatomy and allows detailed physiological assessment and surgical planning. It aids in defining the size of the VSD and the RV, the relationship of the great vessels, degree of PS, presence and size of the PDA, and the amount of blood flow across these areas. The presence of other associated anomalies such as arch obstruction can also be assessed. Color-flow and spectral Doppler echocardiography can evaluate the adequacy of the atrial level communication (ASD or PFO). Cardiac catheterization is rarely required in the neonatal period unless necessary for balloon atrial septostomy or stenting of the PDA. Cardiac MR and CT may be used occasionally to define unusual anatomy.

Surgical and transcatheter approaches and outcomes

Ultimately TA patients will undergo staged SV palliative surgeries, culminating in the Fontan procedure. However, the necessity and type of neonatal intervention differ according to the anatomical classification and pathophysiologic consequences. The need for neonatal surgical or catheter-based intervention depends upon the degree of obstruction to PBF, the size of the VSD, and the resulting level of cyanosis. Subgroups of neonates with decreased PBF either due to pulmonary outflow obstruction and/or a restrictive VSD will require the provision of a stable source of PBF. Infants presenting with Type Ia or IIa (pulmonary atresia) are ductal-dependent until they undergo either surgical placement of a mBTTS or stenting of the PDA in the cardiac catheterization laboratory. Patients with increased PBF due to an unrestrictive VSD and either mildly obstructed (Types Ib and IIb) or unobstructed pulmonary outflow (Types Ic and IIc) often develop CHF with signs of compromised systemic perfusion. Placement of a PAB for restriction of PBF may be necessary until a superior cavopulmonary connection (SCPC) can be performed at 3–6 months of age. Infants with relatively balanced systemic and pulmonary circulations (Types Ib and IIb), although cyanotic, may not require neonatal surgical intervention and may be followed clinically for increasing cyanosis. Most often, SCPC is their first palliative surgery.

Type II TA patients with restrictive VSDs or significant subaortic obstruction require a PDA to provide systemic circulation and may undergo a "palliative" arterial switch operation (ASO) to place the aorta so that the unobstructed LV ejects into it; the VSD may need to be enlarged in this case to prevent profound cyanosis [130, 131] (See Chapter 29 for a detailed discussion of the ASO). If subaortic obstruction exists despite an unrestrictive VSD, patients may undergo a Damus–Kaye–Stansel (DKS) operation, which bypasses subaortic obstruction by creating an end-to-side anastomosis between the ascending aorta and the proximal stump of the divided PA. Either a mBTTS or RV-PA shunt is placed to provide PBF. The operative and anesthetic considerations for this surgery are similar to those for the Norwood stage I palliation of HLHS. Figure 30.10 demonstrates surgical options for TA type II with significant subaortic stenosis.

Anesthetic considerations

Pulmonary artery banding

Neonates with pulmonary overcirculation and varying degrees of CHF may present for PAB placement to protect the pulmonary vascular bed from high pressure to facilitate successful progression to SCPC and Fontan physiology. Cyanosis is mild in these patients; they are generally tachypneic and often receive diuretic therapy. Preoperative evaluation should include a thorough history and physical examination, a review of the chest radiograph for evaluation of heart size and degree of pulmonary overcirculation, and baseline pulse oximetry. A current hemoglobin level will aid in the assessment of the degree of chronic cyanosis, and serum electrolyte values can evaluate abnormalities due to chronic diuretic therapy. A review of the most recent transthoracic echocardiogram should reveal precise details of the anatomy and functional characteristics, including any mitral valve regurgitation.

Table 30.2 Anatomic and physiologic classification of tricuspid atresia

Type	Major anatomic features	Incidence	Major pathophysiologic features			Neonatal surgical approach
			Cyanosis	CHF	Decreased systemic perfusion	
Type I: Normally related great arteries		70–80%				
Ia	Intact VS with pulmonary atresia		+++	–	–	mBTS
Ib	Small VSD with PS		++	–	–	None
Ic	Large VSD, no PS		+	++	–	PA band
Type II: Transposition of the great arteries		12–25%				
IIa	VSD with PA		+++	–	Yes if VSD restrictive	mBTS
IIb	VSD with PS		++	–	Yes if VSD restrictive	None
IIc	VSD no PS		+	++	Yes if VSD restrictive	PA band
Type II: Transposition of the great arteries with restrictive VSD or subAS			++	+++	++	DKS; or subAS resection, +/– enlarge VSD; or palliative ASO, +/– enlarge VSD
Type III: Normally related or transposed great arteries with other complex cardiac lesions		3–6%	+ to +++	– to ++	Depends on associated anomalies	Depends on associated anomalies

ASO, arterial switch operation; CHF, congestive heart failure; DKS, Damus–Kaye–Stansel operation;mBTS, modified Blalock–Taussig shunt; PS, pulmonic stenosis; subAS, subaortic stenosis; VS, ventricular septum; VSD, ventricular septal defect; +, mild; ++, moderate; +++, severe; –, no effect.

Although cardiac rhythm disturbances are unusual at this stage, a 12-lead ECG is helpful to exclude arrhythmias.

After placement of standard monitors, an IV induction of anesthesia is most commonly performed, utilizing fentanyl in combination with incremental doses of either ketamine or propofol. After administration of a neuromuscular blocking agent and tracheal intubation arterial access is achieved for monitoring. Institutional viewpoints vary regarding the need and best location for placement of central venous access. Some centers advocate the use of femoral venous cannulation, due to concern for potential thrombus formation in the SVC, as it will be necessary later for successful SCPC. Others may choose to place a transthoracic RA line. If appropriate peripheral IV access exists some centers elect not to use central venous access for this procedure. The patient's preoperative condition, along with institutional preferences and the need for postoperative vascular access in the ICU, will assist in decision-making.

Steady-state anesthetic and ventilatory conditions should be maintained during the procedure in order to optimize PAB adjustments. The FiO_2 and $PaCO_2$ at the time of PAB placement should approximate baseline conditions for the patient; communication between the surgeon and anesthesiologist regarding the desired conditions is essential. A FiO_2 of 0.30 or less is generally utilized, and $PaCO_2$ is often in the mid-40s mmHg due to the metabolic alkalosis from diuretic therapy and the mild state of respiratory insufficiency from CHF. Many centers use TEE guidance during PAB placement.

The operation is usually performed through a median sternotomy without CPB. After dissection, the surgeon places a thin cotton tape or strip of Gore-Tex around the main PA, using care not to impinge on the branch PAs or pulmonary valve. A formula derived by Trusler advocated an initial band circumference of 24 mm + 1 mm/kg body weight for infants with bidirectional mixing disorders, but this was subsequently modified for patients with univentricular physiology, narrowing the circumference further to 22 mm + 1 mm/kg [132, 133]. Various methods may be used to assess and adjust PAB tightness. The primary method is to assess the change in pulse oximeter saturation and the measured arterial PaO_2 saturation after band placement, with a SpO_2 of 75–85% and a PaO_2 of approximately 40–45 mmHg customarily targeted. Transesophageal echocardiography helps measure peak velocity (V) across the PA band; 3 m/s is a frequent goal and corresponds to a pressure gradient of 36 mmHg using the modified Bernoulli principle (peak velocity = $4V^2$). Additionally, echocardiography can reassure that no encroachment on the pulmonary valve or distortion of the pulmonary arteries has occurred. Finally, direct pressure measurement in the surgical field is utilized by some institutions; a PA pressure distal to the PAB that is about one-third of systemic arterial pressure (range, 25–50%) is a frequent goal. The PAB is adjusted temporarily with surgical clips, blood gas measurements can be obtained after steady-state conditions are achieved, and the band is then permanently secured with non-absorbable sutures. An overly tight PAB will produce profound cyanosis and bradycardia, while one that is too loose will produce little change from baseline conditions. The final PAB circumference is often determined by surgical judgment, hence the importance of achieving and maintaining steady-state anesthetic and ventilatory conditions.

Although usually not necessary, inotropic support should be readily available as afterload will increase after placement

AL Grawany

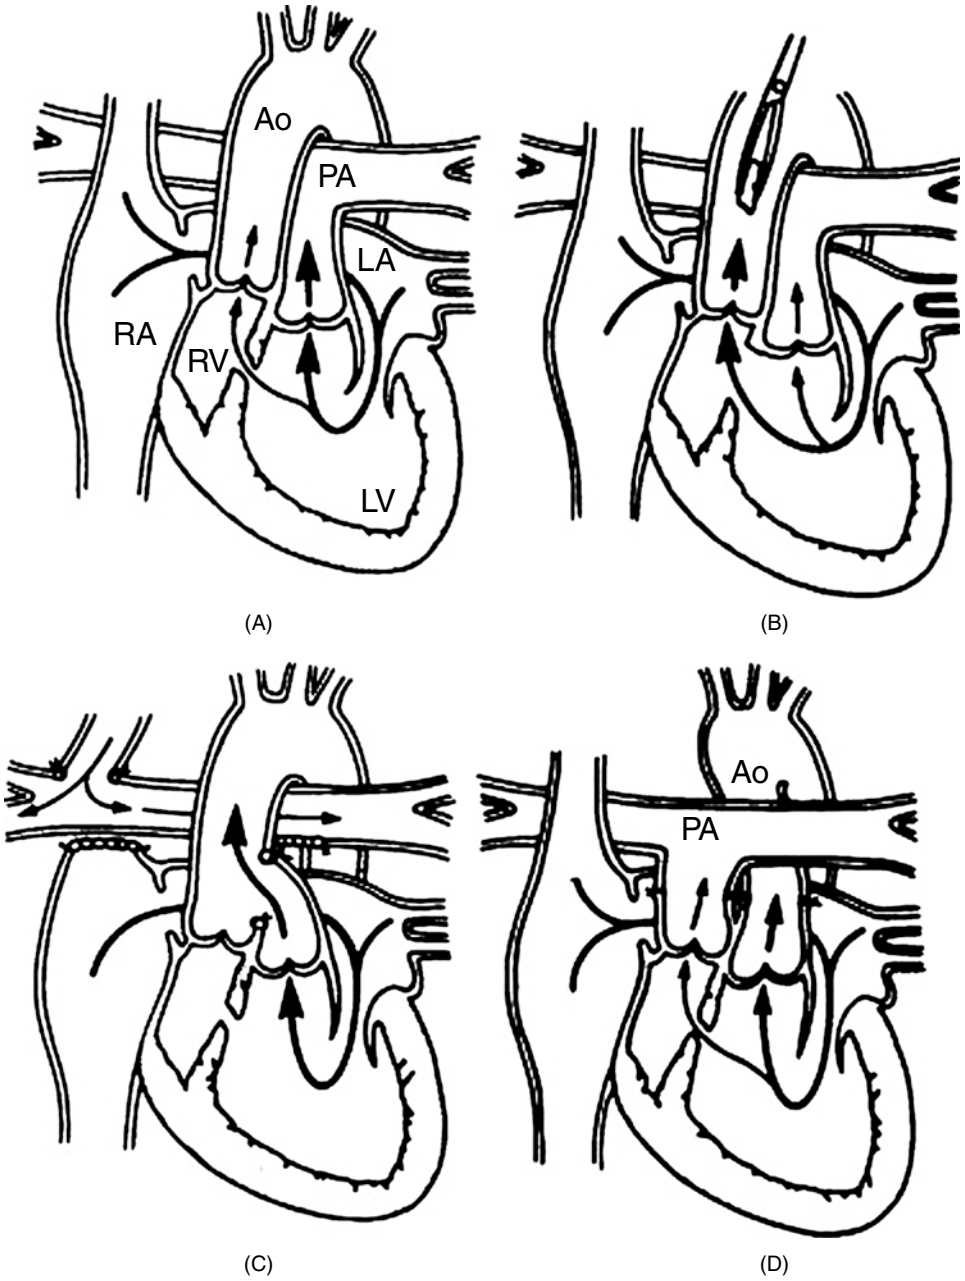

Figure 30.10 Surgical methods for tricuspid atresia type II with significant subaortic stenosis. (A) Preoperative anatomy of tricuspid atresia type IIc. (B) Direct resection of subaortic myocardium with enlargement of the ventricular septal defect. (C) Damus–Kaye–Stansel operation: main pulmonary artery to aorta end-to-side anastomosis. (D) Palliative arterial switch operation. Ao, aorta, LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

of the PAB once the pulmonary circuit no longer provides a low resistance "pop-off." Placement of a PAB mechanically increases the resistance to PA flow, and therefore, more blood flow is directed out through the aorta. Systemic arterial pressure often increases after placement of a PAB, and occasionally a vasodilator such as sodium nitroprusside is necessary to control blood pressure. After surgery, tracheal extubation may occur in the OR or within the first few hours of ICU admission.

As the patient emerges from anesthesia, CO changes, along with the relative tightness of the band. As infants are in a period of rapid somatic and cardiac growth, they often "outgrow" the PAB, and cyanosis increases. As nearly all of these infants undergo an SCPC within a few months, this issue is not usually problematic in the infant SV population.

Systemic-PA shunt and ductal stenting

Patients with TA and either pulmonary atresia or significant PS who require PGE_1 and maintenance of ductal patency for PBF may present for either surgical placement of a mBTTS or placement of a ductal stent in the cardiac catheterization

laboratory to establish a stable source of PBF. Occasionally an older infant with profound cyanosis and a closed ductus arteriosus may also present for placement of an mBTTS. Although an mBTTS can be performed via right thoracotomy, the median sternotomy approach is most commonly utilized. Unless necessary due to hemodynamic instability or significant hemoglobin-oxygen saturations during the procedure, CPB is not utilized. The anesthetic considerations for placement of an mBTTS are presented in detail in Chapter 28.

Percutaneous transcatheter stenting of the ductus arteriosus was first described in 1992 and has continued to increase in prevalence as an alternative palliative approach to secure PBF in patients with duct-dependent lesions [134]. Ductal stenting (DS) has proven to be a reasonable alternative to the mBTTS, as it is associated with similar or improved symmetrical PA growth, fewer procedural complications, a shorter ICU and hospital length of stay, and improved survival compared to surgical shunt [135, 136]. In comparing the two procedures, cardiac arrest, the need for extracorporeal circulatory support, arrhythmias requiring therapy, and bleeding were observed only in the mBTTS group, while access site injury was observed in the DS group [137]. As the experience continues to grow and early technical challenges are overcome, DS is emerging as a preferred alternative to the mBTTS. Further detail about ductal stenting is presented in Chapter 34.

Unplanned reinterventions to treat cyanosis before SCPC may be required in patients with either mBTTS or DS. These interventions most commonly involve either balloon or stent angioplasty of the PDA stent or mBTTS, or surgical revision [136]. Planned reinterventions may also occur in DS patients, with reexpansion of the stented ductus allowing adjustment of PBF over time. A study comparing pre-SCPC hemodynamics and PA growth in SV patients palliated with either DS or mBTTS found no significant differences between the two [138].

Damus-Kaye-Stansel operation and palliative ASO

Management of patients with unrestrictive PBF and systemic ventricular outflow tract obstruction (TA with associated TGA) remains challenging. Systemic blood flow must pass through the VSD, or bulboventricular foramen, to a rudimentary subaortic outlet chamber. The VSD may become restrictive, limiting blood flow, or ventricular hypertrophy after placement of a PAB may further increase outflow obstruction. While early relief of obstruction is essential, surgical management of this issue has not been uniform. Although subaortic stenosis may be relieved directly by means of VSD and/or subaortic chamber enlargement, this incurs the risks of heart block, recurrent stenosis, and ventricular dysfunction due to the ventriculotomy. As noted earlier, the DKS operation may be performed for TA variants with significant subaortic or aortic obstruction or with a restrictive VSD. The anesthetic considerations are very similar to those for Norwood stage I palliation, as discussed earlier. Because the single functional ventricle is an LV, and because the aortic valve is not atretic and the coronary artery circulation not as tenuous as in HLHS, these patients are generally expected to have a more stable pathophysiologic condition after DKS, compared with the Norwood stage I palliation. The palliative ASO has many anesthetic considerations in common with the standard ASO for d-TGA with two ventricles (discussed in Chapter 29). The major difference is that TA remains, and adequate PBF needs to be assured after the ASO, often requiring enlargement of the VSD or possibly placement of an mBTTS.

KEY POINTS: TRICUSPID ATRESIA

- TA results in a single systemic LV with a rudimentary RV.
- Type I TA has normally related great vessels, type II has d-TGA, and type III has l-TGA or additional complex cardiac defects.
- Subtype *a* has pulmonary atresia, *b* has PS, and *c* has no PS.
- Neonatal surgical palliation depends on the size of the VSD and the degree of obstruction to pulmonary or systemic blood flow. The majority of patients require the establishment of stable PBF via either mBTTS placement or DS. Patients with unrestrictive PBF often require PA banding. Complex repairs such as the DKS operation or palliative ASO can be required in patients with TA and TGA.

Other forms of univentricular hearts

In addition to HLHS and TA, other forms of univentricular hearts exist and can present in the neonatal period for initial surgical palliation [137]. These patients virtually always undergo staged palliation with SCPC at 3–6 months and Fontan completion between 18 months and 4 years of age. Although collectively accounting for only 1–2% of all CHD patients diagnosed at birth, the congenital cardiac anesthesiologist frequently encounters these patients for surgical and catheterization procedures, imaging procedures, and noncardiac surgery. Table 30.3 summarizes other univentricular heart variants.

Double inlet ventricle

In a double inlet ventricle, both atria connect only to a single ventricular chamber, either via a common AV valve or two separate AV valves. The AV valves may be normal, or one may be hypoplastic, stenotic, or atretic [137]. The additional ventricle is hypoplastic; in some cases, there can be a partial connection to the rudimentary ventricle via a straddling AV valve. In general, the rudimentary ventricle lacks an inlet portion, but the outlet chamber can also be absent. A VSD or bulboventricular foramen is usually present and may restrict flow to the outlet chamber and the attached great vessel. Although the single functional ventricle can be a morphologic LV, RV, or have indeterminate morphology, double inlet left ventricle (DILV) is the most commonly seen variant (see Figure 30.11).

A right-sided anatomic LV exists in the double-inlet left ventricle (DILV) along with frequent ventriculoarterial discordance, with l-TGA occurring slightly more frequently than d-TGA [137, 139]. The clinical picture varies according to the size of the VSD or bulboventricular foramen, the

Table 30.3 Other types of univentricular heart variants presenting for neonatal cardiac surgery

Lesion	Morphology of systemic ventricle	Associated cardiac findings	Neonatal surgical palliation options
Double inlet ventricle	Left is most common	L-transposition of the great arteries; subAS; subPS	Damus–Kaye–Stansel; palliative ASO; PA banding
Mitral atresia with VSD	Right	Restrictive bulboventricular foramen; hypoplastic aortic arch	Damus–Kaye–Stansel; PA banding
Unbalanced common AV canal	Right or left	Coarctation or arch hypoplasia	Aortic arch repair; PA banding
Heterotaxy syndrome with single ventricle	Right, left, or indeterminate	PS; bilateral SVC; interrupted IVC; TAPVR	mBTS; TAPVR repair; PA banding

AS, aortic stenosis; ASO, arterial switch operation; IVC, inferior vena cava; mBTS, modified Blalock–Taussig shunt; PA, pulmonary artery; PS, pulmonic stenosis; SVC, superior vena cava; TAPVR, total anomalous pulmonary venous return; VSD, ventricular septal defect.

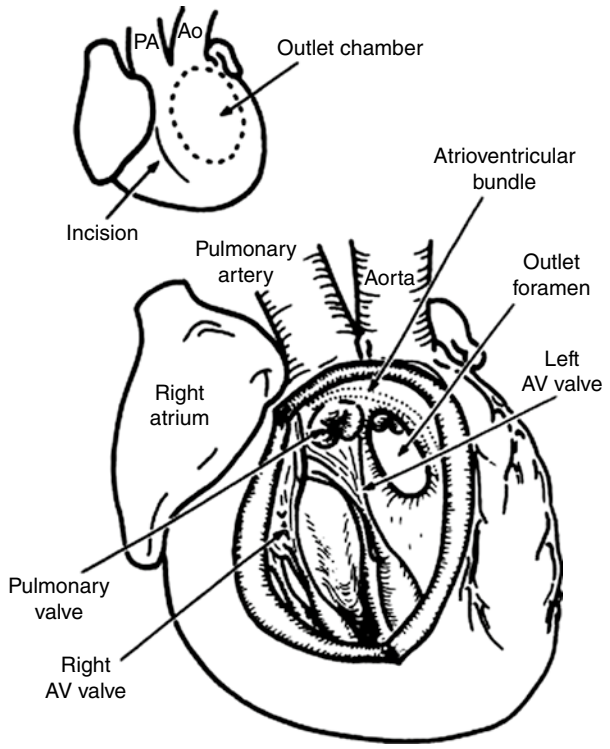

Figure 30.11 Double inlet left ventricle with hypoplastic right ventricle. Relationships of the intracardiac structures and the disposition of the conduction tissue (atrioventricular bundle). Ao, aorta; AV, atrioventricular; PA, pulmonary artery.

presence of AV valve hypoplasia or stenosis, and the morphology and degree of pulmonary or systemic outflow obstruction. Three subtypes of DILV have been described according to the relationship of the great arteries [140].

- **Type I**: Normally related great arteries are found; this anomaly is also known as the "Holmes" heart.
- **Type II**: d-TGA exists, often associated with obstruction of the bulboventricular foramen and subaortic stenosis. Aortic arch anomalies exist approximately 50% of the time as well.
- **Type III:** l-TGA is present. Subaortic obstruction occurs in two-thirds of patients due to a small bulboventricular foramen or left AV valve tissue obstruction.

The appropriate neonatal surgical palliative approach will depend on the exact anatomy and its pathophysiological consequences. Patients with restrictive PBF require a mBTTS or PDA stenting, while those with aortic valve and aortic hypoplasia may require a Norwood procedure, DKS operation, or palliative ASO (see earlier). Some centers may choose the placement of a PAB along with aortic arch repair. Patients without restriction to either pulmonary or aortic outflow usually require placement of a PAB, while in patients with a balanced circulation the initial palliative surgery is generally an SCPC. Anesthetic considerations for these procedures are discussed earlier in the chapter. Current outcomes of multistage palliation for DILV compare favorably with those reported for other SV anomalies [139].

Mitral atresia with VSD

Mitral atresia with VSD denotes the absence of the left AV valve connection from the LA to the LV, resulting in a functionally univentricular heart with a dominant RV and a hypoplastic LV connected to the RV via a VSD or bulboventricular foramen. Both the aorta and PA may arise from the RV, and the aortic root may be normal, or the aorta can arise from the small LV, in which case the aorta is often hypoplastic and classification then becomes HLHS. The majority of cases are seen in conjunction with other ventricular anomalies such as HLHS, left ventricular outflow tract obstruction, and double outlet RV. Neonatal palliation often consists of PAB placement in patients with unrestrictive flow through both great vessels; a DKS or Norwood stage I palliation operation is usually necessary if subaortic obstruction or hypoplasia of the ascending aorta also exists.

Unbalanced complete atrioventricular septal defect

Unbalanced complete atrioventricular septal defects (uCAVSDs) compose approximately 10% of CAVSDs [137]. As in balanced CAVSD (see Chapter 26), a single common AV valve exists along with a large primum ASD and a large inlet VSD. However, in uCAVSD, one ventricle is hypoplastic, often resulting in a single functional ventricle. A right dominant uCAVSD is more commonly seen, with a large RV and hypoplastic LV. Conversely, a left dominant uCAVSD has a large LV and hypoplastic RV. Abnormal development of aortic outflow, with arch hypoplasia or coarctation, may be observed in uCAVSD, but PS is unusual.

Surgical decision-making for the patient with an uCAVSD is guided by the percentage of ventricular imbalance and the adequacy of the AV valves [141]. Echocardiography plays a vital role in determining the suitability of a candidate for single vs. biventricular repair. If the LV or RV apex is present ("apex-forming") in an otherwise small ventricle, a patient may be considered for biventricular repair. Echocardiographic measurement of the AV valve index, the ratio of the smaller AV valve component over the larger component, can offer guidance [142]. Cardiac MR imaging can yield information regarding ventricular volumes to further assist decision-making [143].

Unbalanced CAVSD patients often present in early infancy with pulmonary overcirculation. They may require placement of a PAB, either as part of a staged univentricular palliation or to allow delayed decision-making regarding the feasibility of biventricular repair. Infants with abnormalities of aortic outflow may require coarctation repair or aortic arch repair, with a PAB frequently necessary as well. As in other SV anomalies, the SCPC is performed at 3–6 months. Patients with uCAVSDs who undergo SV palliation represent a challenging group of patients, with substantial early mortality and <60% survival at 20 years [144]. In particular, trisomy 21 patients with severe ventricular hypoplasia are reported to have poor outcomes, regardless of their dominant ventricle [141].

Single functional ventricle with heterotaxy syndrome

The International Society for Nomenclature of Pediatric and Congenital Heart Disease defines heterotaxy as "an abnormality where the internal thoraco-abdominal organs demonstrate abnormal arrangement across the left-right axis of the body." Heterotaxy does not include patients with situs inversus or complete mirror imaging of cardiac and abdominal organs around the right-left axis [145]. Chapters 6 and 7 have an extensive discussion of the embryology and nomenclature of heterotaxy syndrome. Constellations of cardiac manifestations are frequently seen in patients with heterotaxy syndrome, with many requiring SV palliation. In addition to cardiac anomalies, malrotation of the intestines may be present, predisposing the patient to intestinal volvulus, and therefore, all babies with heterotaxy should be evaluated to rule out intestinal malrotation. Patients often have impaired or absent splenic function, even in the presence of polysplenia. Functionally asplenic patients are susceptible to pneumococcal and other bacterial sepsis and require lifelong penicillin prophylaxis.

Isomerism reflects the duplication of one vertical half of the body in regard to the thoracic organs, with unusual arrangements of the abdominal organs (visceral heterotaxy). Atrial appendage morphology should be the basis for segregating right and left isomerism; if morphology cannot be assigned to either right or left atrium, isomerism may be considered indeterminate. Classification is essential because right and left isomerism are associated with markedly different anatomical findings of the affected organs that can be clinically significant. Isomerism can significantly impact surgical outcomes for SV palliative surgeries, and mortality before stage I palliation and during the stage I to stage II interstage period is greater in patients with isomerism [146].

Right atrial isomerism (RAI) is associated with bilateral morphologically right atrial appendages, bilateral trilobed lungs, central nervous system anomalies, and asplenia. Associated cardiac abnormalities may include a constellation of many or all of the following: AVSD, total anomalous pulmonary venous connection (TAPVC), TGA, and bilateral SVCs. The presence of extracardiac TAPVC in a patient with heterotaxy is highly correlated with RAI [147]. Patients with RAI generally have bilateral sinus nodes, leading to a propensity for atrial arrhythmias later in life. The absence of the coronary sinus is a near-universal finding in patients with isomeric right atrial appendages [148].

Left atrial isomerism (LAI) is associated with bilateral morphologic LA appendages, bilaterally bilobed lungs, and asplenia or polysplenia. Cardiac anomalies can include all or some of the following: AVSD, partial anomalous pulmonary venous connection (PAPVC), interruption of the IVC, absence of the coronary sinus, mirror-imaged spiraling of great arteries, and AV block. Interruption of the IVC in the presence of heterotaxy is highly correlated with LAI compared to RAI. An interrupted IVC can drain into either the azygos or hemiazygos vein and from there into a right or left-sided SVC. In addition, the IVC may be left-sided and drain into a common atrium separately from the hepatic veins, presenting complexities at the time of Fontan completion. The sinus node may be abnormally located or absent in LAI, making these patients more susceptible to arrhythmias and complete heart block (see Figure 30.12) [149].

Because of the anatomical variation possible in heterotaxy syndrome, neonatal surgical palliation varies widely. Given the frequent abnormalities of systemic and pulmonary venous drainage, echocardiography alone may not sufficiently define the anatomy. Cardiac MRI, CT, or catheterization is frequently useful in this population. Because TAPVC is common, surgical repair of this condition is often the initial operation. Pulmonary valve stenosis or atresia occurs in approximately 50% of patients with RAI and <10% of those with LAI and may necessitate placement of an mBTTS or PDA stent [150]. Conversely, PAB placement may be required for patients with pulmonary overcirculation. The management of TAPVC is discussed in Chapter 26. Precise details of the patient's anatomy are essential to understand the planned surgical approach and to guide decision-making regarding the placement of invasive arterial and central venous access catheters. The presence or absence of a spleen and intestinal malrotation can be determined by abdominal ultrasound; nuclear medicine scan (hepatobiliary iminodiacetic acid [HIDA]) is used in cases where the splenic anatomy is not clear. After initial neonatal surgical palliation, approximately 85% of heterotaxy syndrome patients undergo staged palliation to a Fontan circulation. Table 30.4 summarizes the findings in heterotaxy syndrome.

Heterotaxy syndrome presents a number of challenges for perioperative teams. Despite improving statistics, hospital mortality remains consistently higher in patients with heterotaxy [151]. Within heterotaxy syndrome, survival is consistently higher for patients with LAI compared to RAI [147, 152]. Patients with RAI are nearly five times as likely to have TAPVC compared to patients with LAI, and approximately two thirds of patients with RAI have SV physiology as well. These patients

AL Grawany

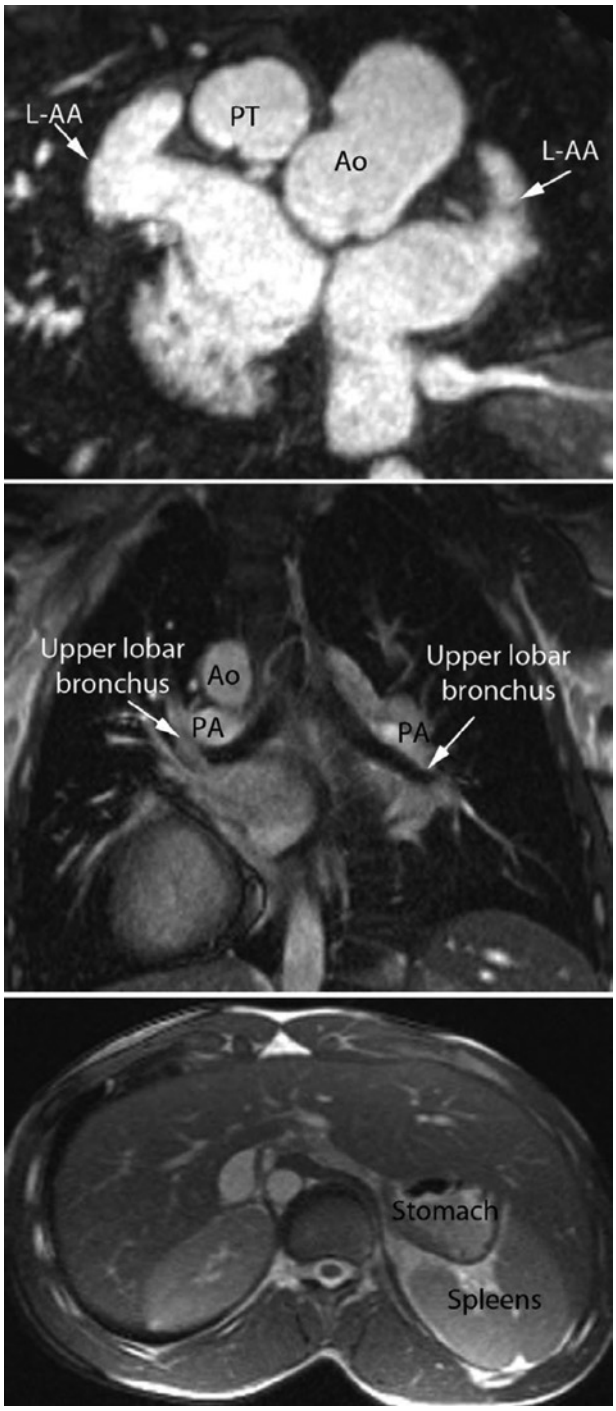

Figure 30.12 Heterotaxy with classic left isomerism and polysplenia. Both side atrial appendages are long and narrow. No pectinate muscles are seen along the wall of either atrium. The main bronchi are symmetrically long. Note the epibronchial pulmonary arteries (PA) and the hyparterial upper lobar bronchi. Two spleens are seen along the posterolateral wall of the stomach. Ao indicates aorta; DsAo, descending aorta; IVC, inferior vena cava; and PT, pulmonary trunk. (Source: Yim et al. [149]. Reproduced with permission of Wolters Kluwer Health, Inc.)

are a particularly high-risk neonatal surgical population, with 10-year survival nearly twice as high in patients without TAPVC compared to those with TAPVC [147].

KEY POINTS: OTHER UNIVENTRICULAR HEARTS

- Other univentricular hearts include double inlet ventricle, MA, unbalanced CAVSD, and various forms of SV anatomy with heterotaxy syndrome.
- Neonatal palliation depends on the degree of obstruction to pulmonary or systemic blood flow and may involve no surgery, PAB placement, systemic-to-pulmonary artery shunt, or complex repairs such as the DKS procedure or palliative ASO.
- Heterotaxy is a complex malformation syndrome involving abnormal sidedness of thoraco-abdominal organs, with isomerism classified according to atrial anatomy (right, left, or indeterminate).
- Abnormalities of systemic and pulmonary venous return are common in heterotaxy and often need to be addressed during neonatal palliation.

Superior cavopulmonary connection

Surgical procedure

The term "superior cavopulmonary connection" describes the creation of a surgical anastomosis between the SVC and the pulmonary arterial bed. If an mBTTS or RV-PA shunt is present, it is taken down at the time of SCPC; similarly, for a stented PDA, the stent(s) and PDA are excised and the aortic and pulmonary insertion sites oversewn. For patients with shunt-dependent PBF, conversion to an SCPC means that the heart is no longer required to eject systemic output plus additional output to provide PBF via the shunt. Conversion to SCPC increases effective PBF, resulting in improved systemic arterial oxygen saturation. Volume unloading of the SV also occurs, facilitating subsequent remodeling of ventricular geometry with a reduction in end-diastolic volume before Fontan completion [153, 154]. Although SCPC is the second stage in the palliative surgical sequence for most SV patients, for patients with balanced circulations who did not require a neonatal intervention the SCPC will be their first palliative surgery.

Two primary surgical options currently exist for SCPC. As outcomes appear equivalent, preference for one technique over the other tends to be institution specific. The bidirectional Glenn (BDG) is an end-to-side anastomosis of the SVC to the PA, along with ligation of the prior mBTTS or Sano shunt. A modification of the original Glenn shunt facilitated SVC flow to both left and right PAs, hence the term "bidirectional" Glenn shunt [155, 156] (see Figure 30.13). Most commonly, the BDG is followed by an extracardiac Fontan. The hemi-Fontan (HF) procedure is technically more complex and maintains the native connection between the SVC and RA; it also enables PA augmentation. The SVC-RA confluence is anastomosed to the branch PA, utilizing a "dam" within the RA to redirect SVC blood flow to the pulmonary arteries. The HF facilitates a subsequent lateral tunnel Fontan completion (see Figure 30.14). In a study utilizing multi-scale computational modeling, no significant differences in hemodynamic or physiological outcomes were seen between the HF and

Table 30.4 Findings in heterotaxy syndrome with single ventricle

Syndrome	% with single ventricle	Common cardiac variants	Pulmonary stenosis/atresia	SVC/IVC	TAPVR	SA nodes	Atrial morphology	Lung morphology
Asplenia	>50%	Single RV common; DORV, unbalanced CAVC	Common (>90%)	Bilateral SVC common	Common; to extracardiac vein	Bilateral	RA isomerism	Bilateral trilobed (right)
Polysplenia	<50%	RV or indeterminate morphology	Less common (<50%)	Interrupted IVC (80%)	To right atrium	Hypoplastic or absent	LA isomerism	Bilateral bilobed (left)

CAVC, complete atrioventricular canal; DORV, double outlet right ventricle; IVC, inferior vena cava; LA, left atrium; RA, right atrium; RV, right ventricle; SA, sinoatrial; SVC, superior vena cava; TAPVR, total anomalous pulmonary venous return.

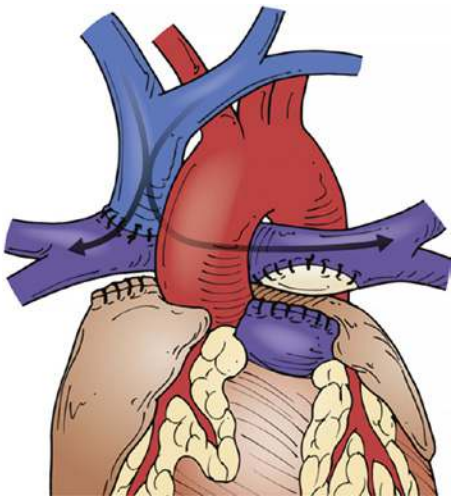

Figure 30.13 Bidirectional Glenn procedure. The superior vena cava (SVC) is anastomosed in an end-to-side fashion to the pulmonary artery. It is important to ligate the azygous vein (to limit decompression of SVC blood via the azygous to the intact inferior vena cava (IVC) circulation). The atrial junction from the SVC site is oversewn. When performed on CPB, it is often possible to complete an atrial septectomy through the atrial junction before oversewing it. Cannulation of the SVC must be performed meticulously to prevent stenosis to the Glenn circuit after the cannula is removed at the completion of the case. (Source: Murthy et al. [127]. Reproduced with permission of Elsevier.)

BDG models, suggesting that patient-specific physiology and condition are more important in determining the outcome [157]. Evaluation of infants in the SVRT dataset was done through 1 year of age, based on the type of SCPC performed. Although CPB times were longer and the use of DHCA more frequent in the HF group, no difference in transplant-free survival at 1 year was observed between groups [158].

Although SCPC may occasionally be performed as early as 2 months of age, most patients undergo this procedure at 3–6 months to allow sufficient time for PVR to decrease and permit sufficient PBF, systemic oxygenation, and systemic CO with the SCPC circulation. Consideration may be given to proceeding earlier with SCPC if increasing cyanosis from mBTTS or RV-PA shunt narrowing is present or if an urgent need exists to address other surgical issues such as coarctation of the aorta. The development of interstage home monitoring programs has dramatically improved interstage mortality for patients after Stage I palliation and assisted in planning appropriate timing of the Stage II procedure [104]. Patients with bilateral SVCs often undergo a bilateral SCPC with each SVC anastomosed to its ipsilateral PA. In this case, each SVC is generally smaller than a normal single SVC, producing increased resistance to flow. Patients requiring bilateral SCPC before 120 days of life have poorer outcomes for the Stage II procedure, but subsequently, results are equivalent for patients with either single or bilateral SVCs [159].

The HF is performed utilizing CPB. The BDG is performed with CPB support in most institutions; however, if other cardiac surgical procedures are not required, it is possible to perform an isolated SCPC without CPB with the aid of a temporary shunt from the SVC to the RA and partial heparinization. This technique is designed to prevent cerebrovenous hypertension and hypoxic-ischemic brain injury during the period of SVC occlusion. The surgical technique for isolated BDG involves the institution of CPB with cannulae in the aorta, high SVC, and RA. Cross-clamping of the aorta is avoided unless additional intracardiac procedures are planned, and mild hypothermia (32–34 °C) is generally utilized. The mBTTS or RV–PA shunt, if present, is occluded immediately after the institution of CPB and then divided and oversewn. The SVC is transected at its junction with the RA, taking care not to injure the SA node. The RA is then oversewn and the SVC anastomosed to the right PA. If pulmonary atresia does not already exist (either congenitally or as a result of incorporating the native pulmonary valve into the neo-aorta during Norwood stage I palliation), the main PA is oversewn. The pulmonary valve leaflets are also sewn closed to prevent thrombus formation in the pulmonary valve sinuses, which can embolize retrograde into the single systemic ventricle. The term "pulsatile" BDG refers to intentionally leaving some ejection from the pulmonary ventricle directly to the PA in addition to the SCPC. This elevates PA pressure and produces a pulse pressure. Reasons for utilizing this configuration can include tricuspid stenosis or other forms of mild RV hypoplasia in which the RV is deemed inadequate to receive the sum of all SVC and IVC flow. This operation is also termed a one-and-a-half-ventricle repair. Although maintaining antegrade PBF at the time of SCPC can be beneficial for oxygen saturations and the growth of pulmonary vasculature before the Fontan procedure, it has been shown to be unfavorable for overall transplant-free survival, with a higher risk of death or transplant until the antegrade flow is eliminated. [160].

Single-ventricle patients with heterotaxy syndrome (see earlier) often have bilateral SVCs, requiring bilateral SCPC.

AL Grawany

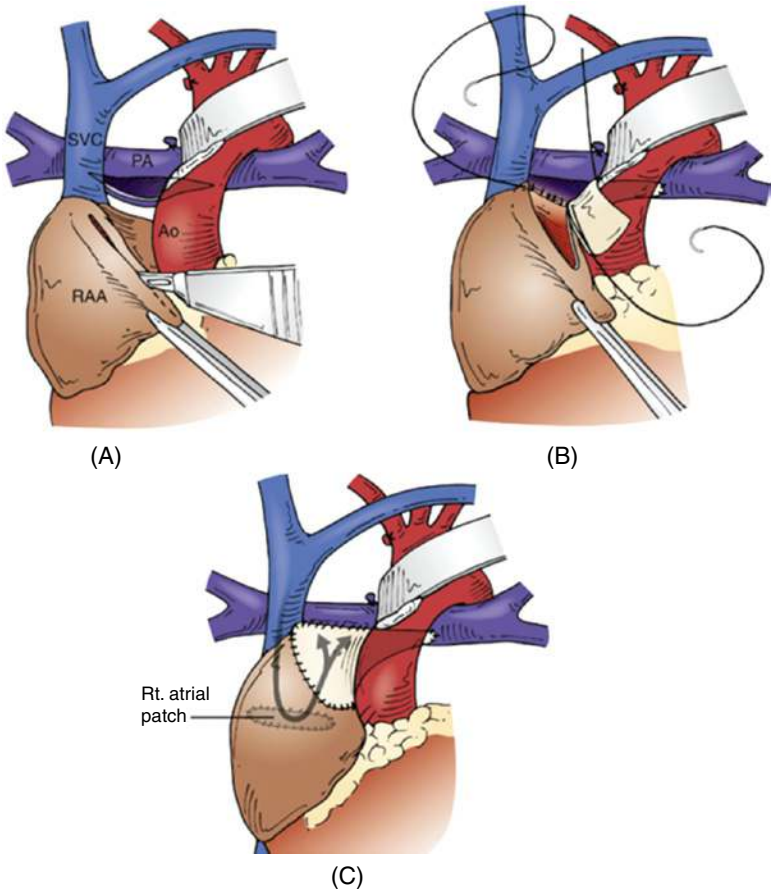

Figure 30.14 Hemi-Fontan procedure. (A) Central pulmonary arteries (PAs) are opened anteriorly from posterior to the superior vena cava (SVC) to distal to insertion of the ligamentum arteriosum. An incision is made in the base of the right atrial appendage extending up to the SVC/right atrium (RA) junction. (B) The inferior aspect of the pulmonary arteriotomy is sutured to the outside of the SVC. (C) A patch of polytetrafluoroethylene (PTFE) is sutured within the RA at the level of the limbus. (Source: Murthy et al. [127]. Reproduced with permission of Elsevier.)

These patients may also require either revision or primary repair of anomalous pulmonary venous drainage at the time SCPC is performed. Many heterotaxy patients with LAI also have interruption of the IVC. In these patients, the suprahepatic IVC is not present. Subdiaphragmatic systemic blood return occurs via collateral circulation reconstituted above the diaphragm, ultimately entering the azygous or hemiazygous circulation. Consequently, after SCPC, 75–85% of the total systemic blood flow is directed to the PAs, excluding only hepatic venous and coronary sinus drainage. The resulting physiology thus more closely approximates that seen after the Fontan operation. This operation is known as the Kawashima procedure [161]. A Fontan-type intervention is still generally performed later to incorporate hepatic venous blood into the pulmonary circulation, as these patients are at increased risk for the early development of pulmonary arteriovenous malformations (PAVMs) with resultant cyanosis due to the lack of an uncharacterized "hepatic factor" directly perfusing the pulmonary circulation. Despite this, PAVM regression remains unpredictable in these patients [162, 163].

Additional surgical procedures are frequently necessary at the time of SCPC. These can include patch augmentation of the PAs, atrial septectomy, correction of residual coarctation after Norwood stage I palliation, annuloplasty for AVVR, or correction of other significant anatomic problems. For patients who have undergone a hybrid Stage I procedure, the comprehensive Stage II procedure will involve a Norwood-type arch reconstruction, PAB removal, atrial septectomy, and removal of the DS in addition to SCPC [41, 164]. A thorough understanding of additional surgical procedures and preoperative discussion of the intraoperative plan with the surgeon and perfusionist are essential to ensure optimal patient outcomes.

Anesthetic considerations

Preoperative considerations

A successful conversion from a "parallel" circulation based upon complete mixing and parallel perfusion of both the systemic and pulmonary vascular beds via an arterial shunt to a "series" circulation where PBF becomes a diversion of systemic venous return requires certain preconditions. Preoperative evaluation should assure adequate candidacy for the SCPC, evaluating PA pressures, the size of the branch PAs, and any other anatomic issues requiring surgical intervention. As blood flow through the pulmonary circulation will be passive and dependent on the TPG after SCPC, pulmonary venous obstruction or elevations in either PA pressures

Table 30.5 Optimal pre-superior cavopulmonary connection characteristics

Age 4–6 months
Normal weight for age
Normal caloric goals during the inter-stage period
Competent systemic atrioventricular valve
Pulmonary vascular resistance <2 U/m^2
Mean pulmonary artery pressure </ = 18 mmHg
Normal ventricular function
Transpulmonary gradient <9 mmHg
No pulmonary disease leading to pulmonary venous desaturation
No venovenous collaterals
No aortic arch narrowing or re-coarctation
No pulmonary artery distortion
Single-ventricle end-diastolic pressure <12 mmHg

or PVR will not be well tolerated. Optimal pre-SCPC characteristics are listed in Table 30.5 (See Table 30.5) [28].

Cardiac catheterization remains the standard imaging modality for assessing vascular anatomy before SCPC; it also provides the opportunity to measure PA pressures and resistances and perform interventions if necessary. Noninvasive methods of assessing the anatomy and physiology, such as cardiac MRI or cardiac CT angiography, have also been successfully utilized in patients who do not require catheter-based interventions before surgery [165]. Knowledge of PVR, ventricular end-diastolic pressure, AV valve function, and any residual obstruction at the atrial septum remnant is desirable before surgical intervention. Elevated PVR can encompass two distinct mechanisms: the size of the major branches and the state of the arteriolar resistance vessels. Patients who have undergone a hybrid procedure are more likely to develop PA stenosis requiring intervention. In contrast, infants who underwent conventional Stage I palliation are at a higher risk for aortic arch narrowing or re-coarctation [166, 167]. In addition, angiography can evaluate for the presence of accessory venous communications between the superior venous drainage and the heart or IVC (e.g., left SVC to coronary sinus). Postoperatively, such vessels can serve as a mechanism by which upper body venous return is diverted to the heart without passing through the pulmonary circulation, resulting in increased levels of hypoxemia. Pulmonary vein desaturation noted preoperatively may result from lung disease and later help explain low postoperative oxygen saturation.

In addition to catheterization or other imaging data, a recent ECG and echocardiogram should also be reviewed. An evaluation of other vital organ systems with a history of primary or secondary dysfunction should be incorporated, along with a detailed history regarding the child's response to sedative medications and anesthetics. For patients receiving anticoagulant medications or functional platelet inhibitors, plans for perioperative management of those therapies should be formalized. Often patients are taking low-dose aspirin with the goal of inhibiting platelet function to maintain mBTTS patency; some institutions routinely discontinue aspirin 7–10 days preoperatively, while others do not. Risk factors that have been identified for postoperative complications after SCPC include lower weight for age, female sex, and aortic atresia with mitral stenosis [168].

Intraoperative considerations

When infants return for SCPC, some may manifest early signs of separation anxiety. Although the use of sedative premedication such as oral midazolam may be considered before separation from the parents, some institutions prefer not to premedicate these patients. After placement of standard non-invasive monitoring, anesthesia can be induced with a variety of IV or inhaled agents unless preoperative assessment demonstrated ventricular dysfunction or other anatomic concerns. Although these infants have the same anatomy and physiology as neonates following Stage I palliation, maturation and compensatory mechanisms in myocardial development make them significantly more resilient. As baseline PVR is low, even extreme measures cannot produce a substantial reduction in PVR from baseline values, and therefore changes in Qp: Qs are relatively small.

Following induction and tracheal intubation, direct arterial monitoring access is obtained. The site chosen for arterial access may vary according to several considerations. The placement of an mBTTS may have compromised the ipsilateral subclavian artery, and, additionally, previous monitoring and catheterization sites may not be available. A variety of aortic arch branching patterns also exist, which can result in subclavian artery stenosis. Non-invasive arterial pressure measurement on all four extremities can aid in providing information to identify the most appropriate site(s). Institutional preferences vary regarding cannulation of the central veins, with some institutions avoiding accessing the internal jugular (IJ) or subclavian veins due to concern for thrombosis. Others may choose to cannulate the femoral vein as the major central venous access, also placing a small (3 French) catheter in the right IJ vein to monitor PA pressure for 12–24 hours postoperatively. If the IJ vein is utilized, it is essential to note catheter length and placement, as surgical cannulation occurs high on the SVC for this procedure. In addition, many centers use NIRS monitoring intra- and postoperatively, measuring both cerebral and somatic saturations.

The majority of SCPC patients are undergoing repeat sternotomy and may have mediastinal adhesions, incurring an increased risk for bleeding and pre-CPB arrhythmias from the extensive electrocautery required at times. Appropriate precautions include administration of antifibrinolytic agents, large-bore IV access with blood products prepared for immediate administration, the application of external cardioversion/defibrillation pads to the patient, and preparation of the heparin dose and a primed CPB circuit.

Unlike stage I palliation, the SCPC provides significant hemodynamic benefit. As the circulations are no longer connected in parallel postoperatively, the volume output demand for the SV is now reduced to that necessary to perfuse the systemic circulation alone. Pulmonary blood flow becomes a diversion for venous return from the upper body, effecting a "series" circulation of a pump and two resistors. As the volume of blood flow to the upper body is at least as great as that to the lower body at 6 months of age, the mixture of oxygenated and deoxygenated blood remains 1: 1 or

AL Grawany

higher. Thus, although the expected systemic oxygen saturation does not change appreciably, the heart is only required to perform half the volume work (Qs) to accomplish this. Although most patients exhibit robust hemodynamics on completion of this procedure, the ready availability of inotropes including epinephrine and inodilators such as milrinone is recommended, as infants with diastolic dysfunction or valvular regurgitation may benefit from them.

With PBF now reliant upon passive venous flow from the SVC, measures designed to minimize the impediments to PBF assume paramount importance. As medical therapies are limited in their capacity to produce reliable, substantial improvement in ventricular compliance or AV valve function, attention is focused on minimizing PVR. Shortly before the termination of CPB, the tracheal tube should be cleared of secretions and the lungs completely re-expanded, as PVR will be minimized at normal FRC and both atelectasis and alveolar overdistension increase PVR. A tidal volume designed to achieve a normal $PaCO_2$ at a respiratory rate no greater than 20 should be selected. Doppler flow studies have demonstrated that PBF occurs preferentially during the expiratory phase of positive pressure ventilation (PPV) in patients following cavopulmonary anastomosis and thus attempts to limit the respiratory rate and inspiratory time to <1 second are warranted [169]. Positive end-expiratory pressure (PEEP) is applied judiciously to preserve normal FRC. Ventilatory strategies producing a $PaCO_2$ of 45–50 mmHg will increase cerebral blood flow (CBF), increasing PBF through the direct SVC–PA connection. This strategy not only increases systemic and cerebral oxygen saturations but also facilitates increases in systemic oxygen delivery [170]. In instances where significant hypoxemia persists despite optimization of other measures, iNO can be used to lower PVR.

Modified ultrafiltration (MUF) offers significant benefits to patients following SCPC and is utilized immediately following the termination of CPB [171]. Postoperative blood loss and the proportion of patients demonstrating significant pleural and pericardial effusions are significantly reduced. Other investigators have shown benefits in pulmonary function that may prove particularly crucial in this population. Infants for SCPC represent a high-risk group for postoperative bleeding as they have multiple risk factors that can exacerbate bleeding, including age <2 years, reoperation, hypoxemia, frequent use of aspirin, and, for some, the use of deep hypothermic bypass management. Upon completion of MUF, the heparin effect is reversed with protamine. After acceptable hemodynamics and hemostasis are achieved, most patients can be extubated in the OR or shortly after arrival in the ICU.

Postoperative considerations

Cardiopulmonary interactions assume great importance after SCPC. Maintaining a low trans-pulmonary gradient (TPG) is essential to encourage PBF and optimize CO. Early extubation, whenever possible, facilitates this goal as PPV has been shown to reduce PBF in patients after SCPC or Fontan palliation [172]. Cerebral NIRS and cardiac index have been shown to increase while CVP decreases after extubation, suggesting that improvements in cerebral perfusion pressure (CPP) occur [173].

Systemic oxygen saturation of 75–80% is typically expected after SCPC. The presence of an SVC catheter measuring PA pressure used in combination with atrial pressure measurement yields important information. A CVP of 12–18 is often observed post-SCPC, and normovolemia should be maintained. Most institutions prefer hemoglobin levels to be maintained >13 to maximize oxygen-carrying capacity. Flow from the SVC to the pulmonary vascular bed provides approximately one-third of CO, while flow from the IVC to the atrium provides two-thirds. Assuming an oxygen saturation of 100% from the pulmonary veins and a SvO_2 of 70% from the IVC, an approximate systemic saturation of 80% can be anticipated (100 + 70 + 70/3). Decreases in PBF may therefore not affect systemic oxygen saturation as much as decreases in systemic blood flow. As multiple factors affect systemic saturations, all possible etiologies should be considered when postoperative hypoxemia of greater magnitude than anticipated persists (see Table 30.6) [174].

Low CO should be recognized promptly, as resultant decreases in SvO_2 will adversely impact systemic oxygenation and increases in ventilation will not address this issue. Instead, the goal should be to increase CO and raise IVC saturations to 70%. Although the incidence of myocardial dysfunction is low following SCPC, it does occur. In the absence of significant hemodynamic causes (e.g., aortic arch obstruction or AVVR), an issue with myocardial protection or coronary perfusion might be suspected. Despite their young age, some infants have developed extremely thick ventricular walls, particularly in the context of a high Qp:Qs and residual aortic arch obstruction. Even under optimal conditions, the compliance of these hearts may not return quickly.

Table 30.6 Potential causes of early cyanosis postbidirectional Glenn/Hemi-Fontan procedure

Pulmonary venous desaturation
Lung disease (V/Q mismatch)
Systemic venous desaturation
Low-cardiac output
Anemia
Right-to-left shunts
Venovenous collaterals (i.e., SVC to pulmonary veins or SVC to IVC)
Failure to ligate azygous or hemiazygous veins
Undiagnosed contralateral SVC (usually LSVC)
Hemi-Fontan baffle leaks (unique to HFP)
Decreased pulmonary/cerebral blood flow
ASD restriction
PA stenosis
PA thrombosis
SVC stenosis
SVC thrombosis
Elevated pulmonary vascular resistance
Elevated systemic ventricular EDP
Increased PA pressures due to additional sources of pulmonary flow
Increased intrathoracic pressure

Abbrevations: ASD, atrial septal defect, EDP, end-diastolic pressure; HFP, hemi-Fontan procedure; IVC, inferior vena cava; LSVC, left superior vena cava; PA, pulmonary artery; SVC, superior vena cava; V/Q, ventilation/perfusion.

Potential factors affecting pulmonary venous return and its impact on oxygen saturations should be considered. Pulmonary venous return can be diminished in the setting of diastolic dysfunction, AV valve insufficiency, loss of AV synchrony, or a restrictive atrial septum. Obstruction or thrombosis within the SCPC can exist; an increase in CVP aids in recognizing this issue. Veno-venous collaterals may allow a "pop-off" of venous blood from the SVC or pulmonary vascular bed to the IVC, decreasing blood flow to the lungs and negatively impacting systemic oxygen saturation. Echocardiography can detect many causes of refractory cyanosis. However, if venous collaterals, SVC or PA thrombosis, or a restrictive atrial septum are suspected, a diagnostic cardiac catheterization with the potential for intervention may be indicated. If diminished SCPC flow is believed to be due to increased PVR, treatment with oxygen or pulmonary vasodilators may prove beneficial. Patients with pre-existing lung disease often have pulmonary venous desaturation.

The "cavopulmonary–cerebral" circulation, referring to the connection of the SVC, which drains the cerebral circulation, to the PA, is an important physiological principle following SCPC (Figure 30.15). The transition to SCPC physiology is associated with increased cerebral oxygen saturation and a decrease in CBF velocity [175]. Because of the relatively large size of the young infant's brain and the responsiveness of CBF to $PaCO_2$, the $PaCO_2$ has an enhanced direct effect on PA flow after SCPC. A $PaCO_2$ of 40–45 mmHg results in improvements in cerebral and systemic oxygenation and systemic CO when compared with a $PaCO_2$ in the 30–35 mmHg range [170]. In the setting of a lower PaO_2 and SpO_2 than desired, appropriate $PaCO_2$ levels should be ensured. Among other benefits of early tracheal extubation, the mild elevation in $PaCO_2$ observed with spontaneous ventilation has significant advantages for the cavopulmonary–cerebral circulation. In addition, elevating the head 30–45° and maintaining a neutral neck position, without rotation, extension, or flexion, promotes optimal cerebrovenous drainage and improves oxygenation.

Systemic hypertension is another commonly observed problem early in the postoperative period. One of the proposed mechanisms for this phenomenon is the readjustment of the cerebral circulation to higher venous pressures after SCPC. Before SCPC, the cerebral venous pressure is usually 4–8 mmHg; after SCPC, SVC pressure is equal to PA pressure and is elevated to a mean of 12–18 mmHg. The CPP is thus reduced, and hypertension is thought to be a response to preserve CPP. Table 30.7 presents hemodynamic and oxygenation status problems and differential diagnosis in the early postoperative period after SCPC.

Special considerations exist for patients who require CPR or mechanical circulatory support (MCS) post-SCPC. Chest compressions will create systemic blood flow but little PBF in this patient subset, limiting oxygenation and CO. Adequate chest recoil will allow blood flow through the lungs and enhance flow from the IVC, providing preload [118].

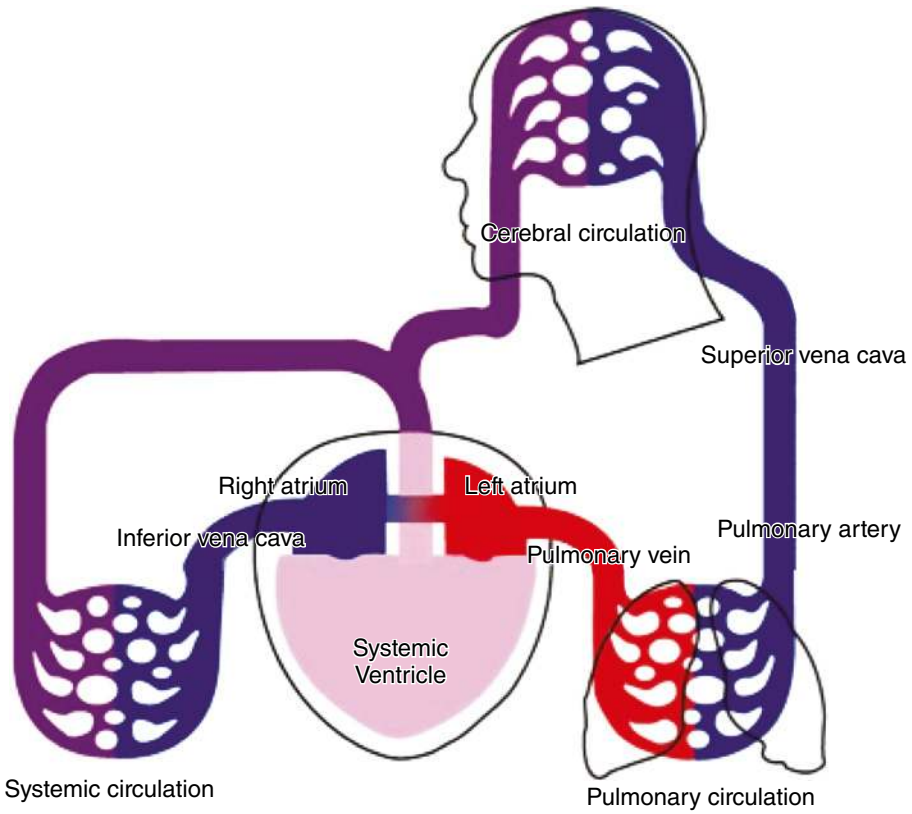

Figure 30.15 The cavopulmonary–cerebral circulation after superior cavopulmonary anastomosis. The relatively large brain of the young infant carries a large percentage of the cardiac output. Hyperventilation will decrease $PaCO_2$, constricting the cerebral arterioles and decreasing cerebral blood flow and cerebral oxygen saturation. This, in turn, decreases superior vena cava flow, decreasing pulmonary artery flow, which will lead to decreased systemic arterial oxygenation. (Source: Stephen A. Stayer, MD. Table 30.7 Hemodynamic status and differential diagnosis in the postoperative superior cavopulmonary anastomosis patient

Status	PAP (mmHg)	LAP (mmHg)	TPG (mmHg)	SpO_2 (%)	Etiologies
Normal	10–15	2–6	<10	80 ± 5	Ideal status
Elevated PAP	>15	2–6	>10	<75	High PVR; PA or PV obstruction
Elevated LAP	>15	>8–10	<10	<75	Ventricular systolic/diastolic dysfunction; sub-AS; AVVR; tamponade
Cyanosis	10–15	2–6	<10	<75	Decreased CBF; PV desaturation; decompressing veins; hypovolemia; anemia

PAP, pulmonary artery pressure as measured in the superior vena cava; LAP, left or common atrial pressure; TPG; transpulmonary pressure gradient (PAP–LAP); PVR, pulmonary vascular resistance; PV, pulmonary vein; AS, aortic stenosis; AVVR, atrioventricular valve regurgitation; CBF, cerebral blood flow.

Resultant elevations in SVC pressure and decreases in CPP will also increase the risk of subsequent neurological injury. Longer-term MCS is emerging as an option for SV patients after SCPC [176].

Outcomes

Overall outcomes following SCPC have been excellent in experienced centers, with a low early mortality rate of 3–4.7% [177]. Similar outcomes (mortality 4%) have also been reported for patients undergoing a comprehensive stage II procedure after an initial hybrid Stage I procedure [163]. A list of risk factors for complications, length of stay, and transplant-free survival has continued to evolve over the past decade [178]. Attrition between the SCPC and Fontan completion for HLHS patients has been reported to be independently associated with moderate or severe tricuspid valve regurgitation and low weight at the time of SCPC. Recent data from interstage home monitoring programs also indicate a continuing vulnerability and divergence in survival at 1 year for patients who required inpatient surveillance between their Stage I and II procedures [179].

KEY POINTS: SUPERIOR CAVOPULMONARY CONNECTION

- SCPC is generally performed between 3–6 months of age and is normally the second stage of palliation for SV patients.
- SCPC results in significant unloading of the systemic ventricle and stabilization of the circulation, particularly in HLHS.
- The creation of a "cavopulmonary–cerebral" circulation with SCPC is an important concept. Mild hypercarbia will promote cerebral and cavopulmonary blood flow, improving cerebral and systemic oxygenation and oxygen delivery.

Fontan completion

Surgical procedure

The Fontan procedure is the final stage in staged surgical single-ventricle palliation. The two Fontan variations currently used are the lateral tunnel (LT) and the extracardiac conduit (ECC), both also referred to as total cavopulmonary connection (TCPC) (see Figure 30.16). In earlier versions of the Fontan operation, the RA appendage was directly anastomosed to the PAs; this approach was known as an atriopulmonary Fontan and has been abandoned due to long-term adverse hemodynamic sequelae. These variations and conversion to modern Fontan configurations are discussed in Chapter 20.

The LT Fontan procedure is generally performed after the HF. After the institution of CPB with aortobicaval cannulation, moderate hypothermia and aortic cross-clamping are utilized. The RA is opened, the PTFE patch beneath the SVC-PA anastomosis is excised, and an intra-atrial PTFE tunnel is placed between the SVC-PA anastomosis and the orifice of the IVC [180]. Additional surgical procedures such as AVV repair, PA augmentation, atrial septectomy, and correction of residual coarctation can be performed simultaneously if necessary. Some surgeons create a 3–5 mm fenestration in the wall of the PTFE graft to permit blood flow from the higher pressure Fontan pathway to the lower pressure common atrial chamber (see Figure 30.17). Blood shunting via the fenestration to the common atrium augments CO, although this occurs at the expense of increased arterial desaturation due to the right-to-left shunt. As LT Fontan does not include circumferential graft material, pathway growth can occur, making the procedure possible in patients as young as 18 months of age.

In contrast, the ECC Fontan is generally performed following a BDG procedure. Mild hypothermic CPB is used, and aortic cross-clamping may not be necessary unless additional intracardiac procedures warrant its use. An 18–20 mm PTFE tube graft is sewn outside the heart, connecting the IVC directly to the underside of the right PA. As this tube graft will not grow, patient size is a consideration when performing an ECC Fontan. In some institutions, the ECC Fontan is performed with only partial right heart bypass, reducing circuit volume and obviating the need for blood transfusion in many patients [181]. The graft may be offset medially from the SVC–right PA anastomosis to improve flow dynamics so that IVC flow is preferentially directed to the left PA and SVC flow to the right PA. A potential drawback to this offset is that "hepatic factor" from the IVC may not perfuse the right PA, resulting in the development of PAVMs in the right lung. A fenestration may also be placed in the ECC configuration, though this is less commonly done to avoid arterial desaturation, ongoing risk of thromboembolism, and the potential need for intervention and fenestration

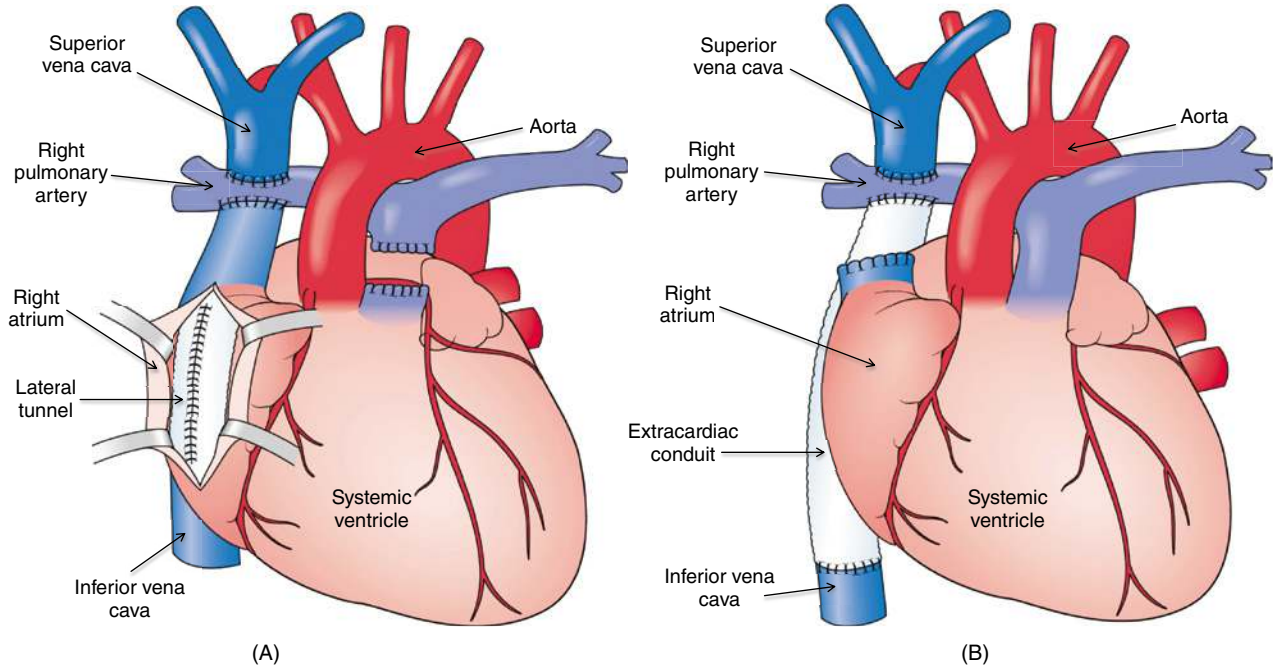

Figure 30.16 A lateral tunnel Fontan total cavopulmonary connection. (A) A polytetrafluoroethylene (PTFE) patch or tube is fashioned inside the right atrium. (B) Extracardiac conduit Fontan. The PTFE tube is anastomosed outside the heart from the detached inferior vena cava directly to the right pulmonary artery. (Source: Andropoulos et al. [35]. Reproduced with permission of Elsevier.)

closure at a future date. However, if the creation or enlargement of a fenestration becomes necessary in the future to treat Fontan failure or perform an electrophysiologic study, it is considerably more challenging to perform in an ECC Fontan due to anatomic considerations. A recent meta-analysis examining the effect of fenestration on outcomes demonstrated that having a fenestration reduced pulmonary pressure and reduced prolonged pleural drainage after the Fontan procedure, with no increased incidence of stroke observed. However, fenestration did not decrease the risk of Fontan failure, early death, or hospital stay after Fontan completion [182]. The intra/extracardiac conduit, a modification of the ECC Fontan, more easily permits the creation of a fenestration. This configuration alters the IVC connection to the ECC in that a small incision is made in the atrium, with the ECC then connected to the orifice of the IVC. A 4-mm fenestration is made in a short segment of the PTFE graft in the atrium before the ECC emerges out of the side of the atrium to continue to the PA anastomosis as in a standard ECC [183] (see Figure 30.18).

As the Fontan pathway is a low-flow system, optimizing fluid dynamics and minimizing energy loss is essential. Computational fluid dynamic models pioneered by de Leval have demonstrated hemodynamic performances of various Fontan anastomoses [184]. The combination of the HF followed by the Fontan procedure showed the lowest energy losses in a study by Bove et al. [185]. More recently, a Y-graft ECC Fontan, designed to allow more even distribution of hepatic blood flow, was shown over 3 years to significantly balance flow [186] (see Figure 30.19). To date, flow studies have still not definitively identified the best Fontan technique.

The choice between an ECC or LT Fontan is often institution or surgeon-specific and may also depend on the type of SCPC previously created. Early studies suggested that complications such as atrial arrhythmias and sinus node dysfunction might be due to intra-atrial suture lines and atrial manipulation during the creation of an LT Fontan [187, 188]. However, in a meta-analysis comparing early and long-term mortality, long-term arrhythmias, Fontan take-down, postoperative ventilation, ICU stay, thrombosis, and pleural or pericardial effusion, no differences were observed between patients with ECC or LT Fontan. The ECC Fontan patients had a lower incidence of supraventricular tachycardia 30 days post-Fontan and a lower rate of protein-losing enteropathy (PLE) compared with LT Fontan [189]. In 2020, an extensive retrospective analysis compared the LT and ECC techniques, finding that patients with LT Fontan had improved short- and mid-term survival and more extended freedom from Fontan failure compared with ECC Fontan patients [190]. Evidence has demonstrated that both procedures provide effective Fontan circulations with excellent outcomes.

Fontan physiology

The cardiovascular system in a biventricular patient has two circuits connected in series: pulmonary and systemic, each supplied with energy from a ventricular pump. In contrast, in SV patients after Fontan palliation, energy for both circuits must be provided by a single ventricular pump. After traversing the systemic circulation, the remaining energy in the systemic central veins must drive blood through the Fontan pathway and the pulmonary circulation. A visual of blood

AL Grawany

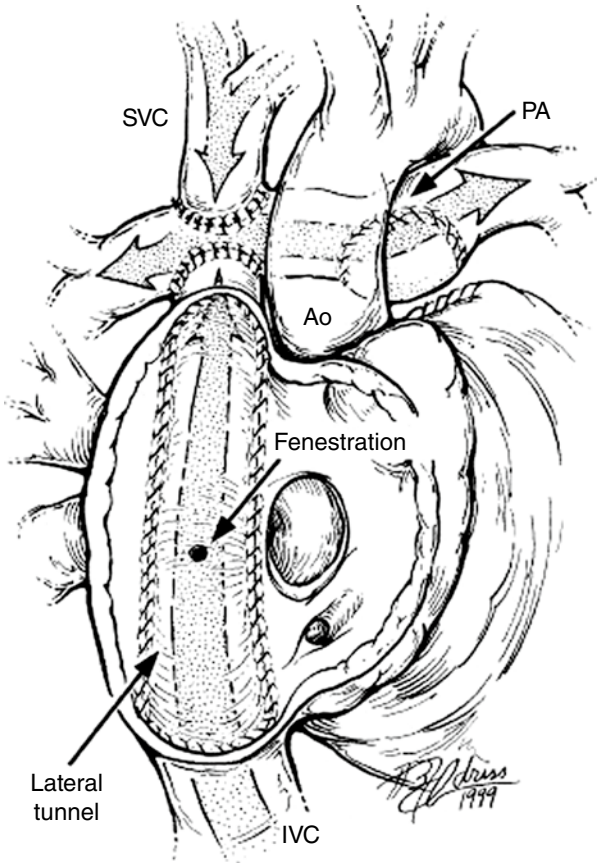

Figure 30.17 Lateral tunnel Fontan demonstrating a fenestration in the wall of the polytetrafluoroethylene tube that allows right-to-left blood flow from inside the Fontan circuit to the left atrial side. The fenestration is 3–5 mm in diameter and results in higher total cardiac output and oxygen delivery early in the postoperative course, at the expense of some arterial desaturation. (Source: Andropoulos et al. [35]. Reproduced with permission of Elsevier.)

traversing these different circulations is shown in Figure 30.20. Fontan physiology has two significant consequences that affect all Fontan patients to varying degrees: elevated CVP and diminished effective CO. As a result of these, a myriad of end-organ sequelae develop [191].

The TPG measures the pressure gradient driving blood from the central veins via the Fontan pathway through the lungs and into the common atrium. If PVR is elevated, blood flow through the lungs will be impeded, resulting in diminished ventricular filling and decreased CO. *The classic physiologic elements which control CO in a biventricular circulation – heart rate, preload, afterload, and contractility – do not do so in the Fontan circulation*. In a Fontan circulation, except for physiologic extremes such as significant tachycardia, bradycardia, or severe ventricular dysfunction, CO is determined by PBF [192].

This concept is modeled in Figure 30.21, which depicts differences between low, medium, and high PVR and the effects on CO [193]. Due to limited ventricular filling, CO in a Fontan patient is 70–80% of that expected for age and body surface area in a biventricular patient [194]. An inverse relationship exists between PVR and CO. Additionally, the benefit of increasing contractility in a Fontan circulation is limited, as greater contractility does not increase output when filling is limited.

Anesthetic considerations

Preoperative considerations

The Fontan pathway is a low-pressure system and is significantly affected by pressure elevations due to anatomic obstructions and resistance to flow. Ideal pre-Fontan characteristics include normal AV conduction, normal mean PAP, normal atrial pressure, normal systemic venous return, PVR <4 Woods units/BSA, PAs of adequate size that lack distortion, a competent AVV, and good ventricular function (see Table 30.8) [28].

Cardiac catheterization has been the traditional gold standard for preoperative assessment before the Fontan procedure, as not all SCPC patients are good candidates for Fontan completion. Criteria for cardiac catheterization include the following: patients with severe AVV or ventricular dysfunction, pulmonary vein stenosis, systemic obstruction, suspected pulmonary or SCPC obstruction, history of a complicated post-SCPC course, current oxygen saturation <75%, or suspected veno-venous or arteriopulmonary collaterals. Catheterization can provide information regarding the TPG, ventricular end-diastolic pressure, PVR, mean PA pressure, and common atrial pressure. However, cardiac catheterization is an invasive procedure utilizing ionizing radiation and, often, general anesthesia. Non-invasive imaging techniques such as cardiac MR or CT, along with echocardiography, can be used to assess low-risk patients who do not require presurgical intervention. These modalities also often require anesthesia or sedation. Fogel et al. compared the quality of information achieved in 410 patients utilizing cardiac MR, cardiac catheterization, or both. Diagnostic success was >95% in all three groups, and early post-surgical outcomes were equivalent. Significant radiation exposure was avoided in the cardiac MR patient group, but general anesthesia was used for this procedure [195].

Preoperative assessment should also include a review of the most recent cardiology visit and at-home medications. Management of anticoagulant medications often occurs in conjunction with the pediatric cardiologist. Patients whose medications include diuretics and afterload reducing agents should be advised to hold their day of procedure doses to decrease the risk of hemodynamic instability in the pre-CPB period. Additionally, information about prior sedative and anesthetic encounters, including airway management, should be ascertained.

Intraoperative considerations

Patients commonly present for Fontan completion between 18 months and 4 years, and as they have had many previous procedures, significant separation anxiety is not unusual. Anxiolysis may be achieved with midazolam, administered either orally or intranasally, or intranasal dexmedetomidine. It is helpful to review and discuss with the parents the history of the individual child's response to previous sedatives in order to choose the optimal premedication.

As with SCPC, anesthesia for Fontan completion can be induced with any of several IV or inhaled agents after the

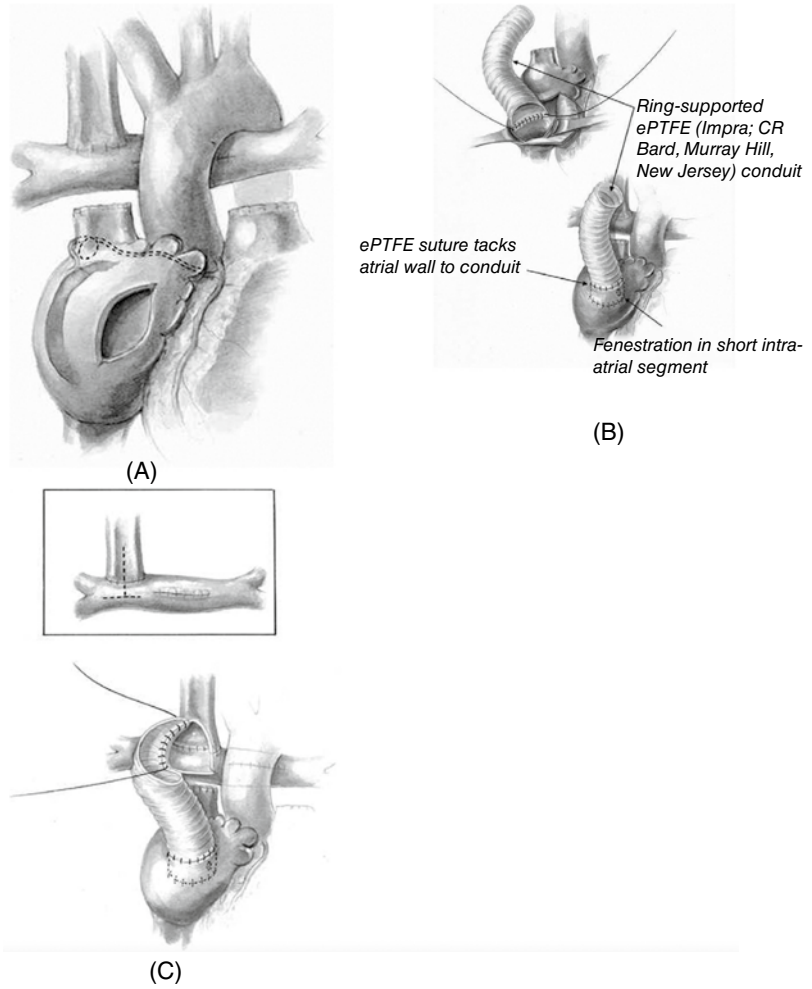

Figure 30.18 (A) The intra/extracardiac conduit fenestrated Fontan procedure incorporates an atrial incision that avoids injury to the sinus node, the sinus node artery and the crista terminalis. (B) A ring-supported ePTFE conduit is sutured to the internal orifice of the inferior vena cava. The short intra-atrial segment is fenestrated. A ePTFE suture tacks the atrial wall to the external surface of the conduit. (C) The beveled distal anastomosis of the intra/extracardiac conduit is usually fashioned to an inverted T incision that crosses the bidirectional Glenn anastomosis with extensions into the proximal and distal right pulmonary artery. application of standard non-invasive monitors and NIRS monitoring. Unless myocardial dysfunction or unusual hemodynamic loading conditions (e.g., aortic arch obstruction or AV valve insufficiency) are present, SCPC patients generally tolerate the qualitative hemodynamic effects of anesthetic agents similarly to children without CHD. However, inhalation induction is slower due to the right-to-left shunting bypassing the lungs and delaying anesthetic uptake [196]. Some anesthesiologists prefer lower extremity peripheral IV access in patients with SCPC circulation as volume infused into an upper extremity IV will travel via the SVC into the pulmonary vascular bed before entering the common atrium. However, vascular access can prove challenging in patients with multiple prior procedures, and choices for placement may be limited. Cannulation of the IJ or subclavian vein is often used for central pressure monitoring, with the recognition that in SCPC patients, this catheter will measure PA pressure. The surgical team will usually place a transthoracic monitoring catheter in the common atrium to allow TPG calculation. Centrally located catheters are frequently removed early in the postoperative period to avoid the risk of thrombosis. During the pre-CPB period, the

AL Grawany

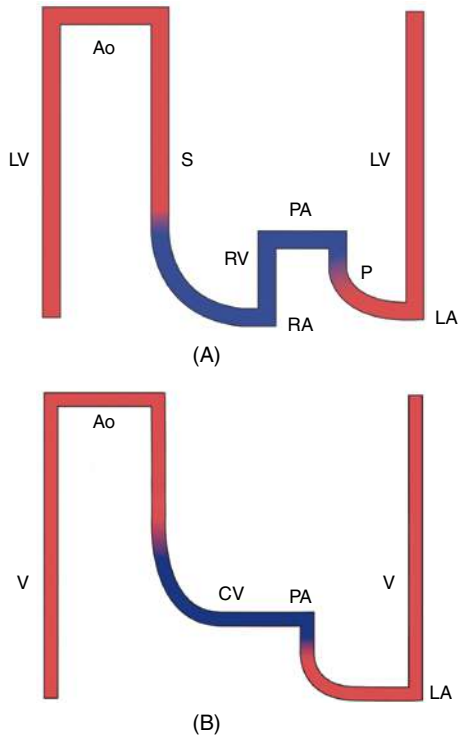

Figure 30.20 Scheme of the normal cardiovascular circulation (A), and the Fontan circulation at different stages B. (A) Normal biventricular circulation: the pulmonary circulation (P) is connected in series to the systemic circulation (S). The compliance of the right ventricle ensures that the right atrial pressure remains lower than the left atrial pressure and delivers the driving force to the blood to overcome pulmonary impedance. (B) Fontan circuit: the caval veins are directly connected to the PA; systemic venous pressures are markedly elevated. Ao, aorta; CV, caval veins; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RV, right ventricle; V, single ventricle. Line thickness reflects output, and color reflects oxygen saturation. Figure 30.21 Output at rest modulated by pulmonary vascular resistance (PVR). In a normal subject (black line), the ventricular function has little effect on cardiac output except when very poor. The principal determinant of output in patients with Fontan circulation (colored lines) is the degree of the impedance of the pulmonary vasculature resistance (PVR). The higher the PVR (at rest), the lower the cardiac output even in the presence of normal systolic ventricular function; improving systolic function will have no influence on increasing cardiac output at rest. (Source: Gewilig & Goldberg [193]. Reproduced with permission of Elsevier.)

Table 30.8 Optimal pre-Fontan characteristics

Age <15 years
Normal atrioventricular conduction
Normal right atrial volume
Mean pulmonary artery pressure </ = 15 mmHg
Normal systemic venous return
PVR <4 wood units/m² BSA
No pulmonary artery distortion
Pulmonary artery: aortic diameter ratio > / = 0.75
Competent systemic atrioventricular valve
Left ventricular ejection fraction > / = 0.6

SCPC circulation remains dependent on blood return from the SVC to provide PBF. As hyperventilation can decrease CBF, hypocarbia should be avoided and maintenance of normocarbia or mild hypercarbia should be the goal. As patients presenting for Fontan palliation have had prior sternotomies, the potential for significant bleeding upon entering the thoracic cavity exists and appropriate precautions should be in place.

A balanced technique combining inhaled sevoflurane, opioid, and neuromuscular blockade is commonly used for anesthetic maintenance. The total opioid dose is often limited to the equivalent of fentanyl 7–15 mcg/kg to facilitate the goal of sufficient emergence from anesthesia to permit tracheal extubation in the OR or soon after arrival in the cardiac ICU. Due to its analgesic and sedative properties, as well as a favorable hemodynamic profile, the use of a dexmedetomidine infusion has become the mainstay in the cardiac OR and it is frequently continued postoperatively in the ICU as well.

Epidural opioids administered via the caudal route have been used by some institutions to facilitate analgesia and early tracheal extubation. A prospective, randomized, double-blind study comparing caudal morphine (100 mcg/kg before incision) with saline placebo found no difference between groups in achieving either extubation within 30 minutes of surgical end time or freedom from reintubation within 24 hours. The authors concluded that early extubation was feasible for most patients with or without caudal morphine [197]. Recently interest has grown in using regional blocks as part of a multimodal approach to postoperative pain management in pediatric cardiac surgery patients [198]. These techniques avoid concerns regarding the risk of epidural hematoma with central neuraxial blocks in cardiac surgery patients undergoing full heparinization. However, to date, no data exist specifically examining these techniques in patients undergoing the Fontan procedure.

Children entering the OR have SCPC circulation and are cyanotic to varying degrees. The compensatory polycythemic response to cyanosis leads to higher hemoglobin levels to increase oxygen-carrying capacity, and some patients may not require a blood transfusion during the Fontan procedure. Thromboelastography or thromboelastometry are often used to measure routine coagulation parameters and guide the use of specific clotting products. The immediate results from the Fontan operation should be the improvement of systemic oxygenation, with an accompanying higher CVP. Post-CPB management should include volume resuscitation to ensure

adequate CVP to support the Fontan circulation, meticulous attention to ventilation to minimize PVR, low-dose inotropic support, and rapid restoration of hemostasis. As noted previously, PEEP is employed only as necessary at physiologic levels to preserve normal FRC. The Fontan operation is well tolerated by the majority of children. Despite this usual stable course in the operating room, some Fontan patients have prolonged chest tube drainage postoperatively, which can lengthen hospital stay. Vasopressin infusion started in the operating room after CPB and continued for 24–48 hours postoperatively has been reported to reduce chest tube drainage, transpulmonary gradient, postoperative fluid administration, and days chest tubes are indwelling [199, 200]. A number of institutions have added vasopressin to their immediate postoperative regimen for the Fontan operation.

Positive pressure ventilation increases intrathoracic pressure, causing a decrease in central venous inflow. Spontaneous ventilation increases central venous filling, increasing blood flow through the Fontan pathway into the lungs. The avoidance of prolonged postoperative PPV should be a routine strategy for patients with Fontan physiology. In a retrospective study, the duration of CPB did not impact the ability to safely extubate patients within 6 hours post-Fontan. The early extubation group had higher mean arterial pressure and lower mean pulmonary pressure at 6, 24, and 48 hours postoperatively compared with the group with prolonged intubation, leading the authors to conclude that early extubation should be a primary aim to improve postoperative Fontan outcomes [201]. Another retrospective study examined 253 patients before and after a programmatic change to extubate all Fontans within 12 hours postoperatively regardless of hemodynamic status, challenging a standard convention of avoiding early extubation in less stable patients. "Instability" was defined as having higher postoperative inotropic scores and volume requirements. Successful extubation was possible in all patients, although a higher reintubation rate was observed in unstable patients. Extubation in the unstable patients ($n = 50$) led to an acute rise in mean arterial pressure and decreases in the inotropic score and volume requirement [202].

Postoperative considerations

Diminished PBF after the Fontan operation will cause reduced CO, unlike SCPC physiology, in which decreases in PBF result in reduced systemic oxygen saturation. Extreme vigilance is required to maintain adequate intravascular volume in the setting of ongoing blood loss in the early postoperative period. Avoidance of any elevation in PVR is essential. A fenestration may ameliorate some early postoperative hemodynamic instability but will lead to arterial desaturation as deoxygenated blood in the Fontan pathway shunts right-to-left into the common atrium, effectively adding ventricular preload. The use of low ventilatory pressures with early extubation should be the aim.

Systemic oxygenation saturation should be near normal in the postoperative period in a patient without a fenestration. A modest degree of hypoxemia can be expected due to a fenestration along with coronary sinus blood flow, which usually enters the common atrium on what is functionally the pulmonary venous side. Persistent systemic oxygen saturation less than 85–90% can result from one or more of the following causes: (i) greater fenestration flow than anticipated; (ii) lung pathology; (iii) venovenous collaterals; (iv) PAVMs causing intrapulmonary shunting; or (v) increases in oxygen demand as seen with decreased CO or sepsis. Differentiating between these concerns can require cardiac catheterization.

Myocardial dysfunction typically follows the same differential described previously for post-SCPC. Hemodynamic etiologies should be investigated and corrected. However, myocardial dysfunction may also occur as the result of inadequate myocardial preservation, coronary perfusion, or a metabolic process. In the absence of correctable causes such as hypocalcemia, supportive measures represent the mainstay of therapy. Postoperative arrhythmias can occur, and while heart block is uncommon, junctional rhythm may occur in up to 25% of patients. If the escape rate is low enough to cause hemodynamic instability, the use of epicardial, atrial, or AV pacing usually proves beneficial. Tachyarrhythmias are less common in the early postoperative period but are more likely to have a negative hemodynamic impact when present. Doppler interrogations of PBF patterns suggest that diastolic flow is best under normal circumstances [203], perhaps explaining the intolerance of tachyarrhythmias. Alternatively, unfavorable hemodynamics may serve to provoke tachyarrhythmias. Table 30.9 presents the differential diagnosis for low SpO_2 and blood pressure in the postoperative Fontan patient.

Several risk factors have been identified that can predict prolonged ICU length of stay, which is, in turn, associated with late mortality and the need for late cardiac reoperation. Pre-existing anatomic risk factors include HLHS, anomalous systemic venous drainage, heterotaxy, and systemic RV. Preoperative predictive factors are higher preoperative hemoglobin and low preoperative oxygen saturation, elevated PAP, and high preoperative TPG. Identified postoperative risk factors include pleural effusion, chylothorax, ascites, and infection [204–206].

Long term complications and outcomes

Long-term survival has improved significantly since the Fontan procedure was initially described in 1971 [1]. Early atriopulmonary Fontan patients have demonstrated worse long-term outcomes than those with the contemporary forms of TCPC, with a recent study describing only 45% of atriopulmonary Fontan patients free from heart failure, transplantation, or death at 28-year follow-up [207]. Patients undergoing Fontan completion in the current era have an approximate 30-year survival of 85% [208]. However, the quality of these years can be variable, with half of the patients experiencing a major adverse event before 14 years of age [209]. However, a recent study from the Australia and New Zealand Fontan Registry examined patients without a single complicating event before age 16; this included nearly 75% of their Fontan population. Survival in this group was 94% at 30 years, and projection models suggested potential survival for this low-risk cohort at 60 years to be 49–67% [210].

A meta-analysis evaluating risk factors for late Fontan failure and death found >80% of patients alive 20 years post-Fontan. Risk factors for late death included PLE, increased

AL Grawany

Table 30.9 Hemodynamic status and differential diagnosis of abnormalities in the postoperative Fontan patient

Status	PAP (mmHg)	LAP (mmHg)	TPG (mmHg)	Systolic BP (mmHg)	SpO_2	Etiology
Normal	10–15	2–6	<10	85–95	95 ± 5	Ideal status
Decreased PAP and LAP	8–10	0–4	<10	<80	90 ± 5	Hypovolemia
Elevated PAP	>15	2–6	>10	80 ± 5	90 ± 5	High PVR; PA or PV obstruction

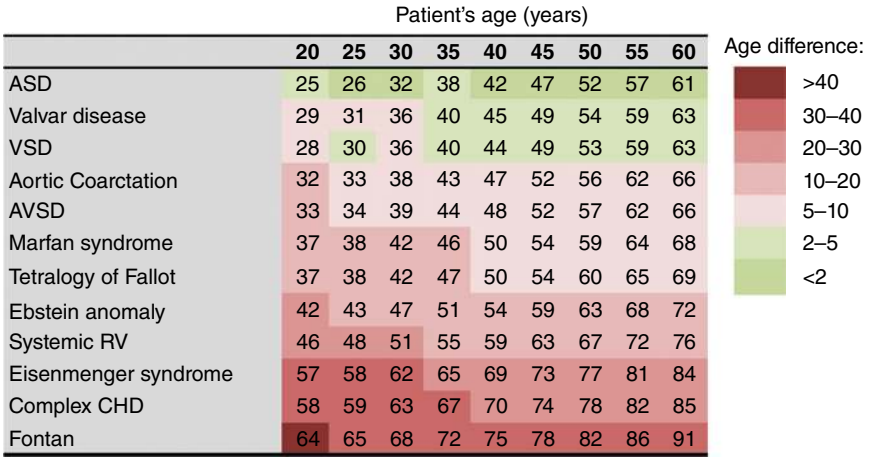

Figure 30.22 Mortality in subgroups of patients compared with mortality in the age-matched United Kingdom (UK) population. Numbers on the colored surface present the equivalent age – expressed as the age of subgroup of UK population, having similar 5-year mortality rates. Colors reflect the difference between the relative age and the actual age of patients. The curved line corresponds to the 5-year risk of death of the general UK population according to life table data. ASD indicates atrial septal defect; AVSD, atrioventricular septal defect; CHD, congenital heart disease; RV, right ventricle; and VSD, ventricular septal defect. (Source: Diller et al. [212]. Reproduced with permission of Wolters Kluwer Health, Inc.)

end-diastolic volume (as a surrogate for ventricular dysfunction), and the need for a pacemaker. Causes of death were late Fontan failure (34%), sudden death (19%), and perioperative death (16%). Survival post-Fontan at 5, 10, and 20 years was 95, 91, and 82% [211]. Overall, in calculating life expectancies for congenital heart defects, the life expectancy for a 20-year-old Fontan patient was estimated to be equivalent to that of a 64-year-old without heart disease [212] (see Figure 30.22).

Significant morbidity in Fontan patients can include heart failure, AVVR, arrhythmias, thrombotic events, lymphatic dysfunction causing PLE and plastic bronchitis (PB), chronic venous insufficiency, renal disease, Fontan-associated liver disease (FALD), and neurocognitive and psychosocial issues. An increase in PVR normally occurs with aging, and for Fontan patients, this has significant implications. Increased filling pressure accompanying the increasing PVR over time can lead to more substantial decreases in CO and Fontan failure, as shown in Figure 30.23 below [213].

Heart failure can be classified as either classic pump failure or failure of the Fontan circulation with elevated CVP and diminished CO but preserved function. Many patients have elements of both. Heart failure predicts poor outcomes, with a 1-year mortality of 24% and 3-year mortality of 35% [214]. Evidence is lacking to support the use of standard heart failure medications in Fontan patients, and concerns exist that vasodilators and diuretics could worsen heart failure in patients with Fontan physiology. However, afterload reduction agents and diuretics are widely used to treat Fontan failure [215]. A study examined sildenafil in a double-blinded, placebo-controlled, crossover trial of 27 healthy Fontan outpatients, finding that global ventricular performance and measures of CO improved, although diastolic function did not change [216]. Phosphodiesterase-5 inhibitors and endothelin-1 inhibitors are commonly used to treat Fontan failure.

Atrioventricular valve regurgitation contributes to long-term morbidity and mortality in Fontan patients, causing

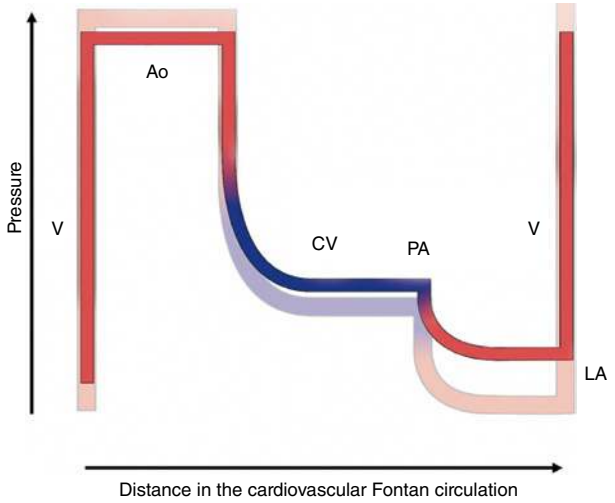

Figure 30.23 Flow/pressure/saturation diagram of the Fontan circulation: changes over time. Fontan haemodynamics late (full color) superimposed on Fontan early (transparent): with time the ventricular end-diastolic pressure and pulmonary vascular resistance increase, resulting in overall decreased flow and increased caval vein pressure/congestion. A downward progressive spiral ensues. Ao, aorta; CV, caval veins; LA, left atrium; PA, pulmonary artery; V, single ventricle. (Source: Gewillig et al. [213]. Reproduced with permission of John Wiley & Sons.)

Fontan failure at twice the rate compared with patients who do not have AVVR. One third of patients will require AVV repair by age 30 years. Atrioventricular valve regurgitation can lead to ventricular dysfunction or may itself be caused by ventricular failure. Diuretics and afterload reducing agents are frequently utilized, although solid evidence for this therapy is lacking. Optimal timing of valve repair and when and if valve replacement should occur remain unknown [217].

Arrhythmias are a common complication of Fontan surgery, with a recent study finding an incidence of 18.9% [218]. In the early postoperative period, AVVR is a risk factor for arrhythmias, and later, older age at Fontan and high PAP become predictors [219]. Arrhythmia development is an independent risk factor for late Fontan failure and has not been shown to be related to the type of Fontan (LT or ECC). Forty percent of patients with arrhythmias developed reduced ventricular function within 10 years. Ablation was effective, with 50% of patients arrhythmia-free at 10 years post-ablation [218]. Up to 25% of patients with a Fontan require epicardial pacing to manage late arrhythmias [220].

The incidence of thrombosis in one study of 111 patients was 31% at 2.5 years. The risk of thrombosis is highest immediately postoperatively, but the ongoing lifelong risk exists. Prolonged presence of a central line, uncontrolled warfarin use, and lower fraction of inspired oxygen use are all risk factors for postoperative thrombosis [221]. Many cardiologists treat low-risk Fontan patients with antiplatelet medications and add warfarin for higher-risk patients. Currently, standardized anticoagulation guidelines are lacking.

Fontan-associated liver disease is likely related to chronically high CVP and diminished effective CO. Hepatic stiffness has been shown to occur immediately after the Fontan operation [222]. The liver, despite its dual blood supply, can be compromised when decreased CO results in decreased hepatic arterial flow as the portal system cannot compensate due to a lack of autoregulation. The liver may then be especially susceptible to hemodynamic insults [223]. Liver biopsy remains the gold standard for assessing liver dysfunction. However, this is an invasive procedure and incurs the risk of bleeding as well as sedation and anesthesia risks. A recent study using ultrasound-guided percutaneous liver biopsy in patients at least 10 years post-Fontan demonstrated that hepatic fibrosis is a universal characteristic of Fontan physiology. Fontan hemodynamics, ventricular function, and AVVR were not associated with the degree of fibrosis [224]. Over time, hepatic fibrosis may progress to cirrhosis and hepatic failure. In another study of prospective hepatic screening for Fontan patients >18 years old, 50% were found to have varices, and 25% had hyper-enhancing liver nodules. Routine imaging, elastography, and biomarkers were unable to assess the severity of liver fibrosis accurately [225]. Hepatocellular carcinoma has been reported in young Fontan patients. These findings indicate that ongoing hepatic surveillance is necessary for Fontan patients, but no consensus guidelines currently exist.

The renal system is at risk as well, with a retrospective study showing that acute kidney injury (AKI) was present in 42% of patients post-Fontan. Independent predictors of AKI included lower renal perfusion pressure and higher inotrope score [226]. Using a stringent AKI definition in a prospective study of adult patients with an average age of 28.4 years, 46% had evidence of chronic kidney disease, suggesting that long-term follow-up of renal function in Fontan patients is also essential [227].

Patients with Fontan circulation might also be expected to experience a range of psycho-social- neurocognitive challenges due to frequent hospitalizations and surgeries and the effects of living with a chronic disease. A recent meta-analysis examining patients and parent-proxies reporting on the quality of life of children, adolescents, and adults with Fontan physiology showed that health-related quality of life (HRQOL) was lower in patients with Fontan physiology than the general population, with the most significant differences being physical functioning and school/work functioning. Older age at the time of Fontan was associated with worse emotional HRQOL, and HLHS was associated with lower social HRQOL [228].

Protein-losing enteropathy and plastic bronchitis

Protein-losing enteropathy (PLE) and PB are two relatively rare complications with a combined incidence of 4.9% at 30 years and 7.4% at 35 years post-Fontan operation. Freedom from death or transplantation at 5, 10, and 15 years after diagnosis was 70, 65, and 43%, respectively [229]. Protein-losing enteropathy causes leakage of protein-containing lymphatic fluid into the intestinal lumen. Specific loss of albumin, anticoagulant proteins, and immunoglobulins can result in ascites, malnutrition, thrombosis, and infection. Plastic bronchitis is characterized by leakage of proteinaceous lymphatic fluid into the bronchial tree. This leakage can solidify into casts, which are then coughed out or can result in airway obstruction. Patients typically have a chronic cough and

hypoxemia. With the onset of either PLE or PB, evaluation of the Fontan circulation should be undertaken to rule out any anatomic obstructions. Pulmonary vasodilators, along with diuretics, may be used to treat both PLE and PB.

The altered hemodynamics of patients with Fontan physiology affect the morphology and function of the lymphatic system, rendering this population prone to the development of lymphatic complications, including PB, PLE, chylous pleural effusions, and ascites. The primary circulatory role of the lymphatic system is to transport fluid from the tissues back to the venous system via lymphovenous connections. Despite awareness of this role for many years, lymphatic flow pathophysiology has been poorly understood due to a lack of reliable non-invasive lymphatic imaging techniques. This has limited treatment options, resulting in significant morbidity and mortality. Two specific factors exist and contribute to pathologic findings: increased lymph flow in patients with chronically elevated CVP due to BDG, HF, or Fontan physiology, and lymphatic anatomical variants that allow lymph flow near serous (pleural space in chylothorax) or mucosal (PB, PLE) surfaces. Recently developed intranodal (inguinal, liver, and mesenteric) lymphangiography and dynamic contrast-enhanced MR lymphangiography have enabled visualization of the central lymphatic anatomy and flow dynamics with high resolution, enabling elucidation of the mechanism behind these conditions.

In patients with PB imaging demonstrates retrograde lymphatic flow from the thoracic duct (TD) toward the lung parenchyma. Embolization or TD stenting with covered stents to exclude retrograde flow to the lungs and eliminate lympho-bronchial airway communication has resulted in durable remission of the disease, including at least temporary cessation of cast formation in a high percentage of patients [230] (see Figure 30.24). In patients with PLE, liver lymphangiography demonstrates leakage of liver lymph into the duodenum through abnormal hepatoduodenal lymphatic communications. Liver lymphatic embolization with lipiodol (ethiodized oil) or glue (cyanoacrylate) has resulted in improvement of symptoms and an increase in serum albumin levels in a significant number of patients [231].

Although embolization of abnormal lymphatics has improved outcomes for some, alternative treatment strategies have been proposed to enhance lymphatic drainage while leaving the lymphatic system intact. Diverting lymph drainage to the low-pressure pulmonary venous atrium is one treatment that may also prevent or decrease end-organ fibrosis or failure, although at the expense of increased cyanosis. This has been accomplished via catheter-based or surgical re-routing of the innominate vein and TD to the low-pressure atrium (Figure 30.25) [232]. The micro-surgical creation of lymphovenous anastomoses is another treatment option.

Consideration should be given to using T2 weighted MR imaging sequences to assess lymphatic perfusion abnormalities in all patients after completing the SCPC to risk-stratify patients before Fontan. Patients with high-grade lymphatic abnormalities had six times greater odds of developing early lymphatic complications, longer lengths of stay, and an increased likelihood of Fontan failure [233]. Prophylactic innominate vein turndown may be considered at the time of the Fontan for patients who are at high risk for lymphatic complications. If imaging is not feasible or deemed not necessary in all patients, imaging should be applied early in the course of symptomatic lymphatic disorders, which may prevent progressive debilitation when these complications go untreated.

Anesthetic considerations for lymphatic intervention

Many of the current population presenting for lymphatic procedures have had lymphatic flow abnormalities for months or years that have been unresponsive to medical therapies. As a result, many have a significant functional impairment and poor quality of life due to longstanding lymphatic loss and replacement. The outcome for these patients without effective treatment is increasing morbidity and, for some, death.

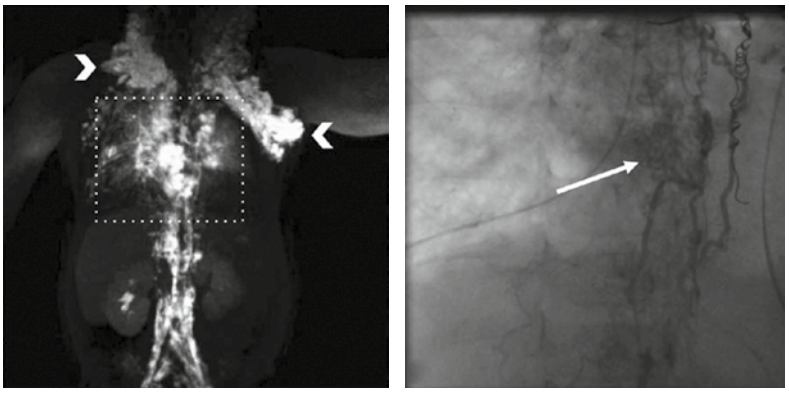

Figure 30.24 MIP of DCMRL (A) and lymphangiogram (B) images of the central lymphatic system of a patient with type 5 PB. (A) MIP of the DCMRL shows diffuse perfusion of both lung fields (box). Also seen are the filling of cervical and left-sided axillary lymphatic networks (arrow heads). (B) No identifiable TD is seen, but, instead, multiple dilated ducts are seen supplying both lungs (arrow). DCMRL indicates dynamic contrast-enhanced magnetic resonance lymphangiogram; MIP, maximum intensity projection; PB, plastic bronchitis; and TD, thoracic duct. (Source: Dori et al. [230]. Reproduced with permission of Wolters Kluwer Health Inc.)

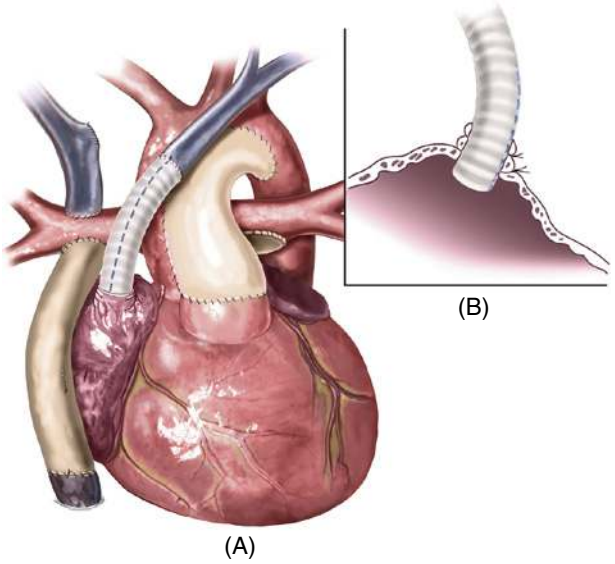

Figure 30.25 Innominate vein turndown with an interposition graft. (A) Graft from distal innominate vein to right atrial appendage with a ringed polytetrafluoroethylene graft. (B) "Dunk" technique with 3–4 rings inserted inside the atrium to prevent obstruction. This technique can also be accomplished without a graft by direct anastomosis to the left atrial appendage. Postoperative system oxygen saturations often decrease by about 5% due to the creation of a veno-venous shunt. (Source: Hraska et al. [232]. Reproduced with permission of Elsevier.)

Thus, practitioners, patients, and families are willing to accept the risks of anesthesia and lymphatic interventions.

Assessment of intravascular fluid volume status is essential in patients with drainage tubes for pleural effusion or ascites and those receiving diuretics. Failure to correct hypovolemia will result in systemic hypotension due to vasodilation from anesthetics and reduction of venous return from PPV. Many patients with ongoing drainage have resultant hypoalbuminemia, resulting in partial protein binding and increased free drug with consequent greater potency. Chronic steroid therapy can result in adrenal suppression, and these patients require stress-dose steroids before anesthesia.

An essential component of anesthetic management involves preventing patient movement that could dislodge precisely placed needles or catheters during imaging, intervention, or transport of patients between catheterization laboratory or interventional radiology suite and MRI. Sedation alone is not adequate due to the duration of the procedures and respiratory and circulatory compromise from lymphatic pathology and other comorbidities. Concurrent ancillary procedures, including cardiac catheterization, bronchoscopy, endoscopy, vascular access, and drain placement, also require general anesthesia. Given these considerations, general endotracheal anesthesia with neuromuscular blockade is preferred. Casts in patients with PB can completely obstruct the trachea or endotracheal tube after induction of anesthesia, and consideration should be given to routine bronchoscopy and removal of casts immediately after intubation. A urinary drainage catheter is placed to prevent bladder distention and increased abdominal pressure during lengthy procedures. It is also helpful as cardiac catheterization with angiography is performed, and a full bladder may obstruct visualization of the lower pelvic lymphatic pathways. Careful body positioning and pressure point padding are necessary as later adjustments cannot be made once needles are placed in the lymph nodes. Monitoring and maintenance of body temperature are critical. Administration of IV antibiotics before needle placement and interventions is necessary due to trans-abdominal passage of needles through the gastrointestinal (GI) tract.

Access to both radiologic imaging and MRI requires the transportation of anesthetized patients. When separated by distance, IV anesthesia and manual ventilation along with a transport monitor are used. A wheeled transport table mated to both the X-ray and MRI tables maintains patient immobility. Scheduling must be coordinated among multiple disciplines, including anesthesia, radiology, cardiology, and depending on the lymphatic issues, pulmonary and gastroenterology.

Post-procedure, it is recommended that all patients undergoing lymphatic intervention be admitted to the ICU for observation as an escalation of care or complications (fever, hypotension, bleeding, stroke) occur in approximately 25% of patients in the first 24 hours post-procedure [234]. In most patients, postprocedural mechanical ventilation is unnecessary unless it was required preprocedurally. Abdominal pain is common after trans-abdominal needle passages. Patients are monitored for infection and bleeding from needles passing through intra-abdominal blood vessels, liver, GI tract, and bile ducts. A percentage of patients will manifest a systemic inflammatory response requiring IV fluids, inotropic agents, and/or vasoconstrictors for stabilization. Neurologic status is monitored for systemic embolization of endovascular glue or lipiodol in patients with right-to-left shunts.

Pregnancy

Up to 70,000 patients with a Fontan circulation are estimated to be alive today, with that number expected to double in 20 years. For women with Fontan physiology, common maternal cardiovascular events during pregnancy can include supraventricular arrhythmias (8.4%) and heart failure (3.9%), with heart failure also occurring in the postpartum period. One study found that most (89%) received anticoagulant therapy, and Caesarean-section was performed in 57.1% of pregnancies. Fifty-nine percent of the babies were premature, 20% were small for gestational age, and 5% died in the neonatal period. Further reviews with larger patient populations and longer follow-up are needed to assess late sequelae of pregnancy in Fontan patients [235]. Further discussion of pregnancy after Fontan operation is presented in Chapter 20.

Mechanical circulatory support

Interest and experience continue to grow regarding MCS as a bridge to transplant or as destination therapy for failing Fontan patients, but no large studies exist offering established guidelines for MCS use in this population. Mechanical circulatory support is indicated when the Fontan circulation has failed to maintain adequate oxygenation and CO despite maximal medical therapy. Ideally, with MCS, improvement can occur in end-organ, nutritional, and physical function which will improve the patient's health and likely make cardiac transplantation more successful

AL Grawany

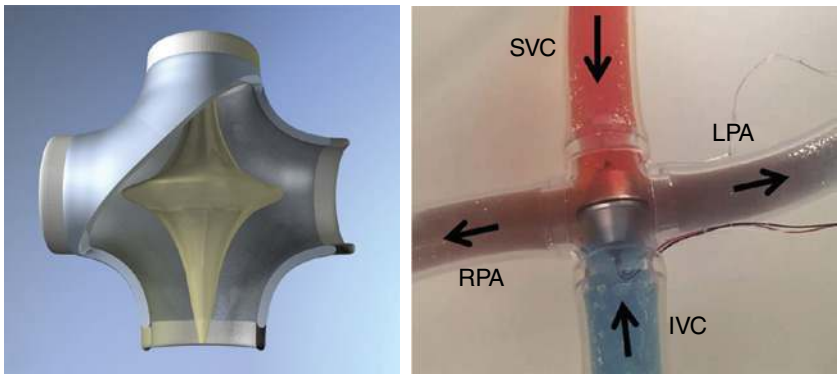

Figure 30.26 Implantable cavopulmonary assist device. (A) Conceptual image. A central impeller contains the motor (impeller support shaft and struts not shown). The external housing is a thin-walled, hard case shell that has no component bulk and serves only to direct Fontan flow. The wide gap between the impeller and the housing must support passive total cavopulmonary connection flow at low resistance in the event of device dysfunction. (B) Advanced prototype image depicting pump function. Color contrast demonstrates superior vena caval (SVC) flow (red) and inferior vena caval (IVC) flow (blue) mixing to both left pulmonary arterial (LPA) and right pulmonary arterial (RPA) outlets (purple). (Source: Rodefeld et al. [237]. Reproduced with permission of Elsevier.)

[236]. Due to patient variability, each patient must be considered individually. Patients with ventricular dysfunction may benefit from a ventricular assist device (VAD), while patients with preserved ventricular function but circulation failure may benefit from a total artificial heart (TAH). Extracorporeal membrane oxygenation may offer a temporary solution. Future options may also include a cavopulmonary assist device. One such device currently being developed is a rotary motor placed into the Fontan pathway to propel blood through the pulmonary circulation (see Figure 30.26) [237].

Specific anesthetic goals, similar to managing any patient with poor ventricular function, include cautious use of induction agents, use of a balanced technique (narcotic, low levels of inhalational agent, and dexmedetomidine), and readiness to treat hemodynamic instability. As patients have previously had multiple sternotomies and have poor functional status and high bleeding potential, these surgeries are complicated and lengthy. Weaning from CPB should include the use of TEE to ensure a nondilated, well-filled ventricle with CVP in the low teens and mean arterial pressure in the 60–70 mmHg [238]. The use of coagulation products is guided by thromboelastography or thromboelastometry. Post-VAD placement, PBF can be maintained with the use of iNO and milrinone. Hemodynamics may be supported with norepinephrine, epinephrine, and, if necessary, vasopressin. The goal should be to achieve early postoperative spontaneous ventilation and early extubation if possible [239]. Patients with MCS are often anticoagulated with heparin or unfractionated heparin. More recently, bivalirudin, a competitive, reversible thrombin inhibitor that prevents thrombin activation of fibrinogen to fibrin, has been used. Bivalirudin may be administered as a continuous infusion with dosing based on PTT [240]. After the immediate postoperative period, patients are often transitioned to warfarin and aspirin. A reasonable estimate of survival in a Fontan patient requiring MCS is about 60% [238]. See Chapter 37 for further discussion of mechanical circulatory support.

Cardiac arrest in the Fontan patient

Survival after cardiac arrest in a patient with Fontan physiology is approximately 60% [119]. This low survival is likely due to specific characteristics of the Fontan circulation. Maintenance of some coronary and cerebral pressure during CPR is essential to minimize neurologic injury and mortality. However, in a Fontan patient, during chest compressions, CVP increases, with a resultant decrease in CPP as well as a decrease in venous return. The reduction in venous return will decrease flow through the pulmonary vasculature, decrease ventricular filling, and ultimately decrease CO. In addition, the acidosis which occurs during CPR will cause elevations in PVR, further limiting PBF. Conversion from CPR to ECMO can be challenging in a Fontan patient and almost impossible to perform expeditiously via central vessels in a patient with a well-healed sternum. Peripheral cannulation is difficult due to access-related issues and the need to cannulate both upper and lower extremity venous vessels to decompress the Fontan pathway. Although it may be performed instead of central cannulation it may not allow the adequate circuit blood flow required with a failing, non-ejecting ventricle. As CPR and emergent use of ECMO have poor outcomes, early elective ECMO cannulation should be considered if the potential for reversibility exists. In a study of 230 Fontan patients experiencing cardiac arrest, 35% survived to discharge [241]. See Chapter 25 for further discussion of cardiac arrest and resuscitation.

KEY POINTS: FONTAN COMPLETION

- The Fontan, or TCPC, is the final palliation for single-ventricle anatomy and is normally performed at 18 months to 4 years of age.
- The two contemporary Fontan configurations utilized are the intra-atrial lateral tunnel and the extracardiac conduit.

- A fenestration can be created to lower cavopulmonary pressure and improve systemic CO, at the expense of some arterial desaturation.
- PPV, hypovolemia, and loss of AV synchrony are all detrimental to the Fontan circulation because of the lack of a pulmonary ventricle.
- The classic physiologic elements which control CO in a biventricular circulation – heart rate, preload, afterload, and contractility – do not do so in the Fontan circulation. In a Fontan circulation, except for physiologic extremes, CO is determined by PBF

Transplantation for single-ventricle patients

Heart transplantation

Single-ventricle physiology remains the most common subset of CHD requiring heart transplantation, with failing Fontan physiology now the predominant indication for orthotopic heart transplantation (OHT) in children and adults with CHD [242]. It is currently predicted that the heterogeneous group of SV patients will ultimately account for 70–80% of OHT in patients with CHD [243]. Due to the scarcity of cardiac donors, particularly for infants, initial surgical or hybrid palliation continues to be the mainstay in the management of functional SV patients. The number of pediatric heart transplants continues to increase each year, with infants <1 year of age accounting for the largest number of transplants and HLHS remaining the most common diagnosis for infants undergoing OHT for CHD [244, 245]. Continued experience and success with ABO-incompatible infant and pediatric cardiac transplantation should assist in enlarging the list of potential donors for patients who require transplantation [246].

A significant percentage of patients with HLHS experience long-term ventricular failure, and some are listed for orthotopic heart transplantation (OHT) even though the initial intention was to pursue the full Fontan palliation pathway. Patients with SV physiology may present for OHT at a wide range of ages and at various palliative stages. Risk factors for heart transplant listing after the Norwood operation include worse RV function, complicated post-surgical course, and diagnosis other than HLHS [247]. The need for transplant before stage II palliation in HLHS patients is associated with poorer waitlist survival, with patients with an mBTTS faring worse than those with an RV-PA shunt. Post-transplant outcomes were unaffected by shunt type [248]. Tweddell et al. identified other risk factors for intermediate-term mortality after transplant in infants with HLHS, including lower socioeconomic status, comorbid genetic syndromes, lower gestational age, and RV function/anatomy [249].

Murtuza et al. reported on 16 OHTs in HLHS patients from a single center from 2000 to 2011 and compared outcomes of these patients with 154 patients who underwent OHT for cardiomyopathy [250]. The 30-day survival was 100% in the HLHS group vs. 98.1% in the 154 patients transplanted for cardiomyopathy, and there were 1- and 5-year Kaplan–Meier survival rates of 100% for HLHS and 87.5% for the cardiomyopathy group ($P = 0.393$). The authors concluded that early and mid-term survival rates are good after OHT in HLHS patients and that transplantation should be a consideration early in HLHS patients with systemic ventricular failure. However, according to the Pediatric Heart Transplant Study database, infants ≤6 months old with HLHS had worse 1-year survival after transplantation than those with cardiomyopathy or other CHD. Infants with HLHS transplanted prior to surgical palliation had a 1-year survival of 79% ($n = 303$), while those who failed surgical palliation had a worsened survival of 70% ($n = 69$) [245].

Refractory Fontan failure may take two forms and ultimately may require OHT. Patients may have Fontan failure as a result of primary ventricular dysfunction; these patients tend to have normal PVR. Fontan failure may also occur with preserved ventricular function but failing Fontan physiology (high Fontan pressures, ascites, PLE and/or PB), and these patients tend to have elevated PVR. A multi-institutional study identified PLE as the reason for OHT in 23% of post-Fontan patients and primary ventricular dysfunction in 31% [251]. Earlier listing for Fontan patients with circulation failure may prevent the associated end-organ comorbidities from developing, which, in turn, may increase the survival post-transplant [252]. Historically, Fontan patients who underwent cardiac transplantation had decreased survival. However, a 2017 Pediatric Heart Transplant Society database study demonstrated that between 2007–2014, 1-year survival for Fontan patients after cardiac transplantation improved to 89%, similar to children with other forms of CHD (92%) [253]. Another study identifying risk factors for post-transplant mortality in Fontan patients found that Model for End-Stage Liver Disease Excluding INR (MELD-XI) scores, history of PLE, and having a VAD at the time of transplant were independent predictors for postoperative mortality [254]. Perioperative management for a failing Fontan should recognize the cardiac depressant effects of induction medications and volatile agents. Anesthetic medications combined with PPV can decrease PBF, ventricular filling, and CO. The anesthesiologist should be prepared to treat significant bleeding, hypotension, and arrhythmias during transplantation [255]. Epinephrine, milrinone, norepinephrine, and vasopressin may be required to wean from CPB, and iNO is frequently used to lower PVR. Bleeding may be robust, and ROTEM and TEG are often used to guide therapy.

Details of cardiac transplantation are discussed in detail in Chapter 32.

Post-Fontan heart-liver transplantation

The decision to perform a heart transplant versus a combined heart liver transplant (CHLT) requires careful consideration. The degree of liver dysfunction or cirrhosis present to prompt CHLT is not known. One study, examining seven patients with Fontan failure who underwent CHLT, used evidence of fibrosis or cirrhosis by imaging or biopsy to determine the need for the liver transplant. The CHLT was performed with the heart implanted first; then, the liver was inspected grossly, followed by choosing whether to proceed with liver transplantation. Patients in this study had 100% 1-year survival [256]. Benefits of CHLT with both organs from the same donor include likely immune protection of the heart by the liver, antigen exposure reduction and decreased chronic rejection, and less coronary graft vasculopathy.

In another study, patients were treated with an *en bloc* CHLT. The decision to perform CHLT over heart transplant alone was based on biopsy and imaging of the liver when possible and after multidisciplinary evaluation to determine liver health. With careful coordination between the cardiac surgery team and the liver transplant team, the heart and great vessels are dissected out while the liver vascular structures are dissected out, and the liver mobilized from the retroperitoneum. The aorta is then cannulated, and cross-clamped and the organs are removed *en bloc*. The implantation begins with the left atrial connection, followed by the IVC. The two teams independently and simultaneously proceed with the implantation. The patient is weaned from CPB when both organs are functioning well, and lastly, the biliary anastomoses are completed. Median blood loss was 6 (2–20) liters, intensive care stay was 19 (5–96) days, and hospital length of stay was 29 (13–197) days. Two patients required an intra-aortic balloon pump, and one required veno-arterial ECMO. All nine patients were alive at 1 year after treatment. Benefits of *en bloc* CHLT include less reperfusion injury to the heart and decreased liver ischemic time compared with sequential CHLT [257].

Non-cardiac surgery and anesthesia for the patient with a single ventricle

Single ventricle patients not infrequently require anesthesia or sedation for procedures other than cardiac surgery. Feeding difficulties are common after the neonatal palliation stage, and many of these patients require gastrostomy tube feeds along with fundoplication. If a procedure is elective, the period after SCPC and before Fontan completion confers a more stable circulation, free from cardiac volume load and delicate balance of Qp: Qs in the shunted SV, and also avoiding Fontan physiology with the harmful effects of PPV and hypovolemia. Fasting time should be minimized, and IV fluids should be optimized to maintain intravascular volume. For patients with Fontan physiology, the ventilatory strategy should include maintaining low pulmonary pressures, minimizing inspiratory pressure, allowing for adequate expiratory time, and avoidance of excessive PEEP. It should be recognized that there is no way for an anesthesiologist to measure a filling pressure percutaneously in a Fontan patient. A study examining complications after non-cardiac procedures in adult Fontan patients found a 15% rate of complications, with baseline cyanosis the only multivariable risk factor identified. The most common complication was hypoxia, and mortality was low at 0.2% [258]. Non-cardiac anesthetics for single-ventricle patients are discussed extensively in Chapter 35.

Summary

Patients with SV physiology undergo staged palliative surgical procedures and also require additional anesthetics for diagnostic procedures, cardiac catheterization, imaging, and non-cardiac surgery. Further surgical or catheter-based interventions are often necessary after Fontan completion. An increasing number of the steadily growing adult population of Fontan patients may ultimately require transplantation. Single-ventricle patients comprise a large proportion of the anesthetic population for the pediatric cardiac anesthesiologist in the modern era at major centers. At Texas Children's Hospital, this proportion was 16.7% of anesthetics for cardiac surgery provided by the Division of Pediatric Cardiovascular Anesthesiology from 2014 to 2021 (data from the Congenital Cardiac Anesthesia Society/Society of Thoracic Surgeons Database provided by David Vener, MD).

Planning anesthetic management for SV patients requires careful assessment to ensure a complete understanding of the typical physiology at each stage of the reconstructive sequence, the specific condition of each patient with respect to that physiology, and the impact that the proposed procedure is likely to have. Optimal results entail good communication and carefully orchestrated interactions between anesthesiologists, surgeons, cardiologists, and intensivists.

Introduction

The congenital cardiac anesthesiologist is often faced with caring for patients with lesions and diseases that do not fit neatly into the anatomic and surgical classifications presented elsewhere in this book. This chapter presents vascular rings, coronary artery anomalies, pericardial effusion and tamponade, mitral regurgitation (MR), cardiac tumors, aortic aneurysm and aortopathy, and mediastinal masses. The anatomy, incidence, and natural history are reviewed for all lesions, followed by a discussion of pathophysiology. The surgical approach and outcomes are discussed next, and finally, anesthetic considerations and approaches are presented for each lesion.

Vascular rings

Classification, anatomy, and incidence

Vascular rings have a reported incidence of between 1 in 1,000 births and 1 in 10,000 births [1, 2]. The abnormalities develop from aberrations of the resorption of the six embryonic aortic arches that connect the primitive dorsal and ventral aorta. Normally, the left part of the fourth arch persists as the aortic arch. The persistence of the right part creates a right arch, while the persistence of both parts of the fourth arch creates a double aortic arch. When these arch abnormalities form a ring, partial in some cases, they may produce either esophageal or tracheal compression or obstruction. Chapter 6 presents an extensive discussion of the

embryology of congenital cardiac and vascular defects. The presence of a complete ring would appear to provide an anatomical explanation for obstruction of the encircled structures, but the relationship between symptoms and the ring and whether it is open or closed is complex and varies with the subgroups of lesions. A comprehensive classification of vascular rings is complex, as an extraordinary number of possible combinations of abnormalities are possible. The International Nomenclature and Database Conferences for Pediatric Cardiac Surgery [3] produced a pragmatic summary noting that describing the particular anatomy of the patient and planning for management based on that description (and symptoms) was more important than creating a "classification." These authors noted that more than 95% of cases associated with symptoms could be described by four categories (Table 31.1) [4].

It is noteworthy that a variant of an otherwise normal left aortic arch is the presence of an aberrant right subclavian arising from the distal arch, which occurs in about 0.5% of normal individuals and is usually asymptomatic. This variant occurs in about a third of babies with trisomy 21. Additional chromosomal variants found in vascular ring patients include 47XXY and 22q11 deletion (DiGeorge syndrome) [5]. Since the increasing use of 3-vessel tracheal view fetal echocardiography after 2004, prenatal detection rates have increased significantly (Figure 31.1) and although there is insufficient data on whether prenatal diagnosis reduces overall morbidity, it does allow for a prospective care plan in those diagnosed [6] (Table 31.2).

Diagnosis of vascular rings

Definitive diagnosis of vascular rings, once clinical suspicion has been aroused, relies on imaging and, in some cases, endoscopy. Historically barium swallow was a key investigation demonstrating the indentation of the ring on the esophagus. Magnetic resonance imaging (MRI), computed tomographic and CT angiography are now the modalities of choice, allowing three-dimensional (3D) reconstruction of the images and detailed surgical planning [7] (Figure 31.2). CT provides a more precise definition in the tracheobronchial tree and can often be performed without the need for general anesthesia. Greater refinement of operative strategies based on detailed imaging data can lead to improved outcomes for vascular ring patients [8].

Assessment of the fibrous non-vascular parts of the ring is important. Echocardiography can contribute to the diagnosis but is dependent on achieving adequate echocardiographic windows, which may be difficult and is not suitable for assessing the airway [9]. Bronchography and bronchoscopy may be required to define the functional changes, particularly to assess tracheobronchomalacia and to define the extent of tracheobronchial narrowing associated with a pulmonary artery sling.

Vascular rings due to double and right aortic arches: anatomy and natural history

Double and right aortic arches are the result of the persistence of the fourth right embryonic aortic arch and form complete rings around the esophagus and trachea [1]

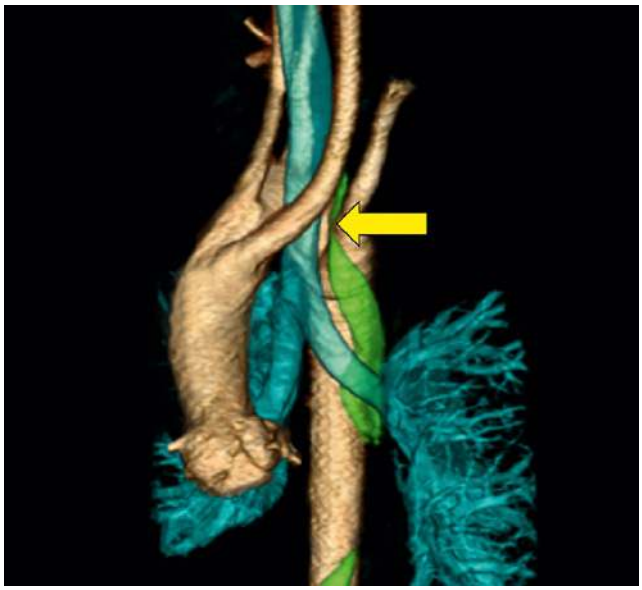

Figure 31.2 Three-dimensional enhanced computed tomography (CT) reconstruction in an 8-year-old patient with right aortic arch, retroesophageal left subclavian artery and Kommerell's Diverticulum. Note severe esophageal compression (yellow arrow) by the Kommerell diverticulum, causing symptoms of "food getting stuck." (Source: Backer [8]. Reproduced with permission of Elsevier.)

(Figure 31.3). They comprise less than 1% of congenital cardiac lesions. The double aortic arch group is commonly described according to whether the left or right arch is dominant or whether they are "balanced," i.e., similar in size. The right aortic arch group may be subclassified by the origin of the left subclavian artery from the right arch. In one-third of right aortic arches, the right arch is a "mirror image" of the normal left arch with the left subclavian branch of the brachiocephalic first branch of the arch, whereas, in two-thirds of cases, the left subclavian is the last major branch of the right arch, passing retro-esophageal to the left upper limb from the right side of the midline. This latter variant may also be associated with dilatation of the origin of the vessel, reflecting the persistence of a segment of fetal aortic arch known as a Kommerell's diverticulum. If this segment is not dealt with at the time of surgical repair, it can cause persistent or recurrent compressive symptoms. Double or right aortic arches with stenosis or coarctation of the aorta are rare. Patients with vascular rings should be echocardiographically assessed for associated cardiac anomalies that occur in approximately 10% of patients [10].

Pathophysiology of vascular rings due to double or right aortic arches

Double and right aortic arches are most commonly present in the first few years of life with respiratory symptoms from tracheal compression. These signs and symptoms include stridor, recurrent respiratory infections, a barking cough, and apnea in infants [4] (Table 31.3). Symptoms of esophageal obstruction are less common, being the primary presentation in about 15% of cases. Esophageal dysfunction may also interact with the respiratory symptoms, because reflux may lead to pulmonary aspiration and episodes of apnea. The development of aspiration pneumonia in the presence of tracheal dysfunction will increase the risk of prolonged pneumonia. The increased work of breathing associated with pneumonia will exaggerate the signs of airway obstruction that may have been absent or subtle when the patient was well. Vascular rings based on double and right aortic arches will encircle the esophagus and trachea. An *in utero* diagnosis by fetal ultrasound does not correlate with the timing and severity of symptoms, and surgery is not indicated unless the patient has symptoms. Children with mild symptoms often have resolution of those symptoms by 4 years of age. Simply observing children who are asymptomatic or mildly symptomatic regardless of aortic arch anatomy is considered a safe approach [11]. However, earlier surgical repair may limit or prevent the development of tracheomalacia, which is not immediately reversed by surgical relief of the obstruction due to the ring. The long-term outcome of vascular ring patients is generally very good. Most commonly these are isolated abnormalities, with approximately 10% of patients also having other significant cardiovascular anomalies. A 2014 study by Razon et al. postulated that although prenatal diagnosis has increased the apparent incidence of disease, the age of surgical repair has decreased. This is perhaps because clinicians caring for these patients now may inherently have a higher index of suspicion that new respiratory or gastrointestinal symptoms are related to the vascular ring. Despite the ability to diagnose prenatally, the authors emphasized that a fetal diagnosis should not be the only indication for surgery [5].

Surgery for right and double aortic arch

Vascular rings are usually repaired through a left thoracotomy. Right thoracotomy or median sternotomy are occasionally used for unusual variants, with median sternotomy being most common when there are other cardiac lesions needing repair. The principle of the surgery is to ensure that the ring is completely divided, which may require division of the ligamentum arteriosum as well as a vascular structure or a fibrous remnant of a vascular structure [1, 12] (Figures 31.4 and 31.5).

If a vascular structure is divided, such as one side of a double aortic arch, it is critical to ensure flow to all parts of the body is maintained. Test clamping and assessment of perfusion to the limbs and head may be required. Some variations of anatomy require reimplantation of blood supply. Such is the case with an aberrant origin of a left subclavian artery from a right aortic arch with a Kommerell's diverticulum – a swelling at the insertion of the left subclavian. The Kommerell's diverticulum can be resected and the left subclavian artery re-implantated onto the left common carotid artery [13] (Figure 31.6). The primary excision of the Kommerell diverticulum is currently the preferred approach since it is now known that its natural history is to steadily enlarge over time [8].

The outcome after surgical repair of vascular rings related to right or double aortic arches is very good with almost no mortality. Relief of obstruction is usually significant. Tracheomalacia may continue to produce postoperative

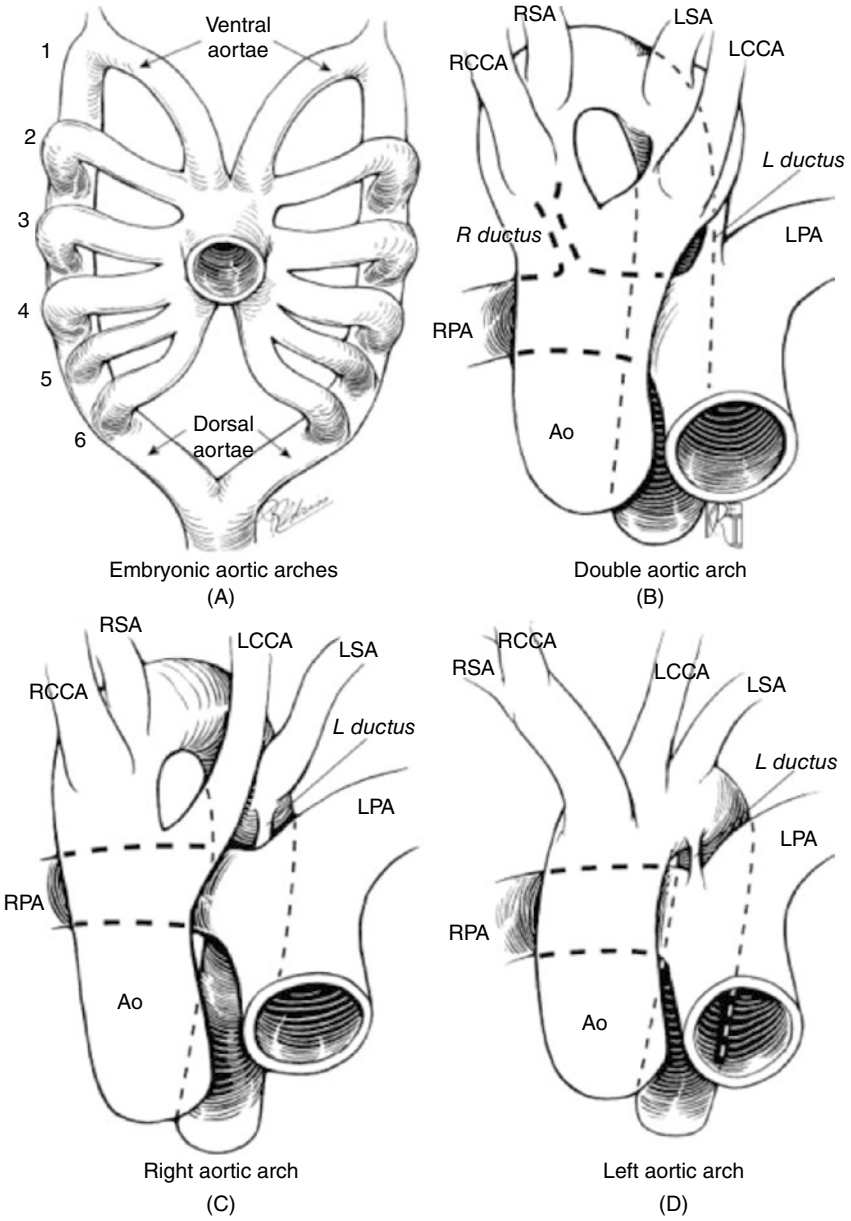

Figure 31.3 Embryonic aortic arches and double aortic arch. (A) Diagram of the embryonic aortic arches. Six pairs of aortic arches originally develop between the dorsal and ventral aorta. The first, second, and fifth arches regress. Preservation or deletion of different segments of the rudimentary arches results in a double aortic arch (B), a right aortic arch (C), or the "normal" left aortic arch (D). symptoms, but these diminish with the growth of the patient and tissue remodeling [14, 15]. Video-assisted thoracoscopic techniques may be used for these procedures and will influence anesthetic management [16].

Anesthesia for division of vascular rings related to double or right aortic arches

The preoperative assessment should consider the impact that the vascular abnormality has had on the patient, the details of the anatomy and function of the components of the vascular abnormality, the surgical plan, and the requirements for postoperative care. The severity of preoperative obstruction and chronic lung damage from recurrent infections is relevant to the risk of difficulty with oxygenation and ventilation during surgery and in the postoperative period. Chest radiograph findings suggesting chronic lung disease, tachypnea at rest, and rapid desaturation with crying are important indicators of associated lung disease. All other imaging studies, including CT scan, echocardiography, barium swallow, and MRI, should be thoroughly reviewed. The medical and surgical team should decide on the optimal timing of surgical intervention, e.g., can the lung function be further optimized prior to surgery vs. the risk of delaying definitive therapy?

The anesthesiologist and surgeon must have a clear plan regarding the need for lung isolation and discuss monitoring

requirements if temporary or permanent occlusions of blood vessels are part of the surgical plan. This will influence whether intraoperative access to limbs for circulatory assessment by clinical means, pulse oximetry, intra-arterial pressure monitoring, transcranial Doppler or near-infrared spectroscopy (NIRS) will be required and whether a particular limb is most appropriate for arterial pressure monitoring (not at risk of being lost due to temporary clamping during the procedure).

Intra-arterial pressure monitoring is usually warranted due to the risk of massive hemorrhage, the need for significant intrathoracic retraction during the procedure, and, in some cases, the need to confirm regional perfusion during intraoperative clamping of intrathoracic vessels. Central venous catheterization is usually done for these cases, especially if aortic clamping and suture lines will be required, as pharmacologic control of blood pressure is more safely performed with central venous access. Substantial peripheral venous access should be secured in anticipation of the possible need for rapid resuscitation in the face of surgical blood loss. The procedures usually are associated with minimal blood loss, but preparation should be made for the possibility of massive transfusion.

The tracheal narrowing from vascular rings will not usually prevent an endotracheal tube from being passed through the narrowing. It is rare that positive pressure ventilation and continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP) will not be sufficient to allow ventilation during the induction of anesthesia. A single-lumen endotracheal tube is usually adequate for open thoracotomy and often acceptable for thoracoscopic procedures where lung retraction provides good surgical access. If desired, lung isolation may be achieved (see Chapter 23 for a discussion of lung isolation techniques). Rigid or flexible bronchoscopy may be performed pre- and post-procedure in some cases.

Most patients will tolerate early extubation if appropriate analgesia is provided. This will vary with the institution and whether an open or thoracoscopic technique was used. Thoracic epidural analgesia is used in some institutions for thoracotomy for vascular rings. Significant preoperative lung disease or predicted postoperative airway obstruction may require more prolonged intubation and respiratory support.

KEY POINTS: VASCULAR RINGS BASED ON RIGHT OR DOUBLE AORTIC ARCH

- It is important to assess the degree of airway obstruction and whether there is chronic lung disease.
  - Prenatal diagnosis has increased significantly (due to increased ultrasound use) but should not be used as the only indication for surgery.
- Confirm surgical approach (mostly left thoracotomy) and whether regional perfusion (limbs and brain) will need to be assessed intraoperatively (monitoring and arterial line placement).
- Plan postoperative management: early vs. late extubation.
- The tracheomalacia associated with most vascular rings is not immediately cured by relief of the vascular ring.

Innominate artery compression of the trachea: anatomy, diagnosis, and natural history

Innominate artery compression of the trachea is not a true vascular ring [1] (Figure 31.7). Some degree of innominate artery indentation is normal in the first years of life, and the origin of the vessel from the aorta to the left of the trachea is also normal in young children. The normal changes in geometry of this region with growth cause the origin of the innominate artery from the aorta to move to the right of the trachea (not crossing it) and to rotate to the cranial side of the aorta. These changes decrease the degree of tracheal compression caused by the innominate artery as a child grows. Tracheal compression is more likely if the origin of the innominate artery from the aorta is more distal (to the left) and posterior than usual, resulting in anterior compression of the trachea as the vessel passes toward the right side across the front of the trachea. Severity of symptoms and efficacy of medical therapy for acute exacerbations associated with respiratory infection will influence the decision about whether to offer surgery or continue observation and medical therapy, knowing that the natural history of the condition is to improve with growth. Some other congenital abnormalities of this region, including congenital heart disease (CHD), and some patients with repaired esophageal atresia and tracheoesophageal fistula may cause "crowding" of the area, making innominate artery compression of the trachea more likely and perhaps less likely to resolve with time. Dynamic multidetector CT scan (MDCT) is a technique that can provide 2D and 3D reconstructions of thoracic structures. End inspiration and end-expiration images can be used to compare airway patency and can potentially diagnose other anomalies [17]. If extrinsic compression is suspected or identified, MDCT can be vital for surgical planning. For patients with symptomatic tracheobronchial malacia (TBM) the Esophageal and Airway Treatment (EAT) Center at Boston Children's Hospital has found that the dynamic 3-phase bronchoscopy has great diagnostic utility. The first phase occurs while the patient is shallow breathing to reveal resting airway compression, secretion accumulation, and vocal cord motion. The second phase is to induce coughing and Valsalva while

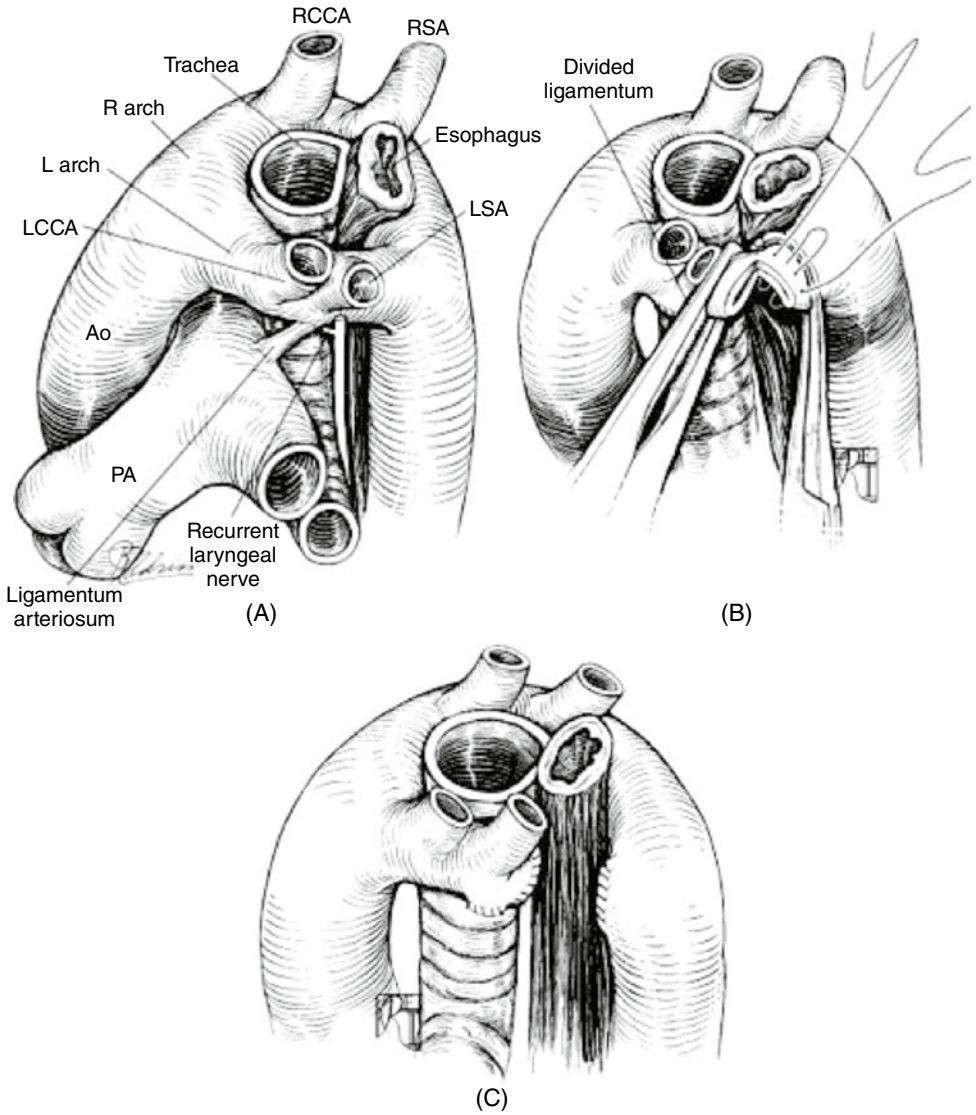

Figure 31.4 Double aortic arch division. (A) Double aortic arch, right arch dominant. (B) Dividing left aortic arch. (C) Arch divided. Ao, aorta; CA, carotid artery; L, left; LCCA, RCCA, left, right carotid artery; PA, pulmonary artery; R, right; SA, subclavian artery. (Source: Backer & Mavroudis [1]. Reproduced with permission of John Wiley & Sons.)

observing for maximum dynamic collapse in the entire airway. The third phase is to distend the airway with 30–60 cm H20 pressure in order to reveal lesions that may not have been previously recognized such as fistulas, diverticuli, and aberrant bronchi. Careful documentation of the area of tracheal involvement can also aid in the correct classification and subsequent response to treatment [17].

Pathophysiology of innominate artery compression of the trachea

Symptomatic innominate artery compression syndrome produces a localized narrowing of the trachea, often with a localized segment of tracheomalacia. Symptoms typically do not appear until there is more than 50% obstruction of the trachea. The condition presents with stridor and airway obstruction, often with an abnormal harsh cough relating to the associated tracheomalacia. Innominate artery compression of the trachea may underlie some presentations of recurrent croup. Because there is some degree of tracheal impression from the innominate artery in normal young children, it is important not to overdiagnose this condition with the risk of significant surgical intervention offered inappropriately.

Surgery for innominate artery compression of the trachea

Surgery for this condition is not commonly indicated except for significantly symptomatic patients where conservative therapy is deemed inappropriate. Most of the procedures are done through a left thoracotomy, but sternotomy and right thoracotomy have been used for vascular suspension procedures. Surgery can involve aortopexy of the innominate artery and aorta anterior to the sternum, which has a modest risk of recurrence, or reimplantation of the

AL Grawany

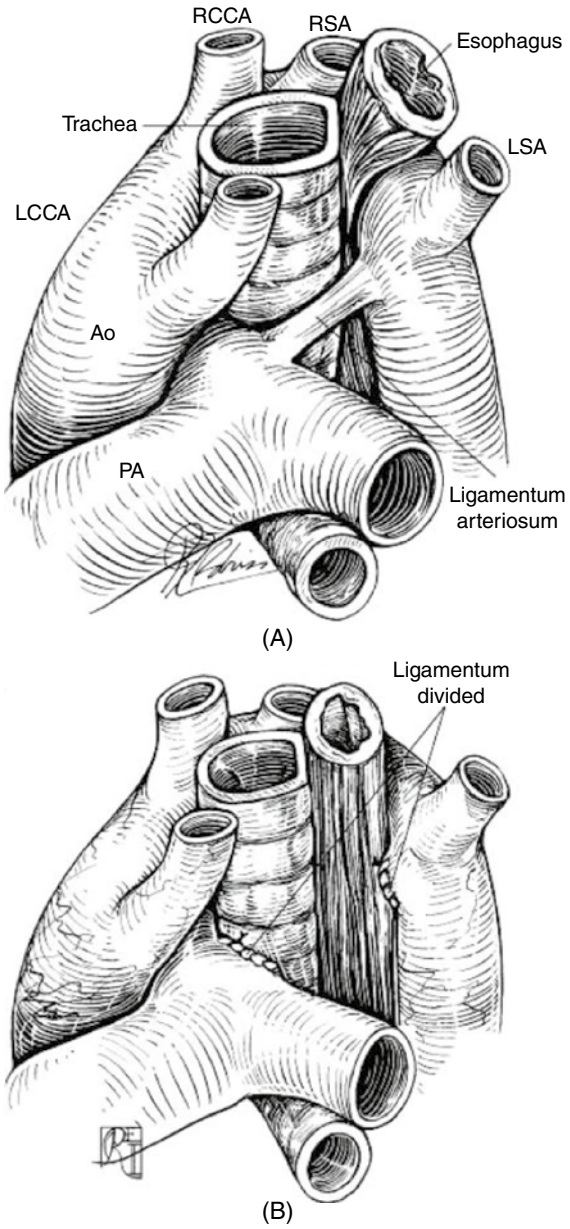

Figure 31.5 Right aortic arch – division and oversewing (B) of ligamentum arteriosum (A). Ao, aorta; CCA, common carotid artery; L, left; MPA, main pulmonary artery; R, right; SA, subclavian artery.) (Source: Backer & Mavroudis [1]. Reproduced with permission of John Wiley & Sons.)

innominate artery so that its origin from the aorta is to the right of the trachea and from the cephalad aspect of the aorta [1] (Figure 31.8). This is a more complex procedure with a greater risk of complications, but it definitively eliminates the innominate artery as a cause of tracheal compression. Anterior and/or posterior tracheopexy have been described as a novel management technique for TBM when aortopexy alone was unable to address tracheal cartilage abnormalities or membranous luminal intrusion. Anterior tracheopexy anchors the trachea to the sternum similar to aortopexy and posterior anchors the trachea to the anterior longitudinal spinal ligament. Both techniques are done with direct bronchoscopic guidance to ensure the sutures remain extraluminal and avoid excess tension in the trachea [17]. either procedure, residual tracheomalacia may cause ongoing symptoms.

Anesthesia for the repair of innominate artery compression of the trachea

The preoperative general assessment is similar to that described for vascular rings. The conduct of anesthesia is simplified if aortopexy of the innominate/aorta is the surgical technique because the risk of major intraoperative complications or the need for vascular clamping is minimal. Reimplantation of the innominate artery will involve more specific and intense intraoperative monitoring, which will include consideration of the aortic surgery and temporary occlusion of the innominate artery. For continuous arterial pressure monitoring, an arterial line can be placed in the left radial artery. Information about the adequacy of collateral perfusion during clamping of the innominate can be gained by placing an arterial line in the right radial artery. Previous case series have not noted stroke as a significant risk during temporary clamping of the innominate artery, but monitoring of cerebral perfusion, e.g., with NIRS, may be warranted to confirm minimal risk of ischemic stroke due to poor perfusion relating to clamping. Anticoagulation (normally 100 units/kg heparin; target activated clotting time 180–200 seconds) is used to minimize the risk of embolus or thrombosis related to innominate artery reimplantation. Bronchoscopy, either rigid or flexible, is frequently performed pre- and post-procedure to assess results of surgery or in the case of tracheopexy may actually be needed to guide the surgical procedure. Postoperative care will be predicated on similar principles to vascular ring procedures.

KEY POINTS: INNOMINATE ARTERY COMPRESSION SYNDROME

- Some innominate artery compression of the trachea is normal.
- Natural history is for obstruction to decrease with growth, so conservative management is often justified.
- Simple suspension aortopexy is usually adequate for cases that require surgery and will "buy time" for growth but more complex procedures such as tracheopexy may be needed.
- Formal reimplantation of the innominate artery is more definitive surgery but far more complex a procedure with a number of potential complications.

Pulmonary artery sling with tracheal stenosis: anatomy and natural history

Pulmonary artery sling results from an aberrant course of the left pulmonary artery around the trachea, which may restrict the space in which the trachea forms [1] (Figure 31.9). The left pulmonary artery arises from the posterior surface of the

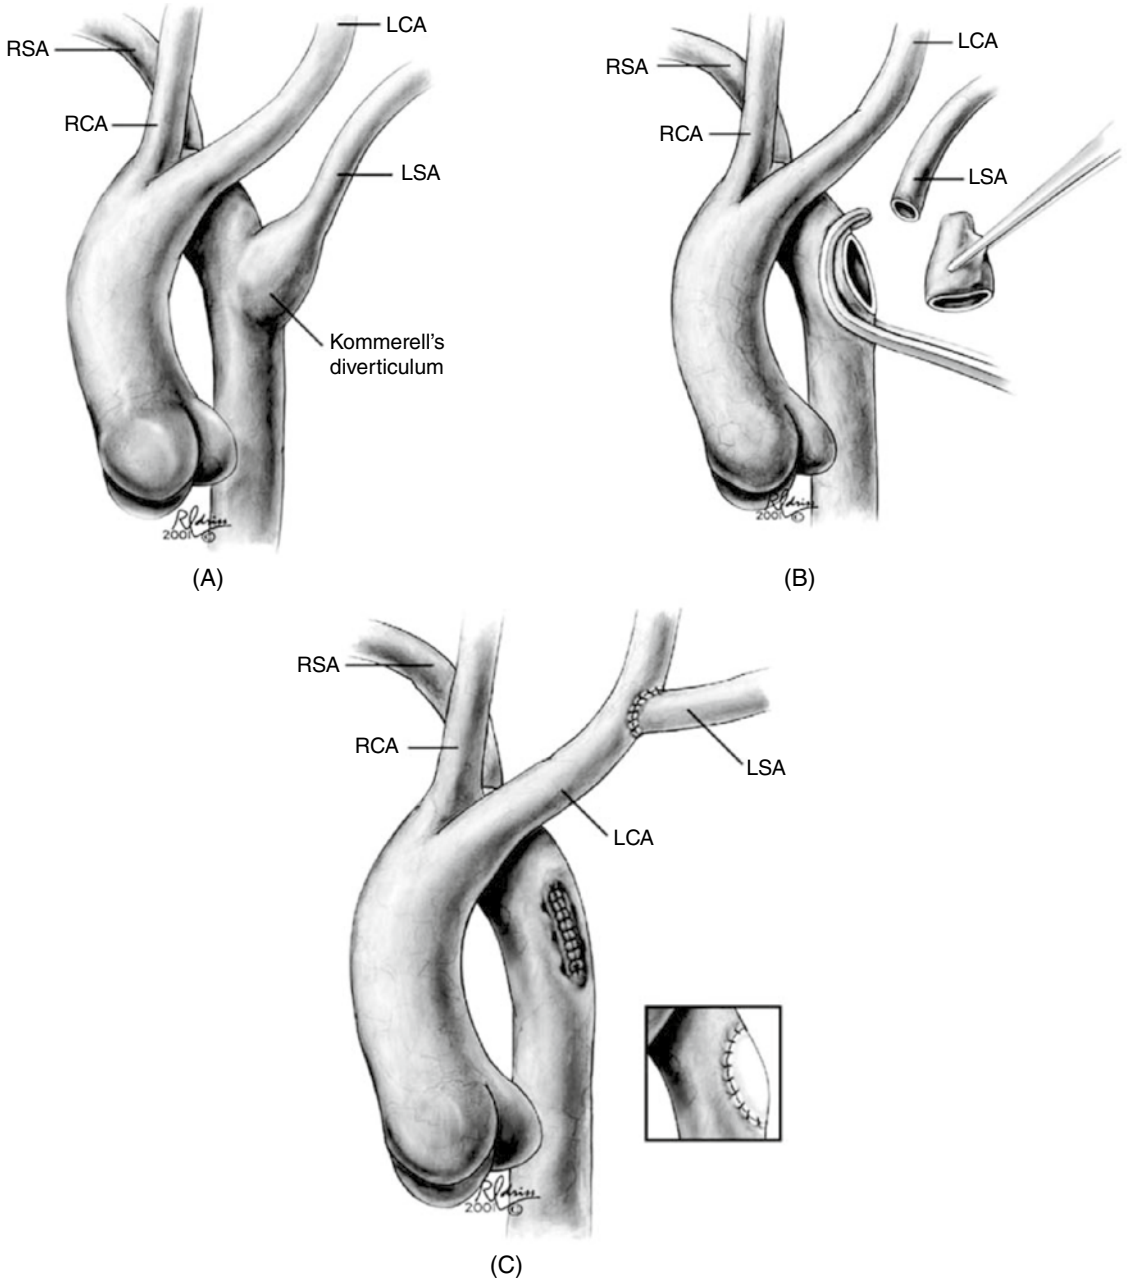

Figure 31.6 Resection of Kommerell's diverticulum. (A) Typical anatomy of a patient with a right aortic arch, retroesophageal left subclavian artery, and large Kommerell's diverticulum. LCA/RCA, left/right carotid artery; LSA/RSA, left/right subclavian artery. (B) There is a vascular clamp partially occluding the descending thoracic aorta at the origin of the Kommerell's diverticulum, which has been completely resected. (C) The completed repair. The orifice where the Kommerell's diverticulum was resected is usually closed primarily or patched if necessary. The left subclavian artery has been implanted into the side of the left common carotid artery. (Source: Backer et al. [13]. Reproduced with permission of Elsevier.)

right pulmonary artery and passes over the superior surface of the right main bronchus then posterior to the trachea and anterior to the esophagus to the left lung. The most important factor that determines prognosis is the association of this lesion with segmental narrowing of the trachea, and sometimes bronchi, with complete cartilaginous rings in the affected segment, the so-called "rat-tail trachea." A long segment of narrowing worsens the prognosis. Curiously, these patients frequently do not present for some months after birth, often with airway obstruction associated with an apparently minor respiratory infection. Recent advances in tracheal reconstruction have been associated with an improved outcome. Imaging studies are crucial for accurate diagnosis. Echocardiography may provide initial diagnosis, but anatomic detail is better provided by CT or MRI; cardiac catheterization is rarely indicated for this problem.

Pulmonary artery sling with tracheal stenosis: pathophysiology

Pulmonary artery sling pathophysiology is focused on the severity and length of the associated tracheobronchial narrowing. It is not clear whether the usual delay in presentation until some months of life represents primarily a failure of further growth of airway diameter or an increase in ventilatory requirements as the child grows. A common clinical scenario is an apparently minor respiratory infection in the middle of the first year of life, leading to obvious signs of increased work of breathing relating to respiratory obstruction with slow or incomplete resolution of the illness. Distinguishing this from the far more common bronchiolitis and laryngotracheobronchitis infections in children with underlying normal airways is difficult at the primary presentation. The severity of obstruction, failure of resolution, and recurrent presentation are the usual triggers for further investigation and diagnosis of the patient with pulmonary artery sling. Huang and colleagues recommend tracheoplasty surgery if the tracheal width is less than 3 mm [18]. An Australian retrospective study of 33 PA sling patients by Yong and colleagues analyzing cases showed that long-term outcomes and survival are often worsened by the need for tracheal surgery [19] (Figure 31.10). Early mortality was clearly increased in those requiring surgery on the trachea. A review of pulmonary function testing several years after tracheal surgery demonstrated that a non-reversable obstructive pattern was often demonstrated on pulmonary function testing suggesting the need for long-term respiratory assessment of these patients.

Surgery for pulmonary artery sling with tracheal narrowing

The long-term outcome of the surgical intervention for these patients depends on the tracheal reconstruction. The surgery

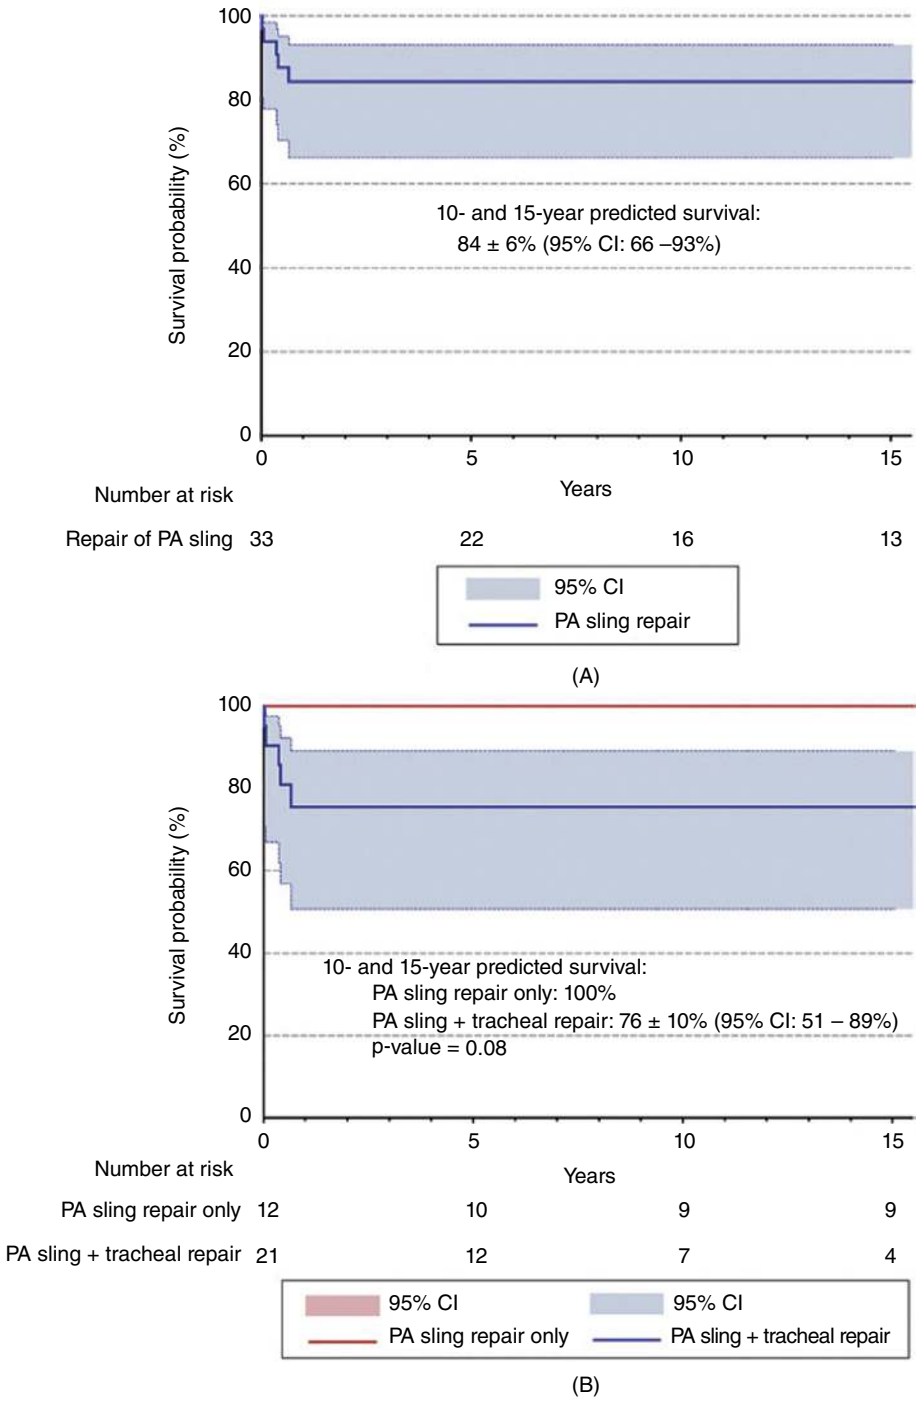

Figure 31.10 Kaplan-Meier curve showing probability of survival in (A) all patients who had pulmonary artery (PA) sling repair and (B) patients who had PA sling repair only compared to patients who had both PA sling and tracheal repair. is done through a sternotomy, on cardiopulmonary bypass (CPB). The aberrant left pulmonary artery can be dealt with at the time of reconstruction of the trachea, most commonly by dividing and reimplanting it, to mimic the normal takeoff from the main pulmonary artery, but alternative methods to relocate the vessel in relation to the reconstructed trachea have been used.

For patients with a short segment of tracheal stenosis, resection of the stenosis, mobilization of the trachea, and direct anastomosis may be sufficient and relatively straightforward surgery [1] (Figure 31.11). For patients with a longer segment of narrow trachea with complete rings, the long-term problem with tracheal reconstruction has been to achieve both continuing adequate airway patency and a functional

AL Grawany

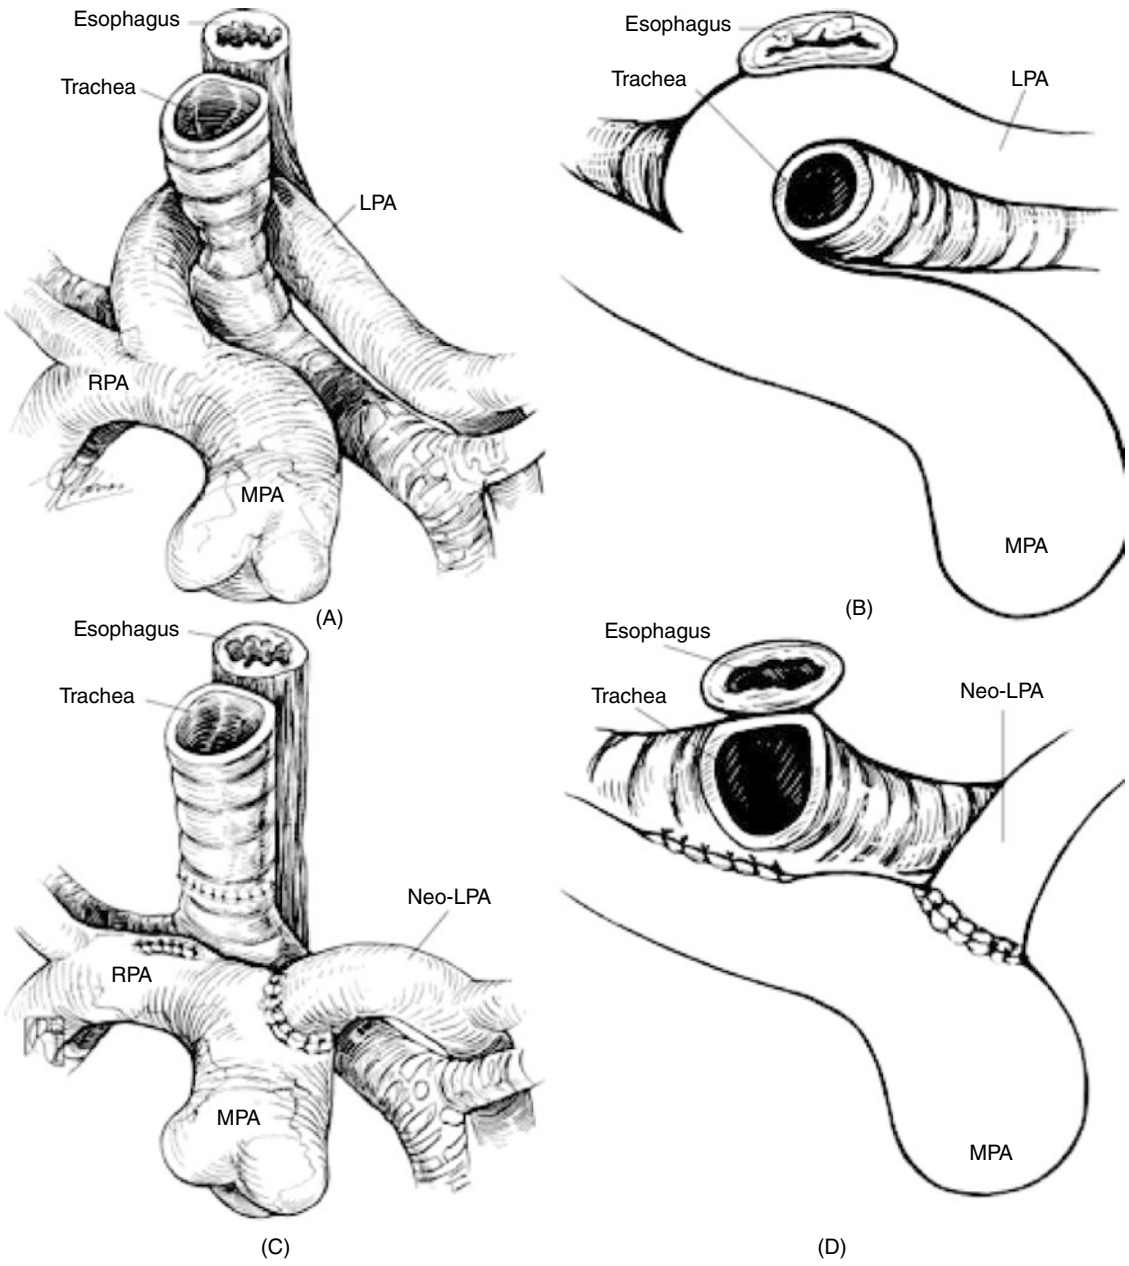

Figure 31.11 Illustration of operative technique for pulmonary artery sling repair with tracheal resection (performed with cardiopulmonary bypass). (A) Left pulmonary artery (LPA) encircles and compresses the distal area of the trachea and right main-stem bronchus. (B) Relationship of the LPA to the trachea and esophagus. (C) Repair is by transecting the LPA at its origin from the right pulmonary artery (RPA) and anastomosing the LPA to the main pulmonary artery (MPA) at a site that approximates the usual anatomic configuration. The tracheal stenosis has also been resected, and an end-to-end tracheal anastomosis is shown. (D) Postoperative relationship of neo-LPA to MPA anastomosis showing the relatively long distance from the original LPA takeoff from the RPA. (Source: Backer & Mavroudis [1]. Reproduced with permission of John Wiley & Sons.)

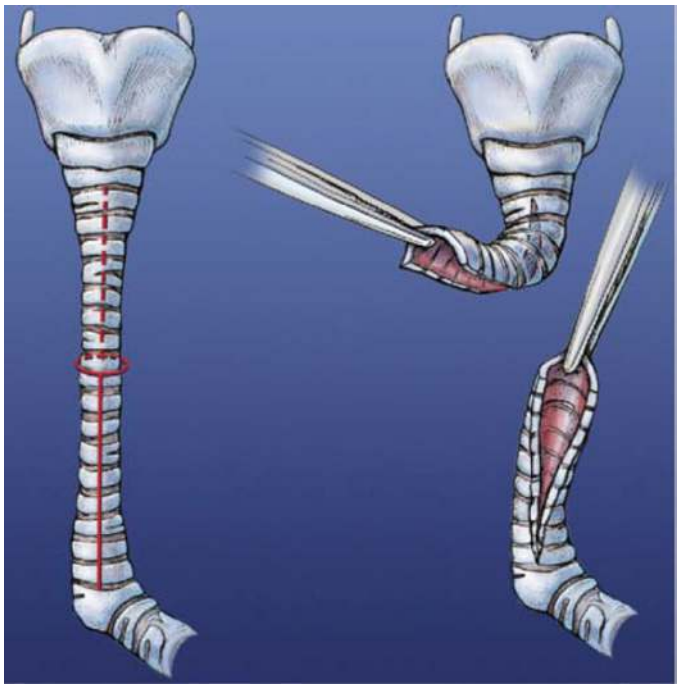
tracheal epithelium. The airway patency must be throughout the respiratory cycle, which requires a degree of rigidity to resist collapse in expiration. For long segment reconstruction, the slide tracheoplasty has become the preferred surgical approach. Tracheal surgery is technically demanding and should ideally be performed in centers that do large numbers of cases [20]. Alternatives, such as simple patches (e.g., with pericardium), will usually be associated with tracheomalacia in the long term. Scarring and granulation formation and the lack of cilial function will often complicate stented patches, whether stented by external, surgically placed cartilage grafts or internal stents, similar to those used for vascular stenting. There is currently no data to support stenting as a primary approach for tracheal stenosis patients but they are often used as a bridge to surgical therapy [20]. The most commonly cited complications of currently available intraluminal stents are stent migration, degradation and fragmentation [21]. A systematic review of 26 studies of intraluminal stents showed an

overall complication rate of 21.7% (8.7% stent fragment foreign body and 4.3% each for stent migration, local stenosis, and granulation tissue) A more complex style of self-expanding helical stent is under preclinical investigation. It is made of nitinol, a nickel-titanium alloy, designed specifically to minimize foreign-body reaction, preserve mucociliary transport, and facilitate atraumatic removal [22, 23]. External custom 3-D printed bio-reabsorbable tracheal splints are also under clinical investigation [18], and may allow time for tracheal growth but require an more complex open surgical procedure [18, 24]. Alternative sources of tissue, such as laboratory-based tissue engineering or donor tissue, are possible, but slide tracheoplasty has the potential to provide airway patency, with a non-collapsing wall and normal functioning respiratory epithelial mucosa.

Slide tracheoplasty is a solution for many longer segment narrowings which optimizes the use of native tissues to reconstruct the trachea and potentially proximal bronchi [25] (Figure 31.12). The technique involves an oblique division of the trachea, with the distal and proximal ends of the incision continued on the proximal trachea and distally, and potentially along a bronchus if there is bronchial involvement. The trachea is mobilized so that the oblique end of the proximal trachea can slide into the apex of the distal incision, and the oblique end of the distal trachea can slide into the apex of the proximal incision. This achieves expansion of the lumen, with essentially normal tracheal tissue and mucosa forming the reconstructed trachea. The long oblique anastomosis is less likely to stricture than a circular anastomosis. The slide maneuver shortens the trachea. Independent of symptom severity, DLR (diameter/length ratio) is defined as the ratio of the narrowest diameter divided by the stenotic segment length. DLR has been reported by Hong and colleagues as a potentially reliable indication for surgery in patients with congenital tracheal stenosis with pulmonary artery sling [26]. According to Harada and colleagues, a DLR of less than 5.9 may be a reliable indicator for slide tracheoplasty in addition to vascular repair [27].

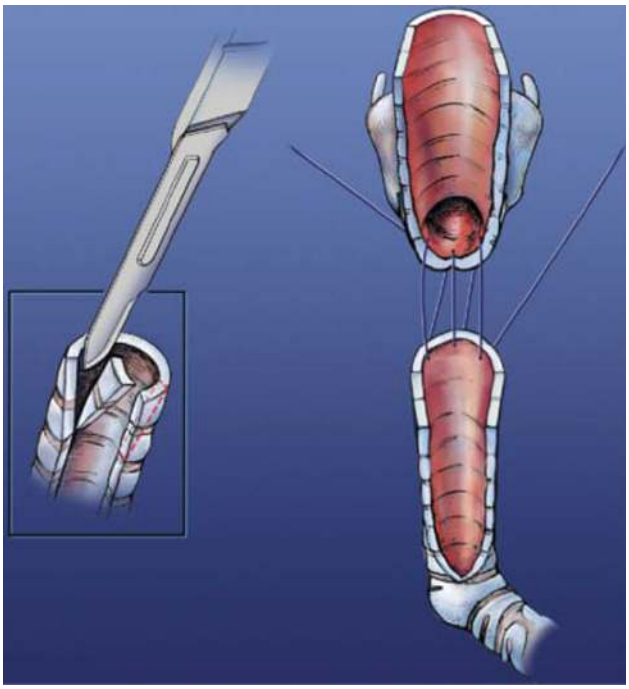
Patients with a long segment of tracheobronchial narrowing in association with a pulmonary artery sling may well benefit from a multidisciplinary assessment. These patients should be managed at an appropriate referral center. According to an analysis by Chen and colleagues of 23 children between 2003 and 2018, slide tracheoplasty can be performed for up to two thirds of the length of the trachea. Beyond this length, tension-relieving maneuvers may be required to prevent complications such as anastomotic breakdown, recurrent granulation tissue, and a narrowed lumen [28]. It is desirable that cardiac surgery, cardiology, thoracic and otolaryngological surgery, anesthesia, pulmonary medicine, intensive care, and medical imaging and intervention should all participate and collaborate in planning the management of these patients.

Anesthesia for the repair of pulmonary artery sling and tracheal stenosis



The anesthesia assessment of these patients is particularly focused on the impact and extent of the associated tracheal stenosis. The indications and timing of surgery are entirely driven by symptoms related to the tracheal obstruction. The spectrum of these patients' conditions may well range from a minimally symptomatic baby who is requiring no current intervention to a patient in a perilous situation with maximum intensive care support, with complex ventilator requirements and potentially requiring extracorporeal oxygenation or carbon dioxide clearance. Positive pressure ventilation in these patients is difficult to optimize and assessing flow volume loops created by different ventilator strategies can be helpful. Common strategies include permissive hypercapnea, attention to adequate expiratory time to minimize hyperinflation which limits ventilation, and continuous positive pressure to maintain airway patency.

Anesthesia is similar to other procedures requiring CPB. Passing an endotracheal tube through the larynx is initially as for a normal patient. The difference is that a tube that is appropriate for the upper trachea will not pass through the narrow segment. No attempt should be made to advance the endotracheal tube through the narrowing. Bronchoscopic assistance may be utilized or the tube can be gently advanced through the larynx until resistance is felt and minimally withdrawn from that point. The narrow segment of the trachea can easily be blocked by blood, swelling, or secretions associated with trauma to the mucosa, with potentially catastrophic results. Avoiding these complications by minimizing airway trauma is a primary aim. If required, suctioning may require a fine catheter and lubrication to clear secretions from the narrow segment. Suctioning may be necessary for adequate ventilation but runs the risk of traumatizing the mucosa. Suctioning may be life-saving if secretions or blood occlude the narrow segment. High inspiratory pressures may be required to inflate the lungs, as the narrow segment may have a very high resistance to flow. For this reason, consideration should be given to ensuring that the largest appropriate tube is placed above the narrowing to minimize the risk of an excessive leak at high ventilator pressures or inability to generate adequate pressure. If there is sufficient length of trachea above the narrowing, a tube with a cuff, particularly one with the minimum distance between the cuff and the tip of the endotracheal tube, may be appropriate. Bronchoscopic confirmation and guidance of placement should be considered.



The mobilization and slide maneuver associated with slide tracheoplasty will tend to draw the trachea down into the chest, meaning that the distance between the larynx and the tip of the endotracheal tube placed at the beginning of the procedure will decrease. This should be assessed, and the endotracheal tube confirmed to be in a good position before transporting the patient to the intensive care unit.

With adequate surgical relief of tracheal obstruction and air-tight closure of the tracheal (or tracheobronchial) anastomosis, the patient should tolerate positive pressure ventilation postoperatively and the endotracheal tube can be left above the anastomosis. Early extubation is usually avoided, as postoperative swelling over the next few days may still be associated with a restricted airway. Fiberoptic bronchoscopic examination via the endotracheal tube can guide decision-making about airway management, as well as provide controlled airway suctioning and assist with deciding the best position for the endotracheal tube during the postoperative course. Although a relatively early return to spontaneous ventilation may minimize the need for positive pressure

ventilation, decreasing the risk of air leak, coughing or straining on the endotracheal tube, perhaps related to decreased sedation to allow spontaneous ventilation, could be associated with a greater risk of air leak. The management plan will require repeated assessment if clinical circumstances change.

Box 31.1 Summarizes the surgical approach to vascular rings and slings [1].

KEY POINTS: PULMONARY ARTERY SLING

- The outcome is mostly determined by the degree of tracheobronchial obstruction.
- The affected segment of the tracheobronchial tree has complete cartilage rings.
- Repair on CPB includes dealing with the pulmonary artery sling but repair of tracheobronchial obstruction is crucial.
- Excision of the narrow segment may be possible for short segments, but slide tracheoplasty is the usual technique for longer segments and long-term outcomes are favorable with excellent late survival
  - Tracheopexy may help treat severe tracheobronchomalacia
  - DLR may be a reliable indicator for surgical intervention
  - Tracheal stenting and splinting are not currently first-line treatment options but improvements in these technologies are currently under investigation.

Box 31.1: Surgical management of vascular rings

Double aortic arch
1. Left thoracotomy (muscle-sparing – fourth interspace)
2. Divide lesser of two arches at insertion with descending aorta
3. Preserve blood flow to carotid/radial arteries
4. Ligate and divide ligamentum arteriosum
5. Leave pleura open

Right aortic arch/left ligamentum
1. Left thoracotomy (muscle-sparing – fourth interspace)
2. Ligate and divide ligamentum arteriosum
3. Resect Kommerell's diverticulum (if present) and transfer the left subclavian artery to the left carotid artery
4. Leave pleura open

Innominate artery compression syndrome
1. Right anterolateral thoracotomy (third interspace)
2. Resect right lobe of thymus
3. Suspend innominate artery to posterior sternum
4. Postoperative bronchoscopy

Pulmonary artery sling
1. Median sternotomy/extracorporeal circulation
2. Ligate/divide left pulmonary artery (PA)
3. Implant left PA into main PA anterior to the trachea
4. Slide tracheoplasty for associated tracheal rings

Anomalies of the coronary arteries

There is a wide anatomic variation of the coronary arteries. There are a number of common variants which are accepted as normal but which may have significance if the disease of the coronaries develops (e.g., proximal atheroma in a single coronary artery which gives rise to left and right coronary arteries) or surgery of the region is required (where intramural or unusually placed vessels may be more likely to be injured). The physiological function of the coronary arteries and the heart is usually normal in these variations.

The focus of this section is congenital anomalies of the coronary arteries. Acquired abnormalities are also important in childhood. These include infective causes, of which Kawasaki disease is the most prominent, iatrogenic causes arising from surgery or invasive cardiological procedures, and the development of abnormalities in relation to other lesions, such as the coronary perfusion issues that can be associated with supravalvular aortic stenosis.

The Congenital Heart Surgery Nomenclature and Database Project provided an excellent classification and review of the significance of anomalies of the coronary arteries [29]. The major types of coronary anomalies are divided into the following seven groups:

1. Anomalous pulmonary origins of the coronaries
2. Anomalous aortic origins of the coronaries
3. Congenital atresia of the left main coronary artery
4. Coronary arteriovenous fistulas
5. Coronary artery bridging
6. Coronary artery aneurysms
7. Coronary stenosis.

Coronary anomalies are a diverse group of disorders with varying clinical manifestations for which history and physical exam are extremely unreliable in diagnosing these rare conditions which rarely cause symptoms at rest. They are the second most common cause of sudden cardiac death in young competitive athletes [30]. A similarly high incidence of coronary anomalies has also been seen at autopsy of young military recruits who died suddenly [31]. A 2018 MRI screening study by Angelini and colleagues of a general population of 5,000 adolescents participating in school sports revealed a 1.3% incidence (70 cases) of high-risk cardiovascular disease including 23 study members with AOCOS anomalies (anomalous origin of a coronary artery from the opposite sinus) [32] (Table 31.4). Left sided AOCOS with an intramural course (L-AOCOS-IM) constitutes the most serious group of all LCA anomalies [34]. During strenuous exercise the proximal intramural course predisposes to lateral compression and phasic narrowing during systole potentially leading to ischemia. An intra-arterial course between the great vessels has also been found to be problematic and is often difficult to confirm with imaging [35]. Screening for these abnormalities in children has become a recent topic of focus but no clear guidelines have yet been established.

Supravalvular aortic stenosis is also clinically important and associated with sudden death, sometimes in association with apparently stable anesthesia, and the complex mechanisms, which may be both structural and dynamic. The development of abnormalities of coronary perfusion in this condition is discussed.

Anomalous pulmonary origins of the coronary arteries: incidence, anatomy, and natural history

These are rare lesions with the commonest and most important being anomalous left coronary artery arising from the pulmonary artery (ALCAPA) with an incidence of only 1 in 300,000 live births. ALCAPA presents early in life with a mortality of up to 90% in the first year, if untreated. Anomalous right coronary artery from the pulmonary artery (ARCAPA) is even rare, usually presenting after a few years of life, but with a wide clinical spectrum. Later presentations are not infrequent and some adults with this condition are at risk of sudden death [36–38]. Common presenting findings in the adolescent or adult population include EKG changes (ST changes and Q waves), cardiomegaly, a pansystolic murmur, and echocardiographic findings of mitral regurgitation [39]. Extensive intercoronary collaterals from the right side of the heart and/or retrograde flow from LCA- derived collaterals back to the pulmonary artery are also often seen in these older ALCAPA patients [30].

Anomalous right coronary artery from the pulmonary artery may be more benign than ALCAPA, as the right ventricle, which is supplied by the ARCAPA, has more favorable myocardial oxygen supply and demand characteristics when compared with the left ventricle. Other, even rarer variants include both right and left coronary arteries arising from the pulmonary artery, anomalous single coronary artery from the pulmonary artery (ASCAPA) (images with permission) as well as accessory coronary artery arising from the pulmonary artery [40] (Figure 31.13). The rest of this discussion will be restricted to ALCAPA.

Pathophysiology of ALCAPA

The pathophysiology of ALCAPA is complex and will vary with the exact anatomy and the changing physiological circumstances as the neonate develops and pulmonary vascular resistance (PVR) and pressure falls. The ALCAPA vessel provides a connection between the pulmonary artery and the myocardium supplied by the left coronary artery. Left ventricular coronary perfusion is dependent on diastolic perfusion, as the pressure generated by left ventricular contraction prevents coronary perfusion during systole. In the early neonatal period, PVR and pulmonary artery pressure are high, compared with later in life. In this phase, the left ventricle may have adequate oxygenation, albeit with mixed venous blood with relatively low hemoglobin oxygen saturation, which can be adequate for left ventricular function. As PVR and pulmonary artery pressure decrease, flow in the ALCAPA vessel may reverse, acting as a fistula and causing run-off of coronary blood flow to the pulmonary artery, creating a "coronary artery steal" and worsening left ventricular perfusion. This will cause ventricular ischemia, which will lead to ventricular dysfunction, especially in diastole, which will lead to an increase in left ventricular diastolic pressures, thus further decreasing the perfusion pressure. The "coronary steal" may also affect right ventricular perfusion in both systole and diastole, if there are significant collaterals, but the presence of some systolic perfusion of the right ventricle muscle, as in normal coronary physiology, is protective. A peculiar potential benefit of the reverse flow in the ALCAPA vessel (towards the pulmonary origin) is that this may help to maintain PVR and pressure, potentially delaying the onset of symptoms.

(A) (B)

Figure 31.13 Anomalous single coronary artery arising from the pulmonary artery. (A) Aortogram with absent coronary ostia. (B) Coronary filling after contrast injection into the pulmonary artery demonstrating a short single coronary artery (1) bifurcating into right (2) and left (3) branches. (Source: Machovec et al. [40]. Reproduced with permission of Wolters Kluwer Health, Inc.)

The worsening left ventricular function will be associated with dilation of the left ventricle. Left heart dilation may be associated with a shift of the interventricular septum towards the right, with associated impairment of right heart function. Mitral valve regurgitation can be induced by both dilatations of the left atrioventricular ring and ischemic dysfunction of the papillary muscles. This will lead to volume loading and further deterioration of left ventricular function with worsening pulmonary congestion and a low output state. The commonest presentation of ALCAPA is at weeks to sometimes months after birth with a condition that is essentially a severe dilated cardiomyopathy of ischemic origin. All infants presenting with dilated cardiomyopathy must be closely screened for anomalies of coronary origin.

Variations in the anatomy of the ALCAPA may influence the presentation. As with normal coronary arteries, there may be significant differences in the balance of these arteries. The more that the right coronary is dominant, supplying significant portions of the ventricular septum and other regions of the left ventricle, the more likely it is that there will be a later presentation with less severe deterioration in myocardial function. Similarly, stenosis of the ALCAPA vessel, which may occur at its origin, will actually lessen the impact of the coronary steal and allow more chance for collateral vessels from the right coronary to perfuse the left side of the heart. There is some evidence that these more delayed presentations may have a long-term negative impact, as the underlying ischemia will have been more long-lasting, producing fibrosis, and ventricular recovery after repair will be impaired. For patients with a dominant ALCAPA distribution, presentation is likely to be early with severe myocardial dysfunction. Although recovery in this circumstance can be excellent, some patients may have completed infarction of regions of the left ventricle with no prospect of recovery of function with reperfusion, and with a risk of formation of aneurysm of the left ventricle. The more severe early presentations are also at risk of lethal complications before surgical repair can be performed. Additionally, about 10–15% of ALCAPA patients are adult-type which without surgical repair results in a risk of sudden death before the age of 35 in 80–90% patients. It is for this reason that surgical repair of all those diagnosed as adolescents or adults is recommended [41].

Surgery for ALCAPA

Historically, simple ligation of the ALCAPA vessel was used, improving survival [42]. This would prevent the coronary steal and, depending on the adequacy of collateral circulation, improve perfusion of the left ventricle. Mortality was still high and recovery of left ventricular function usually incomplete. This procedure is no longer performed in major congenital cardiac surgery centers. Current surgical management involves restoring aortic perfusion of the ALCAPA vessel, thus providing a two-coronary circulation originating from the aorta, usually by mobilization and reimplantation of the ALCAPA vessel onto the aorta [43–45] (Figure 31.14). A specific example that can be used for a very short ALCAPA vessel is the Takeuchi procedure. This involves using an intra-arterial pulmonary baffle to direct flow from a surgically created aortopulmonary window to supply the origin of the ALCAPA vessel with systemic arterial blood in situ, with patch expansion of the pulmonary artery to allow space for the baffle and prevent pulmonary obstruction [46–48] (Figure 31.15).

The unit managing these cases should be able to provide extracorporeal circulatory support with a ventricular assist device (VAD) or extracorporeal membrane oxygenation (ECMO) if required. The techniques may be necessary as part of preoperative resuscitation or for support of the patient in the early postoperative period, as the recovery of myocardial function is usually not immediate [49]. Imamura et al. reported a series of 26 ALCAPA operations over a 20-year

AL Grawany

period [50]. Twenty-one patients did not require ECMO support and five required ECMO for a mean of 10.7 ± 6.7 days. One patient in each group required cardiac transplantation, and four others required six reoperations (five for MR). There were no deaths in the series, and actuarial freedom from transplantation or reoperation at 5 years was 0% in the ECMO group, and 92% in the non-ECMO group. Chapter 37 presents a detailed discussion of mechanical support of the circulation.

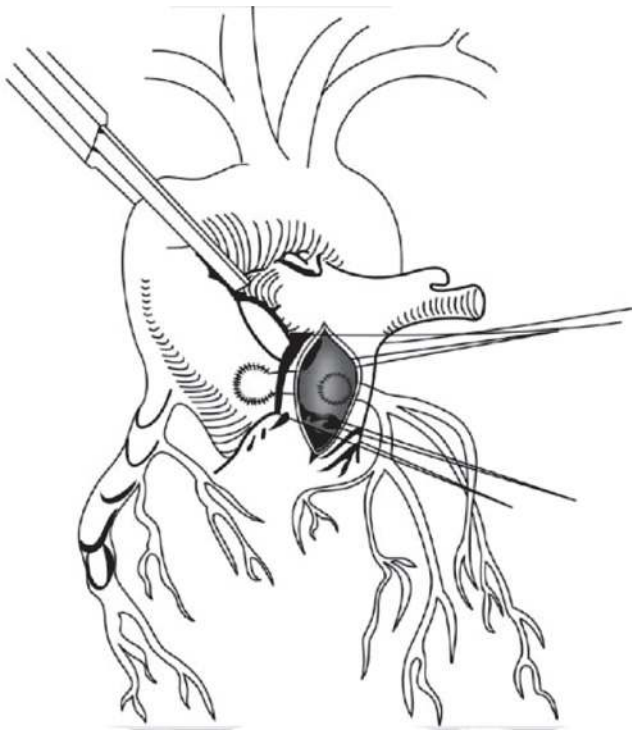

Figure 31.14 Direct aortic reimplantation of the anomalous left coronary artery from the pulmonary artery. The anomalous ostium is excised with a button of the pulmonary artery wall. This button is then implanted into the left lateral side of the ascending aorta. The resulting defect is closed with a pericardial patch (Source: Arciniegas [45]. Reproduced with permission of Elsevier.)

There is controversy about the role of surgical procedures to improve mitral valve regurgitation at the primary operation because mitral valve function usually improves as improved myocardial function results in decreased end-diastolic volume and better papillary muscle function [51]. In a series of 25 operations for ALCAPA, Kudumula et al. repaired the mitral valve only for moderate to severe MR, accompanied by structural mitral valve abnormalities, observed in four patients [52]. Two patients had mitral valve cleft, one had a prolapse, and one had a dysplastic double orifice mitral valve. One patient with a structural mitral valve abnormality that was not repaired at the original operation developed severe MR and required repair at a second operation. Of 14 patients in the series without structural mitral valve problems with moderate or severe MR, 13/14 had none or mild MR at the time of follow-up. A Saudi Arabian retrospective observational cohort of 29 patients from 1999 to 2018 analyzed by Ismail showed similar findings (Figure 31.16). Spontaneous regression of MR was reported by Ismail et al. In these patients, LV systolic function showed echocardiographic improvement within 6 weeks and returned to normal within 1 year's time and in addition somatic growth of children improved 6 months after surgical repair [53]. Some surgeons still argue that there is a reasonable argument that surgical techniques that decrease the mitral valve annulus size but allow for future growth may improve mitral valve function acutely, improving the performance of the dysfunctional early postoperative heart. Although repairing the mitral valve does increase the cross-clamp time on an already ischemic myocardium, this does not seem to have a clinically significant effect on the later normalization of LV function or other postoperative outcomes. According to a 2016 study by Naimo et al. which evaluated 42 ALCAPA patients, late reoperation was uncommon in the 33 patients who did not undergo concomitant MV repair despite MR ranging from none to severe. In fact, late MV reoperation was only needed in 14% at 5 & 10 years, and 19% in 20 years after original surgery. Persistent MR does

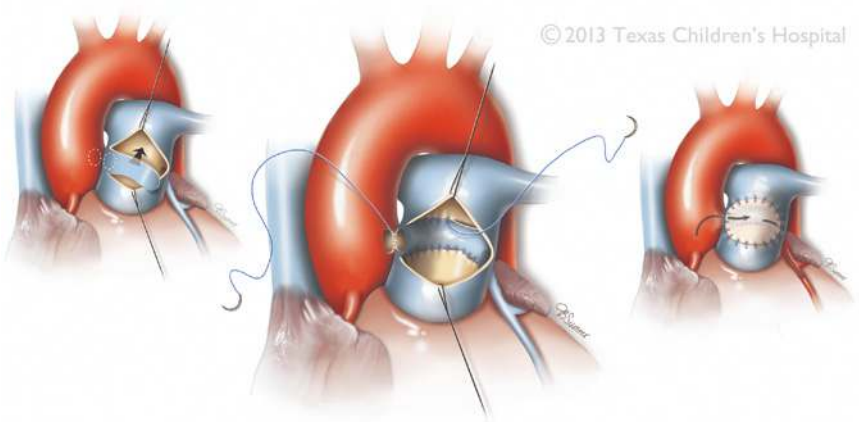

Figure 31.15 Takeuchi procedure through median sternotomy with extracorporeal circulation and cross-clamped aorta. Left: The tunnel for coronary flow has been made between the aorta and the anomalous left coronary artery by means of a flap of pulmonary artery wall. Middle: Construction of the tunnel to direct flow from the aortic root to the anomalous left coronary artery. Right: The pulmonary artery is then reconstructed with pericardium. warrant close followup and late MV operative repair may eventually be necessary in some patients [54].

Anesthetic considerations for ALCAPA

The degree of myocardial dysfunction is the factor that dominates the condition and prognosis of these patients throughout the perioperative period. Preoperatively, the patient with ALCAPA may be receiving cardiorespiratory support, ranging from none to an intubated ventilated patient on ECMO. In between these extremes will be patients with various degrees of inotropic support receiving tailored vasodilators or, in some cases, vasoconstrictors. The general principle that a failing heart, especially with MR, will have output improved by systemic vasodilation is sound, but the severity of the dysfunction in some of these patients means there may be a role for vasoconstrictors. If the patient is already hypotensive, it is possible that the vasodilation is actually excessive for that heart and results in greater tachycardia. The poor coronary perfusion is worsened by both systemic hypotension and tachycardia. In this scenario of myocardial dysfunction with relatively excessive vasodilation, judicious use of vasoconstrictors may improve blood pressure and decrease heart rate, improving coronary perfusion while maintaining an acceptable cardiac output. The patient should be monitored for signs of the inability of the heart to cope with the increased afterload or worsening MR.

Preoperative assessment of patients with ALCAPA should also include assessment of the complications of the myocardial dysfunction, such as respiratory, renal and hepatic dysfunction, as well as a general medical review.

The group of patients with ALCAPA who provide perhaps the greatest challenge for the anesthesiologist comprises those who have been diagnosed after presenting with respiratory distress, but who are stable and do not require acute cardiorespiratory support. They may have intravenous access, and non-invasive monitors have been used for them. Echocardiography will have confirmed the diagnosis and the critically poor myocardial function. The anesthesiologist will be responsible for the induction of anesthesia and stabilization of the patient prior to the initiation of CPB in a situation where minor changes in sympathetic drive or myocardial function might be associated with cardiac arrest. Induction of anesthesia, intubation, positive pressure ventilation, placing a central venous catheter or transesophageal echocardiography (TEE) probe, excessive anesthesia with myocardial depression or depression of central nervous system-driven sympathetic activity, or inadequate anesthesia resulting in excessive sympathetic response can all lead to life-threatening incidents. The anesthesiologist should be prepared to heparinize and defibrillate the patient at any time. The nursing, perfusion, and surgical team should all be prepared for the potential need for emergent sternotomy and initiation of CPB, and they should be in the operating room during the induction of anesthesia. If it is possible to obtain preinduction arterial access without upsetting the patient, this is highly desirable for the earliest warning of cardiovascular compromise. This can sometimes be accomplished in young infants with local anesthesia, either topically or by injection, along with 50% N_2O inhalation or small analgesic doses of fentanyl or other opioids intravenously.

The induction of anesthesia in patients with ALCAPA requires great care in the slow titration of small increments of whatever drugs are selected to minimize the myocardial depression and vasodilation that accompanies the usual doses of most of these drugs. Opioids, such as fentanyl and remifentanil, although tending to spare myocardial function, can rapidly depress central sympathetic drive, causing relative bradycardia and vasodilation, which may be poorly tolerated by these patients. Similar problems can arise even with drugs, such as etomidate and ketamine, that tend to preserve sympathetic function and cardiovascular stability in normal patients. Ketamine is a direct myocardial depressant, and these hemodynamic effects are most commonly seen in the patient who has depletion of endogenous catecholamines, such as the infant with ALCAPA. Ketamine is also implicated as possibly inducing brain injury in the developing brain and some anesthesiologists avoid it in this age group. The complex risk balance of choice of agent and combination of agents for ALCAPA patients makes judicious, cautious use of agents with which the anesthetist is very familiar a reasonable choice.

Preoperative fluid restriction to manage pulmonary congestion may make the patient especially prone to hypotension with the initiation of positive pressure ventilation. Judicious intravascular volume loading at this time may prevent this. Successful transition to anesthesia and positive pressure ventilation may improve lung function and create some afterload reduction, which may improve left ventricular function. Lung compliance is usually low due to pulmonary congestion, and significant ventilator pressures are commonly required.

Maintenance of elevated PVR will minimize the "coronary steal" due to the ALCAPA flow into the pulmonary artery. Avoiding a high inspired oxygen concentration and maintaining a normal or moderately high arterial carbon dioxide

AL Grawany

level are key strategies for maintaining PVR, but pulmonary congestion secondary to left heart failure may mean that increased inspired oxygen levels and high ventilator pressures will be required. Significant PEEP may serve both to improve function in the congested lung and to maintain PVR. Increasing ventilatory pressures, particularly PEEP, will require attention to maintaining adequate intravascular volume to support ventricular filling and avoid low cardiac output and systemic hypotension.

Rapid repetitions of non-invasive blood pressure monitoring should be continued until intra-arterial continuous blood pressure monitoring is available. Adequate monitoring of the circulation, respiration, and depth of anesthesia in these patients requires constant vigilance. It is advantageous to have at least one, and perhaps two, other pairs of experienced hands to perform the procedures required to prepare the patient for surgery after induction of anesthesia, so one anesthesiologist can focus on the monitoring and anesthesia.

Patients with ALCAPA who have been intubated, ventilated and had appropriate vascular access obtained preoperatively may be sicker in many respects than the previous scenario, but the anesthesiologist will have to make less of a transition for the patient to anesthesia and establish invasive monitoring and other preparation. It is still important that there is great vigilance in the transfer of the patient to the operating room and that the whole operative team is present to initiate CPB at short notice before the transfer commences. Patients who have already been placed on mechanical circulatory support present challenges in transfer, but provided, there is no interruption to that support, they are very safely supported. The anesthesiologist must ensure the patient has adequate intravascular volume to allow good venous drainage into the external mechanical circuit. Monitoring the inlet pressure of the circuit can greatly assist this process.

Delivery of cardioplegia in patients with ALCAPA requires variation from routine procedures. Ensuring adequate cardioplegia flow to all the myocardium is crucial for the preservation of myocardial function. Usually, this can be achieved by anterograde delivery of cardioplegia via both the normally placed right coronary and the anomalous left coronary, the latter usually achieved by cannulating and perfusing into the pulmonary artery clamped so that that flow is restricted to the ALCAPA vessel.

After the cross-clamp is removed and the heart is perfused, recovery of electrical and motor function of the heart may be slow. As long as the heart is not distending, perfusion pressure and myocardial perfusion are adequate, allowing the heart considerable time to eject without the work of supporting the full circulation, which is beneficial for myocardial recovery. Forcing the heart to support the circulation with early weaning from CPB and administration of large doses of inotropes carries a high risk of return to CPB and of causing myocardial injury. TEE is crucially important in these infants to assess myocardial function and the degree of MR after repair.

Translocation of a coronary artery has the major risks of bleeding from the suture line and poor flow in the coronary, leading to myocardial ischemia and poor function. Blood loss may be minimized by reversal of heparin (as far as possible, but may be limited by the need for mechanical support of the circulation), by optimizing coagulation with appropriate blood products and the use of an antifibrinolytic. Concern about thrombotic and embolic complications may deter some pediatric cardiac units from using these agents. Poor function of the translocated ALCAPA vessel may require revision of the surgery.

These patients are at significant risk for myocardial failure and circulatory collapse after weaning from CPB. Depending on the circumstances, leaving the sternum open and closing the skin with a membrane and dressing may be safer than formal closure of the chest. Not closing the sternum will prevent early pressure on the heart and allow room for some postoperative swelling without compression of the heart. The membrane closure also allows rapid access for resuscitation and return to bypass in the early postoperative period. Purse strings for cannulation for bypass may be left in place during this period and removed when the chest is formally closed. For patients who are less stable in the operating room, transitioning from a CPB circuit with venous reservoir to other mechanical support such as left ventricular assist device, biventricular assist device or ECMO will provide circulatory support of the patient while the myocardium recovers and improves function. Occasionally, failure to wean from CPB for other operations, i.e., ventricular septal defect (VSD) with left ventricular dilation and failure, may be due to an unrecognized ALCAPA; Callagan et al. reported this occurrence in a 6-week-old patient where pulmonary hypertension was suspected to have prevented severe left ventricular dysfunction, decreased the symptoms and masked the diagnosis of ALCAPA [55]. Coronary angiography confirmed the ALCAPA diagnosis, and emergency reoperation, repair of ALCAPA, and postoperative ECMO were necessary to ensure successful outcome.

KEY POINTS: ALCAPA

- ALCAPA presents with ischemic cardiomyopathy in the first few months of life.
- Decrease in PVR may create a coronary steal phenomenon.
- Early operation within days of diagnosis is recommended, due to the risk of sudden death.
- The risk of circulatory collapse at induction of anesthesia and in the pre-bypass period is high. Immediate institution of CPB should be available.
- Induction of anesthesia should be titrated with monitoring and cardiovascular support.
- Maintenance of both pulmonary and systemic vascular resistance (SVR) is important.
- Translocation of the ALCAPA to the aorta is the operation of choice.
- Availability and a reasonably low threshold for mechanical support (VAD/ECMO) are important considerations.
  - Long-term outcomes after ALCAPA repair are very good
  - Although early operation on the mitral valve remains controversial, early repair is often performed when mitral regurgitation is severe

Anomalous aortic origins of the coronary arteries

Some of the abnormalities historically thought to be benign have more sinister subgroups where coronary perfusion may be jeopardized in certain circumstances and sudden death may occur. Abnormal origins of the coronary arteries from the aorta are most commonly benign; however, if these abnormalities involve a left coronary artery arising from the right coronary sinus (0.15% in adult cardiac catheterization series) and the course of the vessel passes between the aorta and pulmonary artery, then there is a risk of myocardial ischemia with angina and sudden death, especially with exercise. A right coronary artery arising from the left coronary sinus (0.92%) with the vessel passing between the aorta and pulmonary arteries is also associated with sudden death. Most of the variants of the abnormal location of the origin of the coronary artery from the "opposite" coronary sinus do not have the vessel taking a course between the aorta and pulmonary artery and do not appear to be at higher risk. Where the coronary artery does pass between the aorta and pulmonary arteries, it is postulated not only that exercise increases the risk of myocardial ischemia due to increased oxygen demand in the face of some obstruction to flow as a result of constriction between the aorta and pulmonary artery, but also that the increased cardiac output associated with exercise may cause distension of the root of these vessels, especially the elastic pulmonary artery, and worsen the obstruction of the coronary vessel "sandwiched" between the two great arteries.

Deciding about therapy is difficult in the scenario where the first symptom may be sudden death but the lesion may also be benign. Criteria for intervention are based on evidence of obstruction, symptoms, exercise testing, and detailed imaging to quantify lateral compression, and hypoplasia or stenosis associated with the anomaly, especially as there is commonly an intramural portion that may be narrow. Therapeutic approaches have included beta-blockers and/or advice to avoid exercise with substantial effort; cardiological intervention with stenting; and surgery, which may involve rerouting the vessel, unroofing a narrow intramural portion, or providing an alternative inflow by graft or aortic side-to-side anastomosis, distal to the narrow compressed segment [56, 57].

Congenital atresia of the left main coronary artery

Congenital atresia of the left main coronary artery (CALM) is a rare, apparently benign anomaly. It is distinguished from "single coronary artery," where the single vessel has two main branches with distributions similar to the normal left and right coronary arteries, in that CALM has the distribution to the left heart filled retrograde by collaterals. There is an association with supravalvular aortic stenosis, especially Williams syndrome, with coronary anomalies, including CALM, which are associated with intermittent ischemia and sudden death (see later).

Coronary arteriovenous fistulas: incidence, anatomy, and natural history

Coronary arteriovenous fistulas (CAVFs) occur in only 1 of 50,000 live births but are noted in 1 of 500 patients having cardiac catheterization. In those with a congenital fistula, associated CHD occurs in 20–45%. Congenital fistulas may represent the persistence of embryonic sinusoids that provide myocardial blood supply by cross-connecting the lumen of the primitive tubular heart. Although called "arteriovenous," the distal connection is usually to the right side of the circulation but not necessarily to a vein, and termination in any chamber of the heart or in the pulmonary artery is possible [58] (Figure 31.17). CAVF can also be acquired as a

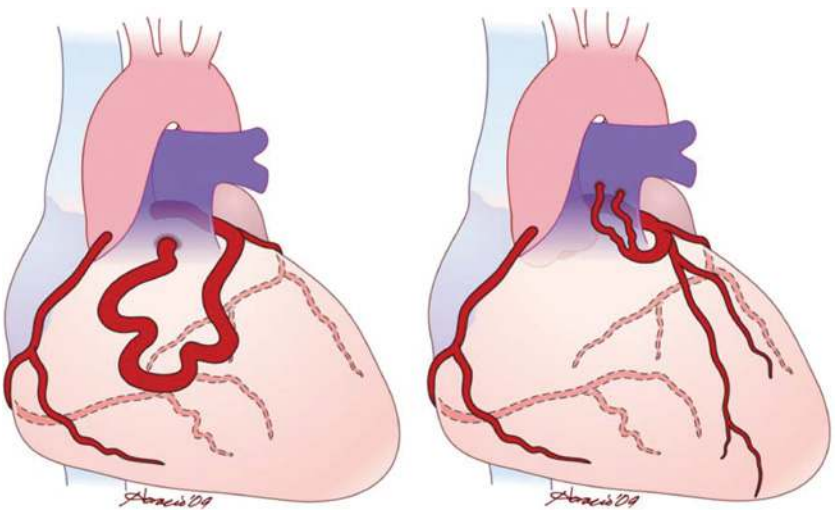

Figure 31.17 Two types of coronary-to-pulmonary artery fistulae (CPAF). (A) There is a single prominent fistulous connection between the left main/left anterior descending artery and the main pulmonary trunk. (B). There are multiple small-caliber fistulous connections between the left main/left anterior descending artery and the main pulmonary trunk. Although both types of CPAF involve the same vessels, anecdotally the CPAF patients with morphology resembling (A) were more likely to be symptomatic as there was greater hemodynamic effect when compared with CPAF patients with morphology resembling (B). AL Grawany

result of abnormal connections made by, for example, trauma, including surgery or cardiological intervention, infection, or ischemia. CT angiography with MDCT (multiple detector computed tomography) is now the test of choice for diagnosing CAVF. It has a short examination time and superior spatial and temporal resolution [58].

CAVFs may be subclassified by angiographic appearance as *type A*, where the coronary artery is dilated proximal to the fistula, but continues with the normal coronary vessel arborizing in the myocardium distal to the fistula; and *type B*, where the coronary artery is dilated over the entire length and terminates on the right side of the heart. These categories may determine management, as suitability for catheter occlusion and surgical approach will depend on the anatomy.

CAVFs may present as incidentally detected asymptomatic murmurs. The natural history is very variable and largely depends on the size of the shunt created, the development of complications (see the next section) and associated conditions. Some smaller fistulas have been noted to close spontaneously [59]. There are currently no established guidelines for deciding whether, or how to treat coronary fistulas [58].

Pathophysiology of CAVFs

Although often incidental findings, there are a number of mechanisms by which these anomalies can produce serious complications. As a connection between a high-pressure and a low-pressure part of the circulation, a high-speed turbulent jet may be created which may be the substrate for subacute bacterial endocarditis or for development of abnormalities of the supplying vessel, with fibrosis, stenosis, and aneurysm formation possible, and with consequent thrombosis, embolus, or rupture of a coronary vessel causing myocardial ischemia or sudden death. Myocardial ischemia may also arise from a coronary steal, with perfusion pressure in related coronary vessels becoming critically low due to the run-off down the sinus. If there is a high flow through the fistula, this may be sufficient to create significant volume loading with heart failure or pulmonary hypertension.

Surgery and catheter treatment of CAVF

There is controversy about whether asymptomatic fistulas should be treated, but some suggest that prevention of complications warrants intervention for all CAVFs. Others are more conservative, noting that spontaneous closure of some small fistulas has been observed and all interventions carry non-trivial risk and favor monitoring and conservative management. Some fistulas are suitable for catheter occlusion techniques if they are accessible and there is a low risk of coil embolus or interruption of distal coronary perfusion.

Surgical interruption of the fistula is the most common treatment. Some may be suitable for proximal ligation on the epicardial surface with a beating heart without CPB. Care must be taken to ensure that there is no myocardium that will become ischemic with ligation of the fistula. To preserve branches that provide myocardial perfusion, some fistulas will require ligation at their termination, which will usually require CPB.

Anesthesia for CAVFs

Anesthesia will be determined by the procedure planned and the complications that the patient has developed. If CPB and an open procedure are planned, the potential for the fistula to jeopardize myocardial protection must be carefully considered and managed. Run-off of the cardioplegia solution down the fistula may result in failure of myocardial protection for substantial segments of the myocardium. Controlling the fistula and then providing more cardioplegia may be warranted. Catastrophic failure of myocardial preservation has been seen to occur in cases where a fistula was undiagnosed or uncontrolled and where other associated congenital lesions were being repaired. Bacterial endocarditis prophylaxis is recommended for all patients with coronary artery fistulas [58].

Coronary artery bridging, aneurysms, and stenosis

Coronary artery bridging represents a common normal variant, with the coronary artery having a segment of the intramural course. Occasionally, this may be associated with stenosis or dynamic occlusion, which may require intervention. It is rare for this diagnosis to be the primary indication for surgery in pediatric practice. In pediatrics, coronary bridging most commonly presents as technical problems for the surgeon, which may complicate surgery and be associated with coronary injury, sometimes producing ischemia and poor function after the surgical procedure.

Coronary aneurysms may be congenital, but acquired lesions due to Kawasaki disease are more commonly encountered in pediatric practice. It is rare that there are surgical or catheter interventions for these lesions, but anesthesia for imaging procedures may be required.

Congenital stenosis of the coronary arteries is rare. Lesions of the left coronary artery may be associated with sudden death. Acquired stenosis may occur in childhood as a result of precocious atheromatous disease in familial hyperlipidemia, secondary to the abnormalities of the aortic root due to arteritis or connective tissue disorders, or in relation to fibrosis arising from turbulence due to regional anatomical abnormalities.

Coronary artery abnormalities associated with supravalvular aortic stenosis

Surpravalvular aortic stenosis, commonly associated with Williams syndrome, can result in abnormal coronary flow and sudden death. There are a number of case reports and series of these patients having circulatory collapse in association with anesthesia [60]. The most disturbing feature of these reports has been the absence of obvious precipitating factors, such as changes in heart rate or blood pressure. This has made anesthesiologists wary of these patients because resuscitation has been unsuccessful in a number of these cases once a cardiac arrest has occurred. These events are not well related to the degree of aortic obstruction, so the anesthesiologist may be falsely reassured that the risk is low, as with aortic valve obstruction of a similar degree.

The mechanisms for abnormal coronary flow in these patients are multiple. [61] There may be associated

congenital abnormality of the orifice of the coronary arteries. There may be a proximal congenital stenotic segment of one of the coronary arteries, the left being the most dangerous. Turbulence related to the abnormal anatomy combined with systolic hypertension proximal to the supravalvular stenosis may lead to acquired changes in the coronary orifice with obstruction secondary to fibrosis or atheroma. Diastolic hypotension proximal to the supravalvular stenosis may decrease diastolic perfusion on which the left ventricle is dependent. Interaction between the tip of the aortic valves and the stenosed aortic segment may result in obstruction to coronary perfusion, either chronically or potentially acutely in relation to a fleeting change in valve disposition.

In summary, patients with supravalvular aortic stenosis are at high risk of acute coronary events that may be triggered by subtle changes in the circulation. Resuscitation may not be possible should cardiac arrest occur. A detailed cardiological evaluation may inform the level of risk, but avoiding anesthesia prior to surgical repair of the lesion may be warranted. The surgical plan should deal with both the supravalvular obstruction and the mechanisms of coronary obstruction. The anesthesia induction should be considered high risk, with immediate availability of emergency access to CPB. Further details about supravalvular aortic stenosis, and its anesthetic and surgical management, are presented in Chapter 27.

Pericardial effusion and tamponade

Incidence, anatomy, and natural history

The pericardium is a double-layered sac in which the heart and base of the great vessels are invaginated. There is normally a minimal amount of fluid, about 10–50 mL, between the inner visceral and tough outer parietal layers. There is enough compliance in this sac to accommodate small amounts of fluid collecting with minimal pressure change. In the acute situation, further fluid collection will be in the face of very low compliance and generate a rapid increase in pressure, which will compress the heart, preventing ventricular filling and decreasing stroke volume. In the more chronic situation, slow accumulation of fluid may allow time for expansion of the pericardial sac and larger volumes to be accommodated with less myocardial compression (than smaller volumes accumulating acutely). Some useful parameters for characterizing pericardial effusions in adult-sized patients are listed in Table 31.5 [62].

A broad spectrum of pericardial syndromes can present with degrees of significance ranging from completely asymptomatic to life-threatening. Chronic inflammatory conditions may induce fibrosis of the pericardium with decreased compliance of the pericardium and potential for a thick pericardium to tightly encase the heart, creating chronic constrictive pericarditis [63, 64]. Chronic pericarditis may be caused by tuberculosis. There are many causes of pericardial disease. In 2015 the European Society of Cardiology (ESC) proposed an updated classification system for pericardial diseases which has been endorsed by the American Society of Cardiology (ACC) [65] (Table 31.6). Tuberculosis is considered the most important world-wide cause of pericardial disease. It widely affects developing countries where this bacterial infection is endemic and is often seen associated with HIV infection [65]. Pericardial disease often requires a combination of procedural and medical management. The acute medical management of pericarditis has historically involved anti-inflammatory medications such as aspirin and non-steroidal anti-inflammatory drugs (NSAIDs). Two significant clinical trials by Imazio et al. in 2010 and 2014, known as the COPPS (Colchicine for the Prevention of the Post-Pericardiotomy Syndrome) and COPPS 2 (Colchicine for the Prevention of the Post-Pericardiotomy Syndrome and Postoperative Atrial Fibrillation), respectively, showed a statistically significant reduction in PPS (Post-Pericardiotomy Syndrome) using colchicine, an anti-inflammatory derived from the autumn crocus plant often used for the treatment of gout. Since these favorable randomized trials colchicine is now a Class 1A agent not only for prevention but also for *treatment* of acute

Table 31.5 Classification scheme for pericardial effusions in adult-sized patients

Onset:
Acute versus chronic
Size:
Small
50–100 mL (or TTE-derived **single** dimension at end-diastole <10 mm)
Medium
100–500 mL (or 10–20 mm on TTE)
Large
>500 mL (or >20 mm on TTE)
Extent:
Localized versus **circumferential**
Hemodynamic impact:
Insignificant versus significant (i.e., cardiac tamponade)
Fluid composition:
Transudate versus exudate

Abbreviation: TTE, transthoracic echocardiography.

AL Grawany

and recurrent pericarditis and post-cardiac injury syndromes [62]. Pericardial disease can have significant long-term consequences. Pericardial effusions should be considered a marker of the severity of underlying disease and when idiopathic are often the first incidental finding of unrecognized disease [66]. A meta-analysis of over 10,000 patients in 2011 by Mitiku et al. showed that the presence of even a small and asymptomatic pericardial effusion (of any cause) increases all-cause mortality; thus, early recognition and therapy are extremely important [67].

Pericardial effusions can be broadly divided into inflammatory and non-inflammatory causes [68] (Table 31.7). Within the pediatric congenital cardiac population conditions associated with tissue edema and capillary leak, such as heart failure or the high venous pressures of a poorly functioning Fontan circulation can be causes [69]. The most common cause of pericardial effusion and tamponade in this subgroup are due to complications after surgical interventions. Cardiological interventions, such as the use of wires, balloon catheters and taking biopsies, and occasionally some anesthesia procedures, such as central venous cannulation, can all result in perforation of the heart and hemorrhage into the pericardium [70, 71]. A detailed history and physical examination with considering the clinical context often point to the cause of an effusion. Any pericardial disease may cause tamponade, but the pre-existing condition and background of the patient may help decide the probability for borderline cases. A Working Group on Myocardial and Pericardial Diseases for the European Society of Cardiology studied the epidemiology of pericardial disease that progresses to tamponade and formulated a triage strategy outlining which conditions are least or most likely to progress to tamponade [72] (Table 31.8).

There are multiple mechanisms for pericardial collections to form as a result of cardiac surgery. Postpericardiotomy syndrome (PPS) may occur after 15–30% of open-heart procedures in children. The incidence is much lower, <2%, after closed procedures. The mechanism is immune-mediated with anti-heart antibodies almost always present. Previous suggestions that these reactions are commonly also linked to new or reactivated viral infections have been questioned in more recent studies. Although there is unpleasant and prolonged hospital stay, PPS only rarely leads to tamponade or death. Steroid prophylaxis does not prevent this condition in children and may lead to a worse course with an increased percentage needing drainage. Steroid treatment of PPS makes a modest impact on the recovery profile [73]. PPS is usually managed with NSAIDS and/ or colchicine and may

Table 31.7 Causes of pericardial effusions

Inflammatory
Infectious:
Viral: enteroviruses (coxsackie B, echoviruses), adenovirus, herpesviruses (EBV, CMV, VZV), parvovirus B19, HIV, HCV
Bacterial: Mycobacterium (tuberculosis, avium-intracellulare), gram positive cocci (Streptococcus, Staphylococcus), Mycoplasma, Neisseria (meningitides, gonorrhea), Coxiella burnetii
Fungal: Histoplasma species, Candida species
Protozoal: Echinococcus species, Toxoplasma species
Cardiac injury syndromes: post-pericardiotomy, post-myocardial infarction, post-electrophysiology or coronary interventions
Autoimmune: systemic lupus erythematosus, Sjögren syndrome, rheumatoid arthritis, scleroderma, eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome), familial Mediterranean fever
Uremic pericarditis
Drug hypersensitivity
Non-Inflammatory
Neoplastic: primary tumors (mesothelioma, sarcoma), secondary (lung and breast cancer, lymphoma)
Metabolic: hypothyroidism (myxedema coma), severe protein deficiency
Traumatic: iatrogenic, direct/indirect pericardial injury (penetrating or blunt chest wall injury, and aortic dissection Reduced lymphatic drainage: congestive heart failure, cirrhosis, nephrotic syndrome

Table 31.8 Causes of pericardial disease and precipitating factors causing cardiac tamponade

Likely to progress to cardiac tamponade
Neoplastic diseases
Infections (i.e., viral: EBV, CMV enteroviruses, HIV, bacterial, especially tuberculosis)
Iatrogenic hemopericardium
Post-traumatic pericardial effusion
Post-cardiotomy syndrome
Hemopericardium in aortic dissection and rupture of the heart after acute myocardial infarction
Renal failure
Rarely progressing to cardiac tamponade
Systemic autoimmune disease
Autoreactive pericardial effusions
Hypo- or hyperthyreosis
Early and late pericarditis (Dressler's syndrome) in acute myocardial infarction
Any other etiology of pericardial disease (i.e., cholesterol pericarditis, chylopericardium)
Never progressing to cardiac tamponade
Pericardial transudates caused by heart failure or pulmonary hypertension
Pericardial transudates in the last trimester of normal pregnancy
Precipitating factors
Drugs
Antihypertensive medications
Anticoagulants, thrombolytics, etc.
Injury
Complex PCI
Pacemaker implantation
Endomyocardial biopsy
Recent cardiac surgery
Indwelling instrumentation
Blunt chest trauma
Septicaemia
Dehydration, diuretics (reduced circulating volume)

occasionally need drainage of the effusion. Hemopericardium may arise from a specific source (or sources) of surgical bleeding, but it is more common for the postoperative bleeding to arise from raw surfaces, and conservative treatment, dealing with any clotting abnormality and having adequate surgical drains in place, will usually prevent the development of tamponade and the need for reoperation. If the bleeding persists or tamponade develops, surgical exploration will be required. Bleeding in relation to the removal of surgically placed intracardiac vascular catheters and temporary pacing wires may occasionally be rapid and lead to cardiac tamponade. Protocols for close monitoring after a line or lead removal, with elective echocardiography to look for an effusion some hours later (or earlier if there is a clinical suspicion of bleeding), have allowed earlier diagnosis of complications. Prolonged duration of effusion can occur in relation to lymphatic interruption, with the effusion being chylous if feeding has resumed. Patients who do not tolerate conversion to a completed Fontan circulation may also develop long-term effusions

Pathophysiology and diagnosis of cardiac tamponade

Tamponade is a life-threatening compression of the heart, which can occur slowly or rapidly, due to the pericardial accumulation of fluid, pus, blood, clots, or gas as a result of inflammation, trauma, aortic dissection, or cardiac rupture [74]. Eventually, the pericardial compliance will reach a limit beyond which even a small increase in fluid volume will lead to a rise in pressure that will cause tamponade physiology [75] (Figure 31.18). The pathophysiology of acute pericardial tamponade involves myocardial compression with restriction of ventricular filling. Venous pressure is raised. As stroke volume decreases, sympathetic stimulation will produce tachycardia to maintain cardiac output and systemic vasoconstriction to maintain systemic blood pressure. Venous and end-diastolic ventricular pressure will rise as the tamponade progresses, and tachycardia and systemic hypotension will become more severe. The minimum pressure in any chamber or great vessel compressed by the tamponade will be the pressure generated by the tamponade, so eventually all intracardiac pressures will equalize [76]. The *normal* inspiratory drop in pulmonary vascular resistance results in increased venous return to the right ventricle (RV) and only a small drop in the left ventricular (LV) filling pressure gradient, resulting in a physiologic drop in systolic blood pressure of <5 mmHg. As fluid collects in the pericardium during tamponade this drop is *accentuated* and during inspiration in the tamponade condition LV diastolic filling pressure remains high (from high pericardial pressure) which causes a decline in the filling pressure gradient thus causing an *even more exaggerated* drop in stroke volume [68]. Figure 31.19 explains these respiratory influences on cardiac filling.

Further compromise to myocardial function during tamponade can arise due to myocardial ischemia, even in patients with normal coronary arteries. Severe tamponade will cause systemic hypotension and high end-diastolic ventricular pressure, which will produce a low coronary perfusion pressure. Tachycardia will be associated with a very brief diastolic duration, the only phase of the cardiac cycle where the myocardium of the left ventricle is perfused. This combination of low perfusion pressure and inadequate time for perfusion can create myocardial ischemia. This will decrease myocardial function, with both diastolic and systolic dysfunction exacerbating the systemic hypotension and increasing end-diastolic ventricular pressure, creating a vicious cycle of worsening myocardial perfusion.

Cardiac tamponade can occur with an open pericardium. The space where the fluid is confined and pressure is created, which compresses the heart, depends on the procedure that has been done. Most cardiac procedures done through a sternotomy will involve opening the pericardium, and many repairs of CHD require harvesting of autologous pericardium for use as surgical patches. Usually, the pericardium is not closed with watertight suturing and it may be left wide open. In this circumstance, fluid collecting in the pericardium can emerge to occupy a larger space in the mediastinum. If drainage is inadequate, the physiological consequences of cardiac tamponade will still develop once the space fills to the point of relative

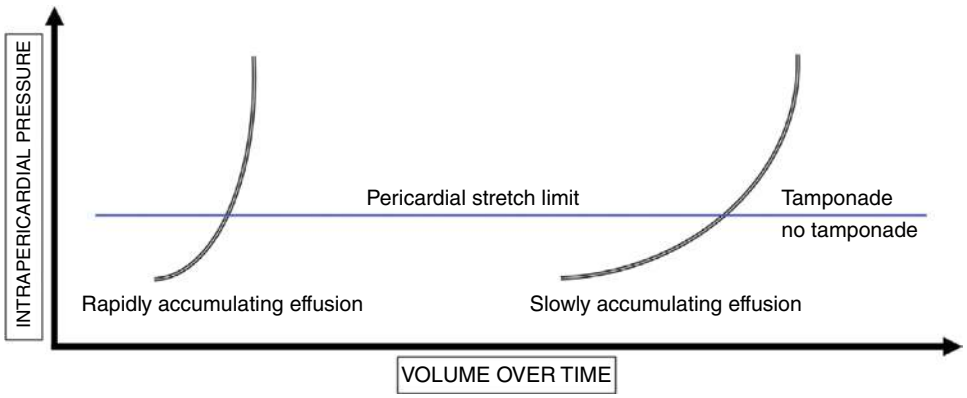

Figure 31.18 Tamponade physiology is predicted by the rate of rise of the effusion and the pericardial compliance. At a certain threshold, the pericardium's compliance will reach a pericardial stretch limit, where even a small increase in pericardial fluid volume will lead to the rise in intrapericardial pressure that causes tamponade. (Source: Alerhand & Carter [75]. Reproduced with permission of Elsevier.)

AL Grawany

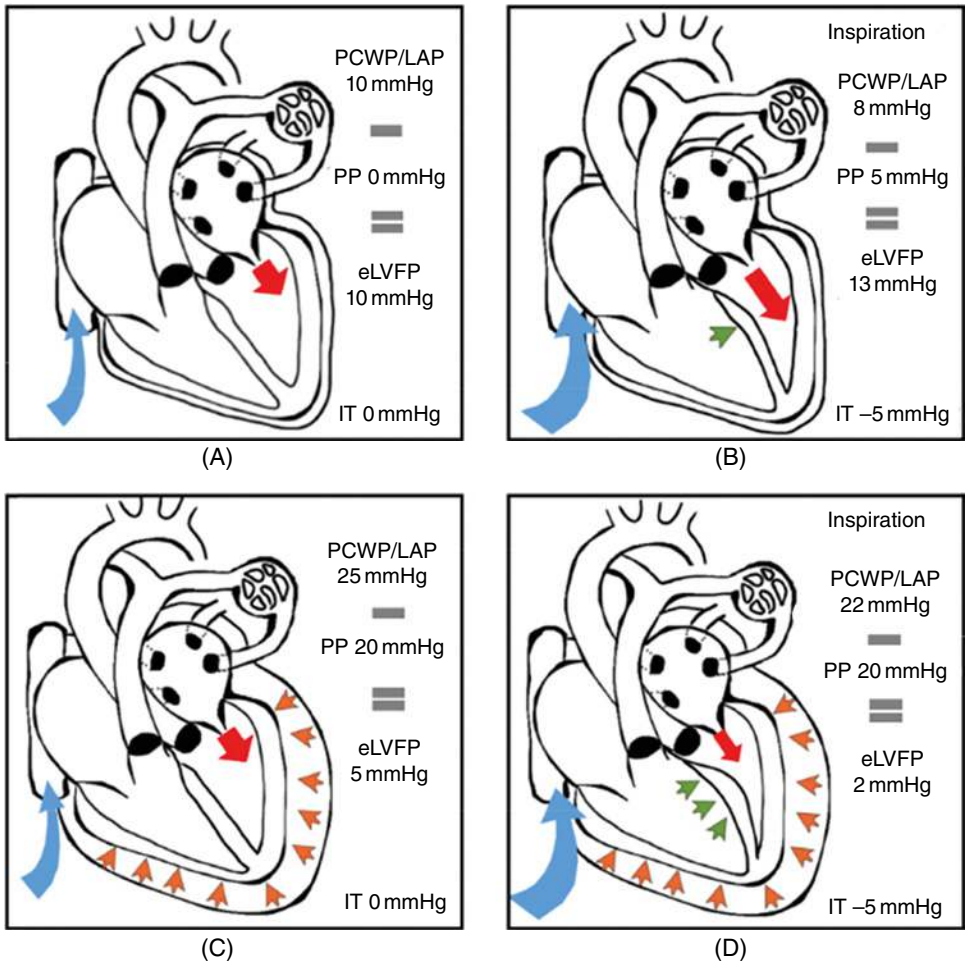

Figure 31.19 Respiratory variation in left ventricular filling. Illustration of effective left ventricular filling pressure (eLVFP) in normal patients at baseline (A) and with inspiration (B) as well as patients with cardiac tamponade at baseline (C) and with inspiration (D). The eLVFP is the difference between the pulmonary capillary wedge pressure (PCWP) or left atrial pressure (LAP) and the pericardial pressure (PP). In normal patients, the PP is low and equal to the intra-thoracic pressure (IT). With inspiration, the PCWP/LAP decreases, and the PP becomes negative, resulting in a net increase in the eLVFP (B). In patients with cardiac tamponade, both the PCWP/LAP are elevated due to the high PP (orange arrows), resulting in a lower eLVFP. With inspiration, there is increased venous return to the right side (blue arrow) and a drop in PCWP/LAP (which lies external to the pericardium) relative to the PP, thus decreasing the eLVFP (D). The LV is consequently restrained both by pressure externally from the pericardium (orange arrows) and internally from interventricular interaction (green arrows). (Source: Vakamudi et al. [68]. Reproduced with permission of Elsevier.)

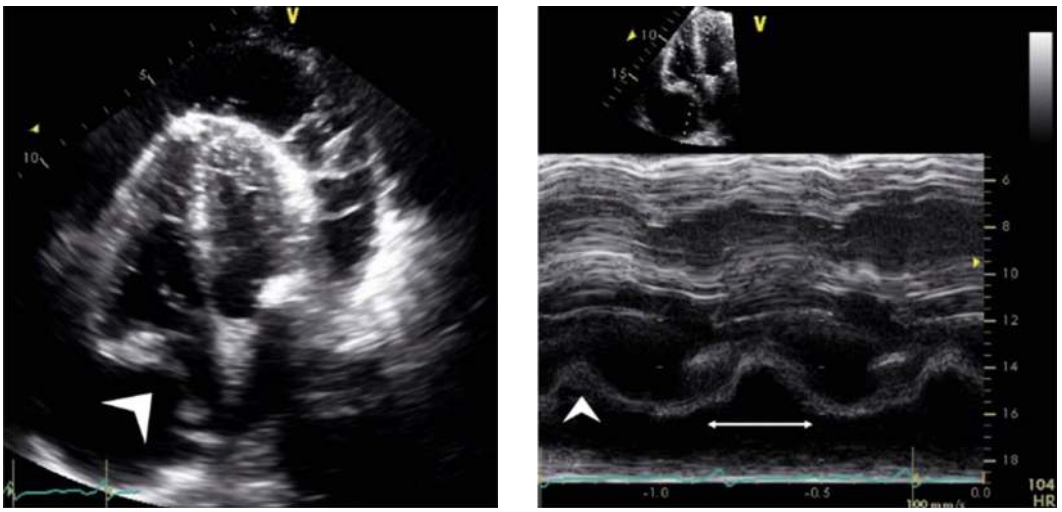
non-compliance and the pressure increases. Edema of the heart and mediastinal tissues in response to surgery and CPB may greatly decrease the volume and compliance of these spaces. Surgery may also have created continuity of this mediastinal space with the pleural spaces, which will allow large volumes of fluid to be accommodated in the pleura, decreasing the risk of tamponade but allowing greater concealed fluid (sometimes blood) loss. Draining the pleural fluid should also drain the mediastinal fluid in this scenario. In high-risk cases where chest closure is likely to create pressure on cardiac structures or vessels, or closure will create a small non-compliant space, with potential tamponade due to perioperative swelling, delayed chest closure can be used. The sternum is left open, and the skin may be closed directly or by a membrane.



Clinical signs of cardiac tamponade include tachycardia and systemic hypotension and high venous pressure. Beck's triad is the combination of hypotension and high venous pressure (distended neck veins in older children) with quiet sounds on cardiac auscultation [76]. Pulsus paradoxus, which is an exaggeration of the usual minimal (<10 mmHg) decrease in blood pressure with inspiration, increases with the degree of tamponade. Pulsus paradoxus can be quantified during auscultatory measurement of blood pressure by noting the difference between the pressure when the first Korotkoff sounds (which appear during expiration in the spontaneously breathing patient) and the pressure when the sounds become continuous. Other signs of sympathetic activation and low cardiac output, such as cool extremities and pallor from vasoconstriction, may be present. Clinical context will usually give some indication of the origin of cardiac tamponade. Obstruction of mediastinal/pericardial drains may be indicated by tamponade after cessation of previously consistent drainage.

Echocardiography provides a rapid, accurate detailed assessment of pericardial effusions. The site, size, and any evidence of loculation should be evident. This information can inform the selection of the approach to drainage. The degree of myocardial compression and restriction of ventricular end-diastolic volume should also be apparent [77]. Other echocardiographic signs of tamponade physiology include inferior vena cava (IVC) dilation and loss of respiratory variation in diameter of the vessel, right atrial collapse during systole (earliest sign), increase of interventricular dependence with respiration, and respiratory variation of mitral, aortic, or tricuspid inflow peak velocity of >25% [68] (Table 31.9, Figure 31.20). Prompt recognition and urgent treatment of tamponade is critical. In the final sections treatment of tamponade and anesthetic considerations for pericardial disease will be discussed.

Table 31.9 Echocardigraphic features suggestive of cardiac tamponade

Echocardiography Sign	Advantage	Disadvantage
2D and M-mode findings		
RA collapse >1/3 cardiac cycle	Sensitive sign of elevated intra-pericardial pressure.	Difficult to time the duration of collapse. May be confused with normal atrial systole.
RV diastolic collapse	Sensitive sign of elevated intra-pericardial pressure.	Non-specific, may be an early sign of tamponade.
IVC plethora with lack of inspiratory variation	Sensitive sign of cardiac tamponade.	Non-specific, commonly occurs in other conditions associated with elevated central venous pressure.
Doppler flow velocity findings		
PW or CW Doppler assessing variation in tricuspid (>60%) and mitral (>30%) inflow with respiration	Specific finding of cardiac tamponade.	Affected by translational motion of the heart and Doppler alignment. May be absent in patients with elevated left atrial pressure.
Inspiratory decrease and expiratory increase in pulmonary vein diastolic forward flow	Specific finding of cardiac tamponade.	May be absent in patients with elevated left atrial pressure. May be technically difficult to adequately sample the pulmonary vein.
Respiratory variation in ventricular chamber size and aortic outflow velocity	Sensitive finding suggestive of inter-ventricular inter-dependence.	Can also be seen in constrictive pericarditis or other causes of exaggerated changes in intra-thoracic pressure.
PW Doppler of hepatic venous flow velocity showing expiratory decrease or reversal of diastolic flow	High positive and negative predictive values for cardiac tamponade.	Cannot be evaluated in one third of patients due to technical limitations.

Abbreviations: RA = right atrium, RV = right ventricle, IVC = inferior vena cava, PW = pulse wave, CW = continuous wave.

AL Grawany

Surgery for pericardial effusion and cardiac tamponade

Ultrasound-guided, percutaneous drainage of pericardial effusion can be done with local anesthesia, especially in older cooperative patients. A pigtail catheter is recommended to be in place for a day or two when there is a risk of recurrence [78]. In patients in extremis due to tamponade, rapid drainage may be life-saving. If active bleeding is likely to be the source of the tamponade, open operation with surgical control of the bleeding will be required and appropriate maintenance of intravascular volume will be needed. For persistent pericardial effusions, surgical creation of a "pericardial window" by resecting a section of pericardium via an open subxyphoid approach can prevent collection of the fluid in the confined space of the pericardium. For the rare cases of chronic constrictive pericarditis, formal pericardiectomy may be attempted, which is a substantial procedure with the potential for significant complications, such as hemorrhage, arrhythmia, and injury to the coronary arteries. Care must also be taken to avoid puncturing intercostal/ intermammary arteries, the liver, and the lung and using ultrasound guidance may help avoid these structures [78].

Anesthesia for pericardial effusion and cardiac tamponade

Ultrasound-guided drainage of a large pericardial effusion in a minimally symptomatic patient with local anesthesia should be a low-risk procedure, potentially performed without the support of an anesthesiologist. However, there is still the possibility of cardiac perforation or injury to superficial coronary arteries with consequent bleeding or myocardial ischemia. Areas of adhesion between the parietal and visceral layers of the pericardium and loculation of the fluid will increase the risk of these complications. Careful ultrasound assessment and real-time guidance of the tip of the needle should minimize these risks [79].

Patients having anesthesia for surgery to create a pericardial window for persistent effusions require careful assessment for the degree of tamponade present, especially if there is no drain currently in place. Most of these cases will have sufficient reserve to tolerate a careful induction of general anesthesia and institution of positive pressure ventilation. If there is evidence of significant tamponade, staged progress in anesthesia and surgery can be planned. Initial modest doses of sedation and analgesia, combined with local anesthesia, can allow percutaneous drainage of the effusion with relief of tamponade before the initiation of formal general anesthesia and controlled ventilation.

The highest-risk scenario is acute severe cardiac tamponade, usually due to postoperative hemorrhage in pediatric cardiac surgical centers, but also seen in trauma. The patient's condition may be deteriorating rapidly and already be perilous. Rapid intervention is required but induction of anesthesia may precipitate cardiac arrest. A well-coordinated rapid team response is required. The patient's underlying conditions and current status should be assessed. There may be time for resuscitation with intravenous fluids, inotropes, and vasoconstrictors to support the patient until the tamponade can be relieved and also to create some reserve to allow safer induction of anesthesia. If the tamponade is severe and resuscitation has already been attempted, the highest priority is facilitating rapid relief of the tamponade. The operating room team should be scrubbed and ready to proceed prior to anesthesia is induced. Blood for transfusion should be available and an appropriate anesthesiology team should be in place. If further intravenous access and (if the patient is stable enough) intra-arterial access is to be gained, multiple anesthesiologists/assistants may allow efficient and safe preparation of the patient. Induction of anesthesia can cause cardiovascular collapse by direct cardiac depression and vasodilation, as well as by decreasing the central sympathetic outflow. Even drugs with minimal direct depressive effects, such as fentanyl, can have a profound effect by this latter mechanism. Synthetic opioids are also prone to decreasing heart rate, which will also jeopardize circulation. Positive pressure ventilation will exacerbate the problems with venous return and compression of the heart that have been created by the tamponade, increasing the chance of circulatory collapse.

The anesthesia sequence in these cases of severe tamponade needs to be tailored to the patient's circumstances. Coagulopathy is a serious consideration in these patients and an INR above 1.5 or a platelet count of less than 50,000 is considered a relative contraindication for pericardiocentesis and may require urgent correction with platelets or clotting factors [74]. Fasting status should be considered and cricoid pressure may be implemented, even if other parts of rapid-sequence induction and intubation are modified due to the risk of circulatory collapse. The possibility of major surgical procedures to remedy the cause for bleeding once the tamponade is relieved should be considered. It may be appropriate to initially drain the pericardium with minimal sedation and analgesia and local anesthetic, which may improve cardiovascular reserve and allow safer induction of anesthesia. Anesthesia induction should be done with low doses of agents that are least likely to decrease sympathetic drive, such as ketamine (despite its potential for direct myocardial depression) titrated slowly, as the central circulation will be small and excess anesthesia effect should be minimized. Drainage of the pericardium before intubation and the introduction of positive pressure ventilation should be considered. When positive pressure ventilation is introduced, providing a substantial expiratory time with minimal or no positive end-expiratory pressure should minimize impairment of venous return. Once the pericardium is drained, hemodynamic stability will usually be rapidly restored. In postoperative tamponade, often an active bleeding point may be easily controlled, such as from the site of an intracardiac catheter that had been removed, but occasionally the hemorrhage will be from a major suture line that is now bleeding vigorously, with an increase in blood pressure and loss of tamponade. This may require ongoing resuscitation and major surgical intervention, including CPB, to revise the surgery.

In the cardiac catheterization laboratory, the heart or the great vessels may be perforated by a catheter or wire, which may result in acute severe cardiac tamponade, diagnosed by angiography or echocardiography demonstrating the blood in the pericardial space. Many of these patients will already be under deep sedation, or intubated general anesthesia. In addition to intravascular volume infusion and resuscitation

drugs, the cardiologist must drain the pericardial space immediately; this is non-clotting blood and can be reinfused directly into the patient via a three-way stopcock. The femoral venous sheath is the preferred route of reinfusion but the anesthesiologist can utilize other appropriately sized intravenous access. This maneuver can be life-saving as preparations are made for sternotomy and repair of the perforation [80](Figure 31.21).

In postoperative patients in the intensive care unit with circulatory collapse secondary to cardiac tamponade, rapid reopening of the sternum in the unit may be life-saving.

KEY POINTS: ANESTHESIA FOR CARDIAC TAMPONADE

- Cardiac tamponade is associated with high venous pressures, tachycardia, and systemic hypotension and may be life-threatening without emergent treatment
- Before anesthesia is induced, the operating room team should be in place and ready to proceed with rapid surgical relief of the tamponade.
- Local anesthesia, with minimal or no sedation and analgesia, and ultrasound-guided drainage may be the safest option and help avoid puncturing important structures
- If greater levels of sedation analgesia or anesthesia are required, slow titration and agents with less sympatholytic action should be used. Initial surgical drainage may be performed with spontaneous ventilation prior to endotracheal intubation.
- Avoiding positive pressure ventilation until the pericardium is drained may avoid circulatory collapse.

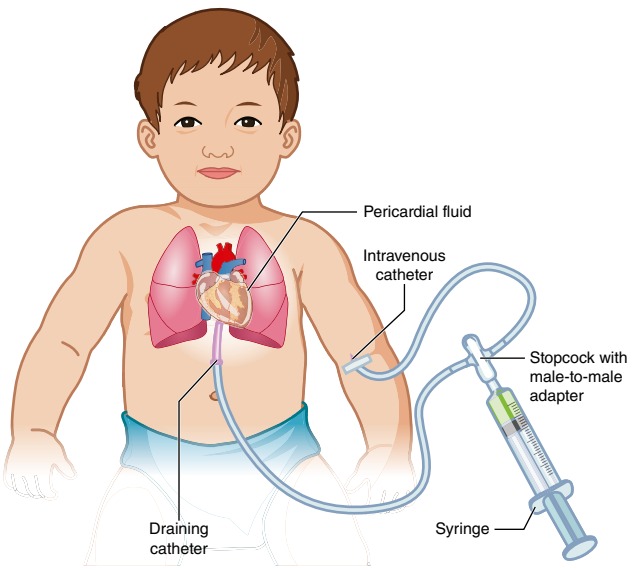

Figure 31.21 Drainage and retransfusion system for acute pericardial tamponade for cardiac perforation in the catheterization laboratory. The femoral venous sheath, if available, is the preferred site for reinfusion of blood. (Source: Mossad [80]. Reproduced with permission of Elsevier.)

Mitral regurgitation

Incidence, anatomy, and natural history of mitral regurgitation

Isolated mitral regurgitation (MR) is an uncommon pathology in childhood. The atrioventricular valve serving the systemic ventricle is not considered a mitral valve in the relatively common atrioventricular septal defect, univentricular hearts and in patients with "congenitally corrected transposition of the great arteries" (i.e., combined atrioventricular and ventriculoarterial discordance). Abnormalities of these "non-mitral" left atrioventricular valves are discussed in the relevant chapters (see Chapters 26, 29 and 30 for further discussion).

Normal anatomy and function of the mitral valve

The normal mitral valve allows low resistance passage of blood from the left atrium to the left ventricle during ventricular diastole and prevents blood from returning from the left ventricle to the left atrium during ventricular systole. Abnormalities of the valve can result in restriction of forwarding flow (stenosis) or the return of blood from the left ventricle to the left atrium during ventricular systole (regurgitation or incompetence). MR and stenosis may occur in combination [81] (Figure 31.22).

The mitral valve consists of an annulus, two leaflets, three types of chordae, and two dominant papillary muscles, as shown in Figure 31.23 [82]. The annulus is part of the continuous fibrous framework separating the atria and ventricles. There are two mitral valve leaflets: anterior and posterior. The leaflets are not symmetrical. The posterior (mural) leaflet is attached to 210 degrees of the circumference of the annulus, where it is continuous with the left ventricular free wall. The annulus is also in continuity with the aortic valve through the fibrous aortic-mitral curtain. The anterior (septal) leaflet is attached to the portion of the ring continuously with the septum and aortic valve over about 150 degrees. The anterior surface of the anterior leaflet is thus the posterior surface of part of the left ventricular outflow. On the closure of the mitral valve, the posterior leaflet forms a crescentic ("C"-shaped) part of the closure of the annulus, contributing only about a third of the cross-section of the closure despite the whole leaflet being much larger than the anterior leaflet. The smaller anterior leaflet contributes the remaining, more oval, two thirds of the closure of the annulus. This arrangement of the valve leaflets means that the posterior leaflet leaves little space between the free wall and the leaflet during systole and the anterior leaflet moves towards the posterior leaflet, increasing the diameter of the left ventricular outflow during systole. The crescentic portion of the posterior valve and the oval portion of the anterior valve, which close off the annulus, are a relatively small proportion of the total surface area of the valves. During mitral valve closure, a significant proportion of the surface area of the valves leans on each other, thus providing "mutual support" during closure. This coaptation of the valve leaflets decreases tension in the valve tissue required to maintain valve closure. The valve leaflets have multiple fibrous bands, chordae tendinae,

which connect them to both the papillary muscles (anterior and posterior), projecting from the inner wall of the mid-left ventricle. The posteromedial papillary muscle has a single blood supply from the posterior descending artery while the anterolateral papillary muscle is usually supplied by both the left anterior descending and the left circumflex. The chordae connect to both the surface and edge of the valve leaflets, distributing the forces of systolic papillary muscle contraction over a wide area of the valve leaflets [83].

Classification of mitral regurgitation

The two broad categories of MR are primary and secondary. Primary MR is a degenerative valvular disease usually caused by leaflet prolapse or flail. Secondary MR, also known as *functional* MR is a heterogenous group of conditions that refer to abnormalities of the systolic tethering of the mitral valve apparatus caused by abnormal left ventricle size, shape, or function. Therefore, therapy is focused on the restoration of LV structure and function rather than mechanical

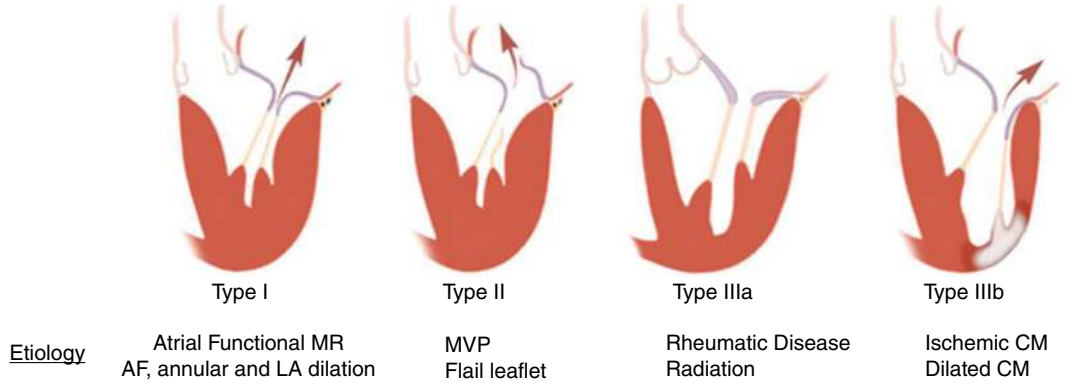

Figure 31.24 Carpentier classification. The Carpentier Classification defines mitral regurgitation (MR) in relation to mitral leaflet motion. Type I signifies normal motion (as in atrial functional MR), type II excessive motion (prolapse/flail) and Type III restricted motion (secondary MR due to underlying cardiomyopathy. (Source: Adapted from Harb & Griffin [82].)

interventions to reduce the MR. Some examples of this therapy are neurohumoral antagonists and resynchronization devices. Questions remain on whether therapy that targets *only* the mitral valve will benefit some of these patients with secondary MR. [84] The Carpentier Classification categorizes MR on the basis of leaflet mobility. Those with secondary MR usually fall into Carpentier Class 3B [85] (Figure 31.24).

Quantifying regurgitant volume is important. Consensus defines *severe* MR as a regurgitant fraction of over 50%, that is, over half of the total stroke volume is directed backwards into the left atrium instead of forward into the aorta. One way of measuring this severity on echocardiography is with the effective regurgitant orifice area or EROA [86]. Unfortunately, the EROA is highly dependent on left ventricular volume (LVEDV), pressure (LVEDV), and function and has significant interobserver disagreement; thus, its reliability has been questioned [84].

Grayburn and colleagues have proposed a new conceptual framework for categorizing secondary (functional) MR as either *proportionate* or *disproportionate* [87]. The principal reason for this is to determine whether interventions directed at the mitral valve can change the clinical course of the disease. In their view, it is important to determine whether the estimated degree of MR is expected or *proportionate* to the degree of LV dilation, or alternatively, whether the severity of MR is unexpected, or *disproportionate* to the degree of LV enlargement. A patient whose MR severity is consistent with their amount of LV dilation (proportionate MR) might not be expected to improve following a valve intervention. On the other hand, a large degree of MR relative to the degree of LV dilation (disproportionate) might respond favorably [87].

Two randomized control trials, MITRA-FR [88] and COAPT [89] support Grayburn's proposed framework. In the French MITRA-FR trial, 307 patients with secondary MR underwent transcatheter MV repair. The patients enrolled showed striking degrees of LV dilation and *proportionate* degrees of MR. These patients at analysis showed no improvement in LV volume after one year of valve repair. In contrast, the U.S.-Canadian COAPT (Cardiovascular Outcomes Assessment of the MitraClip Percutaneous Therapy for Heart Failure Patients with Functional MR) randomized 614 patients to undergo transcatheter MV repair or control. Contrary to the MITRA-FR study, valve repair in this group led to a significant reduction in LV volume at follow-up. The enrolled COAPT patients had MR that was *disproportionately* greater than their degree of chamber enlargement. When COAPT patients are compared to MITRA-FR patients, as a group, the COAPT patients had EROA values 30% *higher* but LV volumes 30% *smaller* [84].

This framework suggests that distinct secondary MR patient subgroups patients will likely benefit from *different* types of medical treatments or valve-directed therapies. Disproportionate MR patients respond poorly to neurohumoral antagonists traditionally prescribed for associated cardiomyopathy but benefit more selectively from interventions that are directed toward restoring valve function such as valve repair/replacement or cardiac resynchronization therapy (CRT). Distinguishing these different types of MR patients is important since the *proportionate* patients have valve disease that can be explained by their degree of LV dilation and thus respond better to neurohumoral antagonist therapies.

Mechanisms of mitral valve regurgitation

Abnormalities of the annulus, leaflets, chordae, or papillary muscles may be associated with MR. Conditions that volume load the left ventricle, such as aortic regurgitation and heart failure with eccentric left ventricular hypertrophy (e.g., dilated cardiomyopathy), may cause annular dilation. Dilation of the annulus increases the area requiring closure and decreases the area of leaflet available for coaptation, both of which increase the mechanical stress on the valve tissue during systole, which may lead to immediate failure of coaptation and regurgitation or valve prolapse (see later) with subsequent regurgitation. A cleft in the annulus may not be able to be sealed by the leaflet tissue [90, 91].

Mitral valve leaflet distension, cleft, or restriction may lead to regurgitation. Distension of the valve, which may result from congenital structural abnormalities or may develop due to connective tissue disorders (e.g., Marfan syndrome) or inflammatory conditions such as rheumatic fever, can cause a portion of the valve to balloon beyond the plane of the annulus during valve closure (i.e., prolapse). This

prolapsed portion is no longer supported by the opposing valve and, as with aneurysms, the law of Laplace will apply, and wall tension will rise as the prolapse progresses and tend to make that region expand until the valve fails to oppose or even ruptures. Restriction of leaflet movement, such as with fibrosis due to inflammation, may prevent a leaflet from coapting with the opposing leaflet and consequent regurgitation. Similarly, elongation of the chordae may cause leaflet prolapse while shortening, and fibrosis may cause restriction of leaflet movement, with regurgitation developing in both scenarios. Rupture of chordae may cause acute regurgitation. Acute MR when it occurs is often a medical *and* surgical emergency. Patients usually present with severe dyspnea, decompensated heart failure, and/or severe pulmonary edema due to the sudden pressure and volume load imposed on a previously normal left atrium [92]. Fibrosis of either leaflets or chordae also tends to be associated with stenosis of the valve. Elongation of papillary muscle can cause valve prolapse and regurgitation of the mitral valve. Papillary muscle dysfunction may also cause MR. For example, in dilated cardiomyopathy, poor contraction and elongation of the papillary muscles and consequent leaflet prolapse will often be exacerbated by annular dilation and cause marked MR. Specific papillary muscle dysfunction can arise in relation to coronary artery problems, as the blood supply of the papillary muscles is usually from separate coronary arteries. Mistiming of papillary contraction in relation to the rest of ventricular contraction may be associated with MR. This may occur with some abnormalities of the coordination of the timing of regional contraction, such as conduction disturbances, some arrhythmias and complications of the pacing of the ventricle. Other rare causes of MR include distortion of the valve apparatus due to tumors [49].

Many of the conditions associated with MR can affect multiple areas of the valve apparatus (annulus, leaflets, chordae, papillary muscles) and compound the problem. Fusion of the valve leaflets at the commissures is usually associated with stenosis rather than regurgitation.

In adults, the commonest mechanism of MR is mitral valve prolapse, which is usually asymptomatic and often presents incidentally with an auscultatory click and murmur. The earliest phase of this may be "superior systolic motion" of mitral leaflet tissue above the plane of the annulus. In clinically normal children, this echocardiographic sign increases in frequency from around 1% in infants to nearly a quarter of 6- to 10-year-olds and more than a third of 11- to 18-year-olds. Some of these cases may progress to prolapse and significant regurgitation, but, given the benign outcome in most, isolated superior systolic motion is usually considered a variation of normal.

Rheumatic cardiac disease is common on a world scale and, although appearing sporadically in a wide range of communities, is commonest in socioeconomically disadvantaged communities with a high incidence of streptococcal infection and poor general health. It is the most common cause of mitral valve *stenosis* worldwide. The highest incidence of rheumatic fever in the world is said to be in the indigenous communities of remote Australia. MR is the commonest rheumatic valve lesion in children with this condition, with mitral stenosis appearing later in the disease progression, and involvement of other valves, such as the aortic, being less common initially. Public health measures for the prevention of rheumatic fever are the most important long-term approach. Valve-preserving reconstructive surgery has a number of advantages for children with rheumatic MR, avoiding the need for replacing an artificial valve due to growth and the need for anticoagulation (which may be difficult to manage in many of the communities with the highest incidence of rheumatic fever).

MR tends to be a progressive condition, as the regurgitation volume loads the left ventricle, which will dilate, exacerbating the regurgitation. Children who have a successful surgical repair of MR tend to have recovery of ventricular function and good long-term outcomes. There is an association between the long-term presence of regurgitation and atrial arrhythmias, which may continue or arise after repair. This is associated with chronic enlargement of the left atrium, which may be addressed in high-risk cases at the time of surgical intervention for the regurgitation.

Pathophysiology of MR

MR will tend to worsen with time unless the underlying pathology is corrected. The presence of regurgitation results in the need for bigger end-diastolic volumes if an adequate forward flow (cardiac output) is to be maintained as well as accommodating the regurgitant fraction, which returns through the mitral valve during systole. Increased left ventricular end-diastolic volume (LVEDV) will promote dilation of the annulus which will tend to increase the regurgitant fraction, thus creating a disadvantageous positive feedback loop of increasing regurgitation and dilation of the left ventricle, until ventricular dysfunction is superimposed on the process, which will result in decompensation of the cardiovascular system.

MR is exacerbated by factors that increase left ventricular afterload and volume loading. Lessening SVR and relieving aortic valvular abnormalities (either stenotic or regurgitant) will tend to decrease MR. If myocardial ischemia is contributing to papillary muscle dysfunction, this may be resolved by restoring coronary artery blood flow. In some cases, MR can resolve without mitral valve surgery, if the underlying precipitating factors are resolved. The onset of atrial arrhythmias, such as atrial fibrillation, associated with left atrial dilation due to MR, may trigger cardiovascular decompensation. Persistent severe MR, especially in association with the onset of ventricular dysfunction and the associated very high left ventricular end-diastolic pressures, may cause significant pulmonary hypertension with impairment of right ventricular function. The right ventricular function may also be impaired by the dilation of the left ventricle, which causes a ventricular septal shift toward the right ventricle.

Surgical approaches and outcomes for MR in children

The advent of high-quality echocardiography, including 3D imaging of the mitral valve, has contributed greatly to the understanding of the mechanisms of MR. Surgical repair can now address all levels of factors contributing to regurgitation [93].

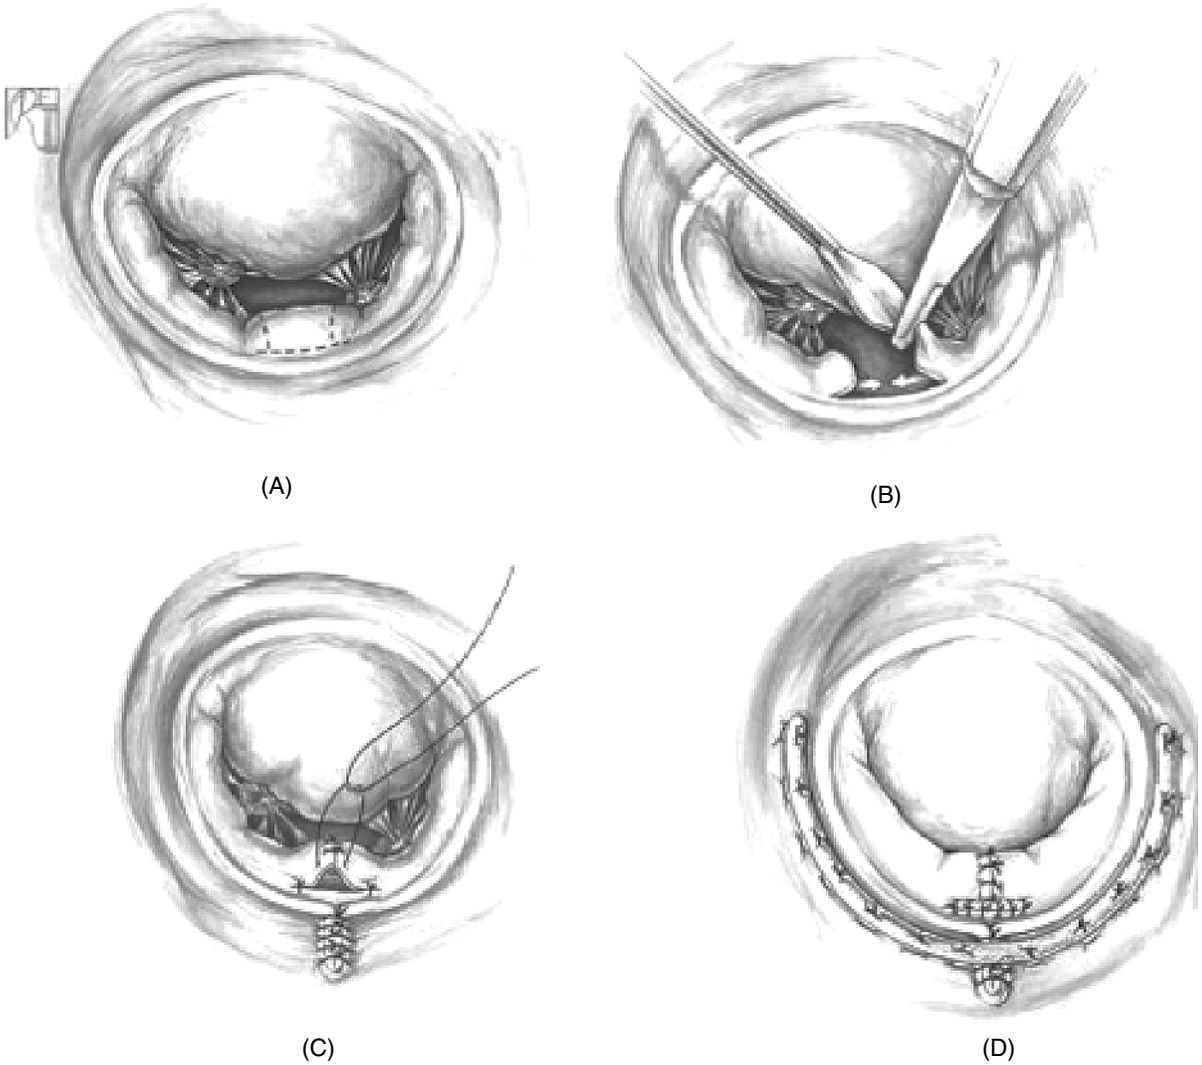

Figure 31.25 (A) Insufficient mitral valve due to annular dilatation. Dotted lines represent the proposed posterior leaflet quadrangular resection and valvular incisions. (B) After quadrangular resection, linear incisions are made in the posterior leaflet to accomplish sliding valvuloplasty (arrows). (C) The posterior annulus is brought together with care not to injure the circumflex coronary artery. Resultant tightening of the annulus brings the remaining scallops of the posterior leaflet into position for valvular repair. (D) The repair is strengthened by a semicircular Gore-Tex® strip. The anterior annulus was not included in the annuloplasty technique to allow for somatic growth. (Source: Mainwaring & Lamberti [81]. Reproduced with permission of John Wiley & Sons.)

Thus the annulus can be supported or decreased in size with a number of techniques, including insertion of a supravalvular ring [81] (Figure 31.25). The leaflets can be modified to prevent prolapse and have patches inserted and fibrotic areas debulked, thus improving coaptation and movement. Fusion of commissures where valve leaflets have joined may need to be freed to allow adequate valve movement and to relieve stenosis, but a more complex repair may be required if commissurotomy creates a cleft or failure of coaptation. Chordae can be reimplanted or changed in length, and papillary muscle elongation shortened. The aim of avoiding valve replacement is realistic for most pediatric cases. Mitral valve replacement has higher long-term mortality than any other valve replacement in children; infant mitral valve operative mortality has been reported to be 5–52%, and 5- and 10-year survival rates to be 33–95% [94]. The benefits of valve repair over replacement include avoiding the need for anticoagulation, the need for replacement of the artificial valve with growth in smaller children, and the high risk of mitral valve replacement in babies. In this last group, there is a lack of very suitable artificial valves and the surgery is complicated, as the artificial valve ring may need to sit above the annulus and the body of the artificial valve may still impair ventricular function. Bioprosthetic valves may avoid the need for anticoagulation necessitated by mechanical valves but structurally deteriorate over time (often within 2.5–5 years) and can be difficult to obtain in small sizes [95]. The lack of papillary muscle connection to the artificial valve is also associated with an abnormal geometry of ventricular contraction, which may contribute to worsening ventricular function. An individualized patient-centered approach based on underlying anatomy, valve pathology, and patient size with an

AL Grawany

understanding that re-do surgery is inevitable in infants and small children to upsize the prosthesis is fundamental and can lead to successful long-term outcomes and excellent survival [96]. Complex valve repairs have been enabled by modern techniques for myocardial preservation that allow long cross-clamp times to be well tolerated with good postoperative myocardial function.

For children with underlying conditions, which may continue or recur, such as connective tissue disease or rheumatic fever, there is a significant risk of recurrence of MR. Time gained in growth before an artificial valve is required is often a great advantage, and repeated surgery for repair of the native valve may still be a reasonable management plan in children.

Transcatheter percutaneous approaches to mitral valve repair have been established as a safe and less invasive alternative to open surgical MV repair. One such device, the Mitra-Clip® (Abbott Vascular, Menlo Park, CA) was modeled after the surgical Alfieri stitch which is the application of a suture at the site of the regurgitant jet, between the anterior and posterior leaflets (usually A2 and P2), creating a "double-orifice" valve without residual prolapse and overall less regurgitation (Figure 31.26). The Mitraclip percutaneous "edge to edge" transcatheter clip technique has been shown in numerous adult clinical trials to be safe and effective. Transcatheter techniques are the natural evolution of modern valve surgery but this technology in pediatrics is still in early clinical stages. Some novel devices and xtremely, such as transcatheter valve in valve insertion, chordae reimplantation, and catheter-based annuloplasty, are currently under development [97]. Pediatric transcatheter techniques pose many obstacles such as device durability, limited device sizes, and the potential need for future procedures with somatic growth and development. The MitraClip for example has an xtremely large 24 French introducer sheath which requires a minimum patient age of about 9–12 years with a minimum weight of approximately 40–45 kg [97, 98]. Although large studies are lacking there have been successful cases of transcatheter MV repair in pediatric patients utilizing both the MitraClip [98] and also the Melody Valve (Medtronic, Inc. Minneapolis, MN), a stented bovine jugular vein graft, commonly used in the pulmonary valve position. The Melody offers the advantage that it can be balloon dilated as a child grows [99]. It has even been modified for use as a surgical implant [100, 101] (Figure 31.27). This allows the option of future transcatheter balloon dilation from a starting size of 12 mm up to 22 mm, the size of an adolescent mitral valve. The procedure requires a fenestrated atrial septum to facilitate future dilations and reported complications include LV outflow obstruction, acute mitral regurgitation or stenosis, left circumflex coronary compression, acute distal obstruction of the valve from stent deformation, and transient complete heart block [101]. Further study is needed to determine the viability and the long-term durability and safety of this device [100, 102].

Surgery is best timed before there is severe chronic dilation of the left ventricle with loss of function, although follow-up studies in children suggest that successful repair is associated with good recovery of function over the long term. Chronic left atrial dilation is associated with atrial arrhythmias, which may persist or commence postoperatively.

Anesthetic considerations for the repair of MR

Functional assessment of the MR is based on the history of activity and exercise tolerance and is a robust measure of cardiorespiratory reserve. In infants, cardiac failure may be indicated by breathlessness and sweating with feeding, and poor weight gain. Physical examination should not only elicit the pansystolic murmur typical of MR but also seek signs of complications such as an enlarged left ventricle, or cardiac failure with a third heart sound and evidence of pulmonary congestion. History and examination may also indicate underlying conditions that may have caused the MR, such as rheumatic fever or Marfan syndrome, as well as signs of other associated cardiac lesions. Echocardiography can provide information about the severity of the regurgitation, associated lesions, and myocardial function [103]. Understanding the mechanism for the regurgitation is crucial for planning the surgical approach to repair. Standard "adult" echocardiographic measures to quantify MR may not be applicable to small pediatric patients and assessment of the severity may require interpretation rather than being able to be precisely quantified. Factors include the diameter of the base of the regurgitant jet, the shape and distance that the regurgitant plume penetrates into the left atrium, whether there is retrograde flow generated in the pulmonary veins and left atrial dilation as well as estimates of the regurgitant fraction (compared with total ejection of the ventricle). Standard estimates of myocardial function may be difficult to interpret in the presence of a dilated ventricle. The increase in volume that occurs with ventricular dilation, proportional to the third power of the diameter, means that a greater volume change occurs with a change in diameter at larger diameters. Therefore, when the dilated ventricle is full, the change in volume with contraction is very much larger than the change in volume caused by a similar decrease in diameter at a smaller starting volume. Thus, apparently small movements of the dilated ventricle may be associated with substantial volumes of ejection. Measures of tissue acceleration or initial rate of change of pressure over time may reflect underlying myocardial function better than measures of ejection fraction. Measures of ejection fraction are also complicated by the fact that there are separate "forward flow" and regurgitant fractions and that the regurgitant fraction can be considered a low resistance pathway and decreases the afterload of the ventricle (this "afterload" reduction arising from the retrograde regurgitant flow). The presence of this low-resistance pathway may also influence functional measures of contraction, in that the rate of contraction may be increased compared with ejection into a higher resistance system.

Patient management up to the time of presentation should also be assessed. Medical therapy for MR with systemic vasodilators such as angiotensin-converting enzyme inhibitors can decrease the regurgitant fraction. Systemic vasodilation will change the balance in favor of "forward flow" compared with regurgitation. Systemic vasodilation, often aided by diuretic therapy, can decrease end-diastolic ventricular volume, which may further reduce regurgitation by decreasing the size of the annulus. Improvements in echocardiographic measures of MR have been noted after the first dose of captopril. Optimizing medical therapy and nutrition should

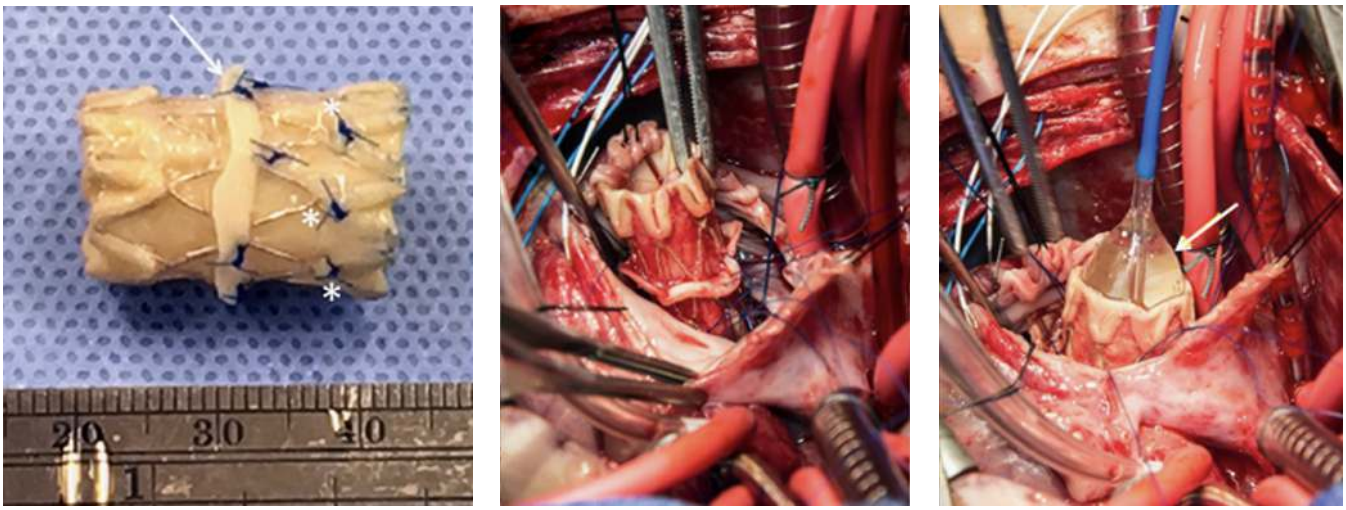

Figure 31.27 (A) Modified Melody valve prepared for implantation. The terminal crowns were folded back on both ends to lie flat against the stent and the anterior folded crowns were stitched down to prevent protrusion into the left ventricular outflow tract (LVOT) upon further expansion (*). A pericardial cuff is sewn into place to secure the valve onto the mitral annulus (*arrow*). (B) The valve is implanted, secured onto the annulus and the distal end stitched to the posterior left ventricular wall to avoid LVOT obstruction, and (C) dilated using a 12 mm balloon (*arrow*). (Source: Sullivan et al. [101]. Reproduced with permission of Cambridge University Press.)

provide more cardiorespiratory reserve for the patient at the time of surgery.

In patients with MR and well-preserved myocardial function, anesthesia is usually well tolerated. Anesthesia induction should avoid increases in SVR. Increased SVR will increase the regurgitant fraction and jeopardize forward flow. Heart rate should be maintained, as the increased LVEDV associated with bradycardia will worsen MR. Excessive intravascular volume loading may also worsen MR by increasing LVEDV and distending the annulus. Positive pressure ventilation and PEEP should improve respiratory mechanics by decreasing lung congestion and optimizing functional residual volume. Cardiovascular performance should also be favorably influenced, as positive pressure ventilation will tend to increase left atrial pressure and decrease the afterload of the left ventricle, both of which should improve cardiovascular performance in patients with MR.

Monitoring should be as for any pediatric CPB procedure. In patients with severe MR and cardiac dysfunction, surgically placed pulmonary artery and left atrial lines may be warranted for the post-repair phase. TEE is very helpful in both planning and assessing the surgical repair, but it can also be a useful monitor to inform decisions about strategies to support the cardiovascular system.

In late presentations of MR, with myocardial dysfunction and pulmonary hypertension, or patients with associated lesions such as mitral stenosis, the risk of cardiovascular decompensation with anesthesia is greater. Apart from having less reserve, some conditions may do better with an opposite strategy to that which is optimal for MR. For example, maintaining, and even increasing, SVR will benefit patients with mitral stenosis, whereas decreasing SVR is an aim for patients with MR. The more severe the cardiovascular disease and the more complex the associated conditions, the more tightly the circulation should be monitored, and titration of anesthesia drugs, cardiovascular agents, and ventilation strategies should be constant to maintain a stable circulation. In pure MR with cardiovascular decompensation, an inodilator such as milrinone or low-dose dobutamine may be useful to provide both low SVR and improved contractility.

Most cases with isolated MR and preserved myocardial function who have successful repair of the lesion and high-quality myocardial preservation during the aortic cross-clamp phase will tolerate the procedure well and are likely to be candidates for early extubation after the procedure. The commonest issue with these patients in the postoperative phase is that the good function with a dilated left ventricle creates an almost obligatory large stroke volume, which may create significant systemic hypertension. Systemic vasodilation and avoiding tachycardia may be indicated. Appropriate sedation and analgesia will assist these aims. Centrally acting α_2-adrenergic agents such as clonidine or dexmedetomidine may be useful supplements in this phase, contributing to sedation, analgesia, systemic vasodilation, and a tendency to a low heart rate. More complex cases with poor function and associated lesions or residual valve lesions will usually require more support and a longer intensive care course.

Patients with poor function and residual regurgitation in the early postoperative phase may have a decrease in the regurgitation as function improves. This may relate to decreasing ventricular dimensions with improved function, which decreases the size of the annulus, and to improvement in papillary muscle function, stabilizing the leaflets and decreasing prolapse. This may influence the judgment of when an immediate revision of the repair is indicated when the intraoperative post-bypass echocardiography demonstrates residual regurgitation. This judgment is also informed by the mechanism of the residual regurgitation, as some mechanisms may be clearly mechanical (rather than

"dynamic"), reparable with further surgery, and unlikely to improve without surgical intervention.

Catheter-based therapy for the treatment of valvular heart disease was developed for aortic and pulmonary valves in the early 2000s and significantly altered the care of this population [104]. Transcatheter mitral valve interventions have been a natural evolution of this technology. Though less invasive than sternotomy and cardiopulmonary bypass procedures, these surgeries pose unique anesthetic risks, especially in their more austerely monitored environment. General endotracheal anesthesia with TEE guidance is the norm. The mitral valve sits in close apposition to the LVOT and reported complications previously mentioned can be clinically significant. In addition, hybrid surgical strategies involving combined cardiosurgical and interventional approaches have been used for other congenital lesions and are currently under investigation for mitral valve procedures [105]. Having intraoperative and postoperative strategies for managing life-threatening arrhythmias, bleeding, or hemodynamic compromise is a critical part of the anesthetic plan in these minimally invasive cases.

KEY POINTS: ANESTHESIA FOR MR

- Isolated MR is uncommon in childhood.
- Associated conditions such as rheumatic fever or connective tissue disorders and other valve lesions should be sought.
- Repair rather than replacement of the valve is the usual aim in childhood.
- Pre-bypass, anesthesia techniques should aim to avoid increases in SVR and bradycardia, which will both increase the regurgitant fraction.
  - Transcatheter mitral valve repair techniques have a good safety record in adults. Successful use in children has been demonstrated but large studies in the pediatric population are lacking. Vigilance for anticipating serious but rare complications during minimally invasive catheter-based valve procedures must be maintained.

Cardiac tumors in childhood

Incidence, anatomy, and natural history

Cardiac tumors in children are rare, with the quoted incidence in the literature anywhere from 0.01 to 0.4% depending on the series and the particular population studied [106]. In a review of 14,000 fetal scans, the incidence of the cardiac tumor was 1.4/1,000 patients [107]. Depending on the definition used, any mass in the heart can be described as a tumor. This discussion will exclude thrombus, vegetations, and other inflammatory masses, but it is important to consider these in the differential diagnosis of a mass under investigation.

Cardiac tumors in children are almost all benign with malignant tumors comprising only a small proportion, including metastases from primary tumors elsewhere. The cardiac anesthesiologist may also see patients with tumors arising in remote tissues that have grown extensions along the venous system toward the heart. Wilm's tumor (nephroblastoma) and, less frequently, rhabdosarcoma can present like this. Although these are not technically "cardiac tumors," they may require cardiopulmonary bypass for excision. The prognosis of secondary malignant cardiac tumors is usually poor and based on the progression of, and response to treatment of, the primary malignancy.

As can be seen from Figure 31.28, the prevalence of different tumors varies with age from fetus through to adolescence [108].

The most common cardiac tumor in children is rhabdomyoma, comprising more than half the cardiac tumors in most pediatric series [109] (Table 31.10). Rhabdomyoma is usually (although not exclusively) associated with tuberous sclerosis complex. This autosomal dominant condition with variable penetrance is mostly related to abnormalities in either of two genes, TSC1 and TSC2, which are tumor suppressor genes. About two-thirds of cases of tuberous sclerosis complex arise as de novo mutations, and about 80% of cases have an identifiable abnormality in TSC1 or TSC2.

AL Grawany

Tuberous sclerosis complex affects many tissues in the body with lesions in the brain usually having the most profound clinical effects, while kidney, liver, heart, and lung lesions can also be clinically significant. Cardiac rhabdomyomas appear in the second half of pregnancy and tend to regress after birth. As many as 90% of patients with tuberous sclerosis complex have cardiac tumors at birth, but the figure decreases to about 20% in adults. There may be multiple cardiac rhabdomyomas in patients with tuberous sclerosis complex, usually occurring in the ventricular muscle or on the atrioventricular valves.

The drugs Everolimus and Sirolimus, inhibitors of the mammalian target of rapamycin (mTOR), have been shown to be effective in controlling seizures in patients with tuberous sclerosis complex, as well as reducing the size of subependymal giant cell tumors in the brain and rhabdomyomas in the heart. The mTOR is involved in the control of the cell proliferation cycle which is accelerated abnormally by defective TSC1 or TSC2 genes. In a recent systematic review of patients with TSC and cardiac rhabdomyomas, 90% of patients experienced a reduction in the size of symptomatic tumors when treated with either everolimus or sirolimus, thus offering a possible alternative to surgical resection for these patients [110].

Fibromas are the tumors of fibroblast cells and are the second most common cardiac tumor in children, accounting for 10–25% in most series. There is an association with the presence of nevoid basal cell carcinoma syndrome (also known as Gorlin syndrome) and cardiac fibromas. They are slow-growing or stable in size and most commonly occur in the ventricular free wall or interventricular septum. Unlike rhabdomyomas, they do not usually recede. However, the patient often grows faster than the tumor so adverse effects can become less severe with time. Partial resection of the tumor is acceptable for symptom relief and cardiac transplantation or single ventricle palliation has been used with some success for cases deemed non-resectable [111]. The overall prognosis is better in tumors that are able to be successfully resected.

Myxomas occur rarely in children, making up less than 10% of most series, and are largely seen in older children. They are very rare in the fetus or neonate. However, they are the commonest cardiac tumors in adults with females affected slightly more than males. The left atrium is the most common site for these tumors (75%), mostly arising from the fossa ovalis, but they can arise from any of the cardiac chambers. They are often pedunculated and lobular, may have frond-like projections but can also be sessile. About 10% of myxomas are associated with the Carney complex, an inherited tumor disorder characterized by cardiac and extra-cardiac myxomas, schwannomas, and endocrine tumors. Cardiac myxomas do not recede and need to be surgically resected in order to minimize complications due to cardiac obstruction or embolization as discussed later in this section.

Teratomas account for a small but varying proportion of cardiac tumors, 2% in one series [112], although in neonates they are second commonest after rhabdomyoma [109]. They are comprised of cells from one or more of the embryonic germ lines and are midline tumors that usually present early in life and are increasingly being diagnosed on fetal ultrasound. They can grow rapidly and if not diagnosed on fetal ultrasound, they will very likely present early in the neonatal period. It is very unusual for a teratoma to be an incidental finding.

The majority of teratomas are not malignant and surgical resection is the usual treatment. Although often arising above the heart in the anterior mediastinum, the heart and great vessels may be involved in these sometimes very large masses. They can occur within the pericardium, often causing pericardial effusion and/or compression of the right atrium. They derive blood supply from fibrous attachment to the aorta or pulmonary trunk which may make resection difficult, with some procedures requiring cardiopulmonary bypass. *In utero* and *ex utero*, fetal surgery has been successfully performed for mediastinal teratoma.

Hemangiomas can occur anywhere in the heart and may be asymptomatic, may regress, and may respond to medical therapy. Depending on the position and complications, some will require surgical resection. Some can present in infancy. There have been major advances in understanding the biology of various forms of hemangioma, and prognosis and treatment are evolving. If surgery is not required urgently, cardiac hemangiomas should be assessed by an expert vascular malformation clinic, as medical therapy may be available and detailed prognostic information may be attainable, particularly with regard to the possibility of spontaneous regression.

Pathophysiology of cardiac tumors

The pathophysiology of the various cardiac tumors is dependent upon their location as well as their size and relationship to surrounding structures.

Tumors may protrude into the cardiac chambers or outflow tracts causing obstruction to flow. In the case of rhabdomyomas, many of these tumors will recede with time so an expectant, conservative management strategy may be indicated. However, severe obstruction will require surgical resection or de-bulking (Figures 31.29 and 31.30). Rhabdomyomas can cause hydrops or fetal demise by mechanisms such as arrhythmia, obstruction to flow or extrinsic compression of coronary arteries causing loss of functional myocardium. The neonatal or infantile presentation may be due to similar mechanisms with arrhythmia being present in about 30% of cases in one series [112].

Fibromas can present with a variety of symptoms or signs depending upon their location and size (Figure 31.31). Arrhythmia is again a feature, with ventricular tachycardia (VT) being particularly common, 64% in one series [112], which resolved after resection or debulking in 13 of 16 patients. Post-surgical complications tend to be related to the location of the tumor with resultant regional wall motion abnormalities at the site of resection or valvular pathology requiring reoperation in some cases. Heart transplantation is considered in cases of massive tumors that are thought not to be resectable.

Myxomas are often readily distinguished from other cardiac tumors due to the fact that they arise most commonly from the left side of the fossa ovalis and have a characteristic pedunculated appearance. They are seen to intermittently obstruct the mitral inflow to the left ventricle in a

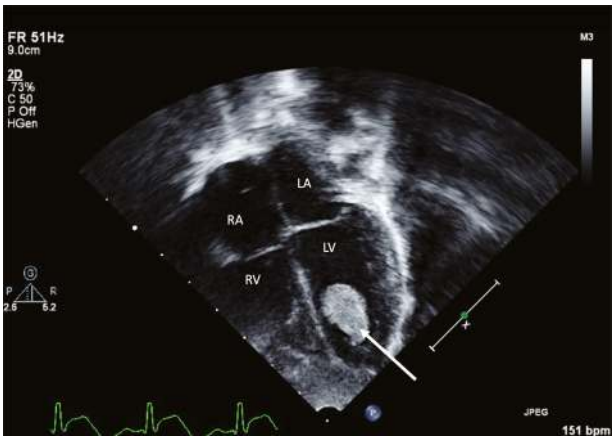

Figure 31.29 Transthoracic echocardiography image of rhabdomyoma in the left ventricle (arrow) of a 3-month-old infant, diagnosed antenatally and followed with serial scans. "ball-valve" type manner. Not only can they present with symptoms of obstruction to cardiac output, which can be intermittent and positional, but they are also often implicated in embolic phenomena. The emboli consist of a thrombus formed on the tumor surface or fragments of the tumor itself. In fact, cardiac myxomas can be found in the brain after having embolised and seeded the cerebral vasculature. The embolic phenomena can lead to presentation similar to infective endocarditis with any tissue bed in the arterial tree potentially affected. Non-specific symptoms and signs including fever and malaise occur in about a third of patients. These constitutional symptoms are thought due to increased levels of the inflammatory mediator interleukin-6.

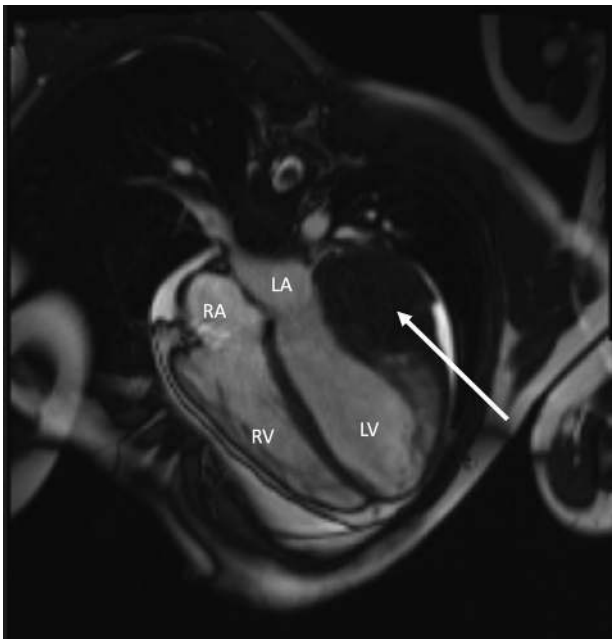

Figure 31.31 Magnetic resonance image of a large fibroma of the base of the LV in an adolescent. This was under surveillance with serial scans and eventually required resection due to the development of ventricular tachycardia. Courtesy of Dr. Bryn Jones, Cardiologist, The Royal Children's Hospital, Melbourne, Australia.

Surgical approaches and outcomes for cardiac tumors

Surgical planning and decision-making for cardiac tumors will depend on the following factors: tumor type, tumor position, pathophysiologic effects, and the risks of excision. Most procedures for cardiac tumors will involve CPB, but occasional lesions involving structures that do not require opening of the heart may not. Sternotomy is the usual approach, but various less invasive approaches have been used for tumors such as atrial myxoma where the lesion is pedunculated, and the surgery can be performed through a left thoracotomy or partial sternotomy.

For pedunculated intravascular tumors that have grown into the heart along the great veins, e.g., Wilms tumor, strategies to deal with the intravascular tumor, prevent embolization, and have adequate CPB may require tailoring of the perfusion plan to the exact anatomy and include having venous drainage from sites external to the heart (Figure 31.32).

If cardiac tumors can be removed without disrupting the postoperative function of the heart, outcomes are usually good. The degree of resection attempted will be informed by this, as partial resection may be preferable for rhabdomyomas and fibromas if more radical surgery will jeopardize the functional outcome. As these tumors are slow growing or tend to stabilize and even regress, partial resection that relieves symptoms will often be adequate. Atrial myxomas are occasionally locally aggressive and may recur if the base is not adequately excised. The outcome for surgical excision of myxomas is usually very good, but occasionally, a child with myxoma is in the high-risk familial, genetic group, making recurrence more likely both locally and at a separate cardiac location.

AL Grawany

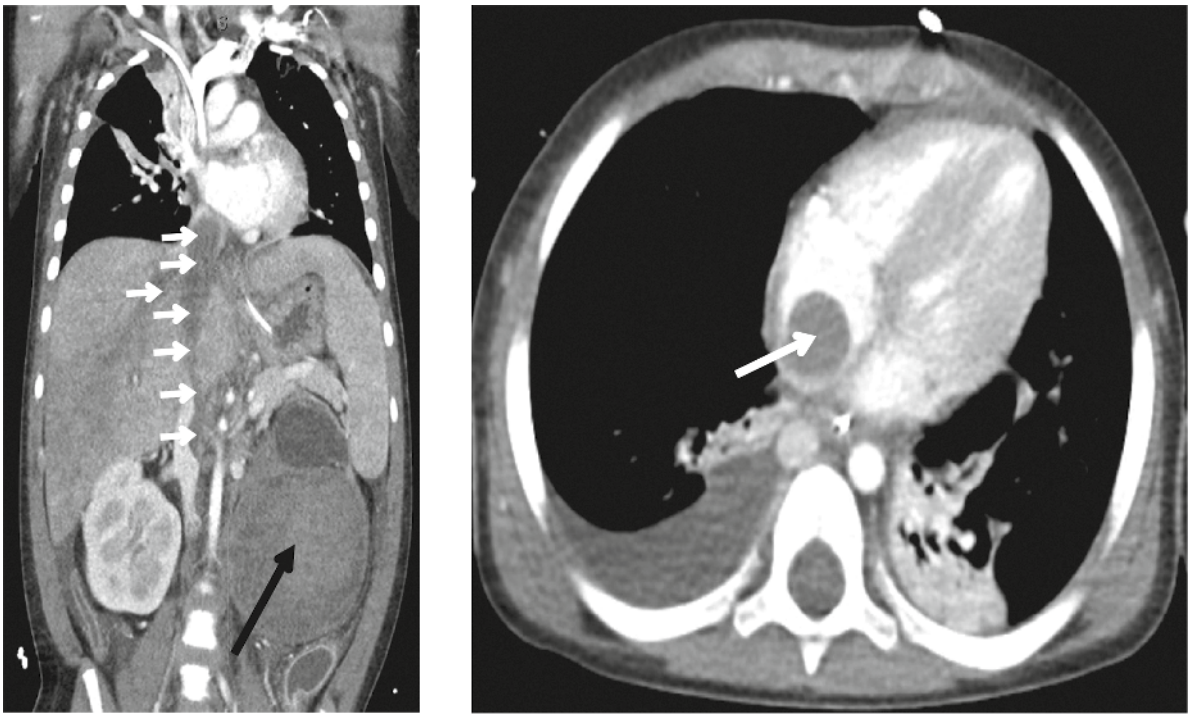

Figure 31.32 A 4-year-old child with Wilm's tumor extension into the right atrium. (A) Computed tomography scan with contrast of abdomen and thorax, coronal view. There is a large 7 × 8 cm left renal mass (black arrow) with extensive tumor thrombus involving the left renal vein, inferior vena cava, right hepatic vein, and right atrium (white arrows). (B) Axial view demonstrating large tumor thrombus in the right atrium. (Arrow). The patient underwent radical left nephrectomy with tumor thrombus removal and closure of the patent foramen ovale with cardiopulmonary bypass.

Teratomas arising at the base of the heart may be large and grossly distorted and may involve the great vessels and the coronary arteries. Surgery may be technically difficult and a multidisciplinary team involving cardiology, medical imaging, cardiac surgery, oncology, perfusion, and anesthesia should carefully plan the approach to excision. Successful excision, however, should be curative.

Anesthesia considerations for cardiac tumors

Anesthesia for the wide range of possible procedures relating to cardiac tumors needs to be tailored to the patient's condition and the planned surgical approach. Most rhabdomyomas will not require surgery, but those that do will usually have a significant cardiovascular impairment which will need to be defined. Patients with tuberous sclerosis complex are likely to have multiple other systems involved and behavioral issues such as developmental delay and autism that will require special attention to minimize distress for the patient and family.

Tumors that involve the right side of the heart and pedunculated lesions that have passed centrally from peripheral origins may require consideration with regard to where vascular access is placed, with lesions involving the inferior vena cava (such as the venous extension to the atrium of Wilms' tumor) having vascular access in the upper limb and avoiding femoral central access. Similarly, lesions arising in the neck and upper limbs (which are less common but can occur with rhabdosarcoma) require lower limb vascular access to avoid the possibility of injected medications and fluids being obstructed from reaching the central circulation during resection.

Patients with malignant lesions involving the heart will often have received chemotherapy. Complications of these therapies should be assessed. Bone marrow status should be checked to confirm or plan for appropriate recovery or management of anemia, thrombocytopenia, and neutropenia. Consideration should be given to previous use of agents that sensitize the lungs to hyperoxia, such as bleomycin, or those with potential for cardiotoxicities, such as doxorubicin or other agents of the anthracycline class. Surgery is rarely indicated for malignant lesions not arising in the heart, but debulking recurrent lymphoma that has invaded the pericardium from the anterior mediastinum is occasionally required. These recurrent lesions involving the pericardium are rarely of size or in a position to create the issues described in the section on mediastinal masses. Lymphomatous pericardial effusion may also need drainage either for diagnostic purposes or to relieve tamponade. Careful assessment and management of the patient with the potential for tamponade are required (see previous section).

Teratomas arising in the midline at the base of the heart will usually be present at birth and may be very challenging for all clinicians involved. The patient's preoperative condition may be poor, with obstruction to major vessels, distortion of the heart and coronary vessels, and potentially high-output cardiac failure and persistent pulmonary hypertension due to the large blood supply of the lesion. Excision without injuring important cardiac structures (such as

coronary arteries), leading to postoperative myocardial dysfunction, may be difficult and intraoperative blood loss may be extensive and difficult to control. Pre-operative planning to support massive transfusion and prevention of coagulopathy is appropriate.

Anesthesia may be required for interventional imaging procedures to define, biopsy or treat tumors of the heart.

KEY POINTS: ANESTHESIA FOR CARDIAC TUMORS

- The most common cardiac tumor in childhood is rhabdomyoma.
- Myxomas are the commonest intracardiac tumors in adults, but they are rare in young children.
- Teratomas are midline and may arise at the base of the heart and present as large tumors in the neonatal period.
- Malignant tumors involving the heart are rare and have a poor prognosis.
- CBP may be required for pedunculated tumors that have grown along venous paths to the atrium, such as a Wilms tumor.
- Anesthesia for cardiac tumors is based on the preoperative patient condition and the nature of the surgery planned.

Aortic aneurysm and aortopathy in children

Classification and definition of aortic aneurysms (and aortopathy)

An aortic aneurysm is defined as a permanent localized dilatation of the aorta, having at least 50% greater diameter than that expected for age and sex [113]. It may occur anywhere from the aortic valve annulus to the bifurcation of the abdominal aorta. A true aneurysm involves all layers of the vessel wall (intima, media, and adventitia). Those involving circumferential dilatation of the vessel are called fusiform aneurysms and are the most commonly occurring type. Saccular aneurysms are berry-like expansions, sometimes with a narrow neck, at a weak spot in the vessel wall. Aneurysms of a single sinus of Valsalva are of the saccular type.

False aneurysms, also known as pseudoaneurysms, can occur secondary to local pathologies, such as trauma or infection, and involve the creation of a space in continuity with the lumen of the vessel. A false aneurysm is not bounded by the vessel wall but by external tissue, such as the wall of an abscess that has eroded the vessel or the site of previous trauma where hematoma and fibrosis now form the containing layer.

A mycotic aneurysm is a specific term that relates to the formation of infection within the wall of an artery secondary to embolization from infective endocarditis seeding the vasa vasorum of the arterial wall.

Dissecting aneurysms (or "dissections") occur when an aneurysm, usually fusiform, creates an intimal tear, sparing the adventitia and sometimes the media. The arterial pulsations then split the internal layers, creating a blood-filled space in the wall, which tracks along the vessel and continues to split the layers apart, still leaving the adventitia intact. The dissection may rupture internally by tearing the intima at another site or eventually rupture through the adventitia externally. The dissection process can occlude branches of the vessel, leading to end-organ ischemia, and may be the site of thrombosis and/or a source of emboli.

The term "aortopathy" refers to the clinical association of aortic pathophysiological abnormalities and aortic dilatation [114]. Aortopathy is increasingly being recognized as part of the spectrum of presentations and natural history of many types of congenital heart disease (CHD).

Incidence, anatomy, and natural history of aortic aneurysms in children

Aortic aneurysms are rare in children and can be classified according to the site, type, acuity, and underlying pathology. Dissection of the aorta is extremely rare in children and, if it occurs, it tends to occur later in childhood in patients with underlying connective tissue disorders and large fusiform aneurysms.

The majority of pediatric aortic aneurysms involve the ascending aorta and the aortic root with far fewer occurring in the transverse arch, descending thoracic aorta, or abdominal aorta. The commonest causes of aneurysms of the ascending aorta and aortic root in children are genetic conditions, especially connective tissue disorders, with Marfan syndrome being the most common of these. Inflammatory conditions such as autoimmune disease and arteritis may also affect the aorta and be associated with aneurysm formation. Inflammatory conditions such as Takayasu arteritis or Kawasaki disease will usually have multifocal arterial lesions, often stenotic, as well as other features, such as systemic illness, with aortic aneurysm as an occasional complication. As alluded to above, there is an increasing number of patients with congenital heart disease surviving into adulthood and displaying signs of aortopathy not previously seen.

Genetic conditions associated with aortic aneurysm

Marfan syndrome

Marfan syndrome is the genetic condition most commonly associated with an aneurysm of the aorta, usually involving the ascending aorta and often the aortic root. The clinical diagnosis of Marfan syndrome is based on the revised "Ghent" criteria [115, 116] (Tables 31.11 and 31.12). Variations based on the presence of family history and the age of the patient are included. The existence of related syndromes, including those featuring aortic dilatation but differing genetics and a spectrum of either differing or overlapping (with Marfan) associated features, such as Sphrintzen–Goldberg syndrome, Loeys–Dietz syndrome, and the vascular form of Ehlers–Danlos syndrome, are specifically included in the differential diagnosis and actively sought, to make misdiagnosis less likely. "Typical" patients with Marfan syndrome will often have particular facial features and body habitus with long thin limbs, tall stature, and hypermobility of joints. Arachnodactyly

can be demonstrated by the thumb sign (the adducted thumb has the whole of the nail protrude beyond the ulnar margin of the palm) and the wrist sign (when encircling the opposite wrist, the thumb, and fifth finger overlap). These and many other physical signs are codified in the Ghent criteria.

Marfan syndrome has an incidence of between 1 in 3,000 and 1 in 10,000 with the variation likely due to missed diagnoses in some populations. [117] It is an autosomal dominant condition with variable penetrance although about 25% of cases involve new mutations, with some effect

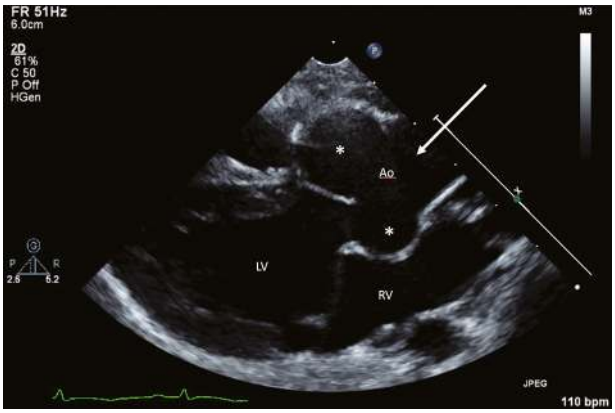

Figure 31.33 Parasternal long axis echo view of the dilated aortic root in a patient with Marfan syndrome. Arrow denotes the dilated root, asterisks the dilated sinuses of Valsalva. of parental age. Mitral valve regurgitation may also occur, often earlier than the aortic dilatation but usually with less severe consequences. Aortic regurgitation is secondary to aortic root dilatation (Figure 31.33). Skeletal abnormalities including long bone overgrowth and ophthalmic abnormalities including ectopia lentis (lens dislocation) are the other main features of the syndrome. The abnormal gene in most patients with Marfan syndrome is FBN1, which lies on chromosome 15 and encodes for type 1 fibrillin, a protein that forms part of the microfibrils in the extracellular matrix, contributing to the formation and maintenance of elastic fibers. There are a large number of mutations of FBN1 that cause Marfan's syndrome, most of them altering a single amino acid. The phenotype produced is highly variable and does not correlate well with the different mutations. There are also a series of related "fibrillinopathies" with associated genetic abnormalities that give rise to variants of Marfan syndrome; these may not have all the clinical features of Marfan syndrome but some are associated with aortic aneurysm. There is a rare neonatal form of Marfan syndrome which is usually rapidly progressive and fatal. About 10% of patients with Marfan phenotype have a mutation in TGF-βR2, which encodes for transforming growth factor beta-receptor type II, a controller of extracellular matrix production, interacting with fibrillin formation, and some authors argue that these patients should be classified as having Loeys–Dietz syndrome as this diagnosis highlights the risk of more severe aortic dilatation and dissection (see later in this section).

Management usually includes pharmacological treatment aiming to prevent or slow the progression of aortic root dilation, such as beta-blockade, which is probably effective [118]. The evidence for beta-blockers in children with Marfan syndrome is even less robust, although most centers still routinely use this therapy as the first line. Angiotensin II receptor blockers (ARBs) such as losartan, may be used if beta-blockers are not tolerated with studies showing equal efficacy. In patients with Marfan syndrome and aortic dilatation, ARBs are added to beta-blockers although the evidence for this is mixed. Advice should be given about avoiding

activities that might cause aneurysm rupture, such as contact sport or isometric efforts involving a Valsalva maneuver, such as weight-lifting, whereas mild to moderate aerobic activity is acceptable and in fact, encouraged. Pregnancy increases the risk of aortic rupture, especially if the aortic root is already 4 cm at the beginning of the pregnancy. Regular ophthalmic follow-up is also required for patients with Marfan syndrome. Historically, 50% of patients with Marfan syndrome died before the age of 40, whereas more recently median survival can be greater than 70 years [119].

Serial echocardiography to monitor the aortic root and also the aortic and mitral valves and the pulmonary artery should commence at diagnosis of Marfan syndrome and be at least yearly at first. Significant aortic dilatation is unusual in children less than 10 years of age. Following the "*z* score" (z score of +2 is 2 standard deviations above mean normal diameter for age or body surface area, for example) for aortic root dimensions is appropriate in childhood, rather than an absolute value for aortic dimension. Correlation of the aortic diameter with the body surface area can also be used to track dilatation with respect to overall patient size. Indications for elective surgery for aortic root dilatation in older children will depend on both the degree of the dilatation and the rate of increase in size. Dissection of the aorta due to Marfan syndrome is very rare in childhood. Associated aortic or mitral valve regurgitation is a more common indication for surgery in children.

Loeys-Dietz syndrome

Loeys-Dietz syndrome (LDS), first described in 2005, is an autosomal dominant inherited condition characterized by vascular findings (cerebral, thoracic, and abdominal arterial aneurysms and/or dissections), skeletal manifestations (pectus excavatum or pectus carinatum, scoliosis, joint laxity, arachnodactyly, talipes equinovarus, cervical spine malformation and/or instability), craniofacial features (widely spaced eyes, strabismus, bifid uvula/cleft palate, and craniosynostosis that can involve any sutures), and cutaneous findings (velvety and translucent skin, easy bruising, and dystrophic scars). Individuals with LDS are predisposed to widespread and aggressive arterial aneurysms and pregnancy-related complications including uterine rupture and death [120].

Diagnosis is by the presence of one of the associated genes (SMAD2, SMAD3, TGFB2, TGFB3, TGFBR1, or TGFBR2) along with characteristic features in the proband or family members.

The arterial disease is more aggressive than that in other connective tissue diseases such as Marfan syndrome, with aortic dissection and rupture occurring at younger ages and smaller aortic diameters, occasionally described in children as young as 3 months of age [121]. One Center's experience with elective aortic root replacement in patients with LDS showed 95% survival and 54% freedom from reoperation at 10 years. The average age at operation was 10 years, the average aortic z-score was 7.8 and most had a valve-sparing root replacement [121].

Ehlers–Danlos syndrome

Ehlers–Danlos syndrome has six subtypes. The main general features are hyperextensible skin, hypermobile joints, and connective tissue fragility. Type IV is known as the vascular type. This is an autosomal dominant condition associated with mutations in the COL3A1 gene on chromosome 2, which encodes for the collagen alpha 1 (III) chain. It has an incidence of about 1 in 5,000–20,000. About 50% of cases arise as new mutations. This variant is associated with arterial aneurysms at many locations, including the aorta. There is also an association with gastrointestinal perforation and uterine rupture in pregnancy related to vascular Ehlers–Danlos syndrome. Recognition of the syndrome before these life-threatening complications occur may allow prevention or earlier intervention.

Other examples of syndromic genetic conditions associated with aortic aneurysm formation include Noonan syndrome, Williams syndrome, autosomal dominant polycystic kidney disease, Turner syndrome, homocystinuria, osteogenesis imperfecta, and pseudoxanthoma elasticum.

Sinus of Valsalva aneurysms

Aneurysm of a sinus of Valsalva may affect any one of the three sinuses. Dilatation involving all three sinuses is classified as an aneurysm of the root of the aorta and usually relates to fusiform dilatation due to connective tissue disease [122]. The sinuses of Valsalva together form the aortic root, originating at the aortic annulus and terminating at the sinotubular junction, where the ascending aorta begins. Although acquired aneurysms of the sinus of Valsalva can occur due to trauma, infection, or surgery, most are congenital. Aneurysm of the right sinus of Valsalva is the commonest, accounting for 60–85%, with aneurysms of the non-coronary sinus accounting for most of the rest and aneurysm of the left sinus accounting for less than 5%. There is an association between VSDs just below the annulus fibrosus, and aneurysm of the sinus of Valsalva, where there is a separation of the aortic media from the annulus fibrosus and abnormal elastin deposition, creating a weak area that expands to create the aneurysm. An aneurysm of the right sinus of Valsalva can rupture into the pulmonary artery or any chamber of the heart except the left atrium. This creates a fistula that may be sufficiently high-flow to cause acute cardiac failure. Rupture into the pericardium will cause tamponade. The left and non-coronary sinuses of Valsalva can rupture into any cardiac chamber or the pericardium, but not the pulmonary artery when the great arteries are normally placed. The commonest fistulas are from the right sinus of the Valsalva aneurysm to the right ventricle (about two-thirds). Unruptured aneurysms may be large and obstruct right ventricular outflow or cause coronary compression. Congenital aneurysms of the sinus of Valsalva are more common in males (4: 1) and in some Asian communities, where there is a stronger association with supracristal (doubly committed) VSDs. There is also an association with aortic regurgitation and bicuspid aortic valve.

Aortopathy and aortic dilation with CHD

Bicuspid aortic valve (BAV) is the most commonly occurring CHD with a prevalence of 1–2% in the general population. Concomitant aortic dilatation is seen in up to 80% of patients (Figure 31.34). The lifetime risk of aortic dissection in patients with BAV is reported as up to 9 times that of the general population [123]; however, the large denominator of people

AL Grawany

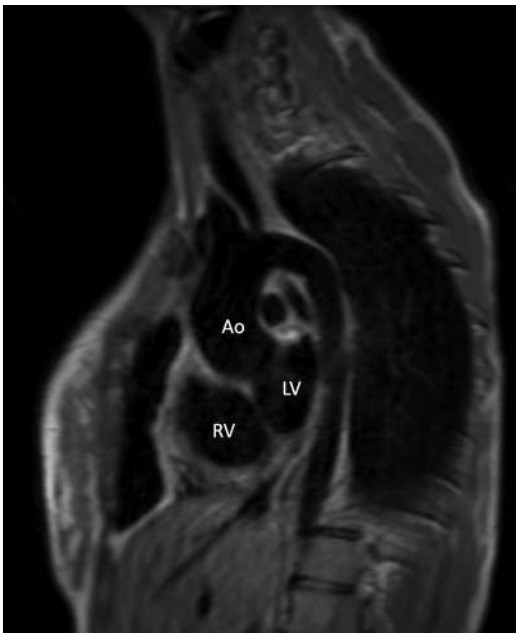

Figure 31.34 Dark blood MRI image of the dilated ascending aorta in a patient with the bicuspid aortic valve. LV, left ventricle; RV, right ventricle; Ao, aorta. Courtesy of Dr. Bryn Jones, Cardiologist, The Royal Children's Hospital, Melbourne, Australia.

with asymptomatic BAV and no aortic dilatation, discovered incidentally with routine cardiac screening, has led to a general reduction in the estimate of dissection risk [124]. Familial studies suggest an autosomal dominant inheritance pattern with incomplete penetrance. There is a 9–20% chance of identifying BAV in first-degree relatives of an affected proband, thus the guidelines recommend echocardiographic screening in all first-degree relatives. There are a small number of genes so far identified in connection with familial non-syndromic BAV aortopathy, including NOTCH-1, SMAD6, and MAT2A. BAV is present in 40% of patients with Turner syndrome and is associated with the presence of mutations in the Tissue Inhibitor of Matrix Metalloproteinase 1 and 3 (TIMP 1 and TIMP 3) genes.

Coarctation of the aorta accounts for 5–8% of all CHDs with more than half of these cases being associated with other lesions such as BAV or mitral valve pathology. Genetic influences play a role and there is a slight male predominance. Further, 10% of patients with Turner syndrome also have coarctation. A dilated ascending aorta and an aortic arch are commonly found in patients presenting late with previously asymptomatic coarctation. This is in contrast to those presenting in the neonatal period, especially if in association with a VSD, whereby blood is preferentially directed into the pulmonary trunk and across the ductus arteriosus. It seems that early operation for coarctation is protective against future aortic dilatation.

Conotruncal defects including truncus arteriosus, transposition of the great arteries (TGA), tetralogy of Fallot (TOF), and double outlet right ventricle are frequently associated with thoracic aortic dilatation [124]. However, there does not seem to be the same risk for progressing to aortic dissection with conotruncal lesions as there is with aortopathy associated with BAV. TOF is the commonest form of cyanotic CHD and accounts for 10% of all CHD. Dilatation of the aortic root and ascending aorta is common in ToF and can be observed in fetal echocardiography. Persistent aortic root dilatation is more commonly reported in adult patients after childhood TOF repair, now that survival to adulthood from this condition is around 90%. A right-sided aortic arch, male gender, history of an aortopulmonary shunt, and complete repair at an older age have been associated with late aortic dilatation [123]. Significant regression of indexed aortic root diameters over time after early repair in infancy, with a chance of normalizing the initially dilated root within 7–8 years has been demonstrated. [123]

Secondary aortic root dilatation can be seen after surgical correction of congenital heart diseases during which the native aortic root is replaced with a pulmonary homograft (Ross procedure), is modified (the arterial switch operation [ASO] as described by Jatene), or reconstructed (Damus Kaye Stanzel anastomosis for single ventricle palliation of hypoplastic left heart lesions). Literature on this particular variant of aortopathy is less extensive than that for BAV or TOF as it was only recognized as an emerging feature of the disease within the last decade or so. Risk factors for late neoaortic root dilatation and regurgitation after ASO are the presence of a VSD, previous pulmonary artery banding, older age at repair, and the association with coarctation. Technical factors such as acute angulation of the aortic arch after ASO and closure of the VSD through the pulmonary artery, have been associated with late aortic regurgitation and aortic dilatation in some reports [123]. In a study with a median follow-up of 9 years after Fontan completion, neoaortic root progressively dilated out of proportion to body size over time, with 98% of patients having a root z-score of >2 at the most recent follow-up [125].

Pathophysiology of aortic aneurysms

The law of Laplace (wall tension is proportional to transmural pressure multiplied by vessel radius), as modified and applied to blood vessels, helps explain why aneurysms tend to expand and rupture. The wall tension is proportional to the pressure differential across the wall and the radius of the vessel. From these relations, it can be seen that, as a vessel dilates, its radius increases and, even with the internal pressure unchanged, the wall tension will increase, making further dilatation and rupture more likely. Alternatively, an increase in pressure inside the vessel relative to the outside will also increase wall tension making dilatation and rupture, again, more likely. Tissue stress can be decreased by an increase in the thickness of the wall (allowing the "retaining force" to be distributed over more tissue). However, the dilatation process is often associated with thinning of the vessel wall, which increases the stress on the tissue, thereby increasing the likelihood of expansion of the aneurysm. Some pathologies may be associated with changes, such as fibrosis, that thicken the wall and change the tissue characteristics, decreasing tissue stress and potentially stabilizing an aneurysm. Aneurysmal expansion and, eventually, more rapid dilatation and rupture are likely outcomes, but the time frames for these processes are notably variable depending on the causative pathology. Dissection of the inner layers may occur as the tissues distend or the underlying pathology progresses. In most conditions

associated with aortic aneurysm, abnormalities of the aortic media develop so that loss of elastin and changes in collagen are progressive, with cystic degeneration and necrosis of portions of the media a common finding. If the intima splits with dilation or other pathology, the abnormal media will be especially prone to dissection.

The same picture of maladaptive remodeling of the aortic media seen in Marfan syndrome is also noted in patients with BAV and conotruncal defects. There is extracellular matrix degradation associated with noninflammatory loss of vascular smooth muscle cells. The vascular smooth muscle cell apoptosis is thought to occur secondary to excessive activity of a group of degradative enzymes known as matrix metalloproteinases (MMPs) [124]. Despite similarities in pathophysiology, the frequency of aortic dilation, and more importantly, the risk of aortic dissection, differ considerably among the aortopathies of Marfan syndrome, BAV, and conotruncal defects, as noted in the previous section. In light of these differences, the criteria for surgical intervention also differ.

The exact mechanism of aortic wall degradation is unclear and is thought to be due to a combination of hemodynamic shear stress from altered or abnormal flow in the proximal aorta (the hemodynamic theory) and genetic influences on the elastic fibers and vascular smooth muscle cells in the extracellular matrix (the genetic theory).

Surgical approaches for aortic aneurysms in children

Historically, aortic root replacement consisted of the Bentall procedure, which involved mechanical aortic valve replacement, a tube replacement of the aortic root and reimplantation of the coronary arteries. This procedure had very good results and is still widely used in adults. In children, the issues of lifelong anticoagulation associated with prosthetic aortic valves, and the failure of growth and long-term complications of prosthetic valves and conduits were a major stimulus for attempting surgery to replace the aortic root while leaving the native aortic valve intact. The major surgical advance in aortic root replacement over the last few decades, especially for children, has been the evolution of valve-sparing aortic root replacement [126]. Two major techniques were introduced and there have been many variants. Remodeling, introduced by Yacoub, involved a proximally scalloped aortic tube graft, which is sutured above the aortic annulus with the longer scalloped portions sewn along the line of the attachments of the aortic valves, mimicking the sinuses of Valsalva and providing some distensibility of the aortic root, which is closer to the normal physiology. This is technically a more straightforward procedure than the alternative reimplantation techniques but still requires coronary re-implantation. The greatest medium-term risk with the remodeling technique was recurrent aortic annulus dilatation and aortic regurgitation, especially in children who usually have an underlying connective tissue disorder. Various modifications to support the aortic annulus and prevent subsequent dilatation and aortic regurgitation have been added to this technique to decrease that risk.

Reimplantation, introduced by David, anchored the aortic tube to the ventricular side of the aortic annulus with a second proximal suture line in a position similar to that used for the remodeling technique. The major difference in the medium term is that the aortic annulus is supported and recurrent dilatation at that level and consequent aortic regurgitation should be prevented [127]. In fact, early results showed problems with interference with aortic valve function, partly due to the decrease in aortic annulus diameter, which meant that aortic valve prolapse and poor coaptation could occur, leading to aortic regurgitation. Subsequent techniques have incorporated aortic valve surgery to tailor the valve leaflets to the new geometry and decrease the risk of regurgitation. The reimplantation technique, as originally described, has evolved with more recent techniques and preformed devices focused on restoring the convex curve of the aortic root, which should better mimic the normal function of the sinuses of Valsalva in relation to aortic valve function and coronary artery flow. Ascending aortic dilatation can continue to occur after the aortic root has been replaced (Figure 31.35).

Modern myocardial preservation that affords low morbidity from the long cross-clamp times required for this, often extensive, reconstructive surgery of the aortic root, aortic valve, and coronary reimplantation, have facilitated the advances in this area. The presence of aortic regurgitation preoperatively, common in patients with a dilated aortic root, requires isolated coronary perfusion or retrograde coronary perfusion to effectively deliver cardioplegia.

A recent, exciting development in the prevention of dissection in patients with aneurysms of the aortic root or ascending aorta has been personalised external aortic root

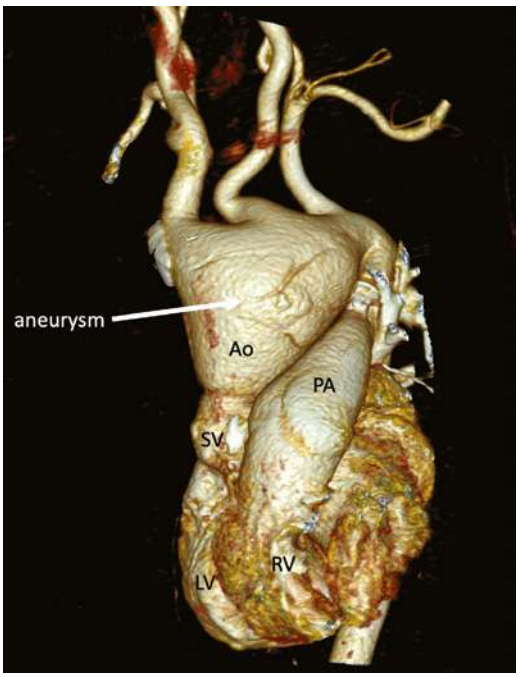

Figure 31.35 Reconstructed computed tomography angiogram of ascending aortic aneurysm after aortic root replacement. support (PEARS). This is a technique whereby a 3D mesh model of the patient's aortic root and the ascending aorta is custom made by computer-aided design and is then implanted via sternotomy but usually not requiring CPB (73% off the bypass in this study), around the existing aortic root and ascending aorta. The mesh provides a "structural framework" against which the aorta is prevented from dilating. This group has published a series of cases from 2004 to 2017 in which 117 patients received an external mesh implant, initially at one center, and then expanding to include 14 teams [128]. The purpose of the procedure is to prevent aortic dissection, so inclusion criteria were aortic diameters of 40–50 mm in asymptomatic patients over the age of 16 years. Results are encouraging so far although the authors acknowledge that long-term follow-up has not yet occurred. They also plan to publish shortly on a series where PEARS has been used to support the neo-aorta after the Ross procedure and they speculate on future potential uses in situations such as aortic dilatation in adulthood following the neonatal arterial switch operation for transposition of the great arteries. While PEARS surgery is not being performed on young children, it is possible that some adolescents may benefit and potentially so too will a population of children having surgery for congenital heart disease who subsequently survive into adulthood.

Anesthesia for aortic aneurysm surgery

The preoperative assessment should elucidate the extent of the lesion being repaired, as well as associated cardiovascular lesions such as aortic and mitral valve regurgitation, which commonly accompany connective tissue causes of aortic aneurysm. Review of imaging studies is crucial; all patients will have echocardiography, but MRI and/or CT scanning are invaluable in defining the size and extent of the aneurysm, and the properties of any aortic dissection. The non-cardiovascular lesions that accompany the various causes of aortic aneurysm, including genetic syndromes such as Marfan syndrome and inflammatory conditions such as autoimmune or infective disorders, should be investigated. A significant percentage of pediatric cases will involve repeat sternotomy, as associated lesions, such as MR in Marfan syndrome, which presents earlier in life than aortic aneurysm, may have already required repair. Valve-sparing procedures for aortic root replacement in young children will have a moderate rate of medium- to long-term complications, such as aortic regurgitation, that will require reoperation. A recurrent aneurysm is rare and may involve suture lines or more distal aorta with the progression of underlying disease. The complex interaction of aortic valve function with the aortic root means that revision surgery for aortic regurgitation may involve the whole aortic root rather than just the valve leaflets. The usual preparation for repeat sternotomy should be considered, such as planning for the possibility of instituting CPB via peripheral cannulation before opening the chest or in an emergency fashion if required during sternotomy, with appropriate access for rapid resuscitation with blood products and external defibrillation pads in place.

Many pediatric patients undergoing aortic root surgery will be older children, in contrast to the large proportion of pediatric cardiac surgeries, which are done in the first year of life (the majority of cases in many specialized pediatric centers). These older children are often systemically well and asymptomatic, having had the size and rate of expansion of the aorta monitored for many years. Careful preparation includes managing patient and parental anxiety and informing them of plans for postoperative care, including options for adequate pain control.

The cardiovascular status of the pediatric patient scheduled for aortic root replacement will usually depend on associated valve lesions. Patients with Marfan syndrome and other connective tissue disorders are likely to have been treated with beta-blockers. Care should be taken to avoid beta-blocker withdrawal syndrome, which may complicate the postoperative course. The sympathetic overactivity associated with beta-blocker withdrawal is a particular hazard in the early postoperative phase when catastrophic bleeding and suture line dehiscence might be induced. Cautious maintenance of beta-blockade throughout the perioperative period is a reasonable strategy. Given the possibility of a long cross-clamp time, and the resultant decrease in intrinsic inotropy, some anesthesiologists will choose to have an esmolol infusion available and use it as required rather than commit to a longer-acting beta-blocker in this instance. Angiotensin II receptor blockers (e.g., losartan) may be withheld on the morning of surgery, due to the risk of hypotension in the immediate postoperative period.

Hypertension should be avoided both pre- and post-bypass. Pre-bypass, it may cause rupture of the aneurysm, and post-bypass, it may cause excessive bleeding and dehiscence of suture lines. Patients with associated aortic and/or mitral regurgitation may have a dilated left ventricle. Occasionally, this will be associated with poor inotropic function, which will be exacerbated by myocardial ischemia associated with prolonged cross-clamp time. Appropriate inotropic support should be provided along with strategies to minimize afterload whilst maintaining an adequate coronary perfusion pressure. More commonly, patients with preoperative regurgitant valve lesions and a dilated left ventricle with the good left ventricular function will have issues of a large stroke volume after the regurgitant lesions are repaired, and avoidance of hypertension may require postoperative vasodilator therapy along with careful attention to adequate analgesia and sedation.

The association of aortic root replacement procedures with reimplantation of the coronary arteries requires careful assessment of the postoperative electrocardiogram in multiple leads to diagnose ischemic complications that may arise from technical issues with the reimplantation as well as air after removal of the cross-clamp, creating a temporary obstruction of the coronary arteries. Coronary flow can be assessed with TEE or epicardial echocardiography. Coronary artery anastomoses may be a source of bleeding, along with extensive aortic suture lines, and therefore the use of an antifibrinolytic agent is usual practice in these cases.

Marfan syndrome is associated with lung abnormalities that are associated with spontaneous pneumothorax. Positive pressure ventilation may cause the rupture of these lesions. The risk of iatrogenic pneumothorax should be minimized

by avoiding inappropriately high ventilator pressures or volumes. A high index of suspicion for pneumothorax should be maintained if ventilator or cardiovascular problems arise.

Perioperative TEE plays a key role during surgery for aortic root replacement with aortic valve preservation. The often-complex surgical plans involving detailed remodeling of the aortic annulus, the curvature of the aortic root, the size of the sinotubular junction, and the position of the aortic valve leaflets in relation to these structures mean that pre-bypass review of the anatomy and post-bypass review of the repair can provide crucial information regarding the need for immediate revision of a suboptimal surgical result. The ready availability of 3-dimensional TEE in many specialized centers has only enhanced the real-time ability to accurately characterize the pre- and post-repair anatomy in these situations.

KEY POINTS: ANESTHESIA FOR CHILDREN WITH AORTIC ANEURYSM AND AORTOPATHY

- Aortic aneurysms are rare in young children and most commonly affect the aortic root and the ascending aorta.
- Aortopathy in the setting of CHD is of growing concern as more patients survive into adulthood.
- Patients with aortic dilatation will usually be treated with beta-blockers and/or angiotensin II receptor blockers.
- Surgery for aneurysm of the aortic root in children most commonly involves "valve-sparing" techniques, which aim to preserve function in a native aortic valve.
- Control of blood pressure is a key requirement during surgery for patients with an aortic aneurysm to minimize the risk of pre-bypass rupture and prevent early postoperative bleeding and suture line dehiscence.

Mediastinal masses

Masses arising in the anterior mediastinum are likely to involve the great vessels and tracheobronchial tree as they expand. This can have grave consequences, as anesthesia-induced changes in the geometry of the mediastinum may produce complete obstruction of the airway or circulation, causing cardiac arrest. This will be the main focus of the following sections. Although masses arising in the posterior mediastinum can exert mass-effects involving the airway and present a range of challenging anesthesia issues, such as catecholamine secretion (neuroblastomas) and the risk of massive hemorrhage during surgical resection, they do not appear to have the risk of catastrophic respiratory or cardiovascular obstruction that may occur with anesthesia for patients with an anterior mediastinal mass, even if there is some encroachment on the trachea. This may be due to these posterior mediastinal tumors' tendency to displace rather than encase the trachea, as occurs with anterior mediastinal masses.

Incidence, anatomy, and natural history of mediastinal masses in children

The mediastinum is a complex area of the thoracic cavity containing most of the important thoracic structures, excluding the lungs. The compartments within the mediastinum are defined in terms of their relationship to the pericardium as superior, anterior, middle, and posterior, although there are multiple classification systems all of which are subtly different. The middle mediastinum is essentially the pericardium and its contents. The anterior and superior compartments of the mediastinum are not separated by any physical anatomical barrier and some classifications, such as in radiology, merge the anterior and superior compartments into a single anterior mediastinum [129]. This classification is usually used when anterior mediastinal masses are referred to in the anesthesia literature. More recently, there has been a collaborative attempt by the International Thymic Malignancy Interest Group to define a CT-based guideline to make interdisciplinary reporting and diagnosis more easily translatable between specialties [130].

Hodgkin's and non-Hodgkin's lymphoma (NHL), leukemias, teratomas, and germ cell tumors arising from the anterior mediastinum account for more than half of all mediastinal masses. Neuroblastoma, ganglioneuroma, and neurofibroma, arising from the sympathetic chain and nerve roots in the posterior mediastinum account for about a quarter of mediastinal masses and a wide variety of rare diagnoses account for the remainder. These include other tumors, inflammatory processes, congenital anomalies (such as a bronchogenic cyst or esophageal duplication cyst) and, in some series, can include vascular anomalies, such as double aortic arch, seen as an expansion of the mediastinum on plain chest x-ray [131].

Diagnosis of anterior mediastinal masses

Clinical presentation, particularly duration of symptoms and associated features of fever and weight loss, combined with imaging (plain chest x-ray, CT scan, echocardiography) and blood tests, looking for blast cells or tumor markers, will often provide a narrow differential diagnosis. If the mass is a tumor, tissue diagnosis will nearly always be critical to creating a treatment plan. Many of these tumors have an excellent prognosis, but the optimum treatment protocols are very specific to the type and subclassification of the tumor, especially so in the case of leukemias/lymphomas.

Expert oncological advice can lead to sophisticated means of obtaining a diagnosis by relatively non-invasive methods, which may avert the need for anesthesia or allow the use of lower-risk techniques rather than general anesthesia and open surgical biopsy. The anesthesiologist's concern about the risks of anesthesia in a patient with a mediastinal mass must be carefully integrated with the risks of all the strategies available and the clinical information about what the tumor is likely to be. The anesthesia risk seems related to the size and position of the mass as well as the anesthesia/sedation/analgesia technique used, but convincing data about the incidence of cardiovascular or respiratory disaster with anesthesia is lacking. Series published from various institutions looking retrospectively at their morbidity and mortality from anesthesia for diagnosis of mediastinal masses all

AL Grawany

suffer from the bias that patients deemed too high risk to anesthetize were pre-treated with steroids before undergoing anesthesia, so a true incidence of anesthesia complications is not possible to ascertain. It is possible that patients treated with steroids, chemotherapy, or (historically) radiation due to the perceived anesthesia risk, prior to making a tissue diagnosis, may be condemned to suboptimal oncologic treatment which is hard to quantify in a disease that has a high rate of cure. Tumors that do not respond to steroids, such as teratomas, will not be reduced in size by this strategy. Some tumors, such as NHL, are so sensitive to initial therapy that biopsy after this may only reveal non-diagnostic necrotic tissue. However, in most published series tissue diagnosis was possible in more than 90% of cases after pre-treatment with steroids and in cases where it was not possible, the duration of steroid treatment prior to biopsy had been longer. [132–134] Clearly, however, it would be catastrophic if the patient were to die during anesthesia in an attempt to make the diagnosis. The major advance in this area has been an appreciation that with early application of multidisciplinary planning, involving oncologist, anesthesiologist, and proceduralist (surgeon or interventional radiologist), to obtain the diagnosis with the most minimal intervention, only a small minority of these patients with very high-risk compression and no means of obtaining a diagnosis by relatively non-invasive means will be managed with pre-treatment. Most of these will be younger children with significant airway compression and a clinical diagnosis of probable NHL.

Planning the least invasive method for making a diagnosis should be tailored to the patient's clinical findings. Blood sampling may reveal blast cells or tumor markers (e.g., with germ cell tumors). Pleural effusion may be easily sampled and very sensitive techniques such as polymerase chain reaction can identify specific tumor nucleic acid sequences in samples that may not have diagnostic cells on microscopy. The patient may have lymph nodes that are easily accessible for biopsy or excision under local anesthesia (potentially with sedation). Bone marrow biopsy is positive in a significant proportion of patients with NHL, but only in a small minority with Hodgkin's lymphoma. Large mediastinal masses often provide an easy target for image-guided needle biopsy that may not require formal general anesthesia. Ultrasound guidance may be adequate and can allow the procedure to be done in an operating room rather than in a CT scanner [135]. Only a small minority of patients will require a thoracoscopic or open procedure to sample an anterior mediastinal mass. A suggested algorithm for obtaining a diagnosis in a new mediastinal mass is presented in Figure 31.36.

Screening for mediastinal mass prior to undertaking anesthesia in patients with possible lymphoma in other parts of the body is a sensible precaution and should include a plain chest x-ray as a minimum first step. There have been complications related to undiagnosed anterior mediastinal mass in patients having anesthesia for biopsy of a lesion that was suspected to be lymphoma. If lymphoma is a genuine possibility, the patient may be better served by referral to a specialist pediatric oncology unit prior to biopsy, rather than undergoing biopsy in an institution with less-specialized services.

Pathophysiology

The anterior mediastinum is shallow inferiorly and crowded with the trachea and great vessels in the superior aspect. Tumors in this position are restricted by the sternum anteriorly and the pericardium posteriorly. The path of least resistance to growth is around the base of the heart and great vessels, anterior to the trachea and bronchi. The tendency is to surround these structures anteriorly and laterally before they are encased. It is important to note that it is not just the

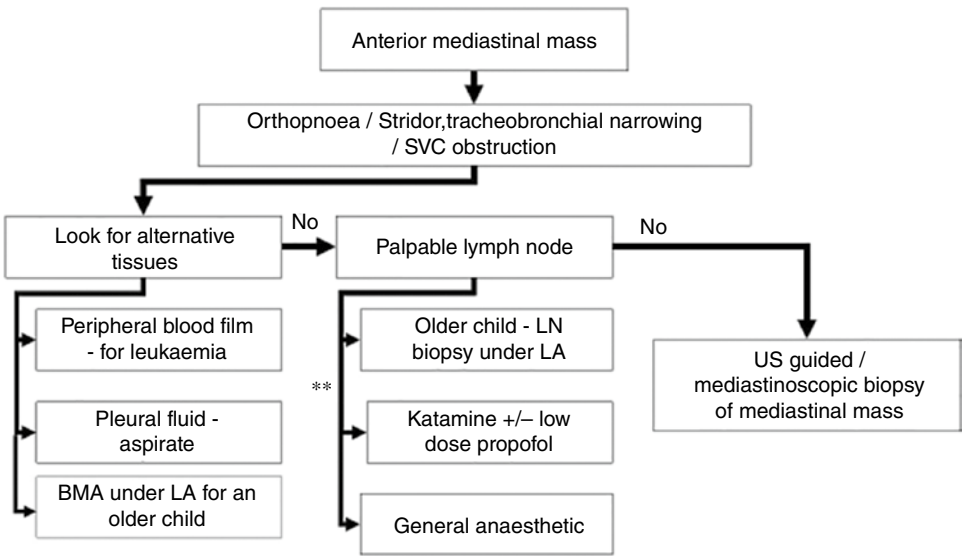

Figure 31.36 Pathway for safe approach for diagnosis of anterior mediastinal mass. Stepwise pathway selecting alternative tissues for diagnosis when available; use of local anesthetic and/or ketamine for peripheral lymph node biopsy, followed by mediastinal access under general anesthesia in very few cases where other options are not feasible. (Source: Malik et al. [132]. Reproduced with permission of Elsevier.)

tracheal part of the airway that might be compressed and that bronchial compression, including bilateral bronchial compression, may be possible. This is of great importance, as not all cases with anterior mediastinal mass where acute airway obstruction is provoked by anesthesia will see the airway obstruction overcome with a rigid bronchoscope.

Catastrophic airway or circulatory complications have been described in case reports of patients with anterior mediastinal masses under anesthesia; however, the mechanism remains uncertain. Case series from major centers have seen respiratory complications occur in about 10–20% of cases anesthetized, but those complications have usually been relatively minor, without long-term consequences. A number of centers did not anesthetize higher-risk patients. [136–138]

All of these reports emphasize efforts to make the diagnosis by minimally invasive techniques and the fact that local anesthesia and selected sedation and analgesia with spontaneous ventilation will allow most diagnostic procedures to be performed. None of the case series has a report of catastrophic airway or circulatory problems under local anesthesia. In one series, there was one patient (not sedated or anesthetized) who received a brief cardiac massage when their airway became obstructed on lying supine in a CT scanner. The case series data support the concept that masses creating more respiratory obstruction and symptoms are more dangerous. However, there have also been case reports of catastrophic complications both in patients with apparently low-risk masses and in those receiving what should be low-risk sedation/analgesia techniques.

One hypothesis for the mechanism of catastrophic obstructive complications is based on the fact that tumor expansion flattens and holds rigid the encased (or partially encased) airways or vascular structures, creating a ribbon-like cross-section. The well-described changes in lung mechanics at induction of general anesthesia include a loss of functional residual capacity based on the diaphragm moving cranially and changes in chest wall muscle tension. It is quite plausible that this change in conformity of the thorax could completely kink the flattened ribbon-like structures created by tumor compression. This concept has informed practice in selecting anesthesia techniques (preferentially choosing sedation techniques more likely to preserve normal lung mechanics and spontaneous ventilation) for managing these patients and likely accounts for the absence of catastrophic obstruction in series from major institutions.

Anesthesiologists should be aware of the extraordinary rate of expansion of some NHLs. The "doubling time" (average time for a cell division cycle which will double the size of the tumor) may range from as little as 12 hours to a few days. A patient presenting with a mediastinal tumor due to NHL may have very significant disease progression and increased compression of cardiorespiratory structures between the time of initial chest imaging and a subsequent procedure involving anesthesia. This should inform efforts to meticulously review their clinical status for worsening obstructive signs or symptoms, even if they have had reassuring imaging in previous days.

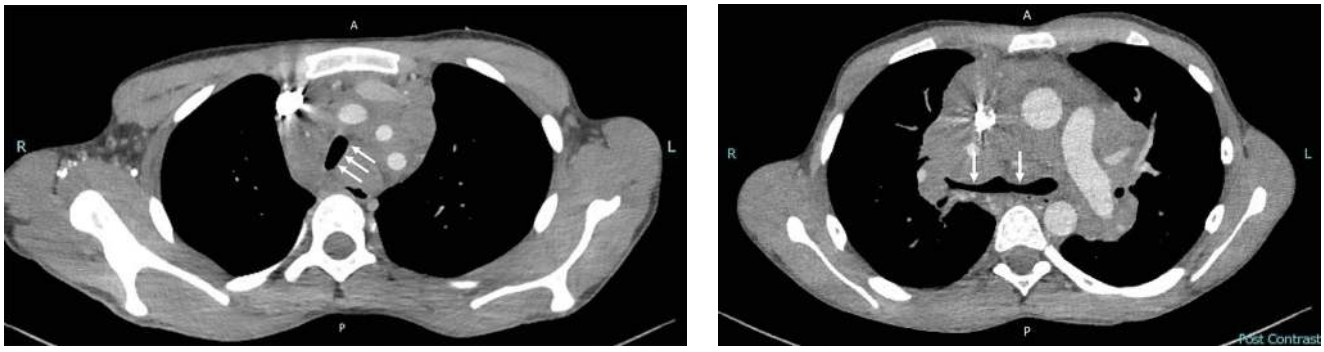
Anesthesiologists should be mindful to avoid the routine use of steroids as antiemetics in these patients. Steroids may cause rapid necrosis of the tumor, which could jeopardize diagnosis, precipitate tumor lysis syndrome, or disturb the current best-practice protocol for curative treatment, potentially worsening prognosis. Tumor lysis syndrome is caused by rapid necrosis of a large tumor when exposed to therapeutic agents, with systemic absorption of the released intracellular contents. Lethal hyperkalemia and renal failure are the most prominent complications and as such, these patients are intensively monitored and managed for tumor lysis syndrome in oncology protocols. Steroid use in a patient with an unsuspected mediastinal mass has been associated with tumor lysis syndrome leading to death.

Surgery for anterior mediastinal masses

Open surgery for the removal of an anterior mediastinal mass is not common in children. Non-lymphomatous tumors and other lesions that cannot be managed medically will, however, likely require surgical resection. The surgical approach will usually be by sternotomy or mediastinoscopy. Mediastinotomy has been used for the biopsy of these lesions, and a technique for doing mediastinotomy with local anesthesia has been described. For some tumors undergoing surgical removal, the use of CPB, although adding complexity and anticoagulation, may allow safer removal of the lesion. Pre-emptive peripheral (e.g., femoral) CPB or ECMO may be indicated in some cases for planned support of respiration and the circulation prior to formal general anesthesia and intubation in a high-risk patient. It should be noted that this scenario is different from the use of CPB or ECMO as a rescue for cardiac or respiratory arrest after induction of anesthesia, which is impractical and should not be considered to be a reasonable management strategy, especially in children.

Anesthesia for patients with an anterior mediastinal mass

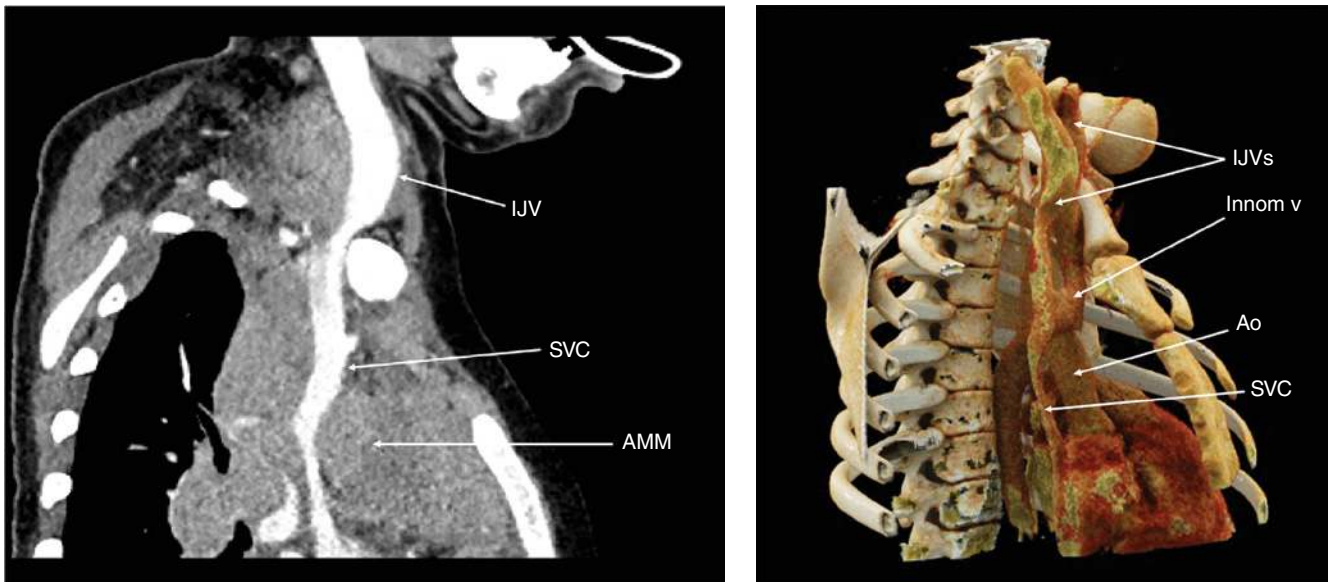
Sudden induction of deep general anesthesia in patients with an anterior mediastinal mass may unpredictably cause complete respiratory obstruction or circulatory arrest. Larger symptomatic masses with airway compression are probably at greater risk, but all patients should be treated with caution.



General assessment should occur along with specific history and examination of the patient to assess mass effects and associated conditions. History may reveal dyspnea or stridor, which may be intermittent. A special inquiry should be made as to whether posture affects symptoms. Some patients cannot tolerate lying flat, especially when supine, but may tolerate being prone. Facing one side or another may worsen or improve symptoms. Signs of superior vena cava compression are ominous. These include upper body and facial edema as well as distended, non-pulsatile, jugular veins. The edema may be worse on waking in the morning and regress with upright posture during the day. Pemberton's sign, which involves evoking symptoms and signs of SVC obstruction when patients stretch both arms above their head, may reveal lesser degrees of obstruction and should be actively sought.

The postural relationship of symptoms and signs may be very important not only for planning safe positioning during procedures but also for defining possible safer positions into which a patient might be moved should severe obstruction

arise. Apart from lateral and prone positioning, it has also been suggested that physically pulling the sternum forward may move the tumor away from the airway or heart and great vessels and may relieve acute compression. The fact that arm and shoulder position may increase pressure on the superior part of the anterior mediastinum may be particularly important in positioning for CT scanning and for some surgeries.



Imaging the chest will provide crucial information. CT scanning is often the technique of choice in symptomatic children, as tolerating the duration and positioning required for an MRI while awake may be impossible. The short time required for CT imaging makes this much more practical, but not without hazard in those children that have difficulty lying flat and putting their arms above their heads, as is usually required for a CT of the chest. A careful review of the CT will outline the degree and extent of compression of the airway, great vessels, and heart. Some CT images are provided showing tracheal, bronchial, and SVC obstruction by tumor. Pleural and pericardial effusions are quite common in these patients, especially those with NHL. Echocardiography will quantify pericardial effusion and should carefully examine the path of the pulmonary arteries, superior vena cava, and right ventricular outflow for obstruction (Figures 31.37 and 31.38).

Widely quoted criteria for critical airway compression in children with anterior mediastinal mass that contraindicate anesthesia are: (i) a 50% reduction in predicted tracheal diameter on CT scan; (ii) a 50% reduction in peak expiratory flow rate on spirometry; (iii) severe narrowing or complete occlusion of one or both main-stem bronchi; or (iv) clinical findings of acute respiratory distress or impending respiratory failure. These points are not robustly defined but have

been widely adopted. The original series that promulgated these criteria involved no patient with those criteria being anesthetized (so there is no estimate of the hazard of anesthesia in those who fulfill the criteria), and the modest number (17 in the original paper) [139] who had anesthesia or sedation in whom there was a lack of serious complications adds to data from similar series, but an unacceptably high incidence of serious complications is likely not to be detected in a series that size. Despite this criticism of the detail of the data, the principles on which this group bases management are very sound. The practical points are that biopsies were performed using local anesthesia in most patients deemed at high risk from general anesthesia. They have since added to the series and refined an algorithm for seeking a diagnosis with the most minimally invasive procedures done first. In a latter series of 40 patients with anterior mediastinal mass who fulfilled their criteria for critical airway compression, only two of the patients had therapy without a tissue diagnosis, and, in that series, only three had general anesthesia [136].

Anghelescu et al.'s [139] analysis of 117 patients with a mediastinal mass who were anesthetized, with 11 having respiratory complications of anesthesia, showed that these complications were statistically associated with orthopnea, upper body edema, great vessel compression, and main-stem bronchus compression. Pleural effusion and tracheal compression did not quite reach statistical significance. This group also emphasized the importance of using minimally invasive techniques to make a diagnosis. They modified the anesthesia technique in an attempt to decrease risk, avoiding muscle relaxants and maintaining spontaneous ventilation.

More recently, in an attempt to find a metric that can be used to stratify risk in terms of whether a patient can safely be anesthetized, a group from Japan have recommended using Standardised Tumor Volume, based on calculating the volume of the tumor as if it were an ellipsoid structure and standardizing it for patient height. At this stage, there are no prospective data confirming this new measurement's utility in stratifying for anesthetic risk [140].

Pragmatically, if a patient can tolerate a procedure done with local anesthesia alone, that should be the aim. If systemic agents are required to achieve sedation and analgesia, careful titration aimed at maintaining spontaneous ventilation can avoid most incidents of catastrophic collapse. There are disturbing isolated case reports of cautious techniques still being associated with significant complications, but there are also a large number of case series with careful case selection and modified anesthesia techniques, without serious complication. In association with local anesthesia, various combinations of midazolam, ketamine, and, more recently, dexmedetomidine, perhaps titrated with small boluses and maintained with an infusion, can provide a low risk of major change in conformation of the chest wall and catastrophic cardiorespiratory compression. Spontaneous ventilation and, in many cases, consciousness can be maintained while a procedure is performed. CPAP by face mask may assist with maintaining airway patency during the procedure. Endotracheal intubation is usually avoided. Topical anesthesia to the airway can facilitate intubation in cases where this is required which may assist the maintenance of spontaneous ventilation with modest anesthesia requirements. The addition of opioids if intubation is required can help with the tolerance of the endotracheal tube but can increase the risk of apnea. Very low-dose infusions (e.g., 2 mg/kg/hour) with small boluses (e.g., 0.2 mg/kg) of propofol may be cautiously introduced for similar indications. The principle is that the minimum necessary degree of sedation/anesthesia should be used and boluses or infusion rate changes should be small and incremental. This will minimize the risk of "overshoot" in the depth of anesthesia, perhaps allowing detection of deterioration before a catastrophe occurs, with a good chance of a rapid return to the depth of sedation/anesthesia that was previously tolerated. Most of these sedation/anesthesia strategies involve agents with effects not well monitored by the proprietary depth of anesthesia monitors.

Emergency equipment and appropriately skilled staff should be immediately available to attempt to reverse a situation of respiratory or cardiovascular obstruction/collapse. This may include a rigid bronchoscope and reinforced endotracheal tubes to overcome a compressed trachea. It is notable that some large masses may cause bilateral bronchial compression, and obstruction at that level will not be overcome by these techniques. As noted above, in rare cases, CPB or ECMO support with femoral cannulation under local anesthesia, occurring before the biopsy procedure, is necessary.

KEY POINTS: ANESTHESIA FOR CHILDREN WITH MEDIASTINAL MASSES

- Anterior mediastinal masses can cause lethal airway or cardiovascular compression with general anesthesia.
- A multidisciplinary team in a specialist center should receive an urgent referral of patients with a mediastinal mass.
- Most patients will not require a standard general anesthetic.
- The most minimally invasive method of obtaining a diagnosis should be attempted prior to contemplating anesthesia.
- Local anesthesia should be used alone or combined with sedation/analgesia/anesthesia to minimize requirements for systemic agents.
- CPB or ECMO may have a pre-emptive role in rare cases of high-risk mass, where it is initiated after preparation for cannulation is done under local anesthesia, with the patient awake or receiving sedation.

Heart transplantation

Following the pioneering adult and infant heart transplants of the late 1960s [1, 2], cardiac transplantation has evolved into a successful, standard therapy for end-stage pediatric heart disease. Advances in immunosuppressant therapy, pretransplant recipient optimization, donor organ procurement/preservation techniques, and post-transplant recipient management have all contributed to improved pediatric outcomes despite increased case complexity [3]. The Scientific Registry of the International Society for Heart and Lung Transplantation (ISHLT) is the main source of international multicenter data and captures approximately 75% of worldwide thoracic transplant activity [3]. Currently, approximately 500–600 pediatric heart transplants are performed annually across the globe, with 210 pediatric centers reporting data to ISHLT [3] (Figure 32.1). Most of the pediatric data are reported from centers in Europe and North America. Centers performing >10 transplants/year perform the majority (nearly 50%) of transplants [4] (Figure 32.2).

Diagnostic indications for heart transplantation

Diagnostic indications for pediatric heart transplantation were updated in 2007 [5] and summarized in recent ISHLT annual reports [4, 6]. As post-transplant survival rates and outcomes have improved, the dilemma is no longer whether to transplant, but rather when to do it [7]. Premature transplantation results in exposure of the recipient to the hazards of transplantation and immunosuppression. Excessive delay may result in death without transplantation or the development of high-risk comorbidities, such as renal and liver dysfunction, malnutrition, and elevated pulmonary vascular resistance (PVR). Optimal timing for listing will vary depending on the primary diagnostic indication and anticipated disease progression.

Primary diagnostic indications for heart transplantation are categorized into four main groups, with dilated cardiomyopathy (DCM) and congenital heart disease (CHD) accounting for the majority of pediatric heart transplants (Table 32.1) [6]. Indications for heart transplantation vary with age; the majority of transplants in infants

Table 32.1 Primary diagnostic indications for pediatric heart transplants

Category (abbreviation)	Diagnoses in category
Congenital heart disease (CHD)	Congenital heart defect: HLHS – unoperated; with surgery; without surgery; previous surgery unknown; or valvular heart disease
Dilated cardiomyopathy (DCM)	Dilated myopathy due to: adriamycin; alcohol; familial; idiopathic; myocarditis; postpartum; viral; or other reasons
Retransplant (RETX)	Retransplant due to: acute rejection; chronic rejection; coronary artery disease; hyperacute rejection; nonspecific; primary failure; restrictive/constrictive causes; or other reasons
Other (OTHER)	Arrhythmogenic right ventricular dysplasia; cancer; coronary artery disease; myopathy-ischemia; hypertrophic cardiomyopathy; muscular dystrophy; restrictive cardiomyopathy (any reason); or other cardiac disease

HLHS, hypoplastic left heart syndrome.

are for CHD, whereas DCM is the leading cause in children >1 year of age [4, 8] (Figure 32.3). Indications for heart transplant also vary with geography (Figure 32.4), such that the primary diagnosis in Europe and other countries is DCM. CHD is a more common indication in North America than in Europe, accounting for 43% of heart transplants in North America versus 22% in Europe. Diagnostic indications for heart transplant are important since they are associated with differences in post-transplant morbidity and mortality. For example, DCM confers a post-transplant survival advantage compared with CHD across all age groups [4].

Mechanical circulatory support as a bridge to transplant is being increasingly used in children for all diagnostic indications. Approximately 30% of patients are currently bridged to transplant with a ventricular assist device (VAD) and approximately 3–5% with extracorporeal membrane oxygenation (ECMO) [4].

Dilated cardiomyopathy

Almost 40% of children presenting with symptomatic DCM receive a heart transplant or die within 2 years of diagnosis [8]. Over 50% of children ≥5 years of age with DCM are bridged to transplant with a VAD [4]. *DCMs* have a diverse spectrum of etiologies and phenotypic manifestations (Table 32.2). Pediatric myocarditis, a secondary cause of DCM, has a 50–80% chance of resolution within 2 years of diagnosis even when patients present with acute, severe symptomatology [9, 10].

Congenital heart disease

CHD as a primary indication for heart transplant includes a diverse group of conditions and accounts for 20–60% of pediatric heart transplants depending on age and geographical

location (Figures 32.3 and 32.4). With improved outcomes and widespread adoption of the neonatal stage I palliation, the number of neonates and infants with single ventricle physiology undergoing heart transplant as a primary therapeutic modality has decreased significantly. However, there is an increasing number of patients presenting later in life with failing single ventricle palliation and this subgroup constitutes at least two-thirds of patients with CHD presenting for heart transplant [11, 12]. Failing Fontan patients are a growing cohort presenting for pediatric heart transplant and are discussed in more detail later.

Other indications

"Other indications" are primarily due to hypertrophic cardiomyopathies (HCM) and restrictive cardiomyopathies (RCM).

HCMs account for 5–6% of pediatric heart transplants and include several genotypes and etiologies including idiopathic, familial inborn errors of metabolism, and malformation syndromes such Noonan's and Beckwith–Wiedemann syndromes. [5]. HCM is a leading cause of sudden cardiac death in adolescents and young adults. A recent independently validated model for risk of sudden cardiac death in pediatric HCM identified a positive associated with nonsustained ventricular tachycardia and unexplained syncope and a nonlinear association with age at diagnosis, interventricular septal thickness z score, left ventricular (LV) posterior wall diameter z score, and left atrial diameter z score [13].

RCMs result in diastolic dysfunction usually with normal ventricular size and function and biatrial enlargement. One-third of patients have a mixed phenotype of RCM and HCM [14]. RCMs are associated with myocardial infiltrative processes, such as amyloidosis, hemochromatosis, glycogen storage disease, mucopolysaccharidosis, sarcoidosis, and endomyocardial fibrosis. Syncope and ischemia indicate a poor prognosis, and elevated PVR is often present. Due to limited medical and surgical treatment options and the risk of irreversible pulmonary hypertension, thromboembolic disease, and sudden death many centers favor an approach of early listing for heart transplant [5].

Retransplantation

Retransplantation accounts for a small percentage (5–7%) of pediatric heart transplants and is more common in North America (6%) than Europe (2%) [4, 15]. Coronary allograft vasculopathy (CAV), the most common indication for retransplantation, is discussed in more detail later. Other indications include acute or chronic rejection and primary graft failure (Table 32.3). Data indicate that retransplantation for early primary graft failure has a worse prognosis than for late graft failure or CAV [16–18]. The best outcomes are associated with those retransplanted for CAV [15, 18]. Children with graft failure due to acute rejection with hemodynamic compromise, especially <6 months post-transplant, are regarded as inappropriate candidates for retransplantation [18]. The majority (65%) of pediatric retransplants occur at least 3 years after the primary transplant [4, 15]. Retransplantation has a similar 1-year survival to primary transplants but is associated with

decreased long-term survival and increased transplant-related morbidities such as renal dysfunction, late rejection, and CAV [4, 15, 18].

KEY POINTS: HEART TRANSPLANTATION

- The number performed per year in the United States is limited primarily by donor organ availability.
- The commonest indication for transplantation in infants is CHD.
- The commonest indication in older children is cardiomyopathy.
- Diagnostic indications have an important impact on post-transplant outcomes.
- Currently, approximately 30% of recipients are bridged to transplant with a VAD.

ABO-incompatible heart transplantation
