Infants listed for heart transplant have the longest waitlist time and a higher waitlist mortality when compared with older children. Infant waitlist mortality in the United States is 25% compared with 15% for children and adolescents [19, 20]. An increasing number of centers are adopting ABO-incompatible (ABO-I) heart transplants as a standard practice to reduce waitlist mortality in this vulnerable population. Historically donor and recipients are matched for ABO compatibility. ABO-I heart transplants have been avoided because of the risk of hyperacute rejection that can occur when recipient isohemagglutinins (serum anti-A or anti-B antibodies) bind to the corresponding blood group antigens on donor organ vascular endothelium. Organ allocation across blood group barriers increases the donor organ pool available for heart transplantation. Since blood group O-type recipients have both anti-A and anti-B antibodies (isohemagglutinins), only an O-type donor is compatible and hence they have the longest waitlist time. Isohemagglutinins are not present at birth, and serum antibody titers remain low until 12–14 months of age [21]. Young infants also have an immature complement system. Therefore, the mechanisms leading to hyperacute rejection in ABO-I heart transplant are absent during infancy. This discovery was pioneered in Toronto in 1996 when the first ABO-I heart transplant was performed [22]. With increasing multicenter experience and data, current United Network for Organ Sharing (UNOS) guidelines recommend ABO-I heart transplant in children under 1 year of age with any isohemagglutinin titer and in 1–2 years with titers less than 1 : 16. In 2016, UNOS also changed its allocation criteria so that patients listed as ABO-I have equal organ priority to ABO-compatible (ABO-C) heart transplants. This has led to an increased number of patients listed and receiving ABO-I heart transplants. Various registry and multicenter data have shown comparable survival and outcomes for ABO-I heart transplants compared with ABO-C heart transplants in infants <1 year and no difference in rates of rejection 1-year post-transplant [23]. There is consistent data that ABO-I heart transplants decrease waitlist time, especially in patients with blood group O [23, 24].

Recipient evaluation

A detailed assessment of patients is required to determine their suitability for heart transplantation (Box 32.1). Factors that must be considered include severe central nervous system, liver or kidney dysfunction, pulmonary infarction, pulmonary hypertension, morbid obesity, and some infections, malignancies, or chromosomal abnormalities. Prediction of mortality after transplantation was more accurate when multiple high-risk criteria were included in the assessment of potential recipients [25].

Transplant centers usually have formal meetings to present a structured multidisciplinary evaluation of recipients prior to accepting for heart transplant listing. At Stanford Children's Hospital, a cardiac anesthesiologist is present at these meetings. Evaluation revolves around four key areas [5]:

1. Comprehensive assessment of cardiovascular system (CVS) anatomy and hemodynamics
2. Assessment of end-organ dysfunction and chronic noncardiac disease including nutritional status
3. Human leukocyte antigen (HLA) sensitization
4. Psychosocial evaluation of patient and patient's family

Box 32.1: Routine precardiac transplant evaluation

History and physical examination
- Age, height, weight, body surface area
- Diagnoses
- Past medical history
- Medications
- Allergies
- Immunization record

Laboratory data
- Liver and kidney function tests
- Urine analysis
- Glomerular filtration rate
- Prothrombin time/INR/partial thromboplastin time
- Complete blood count and differential
- PPD skin test
- Serologies for human immunodeficiency virus, hepatitis, cytomegalovirus, Epstein–Barr virus, *Toxoplasmosis gondii*, syphilis
- ABO type
- Panel-reactive antibody

Cardiomyopathy workup
- Thyroid function tests
- Blood lactate, pyruvate, ammonia, acyl carnitine
- Urine organic acids, acyl carnitine
- Skeletal muscle biopsy
- Karyotype

Cardiopulmonary data
- Cardiac catheterization
- Echocardiogram
- Radionuclide angiography
- Endomyocardial biopsy
- Electrocardiogram
- Chest radiograph
- Pulmonary function tests
- VO_{2max}

Psychosocial evaluation
- Possible relocation
- Long-term supportive care
- Parental substance abuse
- History of neglect or abuse

Consultations as required
- Dental services
- Other services

It may be necessary to repeat some tests if the patient's medical status changes over time. INR, international normalized ratio; PPD, purified protein derivative.

CVS anatomy and hemodynamics

Assessment of cardiopulmonary function usually includes cardiac catheterization and magnetic resonance imaging (MRI) or computed tomography (CT) to delineate the vascular connections, particularly in patients previously palliated for complex heart disease. Abnormal cardiovascular anatomy influences surgical technique during harvesting and transplantation. For example, a patient with palliated hypoplastic left heart syndrome and residual arch obstruction may require extra donor arch material during donor harvesting, or a Fontan patient with branch proximal pulmonary artery (PA) stenosis may need PA reconstruction during transplantation. Identifying anomalous systemic or pulmonary venous return, PA malformations, and accessory collateral pulmonary blood flow is also important for the surgical procedure [5].

Quantifying PVR prior to listing is important because PVR > 6 Wood Units/m^2 or a transpulmonary gradient >15 mmHg is associated with acute right heart failure and increased mortality [26, 27]. The upper limit of PVR associated with successful cardiac transplantation has not been established in children. All patients with pulmonary hypertension have PVR measured at baseline conditions and during administration of oxygen, nitric oxide (NO), and/or other pulmonary vasodilator therapy. When the response is marginal, repeat values after 1–2 weeks of inotropic support, afterload reduction, and pulmonary vasodilation may demonstrate improvement. Experienced institutions may accept children with PVR as high as 8–12 Wood Units/m^2 if it is reactive. Patients whose PVR does not respond to therapy may be the candidates for heart–lung transplantation (HLT) or lung transplantation. Children with RCM are particularly prone to marked elevation of PVR, which may contribute to the poor prognosis in these patients and make cardiac transplantation problematic. Nitric oxide appears to be a good agent to demonstrate reversibility of PVR in these patients [26]. PVR also improves after left ventricular assist device (LVAD) implant, especially for patients with DCM and left atrial hypertension [28]. Endomyocardial biopsy may be required prior to listing for dilated cardiomyopathies to identify acute myocarditis and myocardial infiltrates. A diagnosis of acute myocarditis is important in determining suitability for transplant listing since there is chance of resolution as mentioned earlier [9, 10].

End-organ dysfunction/chronic noncardiac disease

Pretransplant end-organ dysfunction and chronic noncardiac disease have an impact on post-transplant morbidity and mortality. Assessing the degree of pretransplant renal dysfunction is important because reduced estimated glomerular

AL Grawany

filtration rate (eGFR) and pretransplant renal dialysis are associated with increased 1-, 5-, and 10-year mortality [4, 29]. Some centers will treat moderate-severe renal dysfunction with a combined heart kidney transplant.

Assessing liver function is also important especially in failing Fontan patients. Elevated serum bilirubin is a continuous risk factor for 1-year mortality post-transplant [12, 29]. There is an increasing trend of treating irreversible liver disease with a combined heart–liver transplant (CHLT) and is discussed in more detail later.

Assessing the degree of chronic lung disease especially in older children with CHD is important and will include pulmonology assessment and pulmonary function tests. Evaluation of patients with cardiomyopathy should include a metabolic workup to detect potential etiologies such as mitochondrial disorders and genetic studies. Transplant teams are also intensifying attention on the pretransplant nutritional status of the recipient since this may have a significant impact on postoperative hemostasis, wound healing, and recovery.

HLA sensitization and immune function

Infectious disease and immune system evaluation are essential. The child's immunization status should be updated if necessary. Tests are performed for latent infections, such as cytomegalovirus or Epstein–Barr virus, that may become clinically significant during immunosuppression. Donor matching is based on ABO typing. The candidate's blood is also screened for antibodies against sera of random blood donors and, if reactive, a serum crossmatch with the donor is performed.

There is an increased risk for graft dysfunction, acute cellular and antibody-mediated allograft rejection, and chronic rejection/CAV after heart transplantation in patients sensitized to HLAs. The number of heart transplant candidates allosensitized to HLA antigens has increased in recent years because of exposure to blood products, homograft material used in surgical palliation of CHD, use of ventricular assist and mechanical support devices, and patients requiring retransplantation. Determinations of panel-reactive antibody (PRA) are done to delineate a patient's potential for sensitization to donor HLA antigens. Patients with a reaction to >10% of antigens (either class I or II) are generally considered to be allosensitized. However, this is allosensitivity to a "random" donor; having a positive crossmatch with the *actual* donor (HLA antibody toward donor alloantigens) at the time of transplant has been clearly demonstrated to increase the risk for poor outcome after transplant. Donor-directed HLA antibodies are associated with rejection-related mortality from cellular and antibody-mediated acute rejection and CAV. Patients with PRA >10% pretransplant and a positive crossmatch are at high risk for graft loss from hyperacute rejection and early acute cellular rejection (ACR), which in turn increase the risk of CAV.

Allosensitized patients may be excluded from heart transplant, restricted to certain donors, or experience prolonged waiting times. Some transplant programs require a prospective negative donor-specific crossmatch for patients with PRA screens >10%. However, this approach is problematic because of the donor shortage and some patients have antibodies to many HLAs. Therefore, perioperative management protocols for HLA-sensitized children have been developed and include pretreatment of sensitized patients (using treatments such as intravenous immune globulin, cyclophosphamide, mycophenolate mofetil [MMF], and rituximab), intraoperative plasma exchange, post-transplant plasmapheresis, and T- and B-cell suppression [30–34].

Psychosocial evaluation of patient and patient's family

Heart transplantation requires long-term immunosuppression, frequent invasive procedures, and lifelong medical care. Patients must live close to the hospital during the initial months after surgery, and temporary relocation of the family may be necessary. Prolonged periods of stressful hospitalization are likely. A stable social situation is essential for success, and psychosocial evaluation is an important aspect of the pretransplantation process.

KEY POINTS: HEART TRANSPLANT RECIPIENT EVALUATION

- Accurate delineation of the cardiovascular anatomy is required for patients with CHD to plan surgical strategies for harvesting and transplantation.
- Increased PVR is associated with increased mortality after transplantation.
- The PRA test reflects a patient's potential for sensitization to donor HLAs.
- PRA >10% increases the risk of graft loss and is present in about 27% of pediatric recipients.

UNOS waitlist status and mortality

Organ transplantation in the United States is sanctioned by congressional mandate through the National Organ Transplant Act (NOTA). An Organ Procurement and Transplant Network (OPTN) was created and is administered by the UNOS. UNOS has three recipient status categories for patients listed for heart transplantation: status IA, status IB, and status II, with status IA indicating the sickest patients who are in urgent need of transplantation for survival. Status seven patients are those previously listed as status IA, status IB, or status II, but considered temporarily unsuitable to receive a heart transplant, e.g. due to active infection.

Current waitlist mortality ranges from 17 to 30% depending on country and institution. Waitlist mortality also varies with transplant center volume, with a reported 5% mortality in large volume centers compared to 30% in small volume centers [35]. Waitlist mortality is also influenced by patient factors such as age, CHD, weight <3 kg, status 1A, the need for ECMO, and renal dialysis [36, 37]. Increased adoption of VADs and improved pretransplant recipient support has helped to decrease waitlist mortality over time [38].

Recipient pretransplant management

The median waiting period from heart transplant listing to actual surgery currently varies between 60 and 80 days, depending on the child's age, blood group, and list status [39].

Aggressive medical management to achieve stabilization is required and includes supplemental oxygen, diuretics, inotropic support (e.g., dobutamine, dopamine, phosphodiesterase inhibitors), antiarrhythmia therapy, and mechanical ventilation. Children with chronic heart failure often receive digoxin, diuretics including spironolactone, angiotensin-converting enzyme inhibitors, and β-blockade therapy (e.g., metoprolol, carvedilol). Patients with severe LV dilation may need anticoagulation, usually coumadin or heparin, to prevent the development of intracardiac thrombi and systemic embolization. Amiodarone is often chosen for treating arrhythmia. Implantable transvenous defibrillators and, more recently, transcutaneous defibrillators have been effective in pediatric patients large enough for these devices. For patients unsuitable for implantable defibrillators either due to patient anatomy or physiology, Life Vest® (Zoll Medical Corp., Pittsburgh, PA, USA) wearable external cardioverter-defibrillator (ICD) therapy can be a short-term option to enable home discharge while waiting for transplant. Biventricular pacing is an emerging modality to improve myocardial function.

Patients with refractory myocardial failure require mechanical circulatory support as a bridge to cardiac transplantation. Approximately one-third of patients with LVADs have right ventricular dysfunction. Medical support and protection of the right ventricle should be considered during anesthesia induction, maintenance, and surgical dissection. Perioperative management algorithms for VAD-supported patients are delineated in a recent comprehensive review [40]. Extracorporeal life support and other mechanical devices as a bridge to transplant are discussed in Chapters 36 and 37.

Pediatric transplant centers are developing pretransplant management strategies that target modifiable risk factors to reduce post-transplant morbidity and mortality [41]. For example, at Stanford Children's Hospital, identification of perioperative acute kidney injury (AKI) as a risk factor for post-transplant morbidity and mortality especially in the CHD population led to the development of a perioperative renal-protective protocol.

Donor management

In the United States and many other countries, solid organs can be obtained for transplantation by donation after brain death (DBD) or by donation after cardiac death (DCD) [42]. DBD criteria were first established in 1968; prior to this, organs were obtained from DCD, including the first heart transplant. Although DBD soon became the standard for organ procurement, scarcity of available organs led to a reexamination of DCD. During DCD, the goal is to initiate organ procurement as soon as possible after ensuring that death from cardiorespiratory arrest has truly occurred, because viability of the donor organ becomes compromised when the warm ischemic time is prolonged. A North American multidisciplinary panel recently concluded that "Death can be declared after the cessation of circulation and respiratory function for 2 minutes" [43]. Despite DCD being legal and with recipient outcomes that are favorable, ethical issues still surround DCD, and DBD currently remains the primary source of organs [44].

The age distribution of pediatric heart donors is similar to that of heart recipients [3]. Echocardiography is useful for assessment of donor heart function. Widespread malignancy or infection in the prospective donor is an exclusion criterion, but cardiac resuscitation and chest trauma are not contraindications, provided the donor's hemodynamics have been stabilized and inotropic agents are no longer needed or are at minimal doses. Assessing potential donor organs involves evaluating immunocompatability, donor risk factors, travel time, recipient pulmonary hypertension, and donor–recipient size match. In contrast to adult heart transplant, sex mismatch has not been found to significantly affect outcomes [45]. Attempts to limit donor heart ischemia time are important but may be hampered by transport issues.

Donor (allograft) ischemic time is defined as time between donor aortic cross-clamp during organ procurement surgery and donor coronary artery reperfusion during heart transplant surgery [46]. The median donor ischemic time for the current era is 3.5–3.7 hours [46]. Donor ischemic time >4 hours is associated with increased 30-day, 1-year, and 5-year mortality [3, 46]. Conversely, donor ischemic time has not been shown to be associated with major post-transplant morbidity such as CAV or renal dysfunction. Some centers may opt to accept longer donor ischemic times for patients with a high risk of waitlist mortality. At Stanford children's Hospital, our standard strategy is to reperfuse the donor heart for a minimum of one-third the ischemic time prior to cardiopulmonary bypass (CPB) separation.

The anesthetic management of a pediatric organ donor is beyond the scope of this chapter [47, 48].

Developments in donor–recipient size matching

Donor–recipient size matching has important consequences for both organ allocation and post-transplant outcomes for pediatric heart transplantation. Undersized cardiac allografts have the risk of not being able to provide sufficient cardiac output (CO), and oversized allografts confer a risk of compressing neighboring structures such as lungs and subsequent physiological effects [49]. Recent publications have also questioned the approach of using oversized donors for patients with pulmonary hypertension [50]. Approximately 20% of potential pediatric donor allografts without marginal/high-risk characteristics are not used [51]. Innovative techniques to improve donor organ utilization have the potential to reduce pediatric waitlist mortality. Historically, standard clinical practice has been to use donor–recipient body weight ratio (DRBW) and donor–recipient height ratios for allograft size matching. At the time of listing transplant, institutions will define a lower and upper weight limits that they are willing to accept for their patient. A typical range would be 80–160% of recipient body weight. Estimating size match eligibility using traditional measurements such as weight and height assumes a predictable correlation with total cardiac volume. Total cardiac volume, however, may not always correlate with somatic growth. For example, children with advanced heart failure may have a lower than predicted body weight because of failure to thrive or a higher body weight due to fluid overload. Body weight is also an inaccurate correlate of heart size in patients with CHD or RCM where the heart size is often smaller and in patients

AL Grawany

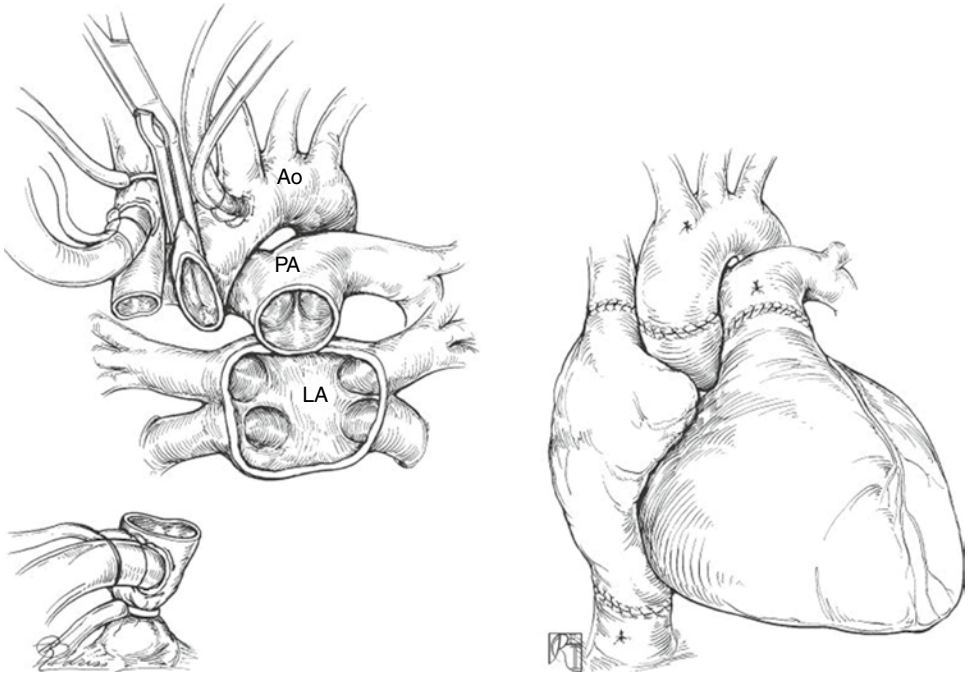

Figure 32.5 "Bicaval" cardiac transplantation. (A) The recipient cardiactomy has been completed. Note the entire recipient right atrium has been removed. (B) The completed implant. The sequence of anastomoses is (i) left atrial, (ii) aortic (cross-clamp removed and heart perfused), (iii) inferior vena cava, (iv) pulmonary artery, and (v) superior vena cava. (Source: Backer et al [56]. Reproduced with permission of Taylor & Francis.)

with dilated cardiomyopathies and cardiomegaly. Heart size matching based on weight also does not account for the complexities of implantation in patients with heterotaxy and cardiac malposition. Waitlist mortality and allograft shortages have led clinical transplant programs to widen their acceptable DRBW to increase the donor pool. Innovative approaches to performing virtual heart transplant fit assessments include using allograft total cardiac volume prediction models and advanced donor imaging such as CT and MRI for a direct virtual transplant assessment [52–54]. Adoption, development, and standardization of these alternative approaches may improve organ utilization.

Surgical technique

Orthotopic heart transplants whereby the recipient heart is excised and replaced in the correct anatomical position by the donor heart is the standard surgical approach. The biatrial anastomoses originally described by Lower and Shumway [55] has now been abandoned in most centers and replaced by the bicaval left atrial cuff technique – the current standard approach for pediatric heart transplant. A small cuff of recipient left atrial tissue is left in place, incorporating all pulmonary veins, and the entire right atrium of the recipient is removed. Standard implantation of the donor heart involves five anastomoses – left atrial cuff, aorta, inferior vena cava (IVC), superior vena cava (SVC) (bicaval anastomoses), and main PA. Surgeons will vary with regard to the order of anastomoses. Two golden rules that apply for all implantations are that the left atrial anastomosis is performed first, and once the left atrial anastomoses and aortic anastomoses are completed, the aortic cross-clamp can be removed and donor heart reperfusion commenced (Figure 32.5) [57]. A meta-analysis found superiority of the bicaval technique in comparison with the biatrial procedure for early atrial pressure, perioperative mortality, tricuspid valve regurgitation, and sinus rhythm [58], although others found no difference in long-term survival [59].

Cardiac transplantation for children with CHD can involve more complex anastomoses and vascular reconstruction such as branch PA reconstruction and aortic arch reconstructions for recipients with palliated single ventricle physiology. Deep hypothermic circulatory arrest may be employed in patients requiring extensive vascular reconstruction.

Anesthetic management

Pre-CPB period

Multidisciplinary preoperative huddle and planning

Children listed for heart transplantation have limited physiological reserves. Even minor changes induced by anesthesia, and surgery can trigger cardiovascular instability and decompensation. Prior to surgery, young infants and children with decompensated heart failure may already be in intensive care with invasive lines and inotropic and respiratory support. More stable patients may be admitted from home at the time of donor acceptance and could have eaten recently. Several hours usually elapse before surgery, but therapy to modify gastric pH and volume and the application of continuous cricoid pressure during induction might be required. Up to 30% of pediatric heart transplants are bridged with a VAD and may be either inpatient or

outpatient and will be on some form of anticoagulation and antiplatelet therapy [60]. Communication between the transplant surgeons, anesthesiologists, operating room staff, and donor procurement team is vital to coordinating care and ensuring allograft ischemia time is minimized. At Stanford Children's Hospital, we hold a preoperative "huddle" attended by the heart failure and transplant teams, intensive care team, the surgeon, anesthesiologists, and perfusionists. At this meeting, donor- and recipient-specific issues are addressed, including allosensitization and plasmapheresis, vascular access, invasive monitoring lines, emergency cannulation techniques, immunosuppressants, including steroids, and the need for urgent reversal of anticoagulation such as warfarin reversal with a prothrombin complex concentrate [60]. We also discuss renal risk stratification and employ renal-protective strategies for patients with a moderate-high risk of postoperative AKI. Stanford Children's renal-protective protocols involve risk stratification of patients for risk of AKI, maintaining adequate renal perfusion through blood pressure management, fluid management, and reducing central venous congestion, pharmacoprophylaxis with pre-, intra-, and postoperative aminophylline and a modified induction protocol to avoid highly nephrotoxic medications in the immediate postoperative period. As part of the huddle, we discuss a patient-specific "flight plan," which addresses all relevant patient specific perioperative issues and is documented in the electronic medical record (Figure 32.6).

Anesthesia induction and monitoring

Premedication and the method of anesthesia induction depend upon the patient's age, cardiac lesion, and cardiopulmonary function. Establishing invasive hemodynamic monitoring prior to induction of anesthesia may not always be feasible and so it is imperative to institute noninvasive patient monitoring prior to the administration of medications that alter hemodynamic and/or respiratory function. Focused transthoracic echocardiography (TTE) may have a role in patients where preinduction arterial lines may not be an option. Qualitative assessment of cardiac function in patients with severely reduced function and septal configuration in patients with pulmonary hypertension can be monitored with a parasternal short-axis view. Anesthesia- or surgery-induced changes in heart rate (HR), preload, afterload, or contractility can precipitate hemodynamic decompensation. Meticulous airway management is vital as hypoxia and hypercarbia aggravate PVR and can further depress CO and high intrathoracic pressures may trigger right ventricular decompensation. Rapid sequence induction may be poorly tolerated in patients with minimal cardiorespiratory reserve. Significant ascites in patients with hepatic dysfunction (e.g. failing Fontan) may necessitate controlled peritoneal drainage peri-induction. A wide variety of anesthetic agents have been used successfully. The desirable and detrimental cardiovascular effects of anesthetic agents are reviewed in Chapter 10. In children with CHD, a fentanyl/midazolam/muscle relaxant anesthetic technique was reported to preserve cardiac index better than volatile agents, provided HR was maintained [61]. Etomidate has minimal effect on hemodynamics and is a useful induction agent in patients with limited cardiovascular reserve. Propofol decreases systemic vascular resistance and reduces preload to the heart, and a bolus should be used with caution if at all. Nitrous oxide has myocardial depressant and pulmonary vasoconstrictor properties and is best avoided. Ketamine supports the circulation by indirectly stimulating catecholamine release. This may be blunted in children with DCM and impaired β-agonist responses, or in patients who are on chronic infusions of β-adrenergic agonists. When the patient's endogenous catecholamine stores are depleted, the drug's direct myocardial depressant effects may then predominate. Regardless of the agent used, hypotension must be anticipated and treated promptly to preserve coronary perfusion. Commencing a low-dose inotrope infusion (e.g. epinephrine 0.01–0.03 mcg/kg/min) prior to induction of general anesthesia provided there are no significant arrhythmias may help avoid hypotension and preserve coronary perfusion. Recent excellent reviews describe the anesthetic management of children in the operating room [62, 63]. A trigger-free anesthetic should be considered for patients with neuromuscular disease such as Duchenne or Becker muscular dystrophy to reduce the risk of malignant hyperthermia like symptoms or anesthesia-induced rhabdomyolysis.

Monitoring during transplantation surgery does not differ from that used for pediatric open-heart surgery. Large-bore vascular access and a rapid infuser device should be available for patients undergoing repeat sternotomy and those on preoperative mechanical circulatory support. Patients with pacemakers or ICDs should have their devices reprogrammed prior to the use of surgical diathermy. TEE is useful for evaluation of intracardiac air, transplanted heart anatomy and function, vascular anastomoses, mural thrombus, and early post-transplant cardiac function. When PA pressure monitoring is indicated, some institutions prefer to place a catheter directly into the PA rather than use a percutaneous balloon-tipped PA catheter. Due to the increased risk of perioperative bleeding in patients with CHD, repeat sternotomy and those on mechanical circulatory support prophylactic anti-fibrinolytics are a useful adjunct.

CPB period

The management on CPB is similar to that in children undergoing cardiac surgery. Ultrafiltration during CPB may benefit the patient by removing excess free water, hemoconcentrating red cells and coagulation factors, and modulating the inflammatory response. Variations in ultrafiltration techniques are institution dependent.

Post-CPB period

Issues of concern include denervated donor heart, global ischemia–reperfusion injury, elevated PVR, right ventricular dysfunction, arrhythmia, hemostasis, and hyperacute rejection.

The transplanted heart is functionally denervated and may have an abnormal response to sympathetic stimulation. Resting HR may be higher than normal because of absent vagal tone. The normal beat-to-beat variations in response to respiration are lost, as are the normal responses of the heart to alterations in body position and carotid body massage. The donor heart cannot abruptly increase HR and CO in

Transplant Flight Plan

Name:
MRN:
DOB:
Date of Listing:
Flight Plan Current as of:

SECTION A: Care Team

Primary Heart failure Cardiologist:
Primary Community Cardiologist:

SECTION B: Risk Assessment

Please identify the degree of estimated risk for each of the following:

AKI: Average - Baseline Creatinine 0.15-0.2
Bleeding: High - Chronic anticoagulation for VAD with aspirin, Plavix and lovenox
Infection: High - Concern for chronic VAD and abdominal infection, on meropenem
Liver Dysfunction: Average - Baseline bilirubin normal at 0.5
Clinically meaningful PH: Average - None, last cath PVR 3.4
Malnutrition: Average - On continuous NJ feeds
Ongoing PLE: Not Applicable

SECTION C: Diagnosis/Physiology/ Anatomy

Current Anatomy: 3-year-old F with DCM s/p Berlin BIVAD (Berlin LVAD, Berlin RVAD).

Most recent catheterization date:
Most recent catheterization data: RA 12, RV 39/14, PA 38/20/29, PCWP 20. CI 3L/min/m2, PVRi 3.4 iWU, SVRi 17.1 WU

SECTION D: LINE MANAGEMENT

Last vascular surveillance:
UE and LE US with Doppler: No thrombus demonstrated. Patent central upper and lower arterial and venous vasculature.
CT Chest/Abd/Pelvis: Thoracic and abdominal aorta is normal in caliber. No evidence of stenosis or aneurysmal dilation.
The following vessels are known to be open: RIJV, RSCV, LIJ, LSCV, RFV, RFA, LFV, and LFA
intravenous/intracardiac Lines Requested During Surgery (in addition to standard CVL, arterial lines, and PIVs: RA and LA.

SECTION E: AKI Prevention Plan

Plan to follow renal protective protocal? yes
Intraoperative Aminophylline: yes
Timing of Aminophylline Administration: Pre-op
Maintain arterial blood pressures around 75th percentile for age? yes
Goal CVP less than 10? yes
Avoid NINJA (nephrotoxic) medications if possible? yes
Intraoperative PD Catheter to be placed during surgery? no
Post-Operative Renal Surveillance Plan (urine collection, biomarkers, etc.): Standard Care

SECTION F: Immunosuppression Plan

Induction: Standard (sensitized)
Plasmapheresis going on to bypass
ATG: yes
Dose/Schedule: 1.5 mg/kg/dose
Total # of Doses: 5 doses over 7 days
Target CD3 Count: < 50

IVIG: yes
Time IVIG to be started: In OR

Maintenance Therapy:

Calcineurin Inhibitor: yes
Drug: Tacrolimus
Anticipated day of initiation: after renal recovery
Anticipated target trough: 10-12

Mycophenolate Mofetil: yes
Anticipated day of initiation: POD #0 per protocol
Anticipated target trough: Not Applicable

Corticosteroid:yes
Anticipated day of initiation: POD #0 per protocol
Anticipated starting dose/schedule: Per Protocol
Anticipated duration of therapy: Not Yet Determined

Surveillance: First biopsy anticipated: Two Weeks

SECTION G: Infectious disease

Recipient CMV status: Pos per transplant, per charting PCR negative, repeat pending
Donor CMV Status: Neg
Recipient EBV Status: Pos
Donor EBV Status: Pos
Other infectious disease issues that need to be addressed: Concern for chronic VAD/abdominal infection, on meropenem. Recommend continuing meropenem post-op.

SECTION H: Pulmonary Vasodilators

Current Pulmonary Vasodilator Therapies: none

SECTION I: Ongoing Management of PLE

Has PLE diagnosis? no

SECTION J: Arrhythmia Management

Has clinically important arrhythmia history? yes
Describe: History of NSVT, EAT, frequent PVCs, ventricular couplets/triplets. Off aminodarone since ..... On Coreg 2 mg BID.
Has pacemaker or ICD that needs to be turned off at the time of surgery? no

SECTION K: Research Protocols

Please describe any research protocols that need to be incorporated into plan, including blood and/or tissue sampling, interventions, and medications: N/A

Figure 32.6 Example of Stanford Children's Hospital pediatric cardiac transplant flight plan. response to stress because the baroreceptor reflex is disrupted, and patients are dependent on circulating catecholamines. With the loss of the baroreceptor reflex, the patient with the denervated heart may initially show an exaggerated response to hypovolemia with a marked decrease in mean blood pressure and then a delayed exaggerated hypertensive and tachycardia response, due to endogenous catecholamine release. The Frank–Starling (pressure–volume) relationship remains intact and compensates for hypovolemia and hypotension by increasing stroke volume secondary to an increased venous return. Therefore, it is important to maintain adequate preload, especially if vasodilators are administered. Innervation of the peripheral vasculature is preserved, and changes in peripheral vascular resistance may still occur in response to alterations in sympathetic outflow from the vasomotor center due to signals from stretch receptors in the great vessels.

Drugs such as atropine, glycopyrrolate, neostigmine, and pancuronium that act on the heart through vagal or sympathetic neuromechanisms usually will not affect HR. However, there are case reports of profound bradycardia and hypotension following glycopyrrolate–neostigmine administration [64, 65]. α- and β-Adrenergic receptors remain intact, and inotropes such as epinephrine and isoproterenol will cause appropriate responses from the heart.

The donor organ is subjected to ischemia–reperfusion injury, and patients usually require inotropic support for separation from CPB. LV diastolic dysfunction is common and characterized by a restrictive ventricular filling pattern, with a reduced preload reserve and a relatively fixed stroke volume. Sinoatrial node dysfunction is relatively common. Dopamine, epinephrine, or isoproterenol is often selected, and epicardial temporary pacing can be instituted if necessary to achieve the desired HR. Arrhythmias are quite common in the early postoperative period, usually premature atrial or premature ventricular contractions. Compression of intrathoracic structures may be problematic during closure of sternotomy, particularly if the donor heart is relatively oversized [66].

It is important to preserve donor right ventricular function by keeping PVR low normal. Catecholamine release is reduced by ensuring the patient remains adequately anesthetized. Ventilation is facilitated by muscle relaxants, and normocarbia is maintained. Elevations in central venous pressure with low or normal left atrial pressure and reduced mean arterial pressure might be related to right ventricular failure. Elevated PA pressures can be detected by echocardiography and measured invasively. Additional measures to control PVR may be necessary, including pulmonary vasodilator therapy such as NO [67], prostacyclin, phosphodiesterase inhibitors, and isoproterenol. At Stanford Children's Hospital, we routinely separate from CPB with inhaled nitric oxide (iNO) 20 ppm, dopamine, epinephrine, and milrinone infusions following pediatric heart transplants.

More extreme hypocapnia may help, but also causes cerebral vasoconstriction and leftward shift of the oxygen dissociation curve. Cerebral oximetry monitoring using near-infrared spectroscopy is helpful. If the patient's CO remains inadequate despite maximal drug therapy, mechanical right ventricular assist or ECMO may be employed [68].

Blood loss during heart transplantation can be considerable and is associated with increased morbidity and mortality. Blood products are cytomegalovirus-matched, leukoreduced, and irradiated, but coagulation management is no different from that for other open-heart surgeries in children (see Chapter 16). For infants, some centers wash packed red blood cells to reduce the potassium load. Citrate-induced hypocalcemia impairs contractility and coagulation; this may be minimized by initiating a calcium infusion (calcium chloride 10–30 mg/kg/hour). Rapid platelet transfusion may aggravate PVR. Patients on preoperative mechanical circulatory support often have an acquired von Willebrand deficiency, and cryoprecipitate can be a useful adjunct to help achieve hemostasis [69]. A multimodal approach to hemostasis management should be employed and there is an increasing trend for centers to use prothrombin complex concentrates to achieve perioperative hemostasis [60, 70].

Intraoperative immunosuppression regimens are institution specific. At Stanford, this is discussed during the preprocedural huddle and the medications are ordered by the transplant team to arrive in the operating room with the patient.

KEY POINTS: HEART TRANSPLANT: PERIOPERATIVE MANAGEMENT

- Patients with end-stage heart failure often require anticoagulants and antiarrhythmia therapy.
- Satisfactory transplantation outcomes require excellent communication and collaboration between the multiple disciplines involved in perioperative care.
- Many transplant candidates have minimal cardiopulmonary reserve and may decompensate during anesthesia induction.
  - 17–30% of listed children die while waiting for a donor heart, with infants having the highest waitlist mortality.
  - Increased use of VADs has helped to reduce waitlist mortality.
  - Failing Fontans are an increasing cohort of pediatric heart transplants.
- Postoperative morbidity is directly related to the number of blood products transfused.

Failing Fontan transplants

In North America, a growing cohort of pediatric heart transplants are for failing single ventricle palliation. Failing single ventricle physiology accounted for 36% of CHD transplants in the early era (1990–2002) compared to 67% in the more recent era (2006–2017) [11, 12]. Most of the single ventricle transplants are for failing Fontans, followed by the failing Glenn stage [71]. Transplantation after stage 1 palliation is relatively uncommon [71].

Failing Fontan patients may be listed for heart transplant for several different reasons, including ventricular systolic or diastolic dysfunction, atrioventricular valve regurgitation, atrial or ventricular arrhythmias, high Fontan pressures and venous congestion, lymphatic failure such as plastic bronchitis or protein-losing enteropathy (PLE), and hepatic or renal

AL Grawany

dysfunction. Because of this heterogeneous and often-slowly progressive nature of Fontan failure, there are no clear consensus guidelines for optimal timing for heart transplant listing. Fontan heart transplants represent a high-risk cohort with increased CPB times, increased donor ischemic times, and increased bleeding risk [71, 72]. Early era multicenter registry studies and single-center studies reported that Fontan patients had decreased early survival after heart transplant when compared with other forms of CHD and cardiomyopathies. In the current era, expected survival after heart transplant for Fontan patients is comparable to other CHD patients [41]. This is a reflection in improved overall survival for pediatric heart transplantation despite increased case complexity [15, 71]. Improvements in perioperative care, recognition, and mitigation of modifiable risk factors have helped with improved outcomes. Institutions have developed their own multifaceted approach to deal with issues specific to this population [41]. Issues include complex surgical dissection and implantation, longer allograft ischemic times in Fontans (>4 hours), vasoplegia, aggressively treating for and monitoring primary graft failure, AKI, and the impact of PLE [41]. The association between the Fontan circulation and renal dysfunction, driven by renal venous congestion and low CO, has led to increased efforts to target the prevention of perioperative AKI in this population [73]. Data also suggest there may be an opportunity to improve outcomes by optimizing nutrition and reducing malnutrition in Fontan patients [74, 75]. Figure 32.7 illustrates a single-center checklist to guide perioperative management for Fontan heart or CHLTs.

Combined heart and liver transplantation

Pediatric patients with relatively simple cardiac defects can successfully undergo liver transplantation with equivalent outcomes reported for children with and without CHD [76, 77]. The consensus remains that severe cardiac defects should be corrected prior to liver transplantation to avoid unacceptable transplantation mortality. Lesions of concern include significant cardiopulmonary disease, pulmonary hypertension [78], hypoxemia (PaO_2 < 50 mmHg) – either from cardiac shunt or hepatopulmonary syndrome – elevated central venous pressure (>15 mmHg), and low CO. Successful liver transplantation outcome after bidirectional Glenn palliation for HLHS has been reported [79]. Although the first pediatric CHLT was reported in 1984, this remains relatively uncommon in children [80]. UNOS database shows that only 21 out of 387 heart liver transplants reported to date (2021) were in patients under 18 years of age.

Elevated central venous pressure, hepatic congestion, and reduced CO in the Fontan circulation lead to the development of Fontan-associated liver disease (FALD). All patients develop some degree of FALD after a Fontan, but it is unclear which ones will develop clinically significant liver disease. Studies have shown that the severity of FALD-related liver histopathology most strongly correlates with overall time since Fontan completion [81]. Almost 100% of Fontan patients have histological evidence of fibrosis by the time they reach adolescence and 40% develop bridging fibrosis at 10 years post Fontan [81]. FALD ranges from bridging liver fibrosis to cirrhosis, portal hypertension, and, rarely, hepatocellular carcinoma [82]. Variceal-related gastrointestinal bleeding and liver synthetic function derangements remain uncommon. Improved awareness and surveillance for FALD have led to an increasing number of patients being listed for CHLT. Currently, there are no consensus guidelines for diagnosing and monitoring FALD and which patients to list for heart–liver versus heart transplant. A recent study suggested that cirrhosis on imaging should prompt consideration for CHLT rather than heart transplant alone [82]. A multidisciplinary group recently proposed an algorithm of who to list for heart transplant versus heart–liver transplant (Figure 32.8). Some centers have adopted surveillance cardiac catheterization combined with transjugular liver biopsy in all patients 10–15 years after Fontan completion. Liver fibrosis seen in these patients are heterogeneous and, therefore, biopsy sampling error may underestimate the degree of liver involvement. Despite the difficulties with deciding who to list for heart–liver transplant, studies have shown that CHLT patients have 1- and 5-year survival rates similar to heart transplant alone [70, 83]. Although the etiology is unknown, CHLT patients appear less vulnerable to acute cellular- and antibody-mediated rejection (AMR) [83]. The adult transplant literature indicates that CHLT attenuates cardiac allograft vasculopathy by decreasing the rate of plaque volume and plaque index progression, thereby providing better coronary-related clinical outcomes [84]. A recent single-center study of pediatric and young adult Fontan recipients also reported comparable post-transplant outcomes in patients receiving heart–liver transplants and heart transplant alone despite higher inotropic requirements and more advanced liver disease in the heart–liver cohort [82].

Stanford University investigators have published reports of up to nine pediatric heart–liver transplants for failed single ventricle palliation where the organs were procured and implanted en bloc [70, 82]. An advantage of the "en bloc" technique when the heart and liver are implanted together during CPB is that the new heart is protected from the hemodynamic and metabolic derangements that are typically seen when the liver is implanted and reperfused separately after CPB separation.

Reliable estimation of perioperative mortality is challenging and requires separate consideration of the risks posed by hepatic and cardiac dysfunction. Important challenges include the intraoperative management of massive transfusion and vasoplegia [70, 82] and postoperative renal dysfunction [82, 84, 85].

Overall risk and transplant listing for CHLTs is influenced more by cardiac status than liver status [86]. Current UNOS policy allows patients waitlisted for heart–liver to be also waitlisted for heart-only and liver-only transplantation. If a heart–liver patient is offered a heart or a liver, the additional organ from the same donor is also allocated.

Heart–lung transplantation

HLT is covered in detail later in this chapter. Briefly, institutional preferences drive HLT versus single- or double-lung transplant in patients with elevated PVR. Current ISHLT data show comparable outcomes for HLT versus lung transplant or double-lung transplant for patients with idiopathic pulmonary arterial hypertension [87]. Disadvantages of HLT include significantly

Perioperative Checklist for Fontan Heart and Heart-Liver Transplants

Preoperative huddle discussion topics

Vascular access-Check recent vascular map (CT/US) to confirm patency of vessels.

Difficulty of re-opening & rescue strategy-right neck vs right groin.

Significant collaterals (Aorto-Pulmonary or Veno-Venous): bleeding risk during re-opening.

Significant Aorto-Pulmonary (AP) collaterals: run higher flows on CPB & maintain higher MAPS to preserve end organs e.g., kidneys/liver.

Baseline renal function & renal protective strategies: Peri-op aminophylline & higher intra-op target MAP. Post op HD line: need & timing.

Recent INRs & Coagulation results: Reversal with KCentra (see below) & products during dissection.

Esophageal/gastric varices. Consider pediatric TEE probe if concern for varices.

Significant abdominal ascites: plan for controlled intra-operative drainage.

Octreotide infusion for portal hypertension.

Antibiotics (consider piperacillin/tazobactam for heart-liver patients).

Anesthesia induction/maintenance

Check *insitu* lines e.g. PICC- is it central.

Sedated peripheral arterial line if possible.

If systolic function moderate/severely reduced & no arrythmias consider low dose epinephrine e.g. 0.02-0.03mcg/kg/mn peri-induction.

Patients with diastolic dysfunction/PLE/liver dysfunction often in vasodilated state: consider vasopressin infusion.

Right internal jugular triple lumen line (high approach in neck).

If possible: left femoral arterial line and left femoral venous sheath (surgeons may need right groin for heart-liver cannulation). Venous sheath connected to rapid infuser.

Once donor heart visualized: reversal with KCentra + Vit K if INR > 1.8 & start coagulation products (e.g. platelets) for dissection if needed.

Pre-treatment INR	1.8–<4	4–6	>6
Kcentra dose (units based on Factor IX content)	25 units/kg	35 units/kg	50 units/kg
Maximum dose	Not to exceed 2500	Not to exceed 5000	Not to exceed 5000

Vitamin K Dose 5-10 mg IV. Administering with Vit K will help maintain factor levels

TXA as per intra-operative coagulation pathway.

Cerebral and renal oximetry monitoring.

Octreotide 1-2 mcg/kg/h, max dose 100 mcg/h until shortly after reperfusion-stop after separation from bypass.

Start insulin infusion for blood glucose > 200.

CPB strategy

Consider higher flows to maintain higher MAPS & end organ perfusion especially if AP collateral burden is high.

Ensure adequate venous decompression (brain, liver, & kidneys).

Minimum Hct on CPB: 30%.

Vasoplegia: Consider vasopressin to maintain MAPS.

Refractory vasoplegia (seen more often with Fontan VADS): Consider adding methylene blue (2mg/kg over 30 mins); methylene blue infusion if needed (0.5mg-1.0 mg/kg/hr); Consider switching vasopressin to norepineprhine infusion. Consider hydroxycobalamin 5g over 15 min (obtained from Stanford adult hospital).

Post bypass

Goals: 1. Protect right heart & liver allograft (for heart-liver patients).
2. Be prepared for massive blood product transfusion (especially heart-liver patients).

Dopamine/epinephrine/calcium infusion +/–milrinone (if not vasoplegic).

Consider vasopressin for post-operative vasoplegia.

Nitric oxide 20 ppm; Consider ICU ventilator & in-line suction catheter.

Single digit CVP; Keep a close eye on right heart function by TEE.

Have Feiba available (Recommended dose: 10 units per kg X 2–3).

Fibrinogen concentrate to optimize fibrinogen level (Goal fibrinogen 300).

Platelets (usually minimum 2-4 units). May need more for heart-liver.

Cryoprecipitate (usually 10 pack for heart transplants and 20 pack for herat-liver).

Massive transfusion or keep ahead with PRBC & FFP.

Check Lactates & correct base deficit; Repeat TEG & fibrinogen for refractory bleeding/ongoing coagulopathy.

Immunosuppressants – IVIG (*see IVIG tip sheet*).

Hematocrit Goals per Intraoperative coagulation pathway

Non-neonate: complex 2ventricle repair
Minimum Hct pre-CPB (%): 30
Minimum Hct on CPB (%): 30
Target Hct CPB separation (%): 30–35
Minimum Hct for transfer to ICU (%): 30

Obtain satisfactory hemostasis prior to leaving operating room.

Take spare blood products for transport in case of re-bleeding.

Figure 32.7 Perioperative checklist for Fontan patients undergoing heart or combined heart–liver transplants: Stanford Children's Approach. CT, computed tomography; US, ultrasound; CPB, cardiopulmonary bypass; MAPS, mean arterial pressures; HD, hemodialysis; INR, international normalized ratio; K_{Centra}, prothrombin complex concentrate; TEE, transesophageal echocardiography; PICC, percutaneously inserted central line; PLE, protein-losing enteropathy; TXA, tranexamic acid; VAD, ventricular assist device; PRBC, packed red blood cells; FFP, fresh-frozen plasma; TEG, thromboelastogram; IVIG, intravenous immunoglobulin.

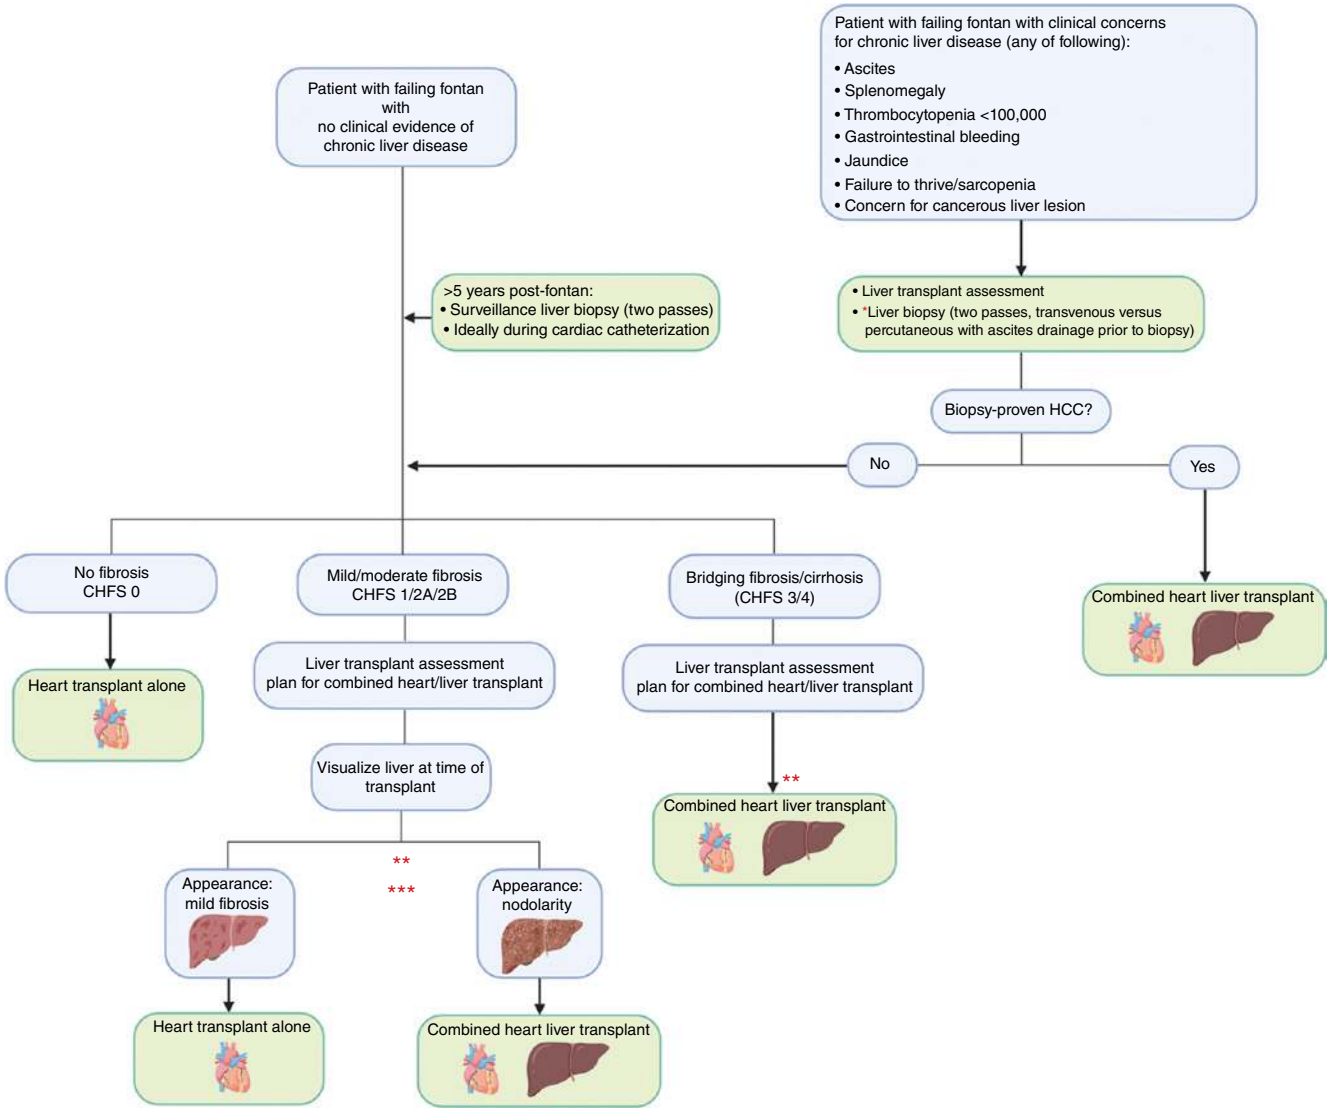

Figure 32.8 Algorithm for heart transplant versus combined heart–liver transplant in patients with Fontan-associated liver disease. (Source: Emamaullee et al. [81]. Reproduced with permission of Wolters Kluwer Health, Inc.)

longer wait times, the need for higher levels of immunosuppression in patients with double-organ transplants, and surveillance of two organs for rejection. Currently, HLT is recommended in patients with demonstrable LV dysfunction and/or in patients with complex CHD with elevated PVR.

Immunosuppression

Immunosuppression following heart transplantation is lifelong. Despite advances in immune therapy, rejection continues to be a major source of morbidity and mortality in the postoperative period. Pediatric heart transplant provides a unique immunological opportunity because the development of the immune system extends beyond infancy into childhood. T-cell responses and phenotype are naive compared with adults, with decreased expression of integrins and adhesion molecules. Younger age at the time of transplantation is associated with better long-term survival and lower frequency of rejection compared with older children [88]. Infants and young children (up to 5 years of age) have undergone transplantation across ABO barriers without developing clinical rejection as discussed earlier.

Choice of immunosuppressives is largely guided by institutional experience and the recipient's clinical profile, rejection history, and comorbid associations. Currently, there are no randomized trials to guide management. Stanford Children's Hospital current immunosuppression protocol is attached as an example (Table 32.4). Typical clinical use of these agents is summarized below [89].

Immunosuppression consists of an induction and maintenance phase with additional therapies to manage rejection.

Induction therapy. Induction phase allows for rapid establishment of immunosuppression. Approximately 75% of transplant recipients between 2010 and 2018 received induction therapy [4]. The most common agent used are polyclonal antilymphocyte or antithymocyte globulin. Despite its popularity in children, significant benefits of induction therapy for survival, CAV, or incidence of rejection are yet to

Table 32.4 Induction and maintenance of immunosuppression following heart transplantation in children: stanford protocol

Induction therapy: Administered in the operating room following hemostasis from CPB.
Methylprednisolone: 10 mg/kg (max. dose is 500 mg).
POD# 0–7: 1. Rabbit antithymocyte globulin 1.5 mg/kg/dose; 5 doses given over 5–7 days.
2. Methylprednisolone: 3.3 mg/kg every 8 hours X3 doses and then tapered to 0.4 mg/kg/dose, twice daily. Once tolerating oral medications prednisone/prednisolone at 0.5 mg/kg, twice daily can be started.
3. Mycophenolate mofetil: 600 mg/kg twice daily.
4. Tacrolimus: 0.05 mg/kg orally started on POD#5 and if renal function is normal.

Maintenance therapy: Patients may be weaned from prednisone based on the following criteria
If first biopsy is negative or on POD #7–14, whichever comes first:
- Did not receive preoperative desensitization therapy pretransplant
- Compatible retrospective crossmatch (regardless of virtual crossmatch results)
- Tacrolimus trough >7 ng/mL
- Ventricular function is normal
- There are no concerning donor-specific antibody.

If above criteria are not met, steroids are continued and weaned gradually over 6 months.
Tacrolimus: Dose is adjusted to achieve target troughs of 10–12 ng/mL for the first 3 months, then 8–10 ng/mL for months 3–6, then 7–10 ng/mL for months 6–12, then 5–8 ng/mL after the first postoperative year. This is continued indefinitely. Dose/target trough may be adjusted in patients receiving PSI medications and/or those with or at risk for chronic kidney disease.
Mycophenolate mofetil: Dose: 600 mg/m^2/dose PO (max. 1,000 mg) twice daily. To be continued indefinitely.

Sensitized protocol
If the patient is being treated under "sensitized" protocol due to the presence of antibodies, additional medications may be necessary during the perioperative and induction phase. Plasmapheresis 1.5 volume exchange during CPB.
Intravenous gammaglobulin after separation from CPB.

be demonstrated in children [4]. Results of a prospective multicenter clinical trial are awaited.

Maintenance therapy. The objective is to prevent acute and chronic rejection while minimizing the adverse effects of immunosuppression. All regimens involve a calcineurin inhibitor. Adjunct therapy may include an antipurine agent or mammalian target of rapamycin (mTOR) inhibitor. Often, corticosteroids are also administered, although many programs attempt to limit or avoid their long-term use. Tacrolimus and MMF or mycophenolic acid (MPA) are the most common agents for maintenance immunosuppression at the time of hospital discharge [4] (Figure 32.9).

Immunosuppressive therapies can be categorized by their actions into seven groups as follows:
1. Broad-spectrum immunosuppressants – corticosteroids
2. Calcineurin inhibitors – cyclosporine and tacrolimus
3. Antiproliferative(purine) agents – MMF and azathioprine
4. Antibodies against interleukin-2 (IL-2) – basiliximab and daclizumab
5. TOR inhibitors – sirolimus
6. Monoclonal and polyclonal T-cell antibodies – anti-CD3 monoclonal antibody (OKT3), antithymocyte globulin (ATG), antilymphocyte globulin
7. Nondrug therapies – total lymphoid irradiation, photopheresis, and plasmapheresis.

Calcineurin inhibitors

Overall survival of transplanted patients increased from 40 to 70% after the introduction of cyclosporine (Sandimmune, Neoral) in 1982. Cyclosporin binds to cyclophilin within the cytoplasm of T cells; this complex inhibits calcineurin phosphatase, thus interfering with the transcription of key cytokines such as IL-2, required for T-cell activation and proliferation. It is not a myelosuprressant and B cells, macrophages and granulocytes are unaffected. Microemulsified formulation of cyclosporin provides better bioavailability and lower rejection rates than the original preparation that had unpredictable absorption. Therapeutic drug monitoring is essential because the therapeutic window is narrow and other drugs influence drug levels. Cyclosporine trough levels are usually maintained in the range of 100–300 ng/mL. Adverse effects may be dose-related and include toxicity of renal, hepatic, and neurological systems, hypertension, hyperlipidemia, hirsutism, and gingival hyperplasia.

Tacrolimus (Prograf, FK506) binds to a different cytosolic-binding protein (FK-binding protein) and has been particularly effective as a rescue treatment in cases where recurrent rejection has occurred with cyclosporine. Overall patient survival does not differ between the two agents, but there appears to be less rejection with tacrolimus and an improved adverse effects profile with respect to hypertension, dyslipidemia, and long-term renal function [4, 90, 91]. Like cyclosporine, the therapeutic window is narrow and blood levels can be affected by other medications. Trough levels are maintained in the range of 5–15 ng/mL. In recent years, cyclosporine and tacrolimus have been used in a similar percentage of patients and MMF has largely replaced azathioprine use early after transplant (Figure 32.9). There is a trend to shift patients who are 5 years post-transplant from cyclosporine-based regimens to tacrolimus-based regimens [4].

Antiproliferative agents

Agents such as azathioprine (Imuran) and MMF (CellCept) inhibit lymphocyte proliferation by interfering with purine synthesis. One of these agents may be added to calcineurin inhibitor therapy. The choice of either MMF or azathioprine did not have an impact on rejection rate within the first year in the pediatric heart transplant population [4].

Azathioprine is a purine antagonist that inhibits T and B cells. Bone marrow depression is common, and dosing is guided by the white blood cell count. Its use has declined considerably in the past decade.

MMF converts to MPA, an inhibitor of purine synthesis. B- and T-cell lymphocytes are suppressed because they lack a salvage pathway. Absorption is variable, and dosing

AL Grawany

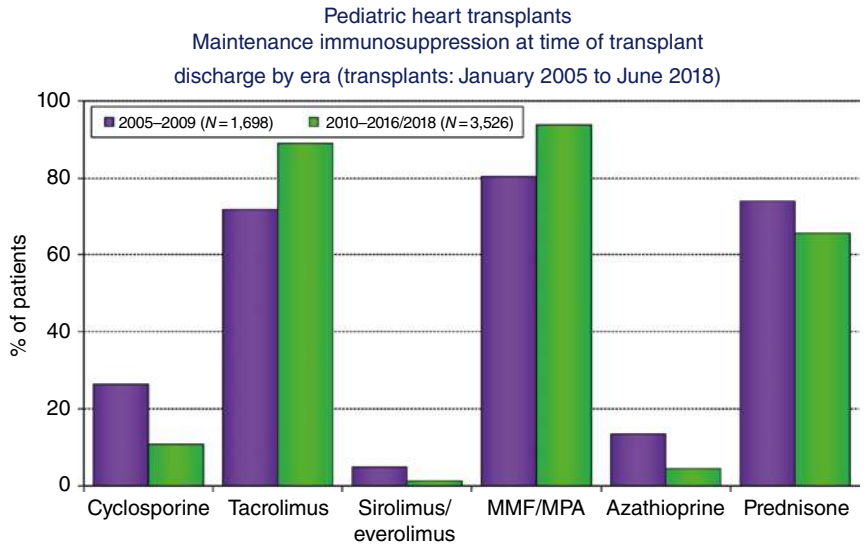

Figure 32.9 Maintenance immunosuppression at the time of hospital discharge following heart transplantation by era (pediatric transplants, January 2005 to June 2018). Analysis is limited to patients who were alive at the time of the discharge. MMF, mycophenolate mofetil; MPA, mycophenolic acid. (Source: Rossano et al. [4]. Reproduced with permission of Elsevier.)

may be guided by blood levels. Gastrointestinal side effects rather than bone marrow depression are the usual dose-limiting factor.

mTOR inhibitors

Proliferation signal or mammalian TOR inhibitors, everolimus and sirolimus (rapamycin), are newer agents that provide attractive options for use in heart transplantation because they are immunosuppressive and antiproliferative, inhibit vascular smooth muscle and myofibroblast proliferation, and can prevent progression of CAV. mTOR inhibitors work synergistically with calcineurin inhibitors and thus permit the minimization of calcineurin inhibitors without compromising efficacy. This approach is advantageous for most heart transplant recipients and might provide particular benefit in specific cases, such as patients with cardiac allograft vasculopathy, malignancies, and renal dysfunction, or in patients intolerant to other immunosuppressive agents. Sirolimus may inhibit the process of CAV. Adverse effects include hyperlipidemia, wound healing complications, and proteinuria [92]. These drugs inhibit wound healing. Patients taking mTOR inhibitors and scheduled for elective surgery must be switched 2–4 weeks preoperatively to other medications and then restarted 2–4 weeks postoperatively.

Corticosteroids

Corticosteroids are nonspecific anti-inflammatory agents widely used in the precyclosporine era. Steroids decrease cytokine production and reduce the circulating CD4+ T cells. Although a mainstay in induction therapy, steroids are currently used in combination with other immunosuppressants early in transplant. Centers try to minimize the dose and taper off by 6 months because of the myriad of side effects including higher infection risk, diabetes mellitus, bone demineralization, and coronary artery disease. Rejection risk may increase when steroids are withdrawn.

Rejection therapy

High-dose corticosteroid, usually methyl prednisolone, is the first-line therapy for acute rejection. Recurrent moderate rejection can usually be controlled with enhanced maintenance therapy (tacrolimus, sirolimus) and corticosteroids. Other agents such as polyclonal anti-T antibodies are reserved for severe rejection that is refractory or causing hemodynamic compromise.

Chronic rejection is manifest as coronary vasculopathy. There are no proven therapies that can halt or reverse this process, and retransplantation is the most suitable option for advanced diffuse disease. It remains controversial whether statins affect the progression of allograft vasculopathy or aid in its prevention in children [93].

KEY POINTS: IMMUNOSUPPRESSION AND REJECTION

- Infants have immature immune systems and appear immune-tolerant, as evidenced by their better long-term survival and the success of ABO-I heart transplantation.
- Although induction therapy is commonly employed, it does not appear to convey any survival advantage in children.
- CAV is the leading cause of death after 1 year of pediatric heart transplant.
  - Recipients in acute rejection represent an extremely high-risk group for general anesthesia and require careful hemodynamic monitoring.

Outcome following heart transplantation

Kaplan–Meier survival curves for patients of differing ages at transplant are shown in Figure 32.10. The youngest recipients have the longest median survival to 24.5 years, although

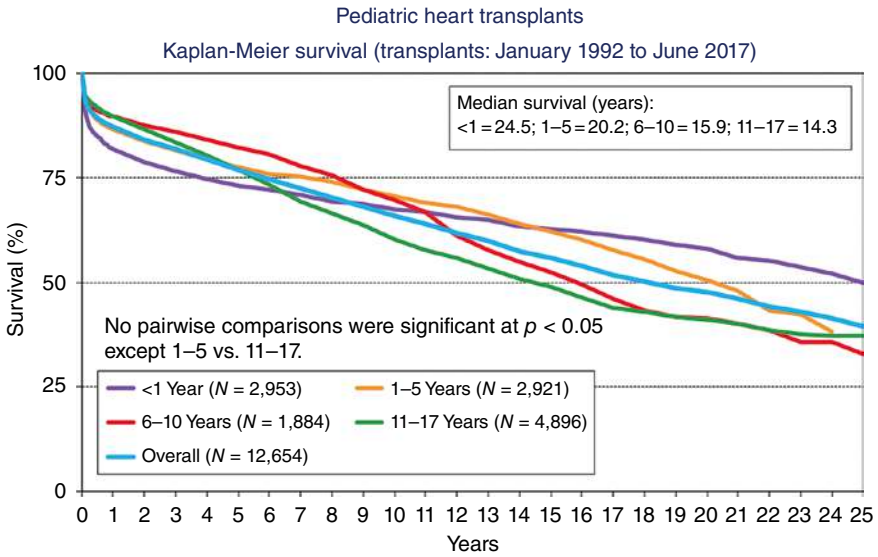

Figure 32.10 Kaplan–Meier survival after heart transplantation (transplants: January 1982 to June 2017). (Source: Rossano et al. [4]. Reproduced with permission of Elsevier.)

Table 32.5 Causes of early and late mortality after pediatric heart transplantation (deaths: January 2005 to June 2018)

Pediatric heart transplants cause of death (deaths: January 2005 to June 2018)						
Cause of death	**0–30 Days (*N* = 280)**	**31 Days to 1 Year (*N* = 347)**	**>1–3 Years (*N* = 283)**	**>3–5 Years (*N* = 235)**	**>5 –10 Years (*N* = 435)**	**>10 Years (*N* = 554)**
Cardiac allograft vasculopathy	3 (1.1%)	9 (2.6%)	37 (13.1%)	39 (16.6%)	90 (20.7%)	127 (22.9%)
Acute rejection	14 (5.0%)	52 (15.0%)	47 (16.6%)	35 (14.9%)	44 (10.1%)	24 (4.3%)
Lymphoma	0	10 (2.9%)	9 (3.2%)	10 (4.3%)	19 (4.4%)	36 (6.5%)
Malignancy, other	0	2 (0.6%)	3 (1.1%)	1 (0.4%)	7 (1.6%)	22 (4.0%)

CMV, cytomegalovirus

the attrition rate is highest in the first few months [4]. Recipients who survive to 1-year post-transplant have excellent long-term survival. Table 32.5 lists the causes of early and late (10-year) mortality from ISHLT registry data [4]. ISHLT follow-up data on complications up to 10 years after transplantation are shown in Table 32.6 [94].

Rejection

Rejection is defined by the Pediatric Heart Transplant Study Group as the clinical decision to intensify immunosuppression in association with either histopathology or myocardial dysfunction [95].

The overall incidence of treated rejection in all age groups from hospital discharge to 1-year post-transplant has decreased from 24 in the prior era (2005–2009) to 13% in the most recent era (2010–2018). [4] An episode of treated rejection within 1-year post-transplant is associated with worse survival. The use or type of induction therapy at the time of hospital discharge was not associated with an increased risk of rejection [4]. However, the use of cyclosporine for maintenance therapy at the time of hospital discharge was associated with a higher risk of rejection compared with tacrolimus [4].

Four clinical types of rejection are described (Table 32.7). Hyperacute rejection is rare and manifests soon after

AL Grawany

Table 32.6 Post-heart transplant morbidity. Cumulative prevalence in survivors within 10 years post-transplant (follow-ups: April 1994 to June 2006)

Outcome	Within 10 years (%)
Hypertension	72.3
Renal dysfunction	17.4
Abnormal creatinine <2.5 mg/dL	13.2
Creatinine > 2.5 mg/dL	1.6
Chronic dialysis	1.6
Renal transplant	1.1
Hyperlipidemia	38.2
Diabetes	4.5
Coronary artery vasculopathy	16.7

Table 32.7 Characteristics of cardiac rejection

Type of rejection	Mechanism	Approximate onset after transplantation
Hyperacute	Preformed antibodies	Minutes to hours
Acute cellular	T-cell-mediated	Any time (often first 3–6 months)
Acute humoral	Antibodies	Days to weeks
Chronic (coronary artery vasculopathy)	Both humoral and cellular	After the first year

Source: Data from Chan et al. [90].

transplantation. It is mediated by preformed recipient cytotoxic antibodies against donor heart antigens and often leads to intractable heart failure. On average, pediatric heart transplant recipients have two acute rejection episodes during the first 3 years after transplantation, although about one-third remain rejection free. ACR is fatal in <10% of episodes; however, it is the commonest cause of death between 30 days and 3 years after heart transplantation. Acute rejection that occurs more than 2 years after transplantation is linked to poor compliance with therapy and carries a poor long-term prognosis.

Clinical evidence of rejection ranges from no symptoms to tachycardia, tachypnea, lethargy, irritability, poor feeding, fever, hepatomegaly, new murmur, gallop rhythm, and new-onset arrhythmias. Endomyocardial biopsy remains the "gold standard" for the diagnosis of acute allograft rejection. Specimens are graded for rejection based on the numbers of infiltrating lymphocytes and the presence of myocyte injury [96]. Rejection is graded using standardized scales. For ACR, grade 0 R indicates no rejection, grade 1 R mild rejection, grade 2 R moderate rejection, and grade 3 R severe rejection. In the diagnosis and treatment of AMR, ISHLT developed a pathology-based AMR grading system [97].

Endomyocardial biopsy is expensive, invasive, technically challenging in small children, and carries some risks of cardiac perforation and tricuspid valve damage in addition to the need for anesthesia and sedation. Further, "biopsy-negative" acute graft dysfunction can occur. Noninvasive surveillance such as circulating donor-derived cell-free DNA is being considered [98]. The use of echocardiography as a noninvasive method of diagnosing acute rejection is unresolved. Indices of systolic and diastolic dysfunction are reportedly useful but have disadvantages [99–101]. However as of now, there are no noninvasive surveillance techniques that consistently or accurately diagnose or predict rejection.

Surveillance for late rejection is controversial, and experience in children is limited. Our institution performs annual cardiac catheterization, biopsy, and coronary angiography. In adults, intravascular ultrasound findings at 1 year are a powerful predictor of subsequent mortality, nonfatal cardiac events, and the development of angiographic coronary disease.

Treatment of rejection

Treatment depends on several patient factors such as time after transplant, type of rejection, presence of symptoms, infection, hemodynamic changes, and compliance with medications. While mild rejection may not require any acute changes to therapy, moderate or severe rejection will require treatment and/or hospital admission.

High-dose corticosteroid, usually methylprednisolone, is the first-line therapy for acute rejection. Recurrent moderate rejection can usually be controlled with enhanced maintenance therapy (tacrolimus, sirolimus) and corticosteroids. Other agents such as polyclonal anti-T antibodies are reserved for severe rejection that is refractory or causing hemodynamic compromise.

Coronary allograft vasculopathy

CAV and primary graft dysfunction (PGD) are the two leading causes of mid- and late-term mortality after pediatric heart transplant [101]. CAV accounts for >25% of late deaths and is the most common indication for retransplantation [16, 18]. A recent multicenter study demonstrated freedom from CAV at 10 years post-transplant of 77%. [102]. However, by 15 years post-transplant, almost 50% of all transplant recipients have developed CAV [4]. CAV is a diffuse disease characterized by concentric smooth muscle and intimal hyperplasia that begin in the distal, small vessels and progress to involve the intramyocardial and epicardial arteries. It is not only immune mediated but also influenced by non-immune risk factors such as dyslipidemia, hypertension, donor and recipient age, allosensitization, frequent cellular-mediated rejection and AMR, donor cigarette use, retransplant and the absence of induction therapy [4, 102, 103]. Recipient age is an important risk factor for CAV; infants had the lowest risk and adolescents had the highest [4]. A rejection episode within the first year of transplant is associated with a higher incidence of CAV 3 years post-transplant [4]. The risk was not associated with graft ischemic time or calcineurin inhibitors [4].

Intravascular ultrasound to detect CAV has size limitations in children and hence coronary angiography remains the gold standard. Detection rates are higher when angiography is performed for symptomatic patients compared to asymptomatic patients. However, most cases are detected during routine angiography [102]. Once detected, survival outcomes are poor with 50% mortality 10 years after diagnosis and a 5-year mortality of >66% when CAV is diagnosed in the presence of

symptoms or signs [102]. The risk of graft failure is increased when CAV is detected angiographically in the presence of RAP > 12, PCWP > 15, or EF < 45% [104]. Although the overall reduction in CAV in the recent era may be associated with reduced rates of rejection, more routine use of statins, and early use of mTOR inhibitors, there are no proven therapies that can halt or reverse this process. Retransplantation is the most suitable option for advanced diffuse disease.

Infection

Infection is a significant cause of morbidity and mortality, particularly in the first 12 months after transplantation when immunosuppression is greater [4]. The most common types of serious infection are bacterial (60%), cytomegalovirus (18%), other viral (13%), fungal (7%), and protozoal (2%) [105]. Bacterial, protozoal, and fungal infections commonly involve the respiratory tract or sternal wound. Viral infections increase the risk of graft rejection, and Epstein–Barr virus is associated with lymphoproliferative disease.

At 5-year follow-up, infant recipients had higher occurrence rates of severe and chronic infections compared with older recipients, and the infections were more resistant to treatment. Additionally, the incidence of autoimmune disorders (commonly autoimmune cytopenias) was noteworthy [106].

Malignancy

Although there is an increased risk of malignancy in children after heart transplantation, the risk is low. Freedom from malignancy was >90% in 10-year survivors. Sixteen percent of survivors developed a malignancy by 15 years post-transplant [4]. Most malignancies are lymphatic in origin. Many post-transplant lymphoproliferative disorders (PTLDs) respond to reduction in immunosuppression.

KEY POINTS: HEART TRANSPLANT: MORTALITY RISK FACTORS

- Measures of pretransplant acuity:
  - ECMO
  - renal dialysis
  - mechanical ventilation
- Congenital heart disease
- Retransplantation
- Increasing body mass index.
  - Overall improved after heart transplant survival despite increasing case complexity related to improved perioperative care and optimizing modifiable risk factors.

Renal dysfunction

Acute renal dysfunction may occur in the immediate postoperative period, probably because of the cumulative negative effects of a chronic low CO, CPB, venous congestion, and nephrotoxic drugs. Renal dysfunction increased from 6 at 1 year to 17% at 10 years. However, the need for renal transplant was seen in only 1% by 10 years and freedom from severe renal dysfunction (defined as serum Cr > 2.5 mg/dL) was approximately 90% at 9 years [4]. The risk of developing severe renal dysfunction differs with age at transplant. At 10 years post-transplant, 2.4% of patients transplanted during infancy versus 14% transplanted at age 11–17 years developed severe renal dysfunction [4]. A similar age-related finding is seen in freedom from renal replacement therapy [4]. Multivariable analysis from ISHLT registry data has shown that CHD and retransplant are independently associated with developing renal dysfunction 5 years post-transplant compared with DCM [6].

Other risk factors for chronic renal insufficiency included pretransplant dialysis, HCM, and African American race. Adjusted risk of death in those who developed chronic renal insufficiency was ninefold higher than in those who did not [107]. Renal-protective bundles as mentioned earlier are important.

Other complications

The percentage of recipients with hypertension increased over time to 72% at 10 years post-transplantation. The only medication significantly associated with hypertension was prednisone. Hyperlipidemia also increased steadily to 38% at 10 years after transplantation. There continues to be a lack of consensus on whether abnormal cholesterol values should be treated empirically with statins or whether target ranges for intervention should be established.

Serious gastrointestinal complications have been reported in 18% of recipients (median post-transplant follow-up was 3 years). Complications included (in order) pancreatitis, cholecystitis, recurrent abdominal infection, malignancy, and intestinal pneumatosis. Half of the patients with complications required abdominal surgery [108].

Children with CHD who required extensive reconstruction of vessels during transplantation may develop stenoses at anastomotic sites (e.g. aorta, pulmonary veins). This can usually be relieved by interventional catheterization techniques, but some cases may require surgery.

Quality of life

Most pediatric recipients are rapidly rehabilitated, and full-time attendance at school is achieved in almost all patients within a few months of transplantation. Approximately 50% of children do not require hospitalization in the first year after transplantation. Rejection and infection are the major causes for hospitalization. The functional status of survivors is excellent. The percentage of survivors without functional limitation was 93% at 1 year and 95% at 5 and 10 years. Less than 1% required total assistance. Preadolescent children exhibited "catch-up" growth in height and weight after transplantation. Failure of linear growth was correlated with steroid requirements [4].

Formal exercise testing reveals that maximum capacities for physical work and peak HR are only approximately two-thirds of predicted. A longitudinal assessment found low-peak aerobic capacity and diastolic dysfunction [109], although perhaps less so in infants [110].

A review of cognitive and psychological outcomes after pediatric heart transplantation found that recipients generally functioned within the normal range on most measures of cognitive function [111]. About 20% experienced significant symptoms of psychological distress during the first year after transplantation [112]. Post-traumatic stress disorder seems to be relatively common in parents of pediatric heart transplant recipients [113].

Evidence indicates that children with CHD should be considered separately because they have significantly lower scores on IQ and neurodevelopmental tests when compared with a normative sample [114]. Transition of care from a pediatric to adult heart transplant program needs to start well before the child reaches teen years. Outcomes are impacted by poor transitions [115].

Anesthetic management of children who have undergone heart transplantation

Patients may present for surgery because of complications from cardiac transplantation (e.g. infection, malignancy, drug adverse effects), or the indication for surgery may be unrelated to heart transplantation. Successful anesthetic management requires consideration of the patient's medical status, the physiology of the transplanted heart, and the implications of immunotherapy. These have been discussed earlier.

Future prospects

Donor shortage remains a frustrating problem and is the primary limitation to the number of transplants performed. Efforts to further the care of children with end-stage cardiac disease can be broadly categorized as described in the following sections.

Alternative therapeutic modalities

Research continues on the development of small, implantable VADs suitable as destination therapy or as a bridge to recovery for children of all ages [40]. Another avenue of intensive research is cell-based engineering to replace damaged or dysmorphic heart tissue [116]. In animal models, intravenous injections of bone marrow-derived mesenchymal stem cells readily express phenotypic characteristics of cardiac myocytes, localize at sites of myocardial injury, prevent tissue remodeling, and improve cardiac recovery. When provided with a scaffold such as a prefabricated matrix or decellularized heart tissue, stem cells can localize, differentiate, and function [116]. Heart muscle patches, heart valves, and perhaps the entire heart may in the future be engineered in the laboratory [116].

Improving current therapeutic modalities

Opportunities abound for further refinement of existing therapies. These include reexamination of the allocation of donor organs, ethical analysis of the practice of retransplantation (which is associated with a poor outcome) [18], extended donor organ criteria, better protocols for highly sensitized patients, improved understanding of the timing of interventions such as mechanical ventricular assist (balancing the risks of intervention against the benefit of preserved end-organ function), miniaturization of pediatric CPB circuits, efforts to reduce the side effects of immunosuppression and increase immunotolerance, better therapies to diminish the likelihood of acute and chronic rejection, and improved patient/family support and transitions to enhance compliance with care [117]. Identifying best practices with multiinstitute collaboration and learning networks will help move the field forward [118].

Pediatric lung transplantation

Lung transplantation surgery is a relatively uncommon surgery in the pediatric age group, offered at few centers globally as a life-extending measure for children with irreversible, end-stage, vascular, or parenchymal lung disease. Compared to adults, the experience with pediatric lung transplantation remains modest. Since 2007, the number of centers performing pediatric lung transplant surgery and transplant surgeries performed annually has remained relatively constant (Figure 32.11) [119]. Thirty-seven centers across the world perform approximately 100 lung transplant surgeries annually in children [120]. The outcomes of pediatric lung transplantation, although comparable to adults, remain worse than other solid organ transplant surgeries [121]. Numerous unique challenges related to the patient's medical condition, donor–recipient match, development, and growth of the transplanted organs can affect the long-term outcomes after pediatric lung transplant surgery.

Indications, contraindications, and listing criteria in children

The majority of pediatric lung transplant recipients are between the ages of 11 and 17, and only 20% of lung transplant surgeries are performed in children 6–11 years of age. Generally, lung transplant surgery is considered a treatment for any end-stage lung disease. Indications for listing a child for lung transplant surgery vary by age (Table 32.8) [122]. Overall, cystic fibrosis (CF) remains the most common indication in older children whereas pulmonary hypertension is the common reason for lung transplantation in children aged 1–5 years. Only a handful of transplant centers offer lung transplant surgery to infants and neonates. Common indications for severe irreversible respiratory failure in neonates include congenital and acquired diseases such as surfactant protein (B and C) deficiency, interstitial lung disease, pulmonary vein stenosis, pulmonary hypoplasia, and alveolar capillary dysplasia. In the United States, the OPTN is a federal government agency that regulates organ transplantation. OPTN data for 2020 and 2021 suggest a dramatic decrease in transplantation for CF, despite an overall stable number of lung transplants for all age groups. In the 11- to 17-year-old age group, lung transplants for CF decreased from about 20 $year^{-1}$ in the United States, from 2000 to 2019, to only 3–4 $year^{-1}$ in 2020–2021 (Table 32.9) [123]. The overall number of pediatric lung transplants has also decreased, with almost all of the decrease attributable to the decrease in the 11- to 17-year-old age group.

Cystic fibrosis

CF is an autosomal recessive disorder caused by mutations in a single gene. These mutations cause loss of function of cystic fibrosis transmembrane conductance regulator (CFTR) protein, which affects the epithelial cells in the lungs, gastrointestinal tract, pancreas, sweat glands, and male reproductive system. So far, more than 2,000 gene mutations have been identified. The core CFTR mutation reduces chloride and bicarbonate in the airway secretions and decreases the water content in the airway epithelial layer. These changes result in thick mucus secretions that are the hallmark of CF. These secretions produce obstruction, persistent inflammation, and superimposed infections of the airways. The ciliary function of the epithelial layer is also depressed (Figure 32.12) [124, 125]. Approximately 10% of CF patients have associated liver and pancreatic

disease related to the same mutation, resulting in clinically significant pancreatic insufficiency and malabsorption of key nutrients.

The treatment of CF has significantly improved during the past two decades, and in the current era, most children born with CF are expected to survive into adulthood [125]. Improved abilities to diagnose the disease early, the introduction of multidisciplinary care, and the use of newer targeted therapies have resulted in better preservation of lung function in patients with CF. The core treatment aims to improve mucus clearance by increasing hydration of the airway secretions using saline and mannitol nebulization. Recombinant human DNAse-1 use also improves ciliary clearance by decreasing mucus viscosity [126].Drugs such as Ivacaftor and Lumacaftor target specific genetic mutations and have been approved for clinical use [127, 128]. These drugs have been shown to improve lung function, increase body mass index, minimize infections with *Pseudomonas*, improved glucose tolerance, and reduce the number of lung infections. Unfortunately, these drugs target specific mutations seen in approximately 40–50% of patients and are remain extremely expensive [129].

Despite the maximal therapy, a few children suffer from repeated pulmonary infections with multidrug-resistant bacteria and develop irreversible respiratory failure. For these children, lung transplant surgery becomes the only viable treatment option. A significant and rapid decline in the clinical status despite the maximal therapy should trigger a referral to a transplant center.

Life expectancy in CF has continued to improve, and in the current era is 46.2 years, due to widespread routine newborn screening, publication of evidence-based guidelines to optimize nutrition and pulmonary health, and also the development of CF-specific interdisciplinary care centers [130]. As noted above, the CFTR modulator therapies, which can be classified as potentiators, correctors, and amplifiers, have significantly changed the progression of CF lung disease and are among the primary reasons why fewer CF patients are reaching end-stage lung disease in teenage and early adult years [131]. In 2019, the U.S. Food and Drug Administration approved a triple-drug combination therapy, elexacaftor/texacaftor/ivacaftor, for patients aged 12 years and older that will allow almost 90% of CF patients to have a highly effective therapy. CF-related liver disease results in cirrhosis in approximately 3% and occasionally leads to combined lung–liver transplantation.

Pulmonary hypertension

Severe pulmonary hypertension can occur in diverse group diseases that affect children of all age groups. The progression of clinical symptoms and prognosis depend on the underlying condition. As a diagnosis, pulmonary hypertension is the second most common indication for lung transplantation in children, but for neonates, younger children, and infants, it is the most common indication for lung transplant surgery. In contrast, for older children aged 6–17 years, pulmonary hypertension accounts for 7–8% of lung transplant surgeries [132]. Medical treatment of pulmonary arterial hypertension has improved considerably. Newer medications, such as endothelin receptor antagonists (bosentan), phosphodiesterase inhibitors (sildenafil), and prostacyclin analogs, have improved 5-year survival to more than 80% [133]. These drugs reduce the pulmonary arterial pressure and possibly reverse long-standing changes in the pulmonary vascular architecture. Many children eventually fail maximal medical therapy, and for those patients, lung transplantation remains the only treatment option available. Atrial septostomy has been advocated as a temporizing measure, to improve symptoms and serve as a bridge to transplant, although whether this procedure confers a survival advantage is less clear [134]. More recently, many centers have offered a palliative Potts shunt (a pulmonary systemic central shunt from descending aorta to left PA) to decompress the right ventricle, prevent right ventricular failure, and prolong life. In small series, mid-term survival outcomes and functional status after Potts shunt surgery were similar to patients after lung transplant surgery [135]. For children who develop irreversible pulmonary hypertension secondary to a congenital cardiac defect, the complexity of cardiac lesion dictates the decision to perform lung transplant versus HLT. See Chapter 33 for further discussion of pulmonary hypertension.

Neonatal and infant lung transplant

Few pediatric lung transplant centers have offered lung transplant surgery in very young children. According to the 2017 report of the ISHLT registry, slightly more than 100 patients younger than 1 year of age have undergone lung transplant surgery [122]. The underlying diseases resulting in severe respiratory failure for infants and neonates are different. The major indications for lung transplant surgery in very young children include genetic mutations in the surfactant proteins (B and C), bronchopulmonary dysplasia, CHD, congenital diaphragmatic hernia, and pulmonary dysmaturity. For these patients, severe respiratory failure presents early in life and requires mechanical ventilation and extracorporeal life support [136].

Lung transplant listing criteria

The criteria for listing children for lung transplant surgery are based on the progression of the underlying disease, functional status of the patient, and expected improvement in the quality of life (Table 32.10). It is challenging to develop survival models for rare and uncommon diseases. In the past, a life expectancy of less than 2 years was used for listing a child for lung transplant surgery. Listing a patient for lung transplant surgery is a complex, shared decision-making process that involves numerous conversations among patients, their families, pediatric pulmonologists, pediatric cardiothoracic surgeons, and social workers. Many clinical and social factors such as nutritional status, functional status, patient and family ability to comply with immunosuppressant treatment, and move geographically close to a transplant center are considered.

For CF patients, the international consensus guidelines consider numerous clinical factors such as rate of decline in forced expiratory volume in 1 second (FEV_1) to less

than 30%, elevated $PaCO_2$ (>50 mmHg), decreasing PaO_2 (<60 mmHg), frequency of hospitalizations, and decreasing distance on the 6-minute walk test [137, 138]. For pulmonary hypertension patients, progressive disease, despite the maximal medical therapy, generally initiates a conversation about transplant surgery as a treatment option. Because pulmonary hypertension in pediatric patients can progress rapidly, children should be referred to a transplant center early. Criteria recommended by the International Society of Heart and Lung Transplantation Society include New York Heart Association class III or IV, cardiac index of less than 2 L/min/m^2, and mean right atrial pressure less than 15 mmHg, but are more suitable for adult patients [139]. High plasma levels of biomarkers, such as von Willebrand factor and brain natriuretic peptide, may suggest severe disease [140, 141].

Active malignancy, sepsis, tuberculosis, neuromuscular disease, heart failure, and acquired immunodeficiency syndrome (AIDS) are considered absolute contraindications for any transplant surgery (Table 32.11). On rare occasions, patients with severe renal or hepatic disease may be considered for lung and hepatic or renal transplants. Previously, based on adult data, colonization of the trachea with *Burkholderia cenocepacia* or nontuberculous *Mycobacteria* was considered an absolute contraindication [143]. More recently, some centers have shown that some children with this multidrug-resistant bacterial infection can be successfully transplanted. In patients with pulmonary hypertension, a compromised ventricular function is considered a relative contraindication.

KEY POINTS: INDICATIONS, CONTRAINDICATIONS, AND LISTING CRITERIA

- CF has historically been the most common indication, until recently accounting for >50% of pediatric lung transplants. Effective CF drugs have decreased the numbers of end-stage CF patients requiring transplantation.
- Pulmonary hypertension is the second most frequent indication and is the most common indication for transplant in children <5 years of age.
- Neonatal and infant lung transplants surgeries are uncommon; indications include congenital cardiac defects, pulmonary hypertension, and genetic mutations in surfactant protein synthesis.
- Life expectancy <2 years is a criterion for lung transplant; active malignancy, sepsis, multiorgan failure, neuromuscular disease, and AIDS are contraindications.

Donor management and lung preservation

As with other organ transplants, donor availability has been a limiting factor in offering lung transplant surgery to a larger number of patients. Children face longer wait times and, as a result, children have higher mortality rates while waiting for the organs compared to adults. Only about 15–30% of the cadaveric donor lungs are considered acceptable for transplantation. In the United States, donor organs

Table 32.10 Recommendations regarding timing of referral to lung transplant center

Specific disease	Timing of referral
Surfactant deficiencies	Patients with SP-B deficiency and ABCA3 deficiency with refractory respiratory failure should be referred immediately Patients with SP-C deficiency and less severe forms of ABCA3 deficiency may respond to medical therapy and should be referred when unrelenting progression of disease develops
Primary pulmonary hypertension	Patients who present in NYHA class III or IV or have evidence of right heart failure should be referred immediately Patients who fail to respond adequately to vasodilator therapy should also be referred
Eisenmenger syndrome	When the trajectory of pulmonary hypertension appears to be worsening with impaired exercise tolerance and worsening quality of life
Other pulmonary vascular disorders (pulmonary vein stenosis, alveolar capillary dysplasia)	These patients should be referred immediately since they typically do not respond to medical management and are at risk for sudden death
Cystic fibrosis	Patients with percent predicted FEV_1 values less than 30%, frequent hospitalizations, refractory hypoxemia, or hypercapnia should be referred for transplant
Bronchopulmonary dysplasia	Patients with recurrent or severe episodes of respiratory failure or evidence for progressive pulmonary hypertension
Diffuse parenchymal lung disease	Patients without evidence for systemic disease that could affect outcome should be referred early

are allocated by the OPTN. A new lung allocation system, implemented in 2005, uses a patient's medical condition as the primary determinant of organ allocation and discourages the use of waiting time [145]. Under this system, a lung allocation score (LAS) is calculated for children older than 12 years. Multiple variables such as age, functional status, forced vital capacity (FVC), and oxygen requirement are used for calculating the LAS. The new policy also mandates that the donor lungs from donors less than 18 years of age are preferentially given to pediatric patients [145]. A two-tier priority system based on medical urgency was implemented in 2010 for children younger than 12 years of age. Since its implementation, there has been a reduction in the total number of listed patients, median time to transplant, and waiting list mortality without affecting survival after the surgery [146, 147]. Consequently, the listed patients and recipients at the time of surgery are sicker [148]. Additional changes in the lung allocation system were made in 2017, and as a result, all donor lungs below the age of 18 years are now directed to the children younger than 12 years listed within the same geographical area. Efforts to increase the size of the donor organ pool include the use of organs from extended criteria donors, relaxing size-matching guidelines, using donors after circulatory death, the use of ABO-I transplants in children under 2 years of age, and the use of ex vivo lung perfusion techniques to retrieve organs from geographically remote areas [149].

Donor lungs are selected after a thorough medical screening, and multiple laboratory tests are conducted to rule out any lung pathology or infection. In younger children, comparable age and height with less than 20% discrepancy are considered an acceptable match. An ideal donor is younger than 55 years, a nonsmoker, and has no cardiopulmonary or significant neurological disease history. The donor lungs should produce good gas exchange ($PaO_2 > 350$ mmHg with FiO_2 of 1.0) on a moderate amount of ventilatory support. The chest radiograph and bronchoscopy should rule out any significant infection, consolidation, or malignancy. Ideally, the donor's lungs are accepted only if the ischemic time is expected to be less than 6 hours. Over the past decade, selection criteria for ideal donor lungs have been relaxed [150]. Extended criteria donors with mild lung disease, history of smoking, age above 55 years of age, and mild chest trauma are accepted if the recipient's condition is rapidly deteriorating.

The pool of donors is not limited to brain-dead donors. Organs from the DCD have been used in the adult lung transplant patients, and 1- and 5-year survival in these patients appear to be similar to those who received lungs from brain-dead donors [151]. In addition, normothermic ex vivo lung perfusion techniques are being evaluated to increase the number of suitable grafts. This technique maintains normal physiological status and allows cells to stay metabolically active, thus prolonging the window for transplantation [152].

Efforts to preserve lung function after the determination of death may reduce the incidence of primary graft failure and improve long-term graft function. Ventilation with tidal volumes of 6–8 mL/kg along with aggressive hemodynamic management while restricting fluid to maintain central venous pressures of 4–6 mm has been shown to optimize pulmonary function of the donor lungs [150]. The process of harvest includes systemic heparinization of the donor and infusion of prostaglandin E_1 into the main PA. Lungs are inflated with $FiO_2 < 0.4$ to an airway pressure less than 20 cm H_2O. Lungs are removed en bloc with descending aorta, left atrial cuff, main PA, and thoracic aorta.

Bridge to transplantation

While waiting for the surgery, some patients rapidly deteriorate and require supportive care to bridge the transplant. Infants and neonates have the most extended wait times and, therefore, have the highest mortality while on the waiting list. Almost one-third of the listed children end up requiring ventilatory support while waiting for their transplant surgery. For a few patients, mechanical ventilation fails to ensure adequate gas exchange or oxygenation and use ECMO is needed. However, the use of ECMO has significant morbidity before the transplant surgery, and post-transplant outcomes for these patients remain poor. To minimize the consequences of ECMO, in select patients with low PVR, a paracorporeal lung assist device (PLAD) has been used. The surgery involves redirecting the PA blood flow to the left atrium through an external oxygenator (Novalung GmbH, Germany or the Quadrox-iD Pediatric oxygenator, MAQUET GmbH & Co KG, Germany) without using a pump [153] (see Figure 32.13). Ambulatory ECMO, with veno-venous (VV) or veno-arterial (VA), has also been described to support end-stage lung disease patients as a bridge to transplant [154, 155]. As noted above, another method to bridge some patients to transplant, or avoid lung transplant, is using Potts shunt surgery as an alternative treatment for children with end-stage pulmonary hypertension. Creating a central shunt between the PA and descending aorta can unload the right ventricle, preserve right ventricular function, and extend life. [135, 156]. The preliminary reports suggest that 1-year survival after Potts shunt results is reported to be similar to that after lung transplant.

KEY POINTS: DONOR MANAGEMENT, LUNG PRESERVATION, AND BRIDGE TO TRANSPLANT

- Only 15–30% of donor lungs are considered acceptable; the new LAS, based on medical urgency, is calculated for every patient >12 years of age.
- Children < 12 years of age receive organs based on two-tier waiting list.
- Acceptable gas exchange, "clear" bronchoscopy and chest radiograph, and anticipated ischemic time <6 hours are the usual criteria for donor lungs.
- ECMO, PLADs, and Potts shunt surgery are used as a bridge to transplant in critically ill patients.

Anesthetic management and surgical approach

When listing for lung transplantation, children undergo extensive evaluation, including a visit to the preoperative clinic. Routine testing includes ECG, echocardiogram, pulmonary function tests, arterial blood gases, and complete metabolic panel. Children diagnosed with pulmonary hypertension also undergo a cardiac catheterization where the response to oxygen and nitric oxide is tested and cardiac anatomy is defined. Associated comorbid conditions are optimized. Approximately 10% of CF patients have associated liver and pancreatic disease. Malnutrition due to CF liver disease is associated with worse post-transplant outcomes, and aggressive efforts to improve the nutritional status of CF patients either by the placement of gastrostomy tube or use of parenteral nutrition are often warranted. Chronic antibiotic therapy often results in renal tubular damage and electrolyte disturbances.

Anesthetic management is dictated primarily by the patient's underlying condition. At the time of the match, many patients are at home without the need for oxygen supplementation. An increasing number, especially neonates and infants, are critically ill and require mechanical ventilation and often extracorporeal mechanical support. Like other organ transplant surgeries, the time of surgery is unpredictable. Standard nil per os (NPO) guidelines are followed to minimize the risk of aspiration and contamination of the new lungs. Propofol and etomidate are safe in hemodynamically stable patients, but ketamine may be the preferred drug for inducing children with high pulmonary pressures. Anesthesia is maintained with inhalational agents and supplemented with opioids, midazolam, and muscle relaxants. The airway is secured with a cuffed endotracheal tube, including for those with an existing tracheostomy. Lung isolation is rarely used for pediatric lung transplant surgery. Selective pulmonary vasodilators such as iNO and prostacyclin analogs are continued through the pre-CPB period.

Historically, sequential bilateral lung transplant surgery is performed through a trans-sternal, clamshell incision, though some surgeons have promoted a mid-sternotomy approach. Bilateral pneumonectomies require extensive dissection, which is often complicated by excessive adhesions from previous infections and thoracic surgeries. Antifibrinolytic drugs such as tranexamic acid or aminocaproic acid have become standard of care. Ensuring adequate ventilation and oxygenation during the pre-bypass period can be challenging. Copious

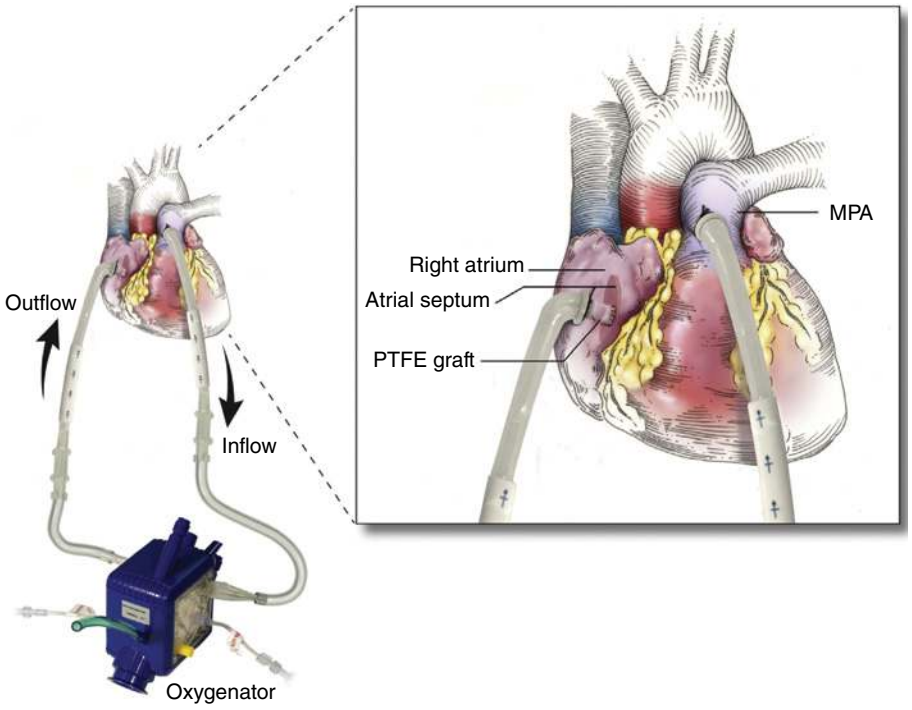

Figure 32.13 The Maquet Quadrox-iD membrane oxygenator is used for paracorporeal lung assist in neonates and infants. A PTFE graft is used to extend a pediatric Berlin Heart cannula through the right atrium and to the interatrial septum for outflow to the left atrium. Table 32.12 Summary of intraoperative considerations for pediatric lung transplantation

Pre-bypass
- Consider pathophysiology of lung disease: CF, PH, CHD, others
- Maintain all pulmonary vasodilator therapy on schedule
- Administer immunosuppressant induction agents and antibiotics according to preoperative plans
- Standard single-lumen TEE for most cases. Plan with surgeon for tracheostomy management
- Vascular access: arterial line (consider femoral if arms up for clamshell incision), CVP, large-bore PIVs
- Discuss surgical approach: BSLT (clamshell incision, separate bronchial anastomoses) vs. en bloc technique with bronchial revascularization (sternotomy, single tracheal anastomosis)
- Ventilate to baseline $PaCO_2$ values (e.g. hypercarbia common)
- ICU ventilator or HFOV may be required for infants
- Maintain pulmonary toilet pre-bypass: suction, bronchodilators
- Prepare for possibility that donor lungs are unsuitable after visualization (limit fixed agents, reverse muscle relaxant, awaken patient, remove lines)

Bypass period
- Normally mild-moderate hypothermic bypass
- Repair any congenital cardiac lesions, e.g. ASD
- Normally no aortic cross-clamp
- Instill antibiotics into trachea for CF patients
- Prepare bronchoscope to visualize bronchial/tracheal anastomoses, suction/irrigate blood, mucus, clot
- Ideally ischemic time goal is <6 hours until lungs reperfused (completed pulmonary artery anasotomoses)

Post-bypass period
- Separate from bypass on ventilator settings that minimize volutrauma, barotrauma, oxygen toxicity: 6–7 mL/kg (donor weight), peak pressure < 25 cmH_2O), PEEP 5 cmH_2O, FiO_2 0.4–0.5 or less
- iNO 20 ppm, epoprostenol frequently used
- Limit fluid administration (no lymphatic drainage): CVP 4–6
- Milrinone, vasopressors (vasopressin, phenylephrine) as needed
- Significant bleeding treated with platelets, cryoprecipitate/fibrinogen concentrate, fresh-frozen plasma/coagulation factor concentrate/activated factor VII
- Consider TEE: intracardiac repair, pulmonary venous anastomoses, PA anastomoses, ventricular function, pulmonary hypertension
- Early graft dysfunction (hypoxemia, pulmonary edema) treated with increased FiO_2, PEEP, iNO to maintain SpO_2 in low 90 second; veno-venous ECMO if needed
- Usually will not extubate in OR; but stable patients can be extubated in 12–24 hours
- Full handoff report from anesthesia/surgical team to ICU team
- Pain management via opioid infusion, dexmedetomdine, patient/nurse-controlled analgesia

CF, cystic fibrosis; PH, pulmonary hypertension; CHD, congenital heart disease; BSLT, bilateral sequential lung transplantation; HFOV, high-frequency oscillatory ventilation; ASD, atrial septal defect.

lung secretions, poor lung compliance, and surgical manipulation of the lung tissue require close vigilance to the patients' ventilatory status. Aggressive ventilation should be avoided in patients with chronic hypercarbia, and ventilation parameters are adjusted to ensure normal pH levels. Significant bleeding is expected during the pre- and post-bypass period. Large-bore venous access and blood products are needed.

All pediatric lung transplant surgeries are performed with the assistance of a CPB machine or ECMO. Invasive monitoring of arterial blood pressure and central venous pressure is a routine. Lung transplant surgery is a class I indication for intraoperative TEE and is used to monitor ventricular function and postoperative pulmonary hypertension and evaluate vascular anastomoses.

Several unique factors make the use of CPB necessary for pediatric lung transplant surgery. In CF patients, the use of CPB allows the resection of both lungs simultaneously and minimizes the risk of contamination of the new lungs. Smaller children are physically too small to accommodate even the smallest double-lumen endotracheal tube. Others with significant pulmonary hypertension, neonates, and infants are often too tenuous to tolerate single lung ventilation. In addition, the use of CPB provides stable hemodynamic conditions during the extensive surgical dissection, greatly simplifies surgical management, and consequently reduces ischemic times. The use of CPB, however, comes with its own risks. Generation of inflammatory mediators and activation of complement cascade during CPB contribute to the ischemic–reperfusion injury to the implanted lungs. More recently, based on the experience in adult patients, VA ECMO has been successfully used to PGD secondary to CPB and reduce postoperative bleeding [157]. Mild hypothermia or normothermia is needed for implanting donor lungs. The use of aortic cross-clamping is rarely warranted unless a correction of an existing intracardiac defect is needed. After establishing CPB, both lungs are removed by ligating and dividing pulmonary arterial, atrial cuff, and bronchial connections (Figure 32.14) [158]. A second surgical team simultaneously prepares the donor lungs. To reduce bacterial contamination of the new tracheobronchial tree, native tracheal stump is irrigated with a concentrated solution of antibiotics such as tobramycin. The implantation of the new lungs begins with an end-to-end bronchial anastomosis. As bronchial blood supply is compromised during the procedure, peribronchial tissue is wrapped around the anastomotic site to enhance healing. Vascular supply to the new lungs is established by an end-to-end PA anastomosis. The pulmonary veins are reconnected to the recipient's left atrium en bloc, using the donor's atrial cuff. Before weaning off the CPB machine, an aggressive pulmonary toilet and visualization of the bronchial anastomosis with a fiberoptic bronchoscope are performed to ensure adequate ventilation.

Ventilator parameters, guided by the donor weight, are titrated to ensure that lungs are well expanded. Trauma to the new ling, caused by overdistension of the new lungs, increases endothelial permeability and potentiates PGD. iNO is routinely used to induce pulmonary arteriolar vasodilation and improve ventilation-perfusion mismatch. A focused TEE helps assess the adequacy of major vessel anastomoses. The transplant surgery disrupts native lymphatic drainage of the donor lungs and their ability to clear intra-alveolar secretion. Judicious fluid management, with a goal of maintaining central venous pressure within 4–6 mmHg range, is recommended.

All patients are electively ventilated during the immediate postoperative period, but many are extubated on postoperative

day 1. Infants and neonates have a more protracted recovery and have prolonged ventilatory needs (median 24 vs. 3 days) [159] Postoperative pain relief is usually accomplished by patient-controlled analgesics and narcotic infusions. Regional anesthesia with an epidural catheter is recommended for older children. Epidural catheters, or other regional techniques such as erector spinae plane catheters, may be placed used 24–48 hours after the surgery when the coagulation parameters have normalized. (See Chapter 24 for a discussion of regional anesthetic techniques for cardiothoracic surgery). Table 32.12 summarizes the intraoperative considerations for anesthesia for pediatric lung transplantation.

Another surgical technique that has been described is the en bloc technique with a single tracheal anastomosis and bronchial artery revascularization using a using a cuff of donor aorta [160]. This approach is performed through a median sternotomy. A potential advantage of this technique is better perfusion to the graft because the bronchial artery circulation normally provides half of the airway's dual blood supply. Theoretically, this could reduce airway and infectious complications and delay the onset of bronchiolitis obliterans syndrome, which can have an ischemic etiology. The descending aorta is clamped with a partial occlusion clamp, and the bronchial artery button is anastomosed to it (Figure 32.15) [160]. After reperfusion of the bronchial arteries, bleeding will be observed from the cut edge of the trachea, and blood return can often be seen in the PAs and pulmonary veins. In theory, this could limit further graft ischemia. A single end-to-end tracheal anastomosis is completed, followed by flexible bronchoscopy by the anesthesiologist for removal of bloody secretions. During aortic cross-clamp, a single left atrial anastomosis is

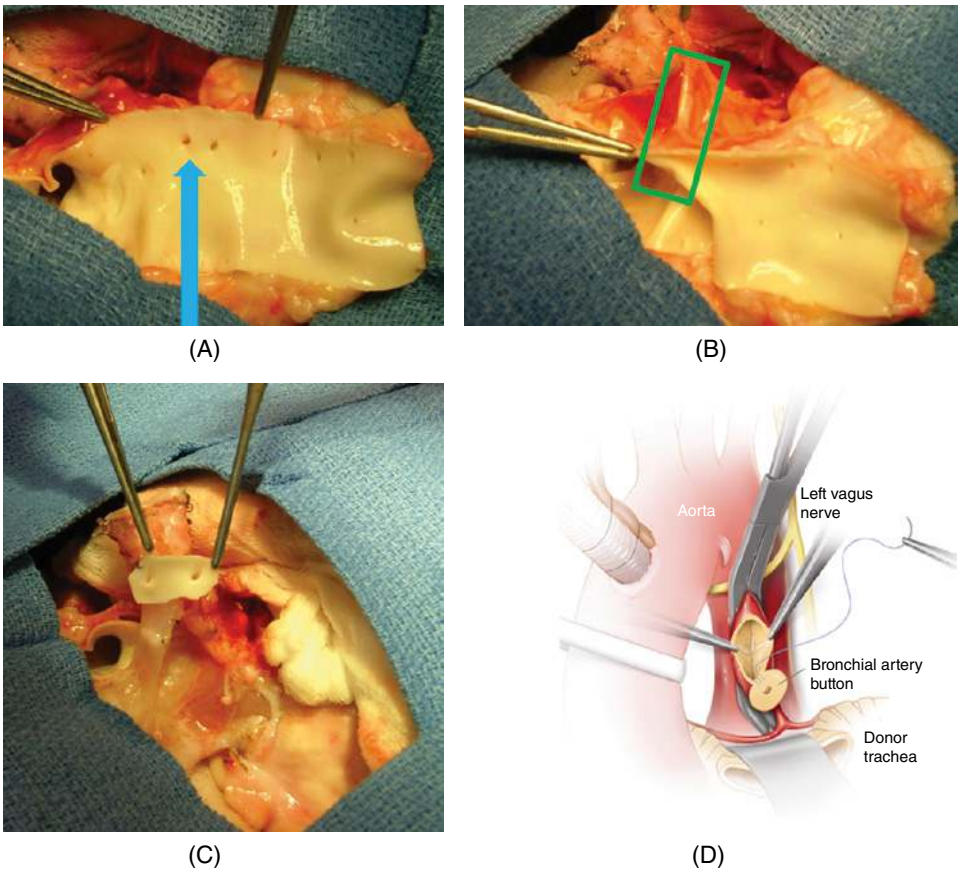

Figure 32.15 Key operative aspects involving bronchial artery revascularization technique: (A) the descending donor thoracic aorta is opened longitudinally; (B) the bronchial artery is identified arising from the aorta; (C) aortic button containing the origin of two bronchial arteries; esophagus previously removed; (D) suturing the bronchial arteries to the aorta. (Source: Guzman-Pruneda et al. [160]. Reproduced with permission from Elsevier.)

performed, and other intracardiac anomalies may be addressed. After removal of the aortic cross-clamp, an end-to-end main PA anastomosis is performed. In a single-institution comparison study of 88 bilateral sequential lung transplants (BSLTs) and 31 en bloc lung transplants (EBLT) with bronchial artery revascularization, there were no differences in bypass or ischemic times, early or longer term survival, graft dysfunction, or cellular rejection scores. BSLT was associated with higher ischemic injury and non-airway complications.

Living donor lobar transplant (LDLT) involves two living donors, each of them donating a lower lobe to the recipient. LDLT had been used to provide organs rapidly to children with CF who underwent an unexpected rapid progression of their disease, which, in the modern era, is less frequent, as noted above. Although outcomes can be comparable to deceased donor transplant [161], and there is some evidence to suggest that the incidence of bronchiolitis obliterans is lower in LDLT recipients [162], the procedure is resource intensive and has ethical implications because 10–20% of donor lobectomy surgeries have serious complications [163, 164]. The 2017 ISHLT report noted the number of LDLT surgeries in pediatric recipients peaked in 1998–1999 and since then has decreased substantially, and none were reported in 2013–2015 [165].

When the recipient's chest is too small to accommodate the donor lungs, the donor lungs can be reduced in size. Options include lobectomy (typically, the right middle lobe or lingula), wedge resection using a linear stapler, single lobe transplant, or split lung "bipartitioned" transplant (in which two smaller "lungs" are created from a single deceased donor lung). Reports suggest that outcomes in pediatric recipients of reduced-size organs can be comparable to recipients of full-sized grafts [166, 167].

KEY POINTS: ANESTHETIC MANAGEMENT AND SURGICAL APPROCH

- The preoperative condition ranges from stable at home to chronic ventilation with a tracheostomy to mechanical support on a bridge to transplant device.
- CPB and the bilateral sequential lung transplant techniques are used for essentially every pediatric lung transplant.
- Ventilation parameters after CPB include limiting inflation pressures and volumes (chosen for the donor lungs), limiting FiO_2 to maintain SpO_2 at 90–95%, and addition of iNO.

AL Grawany

Immediate perioperative complications

Primary graft failure

PGD is a syndrome of acute lung injury that presents within the first week of surgery. In its most severe form, it presents as fulminant pulmonary edema with persistent and severe hypoxemia immediately after reimplantation of the new lungs. The PGD can be seen in approximately 30% of patients and remains a major factor for early and possibly delayed mortality after pediatric lung transplantation. Other potential reversible causes of hypoxemia, such as inadequate ventilation, right ventricular dysfunction, and right-to-left shunt, must be ruled out before the diagnosis of PGD is made.

Vascular endothelium makes up a vast portion of the lung parenchyma. This metabolically active endothelium of the donor lungs is continuously exposed to oxygen during the entire ischemic period, leading to free radicals-related injury and graft failure. The time course of this complication suggests two distinct but complementary mechanisms. The first phase, seen immediately after the reperfusion, is initiated by the donor macrophage-induced release of superoxide anions, inflammatory cytokines, mast cell degranulation, and complement activation. These humoral and cellular mediators damage the integrity of the vascular endothelium and cause movement of fluid to the interstitial and alveolar space. Clinically, this presents as progressive hypoxemia with copious, pink frothy secretions that are not amenable to the conventional treatment methods such as diuresis or positive end-expiratory pressure (PEEP). The release of inflammatory cytokine induces the recruitment of the recipient's neutrophils to the injury site and initiates the delayed phase of PGD within hours after the initial injury. During the late phase, neutrophils produce reactive superoxide anions and hydroxyl ions and greatly amplify the initial injury, causing further damage to the pulmonary endothelium. Neutrophils also produce elastase and block the blood flow in the capillaries, resulting in architectural damage to the lung tissue [168]. Since 2005, ISHLT has implemented a common system grading the severity of the reperfusion injury. This system is based on serial measurements of PaO_2/FiO_2 ratio and the presence or absence of infiltrates consistent with pulmonary edema on chest X-ray [169] (Table 32.13). Based on adult lung transplant patient data, donor factors such as female gender, African American race, age (<21 or >45 years), and positive history of smoking may be associated with increased risk of PGD. Longer Ischemic time is also considered an important factor associated with the development of PGD [170].

Table 32.13 Recommendations for grading of primary graft dysfunction (PGD) severity

Grade	PaO_2/FiO_2	Radiographic infiltrates consistent with pulmonary edema
0	>300	Absent
1	>300	Present
2	200–300	Present
3	<200	Present

Source: Christie et al. [169].

The preventive strategies to reduce the incidence of PGD are mainly focused on improving lung preservation techniques, reducing ischemic time, improving donor management, and minimizing barotrauma. Surgeons routinely allow ejection of a small amount of blood into the PA immediately after establishing the vascular supply to the first lung. Empirical evidence suggests that the prophylactic use of pulmonary vasodilators like PGE_1 and prostacyclin may reduce the incidence and severity of the reperfusion injury. The preventative role of iNO, however, is less clear. There have been few randomized clinical trials, and they have failed to demonstrate the efficacy of prophylactic administration of iNO in preventing primary graft failure. The treatment of PGD is supportive and includes mechanical ventilation, restriction of fluids, and the use of inotropes. For most patients, PGD resolves over few days, but some patients require ECMO support. VV ECMO can provide adequate oxygenation and gas exchange for few days. PGD is associated with a protracted postoperative course and significantly higher early mortality. A retrospective study that included both adult and pediatric patients reported significantly higher mortality in patients who developed primary graft failure. PGD has also been independently associated with bronchiolitis obliterans.

Bleeding

The anesthesia team must expect and prepare for significant bleeding during the pre-and post-bypass periods. Patients who had previously undergone thoracic surgeries or had suffered multiple bouts of infections are expected to have difficult dissection during the pneumonectomy phase. Bleeding is also a major concern in patients who were initially palliated with reverse Potts shunt for pulmonary hypertension as the transplant surgery requires the ligation of the shunt before the initiation of the cardiopulmonary pass.

Physiological changes and growth of the transplanted lungs

Denervation of the lungs is a consequence of transplant surgery. Sensory afferent and efferent neurons connect lungs and brainstem and regulate airway smooth muscle tone and breathing [171]. The physiological consequences of denervation on the transplanted lungs are not fully understood. Few clinically significant effects on the airway reflexes, mucociliary movement, and bronchial hyperreactivity have been reported [172]. The lack of afferent stimuli to the respiratory center can result in poor coordination between thoracic and abdominal muscles – a frequently observed finding during the immediate postoperative period. Adult lung transplant patients show a subnormal increase in minute ventilation with carbon dioxide challenge [173]. Beyond the loss of neural control, transplantation also causes a complete disruption of the lymphatic drainage. During the first postoperative week, transplanted lungs remain more susceptible to interstitial edema. Spontaneous recovery of the lymphatic system has been documented in animal models [174]. The long-term clinical implications of lymphatic injury are poorly understood, but its role in immune response and bronchiolitis obliterans is being investigated.

Serial pulmonary function tests, radiological findings, histological evidence, and clinical examination suggest that donor lungs from younger infants and neonates continue to grow after the surgery. This growth occurs in both lung parenchyma and the larger airway and mirrors the somatic growth of the recipient. Cohen et al. observed that functional reserve capacity increases along with somatic growth [175]. This increase accompanies a similar increase in the FEV_1, suggesting that the growth in the lungs results from an increase in the number of alveoli and not from mere distension of existing alveoli. The lobar lungs transplanted from mature, living-related donors also demonstrate a similar growth pattern. However, morphometric studies suggest that the number of alveoli in these lobar lungs remains constant, and the observed growth in lung volume results primarily from alveolar distension [176]. The measurement of diffusing capacity for carbon monoxide (DLCO) provides an estimate of gas exchange surface area. Serial measurements of DLCO support the opinion that the increase in lung volume seen after mature lobes is secondary to hyperinflation.

KEY POINTS: PRIMARY GRAFT FAILURE, PHYSIOLOGICAL CHANGES, AND SURVEILLANCE

- PGD develops during the first week of transplant surgery and presents with varying degrees of hypoxemia and pulmonary edema.
- Addition of PEEP, diuresis, inotropic support, and VV ECMO are support modalities.
- Transplanted lungs continue to grow in infants and children, in both larger airways and lung parenchyma, including an increase in the number of alveoli.
- Serial pulmonary function tests and bronchoalveolar lavage with biopsies are performed as routine surveillance monitoring.

Surgical complications

Airway complications

In the current era, airway complications are uncommon. Bilateral sequential lung transplant approach without bronchial artery revascularization disrupts the blood supply to the donor bronchus. This may lead to poor healing at the anastomotic site and other airway complications such as the development of granulation tissue, airway stenosis, tracheomalacia, and, rarely, airway dehiscence. Surgical techniques such as the use of peribronchial tissue around the anastomotic site and the use of a smaller segment of donor bronchus can minimize the incidence of these complications. In a single-center study involving 239 transplant surgeries, Choong et al. reported that 13% of children needed surgical interventions for their airway complications [177]. Preoperative bacterial and fungal infections, longer ischemic times, and prolonged mechanical ventilation were identified as significant risk factors. In this study, the younger age of the patient was not identified as an independent risk factor for developing airway stenosis. However, infants may have a higher incidence of tracheomalacia and dynamic obstruction of major airways. Most patients with tracheobronchomalacia show significant improvement without any surgical interventions but may need prolonged mechanical ventilation [178]. Usually, airway complications are diagnosed within the first 3 months of surgery. Airway stenosis is usually treated successfully with repeated mechanical balloon dilatation through a rigid bronchoscope. Children with recurrent airway stenosis after repeated balloon dilations may require mechanical stents to maintain airway patency. A 2018 consensus statement by the ISHLT provided standardized definitions for airway complications in adult and pediatric lung transplant recipients and proposed standardized treatment approaches [179].

Vascular anastomotic complications

Vascular anastomotic complications are rare, mostly related to the pulmonary veins. Significant pulmonary venous obstruction presents immediately after weaning off bypass or in the immediate postoperative period. Clinical signs include persistent hypoxemia and frothy pink secretions in the airway, along with increased pulmonary arterial pressures. Postoperative perfusion scans are routinely performed to rule out any discrepancy in the pulmonary blood flow. If a pulmonary venous obstruction is suspected, a definitive diagnosis can be made during cardiac catheterization. Significant obstruction in the PA anastomosis usually requires urgent surgery.

Nerve injuries

Phrenic, vagal, and recurrent laryngeal nerves lie adjacent to the bronchopulmonary tree, and injury to these nerves during the transplant surgery is frequent. Huddleston reported a 22% incidence of phrenic nerve injury in children [178]. The resulting diaphragmatic paralysis is usually a transient phenomenon but can prolong the need for mechanical ventilation and intensive care stay. Injury to the vagus nerve leads to gastroesophageal reflux, and the incidence of gastric paresis can be as high as 50%. Severe gastric paresis and recurrent silent aspiration have been implicated in deteriorating graft function and bronchiolitis obliterans. Younger patients are especially susceptible to this injury, and many neonatal and infant lung recipients require fundoplication after their transplant surgery. Patients with deteriorating pulmonary function have been shown to benefit from surgical treatment of gastroesophageal reflux. Injury to the recurrent laryngeal nerve (mostly left) and resulting vocal cord dysfunction are seen in 10% of children. Most of these children will recover without any residual vocal cord defects [178].

Arrhythmias

Atrial suture lines are a potential source for abnormal depolarization and repolarization. Clinically significant atrial flutter requiring medical treatment is seen in about 11% of pediatric patients. Supraventricular tachycardia and atrial fibrillation are also seen. Most arrhythmias are amenable to medical treatment alone.

KEY POINTS: SURGICAL COMPLICATIONS

- Airway stenosis, tracheomalacia, granulation tissue, or dehiscence is seen in approximately 13% of pediatric lung transplant recipients.
- Pulmonary vein obstruction is a serious complication heralded by hypoxemia and frothy pink secretions.
- Phrenic nerve, recurrent laryngeal nerve, and vagus nerve injuries are relatively frequent complications after lung transplantation in children.

Medical complications

Graft rejection, immune therapy, and drug interactions

Recurrent graft rejections are more common after lung transplantation compared with other solid organ transplant surgeries. Lungs have a large endothelial surface and contain immunologically active cells, making them more susceptible to immune-mediated rejection when compared with the other solid organs. Hyperacute rejection, mediated by preexisting antibodies to donor HLA, is uncommon and can be prevented by virtual crossmatching where the transplant recipients are screened for antibodies against donor HLA. Acute rejection is common and affects almost all transplant patients within 3 months of the surgery. Infants and younger children appear to be somewhat protected and suffer from fewer episodes of acute rejection [180]. This discrepancy could be explained by their relatively immature immune system. More recently, the role of anti-HLA antibodies in graft rejection has been investigated. The clinical picture of rejection is a nonspecific deterioration in the functional status or pulmonary function parameters and is almost clinically indistinguishable from the infectious process. Any decline in clinical status or pulmonary function tests is further investigated by transbronchial lung biopsy. Once the diagnosis of acute rejection is made, these episodes are treated aggressively with a course of intravenous drugs such as high-dose steroids, antithymocyte globulin, and tacrolimus.

After the induction immunotherapy (IL-2 receptor antagonists or a polyclonal antibody), triple-drug therapy with a combination of a calcineurin inhibitor (tacrolimus), cell-cycle inhibitor (MMF), and corticosteroid (prednisone) is continued for the first year. Side effects related to the chronic use of these drugs include compromised renal function, hypertension, hypercholesteremia, hirsutism, and osteoporosis. About 30% of children have clinically significant renal dysfunction, but others demonstrate subclinical renal dysfunction with borderline serum Cr levels. As many transplant recipients are at risk of developing renal failure, nephrotoxic drugs such as nonsteroidal anti-inflammatory agents are avoided even if renal function is normal. Cystic patients, because of the unreliable gastric absorption and hepatic clearance, are at risk for developing acute toxicity from oral medications like cyclosporine. In fact, the high incidence of central nervous complications like seizures, headaches, and stroke has been attributed to acute increases in plasma levels of cyclosporine. Hepatic enzymes such as cytochrome P450 metabolize commonly used immunosuppressant drugs. Drugs that are commonly used during surgery (e.g. metoclopramide, barbiturates) induce cytochrome P450, resulting in dangerously low levels of cyclosporine.

Opportunistic infections and antibiotic prophylaxis

The risk of viral and bacterial infection remains high throughout the life span of the recipient, but the risk is the highest during the immediate postoperative period. Viral infections are more commonly seen in infants and toddlers. Immunosuppression combined with poor mucociliary clearance, poor cough efforts, and disrupted lymphatics make newly transplanted lungs potential sites for infections. Bacterial infections are the most common, but fungal and viral infections tend to have higher mortality. Cytomegalovirus, adenovirus, Epstein–Barr virus, and influenza are common viral infections. Cytomegalovirus infection is associated with an increased incidence of acute and chronic rejection. Treatment of cytomegalovirus pneumonitis requires 2–3 months of treatment with intravenous or oral ganciclovir. Some patients are prescribed prophylactic trimethoprim/sulfamethoxazole to prevent *Pneumocystis jirovecii* pneumonia. Preoperative infection with aspergillosis is often seen in CF patients, requiring prolonged treatment with antifungal drugs such as voriconazole.

Post-transplant lymphoproliferative disorder

Overall, the incidence of malignancy in the post-transplant period is more than 10% at 5 years. PTLD remains the most common form of malignancy. PTLD is strongly associated with Epstein–Barr virus and results from B-cell proliferation and is commonly seen in patients with T-cell depletion [181]. The hyperplasia of the lymphatic tissue is mostly seen in intrathoracic tissue as lung nodules and mediastinal lymphadenopathy, but it can also present in extrathoracic tissues, such as tonsillar hypertrophy, and cerebral and visceral masses. Most children will respond to a reduction in immunosuppression, but treatment with monoclonal antibodies and steroids may be needed in a few unresponsive patients.

Chronic lung allograft dysfunction

Chronic allograft dysfunction is responsible for poor long-term survival after lung transplant surgery. Bronchiolitis obliterans (BO), the most common type of chronic lung allograft dysfunction (CLAD), is the leading cause of death beyond the first year of survival. Roughly, half of the surviving children develop BO by 5 years after their lung transplant surgery [122]. In addition to increasing mortality, CLAD causes significant morbidity and impairs quality of life after lung transplant. The hallmark of the disease is progressive fibrosis and slow obliteration of the small airways. BO is a histological diagnosis reflecting inflammatory and fibroproliferative changes in the bronchioles. The exact mechanism of BO is unknown, but recent research suggests that both immune-mediated and immune-independent mechanisms are responsible. Alloimmune-mediated mechanisms cause injury by acute rejection, cellular lymphocytic bronchiolitis, activation of the humoral immune system, and autoimmune dysfunction. Immunity-independent mechanisms such as

infections, aspiration, ischemia, and primary graft failure also appear to contribute to progressive destruction of the pulmonary architecture. Injury caused by these mechanisms induces a significant fibrotic reaction, remodeling, and abnormal angiogenesis. Routine transbronchial biopsies are not reliable early diagnosis. The clinical manifestation, called bronchiolitis obliteration syndrome, should be strongly suspected in children where a more than 20% decrease in FEV_1 is noticed in the absence of infection or rejection. A subgroup of CLAD that does not demonstrate restrictive function may stabilize with aggressive treatment with azithromycin and photopheresis. In a retrospective analysis, children with a total ischemic time of less than 2 hours had a significantly lower incidence of BO when compared with a similar group of patients with longer ischemic time (20 vs. 52%) [182]. The incidence of BO is also lower in smaller children (age <3 years at the time of transplant). This is presumably related to a lower annual incidence of acute rejection compared with the older children (0.2 episodes compared with 1.95) [159]. Enhanced immunosuppression is the cornerstone of currently used therapies, though none of the methods have been able to show a consistent benefit to all patients. Antireflux surgery may also prevent or even reverse the decline in pulmonary function in some patients. Statins have the ability to induce apoptosis in fibroblasts and may hold a promise in treating BO. Retransplantation has become more common in older patients, but short- and long-term survival benefits are limited after retransplant surgery.

KEY POINTS: MEDICAL COMPLICATIONS

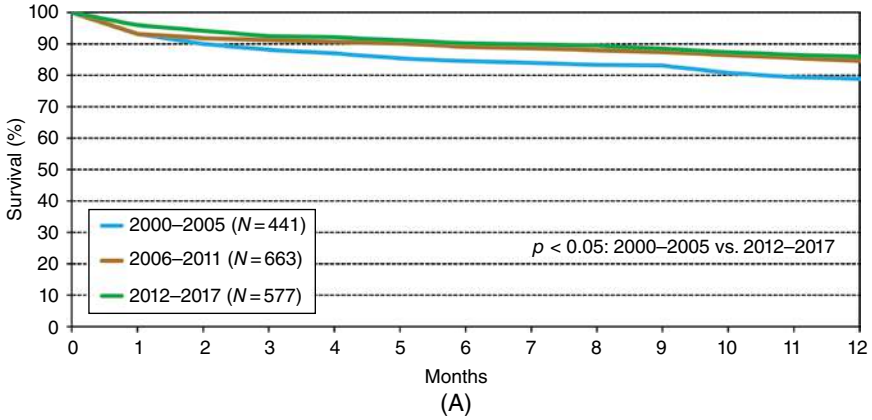
- Infants and young children have fewer episodes of acute rejection, explained by a relatively immature immune system; these episodes are heralded by nonspecific deterioration in functional status.
- Opportunistic infections with bacteria, viruses, and fungi are a constant threat.
- PTLD is usually due to Epstein–Barr virus and is seen in about 8% of patients.
- BO is the leading cause of death after the first year and is the major threat to long-term survival.

Surveillance

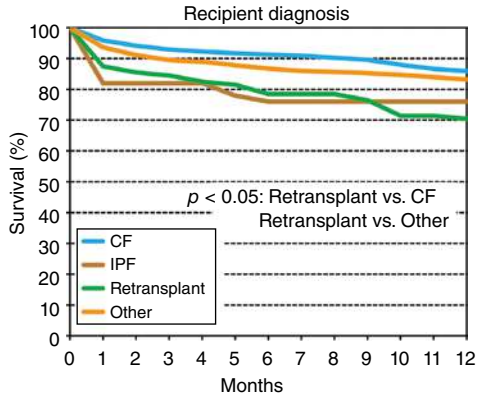
These children are closely monitored for rejection, infection, growth, and BO. Pulmonary function tests, bronchopulmonary lavage, and transbronchial biopsies are performed at frequent intervals. Older children can cooperate to perform spirometric tests, and the values of FEV_1, FVC, and flow-volume loops can be serially measured with reasonable accuracy. In infants and younger children (less than 2 years of age), serial values of peak expiratory flow rates are measured at different values of FRC. Peak expiratory flow rate is measured by rapid inflation, followed by rapid deflation. This is achieved by using mask inflation, followed by a rapid external thoracoabdominal compression. These tests are noninvasive but are physically stimulating and are adversely affected by active patient resistance. Consequently, most of the children require deep sedation and/or general anesthesia for these tests. Any deterioration in the baseline values is further investigated by transbronchial biopsy, bronchoalveolar lavage, and open lung biopsy.

Long-term survival

Overall, long-term survival after a lung transplant in children is improving and remains comparable to adults (5.7 vs. 6.2 years). 56.4% of patients, who received lung transplants after 2008, were alive at 5 years [183].



Unfortunately, during the past 30 years, no significant improvement has been observed in 5-year conditional to 1-year survival, suggesting that improvements in care have resulted in a reduction in the earlier mortality. Still, long-term outcomes after lung transplant surgery in children have remained disappointing. Post-transplant survival is better for children younger than 12 years of age. Mortality is the highest during the first year after surgery, and approximately 15% of transplanted children succumb to primary graft failure and infections in the first year (Table 32.14). For those who survive beyond 1 year, infections, CLAD, and PTLD are the common causes of death. Figures 32.16–32.18 present survival data for pediatric lung transplants by age, era, diagnosis, and early/late deaths, as well as freedom from BO [183].



Few prospective studies analyzing the benefit to pediatric patients have been conducted. Liou et al. performed a Cox

Table 32.14 Causes of death after pediatric lung transplantation

Cause of death	0–30 Days (*N* = 130)	31 Days–1 Year (*N* = 204)	>1—3 Years (*N* = 296)	>3–5 Years (*N* = 148)	>5 Years (*N* = 185)

AL Grawany

proportional hazards analysis in children with CF, using transplant surgery as a time-dependent covariate. The authors observed that, based on the recent data from the OPTN database, children with a 5-year life expectancy of less than 50% at the time of transplant showed no difference from the nontransplanted group with similar severity of the disease. Among 127 children with a 5-year predicted survival greater than 50%, the transplanted group showed a substantial decrease in post-transplant survival when compared with the control nontransplant group. It was concluded that benefit from lung transplantation for CF patients could no longer be assumed [185]. However, the study did not include the impact of the recent changes in the lung allocation system, and the authors were unable to comment on the improvements in the quality of life in CF children after transplant surgery. Another limitation of the study was that it included covariates obtained 2–3 years prior to the surgery and did not account for the medical condition of the patient at the time of transplant. The impact of this highly invasive surgery on the quality-of-life years survived has not been well studied in lung transplant pediatric patients. Future studies are needed to clarify the potential benefit of lung transplant surgery in children with CF and other diseases leading to end-stage pulmonary failure.

KEY POINTS: MORTALITY AND LONG-TERM SURVIVAL

- Overall, pediatric lung transplant survival is worse than other solid organ transplants.
- Median survival since 1990 is 4–6 years, with patients <10 years having longer survival slightly.
- Since 2002, survival has improved slightly in pediatric lung transplant recipients.

Anesthesia for patients with lung transplant surgery

After lung transplantation, pediatric patients will present for routine transbronchial bronchoscopic surveillance, and anesthetic technique is institution-dependent and varies according to the age of the child and function of the lungs. If general anesthesia is required, one technique is to use a laryngeal mask airway, which allows a large diameter airway for bronchoscopic access; topical anesthetic treatment of the larynx and the lower airway is provided by the pulmononologist. Alternatively in older patients, intravenous sedation with any one of a number of agents, with generous topical anesthesia, can be utilized. Noncardiac surgery in this population requires a thorough preanesthetic evaluation, including review of pulmonary function tests, and a plan to continue immunosuppressants, and inhaled and systemic pulmonary dilators. Patients with significant BO can have significantly increased airway resistance and reduced compliance; these patients need to have procedures performed in their lung transplant center with careful multidisciplinary planning involving their transplant pulmonologist.

The COVID-19 pandemic and lung transplantation

SARS-CoV2, the viral etiology of COVID-19 infection, can unleash a severe, destructive inflammatory response that can lead to significant lung damage, destruction of lung tissue, and requirement for mechanical ventilation, mechanical support with VV or VA ECMO, and cause end-stage lung disease that can only be treated with lung transplantation in some cases. Case reports of lung transplantation appeared in mid-2020, and several hundred lung transplants in COVID-19 patients with what was deemed irreversible lung disease have been performed as of late 2021 [186–188]. Significant precautions for personal protective equipment must be taken by the entire surgical team, including at minimum masking with a highly protective medical-grade facemask, e.g., N95 mask, eye protection, double gloving, and gowning, for the entire case. COVID-19 testing of donors and recipients has become the norm in the pandemic era. Concerns arose over the possibility that some patients could harbor latent virus that would be reactivated with the initiation of immunosuppressive regimens. In addition, several reports of COVID-19 infection in lung transplant recipients, and at least one report of COVID-19-positive donor lungs being implanted, have appeared in the medical literature. [189, 190] Long-term survival needs to be determined, and international and U.S. lung transplant registries have added this category of disease to their databases [191].

Incidence, anatomy, natural history

Definition

Pulmonary hypertension (PH) has many different etiologies, in which all share the final common path of elevated pulmonary arterial pressure (PAP). After birth, PAP falls, reaching adult levels within a few months. In normal, healthy individuals, mean pulmonary artery pressure (mPAP) at rest is around 15 mmHg and is independent of age, ethnicity, and gender. During exercise, mPAP increases and is dependent on the level of exertion and age. During mild exercise, mPAP is 20 ± 5 mmHg in subjects under age 50 years compared to 30 ± 5 mmHg in subjects older than age 50 years, which makes it difficult to define normal mPAP during exercise, and hence, the definition of PH uses mPAP at rest [1]. Initially, PH was arbitrarily defined as an mPAP > 25 mmHg. However, this definition has recently changed, as two standard deviations above a normal mPAP of 15 mmHg would suggest an mPAP > 20 mmHg as the upper limit of normal (above the 97.5th percentile). However, this abnormal elevation of mPAP is not sufficient to define pulmonary vascular disease, as it can be due to an increase in cardiac output or pulmonary arterial wedge pressure. Therefore, the 6th World Symposium on Pulmonary Hypertension (WSPH) in 2018 proposed to include pulmonary vascular resistance (PVR) ≥3 Wood Units (WU) in the definition of all forms of precapillary PH associated with an mPAP > 20 mmHg [2]. The current hemodynamic definitions of PH are shown in Table 33.1. The Pediatric Task Force of the sixth WSPH has chosen to follow this new adult definition of PH to maintain a common universal language and to facilitate transition from pediatric to adult care. This Pediatric Task Force further reinforced the need to index PVR to body surface area in children [3]. PVR index (PVRI) relates the absolute value of PVR to the patient's body surface area to account for the effect of body size on blood flow and it should be reported as WU m^2 [4]. An mPAP > 20 mmHg does not carry any implication of the presence or absence of pulmonary hypertensive vascular disease. PVR is important in the diagnosis and management of pulmonary hypertensive vascular disease in patients with congenital heart disease (CHD). PH complicates the course of many children and adults with CHD. The increase in PAP associated with CHD is secondary to either increased "precapillary" pulmonary blood flow (left-to-right shunt lesion) or increased postcapillary pressures (left heart disease). Based on the hemodynamic definition of PH (mPAP > 20 mmHg), almost all patients with a large unrestricted left-to-right shunt will have PH. What is important in this setting is the degree of pulmonary hypertensive vascular disease resulting in an increase in PVR. A patient with a high pulmonary blood flow and low PVR will have PH but can be safely treated with the closure of the shunt. On the contrary, a patient with low pulmonary blood flow, shunt reversal (right to left), cyanosis, and high PVR, the so-called Eisenmenger syndrome, will be harmed with shunt closure due to worsening right heart failure, as there is no longer a "pop-off" for blood flow [5]. Eisenmenger syndrome is an end stage, and usually irreversible, because of PH with a PVRI > 10 WU m^2 with reversed or bidirectional shunting of blood at an aortopulmonary, ventricular, or atrial level. However, between these two

extremes of PH and associated CHD is a challenging gray zone that requires careful diagnostic evaluation to guide future management.

Classification

Since inception in 1973, the World Health Organization (WHO) group classification system for PH has provided researchers and clinicians an evolving framework from which to investigate, diagnose, and treat patients with a diverse collection of pulmonary vascular diseases [2, 6]. The clinical classification of PH has five categories based on shared pathological mechanisms, hemodynamic characteristics, and management strategies (Table 33.2). Subsequent iterations of this clinical classification have maintained a comparable structure with changes paralleling scientific advancement. The definitions are accepted worldwide and used daily in practice by clinicians as inclusion/exclusion criteria for clinical research and in the labeling of new therapeutics for the treatment of PH.

The WHO groups 1–5 classification system for children is problematic, as it does not reflect the complex heterogeneity of factors that contribute to pediatric PH. As a result, the Pulmonary Vascular Research Institute Pediatric Taskforce proposed a new classification of pediatric PH at its meeting in Panama in 2011 [7]. The classification has 10 categories based on clinical pediatric practice and reflects the heterogeneous nature of pediatric PH (Table 33.6). The Panama classification includes an additional definition of PH for children with univentricular circulations: following a cavopulmonary anastomosis, PH is defined as a PVRI≥ 3 WU m^2 or a transpulmonary gradient (mPAP – left atrial pressure) >6 mmHg even if the mPAP is <20 mmHg (Box 33.1) [7, 8]. In this setting of nonpulsatile blood flow to the pulmonary arteries, even though mPAP may not be greater than 20 mmHg, significant pulmonary hypertensive vascular disease can lead to a poor outcome. With the agreement of the Pediatric Taskforce, some of these items were included in the most recent 2018 Pulmonary Hypertension Classification to have a more comprehensive classification, inclusive of both adults and children [9].

Children with CHD and PH are in group 1, pulmonary arterial hypertension (PAH). Group 1.4.4 PAH includes patients with simple operable and inoperable CHD, subgrouped as those with Eisenmenger physiology, those with PAH and left-to-right shunts, those with PAH thought to be incidental to their CHD, and those with postoperative defects. Transient PH following repair of CHD occurs in 21.9 cases per million and is one of the commonest forms of PAH in children, second only to persistent PH of the newborn [10]. Complex heart diseases have been assigned to group 5.4.

Group 2, PH due to left heart disease, includes congenital and acquired left heart inflow and outflow tract obstruction, such as pulmonary vein stenosis, cor triatriatum, mitral stenosis, and cardiomyopathies. This group causes the "postcapillary" increase in PAP. In group 3, PH due to lung disease and/or hypoxia, developmental lung diseases are emphasized due to the important role of abnormal lung vascular growth in the pathogenesis of PH. Examples include congenital diaphragmatic hernia, bronchopulmonary dysplasia (BPD), alveolar capillary dysplasia, and surfactant protein abnormalities. Group 4, PH due to pulmonary artery obstructions, and group 5, PH with unclear and/or multifactorial mechanisms, including complex CHD, are rare causes of pediatric PH.

The characterization of PH according to these classifications is an essential part of the diagnostic workup of PH. The treatment strategy and prognosis of pediatric PH largely depend on its subclass and associated conditions. It is, therefore, important to correctly characterize the type of PH using standardized diagnostic workup (Figure 33.1). However, in pediatric PH, there is often more than one associated condition identified, which leaves it to the clinician to determine the contribution of each condition to the PH and to decide on which condition therapy should be focused. However, there is now a shift away from this historic classification paradigm to a genotype–phenotype model, which potentially removes the boundaries between the current groups [11]. The guidelines for the diagnosis and management of pediatric and adult PH have comparable themes, but recommendations for treatment in children are based largely on expert consensus and extrapolation from adult data [12]. Identifying parallels in the genotype–phenotype profile among adult and pediatric patients with comparable genetic mutations may simplify investigation and treatment. Armed with specific knowledge about genotype–phenotype of their patient, clinicians may be better equipped to provide precision care regardless of patient age. The large-scale PVDOMICS study (Redefining Pulmonary Hypertension through Pulmonary Vascular Disease Phenomics) is utilizing the principle of phenomics (e.g. genomics, transcriptomics, proteomics, metabolomics) to create a rich data resource from which to redefine PH classification at the molecular level [13, 14].

Epidemiology

The major etiologies of pediatric PH cases are idiopathic PAH (IPAH), heritable PAH (HPAH), and PAH associated with CHD (PAH-CHD). Gene mutations involved in the transforming growth factor-β (TGF-β) signaling pathway, primarily within bone morphogenetic protein receptor type-2 (BMPR-2), have been shown to be important in IPAH

Table 33.2 Updated clinical classification of pulmonary hypertension

1. PAH
   - 1.1. Idiopathic PAH
   - 1.2. Heritable PAH
   - 1.3. Drug and toxin induced PAH (Table 33.3)
   - 1.4. PAH associated with:
     - 1.4.1. Connective tissue disease
     - 1.4.2. HIV infection
     - 1.4.3. Portal hypertension
     - 1.4.4. Congenital heart disease
     - 1.4.5. Schistosomiasis
   - 1.5. PAH long-term responders to calcium channel blockers (Table 33.4)
   - 1.6. PAH with overt features of venous/capillaries (PVOD/PCH) involvement (Table 33.5)
   - 1.7. Persistent pulmonary hypertension of the newborn (PPHN)
2. PH due to left heart disease
   - 2.1. PH due to heart failure with preserved LVEF
   - 2.2. PH due to heart failure with reduced LVEF
   - 2.3. Valvular heart disease
   - 2.4. Congenital/acquired cardiovascular conditions leading to postcapillary PH
3. PH due to lung diseases and/or hypoxia
   - 3.1. Obstructive lung disease
   - 3.2. Restrictive lung disease
   - 3.3. Other lung disease with mixed restrictive/obstructive pattern
   - 3.4. Hypoxia without lung disease
   - 3.5. Developmental lung disorders
4. PH due to pulmonary artery obstructions
   - 4.1. Chronic thromboembolic PH
   - 4.2. Other pulmonary artery obstructions
     - 4.2.1. Sarcoma (high or intermediate grade) or angiosarcoma
     - 4.2.2. Other malignant tumors:
       - Renal carcinoma
       - Uterine carcinoma
       - Germ cell tumors of the testis
       - Other tumors
     - 4.2.3. Nonmalignant tumors
       - Uterine leiomyoma
     - 4.2.4. Arteritis without connective tissue disease
     - 4.2.5. Congenital pulmonary artery stenosis
     - 4.2.6. Parasites
       - Hydatidosis
5. PH with unclear and/or multifactorial mechanisms
   - 5.1. Hematologic disorders
     - Chronic hemolytic anemia
     - Myeloproliferative disorders
   - 5.2. Systemic disorders and metabolic disorders
     - Pulmonary Langerhans cell histiocytosis
     - Gaucher disease
     - Glycogen storage disease
     - Neurofibromatosis
     - Sarcoidosis
   - 5.3. Others
     - Chronic renal failure with or without hemodialysis
     - Fibrosing mediastinitis
   - 5.4. Complex congenital heart disease

DLCO, diffusing capacity of the lung for carbon monoxide; PAH, pulmonary arterial hypertension.

and HPAH. There are other mutations, which are also thought to be important in the pathogenesis of PAH, including activin-like kinase-1 (ALK-1), T-box 4, SOX17, and endoglin mutations [15, 16]. BMPR-2 is the most common gene mutation associated with pediatric PAH and can be identified in 10–20% of pediatric patients with IPAH/HPAH [10, 17, 18].

Table 33.6 The Panama classification: 10 categories of pediatric pulmonary hypertensive vascular disease

Category	Description
1	Prenatal or developmental pulmonary hypertensive vascular disease
2	Perinatal pulmonary vascular maladaption
3	Pediatric cardiovascular disease
4	Bronchopulmonary dysplasia
5	Isolated pediatric pulmonary hypertensive vascular disease
6	Multifactorial pulmonary hypertensive vascular disease in congenital malformation syndromes
7	Pediatric lung disease
8	Pediatric thromboembolic disease
9	Pediatric hypobaric hypoxic exposure
10	Pediatric pulmonary vascular disease associated with other system disorders

Box 33.1: The modern definition of pulmonary arterial hypertension in children with biventricular and palliated univentricular circulations.

mPAP = mean pulmonary artery pressure
PVRI = pulmonary vascular resistance index
CO = cardiac output
TPG = transpulmonary gradient

Biventricular circulation

mPAP > 20 mmHg and PVRI ≥ 3 Wood Units m^2
Sitbon criteria for positive acute vasodilator response defined as a decrease in mPAP by at least 10 mmHg to a value of <40 mmHg with sustained cardiac output [62]

Univentricular circulation

Following palliation with a cavopulmonary anastomosis
PVRI ≥ 3 Wood Units m^2 or TPG > 6 mmHg EVEN IF mPAP < 20 mmHg

Two large registries have provided further insights into the etiology of pediatric PH. The Tracking Outcomes and Practice in Pediatric (TOPP) PH registry reported 362 patients with confirmed PH [19]. Of these patients, 317 (88%) had PAH, of which 57% were characterized as IPAH or HPAH and 36% as PAH-CHD. Only three patients had chronic thromboembolic PH. Chromosomal anomalies, mainly trisomy 21, or syndromes were reported in 47 (13%) of the patients. Another large registry for pediatric PH is from the Netherlands. This registry reports 2,845 (87%) of 3,263 pediatric patients with PAH in group 1 of the PH classification, including transient PAH (82%) or progressive PAH (5%) [10]. The most common cause of transient PAH was Persistent Pulmonary Hypertension of the Newborn (PPHN) (58%), and the most common cause of progressive PAH was PAH-CHD (72%). Trisomy 21 was the most frequent chromosomal abnormality (12%), a rate similar to that observed in the TOPP registry.

(Source: Rosenzweig et al. [3]. Reproduced with permission of European Respiratory Society.)

PH is a rare disease. The incidence and prevalence of PH in the pediatric population are not well known. In the Netherlands' registry, the annual incidence of IPAH and PAH-CHD were 0.7 and 2.2 cases/million, respectively. The prevalence of PAH-CHD was 15.6 cases/million [10]. The national registry from the United Kingdom reports similar numbers with an annual incidence of IPAH of 0.48 cases/million children and a prevalence of 2.1 cases/million [20]. In a multicenter study in France, the estimated prevalence of PAH was 3.7 cases/million children, with IPAH (60%) and PAH-CHD (24%) being the main etiologies [21].

Survival for patients with PH has improved with the introduction of management guidelines, dedicated centers, and new drug therapies. Before targeted drug therapies were available for PH, the estimated median survival of children and adults with IPAH were similar, 4.12 and 3.12 years, respectively [22]. After the introduction of targeted pulmonary vasodilators, the survival rate for children with PAH has continued to improve. In the combined pediatric and adult US REVEAL (Registry to Evaluate Early and Long-Term PAH Disease Management) registry, patients with childhood onset PAH had 1-, 3-, and 5-year survival rates of 96, 84, and 74%, respectively [23]. There was no significant difference in 5-year survival between IPAH/HPAH (75%) and PAH-CHD (71%). Similar data have been published from studies in the Netherlands and United Kingdom [20, 24, 25]. Although overall survival has improved, patients with repaired CHD and pulmonary hypertensive vascular disease have a high mortality risk.

Pathophysiology of pulmonary hypertension in congenital heart disease

PH associated with CHD is classified in group 1, PAH. This group distinguishes itself from the other four categories by its characteristic pattern of vascular remodeling, progressive

nature, and response to specific medical therapy. Heath and Edwards published the first description of pulmonary vascular remodeling due to CHD in 1958 [26]. They divided the histological progression from grades 1 to 6 in increasing severity. Later, Rabinovitch developed the morphometric approach, which quantifies the thickness of the pulmonary arterial muscle, the degree of abnormal distal extension of smooth muscle, and the density of small pulmonary arteries relative to the number of alveoli [27]. The morphometric structural findings are graded from A through C in increasing severity of changes. This morphometric analysis has contributed to our understanding of pulmonary vascular remodeling by establishing that abnormal extension of smooth muscle and a reduction of small artery density are a hallmark of pulmonary hypertensive vascular disease. This approach has emphasized that early age to correct congenital heart defects helps preserve small pulmonary arteries and predicts good pulmonary hemodynamics postoperatively. The pulmonary vascular remodeling that is characteristic for PAH involves adventitial thickening, medial hypertrophy, and intimal proliferation, including the formation of plexiform lesions [28]. This vascular remodeling leads to arterial wall thickening and occlusion of small distal pulmonary arteries. Together with other mechanisms including vasoconstriction, inflammation, and thrombosis, the vascular wall thickening and occlusion will consequently increase PAP and PVR (Figure 33.2) [29]. This increase in right ventricular (RV) afterload increases RV workload, eventually resulting in RV failure.

The pulmonary vascular bed plays a key role in the presentation and management of children with almost all forms of CHD. Four variables are important in the development of pulmonary hypertensive vascular disease and whether it will regress or progress after repair of a congenital cardiac shunt lesion:

1. The age of the patient at repair
2. The type of cardiac lesion
3. The PVRI at operation
4. Individual genetic and environment factors and comorbidities

The evolution of PAH-CHD and the age at which it presents itself depends on the type of shunt lesion. In patients with a shunt at the pretricuspid valve level (e.g. ASD), there is an increased pulmonary volume load with a normal pressure load. Only 5–20% of these patients will develop severe PAH, and usually not until the third or fourth decade of life [30, 31]. In patients with nonrestrictive shunts at the posttricuspid valve level, the increased pulmonary volume is accompanied by an increased pressure load due to pressure equalization across the shunt defect. In these patients, PAH usually develops more rapidly during the first few years of life. If left uncorrected, these systemic to pulmonary shunts will result in steadily increasing PVR, and when this exceeds the systemic vascular resistance (SVR), the shunt will reverse resulting in hypoxemia and cyanosis, which are the hallmarks of Eisenmenger syndrome [5]. For this reason, most CHD shunt lesions should be repaired within the first 2 years of life. The exact level of PVRI that precludes safe closure of a defect is often debated and varies with each lesion. The WSPH proposed criteria for shunt closure in patients with net left-to-right shunting (Table 33.7) [32]. Complex congenital heart defects, such as transposition of the great arteries, truncus arteriosus, and aortopulmonary window, present with pulmonary hypertensive vascular disease much earlier and should, therefore, be repaired in the first weeks of life.

Patient genetic and environmental factors may influence the timing of repair of congenital heart defects with PAH. Pediatric PAH occurs in 20–40% of children with genetic disorders, including trisomy 21, Noonan, Velocardiofacial, and Jacobsen syndromes [18]. Furthermore, many children with PAH have clinical signs of a syndrome, such as dysmorphic features, which cannot be explained by a known syndrome diagnosis or genetic test. The frequent occurrence of genetic abnormalities in children with PAH suggests the existence of still unknown genetic pathways involved in the disease process of PAH. The BMPR-2 mutation has been described in 6% of children with CHD [33]. Comorbidities may also exacerbate PAH-CHD. For example, children with trisomy 21 are at higher risk of developing PH due to sleep-disordered breathing, upper airway obstruction, silent aspiration with recurrent pneumonias, and pulmonary hypoplasia [34]. The net result is episodes of hypoxia, which in turn may exacerbate the pulmonary vascular disease from CHD. In developing countries, there may be additional comorbidities to consider. In Africa, in a cohort of children with CHD, 53% were anemic, 47% underweight, and 33% had marasmus compared to a control group without CHD, of whom none had marasmus and only 14% were underweight [35]. Tuberculosis is twice as common in patients with CHD, especially in those with lesions with an increased pulmonary blood flow, and if treatment is available, the major cause of morbidity is delay of cardiac surgery [36]. Unfortunately, tuberculosis may mask the signs of CHD and result in a delay in diagnosis of CHD and subsequent surgical repair. Human immunodeficiency virus (HIV) infection is endemic in sub-Saharan Africa. In Uganda, CHD affects 5% of children with HIV compared to 3% in developed countries [37]. More recently, coronavirus disease 2019 (COVID-19) has had a catastrophic impact on global health. The virus responsible for the pandemic is severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), and the most frequently reported comorbidities in children who become critically ill with the virus are chronic lung disease, obesity, neurodevelopmental disabilities, and CHD. Patients with PH are vulnerable to SARS-CoV-2, as it is a respiratory virus that causes PH via multiple pathways including lung inflammation and fibrosis, vasoconstriction, and thrombosis [38].

Environmental factors may also influence the timing of surgical repair of congenital heart defects. High altitude has effects on normal neonatal pulmonary vascular transition that is related not only to altitude but also to ancestry. Ethnic groups with recent migration to high altitude have lower oxygen saturations and higher PAP than those with a long ancestry of high altitude living, such as native residents of the Andes mountain range and Tibet. In addition, the incidence of CHD increases at higher altitude, the ductus arteriosus is larger, and its closure delayed, with a higher pulmonary to systemic blood flow ratio for a given PVR. As a result, management decisions, particularly the timing of surgical repair, are different at high altitude [39, 40].

AL Grawany

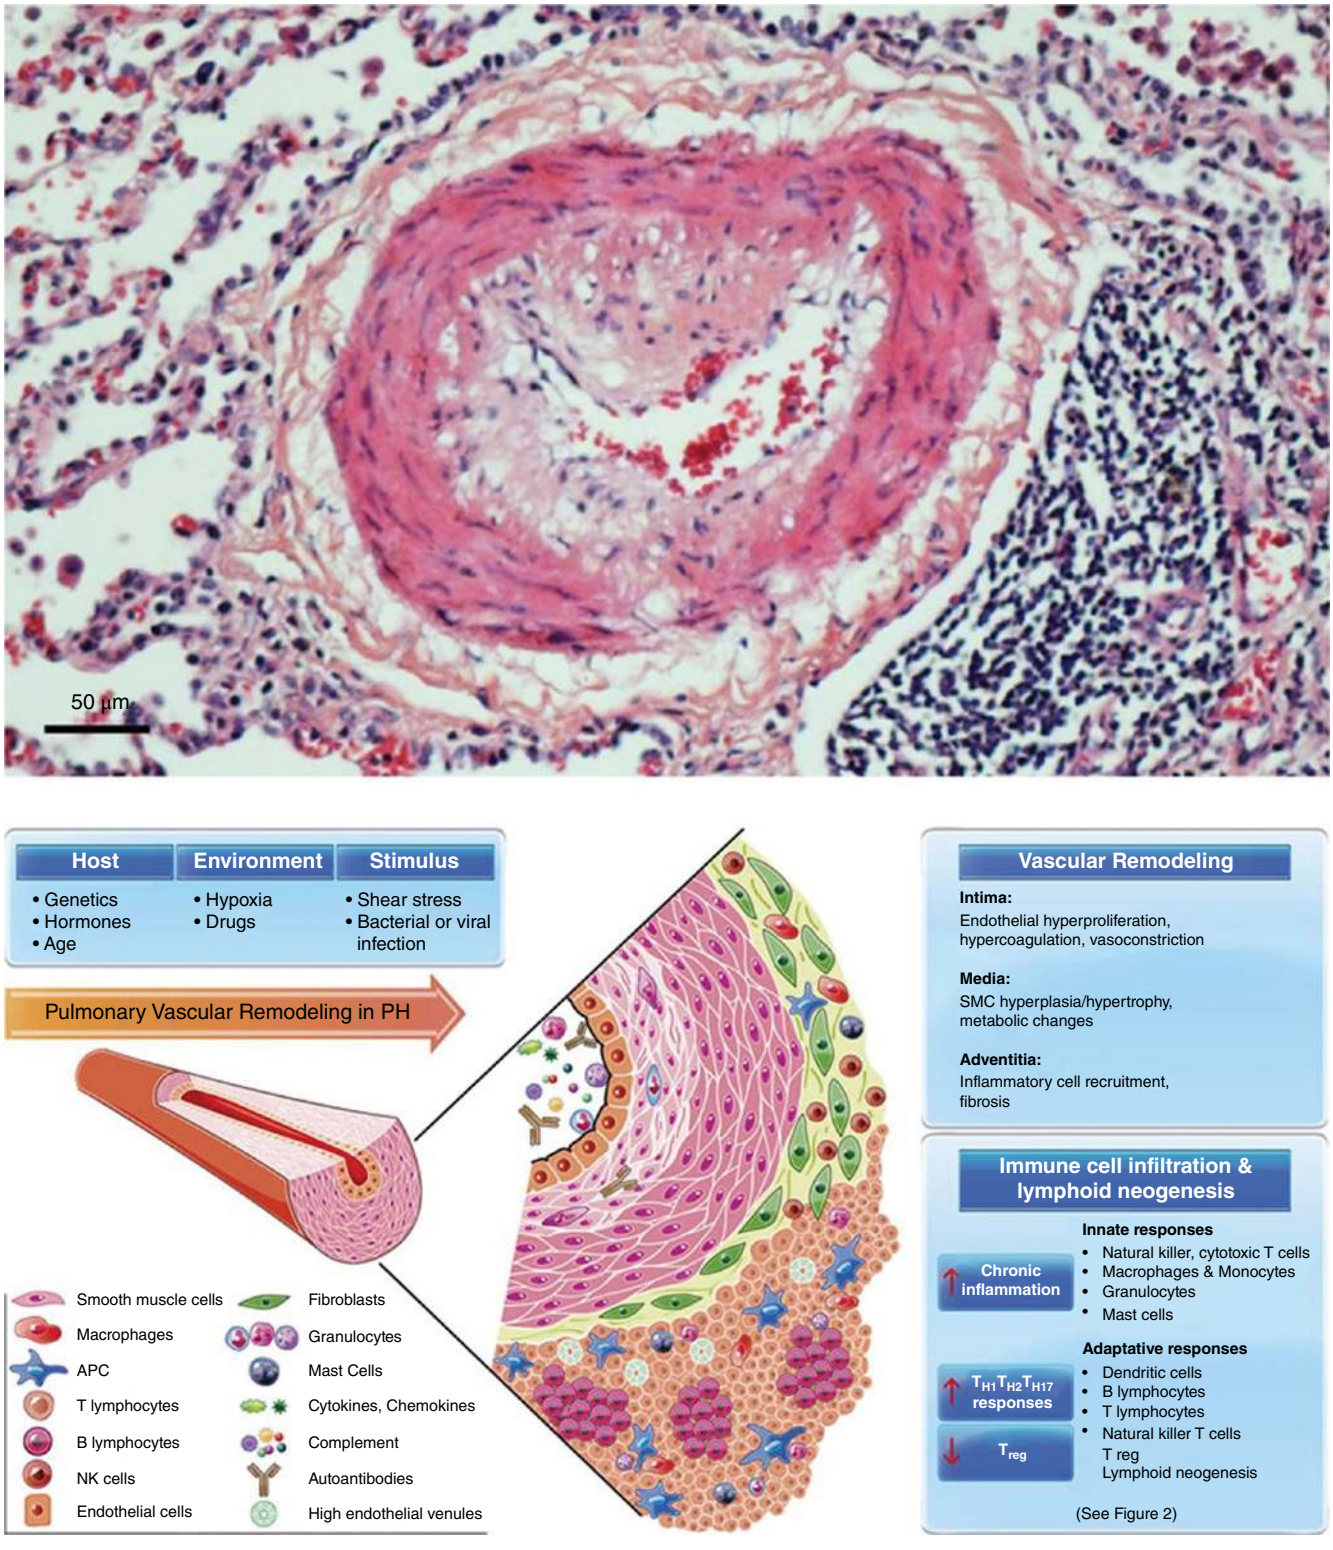

Figure 33.2 Pulmonary vascular changes in pulmonary arterial hypertension includes infiltrating adaptive and innate immune cells. In the top panel is a representative histopathology of a vessel with severe neointimal formation represented below by a diagrammatic illustration. The histopathology shows a single endothelial layer and an eccentric neointima (pale pink) that contains cells that have markers of inflammatory cells and others that stain with markers of smooth muscle but appear poorly differentiated. The medial muscular layer is expanded, and there is an abundant adventitial layer. This vessel is decorated with complement and autoantibodies, infiltrated by neutrophils in the lumen attacking the vessel wall and other inflammatory cells binding to the endothelium and infiltrating. The neointima is composed of pale cells and matrix and infiltrating T and B cells, and in the adventitia, there are dendritic cells, macrophages, and mast cells, and in the periadventitial space tertiary lymphoid follicles characterized by T cells, B cells, and plasmacytoid dendritic cells (APC). NK indicates natural killer; PH, pulmonary hypertension; and SMC, smooth muscle cell. (Source: Rabinovitch et al. [29]. Reproduced with permission of Wolters Kluwer Health, Inc.)

KEY POINTS: CLASSIFICATION AND DEFINITION OF PH

- The current definition of PH is an mPAP > 20 mmHg at rest, as measured by right heart catheterization. However, this abnormal elevation of mPAP in isolation is not sufficient to define pulmonary vascular disease, as it can be due to an increase in cardiac output or pulmonary artery occlusion pressure (PAOP).
- Hemodynamic definitions of PH include precapillary, isolated postcapillary, or a combination of both.
- The clinical classification of PH is divided into five groups.
- There are additional definitions of PH in children, including those with single ventricle physiology.
- Evolving definitions of PH utilize the principles of phenomics (genomics, transcriptomics, proteomics, and metabolomics) to redefine PH at the molecular level.

Table 33.7 Guidance for assessing operability in pulmonary arterial hypertension associated with congenital heart disease

PVRI wood units (m^2)	PVR wood units	Correctability/favorable long-term outcome
<4	<2.3	Yes
>8	>4.6	No
4–8	2.3–4.6	Individual patient evaluation in tertiary center

Special considerations include age of patient, type of defect, and comorbidities, resting or exercise-induced desaturation is a concern and PAH therapy (treat with intent-to-repair approach has not been proven).

Assessment of pulmonary hypertension

The clinical assessment of the child with PAH and CHD is aimed at differentiating those with reversible pulmonary vascular disease who are operable from those with irreversible or fixed disease. In cases that are not straightforward, it is important to put together all the clinical information without relying on one single parameter. The clinical presentation of pediatric PH is nonspecific and age-dependent. The most common presenting symptom is reduced exercise capacity accompanied by fatigue and dyspnea. Young infants may present with feeding problems and failure to thrive. Other presenting symptoms include cyanosis, cough, and chest or abdominal pain. Syncope as a presenting symptom is specific to pediatric PH and is reported in 25–30% of children with PH and is most frequent in patients without a shunt defect [18–20]. There is often a long delay between the onset of symptoms and diagnosis due to the low specificity of presenting symptoms and the rarity of the disease. Screening should take place for children belonging to high-risk groups based on underlying conditions of family members with PH.

The functional status of children and adults with PH, with respect to exercise capacity and symptoms, can be classified using the WHO Functional Classification (WHO-FC) [41]. The WHO-FC scale is based on the New York Heart Association (NYHA) classification, which evaluates symptoms including limitation of physical activity, dyspnea, fatigue, chest pain, and right heart failure. Although the WHO functional class is not designed specifically for children, it has been shown to correlate with 6-minute walk distance and hemodynamic parameters [21, 23, 24, 42]. Another scale has been developed for children, the age-adjusted Panama Functional Classification (Panama-FC) [43]. In children, both the WHO-FC and Panama-FC scales have been shown to correlate well with PH disease progression. The Panama-FC appears to be better for long-term follow-up, while the WHO-FC appears to be better for short-term monitoring, for example, after changes to treatment [44].

After a thorough history and physical examination of the patient, blood should be drawn for laboratory analysis including complete blood count, metabolic panel, coagulation profile, and biomarkers of PH. Biomarkers that specifically indicate the pathologic mechanism, the severity of the disease, and the treatment response would be ideal tools for the management of PH, but they are still the subjects of research. Anemia, hypocarbia, elevated uric acid, and C-reactive protein levels are nonspecific markers of disease severity. Brain natriuretic peptide (BNP) and N-terminal fragment of pro-BNP, which reflect the degree of atrial stretch and heart failure, are recommended for disease monitoring [45].

Noninvasive imaging for the assessment of PH includes chest X-ray, echocardiography, CT scan of the lungs, nuclear medicine ventilation perfusion scan, and magnetic resonance imaging (MRI) [46]. By the time the diagnosis of PH is made, 90% of patients have an abnormal chest X-ray, although sensitivity and specificity are low [47]. Typical features on chest X-ray include elevated cardiac apex due to RV hypertrophy, enlarged right atrium, prominent pulmonary outflow tract, enlarged pulmonary arteries, and pruning of peripheral pulmonary arteries.

Echocardiography provides information about the anatomic details of the lesion, assessment of shunt direction, and estimates of pulmonary artery pressures (PAPs) [48]. Echocardiography may support the diagnosis of PH with qualitative images of elevated RV pressure, such as RV hypertrophy and septal wall flattening. Quantitative information may be obtained on echocardiography if there is tricuspid regurgitation during systole (Figure 33.3). In this case, the modified Bernoulli equation may be applied to estimate PAP with a tricuspid regurgitant velocity of greater than 2.8 m/s being highly indicative of PH (Box 33.2) [1, 49]. Measurement of the end-systolic RV to left ventricular (LV) diameter ratio correlates with invasive measurements of the severity of PH [50]. Echocardiography can provide information on the direction of flow through a shunt. A pure left-to-right shunt across a defect indicates that the PVR is lower than the SVR. The presence of reversed or bidirectional flow across an ASD, PDA, or VSD is concerning and suggests the need for cardiac catheterization and acute vasoreactivity testing. Transthoracic echocardiography is an attractive method to assess children with PH and possibly enable the cardiologists to lengthen the interval between cardiac

AL Grawany

Box 33.2: Estimating PAP from systolic tricuspid regurgitant jet velocity on echocardiography

sPAP = systolic pulmonary artery pressure
RAP = right atrial pressure
mPAP = mean pulmonary artery pressure

Modified Bernoulli equation:

$$\text{sPAP} = 4v^2 + \text{RAP}$$

e.g. $\text{sPAP} = 4\left(2.8^2\right) + 10 = 41\ \text{mmHg}$

Converting sPAP to mPAP

$$\text{mPAP} = (0.61 \times \text{sPAP}) + 2\ \text{mmHg}$$

e.g. $\text{mPAP} = (0.61 \times 41) + 2 = 27\ \text{mmHg}$

v = tricuspid regurgitation velocity using Doppler echocardiography

catheterizations required to monitor ongoing therapy. There are many echocardiographic techniques in the research and validation phase. One technique is to monitor the RV systolic to diastolic duration ratio, in which an increase has been shown to be associated with worse RV function, exercise capability, and survival [51]. Another technique using echocardiography is to measure the degree of tricuspid annular plane systolic excursion (TAPSE), which has been shown to reflect RV function and prognosis in PH [52, 53].

MRI is being increasingly used to evaluate patients with PH. MRI allows high spatial resolution of the intracardiac structures and vasculature involved in PH pathophysiology (Figure 33.4). MRI is not constrained by body habitus and patients with poor acoustic windows and surgical scars. The unusual geometry of the RV does not preclude accurate measurements of RV volume and ejection fraction (EF). Advances in MRI have allowed detailed assessment of flow through the heart and vasculature and reflect vascular hemodynamics and vascular remodeling. Techniques such as four-dimensional flow MRI (4D-Flow MRI) provide blood velocity data in all spatial directions, which allows for flow analysis of complex hemodynamic patterns [54, 55]. An example of how this technology may be applied is shown in Figure 33.5. MRI is a promising tool to comprehensively describe the entire RV–PA axis and the involvement of the left heart. Machine learning approaches to improve automation and accuracy of MRI metrics and identify imaging features of PH are an area of active research with promising clinical utility [46, 56, 57]. The combination of MRI and direct PAP measurement via a catheter may provide more information than either test alone.

Despite advances in noninvasive imaging techniques, cardiac catheterization with vasodilator testing is necessary for diagnosis, treatment stratification, and prognosis of PH in children [58]. There are three objectives during the catheterization procedure: to obtain hemodynamic data, to test vasoreactivity, and to rule out any associated disease states. Accurate hemodynamic data are essential for the diagnosis and ongoing monitoring of patients with PH. End hole or flow-directed catheters are used to obtain hemodynamic data. Catheters with multiple side holes are used for angiography to prevent myocardial staining during injection. During catheterization, baseline measures include right atrial pressure, PAP, systemic arterial pressure, mixed venous and systemic arterial saturation, cardiac output, and PAOP. From these measures, important calculations can be made for pulmonary to systemic flow ratio ($Q_p : Q_s$) (Box 33.3) and PVR (Box 33.4) [59, 60]. It is essential that the anesthesiologist maintains stability during these periods of measurement and that the conditions under which they are made are clearly communicated. Most cardiac catheterization laboratories will

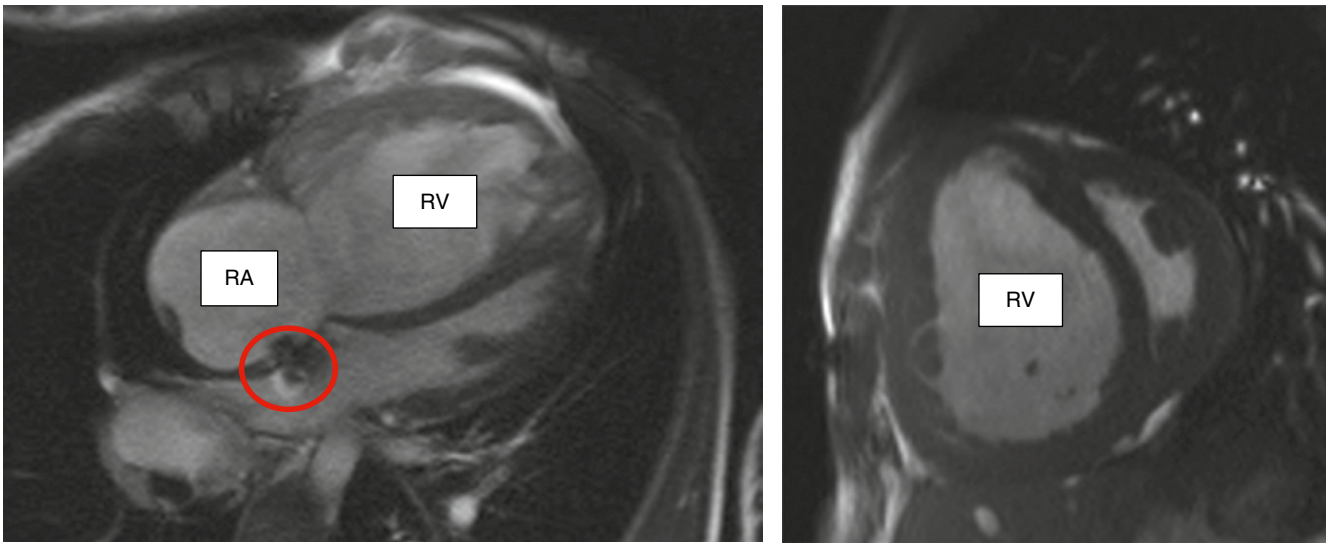

Figure 33.4 Still MRI cine images demonstrating features of pulmonary hypertension. Both images are from the same patient. Left image: this horizontal long long-axis, four four-chamber view of the heart demonstrates an enlarged right atrium (RA) and dilated right ventricle (RV). There is a stent placed in an atrial septostomy (red circle), with dephasing artifact showing bidirectional flow. Right image: this short short-axis, mid-ventricular view shows RV dilation and severe septal flattening and septal shift towards the left ventricle. (Source: Images courtesy of Dr. Richard Friesen.)

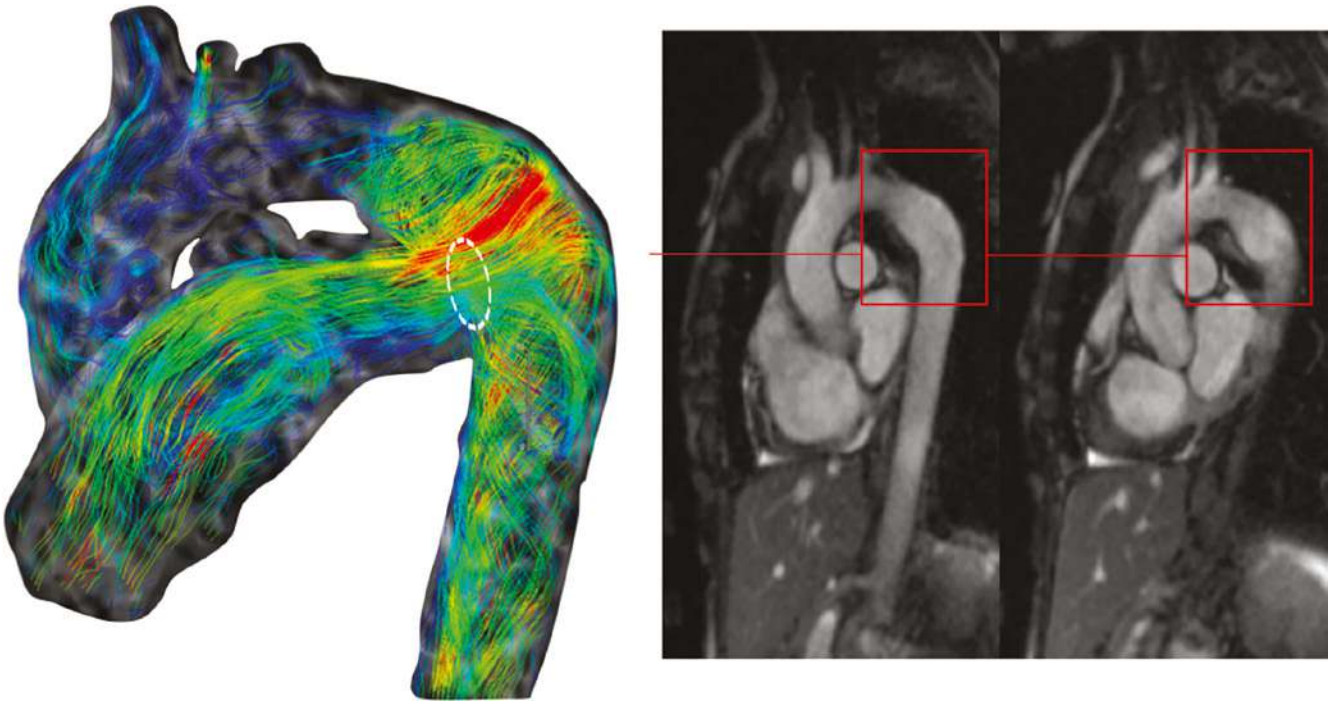

Figure 33.5 Four-dimensional flow magnetic resonance imaging (4D-Flow MRI) of a Potts shunt. Vortex formation is seen at the aortic entrance of the Potts shunt. In this region (red square), aneurysmal dilation of the aorta is demonstrated by bright blood imaging. Aneurysmal dilation in this situation has been postulated to be associated with abnormal flow hemodynamics creating localized pressure-–volume stress on the aortic wall. (Source: Schäfer et al. [55]. obtain baseline measurements in room air, followed by 70–100% oxygen and then introduce an acute vasodilator such as inhaled nitric oxide (iNO) 20–40 parts per million (ppm). In a recent review of cardiac catheterization laboratory protocols and hemodynamic data in pediatric patients with PH, general anesthesia was found to decrease systemic arterial pressure, but there was no difference between general anesthesia and procedural sedation on mPAP or PVRI. It also demonstrated that pediatric patients with PH demonstrate a higher incidence of PH associated with CHD and neonatal-specific disorders compared to adults. The review also points out that pediatric PH had baseline mPAP < 40 mmHg but was

>50% of their systemic blood pressure, illustrating the difficulty of applying adult criteria to children with PH [61].

The degree to which mPAP and PVR can be decreased acutely by the administration of fast-acting, short-duration vasodilators reflects the extent to which vascular smooth muscle constriction is contributing to the hypertensive state. The response to vasodilators has important therapeutic implications in PH, and almost all patients will undergo a vasodilator trial during their initial cardiac catheterization. Three separate situations may be evaluated with the acute vasodilator trial: potential treatment with calcium channel blockers (CCBs), assessment of operability in children with CHD, and determining prognosis. Inhaled nitric oxide at 10–80 ppm is the preferred selective pulmonary vasodilator, but intravenous epoprostenol, intravenous adenosine, or inhaled iloprost may be used as alternatives. However, optimal dosing in small children is not well defined for the latter drugs. The Sitbon criterion for a positive vasodilator response in adults is a reduction in mPAP by at least 10 mmHg, to a value of <40 mmHg, with sustained cardiac output [62]. The same Sitbon criteria are now used in children, as it has been shown that responders have a sustained benefit from CCB therapy [63]. It is estimated that 70–90% of children with severe PH are nonresponders to acute vasodilator testing and therefore require therapy other than calcium channel antagonists [8, 64]. In the cardiac catheterization lab, balloon occlusion of a shunt is the best means of demonstrating the short-term effect of shunt closure on PAP. It must be emphasized that cardiac catheterization of children with PH should be performed in experienced centers able to manage potential complications such as PH crisis requiring extracorporeal membrane oxygenation (ECMO) support [65, 66].

KEY POINTS: ASSESSMENT OF PH

- A comprehensive evaluation of patients with newly diagnosed PH is essential to determine management and prognosis.
- Cardiac catheterization with direct measurement of PAP, calculation of pulmonary vascular resistance and pulmonary vasoreactivity testing, is the gold standard for assessment. It is essential that the anesthesiologist maintains stability during these periods of measurement and that the conditions under which they are made are clearly communicated.
- Noninvasive techniques are used to monitor patients with PH including echocardiography and increasingly cardiac MRI.

Medical management of pulmonary hypertension

The factors leading to an increase in mPAP may all eventually result in increased PVR and pulmonary hypertensive vascular disease. As the pulmonary vasculature remodels in PH, there are changes that may be reactive or fixed. Reactive changes will result in vasodilation of the pulmonary vasculature to an exogenously administered pulmonary vasodilator such as iNO. Fixed changes are unreactive to such pulmonary vasodilators. As the disease processes leading to PH progress, the cross-sectional area of the pulmonary vasculature decreases according to Poiseuille's law leading to increased PVR. Poiseuille's law states that the resistance of a vessel is proportional to the fourth power of the radius. In other words, as the pulmonary arterioles develop thickening of their walls and a smaller intraluminal radius, the resistance will increase exponentially. A pulmonary hypertensive crisis is an acute on chronic increase in PVR during the perioperative period due to an acute increase in vascular tone of the reactive portion of the pulmonary vasculature. Early recognition and appropriate management of a pulmonary hypertensive crisis can be lifesaving.

The current treatment strategies for PH are aimed at three pathological processes. Vasodilators treat reactive vasoconstriction, antiproliferative drugs attenuate vascular remodeling, and anticoagulation may be used to treat and prevent thrombosis from forming in narrowed vessels. On the basis of the understanding of abnormalities of the vascular endothelium, three classes of pulmonary vascular vasodilating drugs have been studied for the treatment of PH: prostacyclin analogs, endothelin receptor antagonists

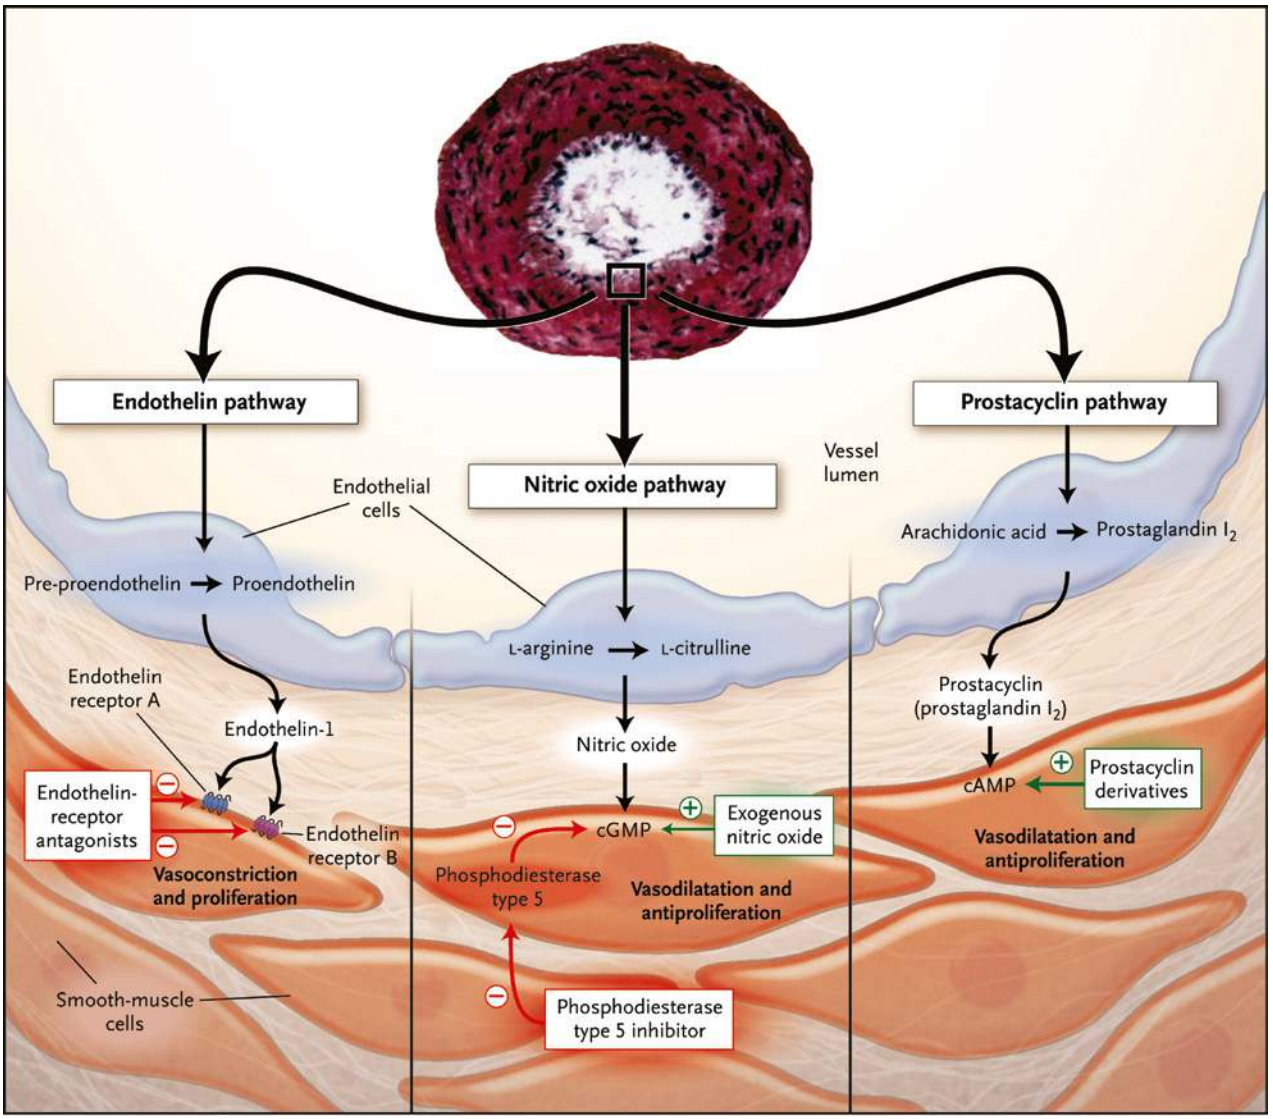

Figure 33.6 Therapeutic drug targets in pulmonary arterial hypertension. At the top of the figure, a transverse section of a small pulmonary artery from a patient with severe PAH shows intimal proliferation and medial hypertrophy. Dysfunctional pulmonary-artery endothelial cells (blue) have decreased production of prostacyclin and endogenous nitric oxide, with an increased production of endothelin-1 – a condition promoting vasoconstriction and proliferation of smooth muscle cells in the pulmonary arteries (red). (Source: Humbert et al. [67]. Reproduced with permission of Massachusetts Medical Society.)

(ERAs), and phosphodiesterase-5 inhibitors (PDE-5i; Figure 33.6) [67–69]. The beneficial effects of these drugs, including increased exercise capacity, improved quality of life, and increased survival, have been demonstrated mainly in adults. Due to the complex etiology and relative lack of data in children with PH, the selection of appropriate therapies remains difficult. A treatment algorithm based on expert opinion was proposed at the WSPH in 2018 (Figure 33.7) [9].

The ultimate management goals of PH in children are to increase survival and allow the normal activities of childhood without the need to self-limit. Supportive therapies may include the use of oxygen, anticoagulants, and digoxin. Diuretics may be used, but care should be taken not to decrease intravascular volume due to the preload dependence of the right ventricle. Although no controlled data exist, vaccination against influenza and pneumococcal disease is recommended in children and adults with PH, and respiratory syncytial virus (RSV) prophylaxis should be considered in infants with PH [70, 71].

Calcium channel blockers (CCBs)

Acute responders to vasodilator testing are treated with CCB such as amlodipine, nifedipine, and diltiazem. CCB inhibits the calcium influx through the slow channel into the cardiac and smooth muscle cells, causing relaxation of the pulmonary vascular smooth muscle. Adults with IPAH, who were acute responders to vasodilator testing and treated with CCB, showed improved 5-year survival (94%) compared to those not treated with CCB (55%) [72]. However, because CCB may have negative inotropic effects in young children, they should be avoided until the child is older than 1 year [62, 73].

AL Grawany

CCB, calcium channel blocker; ERA, endothelin receptor antagonist; IV, intravenous; PDE5i, phosphodiesterase type 5 inhibitor; SC, subcutaneous. (Source: Rosenzweig et al. [3]. Reproduced with permission of European Respiratory Society.)

Prostanoids

Patients with PH have reduced expression of prostacyclin synthetase in pulmonary arteries [74]. The prostanoids, which are prostacyclin analogs, act via cyclic AMP in the smooth muscle cell to produce vasodilation. They may also have some antiproliferative effects.

Epoprostenol (Flolan®)

This prostacyclin analog has a very short half-life (3–6 minutes) and needs to be administered continuously, usually through a permanent central venous catheter. Side effects include facial flushing, headache, jaw pain, and abdominal pain.

Treprostinil (Remodulin®, Tyvaso®)

This prostacyclin analog has a longer half-life (4–5 hours) but needs to be administered by subcutaneous injection. Pain at the injection site severely limits the use of this drug in children. For those able to tolerate frequent subcutaneous injections, the side effects are similar to epoprostenol. Other administration routes are under investigation, and the inhaled route has been shown to be effective [75–77].

Iloprost (Ventavis®)

This prostacyclin analogue is delivered by the inhaled route, and because of its short half-life (20–30 minutes), it needs to be administered six to nine times/day. This frequency of administration, in addition to the side effect of increased lower airway reactivity, has limited its use in the chronic treatment of children with PH [78].

Endothelin receptor antagonists (ERA)

Endothelin is a potent endogenous vasoconstrictor that acts via the endothelin type 1 receptor (ET). This ET receptor has two subtypes, ET_A and ET_B, which are present in pulmonary vascular smooth muscle cells, producing vasoconstriction when activated. ET_B receptors are also present in the pulmonary vascular endothelium and when activated produce vasodilation. Despite the differences in receptor subtype activity depending on location, both nonselective ET_A/ET_B receptor antagonists [*Bosentan* (Tracleer®)] and selective ET_A receptor antagonists [*Ambrisentan* (Letairis®)] are similarly effective in patients with PH. Both ERA may be administered via the oral route and require close monitoring of liver function tests.

Phosphodiesterase-5 inhibitors (PDE-5i)

Nitric oxide acts via a cyclic GMP (cGMP) pathway in the pulmonary artery smooth muscle cell to produce vasodilation. This pathway may be stimulated directly with iNO or the breakdown of cGMP may be inhibited by PDE-5i, resulting in increased cGMP and pulmonary vascular vasodilation. These inhibitors also have antiproliferative effects.

Sildenafil (Revatio®)

Sildenafil is an oral PDE-5i usually administered three times daily. Pediatric PH treatment with sildenafil has changed significantly since the STARTS 1 and 2 trials (Sildenafil in Treatment Naïve Children with PH) [79]. These trials were worldwide, randomized, double-blind, placebo-controlled studies of oral sildenafil monotherapy in low, medium, and

high doses. The studies found that functional capacity only improved with high dose sildenafil and PVR improved with medium and high dose sildenafil, but mPAP was lower only with medium dose sildenafil. However, hazard ratios for mortality were 3.95 for high versus low dose and 1.92 for medium versus low dose. Review of these data by the US Food and Drug Administration (FDA) and the European Medicines Agency (EMA) resulted in different recommendations. Sildenafil was approved for use by the EMA in 2011 with a warning on avoiding higher doses. In 2012, the FDA issued a warning against the use of all doses of sildenafil for children with PH [80, 81].

Tadalafil (Adcirca®)

Tadalafil is an oral PDE-5i that has the advantage of once daily administration. Its side effect profile is similar to sildenafil including headache, flushing, nausea, myalgia, and nasal congestion [82].

Atrial septostomy and lung transplantation

Atrial septostomy performed in the cardiac catheterization laboratory should be considered in the child with worsening PH despite optimal medical therapy. The resulting improvement in cardiac output with decompression of the right heart is at the expense of hypoxemia. Features of a high-risk patient for this procedure include high right atrial pressure and low cardiac output, both of which increase mortality 5–15% [83]. Atrial septostomy may be considered as an initial procedure or as a bridge to lung transplantation. An alternative procedure that has been described as an option for patients with severe PH is the creation of a reverse Potts Shunt. This shunt is a window created between the left pulmonary artery and the descending aorta, which equalizes the pulmonary and systemic arterial pressures (Figure 33.8) [84, 85]. The use of a reversed Potts shunt in suprasystemic PH is considered advantageous compared with atrial septostomy, as it provides high oxygen saturated blood to the coronary arteries and brain, but delivers desaturated blood to the lower body. Another benefit is hemodynamically there is relief of RV pressure overload in systole, and in part, also in diastole, with a subsequent reduction in interventricular septal shift toward the left ventricle with an improvement in LV performance. However, under conditions when the PAP falls below systemic pressure, there is a risk of reversing blood flow through the shunt, creating a left-to-right shunt which could be deleterious to the pulmonary circulation by volume loading the pulmonary arterial bed. Consequently, intermittent assessment of flow direction and patterns through the Potts anastomosis with advanced 4D-Flow MRI may help guide treatment decisions [54] (Figure 33.5). The Potts shunt may be created surgically via a sternotomy or thoracotomy or percutaneously in the cardiac catheterization laboratory. This is a very high-risk procedure with a mortality of 15% [86]. The anesthetic techniques used have been recently described and include a balanced and slowly titrated anesthetic with high-dose opioids and anesthetic agents such as etomidate and ketamine to support blood pressure. Transesophageal echocardiography is helpful to monitor cardiac function and assess the aortic flow pattern. It also helps the placement of the arterial cannula if VA-ECMO is needed emergently. Near infrared spectroscopy (NIRS) is valuable, as the difference between cerebral and renal NIRS values can indicate the adequacy of the Potts's shunt [87, 88]. The optimal timing of these procedures is unclear. End-stage options for worsening PH unresponsive to therapy are lung or heart–lung transplantation. The median survival after lung transplantation in children is 4.9 years [89]. See Chapter 32 for additional discussion of lung transplantation.

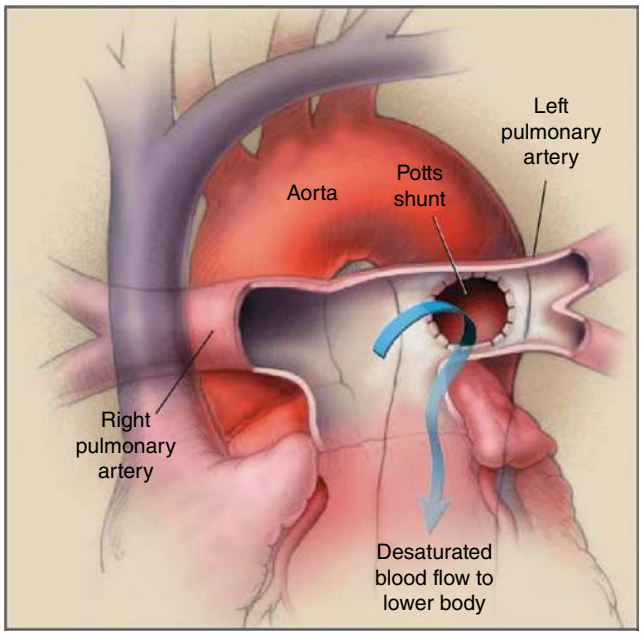

Figure 33.8 The Potts shunt procedure. The left pulmonary artery is anastomosed to the descending aorta, allowing the desaturated blood to go from the left pulmonary artery to the lower part of the body (arrow). In this drawing, the right pulmonary artery passes in front of the ascending aorta because an arterial-switch procedure had been performed in this early case report of two children who had suprasystemic pulmonary hypertension and right ventricular failure several years after an arterial switch surgery for transposition of the great arteries. (Source: Blanc et al. [84]. Reproduced with permission of Massachusetts Medical Society.)

KEY POINTS: MEDICAL MANAGEMENT OF PH

- Three classes of pulmonary vascular vasodilating drugs are available for the treatment of PH: prostacyclin analogs, ERAs, and PDE-5 inhibitors.
- CCBs are selectively used for outpatient PH treatment in patients who have a positive response during acute vasoreactivity testing.
- Inhaled nitric oxide is an effective selective pulmonary vascular vasodilator and is frequently used in the perioperative management of patients with PH.
- End-stage management strategies include atrial septostomy, a reverse Potts shunt and lung transplant.

AL Grawany

Perioperative risk considerations

Children with PH are at risk of experiencing major perioperative cardiovascular adverse events, including cardiac arrest and death. Data from the Pediatric Perioperative Cardiac Arrest (POCA) registry suggest that a benchmark estimate of the incidence of perioperative cardiac arrest in all pediatric patients is 0.014% [90]. In comparison, children with PH experienced an incidence of perioperative cardiac arrest of 1.6% associated with all types of procedures and 10% associated with major surgical procedures, including cardiac surgery [91]. In a report of anesthesia-related mortality in children, PH was found to be present in half of the deaths [92]. Preoperative PH has been shown to be a significant contributor to perioperative death associated with pediatric open cardiac surgery [93].

The presence of PH also adds significantly to perioperative risk in children undergoing cardiac catheterization (Table 33.8). The incidence of cardiac arrest among all children undergoing cardiac catheterization was reported to be 0.45% [94] and 0.96% [95]. This incidence increased significantly when only children with PH undergoing cardiac catheterization were considered, with reports of 0.8% [91], 1.2% [66], 2.9% [97], and 5.7% [98].

Major complications are directly associated with the severity of PH, with suprasystemic PH patients experiencing a disproportionally greater incidence than those with systemic or subsystemic PH (Figure 33.9) [66, 96, 97, 99]. Factors contributing to perioperative risk in children with PH can be categorized into hemodynamic factors, patient factors, procedural factors, and anesthetic factors [100]. These are multiple, interactive, and additive (Table 33.9).

Table 33.8 Estimated incidence of perioperative cardiac arrest and death in children with pulmonary hypertension (PH) compared with all children

Population (reference)	Procedures (*n*)	Cardiac arrest (%)	Death (%)
All children [90]	All types (1,089,200)	0.014	0.004
Children with heart disease [94]	Cardiac catheterization (4,454)	0.49	0.08
Children with heart disease [95]	Cardiac catheterization (7,289)	0.96	0.05

Children with PH [91]	Major surgery (20)	10	0

Pulmonary hypertensive crisis

Cardiac arrest in children with PH is often immediately preceded by an acute pulmonary hypertensive crisis, in which an acute increase in PVR leads to RV failure and a decrease in cardiac output. The right ventricle dilates and encroaches on the left ventricle, thus decreasing LV stroke volume, cardiac output, and mean systemic arterial pressure (MAP). Systemic hypotension then causes a decrease in coronary perfusion pressure, which exacerbates RV failure and causes biventricular ischemia. Monitors will demonstrate an increase in PAP accompanied by decreases in SpO_2 and systemic blood pressure due to inadequate pulmonary blood flow and left heart filling. The self-perpetuating cycle of biventricular failure associated with a pulmonary hypertensive crisis is illustrated in Figure 33.10.

A pulmonary hypertensive crisis can be triggered by several stimuli that directly affect PVR or ventricular function (Box 33.5). The best known stimuli of increased PVR are hypoxia and acidosis, as demonstrated by the classic work of Rudolph (Figure 33.11) [101]. Subsequent confirmatory investigations have shown that low alveolar oxygen tension (P_AO_2) and respiratory acidosis due to hypercarbia are significant stimuli for pulmonary vasoconstriction (Figure 33.12) [102, 103]. Noxious tracheal stimulation is another known factor, as tracheal suctioning in the postoperative intensive care unit triggered a 70% increase in PVR and PAP in children with a history of PH [104]. Systemic hypotension caused by a decrease in SVR, stroke volume, or myocardial contractility can lead to inadequate coronary perfusion and RV ischemia and failure, thus triggering a pulmonary hypertensive crisis at another point in the cycle.

Box 33.5: Triggering stimuli for perioperative pulmonary hypertensive crisis

- Hypoxia
- Acidosis
- Hypercarbia
- Noxious stimuli: pain, tracheal suctioning, agitation
- Hypotension

Treatment of a pulmonary hypertensive crisis is directed toward ameliorating the stimulating event and stabilizing hemodynamics (Table 33.10). Moderate hyperventilation with 100% oxygen, treatment of both respiratory and metabolic acidosis, and removal or attenuation of precipitating stimuli should be undertaken. An inhaled pulmonary vasodilator should be administered. Acute intravenous administration of pulmonary vasodilators can be associated with systemic hypotension, which may worsen coronary perfusion, so CCBs, sildenafil, and magnesium are generally not indicated for emergency treatment. Furthermore, pulmonary

Table 33.10 Treatment of a pulmonary hypertensive crisis

Treatment	Rationale
Administer 100% O_2	↑ P_AO_2 and P_aO_2 can ↓ PVR
Hyperventilate	PVR is directly related to P_aCO_2
Exclude pneumothorax	Optimize ventilation
↓ Mean airway pressure	Avoid $P_{alv} > P_{art}$
Correct metabolic acidosis	PVR is directly related to H^+ level
Administer pulmonary vasodilators	iNO
Support cardiac output	Adequate preload and inotropic support, ECMO
Support coronary perfusion	Maintain SVR with epinephrine or vasopressin
Analgesia	Decrease sensory/sympathetic mediated ↑ PVR

P_AO_2, alveolar oxygen pressure; P_aO_2, arterial oxygen pressure; PVR, pulmonary vascular resistance; P_aCO_2, arterial carbon dioxide pressure; P_{alv}, alveolar pressure; P_{art}, arterial pressure; H^+, hydrogen ion; iNO, inhaled nitric oxide; ECMO, extracorporeal membrane oxygenation; SVR, systemic vascular resistance.

hypertensive crises have been observed to follow initiation of treatment of PH with intravenous prostacyclin analogs. Therefore, it is preferable in an urgent setting to administer pulmonary vasodilators by inhalation. This reduces the risk of systemic hypotension and coronary hypoperfusion by delivering the drug to the target pulmonary vasculature. In addition, the delivery of inhaled pulmonary vasodilators to well-ventilated regions of the lung may benefit oxygenation by improving ventilation/perfusion matching. The standard for inhaled pulmonary vasodilators is iNO, but inhaled prostacyclin analogs, especially iloprost, are also effective in this and similar settings [76, 105, 106].

Early treatment of bradycardia with atropine or another chronotropic drug can be helpful. If systemic hypotension persists following administration of pulmonary vasodilators, inotropic support is indicated. Epinephrine infusion is a good choice for inotropic support during emergent treatment of a pulmonary hypertensive crisis because it will improve ventricular function and raise MAP while reducing the PVR/SVR ratio [107, 108]. Other inotropic drugs have potential disadvantages in this clinical situation. Dopamine can increase the PVR/SVR ratio [107, 109]. Dobutamine can decrease SVR (and coronary perfusion), as can loading doses of milrinone and levosimendan, often requiring coadministration of a vasopressor.

In addition to inotropic support, a systemic vasopressor can improve coronary perfusion and ventricular function by supporting SVR and may avert cardiac arrest. For this purpose, arginine vasopressin and its synthetic analog, terlipressin, which increase SVR but not PVR [110–112], are preferable to phenylephrine, which is both a pulmonary and systemic vasoconstrictor [110, 113]. Although norepinephrine is used less frequently in children, its pressor effects are favorable, as MAP is increased while the PVR/SVR and PAP/SAP ratios are decreased [113–115].

Once the cycle of increased PVR and decreased ventricular function begins, however, cardiac arrest may be difficult to prevent. If cardiac arrest occurs, Pediatric Advanced Life Support guidelines for cardiopulmonary resuscitation should be followed [116]. Cardiac arrest associated with a pulmonary hypertensive crisis can be difficult to treat, and emergent use of ECMO may be necessary [117]. If emergent ECMO is required, improved outcomes are associated with shorter duration of cardiopulmonary resuscitation prior to ECMO [118], so an institutional protocol that anticipates the need for emergent ECMO in these situations is desirable.

KEY POINTS: PERIOPERATIVE RISK

- Children with PH are at increased risk of cardiac arrest and death under anesthesia. Those with suprasystemic PH are at greatest risk.
- Acute pulmonary hypertensive crisis is life-threatening, creating a cycle of ventricular failure, hypoxia, and cardiac ischemia. Triggering stimuli should be avoided, and treatment immediately started.
- Institutions caring for patients with severe PH should have experience in the emergent use of ECMO in these patients.

Anesthetic management

Anesthetic management of the child with PH requires thoughtful preparation regarding the choice of anesthetic drugs, airway management, avoidance of triggering stimuli, prophylactic pulmonary vasodilators, and appropriate monitoring (Box 33.6).

Hemodynamic effects of anesthetic drugs

The ideal anesthetic drug for children with PH would have pulmonary vasodilating effects, would not depress cardiac contractility, would maintain SVR and cardiac output, and would be short lasting and easy to titrate. Such an anesthetic

Box 33.6: Anesthetic management of the child with pulmonary hypertension

- Perioperative inhaled selective pulmonary vasodilator
- Avoid triggers of pulmonary hypertensive crisis
- Balanced anesthetic technique
- Airway and ventilatory support as appropriate for procedure
- Appropriate monitoring

[b] Dexmedetomidine can increase MAP during loading dose administration.

agent, unfortunately, does not exist. Most anesthetics are associated with undesirable hemodynamic effects – depending on dose and speed of administration – by altering heart rate or rhythm, cardiac contractility, SVR, or PVR. Significant hypotension can be observed during the induction period when peak plasma concentrations of anesthetic drugs are present, often requiring vasopressor treatment in patients with severe PH [119]. The cardiovascular effects of anesthetic drugs are discussed in detail in another chapter, but the effects pertinent to a discussion of PH are summarized in Table 33.11 and as follows:

Volatile anesthetics cause a dose-dependent depression of cardiac contractility and a decrease of SVR [120, 121]. These generally undesired effects are usually manageable during anesthesia for children with PH when it is appreciated that they vary among the volatile anesthetics and are dose dependent. Halothane causes greater depression of contractility than the newer anesthetics, while isoflurane and halothane cause a greater decrease of SVR. Furthermore, there is evidence that the volatile anesthetics are associated with a decrease in PVR. They attenuate hypoxic pulmonary vasoconstriction during one-lung ventilation [122], and $Q_p : Q_s$ remains unchanged in children with cardiac septal defects in response to halothane, sevoflurane, and isoflurane [123]. Thus, judicious use of volatile anesthetics is an important part of a balanced anesthetic in children with PH.

Propofol causes dose-dependent depression of cardiac contractility [124]. In both adults and children with cardiac disease, propofol is associated with a marked decrease in SVR and MAP and a slight decrease in PVR and PAP [125, 126]. In adults with artificial hearts, propofol causes vasodilation of systemic resistance and capacitance vessels and a decrease in PAP) [127]. The hypotension associated with propofol can lead to decreased coronary perfusion of the hypertrophic right ventricle, so propofol should be used with caution in children with PH.

While *ketamine* is quite supportive of hemodynamic stability and is frequently recommended as an anesthetic of choice in patients with cardiovascular impairment or instability, its use in patients with PH has been debated because of conflicting results of studies conducted under a variety of conditions [128]. A marked increase in PAP and PVR has been observed during ketamine anesthesia in children with PH breathing room air through the natural airway [129–131]. On the other hand, no change in PAP or PVR has been observed in response to ketamine in children with PH during controlled ventilation or while receiving a pulmonary vasodilator, such as oxygen or sevoflurane [132, 133]. Under controlled airway and ventilation conditions in room air without coadministration of pulmonary vasodilating anesthetics, ketamine was not associated with significant changes in pulmonary hemodynamics in children with PH [134]. A meta-analysis of several studies concluded that ketamine has minimal hemodynamic effects in children with CHD and/or PH [135]. Judicious use of ketamine, therefore, has a place in a balanced anesthetic for children with PH.

Etomidate is known to support systemic hemodynamics in children undergoing cardiac catheterization [136, 137], but studies of its effect on pulmonary hemodynamics are rare. A study of adults with cardiac disease demonstrated minimal effects on PAP [138], while a pediatric study demonstrated a 28% increase in PVR [137].

Dexmedetomidine is associated with acutely decreased HR and increased MAP and SVR, followed over time by a slightly lower but generally stable MAP [139–141]. These changes appear to be dose-dependent. Despite the early significant increase in SVR, a pulmonary vasoconstrictor response was not observed in children with PH who were chronically treated with pulmonary vasodilators [141]. Information regarding dexmedetomidine use in children with severe, untreated, or unstable PH is lacking.

Opioids can be associated with a decrease in HR but otherwise have minimal hemodynamic effects. PVR remains unchanged in response to fentanyl, and pulmonary vascular responses to remifentanil are clinically insignificant in adults with artificial hearts [142, 143]. Furthermore, the increase of PVR in response to noxious stimulation can be prevented by moderately large doses of fentanyl [104]. The opioids, particularly fentanyl and remifentanil, are an important part of the anesthetic management of children with PH.

Midazolam is associated with minimal hemodynamic effects and exerts clinically insignificant effects on the pulmonary vasculature of adults with cardiac disease [144]. Midazolam's sedative and amnestic effects make it an important component of a balanced anesthetic in children with PH.

In order to minimize the undesired hemodynamic effects of a full anesthetic dose of a single anesthetic drug, it is preferable to utilize a balanced anesthetic technique. Balanced administration of subanesthetic doses of several anesthetics can achieve an adequate depth of anesthesia without the

AL Grawany

marked hemodynamic changes that can be associated with a high dose of a single drug. The authors generally employ midazolam, fentanyl or remifentanil, and sevoflurane or isoflurane for most procedures. High doses of fentanyl can be used for major operations if postoperative tracheal extubation is not anticipated. Judicious use of propofol at low-infusion rates can be considered, but its administration should be undertaken with caution because its depression of SVR is not short-lived. Low to moderate doses of ketamine and dexmedetomidine have been used successfully.

Sometimes, systemic hypotension can be observed despite a balanced technique, especially in children who are hypovolemic. In children with hypertrophic right ventricles, hypotension can lead to decreased coronary perfusion and acute RV failure. Judicious use of a vasoconstrictor such as epinephrine or vasopressin, therefore, can be useful when hypotension is encountered intraoperatively.

Perioperative pulmonary vasodilators

In addition to the administration of a balanced anesthetic technique and the avoidance of triggering stimuli, the risk of intraoperative pulmonary hypertensive crisis or cardiac arrest can be reduced by perioperative treatment with pulmonary vasodilator therapy. The odds ratio for children with PH to develop a major perioperative complication was only 0.31 in those who were chronically treated with a pulmonary vasodilator preoperatively [91]. When providing anesthetic care for noncardiac surgery to children with severe PH (systemic or suprasystemic) or those not treated with chronic pulmonary vasodilator therapy, the authors administer iNO perioperatively from induction of anesthesia through recovery. The iNO is delivered at a dose of 20–40 ppm through the inspiratory limb of the breathing circuit; postoperatively, it can be administered via face mask or nasal cannulae [145] and weaned in the postanesthesia care unit. Alternative methods of generating and delivering iNO are under development to improve cost and ease of administration [146, 147].

Inhaled selective pulmonary vasodilators are preferred for perioperative prophylaxis because they deliver drug selectively to the pulmonary vascular bed, thus avoiding the systemic hypotension that can occur with acute intravenous or oral administration of nonselective pulmonary vasodilators. Trials of oral sildenafil for perioperative prophylaxis in patients with PH have had mixed results [148–150]. On the other hand, intraoperative administration of inhaled aerosolized pulmonary vasodilators improved right heart hemodynamics in PH patients better than did intravenously administered pulmonary vasodilators [151]. In addition to iNO, other pulmonary vasodilators that have been shown to be effective when administered selectively by inhalation include the prostacyclin analogs epoprostenol [152], iloprost [153, 154], and treprostinil [77], the phosphodiesterase inhibitor milrinone [155], and the nitric oxide donor nitroglycerin [155]. Of these, iloprost has emerged as a reasonable alternative to iNO for prophylactic perioperative inhaled drug therapy for children with PH [105, 106].

One caveat regarding pulmonary vasodilator therapy is that in patients whose PH is caused by congenital postcapillary obstructive lesions (Group 2.4 of the 2018 Pulmonary Hypertension Classification), as shown in Table 33.2. Pulmonary vein stenosis, which has a very poor prognosis, is emerging as an important cause of sustained PH, especially in the setting of ex-premature infants with BPD) [156]. Administration of a pulmonary vasodilator can dilate the pulmonary arteries without relieving the obstruction to flow, thereby causing acute pulmonary edema and clinical deterioration. However, there is some limited evidence that iNO has improved pulmonary hemodynamics in select patients following interventional balloon dilation of pulmonary vein stenosis [157]. Another caveat regarding iNO use is that rebound PH following weaning of iNO can occasionally occur, especially after prolonged administration or a severe pulmonary hypertensive episode, and may require treatment with another vasodilator to facilitate weaning [158, 159].

Airway and ventilation management

Airway management techniques by the anesthesiologist are chosen as appropriate for the surgical procedure. Although case reports have described pulmonary hypertensive crises in association with tracheal intubation [160, 161], the reports suggest that the patients were either inadequately anesthetized or that the intubation occurred after hemodynamic deterioration had begun. When used alone, intravenous fentanyl 25 mcg/kg attenuates the significant increase in PAP and PVR in response to tracheal suctioning or intubation in children with PH [104, 160]. In the authors' experience, a balanced general anesthetic employing remifentanil or a lower dose of fentanyl as a component will achieve the same goal. The incidence of complications in children with PH undergoing noncardiac surgery or cardiac catheterization was found to be independent of the method of airway management (natural airway, laryngeal mask airway, or endotracheal tube) [66, 97]. Tracheal intubation was preferred in a study of children with PH undergoing noncardiac procedures [96]. Therefore, with adequate topical and general anesthesia, the authors do not hesitate to intubate the trachea when indicated for the surgical procedure or condition of the patient and believe that intubation provides the important benefit of control of the airway and ventilation.

Alternatively, airway management with a face mask, laryngeal mask airway, or the natural airway (with end-tidal CO_2 monitoring via nasal cannula) can be employed when indicated and appropriate for the procedure. It should be remembered that hypoxia and hypercarbia can trigger a pulmonary hypertensive crisis and that airway obstruction or hypoventilation can occur during some sedative and anesthetic management techniques [162]. Thus, the anesthesiologist should consider all options for airway access and ventilatory management.

Ventilatory support should be provided as needed with the goals of maintaining appropriate lung volumes and blood gases. PVR is increased at both very small and very large lung volumes and is lowest at functional residual capacity (Figure 33.13) [163]. Prevention of atelectasis by keeping lung volumes above closing capacity and avoidance of excessive tidal volume are, therefore, both important. Since PVR increases during alveolar hypoxia, hypoxemia, and acidosis, normal blood gases should be maintained with appropriate ventilatory and airway management. Factors that increase RV afterload, such as high PEEP, one-lung

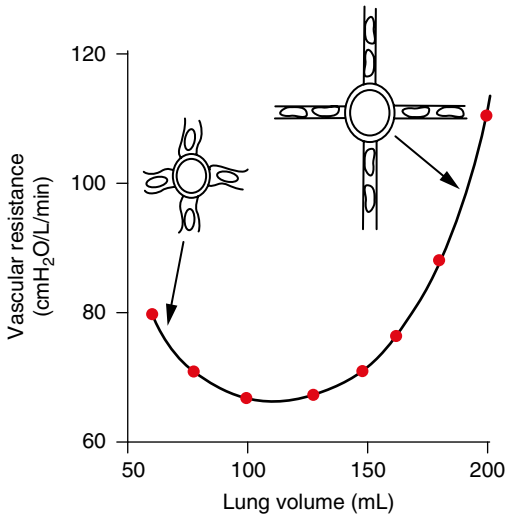

Figure 33.13 Pulmonary vascular resistance (PVR) increases in association with very small and very large lung volumes. At low volumes, PVR is high because the extra-alveolar vessels become narrow. At high volumes, the capillaries are stretched, and their caliber is reduced. (Source: West [163]. Reproduced with permission of Wolters Kluwer Health, Inc.)

ventilation, patient position, and surgical manipulation, should be anticipated and minimized [164].

Monitoring

The American Society of Anesthesiologist guidelines for intraoperative monitoring should be followed. Invasive monitors are used as appropriate for the patient's status and planned procedure. Despite the known risks of pulmonary artery catheters, they provide valuable hemodynamic information, and limited evidence supports their use during major surgical procedures and intensive care of children with PH [165, 166].

Echocardiography offers noninvasive assessment of patients with PH, and both transthoracic and transesophageal echocardiography have been utilized as intraoperative monitors. Estimation of RV systolic pressure can be made by applying Bernoulli's equation to measurement of the tricuspid valve regurgitant jet velocity (Figure 33.3; Box 33.2). The extent of RV dilation and right-to-left interventricular septal shift, as well as biventricular function, can be readily assessed subjectively (Figure 33.14). This is important, as greater RV encroachment on LV volume is associated with greater risk of perioperative adverse events in children with PH [97].

Postanesthesia disposition

The high risk of major cardiovascular adverse events associated with PH continues during the postoperative period [96, 167]. Therapeutic or prophylactic drugs administered intraoperatively, such as iNO and oxygen, should be continued postoperatively and weaned gradually, as the child awakens and remains stable. The possibility of rebound PH following weaning of iNO, especially after prolonged administration or a severe pulmonary hypertensive episode,

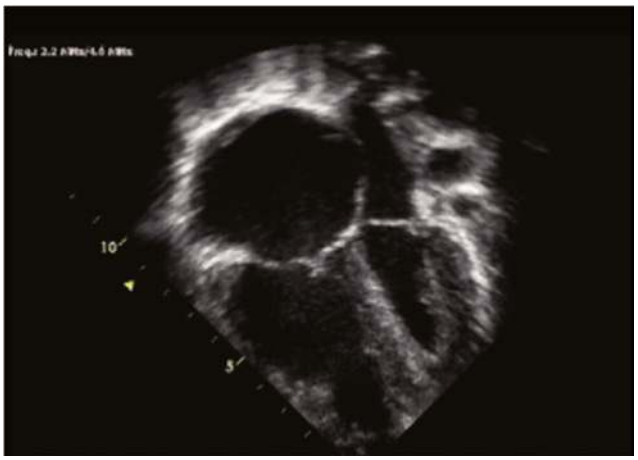

Figure 33.14 The leftward shift of the interventricular septum due to right ventricular dilation causes a reduction in left ventricular stroke volume. (Source: Figure supplied by Dr. Mark Twite and Dr. Robert Friesen.)

should be kept in mind. All precautions should be taken to avoid hypoxemia, hypotension, and hypovolemia. Control of postoperative pain and nausea should be effective. Evidence-based guidelines for postanesthetic disposition of PH patients are lacking, but a proposal based on patient, procedural, and anesthetic risk factors has been offered [168]. Higher risk patients (e.g. systemic or suprasystemic PH, impaired RV function, major surgical procedure, unstable) are admitted directly to the ICU. Lower risk patients (e.g. subsystemic PH, uneventful intraoperative course, minor procedure) can be admitted to the PACU. Following recovery from anesthesia, stable patients in the PACU who have undergone minor procedures without complications can be discharged. It is advisable to admit others to a monitored bed where rapid medical response is possible. There is subjectivity in these decisions; when in doubt, err on the side of safety.

KEY POINTS: ANESTHETIC MANAGEMENT OF PH

- Anesthetic management requires thoughtful preparation regarding the choice of anesthetic drugs, airway management, avoidance of triggering stimuli, prophylactic pulmonary vasodilators, and appropriate monitoring.
- There is no single ideal anesthetic agent for patients with PH. Instead, a balanced anesthetic technique should be adopted using several anesthetic agents to avoid adverse hemodynamic effects.
- The high risk of major cardiovascular adverse events associated with PH continues during the postoperative period. During recovery, all precautions should be taken to avoid hypoxia, hypercarbia, and hypotension, and the control of pain and nausea should be adequate. Final disposition, whether it is being discharged home or admitted to a monitored bed or the ICU should be decided based on individual patient, procedural, and anesthetic risk factors.

Conclusions

PH is a common occurrence in patients with CHD, and it also affects many other children, especially those born prematurely with underdeveloped lungs and patients with other causes of chronic hypoxia. Idiopathic and inherited forms of PH are less common. Recent advances in the understanding of pathophysiology, classification, and medical therapy have led to increased survival in this population. Many of these children should be cared for by congenital cardiac anesthesiologists who are familiar with the pathophysiology of PH and the increased risk of anesthesia in this population. Anesthetic management requires thoughtful preparation regarding the choice of anesthetic drugs, airway management, avoidance of triggering stimuli, prophylactic pulmonary vasodilators, appropriate monitoring, the use of a balanced anesthetic technique, and the ability to rescue the patient during a pulmonary hypertensive crisis. The patient should be monitored closely in an appropriate location after their procedure.

Introduction

Few areas in the field of congenital heart disease (CHD) have evolved as rapidly as the discipline of cardiac catheterization. Lesions that were previously managed with surgical intervention alone or considered inoperable altogether are now treated in the cardiac catheterization laboratory (CCL), with benefits ranging from increased survival to decreased morbidity and lengths of stay. Coincident with these advances, however, have been increases in patient acuity and complexity as well as procedural risk. For the anesthesia team, these changes have underscored the need for risk assessment and preprocedural planning to prevent adverse events, and further, awareness regarding procedure-specific complications and their management. These aspects of anesthetic care are a focus of this chapter and are presented both generally and within the context of individual procedures that may be encountered in the modern CCL.

Diagnostic catheterization

Cardiac catheterizations purely for diagnostic purposes have decreased over the years due to advances in noninvasive imaging. Nonetheless, diagnostic cardiac catheterization remains an important tool in the evaluation of the anatomy and physiology of many patients with CHD. Common indications are as follows [1]:

- To measure intravascular pressures and derive hemodynamic information, such as pulmonary vascular resistance (PVR), systemic vascular resistance (SVR), shunt fractions ($Q_p : Q_s$), and cardiac output. Such information is necessary in the assessment of pulmonary hypertension (PH), pretransplant candidacy in children with end-stage heart disease, and the suitability for progression to the next stage of single-ventricle palliation (e.g., bidirectional Glenn or Fontan) (see Figure 34.1) [2]
- To evaluate the effects of drugs (e.g., inhaled nitric oxide [iNO]) and respiratory interventions (increasing FiO_2) on PVR in patients with PH
- To provide further anatomic definition when noninvasive imaging is inadequate. Examples include the evaluation of coronary artery anomalies or major aortopulmonary collaterals (MAPCAs)
- To perform hemodynamic assessment, endomyocardial biopsies, and coronary artery angiography as part of routine surveillance following heart transplantation. Endomyocardial biopsy is also used in the diagnosis of cardiomyopathy and viral myocarditis
- To distinguish between the diagnoses of constrictive pericarditis and restrictive cardiomyopathy

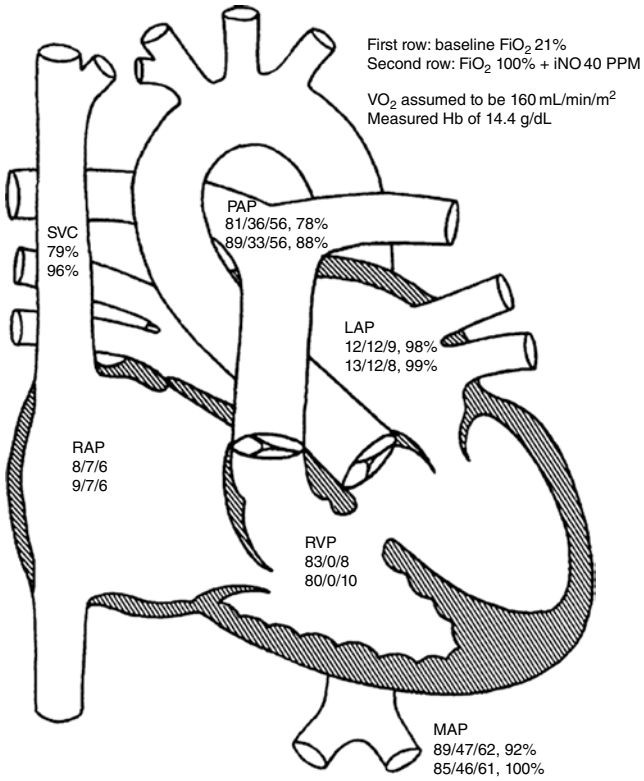

Figure 34.1 Diagnostic catheterization in a child with pulmonary hypertension. A 4-year-old child with a late diagnosis of perimembranous VSD and subsequent pulmonary hypertension presented for hemodynamic evaluation to assess candidacy for VSD closure. Measurements were taken on room air and subsequently on 100% FiO_2 and inhaled nitric oxide as part of acute vasodilatory testing (AVT). At baseline, $Q_p : Q_s$ was 0.65 : 1, indicating right-to-left shunting at the VSD, and PVRi was 11.4 Wood units/m^2. With AVT, no decrement in PAP or PVRi was noted. Surgical closure was therefore deferred and therapy for pulmonary hypertension was initiated with plans to reassess PVR in 6 months. LAP, left atrial pressure; MAP, mean arterial pressure; PAP, pulmonary artery pressure; PPM, parts per million; PVRi, pulmonary vascular resistance indexed to body surface area; RAP, right atrial pressure; RVP, right ventricle; SVC, superior vena cava; VO_2, oxygen consumption; VSD, ventricular septal defect. - To assist in the management and decision-making for complex CHD, either preoperatively or postoperatively (e.g., the postoperative Fontan with persistent pleural effusions without clear etiology, or the evaluation of the coronary arteries in a patient with severely depressed function following an arterial switch)
- To confirm the need for a planned intervention and assess the efficacy of the intervention once performed (e.g., closure of a cardiovascular communication)

As implied, the results of diagnostic catheterizations can have an outsized impact on the management strategy for a given patient. For example, the PVR calculation in a child presenting for a cardiac transplant evaluation may determine whether or not the child is eligible for transplantation. These stakes underscore the need to ensure that the hemodynamic variables being measured are as representative of the patient's baseline physiology as possible. For the anesthesiologist, an understanding of how airway management, common anesthetics, oxygenation, and ventilation can affect these measurements is critical (see Anesthetic techniques). A general strategy to approximate baseline physiology is to conduct the anesthetic on room air with normal ventilation while maintaining an age-appropriate blood pressure and heart rate. For patients who need oxygen (or who are on oxygen at baseline), the higher partial pressure of oxygen is accounted for in calculations of flows and resistances.

Procedure overview

The vessels most commonly accessed are the femoral vein and femoral artery. The femoral artery can be used solely for blood pressure monitoring or to evaluate the coronaries, left ventricular end-diastolic pressure (LVEDP), or MAPCAs as indicated. The internal jugular vein may be used to access the pulmonary arteries (PAs) in patients with Glenn or hemi-Fontan circulations or to facilitate procurement of endomyocardial biopsy specimens in biventricular hearts. Alternative venous approaches, such as transhepatic or transsplenic, may be indicated in children with a history of occlusions at other sites and are associated with increased risks of bleeding.

Following access, pressures and oxygen saturations are obtained in sequence throughout the cardiac, PA, and systemic arterial circulations (see Table 34.1 for normal parameters). These values are then used to calculate shunts (if present), flows (Q_p and Q_s), and resistances (PVR and SVR; see Table 34.2 for calculations). Stable hemodynamics along with constant oxygenation and ventilation (room air and normocapnea if possible) are essential during the sampling of these values.

Flows in children are most often calculated using the Fick principle, which relates oxygen consumption (VO_2) to flow. VO_2 in this equation can be measured directly using respiratory mass spectrometry or estimated using nomograms based on age, sex, and heart rate [3]. Due to ease, estimations of VO_2 are most commonly used, but by virtue of being estimations, they may introduce important error in the calculations of flow and resistance [4–9]. For example, if the estimated VO_2 is significantly higher than actual VO_2, the resulting cardiac output will be overestimated, while the calculated resistances will be underestimated.

Endomyocardial biopsy

The majority of patients undergoing endomyocardial biopsy do so uneventfully, using either general anesthesia with an artificial airway or sedation with a natural one. Certain high-risk patients, however, warrant discussion, including (i) children less than 6 months of age and less than 8 kg who due to their small size are at increased risk of complications such as ventricular perforation and significant arrhythmias [10], (ii) heart transplant patients with an active concern for rejection or a history of coronary allograft vasculopathy (CAV), and (iii) patients otherwise being evaluated for myocarditis. Children with active rejection or myocarditis may have severely depressed function with coinciding arrhythmias due to myocardial irritability. The process of placing catheters within the heart and taking biopsy specimens can further exacerbate or prompt new arrhythmias. Because of tissue friability, these patients may also be at increased risk of

myocardial perforation and tamponade. Preparation should be commensurate with the above risks and entail plans to resuscitate in the event of hemodynamic decompensation (including discussions of extracorporeal membrane oxygenation [ECMO] or prophylactic placement of percutaneous left ventricular (LV) support as a bridge to recovery). If sedation is chosen as the anesthetic technique, one should be prepared as always to escalate to general endotracheal anesthesia (GETA). Of note, in heart transplant patients with signs of heart block and/or rejection, the use of dexmedetomidine may provoke a significant bradyarrhythmia [11]. Attention to the patient's baseline electrocardiogram (EKG) and risk for heart block can inform the decision of whether or not to use this drug (see section on Anesthetic drugs). The use of dexmedetomidine in a heart transplant patient has also been associated with impaired metabolism of tacrolimus resulting in supratherapeutic levels [12]. Though not immediately relevant to anesthetic management, this risk may indicate the need for more frequent monitoring of tacrolimus levels in the postprocedural period.

CAV, or transplant coronary artery disease, is marked by the progressive obliteration of the graft's coronary vasculature and is a result of immunologic and nonimmunologic factors [1, 13]. Due to the variable reinnervation of the transplanted heart, angina may not occur to warn of its presence, and CAV may only be diagnosed incidentally during the patient's annual coronary angiography (Figure 34.2). Risk factors for CAV include rejection within the first-year post-transplant and increasing graft age [13]. Adolescents are at greatest risk, with only 50% remaining CAV free at 10 years post-transplant [14]. The patient who should raise one's concern for CAV would be a teenager several years out from transplant who on prior catheterizations had unexplained hypotension or an elevated right ventricular end-diastolic pressure (RVEDP) (potentially indicative of microvascular disease). In patients with known CAV, graft survival decreases to 50% at 5 years postdiagnosis [14]. As in any patient at risk for myocardial ischemia, anesthetic goals focus on minimizing myocardial oxygen consumption and maximizing oxygen delivery. Hypotension should be diligently avoided.

Pulmonary hypertension study

Right heart catheterization (RHC) remains the gold standard to diagnose and characterize PH, assess the response to AVT, and provide data to guide risk stratification [15] (see Table 34.3). Data is obtained at baseline (or rest) and with AVT. AVT is performed to determine the effect of pulmonary vasodilators on PVR. Protocols and the exact pulmonary vasodilators used vary, but a common process is to deliver a FiO_2 of 1.0 followed by iNO at 40 parts per million (PPM) [16]. A positive response is defined as a decrease in mean pulmonary arterial pressure (mPAP) by 10 mmHg without a fall in cardiac output [15]. The presence or absence of a response directs pharmacologic therapy and is prognostic [15, 17]. In patients with CHD with an intracardiac shunt (e.g., an older child with a large ventricular septal defect [VSD] and bidirectional shunting on echocardiography), a decrease in PVR with AVT can influence decision-making on whether or not to attempt closure (see Figure 34.1).

The utility of this data, however, needs to be weighed against procedural and anesthetic risks. Adverse events in children with PH undergoing catheterization range from 2 to 14%, with an incidence of cardiac arrest between 0.8 and 5.7% and mortality between 0 and 1.4% [18–28]. Those at greatest risk include ages <5 months and those with systemic-to-suprasystemic PAP [28, 29]. Children with newly diagnosed PH, depressed RV function (regardless of the estimated PAP on transthoracic echocardiography [TEE]), poor functional status, and need for preprocedural vasoactive and/or respiratory support represent another highly concerning group [30] (Table 34.4). In such patients, the risks of catheterization likely exceed its benefits, and empiric therapy with PH agents may be indicated to provide stability before proceeding. Decisions regarding the timing of catheterization are thus critical to minimizing risk and underscore the need for anesthesia involvement in coordinating with the pediatric PH and catheterization teams.

Coincident with decreasing risk is the maintenance of preprocedural PH therapy. Patients on oral agents are instructed

to take them as scheduled, including the day of the procedure. Caveats include children on iNO prior to catheterization and those on subcutaneous (SQ) infusions of treprostinil. The preprocedural use of iNO is an indicator of illness severity; however, it may be requested that iNO be turned off during the catheterization to establish baseline conditions. Doing so may induce a PH crisis, however, and is not advised in the critically ill patient. If this is nonetheless thought to be necessary, the process of decreasing iNO should be gradual and with awareness that PH crises are often prompted *not* with incremental decreases, but by going from 1 PPM to off. The team should, therefore, be prepared to reinitiate iNO and

Table 34.4 Determinants of risk in pediatric pulmonary hypertension

Lower risk	Determinants of risk	Higher risk
No	Clinical evidence of RV failure	Yes
No	Progression of symptoms	Yes
No	Syncope	Yes
Normal (height/BMI)	Growth	Failure to thrive
I, II	WHO functional class	III, IV
Minimally elevated	Serum BNP/ NT-proBNP	Significantly elevated or rising
Normal RV systolic function	Echocardiography	RV systolic dysfunction
Minimal RA/RV enlargement		Severe RA/RV enlargement
RV/LV ratio <1		Increased RV/LV ratio
Normal TAPSE		Reduced TAPSE
		Pericardial effusion
CI > 3.0 L/min/m2	Invasive hemodynamics	CI < 2.5 L/min/m2
mRAP < 10 mm Hg		mRAP > 15 mm Hg

These determinants have only level of evidence C because of lacking pediatric data, but are informed by clinical practice and can nonetheless guide preprocedural risk assessment and preparation.

BMI, indicates body mass index; BNP, B-type natriuretic peptide; CI, cardiac index; mPAP, mean pulmonary artery pressure; mRAP, mean right atrial pressure; mSAP, mean systemic arterial pressure; PVRi, pulmonary vascular resistance indexed to body surface area; RA, right atrium; RV, right ventricle; TAPSE, tricuspid annular plane systolic excursion.

resuscitate as indicated. Options for the management of children on SQ treprostinil are to continue delivery as SQ or transition to intravenous (IV) administration. The rationale for the latter is a more stable and visible site for delivery (due to the risks of dislodgement of SQ sites with positioning, variability in SQ perfusion and absorption during anesthesia, and the inability to monitor if under the drapes). If maintaining the infusion SQ, there is a margin of safety even in the event of dislodgement due to treprostinil's long half-life (4 hours).

Anesthetic technique and preparation depend on patient age, comorbidities, disease severity, and institutional practice. Older adolescents or adults who are cooperative can be managed with minimal sedation and local anesthetic infiltration. Upper extremity venous access to perform RHC can be considered to minimize discomfort and the need for analgesics relative to femoral access [31]. Deeper sedation can be used safely in appropriately selected patients but requires attention to avoiding hypoxia, hypercapnea, and acidosis that may prompt either a PH crisis or skew assessment of PAP and PVR. Given the younger age of this patient population, our most common approach is to use GETA. We and others have not observed PH crises related to airway instrumentation [19, 32–34].

Anesthetic induction and maintenance are tailored to the patient's disease severity. A balanced anesthetic using a combination of opioid, ketamine, midazolam, and volatile agent is well tolerated (see Anesthetic drugs). Ketamine and dexmedetomidine do not adversely affect the pulmonary vasculature and can reduce the amount of volatile agent needed [32, 33]. Most commonly observed following induction is relative hypotension secondary to anesthesia-induced decreases in SVR, contractility, and preload (with positive pressure ventilation [PPV]). Phenylephrine boluses or infusions of vasopressin or phenylephrine are useful in increasing SVR and preventing RV ischemia that can lead to cardiovascular collapse. For high-risk patients (those with moderately to severely depressed RV function), infusions of epinephrine and/or vasopressin can be initiated prior to induction. Further, the availability of ECMO should be confirmed in advance (assuming the child is an ECMO candidate). Blood, iNO, vasoactives, adequate vascular access to deliver infusions, and defibrillation pads should be present. A dedicated arterial line should be considered. For all patients following AVT, iNO should be titrated off slowly, particularly in those who have had a positive response. Postprocedural disposition is dictated by disease severity and intraprocedural course. Our practice is conservative, and many of our PH patients are admitted to the intensive care unit (ICU) if only for observation.

Cardiac magnetic resonance imaging-guided catheterization

The number of centers utilizing cardiac magnetic resonance imaging (CMR)-guided catheterization has increased in recent years [35–39]. These procedures have largely been diagnostic only due to limitations in MRI-compatible devices and catheters. The sequence of the procedure varies but most often entails CMR prior to catheterization. Other institutions begin the procedure in the CCL where access is obtained, followed by a transition to CMR where imaging and RHC are performed. The child is then transferred back to the CCL where any interventions, if needed, can be done [39]. Common populations currently assessed include post-transplant patients and those with PH, cardiomyopathy, and intracardiac shunts.

The rationale for using CMR-guided catheterization is the accuracy of the data obtained and decrease in radiation exposure relative to traditional catheterization. Calculations obtained in the CCL are subject to assumptions and sampling error and are further influenced by the child's underlying anatomy, hemodynamic fluctuations, and the use of oxygen and iNO [35, 40]. CMR avoids many of these confounders and is thus regarded as more precise in calculation of flow and resistance. Other advantages include superior assessment of RV volume, function, and valvar regurgitation relative to other diagnostic modalities and the ability to provide enhanced soft-tissue characterization. Potential benefits to the latter could include improved myocardial biopsy yields and electrophysiology (EP) ablation success, as well as earlier detection of bleeding complications [41–43]. No less importantly, the radiation exposure to the child and providers is reduced. For example, in a child undergoing pre-Fontan evaluation who receives CMR prior to catheterization, the fluoroscopy time needed to obtain pressures and saturations can be eliminated.

These benefits, however, come with an increase in the time that the patient is anesthetized and the introduction of other

risks related to the MRI environment and transfers between CCL and MRI. In a review of their initial experience in patients undergoing MRI-guided right heart catheterization (MRI-RHC), Children's National Medical Center reported that the average anesthetic time for a follow-up transplant biopsy was 2 hours and 56 minutes and for all procedures 3 hours and 24 minutes [39]. Risk in the MRI environment is multifactorial, but the foremost concern is the inadvertent entry of ferromagnetic objects. Protocols that prompt metal screening before the start of catheterization and once again prior to entry into MRI can be preventative [39]. Hemodynamic instability and cardiac arrest during MRI-RHC present additional challenges. Much of the equipment used for resuscitation cannot enter MRI safely, and immediate evacuation of the patient to a different location is indicated. Safe and efficient evacuation is dependent on a well-rehearsed plan that also defines provider's roles in such an event [39]. Patient transfers between CCL and MRI (and back) further add to complexity and provide opportunities for unplanned extubation or loss of vascular access. Nonetheless, many of the above risks can be mitigated with appropriate planning, team awareness, and attention to detail. Of the 72 procedures for MRI-RHC at Children's National, no complications from anesthesia or the MRI-RHC were reported [39].

A rational approach when first planning for these procedures is to over-prepare. Simulation involving all team members is helpful in walking through the sequence of the procedure, identifying problem areas, and determining institutional specific responses to critical events. Radiology can often lead team education regarding MRI risk and also help establish protocols for the safe passage of the patient between CCL and MRI. Interval drills to practice evacuation from MRI in the event of emergencies are recommended. Many programs that set out to do MRI-RHC already have protocols in place for hybrid operating room–MRI suites that can be adapted to the CCL. Patient selection is equally important. Experience first with older and healthier patients can guide subsequent planning on higher risk patients. Anesthetic preparation accounts for setting up MRI as well as the CCL (Table 34.5). Monitors, infusion pumps, and the anesthesia machine within the MRI suite will of course need to be MRI compatible. For patients with PH, an MRI-compatible iNO delivery system is also necessary. Given the complexity and novelty of this procedure, GETA is reasonable, and the threshold for placing dedicated arterial access for blood pressure monitoring may be lower.

Table 34.5 Checklist for anesthetic preparation for CMR-guided catheterization

- ☐ Bag-valve mask and MRI-compatible oxygen tank (for the period of transport between the CL and MRI)
- ☐ Complete check of both the MRI and CL anesthesia machines
- ☐ Circuit extensions added to both
- ☐ Extensions added to intravenous lines
- ☐ Emergency medications drawn and available
- ☐ MRI-compatible infusion pumps and monitors available and functional
- ☐ MRI-compatible iNO machine available and checked (if PH study planned)
- ☐ Plan and roles reviewed for emergency evacuations from MRI

KEY POINTS: DIAGNOSTIC CATHETERIZATION

- Anesthetic management can influence the quality of the data obtained during catheterization and can thereby impact clinical decision-making.
- To ensure that the data reflects the child's baseline physiology, variables such as oxygenation, ventilation, and hemodynamics are maintained within the child's usual range during measurement.
- Groups at high risk during diagnostic procedures include neonates and infants, transplant patients in acute rejection or with CAV, those with myocarditis, and patients with systemic-to-suprasystemic PAPs.

Interventional catheterization

The range of interventions offered and the patient types managed in the CCL has broadened significantly in recent years. An overview of common as well as emerging procedures, their anesthetic management, and associated complications are discussed below.

Device closure of cardiovascular communications

Among the most common interventional procedures performed are transcatheter closures of the patent ductus arteriosus (PDA) and certain atrial-level communications such as secundum atrial septal defects (ASDs) and patent foramen ovales (PFOs). Other cardiovascular communications amenable to device closure include muscular VSDs, coronary fistulae, and Fontan fenestrations.

Shared considerations

GETA is used in these cases to minimize patient movement, allow for TEE (ASD and VSD closures), and provide stability in higher risk procedures. This latter group includes the closure of VSDs, preterm PDAs or PDAs in patients with PH, and coronary fistulae. Considerations common to patients undergoing device closure include the need for antibiotic prophylaxis and potential for device embolization (Figure 34.3). Depending on the size of the particular device and where it embolizes, hemodynamic instability can result from obstruction to flow or arrhythmias. Thrombus generation can also lead to stroke in devices lodged within the systemic circulation, thereby necessitating team awareness of the patient's anticoagulation status while attempts at retrieval are made. While most episodes are readily appreciated while still in the CCL, embolization may also occur during the recovery period.

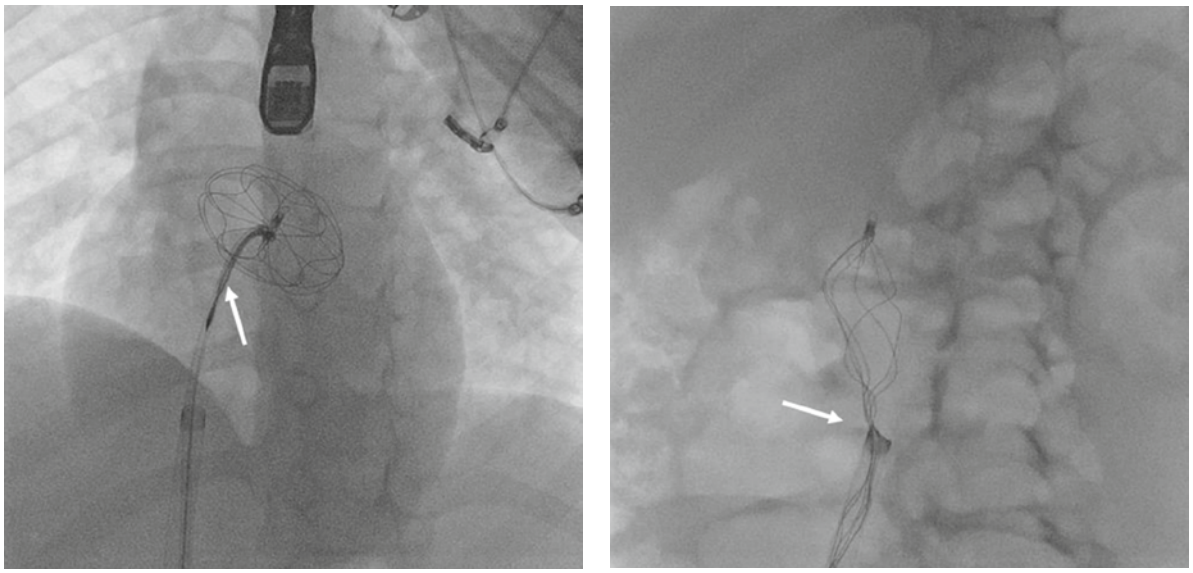

Figure 34.3 (A) A snare (arrow) is used to encircle the device that has embolized into the left atrium. (B) The snare is then used to withdraw the device that is now collapsed (arrow) for removal through the right femoral venous sheath. (Source: Texas Children's Hospital Cardiac Catheterization Laboratory.)

The development of new arrhythmias or changes in hemodynamics should alert one to this possibility. Anesthetic strategies to minimize the risk of delayed embolization include deep extubation (excluding infants or patients otherwise in whom the risk of deep extubation exceeds its benefits), aggressive prophylaxis of postoperative nausea and vomiting (PONV), and extended sedation in the initial recovery period. Dexmedetomidine, morphine, ondansetron, dexamethasone, and/or propofol can be useful agents in achieving these goals, but paramount is communication with the cardiologist to identify those patients at greatest risk. For example, in patients undergoing ASD closure, a large ASD and the presence of multiple deficient rims increase the risk for embolization. If catheter-based retrieval cannot be achieved (e.g., when the device has embolized to the LV and attempts at retrieval may damage the mitral valve apparatus), surgery is indicated.

Atrial septal defects

Complications associated with ASD closure are rare. Apart from embolization (discussed above), the device may encroach upon the atrioventricular (AV) valves or over the ostia of the pulmonary or systemic veins upon release. This risk is minimized by the use of echocardiography to ensure that the veins remain unobstructed and that no new valvular insufficiency or stenosis develops following deployment. Less common are catheter-induced AV block, cardiac perforation, and systemic air embolization (associated with catheter entry into the left heart) [1]. Of note, endovascular and transthoracic echocardiographic (TTE) guidance may occasionally be used rather than TEE to facilitate closure.

The preterm patent ductus arteriosus

Among individuals undergoing PDA closure, preterm neonates and infants pose the greatest challenge due to their associated comorbidities and small size at presentation [44]. Such patients have many of the sequelae of prematurity (intraventricular hemorrhage, bronchopulmonary dysplasia, and a history of necrotizing enterocolitis) and can be as small as 700 g [45]. Due to the increased risk associated with this fragile population, protocols for preparation and the transport of these patients to and from the CCL are necessary (Table 34.6).

Once in the CCL, attention is given to maintaining normothermia and assessing the adequacy of ventilation. Uncuffed endotracheal tubes (ETTs) placed in the neonatal intensive care unit (NICU) usually prohibit accurate $ETCO_2$ monitoring due to associated leaks. Options are to replace the ETT with a cuffed one, or to gauge ventilation by the adequacy of chest rise or $PaCO_2$ via blood gas once femoral venous access is obtained (the femoral artery is avoided due to the potential for leg ischemia with access). Due to issues associated with lung compliance and the inherent limitations of the anesthesia ventilator, a NICU ventilator is used routinely for patients weighing <2 kg. Inadvertent dislodgement of the ETT or IV lines, always a risk in younger patients in the CCL, is a particular concern in this population and mandates communication prior to any movement of the table. Core temperature is measured with an oral esophageal probe, which also serves as a marker for the aortic end of the PDA on fluoroscopy. This gives the interventional team an additional landmark when placing the device (Figure 34.4).

Hemodynamic derangement and desaturations may occur at different points during the procedure. Compression of the chest with the TTE probe can lead to altered ventilation and desaturation (TTE is used in junction with prograde angiography through the venous sheath to assess the PDA and device position before/after release). The catheter used to deploy the device can cause heart block and more commonly can stent open the tricuspid valve. The resulting tricuspid regurgitation (TR) can cause not only hypotension but also

desaturation if an atrial communication is present (due to increased right-to-left shunting). Prior to device release, TTE is used to ensure that the device is not protruding into the aorta and causing arch obstruction. Following release, embolization may occur, either into the aorta or, more commonly, into the left PA.

Total IV anesthesia using low-dose ketamine, fentanyl, and muscle relaxant is a commonly used technique in infants weighing <2 kg due to the use of an NICU ventilator. These drugs have the ancillary benefit of promoting hemodynamic stability. For larger and less tenuous preterm infants for whom an anesthesia machine is appropriate, low-dose volatile

agent is often added. Blood and vasoactive agents should be immediately available. Our practice is to leave these patients intubated for return to the NICU.

Ventricular septal defects

Transcatheter closure of VSDs is similarly fraught with the potential for hemodynamic derangements [46]. These can include heart block or tachyarrhythmias, AV valve (AVV) and/or aortic valve regurgitation, volume overload, bleeding, and cardiac arrest. Heart block can develop either secondary to catheter- or device-induced injury. When deployed in proximity to the conduction system, the device's radial force can compress the surrounding tissue. Consequently, attempts at closure of membranous VSDs are associated with a higher incidence of complete heart block (CHB) than muscular VSDs. Though steroids have been administered prophylactically to prevent and subsequently treat device-related CHB (presumptively to decrease inflammation-mediated edema), their use remains speculative [47–50]. Valvular regurgitation can similarly occur due to device deployment near the AV or aortic valve, or separately as a result of catheter-induced trauma. The approach to the VSD, whether retrograde through the left heart or antegrade through the right heart, can cause injury to the aortic valve either alone or both the tricuspid and aortic valves, respectively (Figure 34.5). Notably, recent advancements in delivery systems and softer devices have led to an improved rate of successful closure of various VSDs with lower rates of heart block and arrhythmia [50]. Transcatheter closure of perimembranous VSDs remains controversial, however, due to concerns of heart block, aortic valve injury, and hemolysis associated with residual defects.

Given the prevalence of catheter-induced disturbances, vasoactive support is commonly initiated to provide hemodynamic stability. Adequate peripheral venous access and dedicated arterial monitoring are, therefore, recommended. Transvenous pacing is indicated if heart block persists (and the availability of this equipment should be confirmed prior to starting). Volume overload secondary to flush and contrast administration is common and managed with IV furosemide. Postprocedural disposition can vary depending on the procedure's course, but ensuring the availability of an ICU bed is advisable should continued intubation or pacing be needed.

Coronary artery fistulas

Coronary artery fistulas (CAFs) are anomalous communications between a coronary artery and a chamber of the heart or another blood vessel (Figure 34.6). In the absence of any other cardiac lesion, these fistulas can be a source of pulmonary overcirculation (in patients with fistulas ending in the RV), myocardial ischemia due to coronary steal, or infectious endocarditis. Interventions to close CAFs can be associated with spasm, thrombosis, or dissection of the coronary [51]. Attention to signs of ischemia on EKG and the availability of vasoactive agents to promote coronary vasodilation (nitroglycerin) or hemodynamic support in the event of hypotension (vasopressin, phenylephrine, and epinephrine) are central tenets of anesthetic management. A dedicated arterial line is indicated as the procedure is performed through the femoral arterial sheath. Following occlusion of the fistula, altered flow dynamics that could lead to stasis and thrombosis proximal to the device with subsequent myocardial

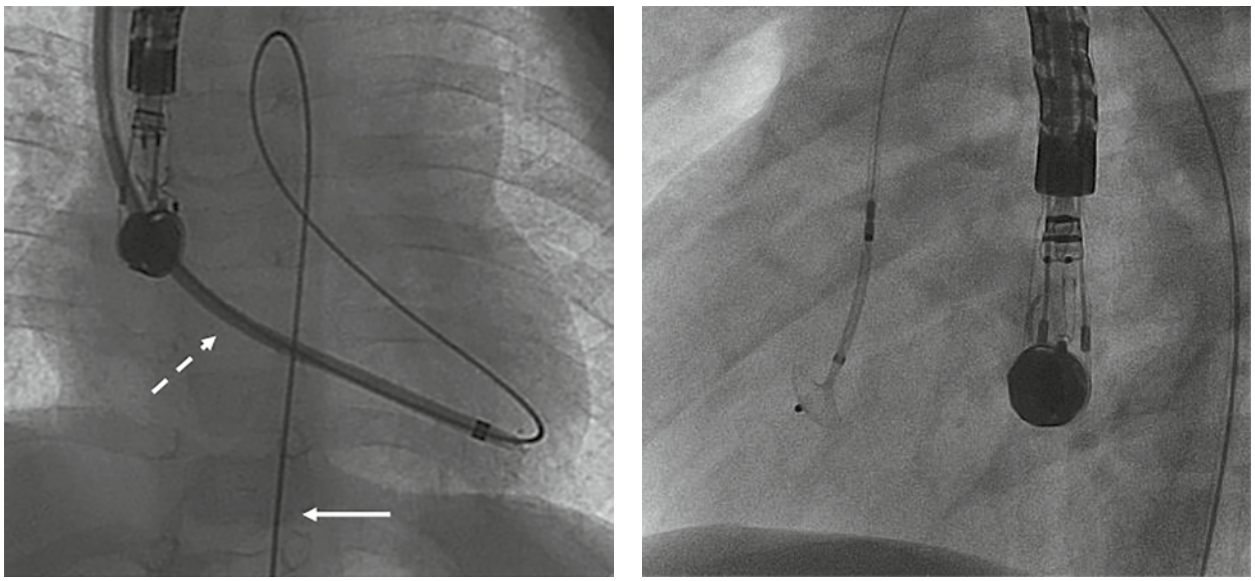

Figure 34.5 Transcatheter ventricular septal defect closure. (A) Antegrade device deployment over an arteriovenous loop. The arterial end of the loop is a wire (arrow) advanced in sequence from the femoral artery through the aortic valve, left ventricle, ventricular septal defect, and into the superior vena cava. The venous end of the loop snares the arterial wire and is externalized through the femoral venous sheath. The delivery sheath (dotted arrow) is then advanced antegrade over the venous end of the loop. (B) Retrograde device deployment entirely from the arterial side. (Source: Morray [50]. ischemia/infarction necessitate the initiation of anticoagulation and postprocedural monitoring in the ICU. A continuous heparin infusion is commonly initiated prior to departure from the CCL to avoid delays in anticoagulation associated with transfer of care.

Balloon dilation of cardiac valves

Pulmonary valvuloplasty

Children with pulmonary stenosis (PS) can range the spectrum from critically ill neonates to older, otherwise healthy, children. The severity of PS and any associated hypoplasia of the RV and tricuspid valve accounts for these differences in presentation. Neonates whose PS is so severe as to require ductal patency for pulmonary blood flow (PBF) are described as having critical PS [52]. These patients, therefore, have single-ventricle physiology and are managed with prostaglandin (PGE_1) in the periprocedural period. Cyanosis is common in the setting of an atrial-level communication due to the presence of suprasystemic RV pressures, RV diastolic dysfunction, and TR that promote elevated right atrial pressure and right-to-left shunting [53]. The RV is typically hypertrophied with preserved systolic function, but occasionally may demonstrate significant dysfunction. GETA is recommended, and attention to oxygenation and ventilation is necessary to balance $Q_p : Q_s$ in the setting of the patent ductus. Diastolic hypotension is avoided as subendocardial ischemia can develop in the pressure-overloaded RV. During the procedure, because the valve is already severely restrictive and PBF is preserved through the ductus, periods of balloon dilation are well tolerated (Figure 34.7). Major complications such as transient or permanent heart block, tricuspid papillary muscle rupture, balloon rupture, and PA tears are rare [53]. Transient bradycardia or catheter-induced arrhythmias are more common. Postprocedure, PGE_1 may be stopped or continued depending on the size and function of the RV. Importantly, even with the complete relief of obstruction, RV diastolic dysfunction will persist as RV hypertrophy subsides over several months. A gradual wean of PGE_1 may be needed in the ICU to assess the ability of RV to promote PBF. For those demonstrating persistent ductal dependency, either ductal stenting or a surgical shunt is indicated.

Older infants and children presenting for pulmonary valvuloplasty are usually at lower risk. They tend to have a normal-sized RV and tricuspid valve and are able to generate adequate prograde PBF without the need for a PDA. Cyanosis is, therefore, not common but can still occur in the patient with severe obstruction and an ASD. Overarching anesthetic goals include maintaining euvolemia and avoiding hypotension to minimize the risk of ischemia in the thick and pressurized RV. For those rare patients who present with RV dysfunction due to long-standing severe PS, inotropes and vasopressors may be needed to bolster cardiac output and achieve normotension while anesthetized. The process of ballooning causes a transient pause in PBF (in contrast to patients with critical PS) and produces predictable changes in hemodynamics and oxygen saturations depending on whether or not an ASD is present. In patients without an ASD, ballooning is associated with periods of hypotension, bradycardia, and desaturation due to the acute loss of LV filling and PBF. In patients with an ASD, blood pressure is typically preserved during ballooning due to right-to-left shunting across the ASD, but desaturation occurs nonetheless. These events usually self-resolve following balloon deflation, but boluses of phenylephrine may be necessary to treat hypotension in at-risk patients who do not recover within seconds. Preoxygenation prior to ballooning can help minimize the severity of desaturation. Development of severe infundibular obstruction after ballooning, although rare, has been reported [54–56]. Adequate preload and a slower heart rate can ensure ventricular filling in these cases. Beta-blockade is rarely necessary. Although this procedure can be performed with sedation in the compensated child or adolescent, the variable length of the procedure and the significant stimulation associated with ballooning lead us to use GETA. If uneventful, patients are commonly discharged on the same day.

Further along the continuum of PS is pulmonary atresia with intact ventricular septum (PA/IVS). As with critical PS, this lesion is ductal dependent for PBF, and decompression of the RV is sought to establish prograde PBF that may allow for a future biventricular or 1 ½ ventricle repair. These patients, however, may have abnormalities in their coronary anatomy that preclude RV decompression. The pressurized RV can result in the formation of fistulous connections between the RV and the epicardial coronary arteries, and when combined with proximal coronary stenosis or occlusion (present in 9–34% of patients with PA/IVS)[57], an RV-dependent coronary circulation (RV-DCC) results [58] (Figure 34.8). Decompression of the RV in this setting would lead to

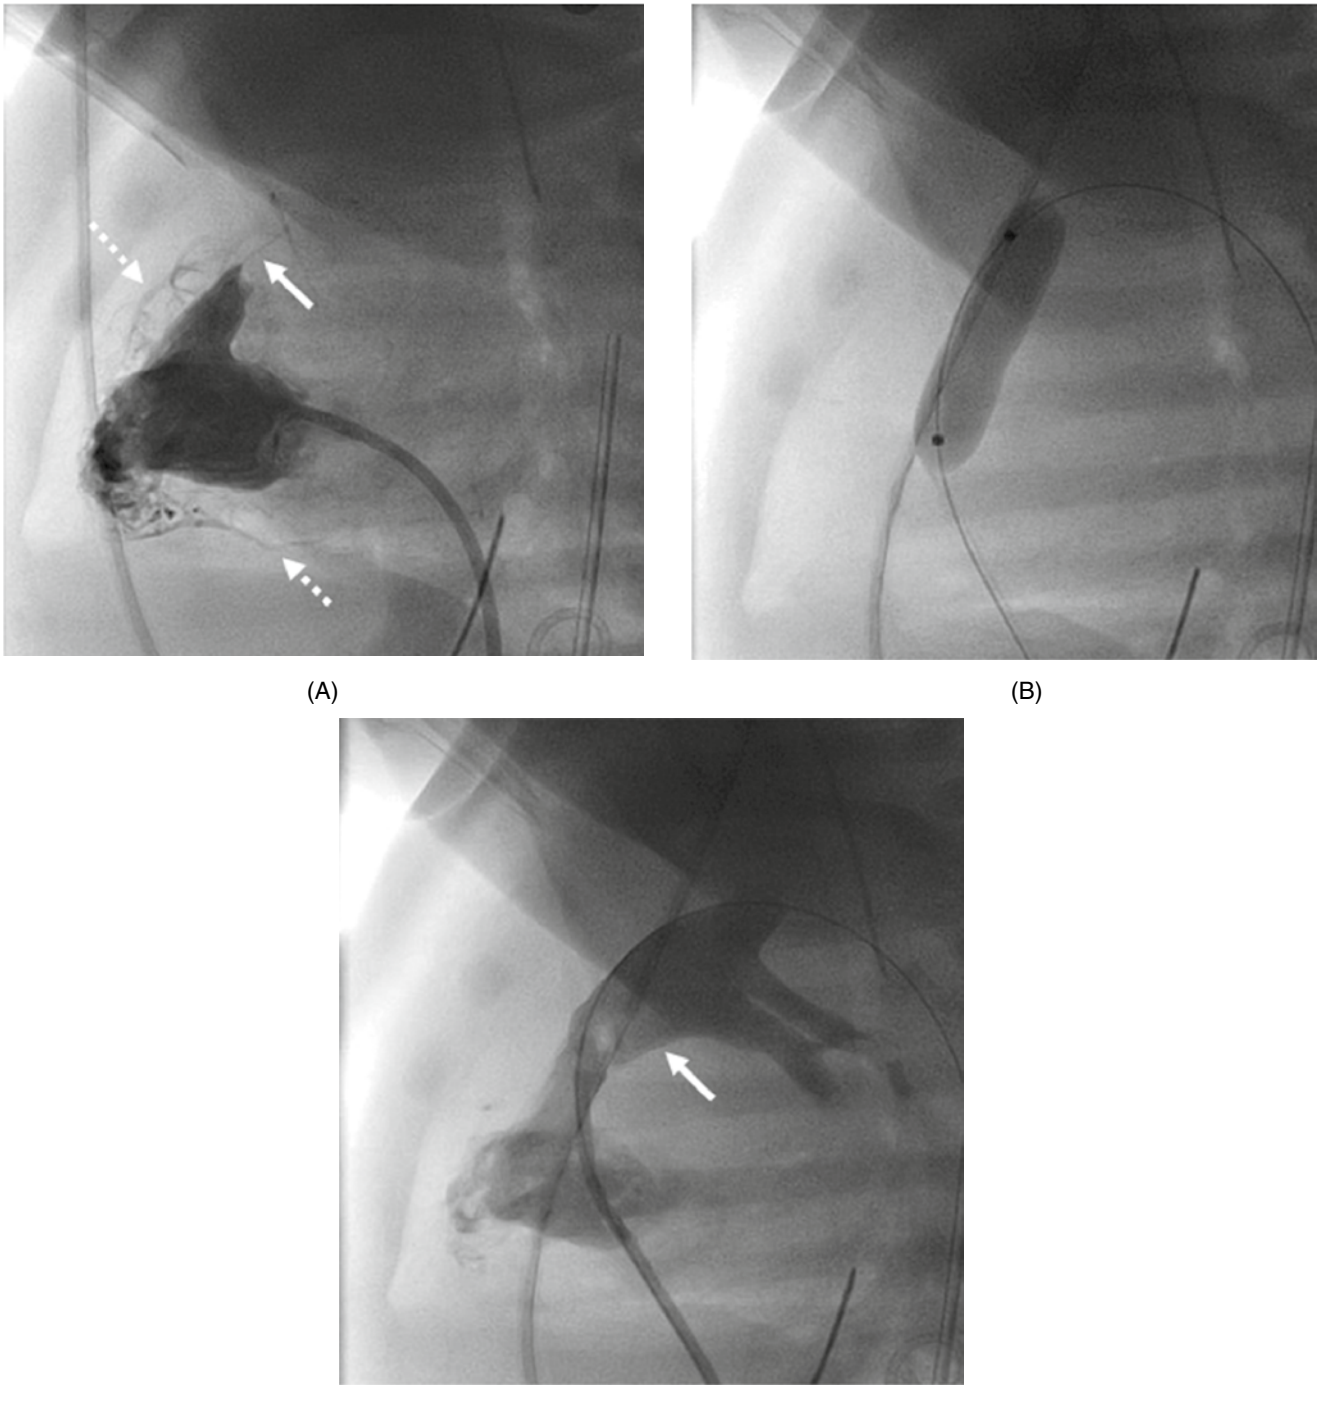

Figure 34.7 Balloon valvuloplasty in critical pulmonary stenosis. (A) Right ventricular (RV) angiogram in a neonate with critical pulmonary stenosis. A very thin jet of antegrade flow can be seen across the pulmonary valve (arrow). Also noted is filling of the coronary arteries (dotted arrows) via fistulous connections (non-RV dependent in this case). (B) The pulmonary valve was crossed with a fine wire and dilated with a balloon. (C) After pulmonary valvuloplasty, there is a wide jet of antegrade flow (arrow) across the pulmonary valve. (Source: Texas Children's Hospital Cardiac Catheterization Laboratory.)

myocardial infarction. Consequently, the first procedure undertaken in the CCL is a diagnostic coronary and RV angiogram to rule out the presence of RV-DCC. For patients without RV-DCC, RV decompression and prograde PBF can be established with wire or radiofrequency (RF) perforation, followed by ballooning of the atretic valve. Given these additional steps, the duration of the procedure is longer and the risks of complications greater than with balloon valvuloplasty alone. Risks can include heart block, right heart perforation, tamponade, volume overload, dilutional anemia, and

acid–base derangement [59, 60]. Ductal stenting may be performed in the same setting or at a later date (see PDA stenting to augment PBF). Timing is often dependent on the size of the ductus and stability of the patient following what may be a lengthy intervention at the atretic valve [61].

Aortic valvuloplasty

As with PS, valvular aortic stenosis (AS) can manifest variably depending on the severity of the obstruction and any associated cardiac lesions. Critical AS is the most severe manifestation and presents in the neonatal period as a lesion that is ductal dependent for systemic blood flow. Definitive treatment entails relieving the valvular obstruction. Medical management prior to arrival in the CCL includes the initiation of PGE_1, and in the subset of patients with compromised end-organ perfusion and respiratory failure, inotropic support, and mechanical ventilation [62]. Of note, hemodynamic and respiratory status should be regarded as tenuous even in the neonate presenting on room air and PGE_1 alone. The LV is most commonly dilated and dysfunctional at baseline, and the procedure may further exacerbate hemodynamics due to catheter-induced arrhythmias, decreases in cardiac output with ballooning, and the potential for new aortic insufficiency following valvuloplasty. GETA is, therefore, used. An infusion of epinephrine is often started with induction of anesthesia if the patient is not already receiving it, and vasopressin may be indicated to optimize coronary perfusion pressure. Due to the risk of arrhythmias, defibrillation pads should be immediately available.

The vascular access approach planned by the cardiologist can provide additional insight into specific risks as well as the duration of the procedure. The carotid approach offers the most direct and expedient route to the aortic valve but can be associated with neurologic injury. It is, therefore, reserved for the smallest of neonates for whom the risk of femoral artery injury is thought to exceed that of the carotid [63–65]. To facilitate carotid access, the cardiologist may request that the patient be turned 180° away from the usual position (such that the airway is furthest from the anesthesiologist). Care with positioning of lines and the ETT is necessary in this circumstance to minimize the risk of line displacement or kinking of the ETT. A more common approach to the aortic valve is retrograde through the femoral artery. Antegrade approaches through the femoral vein (and then in sequence through the atrial septum, mitral valve, and LV) are less common due to the instability associated with passing the catheter through potentially smaller left-sided structures (with risks of arrhythmia, mitral valve damage, and perforation) [59]. If the femoral artery is used, additional arterial access for blood pressure monitoring is indicated. New, hemodynamically significant aortic insufficiency following ballooning (indicated by diastolic hypotension and ischemic ST changes) requires urgent surgical intervention for valve repair/replacement.

Management of reinterventions later in life, or first-time interventions in older children or adolescents, is marked by the usual concern of maintaining an adequate coronary perfusion [62]. Anesthetic technique and risk assessment can be guided by the patient's age, LV function, severity of the gradient, and comorbidities. For older patients who have a borderline indication for intervention based on Doppler-derived mean transvalvular gradients, the peak-to-peak gradient obtained during catheterization can provide definitive information to direct therapy. In such cases, light sedation may be preferable to general anesthesia during the diagnostic portion since the latter

may lead to an underestimation of the actual gradient. Our preference otherwise is to use GETA to avoid the risk of movement with balloon dilation that may increase the risk of aortic valve injury. Importantly, rapid RV pacing may be used to reduce stroke volume and minimize balloon movement during inflation in older patients. The resulting decrease in cardiac output is typically well tolerated in those with preserved LV function but may necessitate treatment with phenylephrine to expedite recovery. As the approach to the aortic valve will most commonly be through the femoral artery, the need for a separate arterial line for dedicated blood pressure monitoring is dictated by the patient's baseline LV function.

Balloon angioplasty and/or stent placement

Pulmonary arteries

A number of pathologies are associated with PA stenosis, including syndromes such as Alagille or Williams-Beuren and different forms of CHD in which stenosis can develop either independently or as a consequence of surgery (ductal origin of the PA, palliated single ventricles, Tetralogy of Fallot (TOF), truncus arteriosus, and transposition, among others).

Similar to valvular PS, anesthetic management in children with PA stenosis is dependent on the degree of stenosis present and its effects on RV pressure and function. Estimates of RV pressure can be gauged by the presence of a TR jet and compensatory RV hypertrophy on echocardiography. Euvolemia and age-appropriate diastolic perfusion pressures should be maintained to decrease the risk of ischemia. Catheter-induced arrhythmias and periodic hypotension (due to TR caused by catheters en route to the PAs) are common, particularly in younger patients. Though well tolerated in children with preserved ventricular function, those with depressed function may need vasoactive support.

Critical events associated with PA angioplasty/stenting include hemorrhage due to vessel rupture, lung reperfusion injury, and occlusion of the left mainstem bronchus with stenting of the left PA [1, 66–69]. The potential for life-threatening hemorrhage, though rare with the introduction of covered stents and vessel occlusion, requires the presence of large-bore IV access and packed red blood cells in the CCL. Lung reperfusion injury is more common, with a reported incidence of 15–22% in published cohorts (higher when segmental and subsegmental branches with severe stenoses are involved) [69, 70]. This presents as a decrease in both lung compliance and PaO_2 : FiO_2, and occasionally with blood-tinged fluid in the ETT. Proposed mechanisms include an acute increase in hydrostatic pressure due to increased flow following angioplasty or the acute increase in LV end-diastolic volume in a noncompliant LV. Treatment entails conservative management with continued mechanical ventilation, increased positive end-expiratory pressure (PEEP), and diuresis if oxygenation and ventilation are compromised. Rarely, one lung ventilation is needed. In patients at high risk for developing hemorrhage or reperfusion injury, we have occasionally placed a bronchial blocker preemptively (Figure 34.9). The potential for acute left bronchial compression should be considered in the setting of a recently deployed left PA stent with a new finding of diminished lung compliance and left lung atelectasis (assessed via fluoroscopy) [67]. Bronchoscopy can be used to confirm this diagnosis.

Additional risk can be inferred based on patient characteristics. Patients with Alagille and Williams-Beuren syndromes may present for PA intervention and carry comorbidities unique to each condition – namely, the risk of liver disease and coincident supravalvar AS, respectively [71]. Moreover, those with a history of D-transposition of the great arteries (d-TGA) status post the arterial switch operation may be at risk for coronary compression with attempts at branch PA stenting. The LeCompte maneuver in these patients can place the branch PAs in proximity to the translocated coronaries, and so testing is done to assess for coronary compromise prior to stenting [72]. The presence of profound hypotension and/or ST changes on EKG with testing also suggests the need to abort.

Pulmonary veins

Pulmonary vein stenosis (PVS) in children can be a relentless disease associated with significant morbidity and mortality [73–75]. Classified as either primary (congenital) or postrepair (acquired), the pathophysiology of PVS is an increase in pulmonary venous pressure that can lead to PH, right heart failure, and, ultimately, death [76–79]. Characteristics associated with increased mortality include earlier age at presentation, bilateral disease, multivessel involvement, and the concurrent presence of CHD and/or prematurity [80–82]. The foundation of management is early surgical or catheter-based therapy to relieve the stenosis followed by repeat catheterizations as indicated to address disease recurrence and/or progression (Figure 34.10).

Due to the risk of RV failure secondary to PH, preanesthetic evaluation focuses on the RV and signs of systemic or suprasystemic PAPs [73]. For those entering the procedure with depressed RV function, preparations to support the RV

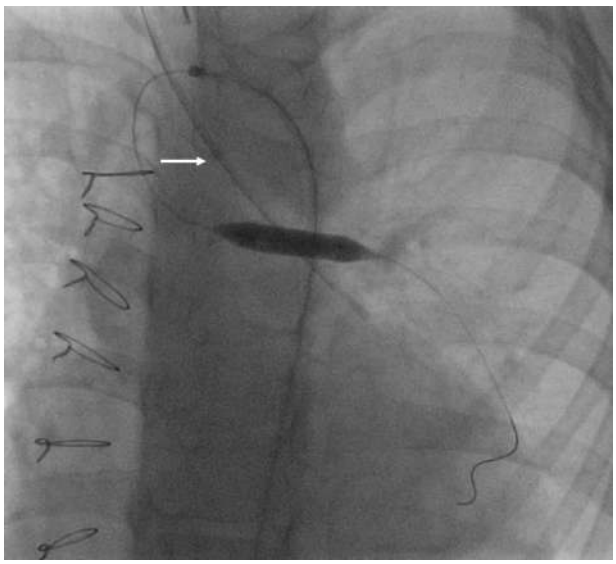

Figure 34.9 Bronchial blocker with pulmonary artery angioplasty. A left bronchial blocker (arrow) has been inserted prophylactically to contain hemorrhage in a 7-year-old child with PA/VSD/MAPCAs undergoing pulmonary artery angioplasty. An angioplasty balloon is seen inflated in the left pulmonary artery. (Source: Texas Children's Hospital Cardiac Catheterization Laboratory.)

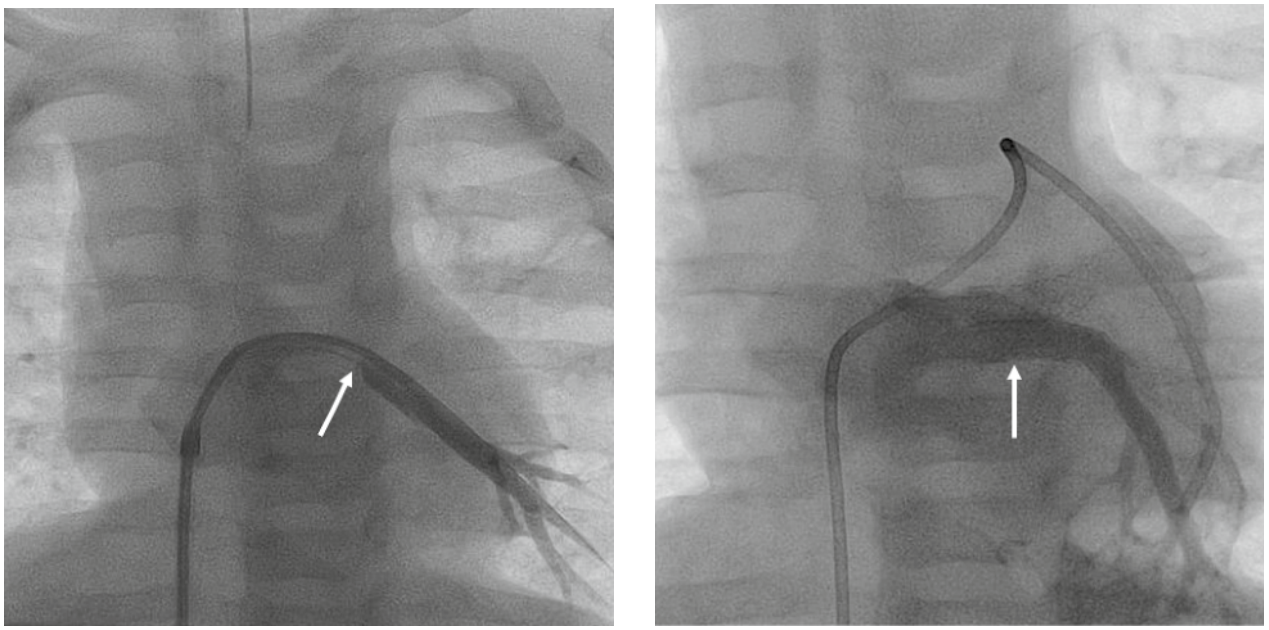

Figure 34.10 Pulmonary vein stenosis angioplasty and stenting. (A) Severe left lower pulmonary vein stenosis (arrow) can be seen in a 1-year-old. (B) After left lower pulmonary vein stenting (arrow), a left lower pulmonary artery wedge injection shows an unobstructed left lower pulmonary vein. Also noted is a stent in the left upper pulmonary vein. (Source: Texas Children's Hospital Cardiac Catheterization Laboratory.)

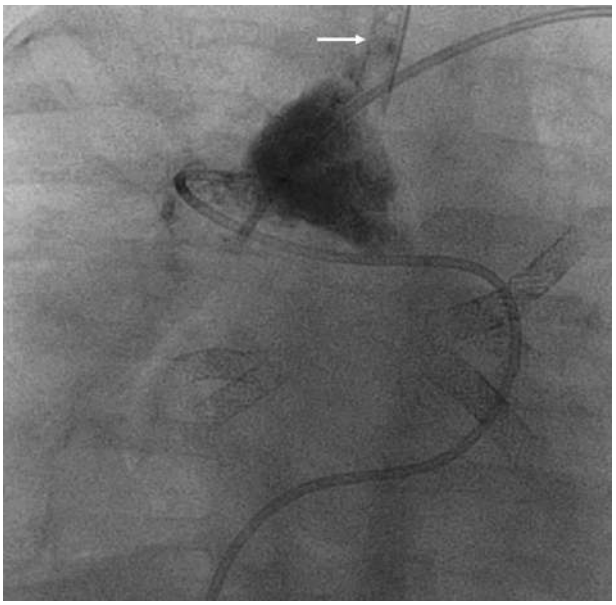
should include the availability of epinephrine, phenylephrine, vasopressin, iNO, and, in the highest risk patients, ECMO. Consideration should be given to starting epinephrine and vasopressin prior to induction in those with moderately to severely depressed function. Though counterintuitive that a pulmonary vasodilator would be useful in patients with a downstream obstruction, some patients with PVS may respond to iNO with a significant reduction in PAP [83]. Its use may be considered if acute reductions in pulmonary afterload are needed (and can be stopped quickly if the patient deteriorates with its initiation).

Preprocedural respiratory status can also indicate disease severity and is related to the number of veins involved and the degree of stenosis. Children presenting in respiratory distress due to pulmonary venous congestion may be tachypneic with retractions and in need of noninvasive ventilatory support or intubation. Even in the absence of RV dysfunction, such signs indicate limited reserve and the potential for instability with anesthetic induction and maintenance. Because lung compliance, oxygenation, and ventilation can all worsen during the procedure (as discussed below), patients already starting with pulmonary edema may demonstrate less tolerance for additional insults than those without it. Preemptive diuresis with IV furosemide (1 mg/kg) is often used in at-risk children (and can be re-dosed as indicated).

Procedural risk and duration can otherwise be gauged by the number of veins needing intervention, whether an ASD is present, and if the femoral veins are patent. Multivessel PVS is associated with both a longer intervention and an increased risk of instability. The latter is related to the potential for pulmonary edema and hemorrhage that increases incrementally with each vein requiring intervention. In the absence of an ASD, transseptal puncture or RF perforation is needed to pass through the atrial septum to access the pulmonary veins. Though generally safe, this added step confers the risk of cardiac perforation while also increasing overall procedural time. Stenotic or thrombosed femoral veins can present another challenge to the interventionalist. Recurring use of the femoral veins with repeat interventions can render them inaccessible. Transhepatic venous access may be needed, which also carries a higher risk of bleeding and AV block [84]. A review of prior anesthetics in patients presenting for repeat intervention can often provide insight into the need for these additional procedures and general information regarding how the anesthetics and interventions were tolerated.

The previously alluded to complications of pulmonary edema and pulmonary hemorrhage can be anticipated in children with severely stenotic veins. Patients without any prior intervention and evidence of significant disease are at the highest risk. Pulmonary edema can present either gradually with fluid overload related to flush and contrast administration or more acutely with the transient occlusion of a pulmonary vein during angioplasty and stenting. The latter can also cause pulmonary hemorrhage. Balloon inflation in such settings can be associated with an acute increase in pulmonary venous pressure that can lead to airway bleeding. More common, however, is pulmonary hemorrhage in the setting of a PA wedge injection (used to define pulmonary venous anatomy). Injections into lung segments that are drained by nearly occlusive veins will result in markedly increased capillary pressures (Figure 34.11). Such bleeding is usually self-limited with subtle changes in compliance but can manifest as gross blood in the ETT or an acute decrease in lung compliance followed by profound desaturation. As



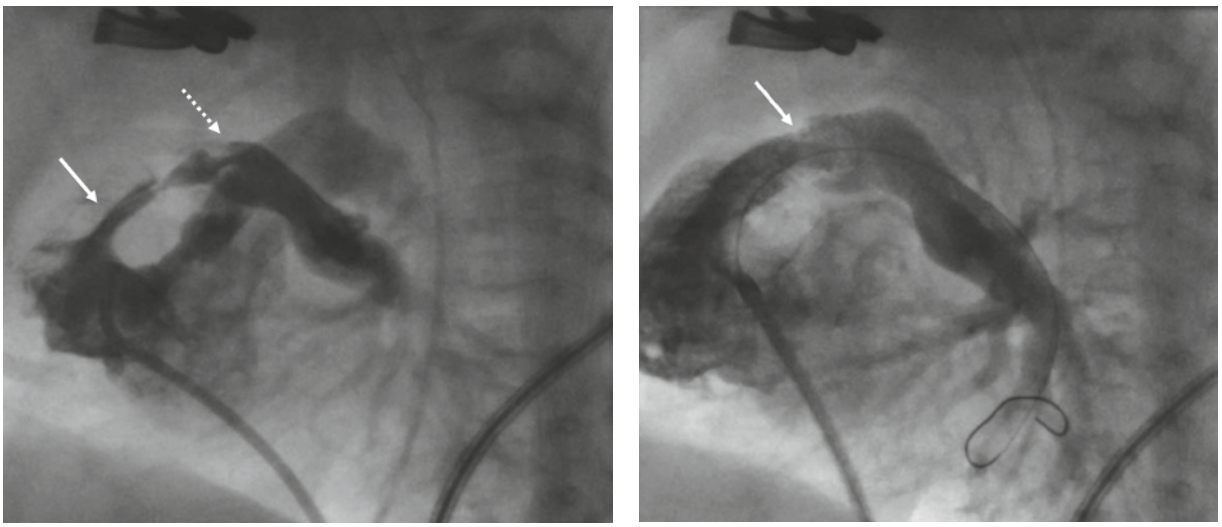


Figure 34.11 Pulmonary hemorrhage with pulmonary artery wedge injection in pulmonary vein stenosis. Right upper pulmonary artery wedge angiogram in a child with an obstructed right upper pulmonary vein. Contrast is seen entering the right bronchus and trachea (arrow). Stents can be also noted in multiple affected pulmonary veins. A peripherally inserted central catheter is also seen entering from the left arm. (Source: Texas Children's Hospital Cardiac Catheterization Laboratory.)

with the management of reperfusion injury, pulmonary hemorrhage can be treated conservatively with suctioning, continued mechanical ventilation, diuresis, and increased PEEP and FiO_2. In severe or persistent cases, endotracheal instillation of tranexamic acid can be efficacious [85]. The need for ECMO is rare, but indicated if hypoxemia is not reversible and contributing to hemodynamic instability. Of note, episodes of either pulmonary hemorrhage or edema that require escalations in hemodynamic and/or ventilatory support should prompt a discussion of whether or not to proceed. If some of the stenotic veins have already been addressed, a reasonable strategy is to return to the CCL once the patient has recovered. If no intervention has yet been performed in the setting of severe, multivessel disease, ECMO cannulation may be needed prior to proceeding.

Right ventricular outflow tract stenting

Stenting of the right ventricular outflow tract (RVOT) has gained acceptance as an alternative to the modified Blalock–Taussig shunt (mBTS) in the initial palliation of premature or severely cyanotic infants with TOF (Figure 34.12). In a single-center review comparing RVOT stenting to the mBTS, patients undergoing RVOT stenting were found to have a shorter hospital length of stay, improved PA growth, and comparable mortality while awaiting complete repair [86].

Common anesthetic concerns in this population include the potential for hypercyanotic episodes, or "tet spells," prior to stent placement, and the presence of significant noncardiac comorbidities that may influence anesthetic planning. The usual measures taken to prevent a hypercyanotic episode should be employed, such as euvolemia, adequate anesthetic depth, and avoidance of decreases in SVR. In patients who are cyanotic, transfusion to a hematocrit >40% can serve the purpose of providing preload while also increasing oxygen delivery and SVR. FiO_2 can be increased as needed. Catheter-induced arrhythmias or TR can precipitate hypotension and are treated with boluses of phenylephrine or the initiation of a vasopressin infusion. TR can also cause systemic desaturation in the setting of an ASD due to increased right-to-left shunting. Transient desaturation can be anticipated with balloon inflation and preemptively

(A) (B)

(Source: Texas Children's Hospital Cardiac Catheterization Laboratory.)

AL Grawany

managed with phenylephrine and preoxygenation. Because RVOT stenting may constitute definitive therapy in those infants for whom operative risk is prohibitive [87], an awareness of the child's noncardiac risk factors and how they may influence anesthetic management is critical. Such patients may also present for reintervention in the setting of in-stent stenosis and remain at-risk for hypercyanotic episodes until the stenosis is relieved.

Procedural risks include perforation of the PA or RVOT, pulmonary edema, tricuspid valve regurgitation, and stent embolization [86]. Perforation of the RVOT can manifest as a pericardial effusion, whereas puncture of the PA can present as hemoptysis or the appearance of contrast in the pleural spaces or lung fields [73]. Significant pericardial effusions require drain placement. Blood drained from the pericardium may be directly transfused back to the patient if the volume is needed. Protamine can be used to reverse anticoagulation in this setting if the activated clotting time (ACT) is prolonged, and surgery may be necessary if bleeding persists. Pulmonary edema develops most often as a result of reperfusion injury following relief of the obstruction to PBF. Treatment is conservative with continued mechanical ventilation, increased PEEP, and diuresis.

Coarctation of the aorta

Catheter-based management of coarctation of the aorta (CoA) entails balloon angioplasty with or without stent placement. Patient size and age dictate which approach is used. Angioplasty alone is typically reserved for neonates and infants, whereas combined angioplasty and stenting is used in older patients [88]. Common indications for catheter-based management include the initial treatment of discrete coarctation in older children and adolescents and reintervention in those presenting with discrete recurrent or residual coarctation (Figure 34.13).

Anesthetic management of CoA varies with patient age and clinical status (i.e., ventricular function) [88]. Sedation has been used successfully in older children and adolescents, but a deep level is required to blunt the noxious stimulus of aortic ballooning. Our practice is to use GETA regardless of patient age or ventricular function to reduce the movement-associated risks of aortic dissection or stent migration.

Common aspects of care include the need for large-bore IV access and blood pressure monitoring in the right upper extremity (RUE). Assuming a left aortic arch with normal branching, the RUE blood pressure reflects both cerebral and coronary pressures (as the innominate artery arises precoarctation). In contrast, a lower extremity or left upper extremity blood pressure would underestimate these values and lead to unnecessary treatment if used. Additional arterial access beyond that placed by the interventionalist is usually unnecessary but may be indicated based on individual patient risk and need for postprocedural monitoring (e.g., infants with severely depressed LV function undergoing angioplasty as a temporizing procedure or for recurrent CoA following stage 1 palliation). Of note, the arterial access placed by the interventionalist is most often at the femoral artery but can include the carotid or axillary arteries in smaller patients (<2 kg) to avoid femoral artery injury. In older patients, rapid RV pacing may be used when stenting is planned to minimize the risk of migration with deployment and is well tolerated in those with preserved LV function. Postprocedural disposition is guided by preprocedural clinical status. For most undergoing elective intervention, neither ICU admission nor IV antihypertensives are needed.

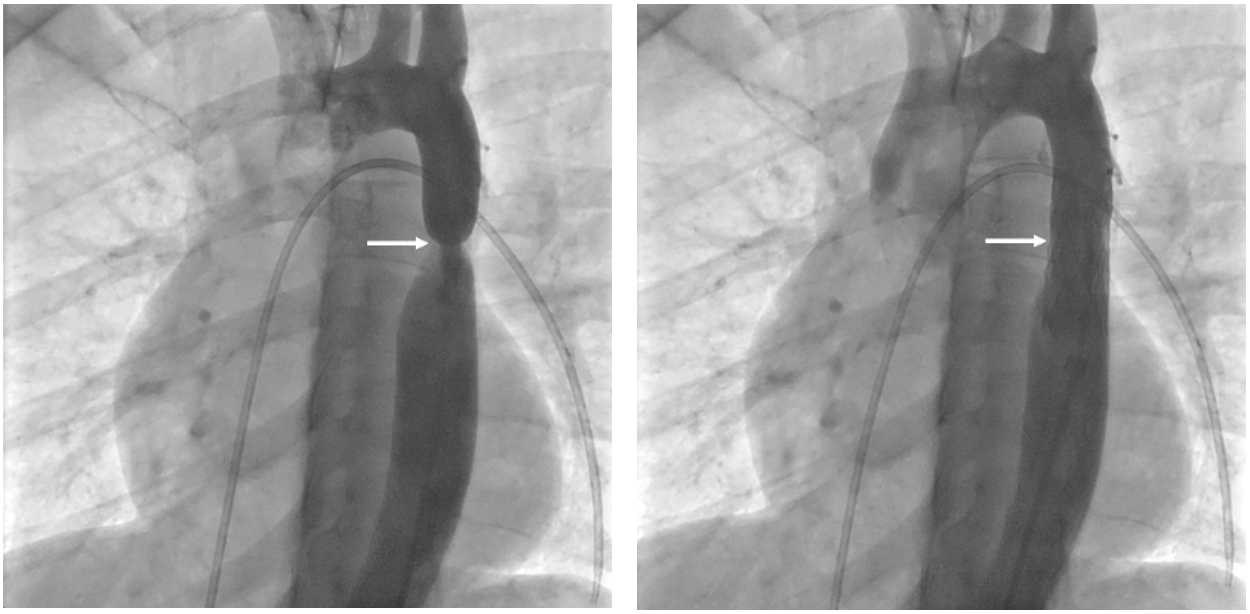

Figure 34.13 Coarctation of the aorta angioplasty and stenting. (A) Severe native coarctation of aorta (arrow) in an 18-year-old adolescent. (B) After bare metal stent implantation (arrow) from a femoral arterial approach, there is unobstructed flow in the descending aorta. (Source: Texas Children's Hospital Cardiac Catheterization Laboratory.)

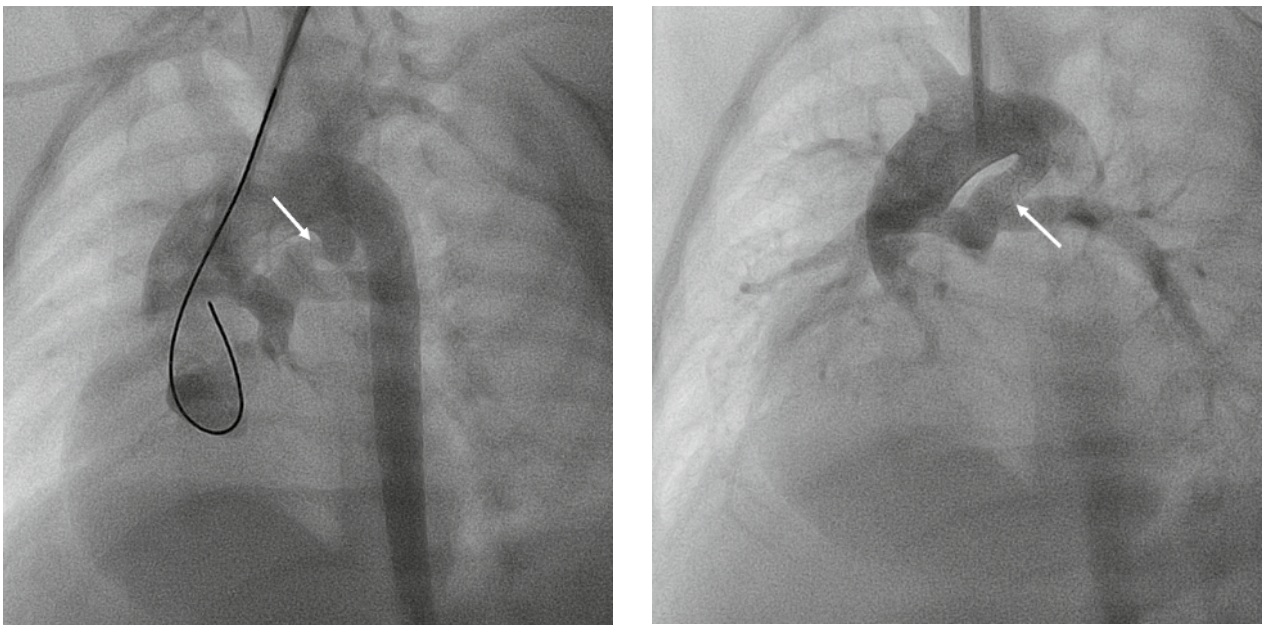

Acute complications include vessel dissection or disruption, cerebrovascular accidents, stent migration, and balloon rupture [89, 90]. Patients weighing <30 kg presenting for stenting should raise concern for the potential for access site injury. The sheath size necessary to deliver the stent can approximate the size of the femoral or iliac arteries themselves, thereby increasing the risk of vascular disruption with both sheath placement and withdrawal. Acute hypotension unrelated to pacing or ballooning should elicit evaluation for contrast extravasation. Temporary balloon inflation and subsequent covered stent placement are used to temporize in such situations. The risks of both aortic dissection and cerebrovascular accidents appear higher with older age, with patients over 40 years of age at greatest risk [90]. Aneurysm formation at the site of intervention is a late complication more associated with angioplasty alone than stenting.

Patent ductus arteriosus stenting to augment pulmonary blood flow

Ductal stents have been used increasingly in recent years in the initial palliation of neonates with ductal-dependent PBF (Figure 34.14). Data comparing ductal stenting to the mBTS have demonstrated comparable outcomes in terms of death and unplanned reintervention to address cyanosis [91]. Children receiving ductal stents have decreased lengths of stay in the ICU, lower procedural complications, and larger and more symmetric PAs at the next stage of palliation relative to those managed with a mBTS [88]. These positives are balanced, however, by an increased need for subsequent reintervention and a higher initial failure rate due to an inability to stent the duct [91, 92]. This latter concern and the unique complications that may occur during the procedure are of interest to the anesthesiologist.

PGE_1 can be either continued or stopped in preparation for ductal stenting. If continued, there may be concern that the PDA is tortuous and at risk for spasm with manipulation. More commonly, PGE_1 is stopped hours prior to the procedure [1]. This is to produce a reduction in ductal diameter that allows the stent to be well anchored on release, thereby decreasing the risk of embolization. Ductal narrowing is clinically apparent when the patient begins to desaturate. The time interval between stopping PGE_1 and the onset of desaturation, often known to the ICU through previous trial and error, can inform scheduling as well as guide urgency. The ideal situation would be to have the child positioned and prepped in the CCL before severe desaturation occurs. In the event of such desaturation, PGE_1 can be restarted (patients who are entirely ductal dependent are particularly vulnerable). For those with an ancillary source of PBF (e.g., PS or PA/IVS following RF perforation and dilation), an alternative strategy can be to start vasoactives to augment PBF while the procedure proceeds urgently.

The duct can be approached from a variety of access points dictated by its location on the aorta [93]. The particular approach used influences patient positioning and any additional monitoring that may be needed. Patients with a percutaneous carotid or axillary approach may require positioning such that the airway is directed 180 degrees away from the anesthesiologist (called the "flip technique") [94]. Care in securing the ETT, IVs, and monitoring lines is essential as patient access is limited in this position.

(A) (B)

Figure 34.14 Ductal stent for pulmonary blood flow. (A) A tortuous ductus arteriosus (arrow) can be seen supplying confluent branch pulmonary arteries in a neonate with ductal-dependent pulmonary blood flow. Also noted is a percutaneously placed left common carotid artery sheath. (B) A ductal stent is seen (arrow) that has been placed via a percutaneous left common carotid artery approach. AL Grawany

Beyond standard monitoring, placement of an additional arterial line is often indicated. Because the arterial access obtained by the interventionalist may be used for deploying the stent, a separate arterial line is needed to provide accurate blood pressure monitoring and blood gas assessment both during and after the procedure. The location of the duct and the interventionalist's approach can guide where to place this line. For example, in a patient undergoing a left axillary artery approach, a left radial arterial line (and the pulse oximeter on that hand) would be blunted. In the absence of central venous access, two peripheral IVs are placed: one to allow for volume resuscitation and bolus drug administration and the other for continuous infusions of vasoactives. It is the norm at our institution to initiate vasoactives during this procedure, whether with epinephrine, vasopressin, or both. For patients undergoing a common carotid approach, cerebral near-infrared spectroscopy (NIRS) on the side being accessed may be useful to detect changes in perfusion [95]. A Foley catheter is routinely placed. Other concerns common to the neonatal population include maintaining normothermia and normoglycemia. A forced air warmer and the use of a dextrose-containing carrier fluid can address these issues.

Critical events that may occur with manipulation of the ductus include ductal spasm and thrombosis. In patients who are ductal dependent, either event can lead to life-threatening hypoxia. Boluses of epinephrine (1–10 mcg/kg) can support hemodynamics while attempts are made to open the ductus, and in the case of spasm, PGE_1 can be reinitiated at high dose (0.1 mcg/kg/min) or given as a bolus (0.1 mcg/kg). PGE_1 should, therefore, always be immediately available. Thrombosis can be managed additionally with a bolus of heparin (100 units/kg). Preparations for ECMO are made if attempts at restoring ductal patency are not rapidly successful. Even in cases when ductal spasm does not obviously occur, passage of the wire through the ductus can also promote desaturation. FiO_2 is increased in anticipation of this event, and vasoactives are titrated to optimize PBF. Other intraprocedural complications of note include dissection and stent embolization [1, 93]. The latter may prove difficult to retrieve and can adversely affect systemic blood flow or PBF. Following successful stenting, oxygen saturations should improve. Attention is then shifted to minimizing the risk of overcirculation by titrating down on FiO_2 and vasoactive support as able. Patients are most often kept intubated following the procedure to allow for further stabilization and optimization prior to extubation. Prior to leaving the CCL, perfusion to the extremity used for access is evaluated. If there are any concerns for inadequate pulses or a cool extremity, a heparin infusion is started. Further discussion of ductal stenting is presented in Chapter 19.

Creation of cardiovascular communications

Balloon atrial septostomy

Balloon atrial septostomy (BAS) is indicated in those forms of CHD that require an unrestrictive atrial septal communication. Examples include d-TGA (to improve systemic saturations through better mixing), hypoplastic left syndrome (to relieve left atrial hypertension), or tricuspid atresia, total anomalous pulmonary venous return, or severe PS/atresia (to off-load the right heart and augment cardiac output).

The procedure is performed through either umbilical or femoral vein access and, in the case of d-TGA, can often be done at the bedside with TTE guidance. Once the balloon catheter is positioned in the left atrium, the balloon is inflated and a forceful jerk is applied to bring the balloon back to the right atrial–inferior vena cava junction [1]. This is repeated as needed to achieve an unrestrictive atrial communication. A subset of patients with thicker atrial septae for whom a BAS alone would be ineffective include neonates with hypoplastic left heart and infants older than 4–6 weeks. An atrial communication in these children is created using RF perforation or blade atrial septostomy, followed by ballooning and/or stenting of the atrial septum. Given the increased complexity of this group and need for fluoroscopy, these procedures are performed in the CCL.

Different anesthetic techniques can be used in the stable neonate undergoing BAS. Our approach is to intubate using low-dose fentanyl (and/or ketamine) and muscle relaxant, and in those with an uncomplicated preprocedural and intraprocedural course, to extubate following successful ballooning. Those who are critically ill beforehand, such as the hypoplastic left heart syndrome (HLHS) patient with a highly restrictive atrial septum, are often already intubated and receiving significant inotropic and ventilatory support. Management is supportive until the atrial septum is opened. Thereafter, oxygen saturations should increase but can occur at the expense of systemic perfusion. Acute hemodynamic instability can result with the increase in Qp and loading of the RV.

Procedural complications are rare but can include balloon rupture and embolization of balloon fragments, stent embolization (if an atrial septal stent is used), vascular injury including avulsion of the pulmonary vein or inferior vena cava, or cardiac injury or perforation [1]. Examples of the latter are mitral valve injury with distal placement of the balloon, or rupture of the atrial appendage.

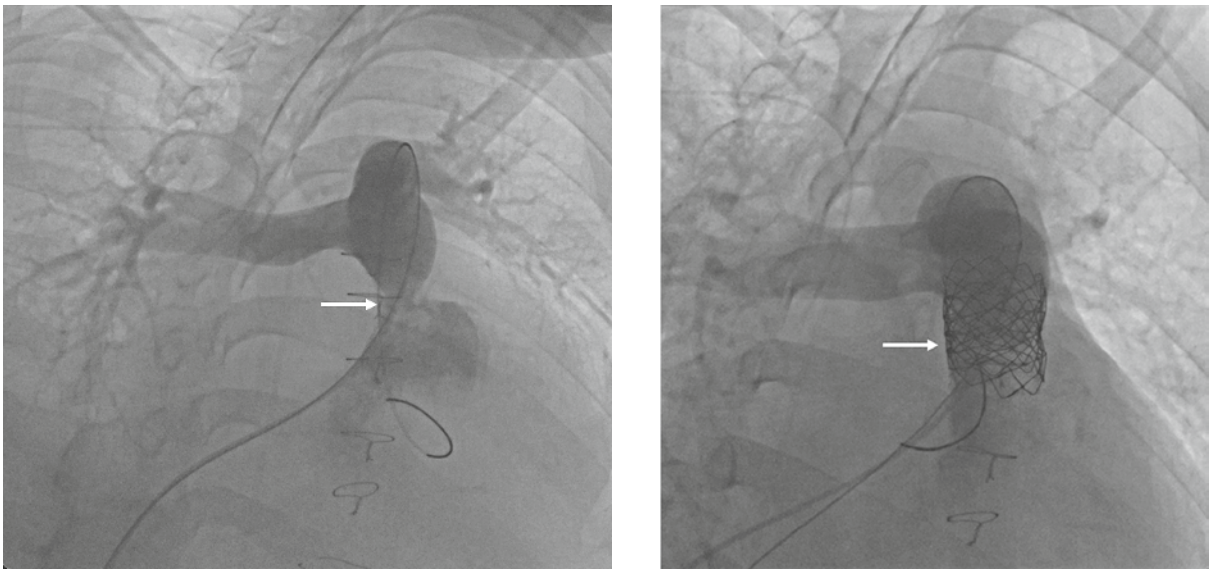
Palliation in pulmonary hypertension

In the child with worsening PH who is unresponsive to medical therapy, catheter-based options for decompressing the RV and pulmonary vasculature include atrial septostomy/stenting, PDA stenting, and the reversed Potts shunt (left PA to descending aorta). While these procedures result in desaturation due to right-to-left shunting, they differ in the end organs affected [15]. With atrial septostomy, all end organs (including the brain and myocardium) are subject to desaturated blood. In contrast, the PDA stent and reversed Potts shunt deliver deoxygenated blood only to the splanchnic and lower extremity circulations (while preserving oxygenated blood flow to the brain and heart). Additional benefits over an ASD include a decrease in RV afterload, with a subsequent improvement in LV performance through a more normalized position of the interventricular septum. The reversed Potts shunt can be achieved via either ductal stenting in those infants and young children who have a still persistent PDA or the *de novo* creation of a left PA–descending aorta connection. The latter is achieved using RF perforation and the placement of a covered stent [96]. Concerns for both techniques include the risk of too large a shunt: decreased PBF with subsequent hypoperfusion of the brain and heart (due to decreased LV filling) and severe lower extremity

desaturation. Alternatively, blood flow from the aorta may be siphoned into the pulmonary circulation when PAP is subsystemic. One-way valves have been used to address this [97]. Such patients are clearly among the highest risk for hemodynamic decompensation. Established strategies for the anesthetic management of severe PH apply.

Fontan fenestration creation

Children with the Fontan circulation may need a fenestration in the setting of worsening systemic venous hypertension (presenting clinically as protein-losing enteropathy or persistent pleural effusions) or to achieve intracardiac access for arrhythmia ablation. An opening is most often created using a combination of needle/RF perforation and ballooning (with or without stenting), fluoroscopy, and echocardiography. Procedural risks include bleeding with pericardial effusion or tamponade, systemic embolization of air or thrombus, and volume overload with lengthy attempts at conduit perforation. Anesthetic risk is associated with the underlying Fontan physiology and the negative effects of PPV (on venous return) and anesthesia (on SVR and venous capacitance).



Transcatheter valve replacement

Transcatheter pulmonary valves

The need for reintervention is almost universal among patients with abnormalities of the RVOT and pulmonary valve. Regardless of the prior palliation (whether a RV to PA conduit, transannular patch, balloon valvuloplasty, or replacement of the pulmonary valve altogether), additional interventions can be anticipated over time to address progressive stenosis and/or insufficiency. Conduits, such as those used in truncus arteriosus, pulmonary atresia, some forms of transposition, and the Ross procedure, fail due to stenosis and insufficiency associated with valve degeneration, loss of conduit diameter, and fixed size as the patient grows. The RV consequently becomes pressure and volume overloaded. On the other end of the spectrum are patients with TOF with transannular patches who develop worsening RV dilation due to free pulmonary insufficiency alone. In both cases, RV failure and intractable arrhythmias can result if the stenosis and/or insufficiency are not addressed.

Transcatheter pulmonary valve replacement (TPVR) has revolutionized the management of many of these patients since its introduction two decades ago. Candidates include those who have an adequately sized conduit or native RVOT to accept the available valves [98–100] (Figure 34.15). Broader application is currently limited by the size mismatch between current devices and their landing zones (e.g., a child with a transannular patch may have a dilated RVOT too large to accommodate a TPVR). Devices that are self-expanding and hour-glass in shape have recently become available, however, and may lead to increased utilization in this population [98, 101].

The status of the RV guides anesthetic management and risk assessment. Patients with preserved RV function undergoing TPVR are at low risk for anesthesia-induced hemodynamic instability. Anesthetic techniques can include sedation with attention to increasing depth during stimulating portions (e.g., initial access, sheath upsizing for valve deployment, and ballooning and/or stenting of the existing valve or conduit) or GETA. Lengthy procedural times, the potential for significant procedural complications, and the need to avoid movement during valve deployment bias our management toward the use of GETA. Patients with preexisting RV dysfunction in the setting of long-standing insufficiency or severe conduit or native RVOT stenosis, in contrast, represent

(A) (B)

Figure 34.15 Transcatheter pulmonary valve replacement. A morbidly obese 27-year-old female status post Ross procedure at age 9, now with severe conduit stenosis and severely depressed RV function, presented for TPVR. (A) A severely narrowed and calcified RV-PA conduit is seen (arrow) with regurgitation. (B) After angioplasty, stent placement, and transcatheter pulmonary valve placement (arrow), there is no significant residual stenosis or regurgitation. AL Grawany

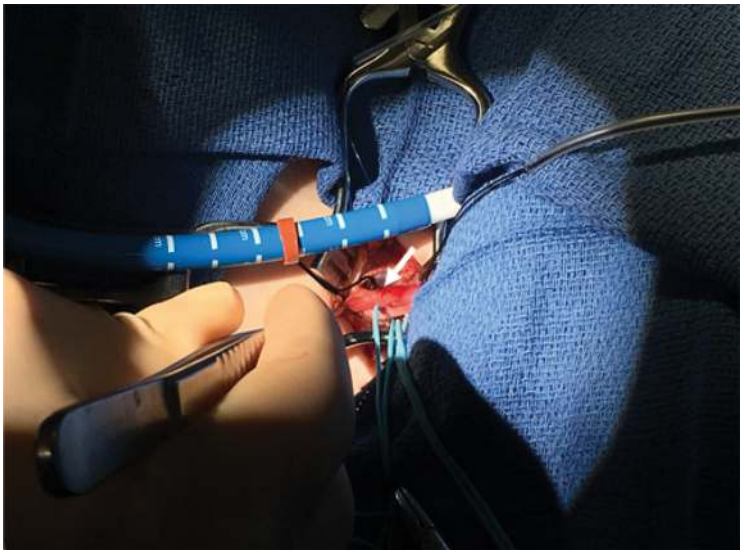
a higher risk group. Such patients may already be receiving inotropic support entering the procedure and may require uptitration and the addition of a vasopressor with the induction of general anesthesia. Occasionally, patients with long-standing RV dilation may also have TR and significant right atrium (RA) dilation, which provides a nidus for atrial dysrhythmias. Maintaining sinus rhythm and age-appropriate systemic blood pressure is central to avoiding RV ischemia in the setting of RV hypertension and elevated RVEDP. Large-bore IV access is routinely obtained to allow for volume resuscitation and vasoactive administration. External defibrillator pads and packed red blood cells need to be immediately available. Additional arterial access apart from that placed by the interventionalist is considered in those with RV dysfunction who may become hypotensive upon induction or with the institution of PPV. Patients who tolerate the procedure well are extubated. Given the large size of the venous sheaths placed (22–24 French), aggressive PONV prophylaxis and analgesia are administered to decrease the risk of bleeding associated with emesis or pain.

Major periprocedural complications include (i) coronary or aortic root compression, (ii) RV to PA conduit rupture, (iii) PA injury, (iv) postdeployment pulmonary edema, and (v) valve malposition/embolization [102–106]. Coronary compression can occur with ballooning of either the RV to PA conduit or the native outflow tract due to proximity of the coronaries to these structures. Consequently, a coronary angiogram is performed simultaneously with RVOT ballooning and after stent and valve placement to ensure coronary patency [100, 105]. Aortic root compression can occur similarly with resulting aortic insufficiency. Partial or total conduit rupture is associated with attempts at ballooning noncompliant conduits, such as those that are heavily calcified and severely stenotic. The subsequent hemorrhage is managed with volume resuscitation and pressor support, while the interventional team places a covered stent to limit further extravasation and a pericardial drain if tamponade develops. Surgery may be needed to provide definitive therapy. PA injury is most common secondary to guidewire perforation and can result in hemoptysis or hemothorax [106]. One lung ventilation may be indicated if severe. Pulmonary edema following the relief of stenosis is thought to be secondary to an acute increase in LVEDP (due to increased PBF) in patients with underlying LV diastolic dysfunction [103] (Figure 34.16). Though this mechanism would suggest a relatively acute presentation, it has also been observed in our institution up to 16 hours after valve deployment. This late presentation may indicate the need for close postprocedural monitoring in the highest risk patients: those with chronic and severe RVOT or conduit obstruction and preexisting LV dysfunction. Management entails aggressive diuresis and supportive mechanical ventilation.

Transcatheter aortic valves

No devices are currently approved for transcatheter aortic valve replacement (TAVR) in the pediatric population. Limitations associated with current devices include their large size (and larger delivery sheaths) relative to that needed for most children. Nonetheless, a transcatheter approach offers a reasonably efficacious alternative to surgery for a select group of children who would otherwise be poor surgical candidates [107].

Underlying LV function and the severity of aortic insufficiency (AI) and/or aortic stenosis (AS) guide anesthetic management. Because this procedure is currently limited to those with a relative contraindication to surgical repair, comorbidities can further guide assessment. GETA is the rule due to the potential for complications, invasiveness, need for TEE, and procedure length. ECMO candidacy or plans otherwise in the event of intraprocedural cardiovascular collapse are determined in advance. As in PDA stenting, the approach to deploy the valve can vary and can impact the location of monitoring lines and pulse oximetry placement. In older patients who have adequately sized femoral vessels, the transfemoral approach is considered. Smaller vessel size



(A) (B)

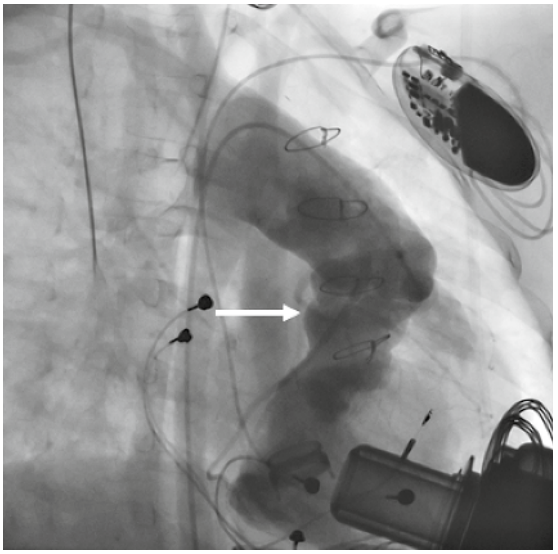


Figure 34.16 Pulmonary edema following transcatheter pulmonary valve replacement. (A) The same patient immediately following transcatheter pulmonary valve replacement. (B) 16 hours postprocedure. The patient developed dyspnea and desaturation requiring re-intubation and ultimately venovenous extracorporeal support. The presumed mechanism was increased preload to a dysfunctional left ventricle resulting in increased left-sided pressures. (Source: Texas Children's Hospital Cardiac Catheterization Laboratory.)

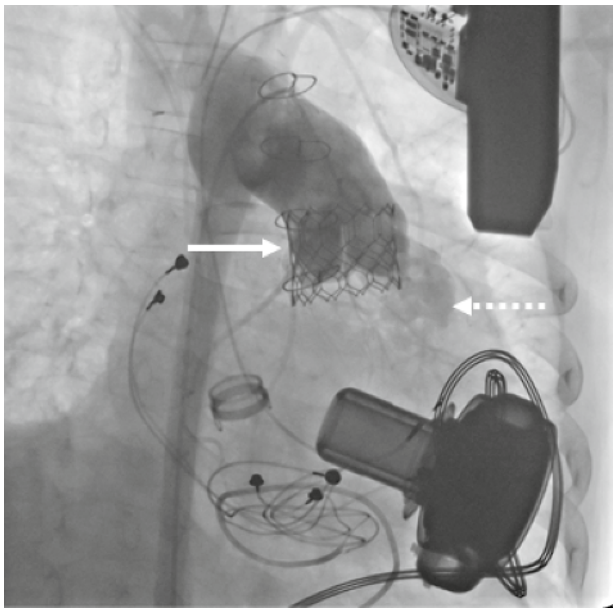
necessitates alternate approaches: a hybrid transapical approach through a thoracotomy and carotid approach via surgical cutdown have been described [107] (Figure 34.17). A dedicated arterial line in addition to the arterial access placed by the interventionalist is obtained, as are large-bore peripheral IVs. Vasoactive agents, blood, external defibrillation pads, and a Foley catheter are indicated. Periods of rapid pacing may be used prior to valvuloplasty and valve deployment. The location of pacing depends on the child's cardiac anatomy but is most often accomplished via the RV. Anticipatory support with boluses of phenylephrine before and after pacing is given.



Complications unique to children undergoing TAVR include the higher risk for vascular dissection/disruption due to mismatch between commonly used delivery devices and vessel size. As for transcatheter pulmonary valves, surgical backup should be available (if not already involved for access). Common risks otherwise include those of valve embolization

(A)

(B)

(C)

Figure 34.17 Transcatheter aortic valve replacement via the right common carotid artery. An 8-year-old child status post Heartware® ventricular assist device placement, now with progressive aortic insufficiency. Due to the high risk associated with repeat sternotomy, bypass, and cross-clamping for surgical valve replacement, a hybrid transcatheter approach was selected. (A) The right common carotid artery (arrow) can be seen exposed via a surgical cutdown, chosen for its larger size relative to the femoral artery. Also seen in the picture is the large delivery sheath used for transcatheter aortic valve placement. (B) Significant aortic regurgitation is seen (arrow). (C) A transcatheter aortic can be seen that was placed (arrow), and 3 years later, the transcatheter aortic valve was working well with trivial paravalvar leak (dotted arrow). and coronary compression with valve placement (due to direct obstruction or ostial narrowing with dilation of the annulus) [107].

Hybrid procedures

Hybrid procedures refer to joint surgical and transcatheter interventions occurring in the CCL or operating room. Though most commonly associated with the initial palliation of HLHS, hybrid approaches have also been used in periventricular closure of muscular VSDs, stenting of stenotic pulmonary veins, and valve replacement, among other procedures [108, 109]. The focus of this section is on the hybrid palliation for HLHS.

Basic aspects of this strategy include surgical placement of bilateral pulmonary artery bands (bPAB) via median sternotomy followed by ductal stenting [110] (Figure 34.18). Variations abound, however, as to (i) whether the duct is stented (some centers may choose instead to maintain ductal patency with PGE_1); (ii) when the duct is stented (either during PAB placement or as a separate procedure); (iii) whether or not an atrial septostomy or atrial septal stent is concurrently performed; and (iv) how to address the risk of retrograde aortic arch obstruction (RAAO). Atrial septostomy is often delayed in the absence of an intact/restrictive atrial septum to allow time for the left atrium to grow. With a larger left atrium, a more aggressive ballooning can be performed, leading to a larger and more durable septostomy [111]. RAAO is an important source of morbidity and mortality in HLHS as the coronary and cerebral circulations are reliant on retrograde flow through the transverse arch (entirely so in the variant of aortic atresia). Clinically significant RAAO is present in 10% of HLHS neonates at birth and can occur in an additional 24% following the hybrid procedure [108, 112]. To decrease this risk of myocardial and cerebral ischemia, some centers also perform a reverse Blalock–Taussig shunt (main PA to innominate artery) at the time of ductal stenting in at-risk patients. Others view preexisting RAAO as a contraindication to the hybrid procedure [113, 114]. For patients who develop RAAO subsequent to the hybrid procedure, treatment is achieved with retrograde arch ballooning and stenting.

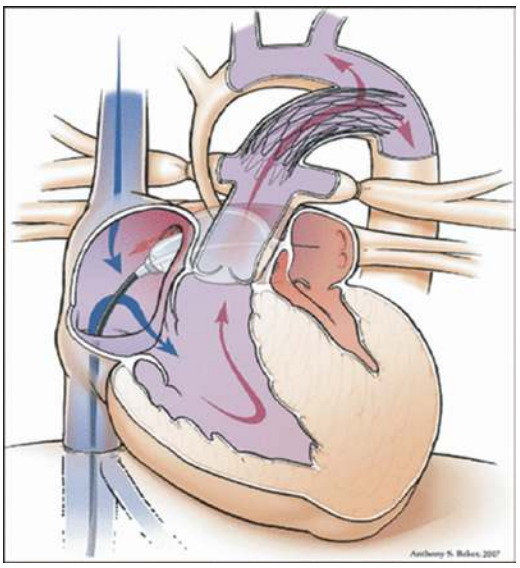

Figure 34.18 Hybrid procedure for hypoplastic left heart syndrome. Common elements include bilateral pulmonary artery bands, transcatheter stenting of the patent ductus arteriosus, and an atrial septostomy or atrial septal stent. (Source: Naguib et al. [110]. Reproduced with permission of John Wiley & Sons.)

The choice of when to use the hybrid approach versus conventional surgical management (the Norwood procedure) is institution specific and often dependent on patient factors. Advantages to hybrid palliation center around its ability to balance $Q_p : Q_s$ without the morbidity associated with cardiopulmonary bypass (and deep hypothermic circulatory arrest or selective cerebral perfusion) in the neonatal period. While few centers use the hybrid approach preferentially, others reserve it for those patients thought to be at highest risk for Norwood palliation. Such patients include those with prematurity, birth weight <2.5 kg, presence of LV to coronary fistulae, intact or restrictive atrial septum, severe RV dysfunction, moderate-to-severe TR, intracerebral hemorrhage, or persistent end-organ injury secondary to shock at initial presentation [115–117]. Disadvantages to the hybrid approach focus on the risk of RAAO, need for repeat catheter interventions prior to stage 2 palliation, impact of the bPAB on PA growth, and the complexity of the comprehensive stage 2 procedure (combined Norwood and bidirectional superior cavopulmonary anastomosis).

Anesthetic concerns specific to the hybrid approach include the potential for instability with bPAB placement and acute RAAO with ductal stent deployment [59, 110]. Arrhythmias, hypotension, and bradycardia may occur with bPAB placement as a result of contact with the left atrial appendage or manual compression of the ductus. Both are more likely to occur with manipulation of the left PA due to its proximity to these structures. Adenosine and cardioversion can be used to treat persistent supraventricular tachycardia (SVT). Compression of the ductus can be particularly threatening due to the transient decrease in myocardial perfusion. Decreases in heart rate and cerebral saturation may be the first signs of ischemia along with ST depression. Epinephrine in bolus doses of 1–10 mcg/kg may be needed to facilitate recovery. Following placement of the bPAB, systemic blood pressure should increase with a coincident decrease in oxygen saturation. If proceeding with ductal stent placement, a sheath is then placed in the main PA and the stent is deployed under fluoroscopic guidance. Because systemic blood flow is transiently altered during stent deployment, instability can also arise during this time. RAAO secondary to stent encroachment into the aorta can manifest as bradycardia, hypotension, and arrest. Monitoring of a right radial arterial pressure and cerebral saturation is recommended to allow prompt detection [59, 110]. Despite these risks, the procedure appears to be well tolerated. Naguib et al. in a review of the anesthetic management of 77 patients undergoing hybrid palliation reported that epinephrine infusions were initiated in only 4 patients and epinephrine boluses were required in only 5. 27% were transfused blood, and 60% of those who were intubated solely for the procedure were extubated at the end of the case. See Chapter 30 for additional discussion of the hybrid approach for HLHS.

Pericardiocentesis

The need for pericardiocentesis may arise acutely during interventional catheterization or more electively in a child with a postsurgical, neoplastic, or infectious effusion. The former may occur during endomyocardial biopsies, interventions at the RVOT (RF perforation in PA/IVS, RVOT stenting, transcatheter PVR, or conduit interventions), or transseptal approaches to the left atrium. Clinically, these acute bleeds can result in precipitous hypotension due to tamponade. Treatment requires emergent pericardial drainage with autotransfusion as indicated [118]. Autotransfusion entails siphoning the blood that is drained (a stopcock can be placed on the drain catheter for pulling blood into a syringe) and immediately returning it to the patient without any delay or storage (see Figure 34.19). Additional nonautologous transfusion is often needed in neonates and infants to maintain intravascular volume. Blood pressure is supported with epinephrine, and protamine may be needed to reverse heparin-induced coagulopathy. Surgery is indicated if the bleeding does not stop with these measures.

Children presenting to the CCL for primary drainage of a pericardial effusion can vary in their clinical presentation. Rarely do they present with signs and symptoms of frank tamponade: low cardiac output as evidenced by anxiety, cool extremities, tachycardia, tachypnea, pulsus paradoxus, and marginal blood pressures [119]. More often, patients appear stable, belying their potential for decompensation. Anesthetic management entails ensuring adequate preload and maintaining SVR, contractility, and heart rate (i.e., fast, full, and tight) [119]. Because stroke volume is relatively fixed in tamponade, marked decreases in heart rate will lead to proportional decreases in cardiac output. Postcardiac surgery patients are often on aggressive diuretic therapy preprocedurally in attempts to decrease the size of their effusions. This population needs volume resuscitation prior to anesthesia.

GETA is avoided to minimize the additional risks of PPV. Spontaneous ventilation is maintained using a combination of ketamine and midazolam. Morphine is not used predrainage because of its potential to decrease SVR, nor are rapid boluses of dexmedetomidine administered due to associated

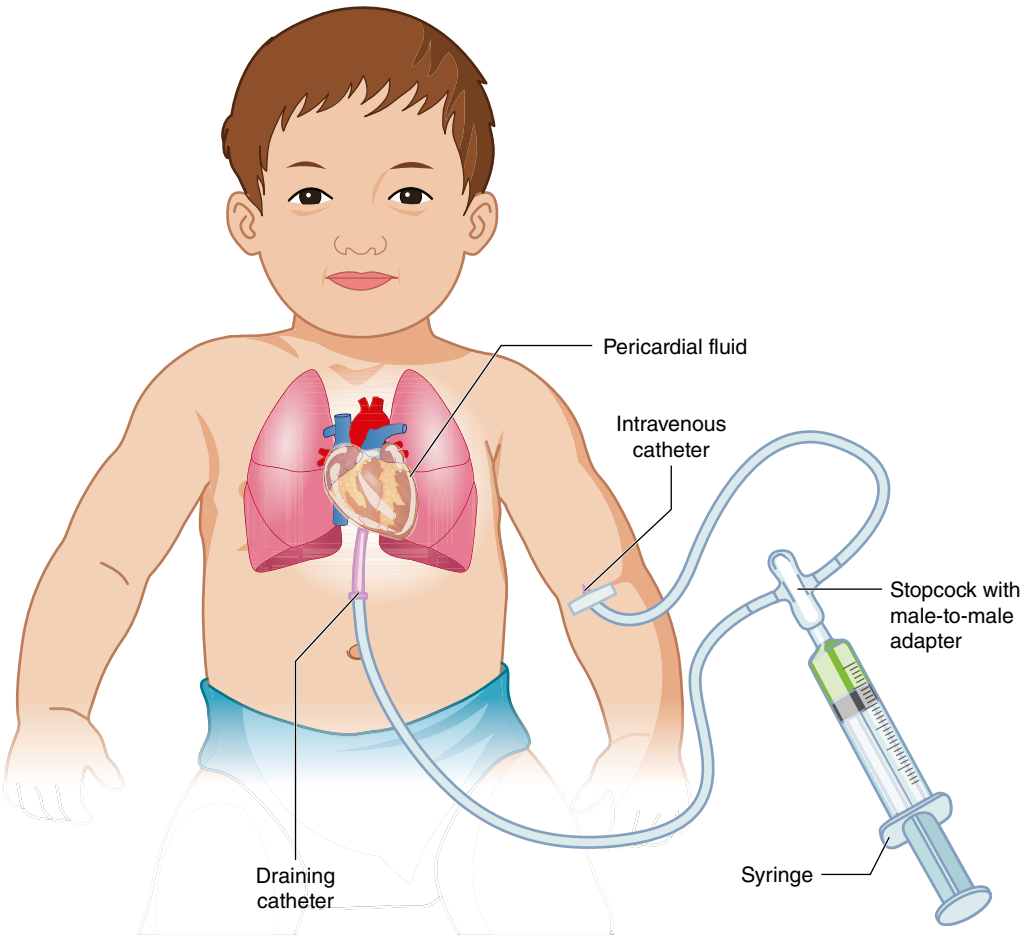

Figure 34.19 Autotransfusion following an acute pericardial bleed. A filter is used prior to reinfusion to avoid embolization of thrombi or fat particles from the pericardial space. Autotransfusion should not be performed when there is suspicion for an infectious or neoplastic effusion to prevent systemic spread. (Source: Mossad [118]. Reproduced with permission of Elsevier.)

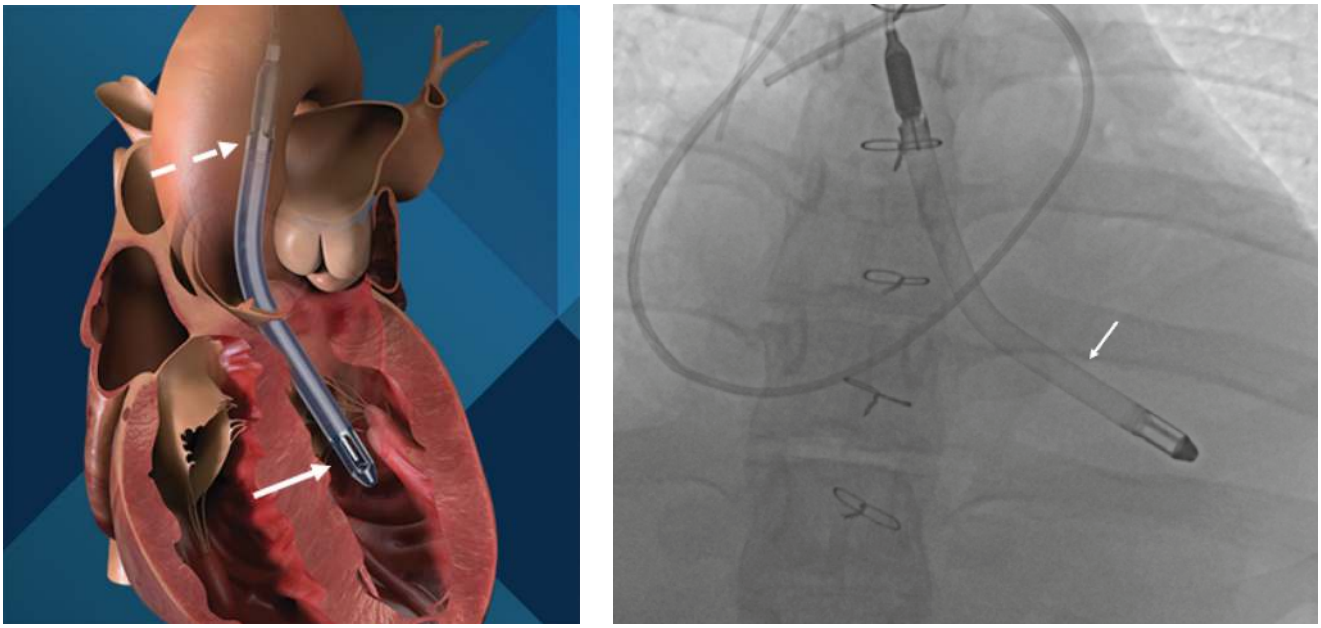
AL Grawany



bradycardia. In children in whom the above efforts are ineffective, an alternative strategy is to use low-dose sevoflurane (2–3%) to maintain spontaneous ventilation. Vasopressors and inotropes should be at the ready if needed. Positioning of the patient in the CCL is in the semi-Fowler's position with back elevated at 30°–45° to allow the pericardial fluid to accumulate inferiorly. The airway remains accessible in this position, but if intubation is required subsequently, the patient is positioned supine. The effusion is drained under echocardiographic guidance following local anesthetic administration. Procedural complications include needle- or wire-induced laceration of the ventricle, coronary artery or vein, arrhythmias, or injury to the lungs or esophagus. Postprocedurally, pulmonary edema may develop due to LV dysfunction associated with the acute increase in LV preload [119]. Additional discussion of pericardial effusion is presented in Chapter 31.

Percutaneous mechanical circulatory support

The role of the interventionalist in mechanical circulatory support (MCS) has grown in recent years in parallel with the increased utilization of percutaneous ventricular assist devices (PVADs) in the management of pediatric cardiogenic shock. Such devices may be placed as the primary procedure (e.g., LV decompression while on venoarterial ECMO or as a bridge to a durable VAD, transplant, or recovery) or as a supportive intervention in the setting of another high-risk procedure (e.g., PVAD backup for an endomyocardial biopsy in a patient with presumed acute graft rejection and tenuous hemodynamics).

The oldest of these devices is the intra-aortic balloon pump (IABP). Used primarily in adults, IABPs have also been used in infants and children [120–124]. IABPs assist the failing ventricle by augmenting diastolic perfusion pressure and decreasing afterload by timing balloon inflation to diastole and deflation to systole [124]. Constraining its use in pediatrics has been the limited support it offers in florid ventricular failure, and technical challenges in timing balloon inflation and deflation to changes in rate and rhythm. Nonetheless, as volumes of adults with CHD increase in pediatric centers, this therapy may experience a resurgence.

A more recent introduction has been the off-label use of the Impella® Heart Pump (Abiomed Inc., Danvers, MA) [125, 126]. The Impella is a continuous axial flow device that extracts blood from the failing ventricle and delivers it to the aorta (Figure 34.20). In doing so, it unloads the ventricle and augments cardiac output. Available configurations include the Impella 2.5, cardiac power (CP), 5, and 5.5, which, respectively, provide flow rates of up to 2.5, 4.3, 5, and 6.2 L/min (Table 34.7). The specific device used is guided by patient size and the indication for support. Most commonly, the 2.5 and CP are used for younger patients or those on ECMO in need of LV decompression. The 5 and 5.5 are used for larger patients and those in need of the higher flows that these devices can provide. The device used, procedural urgency, and anticipated duration of support inform placement at either the femoral artery or surgical cutdown at the axillary artery. Fluoroscopy

Table 34.7 Characteristics of and indications for the different Impella heart pumps

	Insertion site	Indications	Maximum flow (L/min)	Pump motor/catheter diameter (Fr)
2.5	Percutaneous femoral or axillary arteries	• VA ECMO LV unloading	2.5	12/9r
CP	Percutaneous femoral or axillary arteries	• VA ECMO LV unloading • Temporary LV support	4.3	14/9
5.0	Percutaneous femoral or via surgical graft onto the axillary artery	• Temporary LV support • Bridge to VAD or OHT	5.0	21/9
5.5	Percutaneous femoral or via surgical graft onto the axillary artery	• Temporary LV support • Bridge to VAD or OHT	6.2	19/9
RP	Femoral venous only	• RV support	4.6	22/11

ECMO, indicates extracorporeal membrane oxygenation; LV, left ventricle; OHT, orthotopic heart transplant; RV, right ventricle; VA, venoarterial; VAD, ventricular assist device.

and TEE guide placement. Echocardiographic features predicting successful placement include a minimum LV apex to aortic valve length of 7.5 cm and an aortic annulus >1.5 cm, corresponding with an average weight of 23 kg and body surface area (BSA) of 0.89 m^2 [127]. (Morray 2019). The youngest patient to date supported with an Impella was a 4-year-old weighing 15 kg with a BSA of 0.67 m^2. RV support can also be provided by the Impella RP, which has been used in a child as young 14 years of age with a BSA of 1.4 m^2 [126].

Although sedation has been used for femoral Impella placement, our usual strategy in patients not already intubated is to proceed with GETA. The usual considerations for high-risk patients apply and include the availability of blood, vasoactive agents, adequate venous and dedicated arterial access, defibrillation pads, and the preprocedural determination of ECMO candidacy in the event of arrest. A surgical cutdown at the axillary artery with placement of a chimney graft adds to the duration of the procedure both due to the dissection and the time needed to pass the device through the graft. If the arterial line used for monitoring is on the same extremity as that used for axillary device placement, a brief period of dampening is to be expected. Arrhythmias during placement are common due to ventricular ectopy. TEE guidance is essential to diagnose complications such as deep placement within the LV that may entangle the mitral valve chordal apparatus, or incomplete coaptation of the aortic valve leaflets causing new insufficiency [128]. The Impella monitoring screen can help in assessing device placement once TEE is removed [129] (Figure 34.21). Once proper positioning is confirmed, the Impella is initiated between P0 and P9: the higher the number, the greater the revolutions per minute and therefore flow support. Anticipated hemodynamic changes include an overall increase in cardiac output with a decrease in native stroke volume and pulmonary capillary wedge pressure. Vasoactive support is usually not changed in this acute period as the RV may still need support to provide LV filling. Prior to returning to the ICU, a Swan-Ganz catheter is commonly placed to guide ICU management for escalating or weaning support. Periprocedural complications include limb ischemia, vascular injury, bleeding, hemolysis, suction events, and device failure [125]. Anticoagulation is maintained with heparin through the device's purge fluid, and if inadequate, systemic heparin is added.

The use of ECMO in the CCL, still the most common type of MCS in children, warrants further discussion. For high-risk patients who may require ECMO during the procedure, consideration should be given to scheduling the procedure in the lab that is most suited to ECMO. Such a lab is usually large, with adequate oxygen and air attachments to accommodate both the ECMO circuit and anesthesia machine. Moreover, the ECMO circuit should be easily positioned within the room, with unimpeded entry into and exit from the lab. Similar considerations apply for patients already on ECMO who need a diagnostic or interventional procedure. Extensive further discussion of MCS is presented in Chapter 37.

KEY POINTS: INTERVENTIONAL CATHETERIZATION

- The range of interventions possible continues to expand with recent growth in the areas of ductal stenting, pulmonary vein intervention, TPVR, MCS, and transcatheter closure of PDAs in premature infants.
- A corollary of this growth is an increase in the acuity and complexity of the patients presenting to the CCL.
- Such complexity underscores the need for anesthesia involvement in the planning of these increasingly high-risk procedures and for awareness of the unique complications that can arise and how to manage them.

Adverse events

Adverse events associated with catheterization can be related to the procedure, anesthetic, or environment of the catheterization suite [46, 130–132] (see Table 34.8). While the majority of such events are well tolerated and resolve with either minimal or no intervention (e.g., transient catheter-induced arrhythmias or superficial hematomas at vascular access

AL Grawany

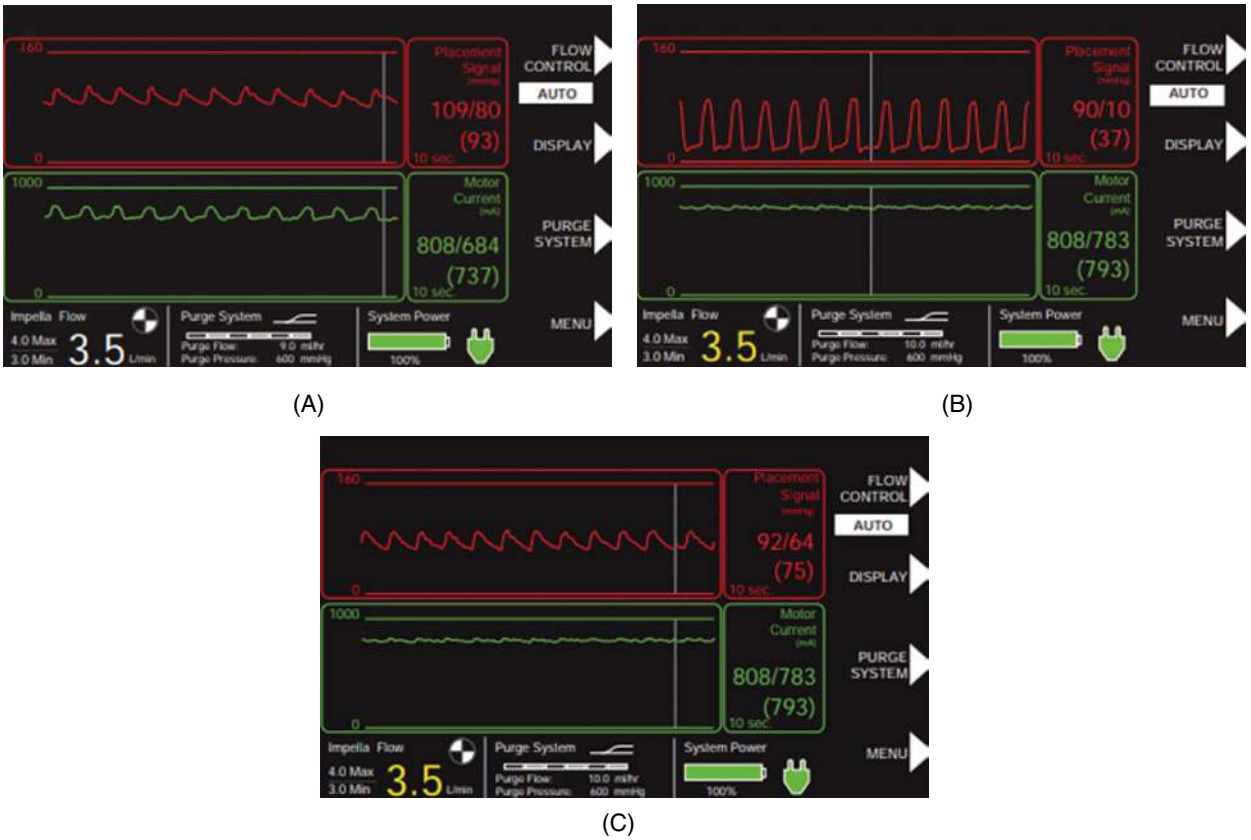

Figure 34.21 Impella controller screen can indicate device malposition. The Impella device can move either into or out of the left ventricle with patient movement. sites), significant life-threatening events can and do occur. Termed major adverse events (MAEs) or serious adverse events (SAEs) depending on the reporting registry, these complications can cause mortality or permanent morbidity and are characterized by an escalation in support, further catheter-based or surgical intervention, and/or an extended length of stay. Examples include pulmonary hemorrhage resulting in hypoxemia and chest compressions, or catheter-induced third- degree heart block requiring transvenous pacing.

MAEs occur in 2–7% of all congenital cardiac catheterizations [130, 131, 133–135]. The wide range is attributable to the varying definitions of what constitutes such events. The most common causes reported include access site complications, hemodynamic compromise requiring inotropic support and/or chest compressions, unanticipated blood transfusion, and hemodynamically unstable arrhythmias requiring electrical and/or pharmacologic therapy. For the subgroup of interventional procedures, the leading causes of high severity events are device or stent migration, malposition, or embolization.

Mortality related to catheterization is rare and ranges between 0.08 and 0.29% [130–132]. Cardiac arrest occurs with a higher frequency, with one group reporting 0.7% [128] and another 0.96% [46]. As a reference, the benchmark estimate of the incidence of perioperative cardiac arrest in all pediatric patients is 0.014% [136].

Significant complications associated with anesthetic induction and airway management appear to be infrequent. In one series of 29,830 pediatric patients from 27 centers, cardiac arrest with induction of anesthesia was observed in 0.12% of all procedures [130]. Airway complications, including accidental extubation during the procedure, failed extubation, unanticipated need for intubation during/after the procedure, and postextubation stridor or laryngospasm, occurred in 0.16% [130]. In another review of 13,611 pediatric patients at eight centers, the most common reported anesthesia- and sedation-related adverse event was hypotension [132]. This occurred in 93 (0.68%) patients and was observed primarily with anesthetic induction. While the majority of hypotensive events were minor-to-moderate in severity, some were associated with cardiopulmonary resuscitation (CPR) and ECMO. High severity events associated with anesthesia, sedation, and airway management were observed in 94 (0.69%) patients, with an overall mortality within this group of 0.015% [132].

Risk assessment

Several risk scoring and risk adjustment models have been developed to identify key contributors to significant adverse events [130, 131, 134, 135, 137, 138]. A consistent theme among these models is the influence of procedural complexity and patient characteristics in determining risk.

Because there are over 200 interventional procedures that may be performed, procedural risk categories were developed to group together those procedures with similar risk [131] (Table 34.9). These categories were based on expert consensus and empirical data. The impact of procedure type on the risk of an MAE can be observed by their associated odds ratios (ORs). A category 2 procedure carries an OR of an MAE of 1.79, whereas a category 6 procedure carries an OR of 9.69. Odegard et al. reported the highest incidence of cardiac arrests in patients undergoing VSD closure (11.9/100 procedures), intervention for intact atrial septum in patients with an atrial restriction (10.0/100 procedures), and pulmonary vein angioplasty (3.6/100 procedures) [46]. These are all defined as category 5 procedures. Of note, diagnostic catheterizations are generally lower risk than interventional ones. An important exception is diagnostic catheterization in neonates and infants.

Patient characteristics are equally significant (Table 34.10). Of patient-specific variables, age <1 year, weight <5 kg, single-ventricle physiology, chromosomal abnormalities, genetic syndromes, and noncardiac comorbidities all increase risk [131]. Among the subgroup of patients aged <1 year, neonates and those weighing <2.5 kg are most likely to experience adverse events. That patients with single-ventricle physiology are at increased risk is consistent with data reported in the Pediatric Perioperative Cardiac Arrest Registry [139]. Within this group, ductal- or shunt-dependent lesions and failing Glenn or Fontan physiologies are most concerning. Examples of other high-risk diagnoses include patients with cardiomyopathies with depressed systolic function, LV outflow tract obstruction (specifically unrepaired supravalvar AS), and PH [130]. Of the latter group, patients with suprasystemic pulmonary pressures, premature neonates, and non-premature infants are at increased risk of catastrophic adverse events [22, 28]. A final population warranting mention are heart transplants with CAV or acute rejection [22]. Such patients are predisposed to myocardial ischemia, ventricular dysrhythmias, and cardiac arrest at baseline.

Of the noncardiac comorbidities observed in patients presenting for catheterization, chronic lung disease is most common. The highest ORs for complications, however, are associated with renal insufficiency, hepatic disease, and coagulation abnormalities [131]. These findings may occur independently of the underlying cardiac disease or represent sequelae of poor cardiac output.

Preprocedural status can further inform a patient's risk. A child requiring vasoactive infusions (including PGE_1) or antiarrhythmics prior to catheterization begins with a lesser margin to tolerate anesthetic- or catheter-induced instability. Precatheterization hemodynamic variables such as systemic or mixed venous desaturation, or evidence of elevations in PVR, $Q_p : Q_s$, or systemic ventricular EDP are also factors associated with complications [130, 131, 135]. While some of these data can only be quantified during the catheterization itself, one can qualitatively assess many of these physiologic variables preprocedure based on prior history, clinical evaluation, and echocardiography.

When examining risk factors in *adults* with CHD undergoing catheterization, many of the same contributors are observed: procedure type, comorbidities, and certain physiologic variables [134, 140, 141]. In one model reviewing data from 87 hospitals in the United States, the strongest variables predicting MAEs were procedure complexity and urgency. Other factors of importance included a history of renal disease, preprocedural anticoagulant use, lower hemoglobin, and older age (Figure 34.22). The physiologic factors indicating risk included a lower oxygen saturation, pulmonary hypertension, elevated systemic ventricle EDP (≥18 mmHg), and a cardiac index less than 2.8 L/min/m^2 [134, 141].

In both pediatric and adult populations, institutional case volume appears to impact the MAE rate. Complications

ASD, indicates atrial septal defect; AVM, arteriovenous malformation; BAS, balloon atrial septostomy; CoA, coarctation of the aorta; MAE, major adverse event; OHT, orthotopic heart transplantation; PA, pulmonary artery; PDA, patent ductus arteriosus; PFO, patent foramen ovale; TPVR, transcatheter pulmonary valve replacement; and VSD, ventricular septal defect.

were highest in those centers performing fewer than 150 cases annually, and conversely, catastrophic complications were observed least in centers with the highest volumes [131, 142].

The question of whether or not general anesthesia with an airway device represents a higher risk for MAEs compared to sedation with a natural airway is unclear. Lin et al. compared outcomes in these groups and found that even when adjusting for procedural risk, hemodynamic factors, and age, an artificial airway was an independent predictor of MAEs and also had a higher OR for adverse events compared to a natural airway [132]. The authors suggested caution in interpreting these results, however, given the potential for unmeasured characteristics or other confounders. Risk for conversion from natural airway to intubation, observed in 1.8% of the patients reviewed, was associated with younger patients (infants), need for inotropic support, and high-risk procedures. A primary conclusion was that while sedation with a natural airway is safe and effective in low-risk patients and procedures, high-risk patients undergoing high-risk procedures are at risk of MAEs regardless of the airway management strategy. The type of anesthesia used in adults (sedation with natural airway vs. GETA) has not been found to predictive of MAEs [134].

KEY POINTS: ADVERSE EVENTS AND RISK ASSESSMENT

- MAEs associated with catheterization are infrequent, but the highest proportion are composed of access site complications, dysrhythmias, unanticipated transfusion, and device migration.
- Key variables that predict risk include the specific procedure and patient characteristics such as age, weight, cardiac diagnosis, comorbidities, and preprocedural physiologic status.
- The need for conversion from a natural airway to an artificial one is associated with age < 1 year, need for inotropy during the catheterization, and high-risk procedures.

Table 34.10 Patient factors associated with increased risk

Age	<1 year (highest in <30 days)
Weight	<5 kg (highest in <2.5 kg)
Chromosomal abnormalities	Trisomy 18
	Trisomy 21
	22q11
Genetic syndromes	Williams-Beuren
	Alagille syndrome
	Heterotaxy
SV physiology	HLHS with restrictive or intact atrial septum
	Ductal or shunt dependent
	Failing Glenn or Fontan circulations
Diagnoses otherwise	OHT with CAV or rejection
	Aortic or mitral stenosis
	Cardiomyopathy with depressed function or obstruction (HCM)
	Systemic-to-suprasystemic PAP (severe PH)
	PA/IVS with RV-DCC
Preprocedural physiologic status	On PGE_1, antiarrhythmics, or MCS
	Systemic desaturation (highest with <65%)
	Dynamic subpulmonary obstruction
	Hypercyanotic spells
	Severe systemic AVVR
	RVSP suprasystemic
Noncardiac comorbidities	Renal insufficiency
	Hepatic disease
	Coagulation abnormalities
	Chronic lung disease

AVVR, atrioventricular valve regurgitation; CAV, coronary allograft vasculopathy; HCM, hypertrophic cardiomyopathy; HLHS, hypoplastic left heart syndrome; OHT, orthotopic heart transplant; MCS, mechanical circulatory support; PA/IVS, pulmonary atresia/intact ventricular septum; PAP, pulmonary artery pressure; PGE_1, prostaglandin E_1; PH, pulmonary hypertension; RV-DCC, right ventricle-dependent coronary circulation

Anesthetic management

Operator-directed sedation versus anesthesia care

The past two decades have seen a transition toward the use of anesthesiology care in place of operator-directed sedation (ODS) for the majority of catheter-based procedures worldwide. As of 2018, ODS was used in only 3% of cases reported to the IMPACT (IMproving Pediatric and Adult Congenital Treatments) registry, down from 19% in 2011 [143]. Several factors have driven this change, but foremost among them has been the shift in procedure type from diagnostic to interventional catheterization, with the latter associated with longer procedure times, complexity, and risk [144]. The benefit of increased anesthesia involvement has been previously demonstrated with a reduction in the frequency of cardiac arrests at one institution [46].

Nevertheless, given the spectrum of providers who can be involved in sedating and monitoring patients in the congenital cardiac catheterization lab, consensus guidelines were developed in 2016 to provide guidance on which cases should involve which providers [145]. Based on an assessment of risk as determined by the Catheterization Risk Score for Pediatrics (CRISP), it was suggested that patients with a higher CRISP score (and therefore higher risk) should be delegated to either an anesthesiologist with expertise in CHD or a pediatric cardiac anesthesiologist, whereas those with lower CRISP scores could be managed by ODS or a sedation team. A recent comparison between the adverse event rates in cases using ODS versus general anesthesia, however, revealed that this approach to provider selection may not be applicable to all settings [143, 144]. Both in observed results and when adjusted for case risk, fewer MAEs were observed with ODS than with general anesthesia. While this association did not persist when assessing only patients aged <18 years, this study nonetheless demonstrated that ODS may be safely administered to a broader range of patient risk categories than previously believed.

Variable	Points
Age 19–40	1
Age 41–65	2
Age >65	3
Underweight body-mass index (adjusted for age)	2
Pre-procedural oxygen saturation <96%	2
No history of prior cardiac catheterizations or surgeries	2
Pre-procedural anticoagulation	3
History of renal insufficiency	3
Hemoglobin <6.8 mmol/L	4
Moderate risk procedure	5
High risk procedure	5
Urgent procedure	7
Emergency/salvage procedure	15

AL Grawany

Implicit in these findings is that the institution providing ODS is experienced in choosing patients appropriate for sedation versus general anesthesia and is properly structured in both training sedation personnel and developing pathways should an escalation of care be needed. Whether or not these findings are generalizable to resource-poor settings or to those institutions considering the initiation of an ODS program remains unclear. Prospective studies comparing ODS and general anesthesia, and specifically evaluating the effects of sedation regimen and patient and procedural risk factors, are needed [144, 146].

Periprocedural planning

Risk mitigation begins prior to the patient's entry into the CCL, and for outpatients, even prior to hospital arrival. This entails coordination with the catheterization team regarding preprocedural screening, medication management, and even case order such that *nil per os* (NPO) times are minimized in at-risk patients.

A primary goal of preprocedural screening is to identify any recent changes in health that may adversely affect the periprocedural course. The presence of an ongoing or recent respiratory tract infection within 2 weeks of the planned procedure is a common finding that confers an increased risk of perioperative respiratory adverse events [147, 148]. Beyond the immediate negative consequences of laryngospasm, bronchospasm, and persistent desaturation, these complications may also render hemodynamic measurements unreliable and, therefore, affect clinical decision-making. Whether or not to reschedule such patients can be made based on the indication and urgency of the catheterization as well as the severity of symptoms. Our approach is a conservative one in which patients with recent or ongoing respiratory infections are commonly rescheduled to a minimum of 2 weeks following the resolution of symptoms.

A review of the patient's medications can also provide insight into the potential for medication-related complications. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor blockers (ARBs) have been associated with hypotension when taken in proximity to the induction of general anesthesia. Anecdotally, these effects can be particularly pronounced during catheterization due to the relative lack of stimulation compared to surgery. We consequently ask that these medications be held for 24 hours prior to catheterization. Further, diuretics like furosemide are held the morning of the procedure with the understanding that an IV dose may be needed subsequently. The management of antiplatelet agents and anticoagulants like warfarin or the non-vitamin K oral anticoagulants (NOACs) should be discussed on a case-by-case basis [149, 150] (Figure 34.23). The planned procedure, relative risk of bleeding versus thrombosis with continuing versus holding therapy, and the availability of reversal agents particularly for the NOACs can inform this discussion. Other cardiac medications like beta-blockers, antiarrhythmics, and pulmonary vasodilators used for the treatment of PH are commonly continued on the day of the procedure.

For procedures on neonates, infants, or patients otherwise at risk for complications from hypovolemia or hypoglycemia, consideration should be given to a morning rather than afternoon start time. Given the occasionally unpredictable length of interventional catheterizations, communication with pre-cath nursing is essential to ensure that the fasting period is not unnecessarily prolonged for patients scheduled as the second or third cases. We provide clear liquids up to an hour prior to the procedure and, in select cases, initiate IV access to maintain hydration.

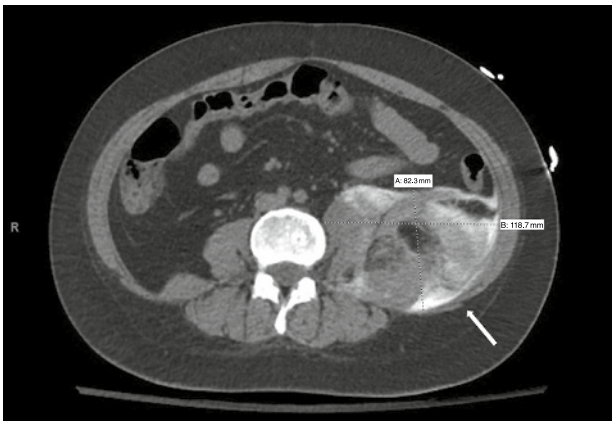

Figure 34.23 Retroperitoneal hematoma demonstrated by computed tomography scan following arterial injury associated with femoral arterial access (arrow). The severity of the bleeding in this patient was related to preprocedural continuation of apixaban, a non-vitamin K antagonist oral anticoagulant. Treatment entailed administration of prothrombin complex concentrate and tranexamic acid. (Source: Texas Children's Hospital Department of Radiology.)

Other key preprocedural factors to consider include the availability of packed red blood cells, postprocedure disposition, and support for high-risk patients. Based on patient weight, comorbidities, and the procedure's risk for bleeding, one can develop a strategy for blood ordering. To promote consistency among our providers and improve the availability of type-specific blood when needed, Texas Children's Hospital Heart Center adopted the following approach noted in Table 34.11. Postprocedural disposition is based on the patient's procedure, comorbidities, and intraprocedural course. During the preprocedure timeout, we tentatively assign status to home discharge versus admission to the inpatient ward or ICU, and once again reevaluate disposition at the procedure's conclusion. Lastly, support for high-risk patients can entail a wide range of equipment needs and multidisciplinary coordination that underscore the importance of early recognition, planning, and communication [59]. For the anesthesia team, preparation often includes the setup of additional invasive monitoring lines, vasoactive support, inhaled pulmonary vasodilators, and/or defibrillation pads depending on both patient and procedural risk factors. For the cardiology team, ancillary equipment like transesophageal echocardiography, percutaneous ventricular support devices, or pacing catheters may be indicated. Certain patients may also prompt consideration for ECMO for either standby or elective initiation. Indications for the former include high-risk anesthetic inductions or concerns for significant procedural instability. Elective initiation of ECMO, on the other hand, is often pursued to allow a procedure to be performed in an otherwise unstable patient. Both forms of

Table 34.11 Approach to facilitate blood ordering and availability for catheterization procedures

Blood ordered *and* in the room	• <5 kg, regardless of the procedure
	• If >5 kg AND undergoing an intervention that is moderate-to-high risk for bleeding, including but not limited to
	  ○ Angioplasty/stenting of an intracardiac- or extracardiac structure
	  ○ Percutaneous valve replacement
	  ○ Pericardiocentesis
	  ○ VSD device closure
	  ○ Transhepatic or transsplenic access
	  ○ Recanalization procedure
	  ○ BAS

Type and screen only	• If cyanotic and undergoing a diagnostic-only evaluation • All inpatients have a type and screen at minimum

No type and screen	• Procedures at low risk for bleeding
	  ○ PDA device closure in the non-premature population
	  ○ ASD device closure
	  ○ Endomyocardial biopsies

ASD, atrial septal defect; BAS, balloon atrial septostomy; PDA, patent ductus arteriosus

ECMO require advance planning with surgery and the ECMO specialists. To ensure that all potential aspects of preprocedural care are anticipated, a checklist tailored to institutional practice that highlights many of the above concerns can be helpful (Table 34.12) [145, 151].

Anesthetic techniques

A variety of anesthetic approaches have been described in patients undergoing catheterization, including spinal or caudal epidural anesthesia, general anesthesia with or without an artificial airway, and sedation with a natural airway. As can be inferred by this breadth of management, no specific anesthetic technique can be recommended for all patients. Rather, anesthetic strategy should be guided by patient and procedural risk factors and an understanding of the pros and cons of the planned technique on both the individual patient and the goals of the proposed procedure.

Advantages of sedation with a natural airway include the potential for greater hemodynamic stability and a more preserved cardiac output in comparison to general anesthesia with PPV. PPV decreases venous return to the heart, thereby decreasing cardiac output and flows across valves and shunts. General anesthesia may also be associated with a more pronounced decrease in SVR and myocardial contractility while also further reducing oxygen consumption [5, 152]. Consequently, the data yielded with general anesthesia and PPV may less accurately reflect the patient's baseline physiology than sedation with spontaneous ventilation. Sedation, however, can be a difficult to control continuum ranging from anxiolysis to conscious sedation to general anesthesia without an airway. As such, the potential benefits of sedation must be weighed against the risks of over-sedation (hypoventilation, airway obstruction, apnea, escalation in airway support, hypotension, and aspiration) and under-sedation (awareness, pain, and movement during inopportune times). Each of these events would negatively affect the quality of data obtained in addition to increasing patient risk. Of note, among patients initially managed with a natural airway, Lin et al. reported that the risk of converting to intubation

Table 34.12 Periprocedural checklist to optimize planning and coordination

Preprocedure	Intraprocedure	Postprocedure
• Confirmation of patient, diagnosis, interventionalist, and procedure • Documented H&P and signed consents • Documentation of allergies (including contrast) • Verified NPO status • Pregnancy test if indicated • Airway status and availability of specialized equipment if difficulty anticipated • Bleeding risk assessed and blood ordered if needed • Availability of implanted devices • Room setup including iNO, TEE, and rotational angiography • Access plan (any known vascular occlusions?) • Anesthesia plan (GA vs. MAC) • Postprocedural disposition (is a bed available if ICU planned?) • Availability of special medications: e.g., vasoactive agents, antiarrhythmics, antibiotics, anticoagulants, or stress-dose steroids • Consideration of the need for ECMO support and surgical backup	• Patient again identified with diagnosis and procedure • Allergies reviewed • Antibiotic needs discussed • Heparin plan • Plan for contrast • Patient position confirmed • Anesthesia plan and use of room air confirmed • Blood availability confirmed if needed • Planned implants available • Specialized equipment/personnel available • Planned disposition reviewed	• All specimens identified, labeled, and sent • Safeguard dressing (time placed, amount of air) if used • Disposition • Need for postprocedural testing or medications • Blood returned if no longer needed • Adverse events • Equipment issues • Review areas for improvement

AL Grawany

was highest in younger patients (specifically infants), those undergoing high-risk procedures, and those needing inotropes or pressors [132]. Sedation with a natural airway, then, may be most safely administered in a child, adolescent, or adult with compensated heart disease undergoing diagnostic catheterization or an otherwise low-risk interventional procedure. Given the potential to escalate airway management in all patients undergoing sedation, accessibility of the airway should also be considered. Extensive draping for neck access and the arms up position can hinder access to the airway relative to procedures involving only groin access. These limitations can be overcome by strategic draping and communication with the cardiologist.

Counterintuitively, sedation may offer the best approach in certain categories of even the sickest patients (e.g., an older child or adolescent status post heart transplant being evaluated for rejection, or a comparably aged patient with a failing Fontan circulation undergoing hemodynamic evaluation). For these and other select classes of patients and procedures, the risks of GETA may exceed the risks of sedation. Assuming adequate patient preparation, reassurance, and cooperation, diagnostic catheterizations in such patients can often be achieved with a combination of IV sedation and generous local anesthetic infiltration. Communication between the cardiologist and the anesthesiologist is particularly important in these cases to allow anticipation and treatment of painful portions of the procedure (i.e., initial infiltration of local anesthetic, placement of sheaths, and later sheath exchanges and removal). As always, one should be prepared to escalate care as indicated.

GETA, on the other hand, may be most suitable for neonates, infants, and those undergoing high-risk procedures with known risk for hemodynamic instability or complications (e.g., ductal stenting, ductal closure in preterm infants, dilation and stenting of PVSs, dilation of peripheral PA stenoses, or VSD closure or creation). Other indications include patients with limited reserve for whom the planned procedure or effects of sedation may precipitate hemodynamic or respiratory collapse, need for transesophageal echocardiography, an anticipated lengthy intervention, risk of sudden movement (e.g., coughing during a PA or aortic intervention), or risk for hemoptysis, pulmonary edema, or postprocedural intubation. Beyond providing a potentially more steady-state condition than sedation with a natural airway, GETA also allows for more specific titration of ventilation, oxygenation, and other adjuncts like iNO. At our institution, the majority of our patients are managed with GETA – whether for diagnostic or interventional catheterization. General anesthesia with a laryngeal mask airway (LMA) is most often used for the stable patient status post heart transplant presenting for endomyocardial biopsy. Hemodynamics are supported by ensuring euvolemia, maintaining relatively light levels of anesthesia (0.5–1 MAC isoflurane), and starting low-dose vasopressors or inotropes as needed to counteract anesthetic-induced reductions in SVR and contractility. In high-risk patients, vasoactive agents are often started prior to induction. A second IV is routinely placed if the risk of bleeding is high or vasoactive initiation is anticipated. The latter can be done safely assuming that the site is monitored (either by direct visualization or indirectly by placing a pulse oximeter on that extremity) and that the lowest concentration vasoactive is used for a given patient weight.

Regardless of the anesthetic technique used, fundamental goals include minimizing pain and anxiety and providing conditions that allow for the accurate interpretation of the patient's hemodynamics. Premedication is often needed to achieve parental separation, particularly for those children and adolescents who present at frequent intervals. Oral midazolam (0.7 mg/kg), ketamine (3–5 mg/kg), or intranasal dexmedetomidine (2–3 mcg/kg) are effective for those without IV access. Following induction, every attempt is made to recreate and maintain the patient's baseline conditions for oxygenation, ventilation, and hemodynamics. To that end, patients are placed on room air or their baseline level of oxygen support, and a minute ventilation consistent with their normal ventilation is targeted. Because oxygen is a potent pulmonary vasodilator and hypoventilation or hyperventilation directly influence PVR, alterations in these variables can affect intracardiac pressure measurements and $Q_p : Q_s$ calculations. Such changes should, therefore, be avoided if possible during the diagnostic portions of the case. An equally important variable to control is pH. Acidosis, whether from a respiratory or metabolic cause, increases PVR. While respiratory acidosis is easily corrected if using mechanical ventilation, some amount of hypoventilation is to be expected with sedation techniques. Metabolic acidosis may indicate a low cardiac output state or the effects of prolonged fasting. The former can be diagnosed based on the patient's underlying condition, point-of-care ultrasound, or monitored values such as mixed venous saturation, lactate, or cerebral oximetry. While definitive treatment is initiated, metabolic acidosis can be addressed in the short term with sodium bicarbonate, assuming an adequate minute ventilation. Lastly, maintaining a sufficient depth of sedation or anesthesia is critical to minimizing intraprocedural hemodynamic swings associated with pain or anxiety that may affect the values measured/calculated. If the patient's condition requires an increase in oxygen levels or the initiation of vasoactive agents while measurements are being made, these changes should be communicated with the cardiologist such that the data obtained can be interpreted accordingly or be repeated after the patient has returned to baseline conditions.

Anesthetic drugs

Almost any anesthetic drug can be used safely provided an understanding of its impact on hemodynamics, synergistic effects with other sedatives and analgesics, and potential for adverse effects on a given patient's physiology (Table 34.13). Factors affecting choice of drugs include the child's myocardial function, comorbidities, and anesthetic plan.

For those patients undergoing sedation with a natural airway, combination of midazolam, fentanyl, ketamine, propofol, and/or dexmedetomidine has been used. Whereas midazolam or fentanyl may be sufficient for the cooperative adolescent or adult, a deeper level of sedation that often becomes a general anesthetic with a natural airway is most often required for younger patients. Common pairings include propofol and ketamine or ketamine and dexmedetomidine [153–156]. Regimens describing the former entail a bolus of propofol (1 mg/kg) and ketamine (1 mg/kg),

Table 34.13 Hemodynamic effects of anesthetic agents used for diagnostic or interventional catheterizations

	SVR	PAP	PVR	Dosing
Volatile	↓↓	↓	↓	0.5–1 MAC
Propofol	↓↓	↓	↓	1–3 mg/kg 100–300 mcg/kg/min
Ketamine	↑	↔↑	↔↑	1–2 mg/kg 0.3–1 mg/kg/hour or 5–20 mcg/kg/min
Dexmedetomidine	↑	↔	↔	0.25–1 mcg/kg (over 10 minutes) 0.2–1 mcg/kg/hour
Midazolam	↔	↔	↔	0.5–0.7 mg/kg PO 0.1 mg/kg IV in children
Fentanyl	↔↓	↔	↔	1–2 mcg/kg

followed by an infusion of each (100 mcg/kg/min of propofol and 1 mg/kg/hour of ketamine) with rescue doses of 0.5–1 mg/kg ketamine as needed. Sedation with ketamine and dexmedetomidine involves a similar approach to ketamine dosing with the addition of dexmedetomidine at a load of 1 mcg/kg followed by an infusion of 1 mcg/kg/hour. When comparing these two approaches, the combination of ketamine and dexmedetomidine appears to be associated with a more frequent need for ketamine rescue doses and a longer recovery time. Alternative sedation strategies can entail dexmedetomidine infusions with or without a loading dose supplemented with midazolam for sedation and ketamine and/or fentanyl timed to the stimulating portions of the case. Ketamine and dexmedetomidine – independent of one another – have also been described as the sole agents used successfully for catheterizations [157–159]. Clinical experience suggests that such an approach is usually inadequate, though, and additional sedative and analgesic adjuncts are needed. For those patients who may be marginal, or in whom propofol or dexmedetomidine may be relatively contraindicated, ketamine with midazolam alone has proven effective.

Caveats regarding the use of propofol, ketamine, and dexmedetomidine during sedation focus on their hemodynamic profiles and side effects. Airway obstruction and apnea with subsequent oxygen desaturation and hypercapnea are more likely with propofol. Attention to airway patency and adequacy of respiratory rate and tidal volumes is essential when using it as an infusion. Decreases in SVR, myocardial contractility, heart rate, and blood pressure also pose a concern. Ketamine, with its increase in sympathetic stimulation, can balance these hemodynamic effects, but caution should still be used with propofol dosing and titration in patients at risk for myocardial ischemia or low cardiac output (e.g., AS, depressed ventricular function, and systemic-to-suprasystemic PH).

Controversy regarding the effects of ketamine in patients undergoing catheterization previously revolved around its effects on mPAP, particularly in patients with PH. But in the absence of hypoventilation or desaturation, ketamine does not appear to cause clinically significant increases in mPAP, PVRi, or PVRi/SVRi [34, 157]. Dysphoria, increased salivation, prolonged recovery, and nausea may, however, occur. Glycopyrrolate (5–10 mcg/kg) may be considered prophylactically for secretions if the patient can tolerate the potential increase in heart rate, whereas a propofol infusion may negate its other side effects.

Concerns regarding dexmedetomidine include its effects on myocardial conduction and potential for either systemic hypertension or hypotension when given as a bolus. In patients who may be at risk for or who have existing heart block or bradycardia, the use of dexmedetomidine may result in a worsened bradyarrhythmia [160]. Caution with dexmedetomidine should also be demonstrated in heart transplant patients presenting in the setting of hemodynamic evaluation for rejection. Schwartz et al. presented such a patient with a history of SVT and first-degree heart block who had a bradycardic arrest following a repeat bolus of dexmedetomidine [11]. The authors hypothesized that while dexmedetomidine was likely the causative agent, a combination of the patient's underlying first-degree heart block and possible acute cellular rejection involving the conduction system could have contributed as well. The use of dexmedetomidine in pediatric heart transplant patients who are otherwise well and with no significant or recent history of rejection appears safe. A group of 12 such patients were given a rapid IV bolus of either 0.25 or 0.5 mcg/kg over 5 seconds, resulting in transient but significant increases in systemic and pulmonary pressure with a more persistent decrease in heart rate [161]. The lowest heart rate observed was 71 at 5 minutes following administration. When assessing the effects of dexmedetomidine on patients with PH, loading doses as high as 1 mcg/kg given over 10 minutes were not associated with statistically significant increases in PAP [33]. Of note, while the most common hemodynamic effects of a loading dose of dexmedetomidine are hypertension and bradycardia, hypotension and a decrease in cardiac index may also result. Particular caution is warranted, then, when considering boluses in those who may be depleted of catecholamines, such as patients in heart failure. A strategy to consider in all cardiac patients is to administer a smaller loading dose over a longer period of time to allow for evaluation of hemodynamic effect (0.25–0.5 mcg/kg over 10 minutes, which can be repeated if needed).

If GETA is planned, myocardial function often dictates whether an inhalation induction with sevoflurane can be used versus an IV induction. For patients with even moderately depressed ventricular function, low-dose sevoflurane (2–3%) can be used for induction provided that IV access is quickly obtained. IV induction using a balanced technique of opioids, benzodiazepines, ketamine, muscle relaxant, and/or inhalational agent is most reasonable in patients with severely depressed function. More important than the drugs chosen, though, are the doses used and careful titration to effect while monitoring hemodynamics. Maintenance can be achieved with isoflurane at 0.5–1 MAC. Adjuncts like dexmedetomidine have been used to minimize the concentration of volatile agent needed, but may not confer any hemodynamic advantage compared to general anesthetics in which it is not used [162]. Chapter 10 presents additional information about anesthetic agents in CHD.

AL Grawany

Monitoring

Monitoring used in the CCL is comparable to that in the operative setting with a few notable differences. Standard ASA monitors are routinely employed using a five-lead EKG, noninvasive blood pressure cuff, esophageal temperature probe, and pulse oximetry. The utility of the EKG and blood pressure monitoring, however, depends on placement. The use of radiopaque EKG leads and cables necessitates lead placement away from the chest and commonly onto the arms to avoid obstructing views of the heart during fluoroscopy. While gross arrhythmias or ischemic changes can be detected in this configuration, the use of radiolucent EKG leads and cables that allow for anatomic placement over the chest offer better diagnostic capability (Figure 34.24). Likewise, the placement of a noninvasive blood pressure cuff on an upper extremity that is then positioned with the arms above the head may occasionally result in lower than actual blood pressure readings. In infants and small children, an alternative may be to place the cuff on the lower extremity not being accessed for the procedure. Respiratory rate and end-tidal CO_2 ($ETCO_2$) are additional monitoring constants and are followed using capnography in both intubated and sedated patients. For sedated patients, the $ETCO_2$ sampling line can be placed either onto a nasal cannula designed to allow such monitoring or under a face mask using an angiocatheter.

Other monitors to consider on a case-by-case basis include a peripheral arterial line, cerebral oximetry, and a Foley catheter. For most procedures, the interventional cardiologist accesses the femoral artery, which can be used for blood pressure monitoring. A separate arterial line, however, may be indicated in at-risk patients for the following reasons: (i) if closer assessment of blood pressure is desired in the peri-induction period; (ii) if the arterial access placed by the interventionalist is to be used for the intervention itself (and therefore would not be available for monitoring); or (iii) if postprocedural hemodynamic instability or blood gas sampling are anticipated. Cerebral oximetry may help in assessing changes in cardiac output and determining transfusion thresholds in critically ill patients. Common indications for a Foley catheter include either an anticipated lengthy procedure or one associated with the need for diuresis (e.g., pulmonary vein interventions).

Though not considered traditional anesthesia monitors, information obtained from arterial blood gases (ABG) and measurements of ACT are also essential to patient management. An ABG is sent with initial arterial access to assess the child's acid–base status, hematocrit, and oxygenation/ventilation. Thereafter, ABGs may be sent infrequently. If the patient's clinical situation dictates that another ABG be sent, a gentle reminder to the cardiologist may be needed. A common practice is to send an ABG along with the ACT so that trends can be followed. ACTs are checked at routine intervals when heparin is administered and is reflective of the patient's level of anticoagulation. Heparin can be administered as a bolus (50–100 units/kg) alone or as part of the flush used to maintain catheter patency. In the latter circumstance, rising ACT values may indicate significant heparinization secondary to large volume flush administration. A protocol-driven approach to heparin and ACT management is desirable; at Texas Children's Hospital, for example, ACT is measured every 30 minutes after heparinization; target ACT is 250 seconds when the left side of the heart or systemic circulation is entered, e.g., transseptal puncture for left atrial access or retrograde access to the aorta.

Equally important to the above data is an understanding of where catheters are within the body at any given time and what potential hemodynamic effects their movements or actions (e.g., balloon inflation) can cause. This information is critical to interpreting hemodynamic changes and anticipating critical events. Direct visualization of these aspects, however, is difficult in the CCL. There are physical barriers to communication and visualization, including lead screens and the lateral cameras. Risk of radiation exposure also increases with proximity to the cardiologist, often leading to the anesthesiologist being at a distance from the cardiology team. Moreover, the monitors displaying fluoroscopy images and intracardiac pressures that allow for an exact understanding of what is happening may be either remote or

(A) (B)

Figure 34.24 Radiolucent electrodes and cables. (A) Examples of radiolucent electrodes (MedGel® and SilverTRACE®) and cables (Vyaire™ Multi-Link EKG Leadwire) used to allow anatomic positioning in the cardiac catheterization laboratory. (B) Comparison of standard radiopaque electrodes and cables (solid arrows) to radiolucent ones (dotted arrow) on lateral fluoroscopy of the heart. Note that the cable attached to the radiolucent lead is not even visible.

entirely out of view from the anesthesiologist. These challenges underscore the need for excellent and interval communication between anesthesiology and cardiology (which at times requires interrupting the procedure). A convincing argument could be made that the ability of the anesthesiologist to view fluoroscopy and hemodynamic data is a patient safety issue, and arrangements should, therefore, be made to allow these monitors to be viewed from the anesthesiology work area. In patients who experience acute desaturations or altered lung compliance, fluoroscopy is particularly useful to assess ETT position and to rule out the presence of pulmonary edema or hemorrhage.

Intravascular volume management

Patients undergoing catheterization are inherently at risk for volume overload by both the anesthesiologist and the cardiologist [145]. For the anesthesiologist, efforts should be made to limit IV fluids, except when indicated in the setting of hypovolemia, bleeding, or instability. A Buretrol® filled to a predetermined level can effectively minimize the risk of inadvertent large volume administration in smaller and younger patients. A more common (and less immediately obvious) cause of hypervolemia is the cumulative effect of intermittent and occasionally rapid infusions of flush and contrast. Clinical consequences include hemodilutional anemia, electrolyte abnormalities, pulmonary edema, and decreased myocardial function due to myocardial stretch. Those at greatest risk are neonates and infants due to their smaller blood volumes and patients otherwise with already depressed ventricular function. Attention to worsening lung compliance, increases in measured ACT independent of heparin boluses (because flush and contrast may also contain heparin), and profuse increases in urine output are common signs of volume overload. Serial blood gases should also be monitored to assess for the impact on hemoglobin and electrolytes. Rarely, transfusion is needed to increase hemoglobin levels. More commonly, IV diuresis (furosemide 1 mg/kg) and time are the only treatments needed. In the event that oxygenation or ventilation is impaired, postprocedural mechanical ventilation is indicated to allow more time for diuresis.

Other causes of anemia include blood loss from attempts at vascular access and sheath/catheter exchanges, and blood sampling for oxygen saturations, ABGs, and ACTs [145]. Blood loss can be insidious. The drapes around the groins are often stained with blood, but it is difficult to use this alone as a marker of blood loss. Much of the administered flush can collect on the drapes and mix with any blood present, giving the appearance of more significant bleeding than is actually present. Trending the patient's hemodynamics and assessing hemoglobin on serial ABGs is one approach to assessing for anemia. As for any patient, the threshold for transfusion should depend upon the patient's underlying physiology and an assessment of the adequacy of oxygen delivery and end-organ perfusion. Whereas a noncyanotic and otherwise healthy child may well tolerate a hemoglobin of 7 g/dL, a cyanotic patient accustomed to a higher hemoglobin almost certainly would not. Cerebral oximetry can be used as a surrogate of end-organ perfusion and adds another data point in the decision of whether or not to transfuse.

Recovery

Stays in the recovery room following catheterization are much longer than that for other anesthetics. The time frame can range from 2 to 6 hours and is directly related to the risks of bleeding and hematoma formation from the vascular access sites. Efforts to minimize these complications include keeping the child supine and relatively immobile for the first few hours postcatheterization. Long-acting sedation and analgesia along with the avoidance of emergence delirium and PONV can be helpful in achieving this goal (particularly in younger children for whom laying still is an oxymoron). Gautam et al. studied the effects of dexmedetomidine for this purpose in children between 1 month and 5 years of age who underwent catheterization. When given as a bolus of 1–2 mcg/kg prior to deep tracheal extubation with sevoflurane (0.8–1 MAC), 91% of patients had a documented smooth recovery requiring no additional analgesics or sedatives [163]. Such an approach, or a comparable one using propofol in those can tolerate its negative hemodynamic effects, may limit postprocedural bleeding associated with movement, coughing, or agitation. While the cardiologist most often infiltrates the access site with local anesthetic at the end of the case, systemic opioids like morphine may be needed particularly if large sheaths are used (e.g., for TPVR placement). Of note, routine deep tracheal extubation requires that the recovery nursing staff be familiar with the airway complications that may occur in this setting and also maneuvers to temporize until help arrives. A pathway for calling for help and the immediate availability of emergency drugs in the recovery room can help ensure a prompt response should an event like laryngospasm occur.

KEY POINTS: ANESTHETIC MANAGEMENT

- Risk reduction begins prior to arrival in the CCL with preprocedural medication management and scheduling such as to avoid lengthy NPO times or concurrent illnesses.
- Preprocedural checklists are useful to identify key anesthetic and cardiology concerns and to ensure the availability of necessary personnel and resources.
- GETA should be considered in neonates, infants, and those patients otherwise undergoing high-risk procedures.
- Monitoring in the CCL involves an assessment of serial ABGs, ACTs, and the position of catheters within the heart in addition to the usual vital signs.
- Recovery can last for several hours due to the need to monitor for access site bleeding.

Electrophysiology procedures

The most common procedures performed in the EP suite are electrophysiology studies (EPSs) and ablations for the management of tachyarrhythmias. Less common are implantation of pacemakers and/or defibrillators, cardioversion, and lead extraction.

Electrophysiology studies and ablations

The purpose of an EPS is to identify the mechanism of the patient's arrhythmia by recording signals from electrodes placed within the heart. The use of fluoroscopy and correlation of electrical signals to anatomic landmarks allow localization of the abnormal pathways or foci responsible for the arrhythmia. Ablation of these pathways is then pursued and is initially successful in 91% of patients with a recurrence rate of 23% [164, 165].

The majority of children presenting for EPSs and ablation are otherwise healthy, have functionally normal hearts, and present with well-tolerated SVT. A minority will have either a life-threatening arrhythmia or an arrhythmia complicating CHD (7.9%) or cardiomyopathy (2.4%) [166]. Anesthetic concerns include the length of the procedure, poor access to the patient, the possibility of anesthetic agents altering the EP of the heart, and occasionally poor cardiac function. Chapter 22 presents an extensive discussion of arrhythmias.

Pathogenesis of arrhythmia

The most common mechanism of tachycardia is reentry, of which atrioventricular nodal reentry tachycardia (AVNRT) is the most common example. This requires a circuit composed of two pathways with different conduction velocities and refractory periods. In AVNRT, the normal AV node receives an input from two physiologically distinct pathways: a slow pathway conducting slowly with a short refractory period and a fast pathway that conducts quickly with a longer refractory period. Normal conduction occurs via the fast pathway. If an ectopic beat reaches the two pathways while the fast pathway is refractory, the impulse is conducted via the slow pathway only. In some individuals, the conduction speeds and refractory periods of the two pathways are such that tachycardia is perpetuated due to a circuit comprising anterograde conduction via the slow pathway, retrograde conduction via the fast pathway, and conduction through the atrial myocardium. Preexcitation syndromes, such as Wolff-Parkinson White (WPW), are a subgroup of reentry tachycardia in which one arm of the circuit is the AV node and the other is a congenital muscular pathway between the atrium and the ventricle [167]. Such accessory pathways can originate in either the right or left atrium.

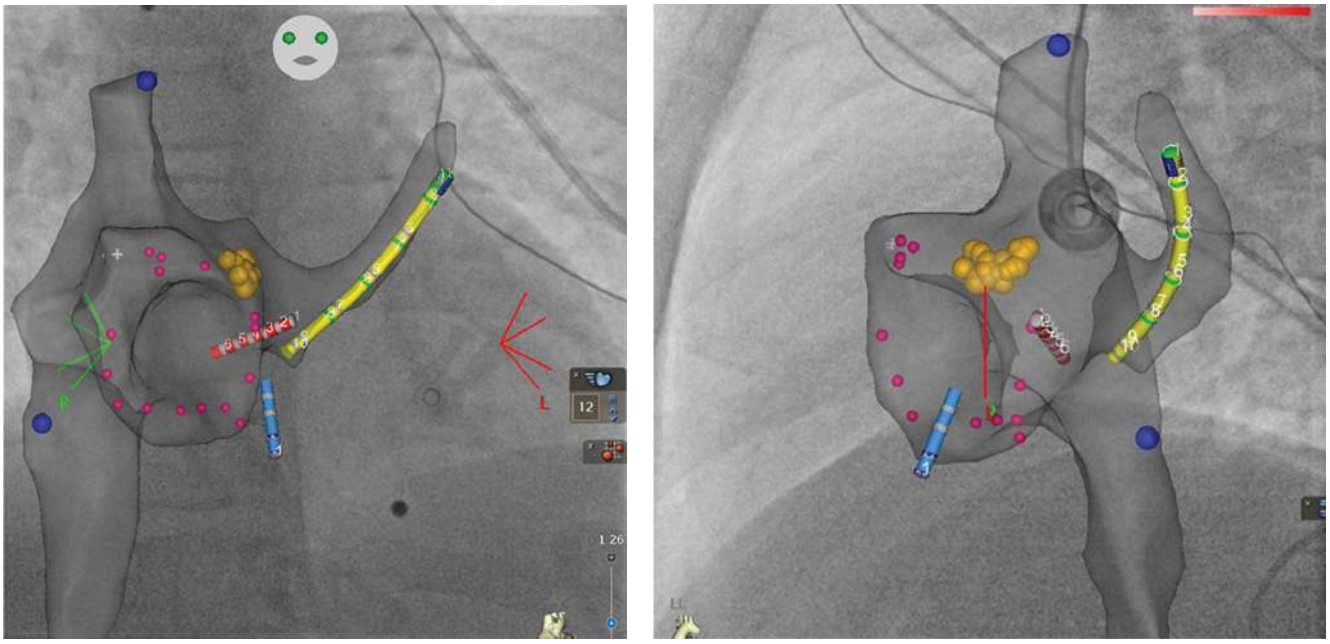
Another mechanism of tachycardia is enhanced automaticity. During sinus rhythm, cells in the sinoatrial (SA) node function as the heart's pacemaker by independently generating rhythmic impulses through spontaneous depolarization. Other cells demonstrate this activity but at a slower rate and will only act as the pacemaker if the SA node is not functioning or conduction is blocked. When these cells are damaged or subjected to extrinsic factors (electrolyte disturbance, hypoxia, hypercarbia, high wall tension, ischemia, and high catecholamine levels), they may spontaneously depolarize at a rate that supersedes the SA node. This leads to rapid repetitive depolarization of a single focus, referred to as ectopic or automatic tachycardia.

Ventricular tachycardias (VTs) and premature ventricular beats (PVCs) are relatively uncommon in the pediatric population. In patients with structurally normal hearts, the most common types are fascicular tachycardia and automatic tachycardia originating in the outflow of the RV. Fascicular VT occurs due a reentry circuit involving the left bundle branch. In patients with operated CHD, VT may occur due to reentry circuits around scar tissue. This is more commonly seen in adults than in pediatric patients.

Electrophysiology techniques

Figure 34.25 demonstrates typical catheter position during an EPS for investigation of SVT.

The electrical signals detected by these catheters can be correlated with anatomic location using electroanatomic mapping systems to produce a three-dimensional representation of the heart. This technology can enhance the safety and efficacy of ablations by providing the precise location of the catheter relative to critical cardiac structures and by creating a visual marker of areas to be ablated (Figure 34.26). An additional benefit of such systems is the decreased need for fluoroscopy and decreased radiation exposure [168].



To identify the mechanism of the arrhythmia, periods of pacing and programmed stimulation are undertaken. Pacing, commonly via the coronary sinus, allows the arrhythmia to be provoked or terminated, permits measurement of the EP properties of the conduction system, and allows for ventricular pacing should CHB occur. Drugs may be used to further refine the study. Adenosine will block normal AV conduction, exposing a concealed abnormal pathway. Isoproterenol, in contrast, will increase SA node rate, speed up AV node conduction, reduce refractory periods, and increase automaticity of other contractile tissue.

Radiofrequency ablation and cryoablation

Destruction of an accessory pathway, the slow pathway of an AVNRT, or automatic foci abolishes the arrhythmia. This is most often accomplished by delivering RF energy to heat and ablate the area. An alternative to RF catheter ablation (RFCA) is cryoablation, the freezing of the foci. This allows for the pathway or foci to be temporarily disabled prior to its destruction. This can be a safer option when the pathway is close to the AV node, such as in AVNRT. In the treatment of preexcitation syndromes, a specialized catheter is positioned along the AV ring, then adjusted to record the earliest conduction via the abnormal pathway (Figure 34.26). When delivering RF energy, the size of lesion created is dictated by the power. Temperature control is used to stop overheating of local tissue and blood. Following ablation, an EPS is repeated to test for residual or additional pathways.

Complications and risk factors with electrophysiology studies

MAEs associated with EPSs and tachyarrhythmia ablations are rare, approximating 0.1% in a recent cohort [169]. Apart from hematomas or injury otherwise associated with vascular access, complications are largely related to ablation attempts and transseptal puncture for left-sided arrhythmias. RFCA can cause acute coronary occlusion or stenosis when performed in proximity to the AV junction [170]. Other complications include arrhythmias requiring cardioversion, AV block requiring temporary or permanent pacemaker, right or left bundle branch block, thromboembolism (stroke),

(A) (B)

Figure 34.25 Electroanatomical map overlying fluoroscopic images of the heart. (A) Anteroposterior view of mapping catheters in the coronary sinus (yellow), right ventricle (blue), and His (red) positions. The catheter in the coronary sinus is multipolar and, therefore, capable of detecting signals along its length. This catheter allows for analysis of left-sided electrical conduction without having to directly access the left atrium/ventricle. The blue circles denote the transition between the electrically inert superior and inferior venae cavae and the electrically active right atrium. The tricuspid annulus is marked by pink circles and the His by yellow circles. (B) Lateral view. (Source: Texas Children's Hospital Cardiac Catheterization Laboratory, Dr. Taylor Howard.)

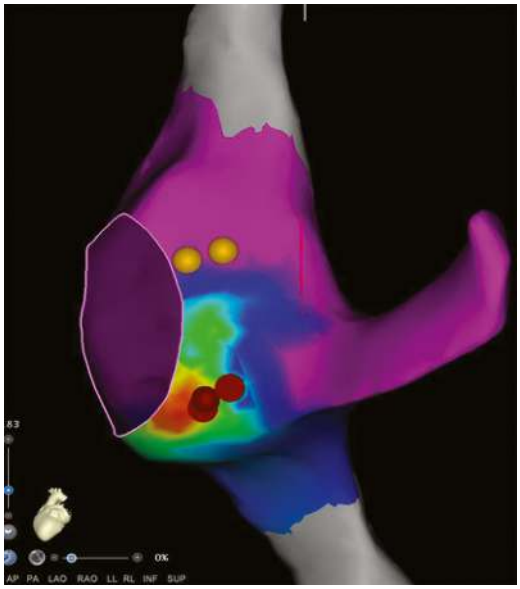


Figure 34.26 Local activation time map highlighting areas of interest for ablation. Accessory pathways such as those in this patient with Wolf-Parkinson White (WPW) syndrome are characterized by electrically conductive fibers, which cross the electrically inert atrioventricular valve. The insertion of this fiber creates a unique signal that, when mapped, appears to be "early" compared to other signals on the valve. All signals are compared to a reference point (in the case of WPW, usually the delta wave of the QRS complex). As the catheter is move around the valve, a color map is created with earlier signals being denoted in red and the later signals in purple. The red circles denote areas of ablation. (Source: Texas Children's Hospital Cardiac Catheterization Laboratory, Dr. Taylor Howard.)

AVV injury, cardiac perforation, pericardial effusion, and tamponade. Risk factors associated with adverse events are younger patient age (infants) and lower weight (<15 kg), patients with CHD, patients undergoing VT rather than SVT ablation, and centers with low ablation volumes [171–173].

The child younger than 4 years presenting for ablation often indicates a significant arrhythmia not controlled by antiarrhythmic drugs. There have been recent reports of successful ablation in children as young as 1 month of age, but complications are more common [171, 174, 175]. Such patients will frequently have abnormal ventricular function and severe refractory arrhythmia prior to an EPS being contemplated.

Patients with CHD may develop arrhythmia in a number of circumstances [168, 176]. Ebstein's anomaly is associated with accessory pathways and preexcitation. Atrial dilation and scarring within the heart may occur secondary to surgical palliation or repair and is often associated with arrhythmia. The latter is especially true following extensive atrial surgery, such as the Mustard procedure or classical Fontan connections. Adults with TOF with long-standing pulmonary insufficiency may also present with RA and RV enlargement with either atrial or ventricular arrhythmias. This group of patients may have poor reserve to tolerate tachycardia, and placement of intracardiac electrodes may be complex.

Anesthetic considerations

As with other catheter-based procedures, it is possible to conduct EPSs in conscious patients or with minimal sedation. These procedures are often hours in length, however, and can require multiple venous and arterial access points.

AL Grawany

Periods of arrhythmia are inevitable and can be unpleasant for the patient. Moreover, movement during the procedure can disrupt the electroanatomic map and interfere with catheter stability and myocardial contact during ablation. The latter diminishes the effectiveness of ablation lesions and may also increase the risk of injuring adjacent structures [169, 177–182]. Deep sedation is unlikely to offer any advantage to general anesthesia, and the additive effect of repeated doses of sedative drugs over a period of time must be considered. Consequently, our practice is to use GETA unless the patient's underlying arrhythmia (PVCs or VT), or prior history of failed ablation, suggests a benefit to conscious sedation.

Preprocedural evaluation entails assessment of the frequency of the arrhythmia, precipitating factors, symptoms during the arrhythmia, and whether treatment is required for termination. Arrhythmias associated with fainting or collapse are likely to be associated with greater hemodynamic compromise. Equally important is the mechanism of the arrhythmia. Certain mechanisms, noted below, are more susceptible to anesthetic depth (and specific agents) than others. Tailoring the anesthetic to the anticipated arrhythmia may avoid a failed ablation or an unnecessarily lengthy procedure due to difficulty in eliciting the arrhythmia. Discussion with the electrophysiologist can identify those patients who require either a lighter plane of anesthesia or minimal sedation initially to facilitate arrhythmia induction.

Though the majority of patients are otherwise young and healthy, the presence of CHD, cardiomyopathy, or familial conditions associated with arrhythmia (long QT syndrome and arrhythmogenic RV dysplasia) may confer increased risk. Adults with CHD presenting for ablation are often in compensated heart failure due to long-standing arrhythmias and poor ventricular function. Further, those adults with rate-controlled atrial arrhythmias may be managed on anticoagulants to decrease their risk of stroke. While these medications are usually held in advance, the decision is made weighing the risks of procedural bleeding with their continued administration versus that of stroke with stopping them. Antiarrhythmics are commonly held several days prior to the procedure. Anxiolysis with midazolam can be helpful in children and adolescents due to the increased time between separation and induction (needed to allow placement of the posterior surface electrodes used for electroanatomic mapping).

Standard monitors and the use of defibrillation pads are routine. Additional vascular access including a dedicated arterial line and a separate site for vasoactive infusions is infrequently needed, but placed as indicated in at-risk patients. If using GETA, a Foley catheter is used as average case lengths approach 4–6 hours. X-ray tables are firm, and patient positioning can be awkward. Care must be taken to avoid injury to nerves and pressure areas.

Periods of tachycardia (either due to arrhythmia or due to pacing) are to be expected during an EPS and healthy patients tolerate this well. Significant hemodynamic compromise can occur, however, with very high ventricular rates or in patients with reduced cardiac reserve. Vasopressors may be used to improve perfusion pressure but can have reflex effects on the EP of the heart (e.g., bradycardia with phenylephrine). Alternatively, vasopressin can be used. Nonpharmacologic interventions entail communication with the electrophysiologist so that the arrhythmia can be terminated rapidly by overdrive pacing, or if the cause of instability is pacing itself, the pacing can be stopped to allow recovery and time for volume/vasoactive management. Adenosine or external cardioversion is rarely required to treat arrhythmias. A common practice in patients who can tolerate the volume load is to administer a fluid bolus with the start of the procedure to ensure euvolemia and minimize the risk of hypotension with the onset of arrhythmias and/or pacing. Adenosine and isoproterenol, used to define and elicit arrhythmias, can also induce hypotension. Importantly, in patients with a history of reactive airways, adenosine can provoke bronchospasm [183].

If the abnormal pathway or foci is left sided, the left atrium is accessed via transseptal puncture, most commonly from the RA. Changes in heart rate or blood pressure with this approach require further evaluation as tamponade is a known complication [184]. As noted above, additional heparin 50–100 units/kg with a target ACT of 250 seconds is often employed in this setting to decrease the risk of thromboembolism.

PONV in children undergoing ablation is unfortunately common with a reported incidence of 7–63% [185, 186]. Because the use of dexamethasone as an antiemetic may hinder scar formation following ablation, alternative agents for PONV prophylaxis including subhypnotic infusions of propofol (10–100 mcg/kg/min) and ondansetron should be considered. Lee et al. reported that infusions of propofol <100 mcg/kg/min were associated with a decrease in postprocedural vomiting, but not nausea, following ablation [185].

Anesthetic drugs and the cardiac conduction system

All anesthetics influence the electrical conduction of the heart. In the context of an EPS, the relevant question is whether the agents used will inhibit the induction of the targeted arrhythmia (and thereby prevent its characterization, localization, and ablation). The answer appears to depend less on the specific drugs administered, and more on the mechanism of tachycardia. Reentry tachycardias are least affected by common anesthetic agents, whereas automatic tachycardias are highly susceptible to the suppressive effects of anesthesia. As such, while any number of drugs can be used successfully in the anesthetic management of a child undergoing WPW or AVNRT ablation, greater caution may be needed to allow arrhythmia induction in the child with ectopic atrial tachycardia (EAT) or automatic VT.

Anesthetic drugs and reentry tachycardias

Many anesthetic agents have been used successfully in the ablation of reentry tachycardia, including various combinations of volatile agent, midazolam, fentanyl, remifentanil, propofol, ketamine, and even dexmedetomidine. As arrhythmia inducibility is less critical to the successful ablation of WPW [169], anesthetic choices for this lesion are broad. More caution has been advised when managing children with AVNRT, but similar rates of success in terms of arrhythmia induction have been noted regardless of the anesthetic technique (GA vs. MAC) or drugs used [169]. A summary of the electrophysiologic effects of common anesthetics and their impact of SVT inducibility is described in Table 34.14 [187].

Table 34.14 Electrophysiologic effects of common anesthetics during SVT ablation

Anesthetic sedative	Effect on AV node conduction	Effect on induction of SVT	Comments
Volatile anesthetics	↔↓	↔	Isoflurane and sevoflurane used successfully
Midazolam	↔	↔	Minimal clinical effect.
Fentanyl	↔↓	↔	Minimal clinical effect. May cause vagal-mediated bradycardia.
Remifentanil	↓	↔↓	Induces bradycardia and has potential to inhibit SVT induction at high doses, but has been used successfully
Propofol	↔	↔	Commonly used but caution in EAT
Ketamine	↔↑	↔↑	May counteract depressive effects of dexmedetomidine
Dexmedetomidine	↓	↓	Controversial. May require additional doses of isoproterenol to elicit arrhythmia; may confound etiology of heart block with RFCA near AV node. Caution in EAT.

Source: Modified Vladinov et al. [187].

↔, no significant clinical effect on conduction or induction of SVT; ↑, speeds conduction and promotes induction of SVT; ↓, slows conduction and inhibits induction of SVT; AV, atrioventricular; EAT, ectopic atrial tachycardia; RFCA, radiofrequency catheter ablation; SVT, supraventricular tachycardia.

Though volatile anesthetics have been demonstrated to slow the SA node and prolong AV conduction time and refractoriness, these findings do not appear to be clinically significant [186–189].

Midazolam has no effect on normal AV or accessory pathway conduction and no important clinical effect on SA node activity [186, 190, 191].

Of the opioids, fentanyl can induce vagally mediated bradycardia but does not adversely affect arrhythmia induction with either boluses or infusions [190]. The combination of fentanyl and midazolam has similarly inconsequential effects on EP variables [192, 193]. Remifentanil is more controversial. At high-dose (0.4 μg/kg/min) and moderate-dose (0.2 μg/kg/min) infusions, remifentanil prolongs the sinus node recovery time, and at the high dose, also suppresses sinus node automaticity [194]. Niksch et al. reported slowing of both SA and AV node conduction at doses of 0.3 mcg/kg/min [195]. These effects may lead to difficulty in inducing arrhythmias, but other groups have demonstrated successful use with doses of up to 0.2 mcg/kg/min in patients undergoing general anesthesia [189, 196]. If using remifentanil, its short context-sensitive half time makes stopping an infusion an option if difficulty arises in eliciting the arrhythmia.

Propofol has minimal to no effect on the SA and AV nodes, intra-atrial conduction, or characteristics of the accessory pathway even at doses of 200 mcg/kg/min [186, 189, 195, 197, 198]. Likewise, ketamine has no significant effect on SA or AV node function but can induce significant increases in heart rate and blood pressure due to its stimulatory effects on the sympathetic nervous system. Its use may be beneficial, then, in patients with preexisting bradycardia or hypotension [189].

Dexmedetomidine induces depression of both the AV and SA nodes and consequently may adversely affect the inducibility of arrhythmias [160]. Tirotta et al., however, concluded that dexmedetomidine does not interfere with EPSs for SVT in their retrospective review of 405 cases between 2007 and 2014 [199]. Three groups were studied: (i) those with no exposure to dexmedetomidine, (ii) those given an infusion of 0.5–1 mcg/kg/hour, and (iii) those given a bolus of 0.5 mcg/kg, followed by an infusion of 0.5–1 mcg/kg/hour. No differences were noted among the groups in terms of SVT inducibility or recurrence, but patients receiving dexmedetomidine did require additional doses of isoproterenol to induce SVT. Char et al. demonstrated that ketamine may also counteract the electrophysiologic effects of dexmedetomidine [200]. Both ketamine and isoproterenol act as sympathetic agonists, and in doing so, may mitigate the negative chronotropy caused by dexmedetomidine. Beyond dexmedetomidine's effects on SVT inducibility, an additional consideration that may impact its use is its potential to confound the etiology of heart block should it occur. CHB is an exceedingly rare complication, but would be most relevant in a child undergoing AVNRT ablation due to the involvement of the AV node.

Anesthetic drugs and automatic tachycardias

Arrhythmias resulting from increased automaticity, such as EAT or VT, can be more difficult to elicit under anesthesia. Many of the extrinsic factors that promote automaticity (such as elevated catecholamine levels) are minimized during an anesthetic. These changes make the choice of anesthetic critical in these patients.

In a comparison of outcomes of pediatric ablation procedures by anesthesia strategy (GA vs. MAC), the use of GA was associated with a higher rate of noninducibility (and therefore nonablation) in children with PVCs or VT [169]. In this group, GA increased the likelihood of a negative EPS with an OR of 2.2. For patients with EAT, however, the type of anesthesia used did not affect inducibility. The authors noted that a larger number of EAT cases were needed to definitively comment on this population. The most commonly used drugs for MAC were propofol, midazolam, and fentanyl, whereas propofol, volatile agent, neuromuscular blockade, fentanyl, and midazolam were most utilized for GA. Exact dosages and the depth of anesthesia obtained with MAC were not specified.

Lai et al. reported different findings in children with EAT who underwent a propofol-based anesthetic (induction with 200 mcg/kg/min followed by reduction to 100 mcg/kg/min) [201]. In four of seven children with EAT, the arrhythmia was

AL Grawany

terminated with propofol and could not be induced despite an infusion of isoproterenol.

Given these data, it is difficult to suggest a best anesthetic technique for EPSs in patients with automatic (ectopic) tachycardias. General suggestions, however, can be made. For cooperative older children or adolescents, an MAC approach may most reliably preserve the ability to induce arrhythmias and allow a successful ablation. In younger children or patients for whom MAC is not an option, GA can be maintained preferentially with lower doses of volatile agent. The expected loss of endogenous sympathetic activity with GA can be supplemented with isoproterenol.

KEY POINTS: ELECTROPHYSIOLOGY STUDIES

- The majority of children presenting for EPS and ablation are otherwise healthy, have structurally normal hearts, and present with well-tolerated SVT.
- More rare and higher risk are patients with CHD and those presenting for ablation in early childhood or infancy.
- A child with VT or EAT should prompt discussion as to whether sedation versus GA would be best to optimize successful arrhythmia induction and ablation.
- Adenosine is used in the assessment of arrhythmias and can produce bronchospasm in children with reactive airway disease or asthma.
- PONV is common following EPSs and should be managed prophylactically.

Implantation of pacemakers and defibrillators

Pacemakers in children are rare [202]. The most common indication is symptomatic bradycardia secondary to congenital or postsurgical AV block. Other indications include antitachycardia pacing for SVT or sinus node dysfunction in the setting of impaired cardiac output.

Leads can be delivered transvenously through the subclavian vein or placed epicardially through a subxyphoid approach (partial sternotomies and thoracotomies have also been used). These leads are then attached to a pulse generator, which is implanted in the SQ tissue of the chest (transvenous leads) or the abdomen (epicardial leads). Alternatively, the generator may be placed deep to the pectoralis or rectus abdominis muscles, respectively, in young or thin patients to minimize the risks of erosion and infection. Factors that influence the choice of transvenous versus epicardial systems include (i) the size of the central veins, (ii) amount of the SQ tissue at the implantation site, and (iii) whether or not the heart can be accessed through a transvenous approach. Smaller vein size is a risk factor for central venous thrombosis or obstruction when using transvenous leads. Consequently, epicardial leads are most often used in patients weighing <15 kg. Epicardial leads are also indicated in children whose hearts cannot be accessed via a systemic vein (e.g., Fontan circulation) or those with intracardiac shunts (due to the risk of systemic thromboembolism with transvenous leads). Challenges common to both systems include the continued growth of the child (relative to fixed leads) and the related issues of lead failure and fracture.

Most recently, leadless pacing systems have been introduced. As the descriptor suggests, neither leads nor a separate generator pocket is needed. Such devices are implanted transvenously into the RV myocardium as a self-contained unit, comprising the functionality of a lead and generator in one capsule that is 90% smaller than the typical pulse generator [203]. While promising in their ability to avoid the morbidity associated with transvenous and epicardial systems, leadless systems are currently restricted to older children and adolescents due to the large size of the transfemoral sheath needed for deployment. Such devices are predominantly used as single chamber ventricular pacemakers. Current indications for use are the need for backup pacing (those with intermittent pauses or block who need only occasional rather than continuous pacing) and those with venous occlusions that preclude standard pacing systems [204].

Children undergoing either epicardial or transvenous lead placement are managed with GETA, while adults who are cooperative can be managed with sedation and abundant local anesthesia. The induction of general anesthesia can occasionally lead to worsened bradycardia. Beta-agonists such as isoproterenol or epinephrine can be trialed to increase heart rate, or temporary pacing may be instituted (transcutaneously, transvenously via a pacing catheter, or transesophageally via an esophageal pacing probe). Regional anesthesia with pectoral nerve blocks may decrease postoperative pain and opioid consumption in patients undergoing subpectoral generator placement [205]. Periprocedural complications associated with transvenous approaches include vascular injury, myocardial perforation, and AVV injury. Acute lead dislodgement or failure can occur regardless of approach and is associated with traction with patient movement.

Implantation of implantable cardioverter-defibrillators (ICDs) is indicated for life-threatening cardiac arrhythmias [206]. Examples include isolated arrhythmia associated with long QT syndromes and patients with hypertrophic cardiomyopathy or arrhythmogenic RV dysplasia who may have more generalized myocardial disease [206–209]. CHD associated with ICDs include TOF, anomalous origin of the coronary arteries, transposition, and Ebstein's anomaly [206]. As with pacemakers, these devices can be placed either transvenously or epicardially [210]. SQ ICDs designed initially for adults are now also being applied in pediatric patients [211–213]. It is usual to test the defibrillator by induction of ventricular fibrillation and it is prudent to be prepared with external defibrillation pads and pharmacologic agents (as indicated by the pathophysiology of the arrhythmia) in the event the device fails. Often, patients present after near-miss sudden death or death of a close family member and can be extremely anxious. Preoperative anxiety can be sufficient to induce arrhythmia, and premedication with an anxiolytic is advisable.

Elective cardioversion

Patients presenting for elective (or nonemergent) cardioversion have stable tachyarrhythmias and are most often adults

with CHD. Atrial fibrillation and flutter (AF/F) are the most common indications, with some presenting for first-time cardioversion and others for breakthrough arrhythmia in spite of antiarrhythmic therapy. Due to the risk of thromboembolism with AF/F, patients are managed with anticoagulation in advance of cardioversion [214, 215]. For patients with AF/F of unknown duration or longer than 48 hours who have not been anticoagulated for the preceding 3 weeks, TEE is performed prior to cardioversion to rule out left atrial appendage thrombus.

Anesthetic concerns are related to patient and procedural factors. Key patient factors include the underlying cardiac diagnosis and current functional status. Long-standing arrhythmias can result in worsened cardiac function that can manifest clinically with signs of heart failure. Conversely, severely depressed function at baseline can serve as the nidus for arrhythmia. The presence of these findings indicates higher risk. Procedure-related factors include where the procedure is to be performed and whether or not TEE is needed. The former influences preparation, whereas the latter can dictate airway management and the choice of sedatives/anesthetics to be used.

Locations for elective cardioversion and/or TEE at our institution have included the EP suite, procedure room, and ICU. Each site has its pros and cons, but in those patients who are at highest risk for anesthesia-induced instability, a plan for resuscitation and the availability of essential personnel (surgeons and perfusionists) in the event of an arrest are likely more important than the location itself. If performing the procedure outside a normal anesthetizing site, usual precautions are taken to ensure the availability of all necessary equipment and drugs.

For patients who need TEE, we commonly secure the airway with an ETT. Of note, many adult institutions perform these procedures as MACs while maintaining a natural airway. Our choice for GETA is informed by the relative infrequency of this procedure (and therefore our inexperience with MAC in these cases), concern that hypoventilation or hypoxemia associated with MAC may result in instability in already tenuous patients, and the unpredictable length of TEE.

For patients presenting for cardioversion *without* TEE, a number of sedatives or anesthetics can be used while maintaining a natural airway. A recent Cochrane review found no consistent difference in safety, efficacy, or adverse events among the most commonly used agents: propofol, etomidate, sevoflurane, isoflurane, midazolam, and diazepam [216]. As with all CHD, the dose of the drug used rather than the drug itself is most relevant. Knowles described the administration of a slow bolus of propofol (0.5–1 mg/kg) with additional doses (0.25 mg/kg) as needed in those with severely limited cardiorespiratory reserve [217]. Phenylephrine or ephedrine can be used in conjunction with such boluses to mitigate the negative hemodynamic effects of propofol. Sevoflurane alone has also been reported as efficacious in high-risk patients [217, 218].

Transvenous lead extractions

Transvenous lead extraction is defined as the removal of a lead that has been implanted for greater than a year or that requires specialized extraction tools [219]. Patients presenting for this procedure are often adults (with a median age of 40 years at Texas Children's) who can have either structurally normal hearts or CHD. Channelopathies or congenital heart block comprise the diagnoses in those with structurally normal hearts, whereas common diagnoses in CHD include D-TGA, TOF, congenitally corrected transposition, and hypertrophic cardiomyopathy. Patient and procedural risk are often higher in this latter group. The foremost indications for extraction are infection (involving the lead, generator pocket, or valve through which the lead passes), lead dysfunction, or SVC or baffle obstruction. The latter conditions require lead extraction because they are treated by stenting. If a stent were deployed without removing the indwelling leads, the leads would be at risk for entrapment or disruption. This indication is most frequent among patients with d-TGA who underwent the Mustard procedure and now have a systemic venous baffle leak or stenosis (Figure 34.27). Of course, after stenting is performed, new leads are necessary.

Techniques for removal range from the basic to the more advanced. Simple traction or the use of locking stylet may be sufficient in some patients [220]. More specialized equipment is needed in leads that are adherent to venous structures or the myocardium, including mechanical sheaths that break fibrotic attachments, rotational sheaths that pierce adhesions, and electrosurgical dissection sheaths that use RF energy to disrupt attachments [221]. Beyond these interventions are laser sheaths that transmit laser light to facilitate extraction [222, 223].

Awareness of the risks associated with this procedure and strategies to address major complications is essential in developing an anesthetic plan (Table 34.15) [223–225]. Catastrophic vascular or cardiac injury with attempts at lead extraction is a primary concern. This risk increases with (i) years that the leads have been in place, (ii) the number of leads to be explanted, (iii) dual-coil ICD leads (since these are larger), (iv) use of powered sheaths for removal, (v) females with a body mass index (BMI) <25 (presumably due to smaller vessels that may be more prone to injury), and (vi) use of a femoral approach for extraction (a surrogate for a technically difficult procedure) [226–230]. For those patients at increased risk, a surgical team is involved with plans for initiating cardiopulmonary bypass in the event of an otherwise uncontrollable hemorrhage. This can be achieved either through a median sternotomy in patients without prior surgical intervention or through the femoral vessels in patients with a history of sternotomies. Given this possibility, these procedures are most commonly performed in a hybrid CCL.

Anesthetic preparation begins prior to induction by ensuring that any anticoagulation has been held, or if reversal is to be administered if continued. Intraprocedurally, GETA is induced as guided by the patient's clinical condition and cardiac function. Large-bore upper and lower extremity venous access is obtained. The latter is useful in the event of superior vena cava (SVC) or RA tear. If no peripheral access is available in the lower extremity, a 9-Fr introducer sheath is placed in the left femoral vein (leaving the right femoral vein available for emergent bypass cannulation). A dedicated arterial line for blood pressure monitoring is placed (with attention to which extremities may provide the most accurate site in patients with multiple prior cardiac surgeries), and consideration is given to a central venous catheter for the

AL Grawany

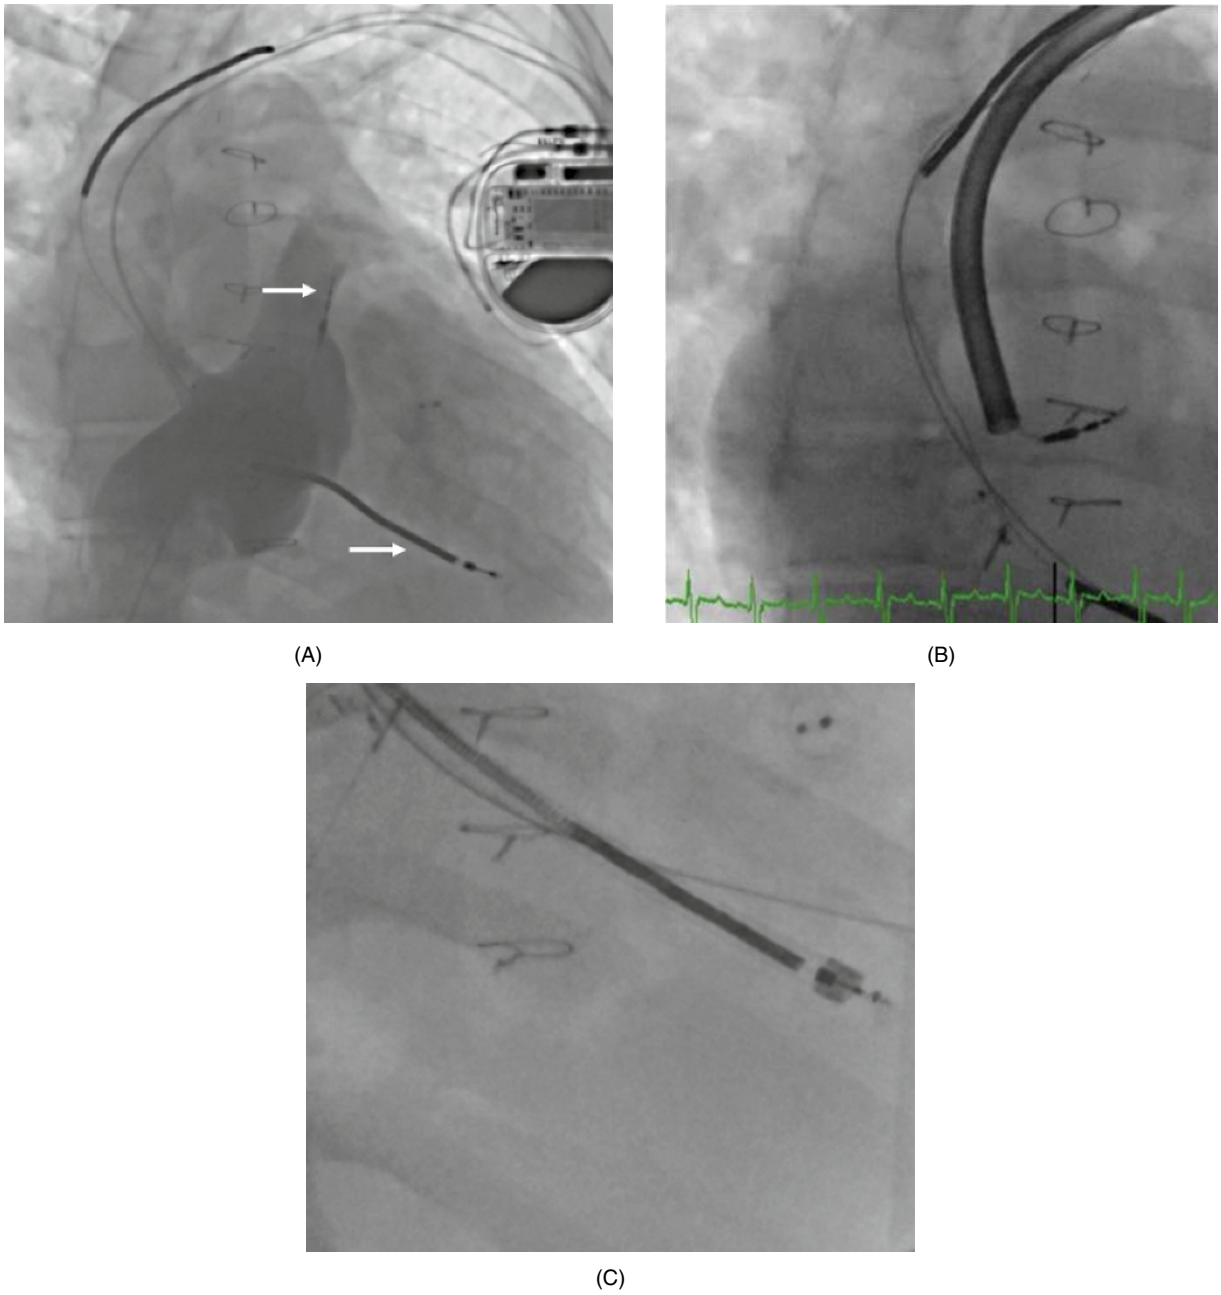

Figure 34.27 Lead extraction. A 33-year-old male with d-TGA status post the Senning procedure and placement of a dual-chamber ICD presented for lead extraction. The leads were 14 years old and were placed for ventricular fibrillation. The ventricular lead was defective and the atrial lead required removal to allow stenting of the baffle stenosis. (A) The atrial baffle of systemic venous blood to the left atrium. Upper arrow marks the atrial lead passing into the left atrial appendage. Lower arrow marks the ventricular lead in the subpulmonic left ventricle. (B) Use of a rotating dilator sheath to extract the atrial lead. (C) Use of a laser device to extract the ventricular lead.

administration of vasoactive agents. Blood, plasma, and vasoactive infusions are ordered and present in the CCL as for a bypass case. In patients who are pacemaker dependent, a temporary pacing catheter is needed in addition to transcutaneous pacing/defibrillation pads. For those undergoing extraction for infection, the development of sepsis should be considered in the differential for hypotension. Imaging of the heart is achieved using a combination of fluoroscopy and echocardiography (intracardiac or transesophageal).

Hemorrhage secondary to venous or cardiac injury is most often temporally related to lead removal. Temporizing measures include administration of volume and pressors while the proceduralist deploys a Bridge Occlusion Balloon™ (Spectranectics) if the source of bleeding is an SVC tear. In the event of hemothorax or pericardial effusion, drains are placed. If needed, the surgical team on standby should be prepared to proceed with cardiopulmonary bypass and sternotomy.

Table 34.15 Management of complications associated with lead extraction

Complications	Management
Hemorrhage	
• Tear at SVC/RA junction	• Passage of a bridging balloon to occlude the tear (performed by the interventionalist) • Administration of volume and vasoactive agents through ***lower extremity*** access • Surgical consult (on standby)
• Cardiac perforation	• Pericardial and/or chest tube drainage and autotransfusion • Surgical consult (on standby)
Hypotension otherwise	
• SVC obstruction by the powered sheath or laser	• Readjust if possible
• Pacing noncapture in those who are pacemaker dependent	• Readjust temporary pacing wire
• Catheter-induced tricuspid valve injury causing severe TR	• Diagnosed via echocardiography. Supportive management with vasoactive agents
• Arrhythmias or decreased contractility associated with tension at the ventricular lead	• Reduce tension applied. Supportive management.
• Blood loss from access site	• Periodically assessed

RA, right atrium; SVC, superior vena cava; TR, tricuspid regurgitation.

Assuming an uneventful extraction, patients are extubated and recovered in the standard anesthesia recovery area. Patients with significant comorbidities, procedural complications, or the continued need for vasoactive agents are monitored postprocedure in the ICU.

Conclusions

The shift from diagnostic to interventional catheterization has resulted in an increase in patient and procedural complexity that has only accelerated in recent years. Such changes have underscored the need for the anesthesiologist to understand each of the ever-expanding variety of procedures that can be performed as well as their associated complications. This added complexity has also highlighted the role that the anesthesia team can play in risk reduction. Through preprocedural communication (with cardiology or the relevant consulting services) and identification of modifiable risk factors, adverse events can be avoided and patient outcomes can be optimized.

Introduction

The commonly reported incidence of congenital heart disease (CHD) in the United States is between 4 and 10 per 1,000 live births. The most common defects are ventricular septal defect, atrial septal defect, valvular pulmonary stenosis, tetralogy of Fallot, coarctation of the aorta, atrioventricular (AV) septal defect and transposition of the great arteries. The National Birth Defects Prevention Network data estimate that there are more than 6,100 cases annually of five defects in the US: truncus arteriosus, transposition of the great arteries, tetralogy of Fallot, AV septal defect, and hypoplastic left heart syndrome (HLHS). Annually, there are an estimated 9,200 patients requiring an invasive procedure related to CHD in the first year of life [1].

With improving survival, the number of unrepaired, repaired, and palliated patients of all ages is increasing. With this increase in the number of patients living with CHD, there is a concomitant increase in the number of patients of all ages presenting for noncardiac procedures requiring anesthetic care. Using data from the Pediatric Health Information System (PHIS), an administrative database that includes the surgical data from 52 freestanding children's hospitals, Nasr et al. report a significant increase in noncardiac surgical encounters from 38,272 in 2015 to 45,993 in 2019 ($p < 0.001$) [2]. In fact, also according to PHIS data, 41% of pediatric patients with CHD requiring surgical management of their CHD in the first year of life also have at least one noncardiac procedure before the age of 5 years, most commonly gastrointestinal or otolaryngologic procedures [3]. Adult patients with CHD are also accounting for an increasing percentage of patients presenting for noncardiac surgical procedures and represent a challenge in perioperative management [4].

Data from the Pediatric Perioperative Cardiac Arrest (POCA) Registry report a higher risk of perioperative cardiac arrest in children with CHD undergoing anesthesia compared with the rest of the pediatric population, and 54% of arrests occurred during noncardiac procedures. Mortality after cardiac arrest is also substantially higher for patients with cardiac disease, being 33% among those with heart disease, compared with 23% among those without. It is

critical to recognize the patients at highest risk of anesthesia-related mortality: infants with single-ventricle lesions and patients with left ventricular outflow tract obstruction (LVOTO), cardiomyopathy or pulmonary hypertension [5, 6]. Risk assessment and stratification has become increasingly important for perioperative planning.

The recognition of high-risk patient groups has led to improved multidisciplinary discussion, selection of appropriate operative venue and recovery area, selection of anesthesia care provider, conduct of anesthesia and surgery, and level of monitoring with the goal of reducing morbidity and mortality. In fact, over the last several years, there has been a reduction in the incidence of mortality in patients undergoing noncardiac surgery at children's hospitals. This is attributed to improved patient selection, medical optimization, and expertise found at dedicated children's hospitals [2].

Over the last several years, the literature suggests that an optimized milieu for the perioperative planning and discussion, acquired and shared expertise in caring for these patients, and multidisciplinary collaboration in care has allowed for improved outcomes in this fragile population undergoing noncardiac procedures. It is possible that shared decision-making allows the group to attempt and be successful in performing procedures on patients that were once deemed too risky.

KEY POINTS: RISKS AND SEQUELAE IN CHD

- There is a higher risk of perioperative morbidity and mortality in patients with CHD.
- Mortality after cardiac arrest is higher for patients with CHD.
- High-risk lesions for anesthesia-related mortality are single ventricle, LVOTO, cardiomyopathy, and pulmonary hypertension.
- Thorough assessment and recognition of high-risk patients leads to improved perioperative planning and optimization of outcomes.

Risk assessment and stratification

Attempts have been made to identify risk factors to help stratify patients with CHD. The pediatric databases of the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) classifies patients with CHD according to the residual lesion burden and cardiovascular functional status, dividing them into minor, major, or severe CHD (Table 35.1). Using data from the same database, Faraoni et al. found that children with major and severe CHD undergoing noncardiac procedures have an increased risk of mortality and a higher incidence of postoperative reintubation compared with matched controls undergoing comparable procedures. Interestingly, there was no difference between children with minor CHD and their matched controls [7].

Taking this into consideration, Faraoni et al. identified eight predictors of in-hospital mortality in patients with major and severe CHD and developed a risk stratification score system (Table 35.2). Patients with an overall score of less than or equal to 3 were associated with a low mortality risk (odds ratio [OR]: 1.54, 95% confidence interval [CI]: 0.78–3.04). Those with a score from 4 to 6 had a medium mortality risk (OR: 4.19, 95% CI: 2.56–6.87). Those with a score above 7 had a high mortality risk (OR: 22.15, 95% CI: 15.06–32.59) [8]. A further study by the same group confirmed that the predominant predictors of perioperative mortality in

Table 35.1 ACS NSQIP classification of CHD based on residual lesion burden and functional status

Classification	Definition and criteria
Minor CHD	• Cardiac condition with or without medication and maintenance (e.g., atrial septal defect, small-to-moderate ventricular septal defect with no symptoms) • Repair of congenital heart defect with normal cardiovascular function and no medication
Major CHD	• Repair of congenital heart defect with residual hemodynamic abnormality with or without medications (e.g., tetralogy of Fallot with wide open pulmonary insufficiency, hypoplastic left heart syndrome including stage 1 repair)
Severe CHD	• Uncorrected cyanotic heart disease • Patients with any documented pulmonary hypertension • Patients with ventricular dysfunction requiring medications • Listed for heart transplant

children with CHD were patient comorbidities and the severity of the cardiac lesion at the time of the noncardiac procedure, not the surgical risk [9].

Preoperative preparation for noncardiac surgery

Multidisciplinary planning

Patients with CHD often have other congenital defects and are often cared for by multiple specialists. Each patient most likely has a pediatrician, a cardiologist, and a cardiac surgeon. The patient may be referred to a general surgeon for a gastrostomy tube placement, a urologist for hypospadias repair, a dentist for dental cleaning and restoration, an orthopedic surgeon for treatment of limb deformities, and multiple other practitioners. In addition, the patient may be scheduled for magnetic resonance imaging (MRI) or computed tomography (CT) scanning to evaluate the cardiovascular system or another co-morbid organ system. Many, if not all, of these procedures require general anesthesia or sedation. The consulted services may not be aware of the patient's anatomy, physiology, and risk associated with anesthesia.

The role of the anesthesiologist in the care of the patient with CHD undergoing noncardiac surgery should not be underestimated. The anesthesiologist may be the member of the collaborative team that understands the most about the surgical procedure, the patient comorbidities, and the anesthetic. A team with ample input from the anesthesiologist should determine where the procedure will take place, such as an outpatient operating room (OR) vs. an OR setup for emergent cardiopulmonary bypass, and how the associated risks can be mitigated. Preoperative management including hydration, medication management, management of anticoagulation, and fasting times should be discussed. In addition, postoperative disposition should be determined in advance, and an intensive care unit (ICU) bed should be reserved if needed.

Multidisciplinary planning can also result in combining multiple procedures under the same anesthetic. The patient may require fewer anesthetics and may be at a lower risk of anesthesia-related morbidity and mortality (see Box 35.1) [10].

Preoperative cardiology visit

The timing of a preoperative cardiology visit prior to a noncardiac procedure depends on the patient's disease, the stage of repair or palliation, and the degree of limitation of activities of daily living (feeding, growing, neurodevelopment for infants; attending school for older children) due to cardiac disease. The type of noncardiac procedure should not impact these guidelines, as a general anesthetic may be required for any procedure. In general, acyanotic patients who are repaired or who have no limitations due to cardiac disease do not require a preoperative cardiology consultation. If these patients have limitations and are not well compensated, a preoperative consultation is indicated within 6 months of the procedure. For patients with cyanotic CHD who are well compensated and have no limitations due to their cardiac disease, a cardiology visit within 12 months of the procedure is adequate. For patients with cyanotic CHD who have limitations due to their cardiac disease, a preoperative consultation is indicated within 6 months of the procedure. Specific recommendations exist for patients with Williams syndrome (see below).

Screening in a pre-anesthetic clinic setting to gather the results of imaging and other diagnostic studies and to review cardiology records is helpful. If necessary, a preoperative cardiology visit can be scheduled, additional tests, studies and consultations can be scheduled, and all data can be collected and reviewed prior to the patient's arrival on the day of surgery. This step facilitates the selection of a properly experienced anesthesiologist as well as the proper setting for the anesthetic, and it allows the anesthesiologist to prepare necessary medications and equipment in advance. A plan for the postoperative recovery site for the patient (post-anesthesia care unit [PACU] vs. ICU) should be made at this time. These preparations translate into fewer cancellations on the day of surgery.

Box 35.1: The advantages of performing multiple procedures under the same anesthetic in patients with congenital heart disease

- Decreased risk of potential anesthetic neurotoxicity (fewer exposures)
- Potential decrease in anesthetic related morbidity and mortality (fewer inductions, intubations, emergences, etc.)
- Less time nil per os
- Less time without cardiac medications such as anticoagulants, diuretics
- Improved patient/parent satisfaction

Interpretation of imaging and hemodynamics

Preoperative imaging and hemodynamic studies are addressed extensively in Chapter 18. Important information obtained from imaging studies and cardiac catheterization include right and left ventricular function, presence of valvular stenosis or regurgitation, the size and direction of flow of atrial and ventricular septal defects, patency of shunts or vascular connections, and an estimate of pulmonary vascular resistance (PVR). These key pieces of information help to identify patients with lesions that place them at an increased risk for perioperative morbidity and mortality (e.g. cardiomyopathy, aortic stenosis, pulmonary hypertension) and to construct an anesthetic plan with appropriate hemodynamic goals.

Nil per os

Fasting times of 6 hours for solids or formula, 4 hours for breast milk, and 2 hours for clear liquids are the recommended guidelines from the American Society of Anesthesiologists.[11]. For patients with CHD, these fasting times are recommended as well. However, there are some important considerations in this patient population. Patients with LVOTO including hypertrophic obstructive cardiomyopathy, subaortic stenosis, aortic stenosis, and supravalvular aortic stenosis (Williams syndrome or non-Williams syndrome); systemic-to-pulmonary artery shunts (e.g. modified Blalock–Taussig shunt, ductal stent, central shunt); and polycythemic, cyanotic patients have an

AL Grawany

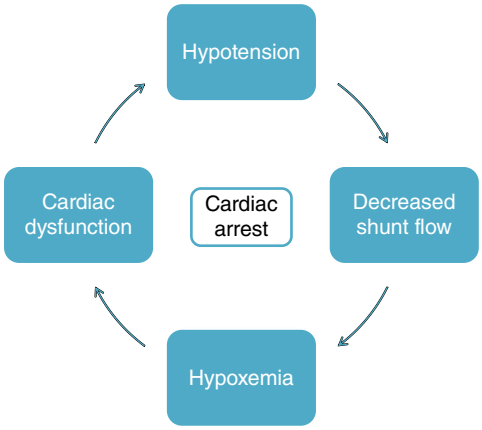

Figure 35.1 The cycle of hypotension and hypoxemia resulting in cardiac arrest in shunted single-ventricle patients.

increased risk of perioperative morbidity and mortality when hypovolemic. Hypovolemic patients with LVOTO may develop significant hypotension during an inhalation induction with a resultant decrease in coronary perfusion pressure that results in unresuscitatable cardiac arrest. Shunted patients with pulmonary blood flow that is completely dependent on systemic blood pressure may become profoundly hypotensive and hypoxemic on induction of anesthesia. Also, when there is decreased blood flow through the shunt, the likelihood of shunt thrombosis increases, as does an unfortunate cycle of hypotension and hypoxemia (Figure 35.1). Other polycythemic, cyanotic patients are at risk for thrombosis and stroke due to increased blood viscosity, which can be due to prolonged fasting. Hypovolemia due to fasting has been reported as a cause of periprocedural morbidity and mortality [12, 13].

Prevention of hypovolemia is the key to minimizing this risk. Careful planning and communication will minimize the time these patients are without fluids. Families should be advised to give clear fluids liberally until 2 hours prior to the procedure, and if the procedure is delayed, clear fluids can be administered by mouth at the hospital until 2 hours prior to the procedure. In addition, intravenous fluids can be started upon arrival in the hospital to replace losses before induction of anesthesia. Patients may also be admitted the night before surgery to receive intravenous fluids while fasting. These strategies may decrease perioperative risk.

Implementation of more liberal guidelines such as allowing clear fluids until one hour prior to the procedure have been shown to be associated with similar aspiration risks as classic NPO guidelines. Liberal guidelines for clears have been adopted in Sweden, Australia, and the United Kingdom with no increase in aspiration. The European Society of Anaesthesiology updated its guidelines as well [14–16]. With this in mind, it may be beneficial to allow patients with a higher hemodynamic risk profile to drink clear fluids until one hour prior to induction to maintain intravascular volume [15, 16].

Continuation of medications

In general, all chronic cardiac medications should be continued perioperatively. Anticoagulants such as aspirin, warfarin, and heparin may be discontinued at the preference of the surgical team after discussion of a perioperative plan for stopping, transitioning, and restarting anticoagulation with the cardiology team. Another exception may be diuretic therapy. Continuation of diuretic therapy in a fasting patient may not be indicated. However, perioperatively, after volume administration, diuretic treatment may be warranted. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers may also be held preoperatively due to a significant incidence of hypotension on induction of anesthesia in the general population [17, 18]. These agents have also been associated with hypotension and hemodynamic instability on induction in pediatric patients with CHD undergoing noncardiac operations [19].

Endocarditis prophylaxis

CHD is the leading risk factor for infective endocarditis (IE) in children in the developed world. Lesions associated with increased risk of IE in children are cyanotic CHD, left-sided lesions, and endocardial cushion defects. In addition, the relative risk of developing IE is higher in the 6 months following cardiac surgery and in children less than 3 years of age [20]. The goal of IE prophylaxis is to provide appropriate antibiotic coverage for procedures that are associated with bacteremia. The three most common bacteria implicated in CHD-associated IE are *Streptococcus* (including *Streptococcus viridans*), *Enterococcus*, and *Staphylococcus* species [21].

The 2007 American Heart Association (AHA) guidelines for IE prophylaxis reduced the number of patients with CHD whom they recommend receive IE prophylaxis and reduced the number of procedures for which IE prophylaxis is recommended. The patients with CHD for whom IE prophylaxis is recommended are those who have the highest risk of adverse outcome from endocarditis and these are listed in Box 35.2. Prophylaxis is recommended for patients who are within 6 months of complete repair with prosthetic material or a device. After 6 months, endothelialization of the prosthetic material has occurred, and IE prophylaxis is no longer recommended for these patients.

IE prophylaxis is recommended when both patient indications (Box 35.2) and procedure indications occur. For example, IE prophylaxis is recommended for all dental procedures that involve the manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa, but only for patients in Box 35.2. It is also recommended for patients in Box 35.2 who undergo invasive procedures of the respiratory tract that involve incision of the respiratory mucosa, such as tonsillectomy and adenoidectomy or bronchoscopy with biopsy. It is not recommended for bronchoscopy that does not involve incision of the

Box 35.2: Cardiac conditions at highest risk of adverse outcome from bacterial endocarditis

- Cardiac valve replaced by, or repaired with, prosthetic material
- Previous infective endocarditis
- Cardiac valve disease in a transplanted heart
- Unrepaired or palliated cyanotic CHD
- Repaired CHD repaired via surgical or catheter-based technique using prosthetic material for the 6 months following the procedure
- Repaired CHD with residual defect adjacent to prosthetic material

Table 35.3 Infective endocarditis prophylaxis for dental procedures in pediatric patients

Route	Drug and dose
Oral	Amoxicillin 50 mg/kg
Oral – penicillin/ ampicillin allergic	Cephalexin 50 mg/kg or clindamycin 20 mg/kg or azithromycin or clarithromycin 15 mg/kg
Intravenous/ intramuscular (IV/IM)	Ampicillin 50 mg/kg or cefazolin 50 mg/kg or ceftriaxone 50 mg/kg
IV/IM – penicillin/ ampicillin allergic	Cefazolin 50 mg/kg or ceftriaxone 50 mg/kg or clindamycin 20 mg/kg

mucosa. The antibiotic regimen should be active against *viridans* group *Streptococcus* (see Table 35.3). Antibiotic prophylaxis solely to prevent IE is not recommended for endoscopic gastrointestinal or genitourinary procedures that do not incise mucosa, that is, uncomplicated endoscopies; if biopsies are taken then IE prophylaxis should be considered. However, if the patient is known to be infected or colonized, they should be treated with an antibiotic that covers *Enterococcus* [22]. IE prophylaxis is also recommended for high-risk adult patients with CHD undergoing similar procedures. It is important to recognize that IE prophylaxis is also recommended for vaginal delivery and hysterectomy and should be considered for tattoos, and body-piercings [23–26].

KEY POINTS: PREOPERATIVE PREPARATION FOR NONCARDIAC SURGERY

- Multidisciplinary discussion and planning are essential for determining the risk/benefit balance for a given procedure and for mitigating perioperative risk.
- Minimize fasting times, especially for patients at increased risk for hypotension and myocardial ischemia during induction of anesthesia.
- Consideration should be given holding certain cardiac medications prior to surgery, e.g., diuretics, angiotensin-converting enzyme inhibitors and angiotensin receptor blockers.

Pacemakers and defibrillators

The number of pediatric patients with cardiovascular implantable electronic devices (CIEDs), pacemakers and defibrillators, has increased as technology has advanced [27]. An increasing number of pediatric patients with these devices will likely present for noncardiac as well as cardiac surgery. It is crucial to manage these devices properly to avoid injury, inappropriate shocking, and hemodynamic instability. A more extensive discussion of pacemaker and defibrillator therapy is presented in Chapters 22 and 34.

Preoperatively, it is important to understand the type of device in place, generator location, associated cardiac disease, indications for placement, and the remaining battery life. The underlying cardiac rhythm and degree of pacemaker dependence for cardiac output (none, partial, or complete) are key points of information. This information is best gleaned from a combination of history, physical exam, review of chest radiograph, discussion with or previous note from the cardiologist, and an interrogation of the device in the holding area by a CIED programmer (cardiologist, specialized nurse, or certified company representative from the device manufacturer).

Electromagnetic interference (EMI) in the OR is most commonly caused by monopolar electrocautery. EMI can result in inappropriate triggering or inhibition of pacing, reversion to asynchronous mode, inappropriate shock or anti-tachycardia therapy, and induction of current in the leads, resulting in myocardial damage. Strategies for reducing EMI include the use of bipolar instead of monopolar electrocautery, using short bursts of cutting rather than coagulation current when monopolar is required, and placing the grounding pad for the electrocautery far from the device site.

If EMI is likely during a procedure, the CIED programmer should reprogram the pacemaker to an asynchronous mode with a rate greater than the patient's intrinsic rate. Similarly, the anti-tachycardia function of a defibrillator should be disabled until the risk of EMI is low. It is critical to monitor the patient for a perfusing rhythm with either a plethysmographic or arterial line waveform, as well as electrocardiogram (ECG), after reprogramming. In addition, temporary pacing/defibrillation equipment must be available at all times, and the availability of appropriately sized equipment must be confirmed.

After the procedure when the risk of EMI is low, the device should be interrogated and reprogrammed back to its original baseline settings. It is critical to monitor for a perfusing rhythm and to have pacing/defibrillation equipment present until the device is reprogrammed [28–30].

A magnet can be used in an emergency situation to reprogram a CIED. It is not a substitute for interrogation/reprogramming by a CIED programmer, and it can have unpredictable consequences, particularly with modern multifunction pacemaker/defibrillator devices. For pacemakers, application of the magnet will usually change the pacemaker mode to an asynchronous mode (AOO, VOO or DOO – see Chapter 22) at a fixed rate, usually between 65 and 100 beats/minute (bpm). This fixed rate is device-specific and dependent on remaining battery life [31]. Untoward effects of magnet application include pacing at a rate or in a rhythm that does not meet the patient's metabolic or hemodynamic needs. For defibrillators, application of the magnet usually suspends the anti-tachycardia function, but does not change the pacemaker to an asynchronous mode. If the patient experiences ventricular tachycardia or ventricular fibrillation while the magnet is applied, the magnet should be quickly removed so that the anti-tachycardia function is restored and the device can deliver a shock [29]. This restoration does not occur with all systems, however; some are disabled until interrogation/reprogramming occurs [32]. There is no substitute for consultation with an expert, assessing the function of the device and converting the functions to an appropriate intraoperative mode. Obviously, there may be emergency situations where this will not be possible. The critical importance of monitoring the patient for a perfusing rhythm throughout

AL Grawany

the procedure, having backup pacing/defibrillation equipment present, and interrogating and reprogramming the device postoperatively cannot be overemphasized. There is a discussion of MRI-compatible pacemakers later in the chapter.

KEY POINTS: PACEMAKERS AND DEFIBRILLATORS

- Preoperatively, all CIEDs should be interrogated and potentially reprogrammed by the CIED service.
- After reprogramming, the patient must be monitored for a perfusing rhythm with an arterial line or plethysmographic waveform.
- Magnet application can have unpredictable consequences and should not be used as a substitute for interrogation and reprogramming.

The patient on ventricular assist device support

Heart failure most commonly resulting from CHD, cardiomyopathy, and myocarditis is the diagnosis associated with more than 12,000 annual pediatric hospital admissions in the United States [33]. Most of these patients can be managed medically or surgically, but there are a growing number of pediatric patients that require extracorporeal membrane oxygenation (ECMO) or ventricular assist device (VAD) placement. There are now devices that are appropriate for all sizes of pediatric patients for long-term support (see Table 35.4) [34, 35]. These devices are discussed in detail in Chapter 37.

After placement, cardiac output can be maintained for these patients until cardiac function recovers or a suitable organ becomes available for transplant. In some cases, the patient can remain on VAD support indefinitely, as destination therapy. Destination therapy has been described in patients with end-stage heart disease due to muscular dystrophy [36]. These patients on long-term VAD support will likely require anesthesia or sedation for multiple imaging procedures and noncardiac interventions and procedures. In order to provide care for this population of patients, one should become familiar with the different types of devices and the management of hypotension, hypertension, and a decrease in output. A perfusionist or VAD-trained nurse should be present for all noncardiac procedures to assist with management and transport of the device. In addition, bacterial endocarditis prophylaxis is warranted in all VAD-supported patients.

The Berlin EXCOR (EXCOR Pediatric Ventricular Assist Device, Berlin Heart, GmbH, The Woodlands, Texas, USA) is a pneumatically driven pump that generates a pulsatile pressure with a rate between 30 and 150 bpm depending on the size of the pump chamber and the size and needs of the patient. The transparent pump chamber allows for visual evaluation of filling, emptying, and thrombus formation. Because of the range of pump sizes, it can be used in neonates, infants, and children, and it is the device that is used most commonly for long-term support in pediatric patients at the present time [35].

Anesthetic management of the patients with a Berlin EXCOR device requires familiarity with the pump and how to troubleshoot hypotension, hypertension, and reduced output. Cave et al. describe a 69% incidence of hypotension in a case series of 29 noncardiac procedures on 11 patients with a Berlin EXCOR device. This group found that hypotension on induction was most associated with the use of remifentanil and was least associated with the use of ketamine as an induction agent. Care should be taken with the administration of anesthetic agents associated with a decrease in systemic vascular resistance (SVR), and intravascular volume and vasoactive agents that increase SVR should be on hand [37].

When caring for a patient with a Berlin EXCOR device, it is critical to maintain the ability to visually inspect the pump. This may require clear drapes, a mirror, and a flashlight. The membrane should be inspected regularly to check for fibrin deposition and for membrane wrinkling. Membrane wrinkling is a sign of incomplete filling of the chamber. Device inspection is a key component of determining the cause of hypotension and the appropriate treatment [34].

Intraoperative emergencies in a patient with a Berlin EXCOR include malignant dysrhythmias, sudden loss of cardiac output, the appearance of air or clot in the pump chamber, and sudden cyanosis. If the patient develops a dysrhythmia, the pump should be examined for filling and output. The right ventricle (RV) can act like a conduit in the short term, and VAD output can be maintained. The patient may require external cardioversion. Loss of cardiac output is most commonly associated with an alarm from the Berlin EXCOR driver unit. It is most commonly caused by a kink in the external tubing of the device. The device should be examined and the tubing unkinked. Appearance of air or clot in the pump chamber can signal an impending embolism.

Table 35.4 Long-term ventricular assist device options for pediatric patients

Device	Positioning	Flow type	BSA (m^2)	Ambulation	Discharge home
Berlin EXCOR®	Paracorporeal	Pulsatile	0.2–1.3	Yes	No
Thoratec®	Paracorporeal	Pulsatile	>0.7	Yes	Yes
Heart Mate II®	Intracorporeal	Axial	>1.4	Yes	Yes
HeartWare®	Intracorporeal	Axial	>0.7	Yes	Yes

Source: Data from Mossad et al. [34].
BSA, body surface area.

A cardiac surgeon and a perfusionist should be called to the bedside for an urgent pump exchange. Sudden cyanosis in a patient with a Berlin EXCOR device may be a sign of pulmonary embolism with right-to-left shunting through an interatrial communication. Transthoracic echocardiography can aid in diagnosis [38].

Most left ventricular assist devices (LVADs) are preload dependent and afterload sensitive. Preload dependence means that, in the case of an LVAD, the left side of the heart must receive enough blood to fill the pump. Lack of left ventricular filling can be due to hypovolemia or right ventricular dysfunction. Treatment can include volume administration and support of the RV either with the administration of inotropic agents or decreasing PVR. Increased afterload can lead to inadequate ejection in the Berlin EXCOR or a decrease in VAD flow in a continuous flow device. The troubleshooting of the Berlin EXCOR and continuous flow devices can be found in Figures 35.2 and 35.3, respectively [39, 40]. In the patient with a right ventricular assist device, the afterload is the PVR which must be managed to facilitate flow.

VAD use in the failed single ventricle population is increasing, although it is fairly uncommon [41, 42]. In the case of the Fontan, there is no "right heart" that must be supported. In this case, preload is maintained through volume administration and the reduction of PVR using standard measures and pulmonary vasodilators such as nitric oxide or sildenafil.

Preoperative evaluation for the patient with a VAD starts with an investigation into the patient's anatomy and indications for VAD placement. An understanding of renal, hepatic, neurologic function should be sought. The patient may be on a variety of medications including diuretics, ACE inhibitors (or other afterload reducing agents), antiarrhythmics, pulmonary vasodilators, and inotropic agents for right heart dysfunction. The patient will also likely be on antiplatelet agents and anticoagulants. The ECG should be reviewed and the rhythm noted. Many patients on VAD

support have CIEDs, which should be managed similarly to other patients in the perioperative period. The cardiologist managing the VAD should be contacted, and the VAD should be interrogated for alarm history including low flow, power elevations, malfunction, and backup battery. A recent echocardiogram should also be reviewed. Information about RV function, PVR, and aortic insufficiency should be sought out [39, 40, 43].

Monitoring should include standard ASA monitors: ECG, temperature, capnography, blood pressure monitoring, and pulse oximetry. Unfortunately, with continuous flow devices, pulse oximetry and noninvasive blood pressure (NIBP) monitoring can be unreliable. Invasive arterial blood pressure monitoring should be considered for all cases and is necessary for major noncardiac operations. NIRS monitoring can also yield important information about perfusion and cardiac output. Intraoperative transesophageal echocardiography can be used to optimize right heart function and filling [39, 40, 43].

Intraoperatively, the VAD console for a continuous flow device should be in plain sight and monitored. For the Berlin EXCOR, the chamber should be visually inspected to look for thrombus or membrane wrinkles. The management of systemic vascular resistance is critical for optimal VAD functioning. An age-appropriate MAP should be selected, and optimization of the MAP may include the manipulation of anesthetic depth and the administration of vasopressors and vasodilators. For teenagers and adults, a MAP of 70–80 mmHg should be adequate to maintain good VAD flow and provide an adequate perfusion pressure to end organs. In adults, a MAP greater than 90 mmHg has been shown to be associated with low VAD flow, pump stasis, and embolic stroke [40, 43]. Right heart function may require augmentation with inotropic agents, and PVR may be manipulated to optimize cardiac output.

Data from an adult cohort of 246 VAD patients undergoing 702 noncardiac procedures provide some useful information about perioperative complications and monitoring. The most common perioperative complications were intraoperative hypotension (27%) and acute kidney injury (18%). Interestingly, invasive arterial blood pressure monitoring was only used in 20% of the cases. There were also gaps in blood pressure monitoring of greater than 20 minutes in 55% of cases. There were no recorded blood pressures in 5.5% of cases. During these gaps in monitoring, there is potential for unrecognized hypotension [44].

Postoperatively, the patient should be monitored in a special care or ICU to monitor cardiac, respiratory, and neurologic status. Increases in $PaCO_2$ associated with hypoventilation can lead to increases in PVR and suboptimal filling of the pump, as can hypovolemia associated with fluid shifts. Pain can increase both PVR and SVR and should be managed carefully.

Patients with VAD support may need to undergo noncardiac surgeries where the intraoperative management for the procedure is not aligned with optimal VAD management. For example, during one-lung ventilation for a video-assisted thoracic surgery (VATS), the patient may become hypercarbic and hypoxemia resulting in an increase in PVR, a decrease in right ventricular function, and a decrease device filling. The anesthesiologist should be prepared to take steps to decrease PVR and augment right ventricular function. Transesophageal echocardiography assessing septal configuration, and central venous pressure (CVP) monitoring can facilitate the diagnosis and treatment [45]. Likewise, during neurosurgical procedures, it is important to balance the provision of brain relaxation with the goals for optimal VAD function. In a report of an adult patient undergoing craniotomy for tumor resection, some of the management goals were similar such as the maintenance of a MAP of 70–80 mmHg and hyperventilation. However, mannitol was held due to the effect on preload and the potential for suboptimal VAD function [46].

Of note, the AHA has issued a new statement on resuscitation for the patient with a ventricular assist device. Defibrillation and medication administration per Pediatric Advanced Life Support or Adult Cardiac Life Support Algorithms are indicated, and at this time, external compressions are advised [39, 47]. See Chapter 25 for an extensive discussion of management of cardiac arrest in patients on mechanical support.

KEY POINTS: PATIENTS ON VAD SUPPORT

- Practitioners should become familiar with the common long-term VADs available for pediatric patients.
- Visual pump chamber inspection is critical for the perioperative management of the patient with a Berlin EXCOR device.
- Right heart failure should be considered when LVAD output decreases.

Management strategies for the stages of single-ventricle palliation

The single-ventricle surgical palliation pathway is presented in detail in Chapter 30. An understanding of the anatomy and physiology and familiarity with basic hemodynamic and ventilatory management strategies for the different stages of single-ventricle palliation are important for the successful care of these patients in the noncardiac OR and radiology suite (see Table 35.5). Instability should be anticipated at any stage of single-ventricle palliation, and vasopressors, inotropes, defibrillation capability, and volume expanders should be readily available. In addition, these patients are frequently cyanotic and thus are dependent upon chronically increased red cell mass for oxygen delivery to tissues; packed red blood cells should be available (type and screen or type and cross-match) to transfuse for most surgical procedures. A hematocrit of 40–45% is recommended for cyanotic and shunt-dependent neonates and infants to maintain oxygen-carrying capacity. The superior cavopulmonary anastomosis or Glenn stage of single-ventricle palliation is generally associated with more

Table 35.5 Anesthetic considerations for stages of single ventricle palliation

Stage of palliation	Cardiac lesion	Surgical palliation	Pathophysiological considerations	Anesthetic considerations after palliation
Neonatal	Hypoplastic left heart syndrome	Norwood stage I palliation	Systemic and pulmonary output both ejected by functional single ventricle; pulmonary to systemic vascular resistance ratio determines cardiac output	Avoid hyperoxygenation and hyperventilation; maintain ventricular function; maintain systemic oxygen saturation 80–90%
Neonatal	Tricuspid atresia with no pulmonary stenosis	Pulmonary artery banding, systemic-topulmonary artery shunt, or no intervention	For shunted patients, see above; management of pulmonary to systemic vascular resistance not as critical in banded patients	Maintain ventricular function; maintain systemic oxygen saturation 80–90%
Infant: cavopulmonary connection	Any single ventricle lesion	Superior cavopulmonary connection (bi-directional Glenn operation)	Cerebral-pulmonary-cardiac circulation is predominant in younger infants	Avoid hyperventilation; most stable stage for elective noncardiac surgery
Fontan completion	Any single ventricle lesion	Total cavopulmonary connection (Fontan operation)	Positive pressure ventilation decreases venous return and cardiac output; intolerant of hypovolemia or non-sinus rhythm	Minimize positive pressure ventilation; maintain ventricular volume, sinus rhythm, myocardial contractility; perform elective noncardiac surgery before this stage when possible

Source: Gottlieb and Andropoulos [10]. Reproduced with permission of Wolters Kluwer Health, Inc.

AL Grawany

resilient physiology. The patient is no longer shunt-dependent, the volume burden on the single ventricle is reduced, and cardiac output is not solely dependent on passive pulmonary blood flow as in the Fontan circulation. If possible, elective noncardiac surgery should take place during this stage [10, 48, 49].

KEY POINTS: MANAGEMENT STRATEGIES FOR THE STAGES OF SINGLE-VENTRICLE PALLIATION

- Shunted patients can develop hypotension and myocardial ischemia when hyperoxygenated and/or hyperventilated.
- The Glenn stage of single-ventricle palliation is considered the most stable stage for undergoing elective noncardiac surgery.
- A decrease of cardiac output in the patient with Fontan circulation should be anticipated when initiating positive pressure ventilation.

High-risk patient groups

All the patients included in this section are at increased risk of myocardial ischemia. If the myocardium is poorly perfused and becomes ischemic, an existing low cardiac output state may rapidly progress to an arrhythmia or cardiac arrest. It is the authors' recommendation that care for this population be provided by an anesthesiologist with skill and experience in pediatric cardiovascular anesthesiology. These patients should not receive care in a surgicenter or institution that lacks experts in pediatric cardiovascular intensive care, pediatric cardiology, and pediatric cardiac surgery.

Ductal dependent unpalliated neonates

With advances in care of single ventricle patients, unpalliated, ductal dependent neonates with significant noncardiac comorbidities are presenting for noncardiac surgery prior to addressing the cardiac diagnosis. These procedures can include congenital diaphragmatic hernia repair, tracheoesophageal fistula repair, duodenal atresia repair, exploratory laparotomy for necrotizing enterocolitis, and diverting colostomy for anal atresia. Other procedures related to planning and stabilization of cardiac disease may include peripherally inserted central catheter (PICC) placement, cardiac catheterization procedures, and brain imaging. These procedures can be elective, urgent, or emergent, and any opportunity for multidiscliplinary discussion and planning should be taken. The anesthesiologist should have a detailed understanding of the patient's anatomy and a plan for managing the ratio of pulmonary to systemic blood flow. Central venous and arterial access is advised, and appropriate vasopressors and emergency drugs should be available. ECMO candidacy should be determined preoperatively, and the family should understand the risk associated with both the cardiac disease and the proposed procedure.

CHD associated with tracheoesophageal fistula/esophageal atresia (TEF/EA) conferred a perioperative mortality of 23% compared with no mortality in patients without CHD in a series of 53 patients reported by Diaz et al. In addition, the risk of perioperative mortality was increased in ductal-dependent patients [50]. Also, in a series of 18 unpalliated neonates who underwent emergent general surgical procedures for necrotizing enterocolitis, intestinal atresia, imperforate anus, or tracheoesophageal fistula, 17/18 patients survived to cardiac surgery or palliation. The patient that did not survive to cardiac surgery had a preoperative echocardiographic misdiagnosis and succumbed 3 days after tracheoesophageal fistula repair. All of the ductal dependent neonates survived to operation [51].

Managing these cases can be difficult in the setting of postnatal changes in PVR coupled with one lung ventilation that can be required for tracheoesophageal fistula repair, making the balancing of $Q_p : Q_s$ challenging. Arterial blood pressure monitoring, pre- and postductal oxygen saturation monitoring, frequent blood gas assessment, and cerebral and somatic NIRS monitoring are helpful in this scenario.

Shunt-dependent single-ventricle patients

These patients have a systemic-to-pulmonary arterial shunt that creates a volume burden on their single ventricle from the parallel pulmonary and systemic circulations. They have a reduced oxygen-carrying capacity, and their normal oxygen saturation is 75–85%. They also have reduced diastolic pressure from the run-off of blood into the low-resistance pulmonary circulation through the systemic arterial to pulmonary artery shunt. Instead of a systemic-to-pulmonary artery shunt, many shunted single-ventricle infants will have a right (systemic) ventricle-to-pulmonary artery shunt (Sano shunt). Although theoretically more stable because diastolic blood pressure is usually higher, similar pathophysiological considerations apply, and there are insufficient data reporting outcomes of noncardiac procedures to determine that this shunt lowers the risk of anesthesia. The approach should be the same for all shunted single-ventricle infants before the bidirectional cavopulmonary connection.

This physiologic combination leaves patients particularly vulnerable to hemodynamic insults, and a mild reduction in blood pressure may produce myocardial ischemia. Up to 16% of patients with HLHS who survive the Norwood procedure and are discharged home die prior to their second stage of palliation, which is a reflection of their fragile circulation [52]. These patients frequently have feeding difficulties, and a number of them will undergo gastrostomy tube placement. Slater et al. described good outcomes among 12 patients with HLHS (9 after stage 1 reconstruction, three after stage 2) [53]. At our institutions, even minor noncardiac procedures on shunted single-ventricle patients are performed in the cardiac ORs, and the patients are admitted to the cardiovascular ICU for postoperative care and monitoring.

The hemodynamic condition is optimized by avoiding myocardial depressants and vasodilators. Diastolic hypotension may develop from the use of high inspired oxygen concentration or hyperventilation due to a reduction in PVR. The anesthesiologist should attempt to maintain the oxygen saturation near the patient's baseline. This is accomplished

primarily through the adjustment of minute ventilation. The inspired oxygen concentration is usually maintained close to room air. In addition, hematocrit should be maintained at approximately 45% to maximize oxygen-carrying capacity.

Palliated single-ventricle patients with atrioventricular valve regurgitation

After the second and third stages of single-ventricle palliation (Glenn and Fontan), the vast majority of patients have good cardiac reserve. The volume burden on the ventricle is greatly reduced during the second stage of palliation, and despite remaining cyanotic, myocardial performance improves. Trivial to mild AV valve regurgitation is observed by echocardiography in essentially all single-ventricle patients. However, patients with moderate to severe AV valve regurgitation commonly have a dilated valve annulus and reduced cardiac output. AV valve regurgitation reduces the forward flow of blood and causes the heart to dilate. In this situation, the hemodynamic status is optimized by reducing afterload and maintaining a normal or slightly increased heart rate. Typically, the myocardial depressant effects of even low doses of inhalation anesthetics are poorly tolerated.

Pulmonary hypertension with systemic or supra-systemic PA pressure

This condition is a well-recognized risk factor for perioperative morbidity and mortality. Recent publications report a significantly higher incidence of intraoperative cardiac arrest and death among patients with supra-systemic PA pressures. In a report of 101,500 pediatric anesthetics, of the 10 patients at the Royal Children's Hospital in Melbourne whose death was related to anesthetic management, 50% had pulmonary hypertension [6, 54]. Pulmonary hypertensive crisis is defined by a sudden increase in PVR that results in the PA pressure exceeding mean arterial pressure. This will compromise systemic cardiac output because reduced right ventricular output decreases left heart filling, and RV dilation shifts the interventricular septum leftward, which further impedes LV filling and ejection. Lower blood pressure with increased myocardial oxygen demands leads to right ventricular ischemia. Cardiac arrest rapidly follows [55] (see Figure 35.4).

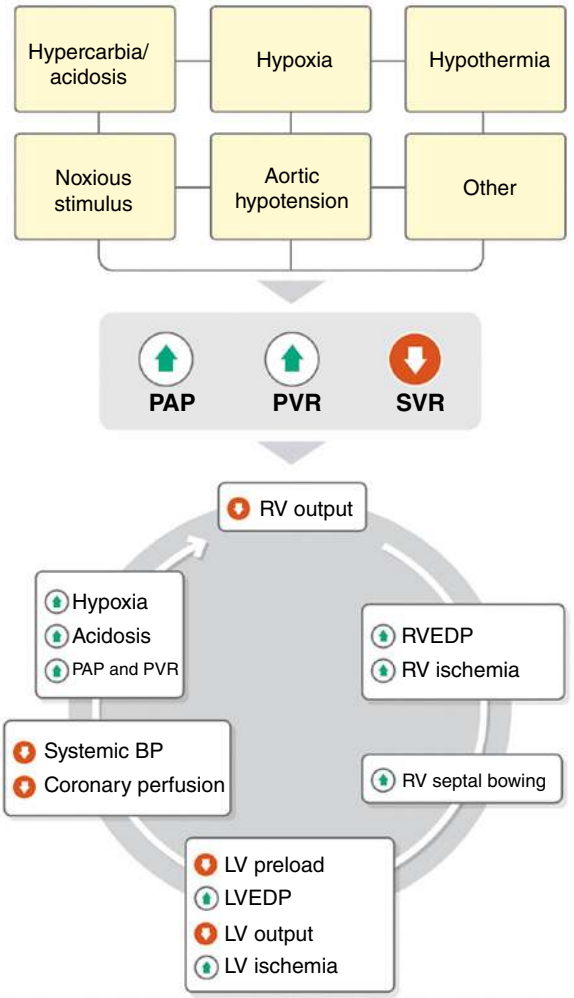

Figure 35.4 The cycle of pulmonary hypertensive crisis. Examples of "other": hypovolemia, anesthesia-induced myocardial suppression, arrhythmias, pneumothorax, pulmonary embolism, sepsis, pericardial effusion, bronchospasm, anaphylaxis, ventilation-perfusion mismatch. BP, blood pressure; LV, left ventricle; LVEDP, left ventricular end diastolic pressure; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance; RV, right ventricle; RVEDP, right ventricular end diastolic pressure; SVR, systemic vascular resistance. (Source: Latham and Yung [55]. Reproduced with permission of John Wiley & Sons.)

First-line treatment includes increasing the inspired oxygen concentration to 100%, reducing $PaCO_2$, increasing the pH (alkalinization), and initiating inhaled nitric oxide. Hypotension should be treated with phenylephrine or vasopressin to increase coronary perfusion pressure. Epinephrine may also be given to improve cardiac output. Overly aggressive manual ventilation should be avoided because the increase in intrathoracic pressure may reduce venous return, therefore further compromising cardiac filling. The pulmonary vasculature is responsive to changes in pH, and alkalinization with sodium bicarbonate or tromethamine (THAM) can be effective in reducing pulmonary pressures. Some authorities recommend prophylactic preanesthetic administration of inhaled nitric oxide for high-risk patients with pulmonary hypertension [55, 56].

With the widespread use of inhaled pulmonary vasodilators, the use of inhaled iloprost or epoprostenol in the OR as rescue agents has become possible. In order to use either of these medications, a nebulizer can be placed in the anesthesia circuit. When caring for a patient with systemic or suprasystemic PH, the need for this type of rescue should be anticipated and the equipment and drug ordered. Iloprost can be dosed intermittently and carries a risk of bronchospasm [57], while epoprostenol requires continuous delivery and may cause clogging of the circuit filter due to accumulation of the glycine diluent.

It should also be recognized that the perioperative risk of these patients extends into the post-anesthesia recovery period. These patients must be closely monitored, and conditions that increase PVR should be avoided, including hypoxemia, hypercarbia, pain, agitation, and acidosis [56]. Chau et al. provide an excellent discussion of the

AL Grawany

postoperative issues of this high-risk population and a strategy for mitigating the risk postoperatively [58]. See Chapter 33 for a complete discussion of pulmonary hypertension.

Severe aortic stenosis (peak gradient >60 mmHg)

The pressure burden from aortic stenosis causes the ventricle to hypertrophy, but not dilate. Therefore, ventricular function is generally well maintained even with a significant degree of stenosis. These children usually have normal exercise tolerance and appear normal to their families. However, the hypertrophied ventricle is at risk for developing ischemia if the patient becomes hypotensive. If the diastolic blood pressure decreases, as it commonly does during a routine inhaled induction, the ventricle may become ischemic. Bradycardia and/or ST-segment changes may be evident on the ECG. If myocardial ischemia progresses to cardiac arrest, closed cardiac compressions are generally ineffective because of the aortic valve stenosis. As these patients may be sensitive to hypotension, an α-agonist such as phenylephrine must be immediately available and used early if diastolic blood pressure decreases or myocardial ischemia is suspected from a change in the ECG.

Care should be taken to avoid hypotension on induction of anesthesia for these patients. Hypovolemia can lead to an exaggerated decrease in blood pressure with induction. Thus, excessive fasting times should be avoided. Clear liquids should be given up until 1–2 hours prior to the procedure. Intravenous fluids may be started the night before or upon arrival to the day surgery unit to maintain euvolemia. A careful intravenous induction may be preferred for these patients. Medications can be titrated gradually to avoid a decrease in blood pressure, and α-agonists can be administered during induction as needed. Monitoring with an arterial catheter placed prior to induction or soon thereafter may be helpful. Chapter 27 presents a thorough discussion of this lesion and other forms of LVOTO (Williams syndrome, hypertrophic cardiomyopathy; see the following sections).

Williams syndrome

Williams syndrome is cause by a deletion on Chromosome 7q11.3 that codes for the elastin gene and has both cardiac and noncardiac manifestations (see Chapter 8). The most common cardiac manifestations included supravalavar aortic stenosis, pulmonary artery stenosis, and coronary artery abnormalities [59]. In 1996, Bird and colleagues reported a series of ten cases of sudden death in patients with Williams syndrome, many of which were associated with an anesthetics or where the patient had had an intraoperative cardiac event previously [60]. And so began the awareness of the risk associated with anesthesia, the path to understanding, and the push for risk stratification and mitigation in this group of patients.

In 2006, Burch et al. improved the understanding of the anatomic and physiologic basis for sudden death under anesthesia, which is the imbalance between myocardial oxygen supply and demand. In short, myocardial oxygen supply can be decreased due to the loss of diastolic elastic recoil in the aorta which decreases the coronary perfusion pressure during diastole, dysfunctional adherence of the aortic valve leaflets to the sinotubular ridge leading to decrease blood flow in the sinuses of Valsalva, and ostial narrowing of the coronary arteries themselves. Decreases in systemic vascular resistance related to anesthetic agents or relative hypovolemia add to decreased myocardial oxygen supply. Myocardiac oxygen demand is increased by ventricular hypertrophy and increased end-diastolic pressure in one or both ventricles. Tachycardia related to stress, laryngoscopy, or a light plane of anesthesia can also increase myocardial oxygen demand. These patients can also be difficult to impossible to resuscitate [61].

Several publications of institutional experiences have helped to define the incidence of cardiac morbidity or cardiac arrest associated with anesthesia and the patient factors that increase risk. Olsen et al. reviewed 108 anesthetics in 29 patients over a span of 35 years, from 1974 until 2009. The incidence of a cardiac complication including bradycardia, hypotension, hypertension, arrhythmia, ECG changes or cardiac arrest was 11.1%, and the risk of cardiac arrest was 1.85%. Severe outflow tract obstruction, abnormal coronary perfusion, and younger age appeared to be associated with a higher risk of cardiac morbidity or arrest [62]. Latham et al. reviewed the records of 48 patients with elastin arteriopathy (both Williams and nonsyndromic) who underwent 141 anesthetics between 1990 and 2013. Seven patients experienced a cardiac arrest (15% of patients, 5% of anesthetics) and there were nine cardiovascular complications (15% of patients, 6% of anesthetics). Extracorporeal support was required in five cases. The highest risk of cardiac arrest was in children less than 3 years old and with bilateral ventricular outflow tract obstruction (BVOTO) [63]. Last, Brown et al. reviewed the records of 75 patients undergoing 202 anesthetics (both cardiac and noncardiac procedures) from 2012 to 2016. Of the noncardiac procedures, there were no cardiac arrests and 95.7% did not have an adverse cardiovascular event. Of the cardiac procedures, there were two cardiac arrests, one requiring extracorporeal support. There were no cardiovascular adverse events in 85.7% of these cases [64].

Risk assessment in patients with Williams syndrome is challenging. There are certainly factors that place a patient in a higher risk category; however, cardiac arrest can occur even in the absence of risk factors [65]. A risk stratification strategy developed by Matisoff et al. and modified by Collins et al. is presented in Table 35.6 [65, 66]. Of note, evaluation of the ECG for a prolonged corrected QT interval is part of the stratification process. A prolonged QTc is seen in 13% of patients with Williams syndrome and may be related to microischemia from BVOTO or to ventricular ectopy and the risk of sudden death from arrhythmia.

Recommendations for perioperative care of patients with Williams syndrome can be found in Table 35.7 [66]. Of note, for all risk categories (including low risk), the induction should take place in a location that is appropriate for a resuscitation. Vasoactive medications and a defibrillator with appropriately sized pads should be immediately available. Patients with Williams syndrome should be cared for at hospitals with pediatric anesthesiologists, pediatric cardiac anesthesiologists, cardiologists, cardiac surgeons, pediatric cardiac intensivists, and ECMO capability. These patients are

Table 35.6 Risk stratification for anesthetic administration in patients with Williams syndrome

Low risk	Moderate risk	High risk
Age >20 years	Hypertension	Age <3 years
No cardiac involvement greater than mild supravalvar or branch pulmonary artery stenosis	Moderate supravalvar or branch pulmonary artery stenosis	History of adverse cardiovascular event
Normal ECG	Mild bilateral outflow tract obstruction	Preprocedural arrhythmia
No renal artery involvement	Renal artery stenosis	Bilateral outflow tract obstruction of ≥moderate severity
	Renal dysfunction	SVAS gradient of ≥40 mmHg and the presence of left ventricular hypertrophy
	QTc on ECG >450 ms but <500 ms	Coronary artery involvement
	Airway abnormalities, lung disease, or severe gastroesophageal reflux	Diffuse stenosis of the thoracic aorta
		≥Moderate left or right ventricular hypertrophy Symptoms or ECG signs of ischemia
		QTc on ECG ≥500 ms

ECG, electrocardiogram; ms, milliseconds; QTc, corrected QT interval on ECG.

not good candidates for outpatient surgery center or office anesthesia or sedation [65, 66].

Preoperative evaluation should include a cardiologist evaluation within one month of the planned procedure [59, 65]. Patients with Williams syndrome can experience rapid changes in the cardiovascular manifestations of the syndrome. In addition, it should be recognized that an unremarkable previous anesthetic does not guarantee an uneventful future anesthetic. The ECG should be reviewed carefully for signs of ischemia, arrhythmia, and prolonged corrected QT interval. Time without fluids should be minimized. Scheduling the patient for the first case of the day helps to avoid lengthened fasting time due to delays. An intravenous catheter can be placed for hydration, as well, and high-risk patients may be admitted preoperatively for intravenous hydration. Postoperative disposition should be determined preoperatively, and a monitored bed should be secured [59, 65, 66]. Williams Syndrome patients with significant SVAS and coronary involvement should be considered for cardiac surgical intervention first, before any noncardiac procedures, whenever possible.

The hemodynamic goals for the anesthetic include the maintenance of preload and systemic vascular resistance and the avoidance of tachycardia and increased PVR. This can be accomplished with various anesthetic agents, and treatment of hypotension should be swift, usually with phenylephrine or vasopressin. The monitoring of frequent noninvasive (or invasive) blood pressures and a five lead ECG for signs of ischemia are critical. Most impending cardiovascular catastrophes in these patients involve ST segment changes, hypotension, and bradycardia.

Many parents of children with Williams syndrome are aware of the risk of cardiac arrest associated with anesthesia. The anesthetic consent process should involve a discussion of this risk and the preparations that are taking place to mitigate the risk.

Adults with Williams syndrome should be evaluated closely as well. Adults with mild disease are usually not at an increased risk. However, adults who have undergone intervention for severe disease earlier in life may need reoperation and should be evaluated for recurrence of obstruction prior to being anesthetized. Electrocardiographic evidence of ventricular hypertrophy should be investigated. Diabetes mellitus, obesity, and accelerated atherosclerosis are also common comorbidities in patients with Williams syndrome and should be noted during preoperative evaluation [67, 68].

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy (HCM) makes up 25% of cardiomyopathies in children, and it is the most common cause of sudden cardiac death (SCD) in children. HCM is most commonly due to mutations in the genes encoding the myosin-binding protein C and the beta-myosin heavy chains. Other etiologies include syndromes (Noonan, Costello, and others) [69, 70].

Preoperative evaluation of the echocardiogram should focus on the degree of hypertrophy and the two-dimensional left ventricular mass (2DLVmass) index. Increased 2DLV mass index can help to risk stratify patients with HCM for perioperative events [70]. Other pertinent echocardiography findings may include LVOTO and evidence of diastolic dysfunction due to the increased ventricular wall thickness. A significant decrease in LV mass over time may represent the progression of the cardiomyopathy into end stage heart disease characterized by systolic dysfunction [71]. The patient's risk factors for SCD should also be noted. SCD incidence peaks in the 8- to 16-year-old age range, and many patients have an implantable cardiac defibrillator in place. Myocardial bridging in which heart muscle surrounds a coronary artery has an incidence of 28% in pediatric patients with HCM undergoing cardiac catheterization. This anatomic condition may also predispose to ischemia [72].

It is important to recognize that the lack of LVOTO on an echocardiogram at rest does not mean that LVOTO will not occur perioperatively. In addition, patients with major risk factors for SCD may also represent patients with increased risk of perioperative morbidity (Table 35.8) [73]. Asymptomatic patients may become symptomatic in the perioperative period.

The perioperative management of HCM-associated LVOTO, diastolic dysfunction, potential ischemia, and dysrhythmias represent challenges to the care team. Increases

AL Grawany

Table 35.7 Anesthetic management of (a) low-risk, (b) moderate-risk, and (c) high-risk patients with WS

Preanesthesia planning	Induction and maintenance of anesthesia	Anesthesia emergence and disposition
(a)		
Schedule preanesthesia visit 1–2 weeks prior to planned surgery focusing on airway, development, cardiac, gastrointestinal, renal disease	Minimize npo (nothing by mouth) time and liberalize preoperative oral fluids	Monitor for emergence tachycardia and ECG changes
Continue beta-blockers on day of anesthesia	May need oral premedication prior to induction with midazolam, pentobarbital, ketamine	Aggressively manage postoperative pain and shivering to reduce oxygen consumption
Induce anesthesia in an area suitable for resuscitation (operating room, catheterization lab, ICU)	Use full ASA monitors, including 5-lead ECG	Monitor after anesthesia for at least 2 hours
Have resuscitation drugs, including vasopressors, immediately available	Use slow, titrated mask induction or IV induction with ketamine, etomidate, narcotics, or small doses of propofol Employ balanced anesthetic with drugs that reduce myocardial oxygen consumption and minimize reductions in SVR Treat ST changes with vasopressors	
(b)		
Consider transfer to center with pediatric cardiology and pediatric anesthesia for all nonurgent anesthesia	Minimize npo time and liberalize preoperative oral fluids	Monitor for emergence tachycardia and ECG changes
Schedule preanesthesia visit 1–2 weeks prior to planned surgery, focusing on airway, development, cardiac, gastrointestinal, renal disease	May need oral premedication prior to induction with midazolam, pentobarbital, ketamine	Aggressively manage postoperative pain and shivering to reduce oxygen consumption
Continue beta-blockers on day of anesthesia	Use full ASA monitors, including 5-lead ECG	Recover in high-acuity setting with capability for resuscitation
Induce anesthesia in an area suitable for resuscitation (operating room, catheterization lab, ICU)	Use slow, titrated mask induction or IV induction with ketamine, etomidate, narcotics, or small doses of propofol	Monitor after anesthesia for at least 6 hours, and preferably overnight, prior to discharge
Have resuscitation drugs, including vasopressors, immediately available	Employ balanced anesthetic with drugs that reduce myocardial oxygen consumption and minimize reductions in SVR Treat ST changes with vasopressors	
(c)		
Pediatric or cardiac anesthesia team involved in care should have experience in managing patients with WS	Place IV for prehydration	Monitor for emergence tachycardia and ECG changes
Transfer to facility with ECMO availability	May need oral premedication prior to IV placement, with small doses of midazolam, ketamine, or pentobarbital	Aggressively manage postoperative pain and shivering to reduce oxygen consumption
Continue beta-blockers on day of anesthesia	Use full ASA monitors, including 5-lead ECG	Recover in high-acuity setting with capability for resuscitation and ECMO deployment
Induce anesthesia in an area suitable for resuscitation (operating room, catheterization lab, ICU)	Induce via IV with etomidate, fentanyl, ketamine	Monitor after anesthesia for at least 6 hours, and preferably overnight, prior to discharge
Ensure that ECMO team is aware and clear-primed ECMO circuit is nearby	Employ balanced anesthetic with drugs that reduce myocardial oxygen consumption and minimize reductions in SVR	
Have resuscitation drugs, including vasopressors, immediately available	Consider direct monitoring of myocardial contractility with echocardiogram in more complicated or prolonged cases Treat ST changes with vasopressors Monitor status of resuscitation with echocardiogram to evaluate contractility Deploy ECMO early if standard resuscitation measures are unsuccessful

PVR, pulmonary vascular resistance; NYHA, New York Heart Association.

in LVOTO can be minimized by maintaining preload and systemic vascular resistance and by avoiding increases in heart rate and contractility. Hypotension should be treated with vasoconstrictors like phenylephrine or vasopressin, rather than ephedrine or other inotropes that increase contractility and heart rate. Hypertrophy-related diastolic dysfunction confounds intravascular volume management and favors a slower heart rate and sinus rhythm. Hypervolemia may result in pulmonary edema and should be avoided. A slower heart rate and the atrial contraction in sinus rhythm facilitate improved filling and coronary perfusion. The risk of ischemia is increased due to LVOTO, the increased myocardial oxygen demand of a hypertrophied ventricle, and a myocardial oxygen supply that changes with heart rate and thus time spent in diastole, as well as the potential for myocardial bridging. Arrhythmias including bradycardia, atrial fibrillation or supraventricular tachycardia, or ventricular tachycardia or fibrillation should be anticipated. The ECG should be monitored closely, and tachyarrhythmias should be managed expeditiously by medication administration or cardioversion, as indicated. Patients with HCM are difficult to resuscitate in the event of a cardiac arrest and early defibrillation is critical. [70, 71, 74].

Transplant coronary artery disease

The incidence of transplant coronary artery disease (TCAD) (also known as coronary allograft vasculopathy) in pediatric patients is 17% at 5 years after cardiac transplantation, and 24% of patients with any degree of TCAD died within 2 years in a recent report. A multi-institutional study found that the major risk factors for TCAD were older recipient age and donor >30 years of age [75]. Patients who have experienced recurrent rejection, new onset arrhythmias, unexplained recurrent chest or abdominal pain, and/or the development of systolic or diastolic dysfunction should may have TCAD [76]. Symptoms of TCAD are often atypical due to the denervation of the transplanted organ. However, the symptom complex of abdominal, chest, and/or arm pain should raise suspicion [77]. These patients should have routine cardiac catheterization with coronary angiography. Hemodynamic assessment is useful as patients with higher right ventricular end diastolic pressure and capillary wedge pressure have an increased risk of TCAD [76]. The anesthesiologist should consider all heart transplant patients to be at risk, even patients who have had normal coronary angiography in the past. This risk increases with greater time after transplant. Excessive decreases in coronary perfusion pressure should be avoided, the ECG should be carefully monitored for signs of ischemia, and hypotension should be treated early with α-agonists. See Chapter 32 for further discussion of this entity.

Eisenmenger syndrome

Eisenmenger syndrome is fortunately rarely seen in this era. In our institutions, most children who have developed Eisenmenger syndrome have recently emigrated from a country where indigent patients do not have access to pediatric cardiovascular surgery. Like pulmonary hypertension, these patients have a reactive pulmonary vasculature and should be managed similarly.

Eisenmenger syndrome is a complication of uncorrected intracardiac shunt or shunts leading to irreversible pulmonary hypertension and shunt reversal. This leads to cyanosis and polycythemia over time. Due to the right-to-left pop-off through the intracardiac shunt, cardiac output can be preserved. Fortunately, Eisenmenger syndrome has become less common due to the early repair of shunt lesions and the now routine repair of cardiac lesions in patients with trisomy 21 and other syndromes. Chronic treatment with medications such as phosphodiesterase-5 inhibitors, endothelin receptor antagonists, and prostanoids leads to increased survival in this group of patients, and these patients will need noncardiac procedures during their lives [78].

The perioperative risk of mortality in patients with Eisenmenger syndrome undergoing noncardiac surgery has been reported to be as high as 20–30% [79, 80]. Indicators of increased mortality and common comorbidities are found in Table 35.9 [81]. However, modern data suggest that this fragile patient population is most safely cared for with proper planning and consultation and adherence to hemodynamic goals. Bennett et al. report their institutional experience in caring for

AL Grawany

33 patients with Eisenmenger syndrome/physiology undergoing 53 procedures. The most common adverse event was hypotension (44%). Two patients in the series expired within 30 days of an anesthetic, yielding a mortality risk of 3.8%. Avoidance of hypotension using vasopressors such as phenylephrine and vasopressin is critical, and the authors recommend the administration of a vasopressor prior to or during induction of anesthesia [81]. Prevention and treatment of increases in PVR are also very important. Hypoxia, hypercarbia, acidosis, light anesthesia, pain and agitation all contribute to increases in PVR. These should be avoided if possible, and maneuvers including hyperventilation, increased oxygen administration, and increased depth of anesthesia should be considered. Medications to decrease PVR including inhaled nitric oxide and inhaled or intravenous prostacyclin should be readily available. Postoperative disposition should be planned preoperatively, as the risk of morbidity and mortality continues in the postoperative period [78, 81].

Adult congenital heart disease

The number of adults living with CHD are increasing in Western countries due to advancements in care (see Chapter 20). The number of adult patients with CHD presenting for noncardiac surgery is also increasing. These patients may be unrepaired, repaired, or palliated. Patients may have residual and acquired cardiac disease, and they may have comorbid conditions associated with CHD such as arrhythmia, renal impairment, pulmonary insufficiency, liver dysfunction, coagulopathy, and cognitive disability. They may also have cardiac and noncardiac comorbidities associated with aging including diabetes, coronary artery disease, chronic obstructive pulmonary disease, and obesity [82].

There is a spectrum of disease and follow up for adults with CHD. Many adult patients with CHD consider themselves healthy after repair of their CHD. Low-risk lesions that are repaired early in life, including patent ductus arteriosus (closed before age 2), isolated ASD (corrected before age 12), and isolated VSD (closed before age 2, without residual shunt), may be considered "cured" [23, 24]. These patients may not be followed for their CHD. These may seek care in the community. Most other patients have residual issues linked to their CHD. These patients are followed by ACHD specialists and should be cared for at ACHD centers [24]. Patients with ACHD are usually either followed specialized ACHD centers which are either pediatric hospitals where practitioners are familiar with CHD or adult hospitals with CHD support. Patients with ACHD treated at specialized ACHD centers have been shown to have better outcomes than those who are not [83]. In addition, the impact and severity of ACHD may be minimized at non-ACHD centers due to a lack of familiarity with rare diagnoses, long interval from original cardiac interventions, and an impression that the CHD is "fixed" and no longer an issue [4].

Patients with ACHD have been shown to be at increased risk of perioperative morbidity and mortality when undergoing noncardiac surgery [4, 84]. An increased risk of death was found to be associated with the presence of a VSD, trisomy 21, and pulmonary hypertension [84]. Data from the Closed Claims Database of adults with CHD undergoing noncardiac surgery indicate that the most common factors contributing to adverse events were preoperative assessment and optimizations (40%), CHD (50%), and postoperative monitoring and care. In fact, up to 48% of the adverse outcomes could be attributed to lack of knowledge about CHD [85].

Risk assessment for these patients is complicated, but some guidance exists. The Mossad Risk Assessment Tool is a point system of preprocedural risk stratification of patients with ACHD (Table 35.10) [82]. Patients in the minimal perianesthetic risk group can usually be cared for in an outpatient setting. Patients in the moderate perianesthetic risk category would likely benefit from postprocedural admission and transfer to a specialized ACHD center should be considered. Patients in the high perianesthetic risk category should be admitted to an ICU and be cared for at a specialized ACHD center [23, 24, 82].

Preoperative evaluation should include a detailed investigation into the cardiac diagnosis, all cardiac surgeries and

Table 35.10 Mossad risk stratification uses a point system to assess adult congenital heart disease

	0	1	2
CHD diagnosis	Simple (ASD)	Moderate (ASD + PS)	Severe (ToF)
CHD intervention	Corrected, No residual	Corrected with residual	Palliated
Ventricular obstruction	None	Yes, gradient <49 mmHg	Yes, gradient >50 mmHg
Ventricle, number, and position	2 LV is systemic ventricle	1 LV is systemic ventricle	1 RV is systemic ventricle
Dysfunction systemic ventricle	Mild	Moderate	Severe
PVR	Normal, <2 wood Units	2–4 wood units	>4 wood units
SaO_2	>90%	75–90%	<75%
Hct	30–45%	25–30% or 45–65%	>65%
Arrhythmias	Seldom	Atrial level	Ventricular level
Number of cardiac medications	1	2	≥3

Note: Points are added for each line, following which risk is assessed based on the total number of points, as follows: 0–6 points: minimal peri-anesthesia risk (outpatient); 6–13 points: moderate peri-anesthesia risk (possible same day admission); 14–20 points: high peri-anesthesia risk (possible ICU admission). Modified from Mossad E, presented during the Society of Cardiothoracic Surgeons Annual Meeting in 2002.

ACHD, adult congenital heart disease; ASD, atrial septal defect; ICU, intensive care unit; LV, left ventricle; PS, pulmonary stenosis; PVR, pulmonary vascular resistance; RV, right ventricle; S_aO_2, systemic oxygen saturation; ToF, tetralogy of Fallot.

catheterizations, ECG or Holter, and recent imaging (cardiac MRI, CT angiogram, echocardiogram). The patient should be questioned regarding exercise tolerance, palpitations, dizziness or syncope, chest pain, orthopnea, or cyanotic spells [23]. For patients in the high perianesthetic risk category according to the Mossad Risk Assessment Tool, a cardiac catherization prior to the noncardiac procedure may be useful for quantifying $Q_p : Q_s$, evaluating the degree of pulmonary hypertension and reactivity, assessing gradients across valves, performing electrophysiology testing and ablation, and possibly ballooning valvular stenoses or placing percutaneous valves to improve the patient's risk profile [24]. In addition, exercise or pharmacologic stress testing should be considered, as well as coronary angiography or CT coronary angiography, as patients with ACHD may have an anomalous coronary, a coronary artery that has been reimplanted as part of a repair/palliation, and/or acquired atherosclerotic coronary artery disease [86].

The 2018 ACC/AHA Guideline for the Management of Adults with Congenital Heart Disease provides a useful recommended checklist for patients with ACHD preparing for noncardiac surgery (Table 35.11) [87].

It is critical for anesthesiologists to be part of the multidisciplinary team that is planning and coordinating care for patients with ACHD with special consideration of SBE prophylaxis, management of anticoagulation, preoperative management, invasive monitoring and postoperative disposition [88]. It is recommended that the multidisciplinary team meet with the patient in advance. Many patients have significant anxiety related to medical procedures and addressing the perioperative issues and plan well before the procedure can help the patient and the care team [23]. Advanced directives should also be considered and clarified. Intentional multidisciplinary decision-making and planning is critical for the optimization of care for this group of patients that is high risk for perioperative morbidity and mortality.

Table 35.11 ACHD management issues for noncardiac surgery

Clarify CHD diagnosis
- Clarify prior procedures, residua, sequelae, and current status, including ACHD AP classification
- Be aware that history obtained from only the patient and family may be faulty or incomplete
- Obtain and review old records to ensure accurate understanding of past procedures and clinical course
- Complete additional investigations required to define ACHD AP classification
- Develop management strategies to minimize risk and optimize outcome

Factors associated with Increased risk of perioperative morbidity and mortality

(S3.12-12):
- Cyanosis
- Congestive HF
- Poor general health
- Younger age
- Pulmonary hypertension
- Operations on the respiratory and nervous systems
- Complex CHD
- Urgent/emergency procedures

Issues to consider
- Endocarditis prophylaxis
- Complications related to underlying hemodynamics
- Abnormal venous and/or arterial anatomy affecting venous and arterial access
- Persistent shunts
- Valvular disease
- Arrhythmias, including bradyarrhythmias
- Erythrocytosis
- Pulmonary vascular disease
- Meticulous line care (also consider air filters for intravenous lines) to reduce risk of paradoxic embolus in patients who are cyanotic because of right-to-left shunts
- Adjustment of anticoagulant volume in tubes for some blood work in cyanotic patients
- Prevention of venous thrombosis
- Monitoring of renal and liver function
- Periprocedure anticoagulation
- Possible need for nonconventional drug dosing
- Increased prevalence of hepatitis C infection because of prior procedures and remote blood transfusions
- Developmental disability

Source: Stout et al. [87]. Reproduced with permission of Wolters Kluwer Health Inc.

ACHD indicates adult congenital heart disease; AP, anatomic and physiological; CHD, congenital heart disease; HF, heart failure.

KEY POINTS: HIGH-RISK PATIENT GROUPS

- Patients with pulmonary hypertension are at an increased risk of morbidity and mortality intraoperatively; it must be recognized that this risk extends into the postoperative period.
- Patients with Williams syndrome may have coronary artery abnormalities in the absence of significant supravalvular aortic stenosis that put them at increased risk for myocardial ischemia.
- The ECG should be monitored closely for signs of ischemia in high-risk patients; ST changes should be promptly addressed.

Intraoperative care

Monitoring

Standard American Society of Anesthesiologists (ASA) monitors provide adequate monitoring for the vast majority of children undergoing less invasive surgical or diagnostic procedures. When caring for healthy children who may be fearful of placing the ECG pads and NIBP cuff, it is common practice to apply these monitors after the initiation of an inhalation induction. Children with CHD should have baseline vital signs before induction, and increasing the frequency of NIBP determination from the default of once every 3 minutes should be considered. High-risk patients, such as those described in the previous section, or patients undergoing major orthopedic, intra-abdominal, or intrathoracic procedures are best managed with invasive arterial monitoring and/or central venous

AL Grawany

monitoring. Invasive arterial monitoring will assist in the early recognition of hypo- or hypertension, and arterial blood gas monitoring allows easy determination of acid–base status, electrolytes, and hemoglobin. There are many cardiac lesions that are sensitive to a reduction in preload, yet these same patients may manifest a reduction in pulmonary compliance with volume overload. In this situation, central venous monitoring is very useful and provides good vascular access for the delivery of vasoactive medications.

There are a number of newer monitors designed to measure cardiac output noninvasively. Some of these monitors have been validated against thermodilution or echocardiographic measurements of cardiac output. However, none of these new monitors have been shown to provide an early warning of a low cardiac output state that improves recognition and outcome. Near-infrared spectroscopy (NIRS) has been most widely studied. This monitor measures oxygen saturation of tissue approximately 2–4 cm beneath the probe. It was originally designed to determine cerebral oxygen saturation in the frontal cortex when the probe is applied to the forehead. It provides a noninvasive assessment of the regional oxygen supply–demand balance to the tissues over which the probe is applied (brain, kidney, gut). It is affected by tissue blood flow, arterial oxygen saturation, hemoglobin saturation, and the ratio of arterial to venous blood flow. These factors should be considered when interpreting changes in tissue oxygen saturation. As a continuous monitor, it has been shown to identify global hypoperfusion produced by a reduction in cardiac output due to a reduction in mixed venous oxygen saturation [89]. The monitor has been used to detect splanchnic ischemia in premature infants [90]. NIRS monitoring has also been shown to provide an early indication of reduced cardiac output after cardiac surgery [91]. It may therefore be a useful addition to routine noninvasive monitors for the child with CHD who has a greater risk of hemodynamic compromise, by providing an early warning and enabling a rapid response. However, no studies have determined the monitor's utility and ability to improve outcomes in the setting of noncardiac surgery. See Chapter 13 for a further discussion of monitoring techniques.

Anesthetic technique

The choice of anesthetic technique depends on the anticipated duration and the hemodynamic consequences of the planned surgery, the hemodynamic consequences of the patient's cardiac anatomy, and the patient's cardiac reserve. In general, patients with CHD are not tolerant of the myocardial depressant effects of higher concentrations of inhalational agents. Opioids are used to reduce the requirement of inhalational agent. See Chapter 6 for a discussion of the hemodynamic effects of anesthetic agents, and Chapter 21 for a discussion of hemodynamic management.

Regional anesthesia is not contraindicated unless the patient is taking anticoagulant medication, and regional anesthesia will allow a reduction in volatile agent requirement without the side-effects of opioid medications. Most patients have improved cardiac output from the sympathectomy that develops from central neuraxial blocks; the exceptions are the patient with aortic or mitral stenosis and those with obstructive cardiomyopathy.

Surgery

Many less invasive surgical procedures can be performed on an outpatient basis, even for ASA 3 and 4 patients. However, all high-risk patients should undergo surgery in a location where appropriate rescue can be performed. Even though complications are rare, the incidence of cardiac arrest or death is significantly greater among patients with CHD, and most surgical centers do not have appropriate rescue capability for these patients. Special consideration should be made for the high-risk population outlined earlier, and they should undergo noncardiac surgery in a location where rhythm disturbances are rapidly recognized and treated, resuscitative medications are present, and rescue with ECMO is available. When dealing with patients with systemic or supra-systemic pulmonary hypertension, inhaled nitric oxide should be immediately available to treat acute increases in pulmonary pressure.

Complex surgical situations

Laparoscopic surgery

Laparoscopic surgery has many benefits, including smaller incision, faster return of bowel function, decreased postoperative pain, and shorter hospital stays. This technique requires insufflation of carbon dioxide into the peritoneum. There has been concern that patients with CHD might not tolerate the hemodynamic effects of abdominal insufflation. For example, the pulmonary blood flow of shunted single-ventricle patients is dependent on PVR. The pneumoperitoneum can result in decreased ventilation due to increased intra-abdominal pressure with an associated increase in $PaCO_2$, absorption of carbon dioxide with an associated increase in $PaCO_2$, a decrease in preload and an increase in SVR. It should be noted that end-tidal CO_2 has been shown to be an inaccurate measure of $PaCO_2$ in patients with cyanotic CHD [92]. However, with close monitoring of blood gases and ventilator adjustments, low insufflation pressures of 8–12 mmHg, and blood pressure support, outcomes can be optimized [53, 93]. In must also be remembered that many patients with CHD have right-to-left intracardiac shunts from septal defects or complete intracardiac mixing; a large CO_2 embolus into the systemic arterial circulation (coronary and cerebral) can rapidly cause cardiovascular collapse or neurological injury in these patients.

The patient with a Fontan circulation requires adequate preload and normal PVR to maintain passive pulmonary blood flow. Concerns regarding a decrease in pulmonary blood flow due to the combination of positive pressure ventilation and abdominal insufflation, as well as an increase in PVR due to carbon dioxide absorption, make laparoscopic surgery appear higher risk in these patients. However, there have been several case reports and small case series noting stable hemodynamics with laparoscopic surgery in Fontan patients with good ventricular function, without the need to augment preload or administer vasoactive medication [94, 95]. For short procedures such as laparoscopic appendectomy or cholecystectomy, arterial and CVP monitoring has not been needed. We recommend discussing the potential need to convert to an open procedure with the surgeon, patient, and/or family prior to surgery. In addition,

insufflation should be gradual and the minimum intra-abdominal pressure utilized.

Hemodynamic changes with the release of pneumoperitoneum should also be anticipated. Studies in healthy children have shown that the release of pneumoperitoneum results in a decrease in SVR and blood pressure, and a decrease in preload due to redistribution of blood into the splanchnic bed and liver [96–98]. Groenewald and Latham report a cardiac arrest in a patient with supravalvular aortic stenosis immediately following release of pneumoperitoneum. It is suggested that patients, especially those at risk for myocardial ischemia, be monitored closely during this period, and that the release of intra-abdominal pressure be gradual [99].

Recent larger studies have examined the safety and outcomes of patients with CHD undergoing laparoscopic procedures with varying results. In a single-institution, retrospective review of 121 laparoscopic procedures and 45 open procedures in patients younger than 5 years with CHD, no significant differences were noted in complications or 30-day mortality between laparoscopic and open procedures. Eighty-seven percent of the patients in the laparoscopic group were infants, and single ventricle diagnosis did not affect outcome [100]. A 2016 study by Kim et al. utilized the American College of Surgeons National Surgical Quality Improvement Project Pediatric (ACS NSQIP-P) Database to compare complications, postoperative length of stay, and 30-day mortality in 3,684 patients less than 1 year of age with CHD undergoing either laparoscopic or open abdominal surgery. The laparoscopic group had a lower overall complication rate and a shorter length of stay with similar 30-day mortality [101]. Also using data from the ACS NSQIP-P Database, Chu et al. looked prospectively at 34,543 children aged 0–17 years with no, minor, major, or severe CHD undergoing laparoscopic surgery. They found that patients with minor CHD had similar mortality but increased 30-day morbidity compared to children with no CHD. In addition, patients with major or severe CHD had higher overall mortality and 30-day morbidity compared to children with no CHD. In fact, children with severe CHD were 12 times more likely to die compared with a matched patient without CHD when undergoing a laparoscopic procedure. The majority of deaths were in patients who were less than 12 months of age at the time of operation. A stepwise increase in postoperative reintubation rate was also observed as severity of CHD increased, possibly indicating limited physiologic reserve [102]. In a retrospective cohort study using the same database, matching patients less than 18 years old undergoing laparoscopic or open procedures, the authors found that in patients with minor CHD, laparoscopic surgery was associated with a lower 30-day mortality, in hospital mortality, and 30-day morbidity. The benefits were not as great or nonexistent for patients with major or severe CHD. However, length of stay and odds of transfusion were decreased for those undergoing laparoscopic procedures compared with open [103]. Herrick et al. looked retrospectively 5,527 patients older than 5 years with CHD undergoing laparoscopic or open procedures. The found that all-cause mortality and length of stay was lower for those undergoing laparoscopic procedures. By studying those >5 years old, the higher risk interstage and infant groups did not affect the data. Patients with Fontan physiology, who one might consider vulnerable to the effects of abdominal insufflation, were not found to be at increased risk of mortality when undergoing laparoscopic surgery compared with an open approach [104].

Otolaryngologic procedures

As reported by Sulkowski and Nasr, otolaryngologic procedures (along with general surgery procedures) are the most common noncardiac surgeries performed in pediatric patients with CHD [2, 3]. This may be expected as the incidence of congenital and acquired airway abnormalities in the CHD population is 8.5 and 9.7%, respectively. Risk factors for airway abnormalities include weight <10 kg, prematurity, the presence of a genetic syndrome, and certain CHD diagnoses (interrupted aortic arch, double aortic arch, arch anomaly, pulmonary artery abnormality, tetralogy of Fallot) [105]. The incidence of respiratory events such as bronchospasm, laryngospasm, difficult intubation, failed extubation and reintubation, and arterial desaturation in patients with CHD undergoing noncardiac procedures is 4.7%, and the odds ratio of having a respiratory event during an otolaryngological procedure is 2.65 [106]. Billings et al. reviewed neonatal microdirect laryngoscopies and bronchoscopies (MLB) over the 10-year period from 2002 to 2012. Of the 162 neonates undergoing MLB, 30.2% had a diagnosis of CHD. In this series, 84.3% of procedures were diagnostic and 15.7% were therapeutic. Patients with CHD had an increased incidence of complete rings, tracheal stenosis, bronchomalacia, abnormal bronchial anatomy, and vascular rings. The patients with CHD were also less likely to have tracheostomy and supraglottoplasty procedures and were more likely to require long-term intubation [107].

Anesthesia for microlaryngoscopy and bronchoscopy can be quite challenging in patients with CHD. The procedure is very stimulating itself, requiring significant depth of anesthesia, and the surgeon often prefers that the patient is breathing spontaneously to assess vocal cord mobility and dynamic airway changes and to delay desaturation. A period of hyperoxygenation and hyperventilation before turning the airway over to the otolaryngologist is helpful for delaying hypercarbia and desaturation during the procedure. Positive pressure ventilation can be supported via a jet port incorporated into the surgeon's laryngoscope and then via the bronchoscope. However, intermittent breaks for mask ventilation or ventilation via endotracheal tube may be necessary to improve oxygen saturations and decrease $PaCO_2$. Anesthetic depth can be achieved with various anesthetic agents including volatile anesthetic, propofol, ketamine, and dexmedetomidine. Whatever anesthetic technique is chosen, the anesthesiologist must maintain close communication with the otolaryngologist, and primary and secondary plans for managing the airway should be discussed before the procedure. Even though most otolaryngologists prefer spontaneous ventilation during rigid bronchoscopy, it is typically only required to assess vocal cord mobility. Once that portion of the examination is complete, the patient can potentially receive muscle relaxant and positive pressure ventilation, and the depth of anesthesia can be reduced.

Patients that are challenging to anesthetize for this procedure include shunt dependent patients, patients with cyanotic lesions and/or pulmonary hypertension, and those

AL Grawany

with poor myocardial reserve. These patients may not tolerate wide swings in PVR or the deep levels of anesthesia required for the procedure.

Spinal instrumentation

Children with CHD have a higher incidence of scoliosis than the general population due to congenital vertebral abnormalities, thoracotomies and sternotomies, neuromuscular issues related to a hypoxic event, or a syndrome associated with neuromuscular scoliosis [108]. As survival of patients with CHD, especially those with single ventricle lesions, has improved, it has become increasingly common to attend to noncardiac issues, such as scoliosis, which affect quality of life. In addition, correction of scoliosis and related improvement of cardiorespiratory factors are important for optimizing Fontan physiology and survival [108, 109].

Multiple studies report on the perioperative outcomes of patients with CHD undergoing spinal instrumentation with low mortality [108–115]. Perioperative complications were increased in patients with pulmonary hypertension [113], single ventricle physiology [109], and a large Cobb angle [109]. In a retrospective study of patients with CHD undergoing scoliosis repair, patients with a biventricular circulation had a 16% incidence of a significant perioperative event and a 32.3% incidence of any adverse event, compared with those with a single ventricle circulation with a 25% incidence of a significant perioperative event and a 68.8% incidence of any adverse event [109].

The complications experienced by single ventricle patients are largely related to increased blood loss and fluid shifts. In a retrospective review of 23 patients with single ventricle CHD undergoing scoliosis repair, 52% of the cohort experienced complications, with pleural effusion being the most common (54%) [108]. Blood loss is higher in the single ventricle population due to Fontan physiology which often necessitates a higher baseline CVP to encourage pulmonary blood flow and maintain cardiac output. Other factors such as positive pressure ventilation, hypoxemia, hypercarbia, hypothermia, and acidosis can also necessitate a higher CVP perioperatively. A higher CVP can result in more intraoperative and postoperative bleeding, more volume administration, and complications due to fluid shifts [109].

In order to reduce blood loss, many centers use a combination of control of blood pressure (mean arterial pressure 50–60 mmHg) and normovolemic hemodilution in patients without CHD. In general, these strategies are not encouraged in patients with CHD. Preoperative blood donation for autologous transfusion in this population has also been described [116]. Arterial blood pressure monitoring is standard; however, the use of CVP monitoring and intraoperative transesophageal echocardiography varies. Cerebral and somatic NIRS monitoring may be useful, as well.

Some of the larger retrospective case reviews spanning up to 25 years note that the incidence of adverse perioperative events and the amount of blood loss have decreased in more recent years. Improvements in perioperative care and strategies for mitigating risk include enhanced multidisciplinary discussion and planning, the routine use of antifibrinolytic medications (tranexamic acid), and a better understanding of how to care for this complex and fragile patient population. Przybylski et al. report a change in goal intraoperative mean arterial pressure from 50–60 to 65–75 mmHg over the course of the study [109]. Cohen et al. report a 67% complication rate without the use of tranexamic acid, and a complication rate of 36% with the use of the drug. Estimated blood loss of 69.8 cc/kg without tranexamic acid usage was reported compared with 26.1 cc/kg with tranexamic acid usage. The reduction in blood loss due to tranexamic acid can result in the need for decreased volume expansion and fewer complications due to fluid shifts (e.g., pleural effusions) [108].

Changes in surgical planning and conduct can also reduce blood loss and mitigate risk. The use of preoperative halo traction to improve the Cobb angle can reduce the length of the scoliosis surgery and the associated blood loss. Other strategies include careful attention to intraoperative time management, using two operative surgeons to work faster, and meticulous attention to hemostasis during the exposure [117].

KEY POINTS: INTRAOPERATIVE CARE

- Monitoring, anesthetic technique, and operative venue are dependent on the patient's disease and the procedure performed; hemodynamic instability should be anticipated.
- The hemodynamic effects of the creation and release of pneumoperitoneum should be anticipated; gradual, low-pressure insufflation and gradual release produce the least disturbance.
- Laparoscopic procedures can be safely performed in patients with CHD, provided there is meticulous attention to hemodynamic and ventilatory management by experienced providers.

Radiologic procedures

Magnetic resonance imaging and computed tomography

Anesthetic care is often required for diagnostic imaging of the patient with CHD, as patient immobility is frequently required for an adequate study. Cardiac magnetic resonance (CMR) and CT imaging of patients with CHD can provide valuable information about anatomy and function. MRI studies of the brain are commonly used to evaluate preoperative or postoperative neurologic abnormality or injury. The approach to reducing mobility for these studies varies from no anesthetic or sucrose, to sedation, to general anesthesia with spontaneous ventilation, to a general anesthetic with breath-holding. It is important to discuss requirements of the study with the radiologist and choose an appropriate plan based on the requirements and patient factors. The choice of CMR or CT imaging depends on the information desired, the potential need for general anesthesia, and the patient's perceived anesthetic risk vs. risk of radiation exposure.

Cardiac MRI can provide information regarding extracardiac arteries and veins, assessment of vascular or valvular flow, quantification of shunts, and assessment of myocardial

function. It is the imaging modality of choice for the evaluation of corrected tetralogy of Fallot, aiding in the determination of timing for pulmonary valve replacement by the measurement of right ventricular volumes. It can also be used for pre-Glenn or pre-Fontan evaluation of single-ventricle patients in lieu of cardiac catheterization [118, 119]]. Risks associated with catheterization, including vascular injury and cardiac tamponade, are removed, and patients are not exposed to ionizing radiation. Compared with diagnostic cardiac catheterization, imaging with CMR is associated with a decreased length of hospital stay [120]. CMR is also the imaging modality of choice for complex aortic coarctations that require further arch delineation [118] and for postsurgical evaluation after coarctation repair [121]. However, for coarctations that have been stented, there is often compete loss of signal, and evaluation for stent restenosis is not possible (Figure 35.5) [122]. CMR can also be performed to gather information regarding myocardial perfusion at rest and with stress using adenosine or dobutamine. CMR also has a role in diagnosing cardiomyopathies, even in pre-clinical stages [123].

Although there is associated exposure to ionizing radiation, cardiovascular CT is especially useful in imaging for vascular rings, where it is important to visualize related airway anatomy, pulmonary venous anatomy, or major aortopulmonary collateral arteries (MAPCAS), and in patients with metallic implants or CIEDs [123]. CT can also be used to evaluate coronary artery anomalies. Advances in CT technology and the introduction of second-generation, dual-source, high-pitch scanners have resulted in cardiovascular imaging that is associated with a significant decrease in exposure to ionizing radiation (equivalent to approximately five chest radiographs for most studies), faster scans, and an elimination of the need for breath-holding. For a significant number of patients, this obviates the need for a general anesthetic [124]. See Chapter 18 for a further discussion of the utility of CMR and CT imaging.

Figure 35.5 Magnetic resonance angiography in a patient who had stent placement for coarctation of the aorta. The stent generates a complete signal void (arrow) making it impossible to investigate for any restenosis within the stent. (Source: Sorensen et al. [122]. Reproduced with permission of Elsevier.)

Anesthetic techniques for these imaging studies vary in the depth and degree of airway manipulation. On the least invasive end of the spectrum, a feed and swaddle technique using a natural airway can be used for CT and shorter MR studies in neonates and young infants. Neonates have undergone cardiac CT angiography using a non-sedated, free-breathing, swaddling technique with excellent image quality [124]. Fogel et al. describe the successful CMR evaluation of aortic arch anomalies using this technique in infants less than 6 months of age. The CMR scanning time in this study was 6.2 ± 3.1 minutes [119]. The success of this strategy hinges on the presence of a cardiac imaging specialist in the control room to evaluate the images as each sequence is completed, and expeditious, efficient scanning that focuses on the diagnostic question.

Children are unlikely to stay still for a longer study without deep sedation or general anesthesia. Many centers employ deep sedation or general anesthesia via intravenous medications while maintaining a natural airway and spontaneous respiration. Medications used for this purpose include propofol infusion, dexmedetomidine infusion, and an infusion of a combination of propofol and ketamine. It is important to monitor the ECG, oxygen saturation, blood pressure, and end-tidal CO_2 during the sedation. End-tidal CO_2 can be monitored via a nasal cannula with a CO_2-monitoring port or through a port placed in a face mask.

Airway monitoring during the procedure is important, as airway obstruction can occur with general anesthesia or sedation. Airway compromise leading to increased $PaCO_2$ and/or decreased PaO_2 is poorly tolerated in some patients, especially those with pulmonary hypertension. These types of patients must be carefully monitored for developing hypercarbia and hypoxemia. A general endotracheal anesthetic is another option for longer procedures or when the airway control is crucial. In addition, it is possible to hold respiration for certain sequences. Another option includes a general anesthetic with a laryngeal mask airway.

The need for breath-holding when carrying out CMR varies according to the structures being imaged, the programmed sequences, and the experience and preference of the imaging team. The need for breath-holding increases as the size of the structures being imaged gets smaller. As many as eight breath-holds of 10–30 seconds are required for some diagnostic scans; the pathophysiological effects of this technique must be considered, i.e., the effect of preoxygenation and the lack of ventilation on shunted single-ventricle infants. Su et al. described an ECG and respiration-gated technique that obviates the need for breath-holding in the great majority of CMR studies. This technique allows selection of sedated, spontaneously breathing techniques for many patients [125].

It is critical to match the patient's cardiac lesion and cardiac function with an appropriate anesthetic. For example, a single ventricle with a modified Blalock–Taussig shunt is

AL Grawany

unlikely to tolerate a deep sedation with propofol. Propofol may lead to a decrease in mean arterial pressure, a decrease in driving pressure through the shunt, and an increase in PVR due to hypoxemia and hypercarbia from hypoventilation. This can result in a further decrease in shunt flow and dangerously low oxygenation saturations and can ultimately result in cardiac arrest (Figure 35.1).

Different institutions have published their experiences with anesthesia for CMR imaging and have found that the risk of adverse events is quite low [126, 127]. However, Stockton et al. reported a 28% incidence of adverse events, higher than that of the general pediatric population. It is important to recognize that practically all risks associated with MRI are related to the anesthetic. Single-ventricle patients are known to have increased risk of morbidity and mortality associated with anesthesia, and this includes anesthesia for CMR [5]. Particular attention should be paid to fasting times and inadequate preoperative hydration. Both Stockton et al. and Brown et al. report major adverse events including death prior to the anesthetic (thought to be dehydration-related), intraoperative cardiac arrest, and shunt thrombosis in this population. These adverse events led to a modification to the CMR protocol to include a preadmission for intravenous fluids and possible heparin administration prior to the study [12, 13]. At our institutions, we have a low threshold to admit these patients to the hospital after the scan for continuation of intravenous hydration as needed and for observation. Inadequate post-anesthetic oral intake and anesthesia-related physiologic alterations, including possible hypotension and reduced shunt flow, can result in significant consequences. Proper multidisciplinary planning, an experienced anesthesiologist, and vigilant perianesthetic care can help to minimize this risk.

Because of the high-risk nature of some CMR studies, appropriate planning for resuscitation and rescue should be in place. Any question about the stability of the patient during the MRI should necessitate stopping the scan and an evaluation of the patient, with a low threshold to remove the patient from the scanner room into an adjacent resuscitation area where ferromagnetic equipment does not pose a safety risk. Many congenital cardiac centers now have MRI incorporated into their catheterization laboratory suites, where rapid imaging after catheter interventions is possible. These scanners double as the CMR diagnostic scanners and have the added advantage of closer proximity to help and expertise to rescue the patient from a critical event.

Until recent years, the presence of a cardiac pacemaker was essentially an absolute contraindication to MRI scanning. However, there are now a number of MRI-compatible pacemaker systems that have been tested in adult patients and which are generally deemed to be safe. It is likely that these systems will be implanted in pediatric patients in the future. The risk benefit of MRI in this situation must be completely evaluated, and alternative means to obtain the imaging data should be sought. A protocol for the device, and the presence of experts in managing the devices during the MRI scan are essential if an MRI-compatible pacemaker procedure is planned [128]. Patients with non-MRI compatible systems may also be able to undergo MRI studies without patient or device complications. However, artifact related to the pacemaker or implantable cardiac defibrillator may render the study useless. This is particularly true for cardiac MRI. It is recommended that patients with non-MRI compatible systems be responsive and communicative during the procedure to monitor for complications [129].

Myocardial stress perfusion MRI is increasingly utilized in the pediatric population to evaluate ischemia due to coronary artery anomalies, both before and after surgical, catheter, or medical intervention. Indications include anomalous origin of the coronary artery from the aorta, myocardial bridge, Kawasaki disease, and postoperative evaluation of coronary re-implantation surgery such as arterial switch operation, anomalous origin of the left coronary artery from the pulmonary artery, and the Ross procedure [130, 131]. Myocardial perfusion is imaged before and after a pharmacological stressor, and assessed for reversible or permanent perfusion defects, to guide future therapy or assess results of past procedures. Several methods have been utilized to produce myocardial stress, including dobutamine infusion starting at 10 mcg/kg/min, and increasing to as high as 40 mcg/kg/min, with atropine added if heart rate increase (>150 bpm in teenaged patients) is not sufficient [130]. Another approach is to add a coronary artery vasodilator such as adenosine, or regadenoson, a selective alpha-2A receptor agonist [131]. Adverse hemodynamic events are a significant risk for these techniques, including ventricular arrhythmias, AV block, hypertension, and hypotension. Dyspnea, chest pain, flushing, headache, and nausea are frequent side effects in conscious patients. Defibrillation capability and resuscitation drugs must be in close proximity during these procedures, in addition to a plan to remove the patient from Zone IV of the MRI scanner for resuscitation. Many patients undergoing myocardial stress perfusion MRI are older and can tolerate an unsedated scan and comply with instructions to breath-hold. Younger patients requiring sedation can potentially receive propofol with a natural airway, but because most of these procedures will require breath-holding, general anesthesia with a laryngeal mask airway or endotracheal tube is often required. In a series of 224 pediatric dobutamine stress cardiac MRI, median patient age was 14 years and weight 58 kg [130]. Sedation was required in 17% of patients; and there were no major adverse events (cardiac arrest, myocardial infarction, ventricular arrhythmia), and 14% of patients had minor adverse events. In a pediatric series of 46 patients undergoing regadenoson stress cardiac MRI, median age was 9 years (range 2 months to 14 years), and 67% required sedation [131]. No patient experienced a major adverse event but there was a 20% incidence of minor events, including 9 with hypotension of which 8 required pharmacologic intervention with phenylephrine.

Lymphatic mapping and intervention

Lymphatic disorders in CHD include a number of conditions that are common sources of morbidity and mortality in patients with single ventricle physiology including pleural effusions, chylothorax, plastic bronchitis, ascites and protein losing enteropathy. Dynamic Contrast-enhanced Magnetic Resonance Lymphangiography (DCMRL) has emerged as a technique for the identification of lymphatic abnormalities,

and percutaneous (transabdominal or transhepatic) access of lymphatic vessels allows for the treatment of these lymphatic disorders by coiling or embolization (see Chapter 30).

The patients undergoing these procedures are largely single ventricle patients who are compromised from a respiratory standpoint, and they may be significantly debilitated. They require immobility for the duration of the procedure, and thus general endotracheal anesthesia is required. These patients may be on chronic diuretic therapy and may be hypovolemic and/or prone to electrolyte derangements. In addition to judicious volume administration, inotropic and/or vasopressor support may be indicated. Invasive arterial blood pressure monitoring may be helpful, and recovery in the ICU should be strongly considered due to complications or escalation of care in 25% of patients having a lymphatic intervention. Other procedures may be performed during the same anesthetic such as direct laryngoscopy and bronchoscopy in patients with plastic bronchitis or esophagogastroduodenoscopy in patients with protein losing enteropathy. Preoperative multidisciplinary planning is essential for the optimized outcome of these fragile patients [132].

KEY POINTS: MRI, CT, AND LYMPHATIC MAPPING AND INTERVENTION

- Risk associated with imaging is almost entirely anesthesia-related.
- Airway monitoring is critical; hypercarbia and hypoxemia can lead to cardiac arrest in high-risk patients, especially those with pulmonary hypertension.
- High-risk patients may require preoperative admission and hydration and/or postoperative admission and monitoring for imaging procedures requiring anesthesia.

Postoperative considerations

Intensive care unit vs. general inpatient unit

Inpatient postoperative recovery may take place in an intensive care setting or on a general inpatient unit. The decision about the postoperative setting should take a number of factors into consideration, including the cardiac diagnosis, the complexity of surgery, and potential postoperative difficulties. The decision to leave the trachea intubated at the end of the case necessitates an ICU admission.

The shunted single-ventricle circulation is fragile, and the risks and benefits of extubation must be weighed carefully. An extubated patient may develop apnea, hypoventilation, hypoxemia, hypercarbia, acidosis, and/or poor pain control; this may be catastrophic in a shunted single ventricle. In a series of five patients with HLHS after stage I palliation undergoing laparoscopic Nissen fundoplication, four were left intubated at the end of the operation. All were transferred to the ICU for recovery, and the remaining four patients were extubated on postoperative day 1. All had good outcomes [93].

Watkins et al. studied perioperative outcomes of 36 patients with HLHS after stage I palliation undergoing fundoplication and gastrostomy. Most patients were extubated in the OR and recovered on an in-patient unit. A substantial number of these patients developed cardiorespiratory instability postoperatively, and an escalation in care was required. During the study period, due to unplanned ICU admissions in this population, a policy was made that all patients with HLHS after stage I palliation should recover in an ICU after a general anesthetic [133].

In most other patients with CHD, recovery on a general inpatient unit is appropriate. However, patients should be monitored closely for respiratory difficulties, hemodynamic instability, desaturation, or arrhythmia, all of which can be poorly tolerated in the patient with CHD.

Home discharge criteria

It is possible to perform outpatient procedures on patients with CHD, but considerations should include the cardiac disease and stability of physiology, the type of procedure, and potential perioperative complications. Christensen et al. reported data on the anesthetic management and outcome in patients with surgically corrected dextro-transposition of the great arteries undergoing noncardiac surgery [134]. In this series of 50 procedures, 71% of patients who had undergone arterial switch operation (corrective repair) and 60% of patients who had undergone atrial switch operation (physiologic repair), were discharged home on the day of the procedure.

It must be recognized, however, that mild complications of anesthesia or surgery, including dehydration due to nausea and vomiting, poor intake of fluids by mouth, or bleeding, can result in serious morbidity for intravascular volume-sensitive patients with CHD [17]. In addition, as stated earlier, the perioperative risk of patients with pulmonary hypertension extends into the post-anesthesia period [55, 57]. These patients should not be discharged home on the day of surgery.

KEY POINTS: POSTOPERATIVE CONSIDERATIONS

- High-risk patients, such as patients with HLHS after the Norwood procedure, are commonly cared for in the ICU after a procedure due to their fragile circulation.
- Well-compensated patients with CHD can be discharged home on the day of surgery.
- Patients with pulmonary hypertension should be observed carefully after anesthesia and surgery.

Introduction

The pediatric cardiac intensive care unit (CICU) serves as the primary destination for critically ill children with congenital and acquired heart disease. It provides an expert model of care by bringing the broad range of specific expertise to the bedside of every CICU patient. Ideally, this allows the cardiac intensivist to engage in collaborative and dynamic decision-making that involves anesthesiologists, cardiac surgeons, interventionalists, imaging specialists, electrophysiologists, and heart failure/advanced cardiac therapies specialists, thus serving to provide highly effective and efficient care delivery to patients.

In contrast to general pediatric intensive care, the majority of CICU admissions are planned. With preoperative and precatheterization review and fetal echocardiography, it is possible and necessary to plan most admissions and their potential need for CICU resources. It is important to recognize that as survival outcomes have improved in children with congenital or acquired heart disease as a result of the current paradigms in management, the proportion of medical cardiac (MC) and unplanned CICU admissions will be expected to increase over time [1, 2].

Collaboration among CICUs and increased emphasis on quality improvement have significantly improved the outcomes of children with critical heart disease in the CICU setting. Efforts from multi-institutional collaborations (e.g., the Pediatric Cardiac Critical Care Consortium [PC[4]], which currently has over 65 CICUs submitting data to its registry) has provided a better understanding of case-mix and outcome variability among CICUs. Figure 36.1 shows multi-institutional data from PC[4] summarizing CICU admissions by age group, illness category (MC, surgical cardiac [SC]), and admission indication from 2018 to 2020.

Pathophysiology of specific congenital cardiac defects and implications

A thorough understanding of the pathophysiology of congenital cardiac defects is essential when managing these patients in the CICU. This will influence not only the preoperative management strategy for stabilization and/or resuscitation prior to surgery, but also preparations for the impact of preexisting physiologies such as cyanosis, pressure overload, and volume overload on myocardial performance and recovery after surgery. Understanding the changes in physiology achieved intraoperatively in SC patients is equally important for identifying expectations and the anticipated course in the CICU. In the presence of hemodynamically-significant residual intracardiac lesions after surgery, the accompanying alterations in pulmonary blood flow, systemic perfusion, and ventricular compliance may significantly affect recovery and length of stay (LOS) in the CICU.

Intercirculatory mixing, complete mixing, and streaming

Confusing terminologies are often used interchangeably to describe common preoperative and postoperative physiologies. It is important for the care provider to understand the essential elements of the circulation in order to react appropriately to perturbations.

Intercirculatory mixing lesions

Patients with D-transposition of the great arteries (D-TGA) have parallel circulations: the deoxygenated systemic venous blood returns to the right ventricle (RV) and is ejected through the aorta while oxygenated pulmonary venous blood is returned to the left ventricle (LV) and is ejected into the pulmonary artery (PA) (Figure 36.2). Although the figure depicts simple transposition anatomy, transposition *physiology* can occur with other anatomic defects such as "Taussig-Bing" type double-outlet right ventricle, where a subpulmonary

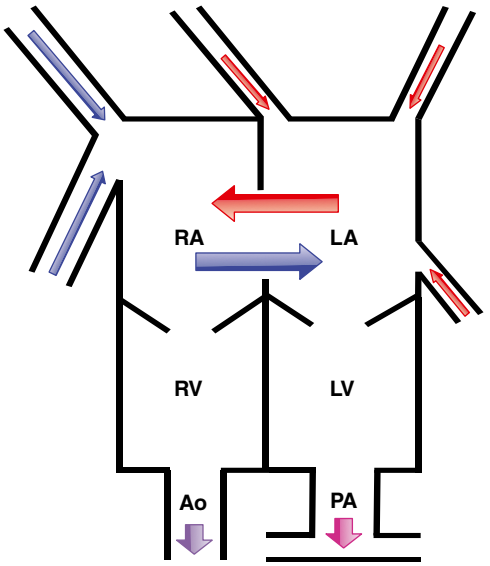

Figure 36.2 The anatomy and physiology of D-TGA. The diagram shows the typical stable circulation in unoperated D-TGA. The desaturated systemic venous (SV) blood (blue arrows) and fully saturated pulmonary venous (PV) blood (red arrows) require free mixing at the atrial level (often after a BAS) resulting in anatomically equivalent, left-to-right and right-to-left shunting. As a result, the saturations show the pattern where $SV_{sat} < Ao_{sat} < PA_{sat} < PV_{sat}$. Ao, aorta; BAS, balloon atrial septostomy; D-TGA, D-transposition of the great arteries; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; sat, O_2 saturation.

position of the ventricular septal defect (VSD) and malposition of the great arteries create an unfavorable streaming pattern resulting in parallel intracardiac circulation similar to D-TGA. Transposition *physiology* is the term used for this parallel circulatory pattern where PA oxygen saturation is greater than the aortic oxygen saturation. Such a circulation is not compatible with survival over time unless there is adequate intercirculatory mixing allowing for the deoxygenated systemic venous blood into the pulmonary circulation (PA), as well as the oxygenated pulmonary venous blood into the systemic circulation (aorta) [3]. Although 25–50% of patients with D-TGA have a VSD, the presence of a VSD does not guarantee adequate intercirculatory mixing, as mixing occurs most effectively at the atrial level. Newborns with D-TGA, irrespective of whether they are diagnosed antenatally or postnatally, can present with profound cyanosis in the absence of respiratory distress due to inadequate mixing. Such patients should be transported to the CICU after commencing intravenous (IV) prostaglandin E_1 (PGE_1) to maintain a patent ductus arteriosus (PDA) as an additional location for mixing. After confirmation of the diagnosis of D-TGA with a restrictive or intact atrial septum, a balloon atrial septostomy (BAS) can be performed at the bedside or in the cardiac catheterization laboratory to improve intercirculatory mixing and systemic oxygen delivery. If the atrial communication is restrictive, administration of usual therapies to improve pulmonary blood flow (e.g., supplemental oxygen, inhaled nitric oxide) are often detrimental if used as ongoing preoperative management strategies. These therapies can generate left atrial hypertension, leading to increasing pulmonary congestion and worsening pulmonary compliance with further impairment of atrial-level mixing. Once an adequate atrial septal defect (ASD) is created, systemic oxygen delivery improves as mixing increases from left to right (saturated pulmonary to desaturated systemic) across the ASD. Subsequently, patients can have the PGE_1 infusion discontinued and wean and extubate to await an elective repair with the arterial switch operation within the first week of life [4]. Some patients with D-TGA may remain hypoxemic despite creation of an unrestrictive atrial communication; such patients are often dependent on PGE_1 infusion in the preoperative period to maintain systemic saturations >65% [5]. The failure of adequate mixing at the atrial level may reflect not only differences in ventricular function, ventricular filling, and/or ventricular end-diastolic pressures (ventricular compliance), but may also be secondary to unfavorable streaming effects. There may also be an element of rebound pulmonary hypertension from PGE_1 discontinuation that reduces the volume of pulmonary blood flow without affecting the amount of intercirculatory mixing. Some investigators have suggested a protracted weaning protocol for PGE_1 to mitigate this effect [6]. See Chapter 29 for further discussion of D-TGA.

Complete mixing lesions

Complete mixing lesions represent a variety of anatomic entities that have a common chamber where pulmonary and systemic venous return completely mix before exiting. The conventional terminology for this is *single ventricle physiology* because it refers to a physiology in which the PA saturation and aortic saturation are equal. These lesions can have either ductal-dependent pulmonary blood flow (e.g., tricuspid atresia, pulmonary atresia with intact ventricular septum, or pulmonary atresia with VSD) or ductal-dependent systemic blood flow (e.g., hypoplastic left heart syndrome [HLHS], double-inlet left ventricle [DILV]). Although the majority of these lesions will require a palliative single ventricle surgical strategy, some patients with single ventricle physiology have two anatomically-adequate ventricles, allowing for an initial septation procedure (e.g., truncus arteriosus, tetralogy of Fallot [TOF] with pulmonary atresia). This is important when considering the systemic oxygen saturation (SaO_2) targets in managing these patients. The traditional targets of SaO_2 of 75–85%, partial pressure of O_2 (PaO_2) of 35–45 mmHg, mixed venous O_2 (MvO_2) saturation, and/or near-infrared spectroscopy (NIRS) of 50–60%, along with oxygen extraction fraction of ~25% together with appropriate blood pressure for age, systemic vascular resistance (SVR) state, and adequate markers of end-organ function (e.g., lactate level, urine output, clinical examination), are important when trying to balance pulmonary blood flow (Q_p) and systemic blood flow (Q_s) in a preoperative or postoperative patient with limited combined ventricular output. When combined ventricular output is not a limiting factor (e.g., preoperative patients with tricuspid atresia, those with truncus arteriosus), it is important to recognize that strict management of Q_p/Q_s balance is unnecessary in the absence of respiratory embarrassment or signs of inadequate systemic oxygen delivery (DO_2). See Chapter 30 for further discussion of single ventricle lesions.

Streaming

Streaming is the phenomenon where systemic venous blood (or pulmonary venous blood) can pass through to the

systemic circulation (or pulmonary venous blood to the pulmonary circulation) due to specific anatomic abnormalities that result in an anatomic chamber that is common to both circulatory systems (e.g., a common atrium, the absence of common arterial septum, truncus arteriosus, double-outlet right ventricle). This streamed blood may or may not be completely mixed before it reaches the arterial outlet. If it is incompletely mixed, the physiology is likely to be that of *transposition physiology* ($PA_{sat} > Ao_{sat}$), whereas streaming that is completely mixed will be *single ventricle physiology* ($PA_{sat} = Ao_{sat}$) [3].

Shunts

Shunting between the pulmonary and systemic circulations can be intracardiac (across an ASD or a VSD) or extracardiac (across a PDA, aortopulmonary window, decompressing venovenous collaterals, aortopulmonary collateral, or arteriovenous malformation). Depending on the size of the communication and the differential pressures and resistances between the pulmonary and systemic circulations, patients may have decreased or increased pulmonary blood flow and may be either cyanotic or acyanotic, respectively.

Increased pulmonary blood flow

Shunts that increase pulmonary blood flow may occur either between the atria, ventricles, or the great arteries, and they can be simple or complex. The degree of restriction across these shunts also affects their potential clinical significance. The most common clinical signs seen with increased pulmonary blood flow are tachypnea, respiratory distress, tachycardia, difficulty feeding in neonates/infants, failure to thrive, and diaphoresis.

Simple shunt

The amount of flow across a "simple" left-to-right shunt depends on the size of the defect and the balance between pulmonary vascular resistance (PVR) and SVR. It is important to understand that this is a physiologic term and has no direct relationship to specific diagnoses (Table 36.1). Therefore, patients who have a simple shunt may have:

1. A normal SaO_2 with two ventricles, such as a large VSD, complete atrioventricular canal (CAVC), and large PDA
2. A normal SaO_2 with a single ventricular outflow trunk and two ventricles (truncus arteriosus)
3. A "low" SaO_2 (80–95%) and two ventricles (D-TGA with large VSD)
4. A "low" SaO_2 (75–85%) and single ventricle (tricuspid atresia or following a Blalock–Taussig (BT) shunt such as in a modified Norwood procedure).

If the simple shunt is "unrestrictive," the physiologic consequence for all the above mentioned diagnoses will be the same, i.e. excessive pulmonary flow and volume overload to the ventricle receiving the increased pulmonary venous blood flow plus secondary respiratory embarrassment. The degree of shunt will be determined not by the size of the defect, but rather by the relationship between SVR and PVR [7, 8]. The clinical manifestation will also be the same, namely congestive heart failure (CHF) and pulmonary hypertension, although some patients will be cyanotic and others acyanotic, depending on the degree of intracardiac mixing and streaming.

On the other hand, for a simple "restrictive" shunt, when the orifice or size of the shunt is small, the size of the communication is the limiting factor determining the increase in pulmonary blow flow; relative SVR and PVR may have little or no impact in this situation. In this circumstance, there is minimal overload to the ventricle receiving pulmonary venous flow, and the pulmonary circulation is protected from excess pressure and flow; as a result, patients may be relatively asymptomatic and present at an older age with nonspecific symptoms such as recurrent respiratory infections or failure to thrive.

Table 36.1 Simple shunts: defects or surgical procedures contributing to an increased pulmonary blood flow/systemic blood flow (Q_p/Q_s)

	Acyanotic	Cyanotic
Two ventricles	ASD VSD CAVC DORV	D-TGA/VSD PA/VSD
Single ventricle		TA ± TGA HLHS DORV/MA Norwood procedure BT shunt
AP connection	PDA Truncus arteriosus AP window	PA/MAPCA

AP, aortopulmonary; ASD, atrial septal defect; BT, Blalock–Taussig; CAVC, complete atrioventricular canal; D-TGA, dextro-transposition of the great arteries; DORV, double-outlet right ventricle; HLHS, hypoplastic left heart syndrome; MA, mitral atresia; MAPCA, major aortopulmonary collateral artery; PA, pulmonary atresia; PDA, patent ductus arteriosus; TA, tricuspid atresia; VSD, ventricular septal defect.

Complex shunt

In the presence of additional pulmonary or systemic outflow obstruction, the ratio of pulmonary-to-systemic blood flow (Q_p/Q_s) is determined by the size of the orifice and the outflow gradient as well as SVR and PVR. The obstruction may be fixed (valvular aortic or pulmonary stenosis) or dynamic (some forms of TOF, tricuspid atresia with normally related great arteries and a dynamically restrictive muscular VSD).

Clinical consequences of increased pulmonary-to-systemic blood flow ratio

If the increase in pulmonary blood flow and pressure persist over months to years, structural changes occur within the pulmonary vasculature until eventually PVR becomes irreversibly elevated [7–9]. The time course for developing this pathology, termed pulmonary vascular obstructive disease (PVOD), depends in part on the degree of volume overload to the pulmonary circulation, degree of pressure overload to the pulmonary circulation, exposure of the pulmonary vascular bed to cyanosis, and duration of exposure to these factors in the setting of a shunt [10]. Changes may be evident by 4–6 months of age in some lesions (e.g., large VSD or CAVC). The progression can be more rapid when the volume and pressure overload to the pulmonary circulation are increased, such as with truncus arteriosus. When pulmonary blood flow is increased in the absence of pressure overload,

such as in simple secundum ASD, PVOD typically develops much more slowly, if at all during childhood.

As PVR decreases in the first days to weeks after birth, and the hematocrit falls to its lowest physiologic value, the increased left-to-right shunt and anemia-related high-output state result in volume loading on the systemic ventricle along with CHF. A typical pressure–volume loop for a volume-loaded ventricle is shown in Figure 36.3. The end-diastolic volume is increased and the end-diastolic pressure–volume line displaced to the right indicating reduced contractility. The time course over which irreversible ventricular dysfunction develops is variable, but if surgical/catheter intervention to correct the volume overload is undertaken within the first 2 years of life, residual dysfunction is uncommon [11]. The volume load on the systemic ventricle and increased end-diastolic pressure contribute to increased pulmonary edema by increasing pulmonary venous and lymphatic pressures. Decreased lung compliance and increased airway resistance occur secondary to small airways compression by distended vessels [12, 13]. This manifests clinically in infants with both tachypnea and increased work of breathing. If tracheally intubated for mechanical ventilation, the lungs may feel stiff on hand ventilation, deflate slowly, and exhibit an obstructive pattern; poor compliance may be apparent during mechanical breaths.

Besides cardiomegaly on chest radiograph, the lung fields are usually congested and hyperinflated. Ventilation/perfusion mismatch contributes to an increased alveolar-to-systemic arterial ($A\text{-}aO_2$) gradient and dead space ventilation [14]. Minute ventilation is, therefore, increased, primarily by an increase in respiratory rate. PA and left atrial enlargement may compress mainstem bronchi causing lobar collapse. PA and left atrial dilation may be seen on chest radiograph in the form of widening at the hilum from PA contour enlargement and upward splaying of the left mainstem bronchus from distortion due to left atrial dilation. Furthermore, tachycardia, increased fussiness/agitation, and poor weight gain may be seen secondary to increased myocardial oxygen demand in response to pulmonary overcirculation and ventricular volume loading.

It is important to appreciate that such clinical scenarios can be present even after surgery in patients who have significant residual intracardiac shunts that cause an increase in Q_p/Q_s. This may manifest during the early postoperative course as low cardiac output syndrome (LCOS) (see the "Myocardial Dysfunction and Hemodynamic Monitoring" section) or become apparent some days after surgery with an inability to wean from mechanical ventilation or a persistent requirement for vasoactive support.

Decreased pulmonary blood flow

Reductions to pulmonary blood flow from structural heart disease are ultimately related to intracardiac right-to-left shunting. The basis for this may be pulmonary outflow obstruction (supravalvar, valvar, subvalvar, or a combination of these), subpulmonary ventricle inflow obstruction (tricuspid stenosis or atresia), or the inability to generate adequate antegrade pulmonary blood flow (Ebstein anomaly, tricuspid valve dysplasia). In patients with noncardiac diseases, such as persistent pulmonary hypertension of the newborn (PPHN), sustained elevations in PVR result in intracardiac (or ductal) right-to-left shunting.

Pulmonary mechanics and lung volumes are generally normal in patients with reduced pulmonary blood flow. Dead space ventilation is increased, although minute

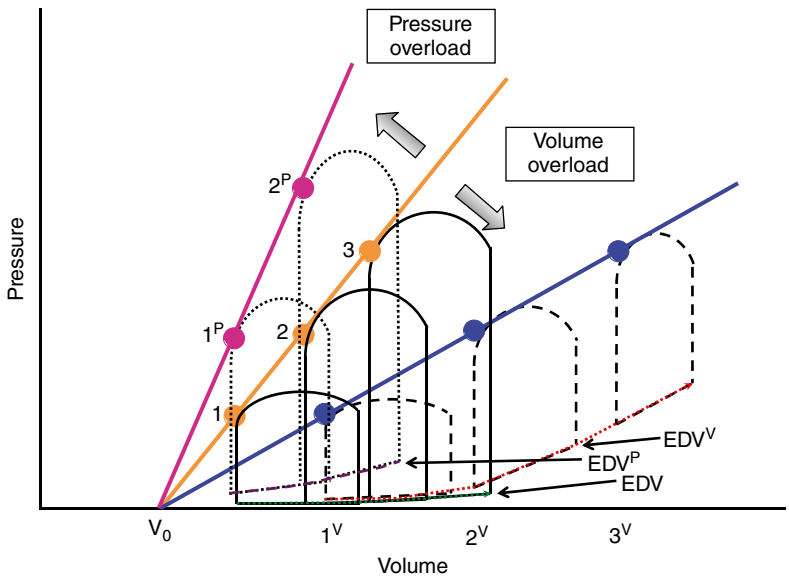

Figure 36.3 Pressure–volume relationships. In a gradual afterload increase on a ventricle that can compensate (orange line moving from 1 to 3), the stroke volume is maintained at the cost of higher intracavitary pressure (wall stress) and lower ejection fraction. Generally, this does not require a higher EDP (dotted green line). In the failing myocardium (blue line), stroke volume can only be maintained (initially) at a higher EDP (dotted red line); ultimately stroke volume will be compromised (moving from 1^v to 3^v). An acute afterload increase on a ventricle (pink line) results in a lower stroke volume (moving from 1 to 1^p to 2^p), despite compensatory mechanisms to augment stroke volume with a higher EDP (dotted purple line). EDP, end-diastolic pressure; EDV, end-diastolic volume.

AL Grawany

ventilation is only slightly increased to maintain normocapnia, and the A-aO_2 gradient may be increased as well. The lung fields appear oligemic on chest radiograph. Some patients may have impairments in pulmonary mechanics due to anatomic interactions between cardiovascular structures and the tracheobronchial tree. One such group are patients with TOF and absent pulmonary valve (APV) syndrome who can have massively dilated branch PAs; in the setting of a freely regurgitant pulmonary valve orifice, the RV and branch PAs become volume loaded and dilate, leading to compression of the large and small airways. These patients have significant gas-trapping and expiratory flow limitations, which is a frequent cause of their respiratory failure. Surgical repair during the newborn period is often required to treat respiratory failure in this scenario. Often in neonates with TOF with APV, early prone positioning with positive pressure ventilation (PPV) is required to alleviate bronchial compression and achieve adequate gas exchange; however, emergent sternotomy in unrepaired patients may still be required in some cases to alleviate airway compression despite mechanical ventilation and proning [15, 16].

Target systemic oxygen saturation level

The postoperative target SaO_2 level is important to establish, as it will guide assessment and therapeutic intervention (Table 36.2). Potential causes of abnormally low SaO_2 include:

1. Pulmonary venous desaturation (normal is 95–99% in ambient air) indicating an intrapulmonary shunt secondary to primary pulmonary pathology (e.g., alveolar edema/consolidation or pleural effusion)
2. A reduction in effective pulmonary blood flow, such as from pulmonary outflow obstruction, reduced aortopulmonary shunt flow from mechanical obstruction, increased PVR, intracardiac right-to-left shunt, or decompressing venovenous collaterals (e.g., from a high-pressure superior vena cava to the inferior vena cava in a Glenn circulation)
3. A reduction in arterial oxygen content (CaO_2), principally in patients who have mixing of systemic and pulmonary venous blood at the atrial-level or single ventricle physiology. The reduction in CaO_2 may be due to low MvO_2 level (such as reduced oxygen delivery due to impaired cardiac output or increased oxygen extraction) or a low oxygen carrying capacity (reduced hematocrit).

Table 36.2 Factors to consider in a postoperative cardiac surgery patient with an arterial oxygen saturation lower than the anticipated range

Etiology	Considerations
Low FiO_2	Inappropriately low-set oxygen concentration for delivery
	Failure of oxygen delivery device
Pulmonary vein desaturation	Impaired diffusion
	Alveolar process: edema, infection
	Restrictive process: effusion, atelectasis, pneumothorax
	Intrapulmonary shunt
	RDS
	Pulmonary AVM
	PA-to-PV collateral vessel(s)
Reduced pulmonary blood flow	Anatomic RV outflow obstruction
	Anatomic pulmonary artery stenosis
	Increased PVR
	Atrial-level right-to-left shunt
	RV hypertension
	Restrictive RV physiology (low compliance)
	Severe tricuspid regurgitation
	Large fenestration (modified Fontan operation)
	Intra-atrial baffle leak
	Reduced aorta pulmonary shunt flow
	Ventricular-level right-to-left shunt
	RV hypertension and residual VSD
Low dissolved O_2 content (SV and TGA physiology)	Low mixed venous oxygen level
	Increased O_2 extraction: hypermetabolic state
	Decreased O_2 delivery: low cardiac output state
	Anemia

AVM, arteriovenous malformation; FiO_2, fractional inspired concentration of oxygen; O_2, oxygen; PA, pulmonary artery; PV, pulmonary vein; PVR, pulmonary vascular resistance; RDS, respiratory distress syndrome; RV, right ventricle; SV, single ventricle; TGA, transposition of the great arteries; VSD, ventricular septal defect.

Outflow obstruction

Severe LV or RV outflow obstruction in the newborn may be associated with ventricular hypertrophy and vessel hypoplasia distal to the level of obstruction. If there is complete or near-complete outflow obstruction, mixing or shunting at the ASD and/or VSD level is required to maintain systemic cardiac output (CO) with adequate arterial oxygen content.

A typical pressure–volume loop from a chronic pressure load on the ventricle is shown in Figure 36.3. The end-diastolic pressure is elevated and the end-systolic pressure volume line is shifted to the left, reflecting increased contractility in the compensated state (purple line), with an upwards shift along the new slope reflecting a higher afterload state (from 1^P to 2^P). Maintenance of preload, stability in afterload, adequate contractility, and normal sinus rhythm are important to prevent a fall in CO or coronary hypoperfusion in states of increased ventricular afterload. Since the time course to develop significant ventricular dysfunction is longer in patients with chronic pressure overload compared to chronic volume overload, symptoms of CHF are uncommon, unless obstruction is severe or prolonged.

In the immediate postoperative period, it is important to evaluate both systolic and diastolic ventricular function in a previously obstructed but still hypertrophied ventricle.

1. A hyperdynamic state may be present following LV outflow reconstruction. This will be manifest by systemic hypertension and should be treated promptly to reduce myocardial work and protect surgical suture lines, especially those in the aorta.
2. Systolic dysfunction of a hypertrophied ventricle may be apparent early after cardiac surgery secondary to myocardial ischemia and ventricular dysrhythmias. Ischemia

may occur particularly if there has been a long aortic cross-clamp time, inadequate myocardial protection with cardioplegia solution, or hypothermia. In the case of the RV, dysfunction may be related to a right ventriculotomy, direct injury to a coronary artery (e.g., a conal branch running across the RV outflow tract), air embolism, or due to inadequate myocardial protection with cardioplegia, hypothermia, or local cooling strategies. This should be evaluated and treated in the postoperative period with inotropic and/or inodilator support (i.e., dopamine or epinephrine, milrinone, and nitric oxide in the case of the RV). The evaluation of ventricular function includes echocardiography and potentially cardiac catheterization to assess hemodynamics and investigate potential coronary complications that may require reintervention.

3. Diastolic dysfunction is usually manifest as a poorly compliant or stiff ventricle that is hypertrophied. It may contract well, but it is unable to relax and fill effectively during diastole. On the left side of the heart, this is usually manifest as left atrial hypertension with either pulmonary edema, atrial dysrhythmias, or pulmonary hypertension. On the right side of the heart, an increase in RV end-diastolic pressure is demonstrated by right atrial hypertension and elevated central venous pressures along with clinical signs such as atrial arrhythmias, lower SaO_2 from a right-to-left shunt (e.g., across a patent foramen ovale [PFO] or ASD), hepatomegaly, diffuse edema (especially in neonates), pleural effusions, and ascites. In the postoperative period, patients with diastolic dysfunction may benefit from lusitropic agents (e.g., milrinone) to improve myocardial relaxation, are typically dependent on adequate preload to maintain sufficient CO, do not tolerate aggressive diuresis because of preload dependency, and may not tolerate rapid volume resuscitation due to the inability of the noncompliant ventricle to accept a large increase in intravascular volume. Patients with RV diastolic dysfunction (e.g., TOF) may benefit from early tracheal extubation, as PPV can increase RV afterload and hinder RV preload. Significant and untreated postoperative tachycardia in this population can also lead to a limitation in CO and increase in myocardial oxygen consumption.

KEY POINTS: PATHOPHYSIOLOGY

- Newborns with CHD may present with cyanosis or shock. This may result from transposition physiology ($PA_{sat} > Ao_{sat}$) or single ventricle physiology ($PA_{sat} = Ao_{sat}$) depending on the balance of mixing, streaming, and shunting.
- As PVR drops in the first few days and weeks of life, CHF may develop in children with large left-to-right shunts.
- Hypoxemia in single ventricle patients may develop from pulmonary venous desaturation, systemic venous desaturation, inadequate pulmonary blood flow, or suboptimal oxygen carrying capacity.

Airway and ventilation management

In all of the examples of mixing, shunting, and outflow obstruction described earlier, the mode and method of mechanical ventilation may have a substantial impact on hemodynamics and systemic perfusion. Particularly for neonates and infants, cardiorespiratory interactions are essential to recognize during postoperative management. While changes in the PaO_2, partial pressure of carbon dioxide ($PaCO_2$), and pH are well recognized to affect PVR, the mean airway pressure and changes in lung volume during PPV will also affect PVR, preload, and ventricular afterload. In addition to evaluating the adequacy of mechanical ventilation settings by arterial blood gas and chest radiography, it is important that ventilator settings be continually evaluated and adjusted according to hemodynamic response.

Airway management

Intubation of the trachea in a neonate or young infant with CHD may elicit undesirable hemodynamic and metabolic responses. Appropriate anesthetic techniques are thus desirable to secure the airway.

Traditionally, uncuffed endotracheal tubes (ETTs) were recommended for children younger than 8 years given the narrowest part of the airway is at the level of the cricoid cartilage. However, more recent studies suggest there is no difference between airway complications with cuffed and uncuffed tubes, particularly in the era of microcuff tubes (high-volume, low-pressure cuff) [17, 18]. If a significant air leak exists around the ETT, lung volume, and in particular functional residual capacity (FRC), will not be maintained and fluctuations in gas exchange can occur. During the ventilator weaning process, a significant leak will also increase the work of breathing for some neonates and infants. In these situations, it is, therefore, preferable to exchange the ETT for a larger-sized tube or to change to a cuffed tube. In contrast, an ETT that is smaller than usual may be necessary in certain situations. This is particularly the case in patients with other congenital defects such as Down syndrome (trisomy 21). Tracheal stenosis may also occur in association with some congenital cardiac defects such as a PA sling. Extrinsic compression of the bronchi may occur by the PA or a dilated left atrium. This may be suspected by persistent hyperinflation or lobar atelectasis on a chest radiograph.

Mechanical ventilation

Altered lung mechanics and ventilation/perfusion abnormalities are common problems in the immediate postoperative period [14]. Patients who have $Q_p/Q_s > 2:1$ may have cardiomegaly and congested lung fields on chest radiograph. Patients who have an elevated left atrial pressure may demonstrate signs of pulmonary venous hypertension and pulmonary edema. Additional considerations include the surgical incision and lung retraction, increased lung water following cardiopulmonary bypass (CPB), possible pulmonary reperfusion injury, CPB-induced surfactant depletion in neonates, and restrictive defects from atelectasis and pleural effusions.

In general, patients with limited physiologic reserve should not be weaned from mechanical ventilation until hemodynamically stable and any problems contributing to an increase in intrapulmonary shunt and altered respiratory mechanics have improved.

Cardiorespiratory interactions

Cardiorespiratory interactions vary significantly between patients and throughout the postoperative course. Consequently, the mode of ventilation must be matched to the hemodynamic status of each patient to achieve an adequate CO and gas exchange. The influence of PPV on preload and afterload is shown in Table 36.3. Frequent modifications to the mode and pattern of ventilation may be necessary during recovery after surgery, with attention to changes in lung volume, compliance, and airway pressure.

Influence of lung volume

Changes in lung volume have a major effect on PVR, which is lowest at FRC. Both atelectasis and hyperinflation may result in a significant increase in PVR, as shown in Figure 36.4 [19–21]. At low-tidal volumes, alveolar collapse occurs because of reduced interstitial traction on alveolar septae. In addition, radial traction on extra-alveolar vessels such as the branch PAs is reduced, therefore reducing the cross-sectional diameter. Conversely, hyperinflation of the lung may cause stretching of the alveolar septae and compression of alveolar vessels.

An increase in PVR increases the afterload or wall stress on the RV, compromising RV function and contributing to decreased LV compliance secondary to interventricular septal shift (from right to left). In addition to low CO, signs of RV dysfunction, including tachycardia, tricuspid regurgitation, hepatomegaly, ascites, and pleural effusions, may be observed.

Table 36.3 Effect of a positive pressure mechanical breath on afterload and preload to the pulmonary and systemic ventricles

	Afterload	Preload
Pulmonary ventricle	Elevated Effect: ↑ RVEDp ↑RVp ↓Antegrade PBF ↑ PR and/or TR	Reduced Effect: ↓ RVEDV ↑ RAp
Systemic ventricle	Reduced Effect: ↓ LVEDp ↓ LAp ↓ Pulmonary edema	Reduced Effect: ↓ LVEDV ↓ LAp Hypotension

LAp, left atrial pressure; LVEDp, left ventricle end-diastolic pressure; LVEDV, left ventricle end-diastolic volume; PBF, pulmonary blood flow; PR, pulmonary regurgitation; RAp, right atrial pressure; RVEDp, right ventricle end-diastolic pressure; RVEDV, right ventricle end-diastolic volume; RVp, right ventricle pressure; TR, tricuspid regurgitation.

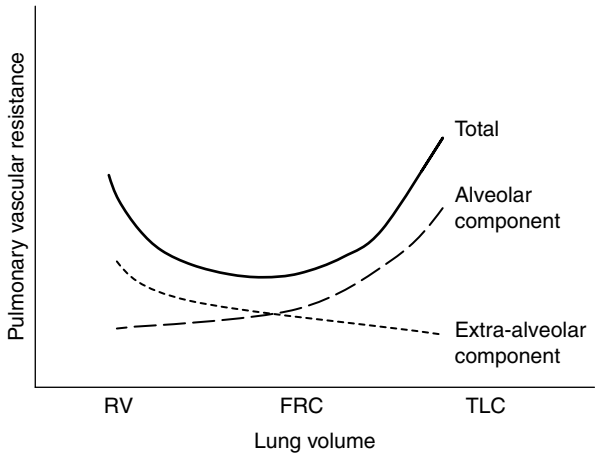

Figure 36.4 Lung volume impacts pulmonary vascular resistance. In the diagram above, there is a marked decrease in pulmonary vascular resistance when lung volume increases from RV (residual volume) to FRC (functional residual capacity). This is primarily a function of alveoli strutting open extra-alveolar vessels as they are expanded (drop in extra-alveolar resistance; dotted line). Further increases in lung volume from FRC to TLC (total lung capacity) cause increases in pulmonary vascular resistance. This is mainly due to compression of intra-alveolar vessels by air-trapping (alveolar component; dashed line). Total pulmonary vascular resistance is minimized at FRC (solid line).

Influence of intrathoracic pressure

An increase in mean intrathoracic pressure during PPV decreases preload to both pulmonary and systemic ventricles, but has opposite effects on afterload of each ventricle [22–24].

Right ventricle

The increase in pressure in the right atrium and reduction in RV preload that occurs with PPV may reduce CO. Normally, RV diastolic compliance is high and the pulmonary circulation is able to accommodate changes in flow without a large change in pressure. An increase in mean intrathoracic pressure increases the afterload on the RV from direct compression of extra-alveolar and alveolar pulmonary vessels. This has a number of clinical consequences (Table 36.3). An increase in afterload causes an increase in RV end-diastolic pressure and myocardial work, which may lead to myocardial ischemia in a patient with limited coronary perfusion. An example of the increase in RV pressure during a positive pressure breath is demonstrated in Figure 36.5.

Patients with normal RV compliance and no residual volume or pressure load on the ventricle following surgery usually show little change in RV function from the alteration in preload and afterload that occurs with PPV. However, these effects can be magnified in patients with RV hypertrophy and those with restrictive RV physiology. At particular risk are neonates requiring a right ventriculotomy for repair of TOF with pulmonary atresia or truncus arteriosus; concentric RV hypertrophy poses additional risk. While systolic RV function may be preserved in these situations, the ventricle often demonstrates diastolic dysfunction with increased RV end-diastolic pressure and impaired RV filling.

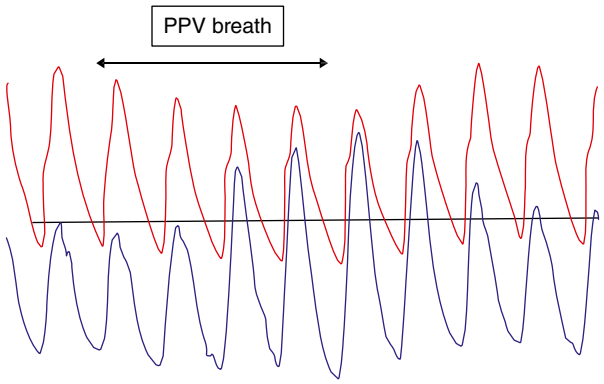

Figure 36.5 Positive pressure ventilation effects on the right ventricle. Simultaneous tracings of aortic (red) and right ventricle (blue) pressure waveforms during positive pressure ventilation (PPV) in a child with pulmonary artery stenosis. Note the increase in right ventricular pressure to approximately systemic (aortic) level during mechanical inspiration when the afterload on the right ventricle is increased.

It is important to emphasize the potentially deleterious effects of mechanical ventilation on RV function. The aims should be to ventilate with a mode that enables the lowest possible mean airway pressure while maintaining adequate lung volume and limiting potential secondary injury to the lung. In patients with lung disease, such as pneumonia, adult respiratory distress syndrome, or lung disease of prematurity, a low tidal volume strategy (4–6 mL/kg) using a low peak inspiratory pressure, short inspiratory time, increased intermittent mandatory ventilation (IMV) rate, and higher levels of positive end-expiratory pressure (PEEP) is recommended. However, this strategy is also associated with a higher mean intrathoracic pressure and afterload on the RV, which reduces antegrade pulmonary blood flow. In contrast, a strategy utilizing larger tidal volumes (10–12 mL/kg), lower IMV rates (15–20 breaths/min), and larger peak inspiratory pressure–PEEP difference with a shorter inspiratory time (0.4–0.5 seconds) may be preferential in patients with restrictive RV.

Left ventricle

LV preload is also affected by lung volume. Pulmonary blood flow and, therefore, preload to the systemic ventricle may be reduced by an increase or decrease in lung volume secondary to alteration in radial traction on alveolar and extra-alveolar vessels.

The systemic arteries are under higher pressure and not exposed to radial traction effects during inflation or deflation of the lungs. Therefore, changes in lung volume will affect LV preload, but the effect on afterload is dependent on changes in intrathoracic pressure alone.

In contrast to the RV, a major effect of PPV on the LV is a reduction in afterload. Using the law of Laplace, wall stress is directly proportional to the transmural LV pressure and the radius of curvature of the LV and inversely proportional to the thickness of the ventricle. The transmural pressure across the LV is the difference between the intracavity LV pressure and the surrounding intrathoracic pressure. Assuming a constant arterial pressure and ventricular dimension, an increase in intrathoracic pressure, as occurs during PPV, will reduce the transmural gradient and, therefore, wall stress on the LV (Figure 36.6). Therefore, PPV and PEEP can have significant beneficial effects in patients with LV systolic dysfunction or failure (Table 36.3).

Patients with LV dysfunction with an increased end-diastolic volume and pressure can have impaired pulmonary mechanics secondary to increased lung water, decreased lung compliance, and increased airway resistance. The work of breathing is increased, and neonates can fatigue early because of their limited respiratory reserve. A significant proportion of total body oxygen consumption is directed at the increased work of breathing (especially the diaphragm) in neonates and infants with LV dysfunction, contributing to poor feeding and failure to thrive. Therefore, PPV has an additional benefit in patients with significant volume overload and systemic ventricular dysfunction by reducing the work of breathing and oxygen demand.

Positive end-expiratory pressure

The use of PEEP in patients with CHD has two important effects: recruiting FRC and O_2 reserve capacity and redistributing lung water from alveolar septal regions to the more compliant perihilar regions. Gas exchange is improved, and the work of breathing reduced. This is particularly important in patients with a volume load, ventricular dysfunction, and elevated end-diastolic volume. PEEP should, therefore, be used in all mechanically ventilated patients following congenital heart surgery. However, excessive levels of PEEP can be detrimental by increasing afterload on the RV. Usually 3–5 cmH_2O of PEEP will help maintain FRC and redistribute lung water without causing hemodynamic compromise.

The use of PPV and PEEP in patients who have undergone either a Glenn or Fontan procedure (cavopulmonary anastomosis) has also been debated. In this group of patients, pulmonary blood flow is nonpulsatile and depends on the pressure gradient between the superior vena cava and the pulmonary venous atrium. During PPV, pulmonary blood flow can be diminished, and during a Valsalva maneuver and at high levels of PEEP, retrograde pulmonary blood flow may be demonstrated by Doppler echocardiography. Nevertheless, the beneficial effects of using low-pressure PPV and PEEP to achieve desired lung volume, minute ventilation and gas exchange following the Fontan procedure are apparent at the bedside. This strategy rarely contributes to a clinically significant decrease in effective pulmonary blood flow and, in fact, may be more than offset when compared to the elevations in PVR related to a strategy of low-volume spontaneous ventilation [25, 26].

Alternative modes of ventilation and respiratory support

The use of high-frequency oscillatory ventilation (HFOV) has been beneficial in the management of hypoxemic and hypercapneic respiratory failure where the goal is to optimize systemic oxygen delivery while minimizing lung injury. The mean airway pressure may be higher than when using conventional ventilation, but can be well tolerated hemodynamically, provided preload is maintained. There

AL Grawany

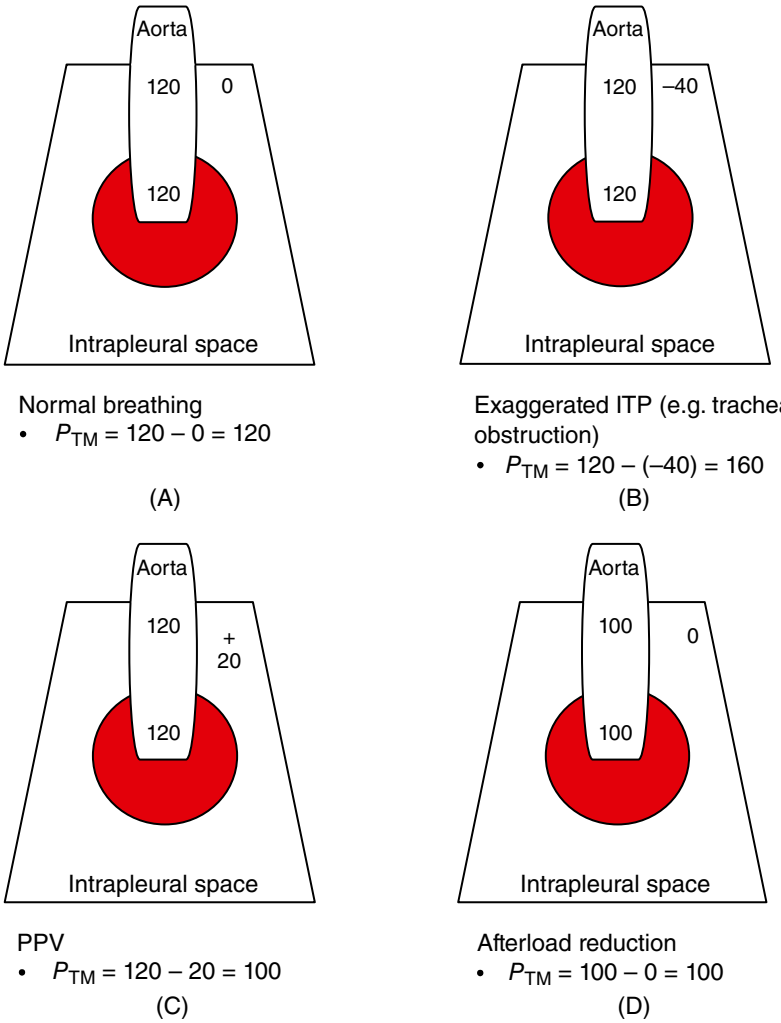

Figure 36.6 Transmural aortic pressure affects left ventricular afterload. By the law of Laplace, the transmural aortic pressure (P_{TM}) is affected by intrapleural pressure. During normal breathing (A), there is very little effect of the intrapleural pressure on P_{TM} and thus left ventricular afterload. Generation of pathologic degrees of negative intrapleural pressure (as with severe airway obstruction or decompensated heart failure) significantly increases left ventricular afterload (B). Provision of positive pressure ventilation (PPV) (C) or pharmacologic afterload reduction (D) can both independently reduce left ventricular afterload. ITP, intrathoracic pressure.

is no defined and agreed-upon indication for HFOV in the literature, but it should be considered in the setting of ventilatory failure with a rising $PaCO_2$ and mean airway pressures >14 cmH_2O in neonates and >16 cmH_2O in older children using conventional ventilator modes. Recent data using propensity matching suggest that HFOV might reduce the length of ventilation after CHD surgery in neonates and infants [27].

Noninvasive ventilation (NIV) using either mask CPAP, bilevel positive airway pressure (PAP), or high-flow nasal cannula (HFNC) can be a helpful adjunct in patients who are tachypneic with an increased work of breathing and those requiring improved oxygenation through maintenance of FRC. In addition, it can potentially improve CO and ventricular function by reducing wall stress and afterload. NIV also avoids the attendant risk of endotracheal intubation, including escalating sedation requirements and ventilator-associated pneumonia and tracheitis [28].

HFNC with humidified oxygen at flow rates of between 3 and 10 L/min can be used to help minimize work of breathing and caloric expenditure in patients recently weaned from mechanical ventilation and/or those awaiting surgery. Although the PEEP delivered through this mode is variable, this mode is a helpful adjunct, especially in small patients with resting lung volumes approaching closing capacity [29].

Early extubation

Early extubation, generally defined as extubation within 6 hours of surgery, has been described for various cardiac lesions. Possible advantages of this strategy include fewer pulmonary complications, reduced sedative and analgesic use, shorter ICU and hospital LOS, and reduced resource utilization. Early extubation can be especially beneficial in patients with restrictive RV physiology or absent subpulmonary ventricle (cavopulmonary connection with the Fontan procedure). Some centers have employed collaborative learning models to develop clinical guidelines for early extubation practices. Although this improved rates of early extubation, ICU LOS did not change [30]. One notable exception is in the Fontan

patient; not only will spontaneous ventilation improve pulmonary blood flow and CO, fast-track extubation in the operating room (OR) is an important predictor of postoperative LOS [31, 32]. Furthermore, rates of successful early extubation vary across institutions, but increased specialized nursing in the CICU may improve outcomes [33]. NIV, including HFNC or PAP, has also been utilized, particularly in high-risk, postcardiac surgical patients, to mitigate the risk of extubation failure. However, there is limited evidence regarding NIV utilization in pediatric CICUs to inform best practice [34].

Weaning from mechanical ventilation

Weaning from mechanical ventilation is a dynamic process that requires continued reevaluation. While most patients following uncomplicated congenital cardiac surgery will wean without difficulty, some patients with borderline cardiac function and/or residual defects may require prolonged mechanical ventilation and a slow weaning process. As spontaneous ventilation increases during the weaning process, swings in mean intrathoracic pressure may substantially alter afterload on the systemic ventricle. The transition to spontaneous ventilation may cause a sudden increase in wall stress, which then contributes to an increase in end-diastolic pressure and volume, leading to pulmonary edema and low CO. Inotropic agents, vasodilators, and diuretics should be continued throughout the ventilator weaning process and early after extubation to maintain stable ventricular function as mechanical respiratory support is reduced.

The method of weaning is variable. Most patients can be weaned using either a volume-limited or pressure-limited mode by simply decreasing the IMV rate. Guided by physical examination, hemodynamic criteria, respiratory pattern, and arterial blood gas measurements, the mechanical ventilator rate is gradually reduced. Patients with limited hemodynamic and respiratory reserve may demonstrate tachypnea, diaphoresis, and reduced tidal volumes as they struggle to breathe spontaneously against the resistance of the ETT. The addition of pressure- or flow-triggered pressure or volume support breaths above PEEP at a level related to the size of the ETT decreases this resistance and is often beneficial in reducing the work of breathing.

A flow-triggered mode of pressure or volume support, with a backup ventilator rate if the patient becomes apneic (assist-control mode), is particularly useful for neonates and infants who received prolonged ventilation following surgery or have a residual volume or pressure load compromising ventricular function. Patients are often more comfortable weaning in this mode and have reduced work of breathing; the level of pressure support is adjusted according to their gas exchange, respiratory rate, and tidal volume.

Numerous factors can contribute to the inability to wean from mechanical ventilation following congenital heart surgery (Table 36.4). As a general rule, however, suspected residual defects causing either a volume or pressure load must be excluded first by echocardiography or cardiac catheterization.

Table 36.4 Factors contributing to the inability to wean from mechanical ventilation after congenital heart surgery

Residual cardiac defects
• Volume and/or pressure overload
• Myocardial dysfunction
• Arrhythmias
Restrictive pulmonary defects
• Pulmonary edema
• Pleural effusion
• Atelectasis
• Pneumothorax
• Chest wall edema
• Phrenic nerve injury
• Ascites
• Hepatomegaly
Airway
• Subglottic edema and/or stenosis
• Retained secretions
• Vocal cord injury
• Extrinsic bronchial compression
• Tracheobronchomalacia
Metabolic
• Inadequate nutrition
• Diuretic therapy
• Sepsis
• Stress response

Restrictive defects

Pulmonary edema, pleural effusions, and persistent atelectasis may delay weaning from mechanical ventilation. Residual chest and abdominal wall edema, ascites, and hepatomegaly can each limit chest wall compliance and diaphragmatic excursion. Chest tubes and peritoneal catheters may be necessary to drain pleural effusions and ascites, respectively.

If atelectasis persists, bronchoscopy is often useful to remove obstructive secretions and to diagnose any extrinsic compression from enlarged PAs, a dilated left atrium, or conduits. Patients rarely fail from mild mechanical or dynamic airway compression alone and often have contributory residual lesions [35].

Phrenic nerve injury can occur during cardiac surgery secondary to traction, thymic resection, thermal injury from electrocautery, or direct transection as a complication of extensive aortic arch and pulmonary hilar dissection. Diaphragmatic paresis (no motion) or paralysis (paradoxical motion) should be investigated in any patient who fails to wean and extubate successfully [36]. Increased work of breathing, abnormal respiratory mechanics, increased $PaCO_2$, and/or an elevated hemidiaphragm on chest radiograph following extubation (i.e., off positive pressure support) are all consistent with diaphragmatic dysfunction. Ultrasonography or fluoroscopy is used to confirm abnormal diaphragmatic movement. For an accurate diagnosis, these imaging investigations must be performed off positive pressure support. Additional discussion of airway management, ventilation, and extubation strategies is presented in Chapters 23 and 24.

Fluids and nutrition

Fluid restriction and aggressive diuretic therapy are commonly used early after cardiac surgery with CPB and can result in metabolic disturbances and insufficient nutritional intake. A hypochloremic, hypokalemic metabolic alkalosis with

AL Grawany

secondary respiratory acidosis is a common complication from high-dose loop diuretic use and can delay the ventilator weaning process. The need for and dosing of diuretic agents should be continually reevaluated. Furthermore, many patients will have limited reserve secondary to preoperative failure to thrive; maintaining adequate nutrition/caloric intake is challenging, given the catabolic state of patients early after surgery with CPB.

Analgesia and sedation

Adequate analgesia and sedation are necessary to optimize synchronization with the ventilator and maintain hemodynamic stability as well as provide comfort. Depending on the age of the patient, the magnitude of the operation, any residual defects, and the preoperative condition, there is potential for both escalation and prolongation of these requirements.

Appropriate analgesia can often be provided with a low-dose opioid infusion. Although escalation may seem necessary based on clinical concerns, in particular hypertension or tachycardia, these are often secondary to inadequate sedation rather than from pain. A benzodiazepine or nonopioid drug such as dexmedetomidine is useful in these circumstances. The appropriate drug must take into account the anticipated duration of mechanical ventilation and the need to titrate rapidly to drug effect. When early extubation is planned, short-acting adjuncts such as dexmedetomidine, ketorolac, and acetaminophen are useful [37]. A propofol infusion can be a helpful strategy in selected patient groups for whom agitation during rapid weaning is a sign of intolerance to airway stimulation as opposed to failure to wean from other causes. However, a propofol infusion must be used with caution because of potential hemodynamic complications and the risk of propofol infusion syndrome [38]. Oversedation can impair the weaning process because of somnolence, leading to hypoventilation, failure to trigger the ventilator, and inability to protect the airway.

For patients who have required mechanical ventilation for several days to weeks, and, therefore, received higher cumulative doses and a range of analgesic and sedative medicines, rapid weans from analgesics and sedatives can result in withdrawal symptoms. These symptoms can often be confused with pulmonary or cardiac reasons for failure to wean, as respiratory and hemodynamic symptoms may predominate. It is important to have a systematic analgesia/sedation weaning protocol that incorporates the timing of weaning with objective withdrawal assessment and knowledge of pharmacokinetics [39].

Sepsis

Sepsis is a particular risk following cardiac surgery for a number of reasons, including the immunomodulating effects of CPB, risk factors such as an open sternum, the use of vascular catheters for invasive monitoring and IV medications, and liberal use of broad-spectrum antibiotics. Sepsis can be a cause of failure to wean from mechanical ventilation because of its systemic effects, the associated increased work of breathing, and the imbalance between oxygen demand and delivery.

Airway

Bronchospasm can complicate mechanical ventilation and the weaning process. While this may reflect intrinsic airway disease, bronchospasm can also result from increased airway secretions, airway infection, and extrinsic airway compression. Treatment with inhaled or systemic bronchodilators may be beneficial, although they should be used with caution because of their chronotropic and tachyarrhythmic potential.

The sudden onset of bronchospasm with increased peak inspiratory pressure and difficulty with hand ventilation should raise the immediate concern for acute ETT obstruction or tension pneumothorax. Bronchospasm in patients with labile PVR may reflect acute pulmonary hypertension, and treatment is directed at maneuvers to lower PVR and improve systemic CO.

Postextubation stridor may be due to mucosal swelling of the large airway, and treatment with dexamethasone before extubation can be beneficial to reduce edema in patients who have required prolonged use of an ETT. Stridor following extubation can initially be treated with nebulized epinephrine, which promotes vasoconstriction and decreases airway hyperemia and edema. If reintubation is necessary, a smaller ETT should be used.

Vocal cord paresis or paralysis can result from surgical trauma to the recurrent laryngeal nerve and can be a cause of upper airway obstruction. Surgery on or near the aortic arch (e.g., repair of coarctation or interrupted aortic arch, and Norwood stage I palliation) is a risk factor for this injury, with symptoms ranging from weak or hoarse cry to significant upper airway obstruction requiring tracheal intubation. Diagnosis is typically made with either awake flexible nasolaryngoscopy or laryngeal ultrasound of the neck; both imaging procedures can be performed at the bedside [40].

The ability to clear secretions and the potential for nosocomial infection are additional concerns in patients who have been ventilated for an extended period of time. Inability to clear secretions because of sedation, bulbar and vocal cord dysfunction, ineffective cough following prolonged intubation, and poor nutritional state with muscle fatigue will result in atelectasis and respiratory failure. Frequent chest physiotherapy and nasopharyngeal suction are beneficial, provided that patients are hemodynamically stable with adequate gas exchange. Furthermore, the use of nasopharyngeal CPAP and/or HFNC can be beneficial by reducing the work of breathing; however, these patients have limited reserve, and frequent reassessment is essential.

KEY POINTS: AIRWAY AND VENTILATION IN CHD

- The lowest PVR is achieved by ventilating around FRC.
- PPV will reduce RV output by reducing preload and increasing RV afterload. This may be clinically deleterious in patients without a subpulmonary pumping chamber or with a restrictive RV.
- PPV will reduce work of breathing, LV afterload, and myocardial work.
- Failure of ventilator weaning can be due to a residual cardiac lesion or can be noncardiac in origin.

Myocardial dysfunction and hemodynamic monitoring

Assessment of cardiac output

The accurate assessment of the postoperative patient's CO should be a focus of management in the CICU. Recognition and effective management of LCOS is critical, as this clinical entity is associated with increased morbidity, including longer duration of mechanical ventilatory support and CICU/hospital LOS, and mortality [41, 42]. Data from physical examination, routine laboratory testing, bedside hemodynamic and electrophysiologic monitoring, echocardiography, and occasionally bedside CO determination are typically sufficient to manage patients optimally. If patients are not progressing as expected and low CO persists, a systematic evaluation for residual lesions should occur. The imaging assessment for residual lesions typically occurs noninvasively first by echocardiography, with the addition of computed tomographic (CT) angiography, if needed. When a more complete assessment with direct hemodynamic measurements is required, then cardiac catheterization should be undertaken.

The systemic CO is defined as the product of ventricular stroke volume (in L/beat) multiplied by heart rate (in beats/min). The ventricular stroke volume is determined chiefly by three factors: afterload (the resistance to ventricular emptying), preload, and myocardial contractility. CO is usually indexed to body surface area (BSA, in m^2) because it is a function of body mass. Thus, CO/BSA is designated as cardiac index (CI, in $L/min/m^2$). The CI varies inversely with age: normal values in children at rest are 4.0–5.0 $L/min/m^2$, whereas the normal resting CI at age 70 years is 2.5 $L/min/m^2$ [43, 44].

Postoperative patients with low CO can present with a variety of abnormalities on physical examination, bedside monitoring, and laboratory assessment. These manifestations of low CO are listed in Table 36.5. Clinical signs on examination include cool extremities and diminished peripheral perfusion, tachycardia, hypotension, oliguria, and hepatomegaly. An increase in the arterial to mixed venous oxygen saturation (A-VO_2) difference of >30% and a lactic acidosis provide biochemical evidence for low CO. The atrial pressure is a useful measure to follow, and either an increase or decrease could be observed in LCOS. Factors that should be considered when evaluating the atrial pressure following surgery are shown in Table 36.6.

The mechanism(s) underlying low CO in a specific patient can be related to either one or a combination of factors following surgery. Strategies for treating the patient with a low CO should focus on optimizing the balance between oxygen consumption (VO_2) and delivery (DO_2). In LCOS, oxygen and metabolic demand should be minimized by maintaining an adequate depth of analgesia and sedation, including chemical paralysis, in order to avoid movement, reduce muscle tone, and limit oxygen consumption. Strict avoidance of hyperthermia from any cause is essential, and in some circumstances, mild hypothermia may be preferable, although the effect of peripheral vasoconstriction and increase in SVR from hypothermia could have an adverse impact on myocardial wall stress and oxygen requirements.

Table 36.5 Manifestations of low cardiac output

Physical examination
- Mental status: lethargy or irritability
- Vital signs:
  - Core hyperthermia (often associated with peripheral vasoconstriction)
  - Tachycardia or bradycardia
  - Tachypnea
  - Hypotension (for age and weight)
  - Narrow pulse pressure
- Peripheral perfusion:
  - Pale or mottled skin color and cool skin temperature
  - Prolonged (>3 seconds) distal extremity capillary refill time
  - Poorly palpable pulses
- Signs of congestive heart failure:
  - Failure to thrive, poor feeding, and diaphoresis
  - Increased respiratory work, chest wall retractions
  - Tachypnea, grunting, nasal flaring
  - Gallop rhythm
  - Hepatomegaly

Bedside monitoring data
- ECG tracing: rhythm other than normal sinus
- Arterial waveform: blunted upstroke and narrow pulse pressure
- Atrial pressure change: see Table 36.6
- Urine output:
  - <1.0 mL/kg/hour in neonates, infants, and children
  - <25 mL/hour in older patients

Laboratory and radiographic data
- SvO_2: decreased (<65–70%) with an increased (>30%) A-VO_2 difference
- Acid–base balance:
  - Metabolic acidosis with increased anion gap
  - Increased arterial lactate (>2.0 mmol/L)
- Electrolytes:
  - Hyperkalemia
  - Elevated BUN and Cr
  - Increased liver transaminases
- Chest radiography:
  - Cardiac enlargement
  - Abnormal (increased or decreased) pulmonary blood flow
  - Pulmonary edema

A-V, arteriovenous; BUN, blood urea nitrogen; Cr, creatinine; SvO_2, systemic venous oxygen saturation.

Surgical factors

Residual or unrecognized defects

A thorough understanding of the underlying cardiac anatomy, surgical findings, and surgical procedures is essential because this will direct the initial postoperative evaluation and examination. Residual lesions may be evident by auscultation, intracardiac pressures and waveforms, and oxygen saturation data. For example, a large V-wave on the left atrial waveform may indicate significant residual mitral valve regurgitation. An increase (step-up) of the right atrial-to-PA oxygen saturation of more than 10% may indicate a significant intracardiac shunt across a residual VSD [45].

AL Grawany

Table 36.6 Factors that should be considered when the measured atrial pressure is outside of the anticipated range

Increased atrial pressure
- Increased ventricular end-diastolic pressure
  - Decreased ventricular systolic or diastolic function
  - Myocardial ischemia
  - Ventricular hypertrophy
  - Ventricular outflow obstruction
  - Semilunar valve disease
- Mitral or tricuspid valve disease
- Large left-to-right anatomic shunt
  - Residual ventricular septal defect
  - Systemic-to-pulmonary artery connection
- Chamber hypoplasia
- Intravascular or ventricular volume overload
- Cardiac tamponade
- Dysrhythmia
  - Tachyarrhythmia
  - Complete heart block
- Artifactual
  - Catheter tip not in the atrium (e.g., in a ventricle, internal jugular vein, or wedged in pulmonary vein)
  - Pressure transducer below level of heart or improperly calibrated or zeroed
  - Concomitant drug infusions through the atrial line

Decreased atrial pressure
- Inadequate preload
- Artifactual
  - Catheter malfunction (e.g., cracked or clotted)
  - Pressure transducer above level of heart, or improperly calibrated or zeroed

However, if there are significant concerns for important residual lesions that are compromising CO and ventricular function, further evaluation with echocardiography and/or cardiac catheterization should be considered. Imaging of the heart may be difficult immediately after surgery because of limited transthoracic access and acoustic windows (e.g., due to chest tubes). During transthoracic echocardiography, it is important that hemodynamics are closely observed, because inadvertent pressure applied with the transducer may adversely affect filling pressures and mechanical ventilation. Similarly, vigorous antegrade flexion of a transesophageal echocardiography probe may induce pulmonary hypertension by altering left atrial filling due to partial obstruction of a mainstem bronchus.

Although surgery may be routine for many uncomplicated defects such as ASD closure, the approach for more complex intracardiac repairs may cause specific postoperative problems. For example, if a right ventriculotomy is performed to close the VSD in a patient with TOF, RV dyskinesia and poor contraction may be apparent. On the other hand, if a transatrial approach had been used to close the VSD in the same patient, the risk for atrioventricular valve injury or dysrhythmias, such as junctional ectopic tachycardia and heart block, is increased. Often unexpected findings or technical difficulties at the time of surgery mean that modifications to the approach or procedure are necessary. A difficult procedure may lead to a longer time on CPB or additional traction on cardiovascular structures.

Complications related to surgery

Failure of adequate hemostasis may expose the patient to significant volumes of transfused blood products, and if there is inadequate drainage via chest tubes placed at the time of surgery, the risk for cardiac tamponade is significant. This may be an acute event, but more commonly, it is evident by progressive hypotension with a narrowing pulse width, tachycardia, an increase in filling pressures, and reduced peripheral perfusion with possible evolving metabolic acidosis. A sudden decrease in chest tube drainage (e.g., caused by an obstructive clot) should raise the suspicion for the potential of tamponade. This is primarily a clinical diagnosis, and treatment (i.e., opening of the sternum and potential need for chest washout and/or clot removal) should not be delayed while waiting for echocardiographic confirmation.

Myocardial ischemia from inadequate coronary perfusion is often an under-appreciated event in the postoperative pediatric patient. Nevertheless, there are a number of circumstances in which ischemia may develop, compromising ventricular function and CO. Myocardial ischemia may occur intraoperatively because of problems with cardioplegia delivery or insufficient hypothermic myocardial protection, and from intracoronary air embolism. In the CICU setting, mechanical obstruction of the coronary circulation is usually the cause of myocardial ischemia rather than coronary vasospasm. Examples include extrinsic compression of a coronary artery by an outflow tract conduit, annulus of a prosthetic valve or chest tube, and kinking or distortion of a transferred coronary artery button. While electrocardiogram (ECG) changes may indicate ischemia (e.g., ST-segment abnormalities), a sudden increase in left atrial pressure or sudden onset of a dysrhythmia such as ventricular fibrillation or complete heart block may be an earlier warning sign.

Cardiopulmonary bypass and the systemic inflammatory response

The effects of prolonged CPB relate in part to the interactions of blood components with the extracorporeal circuit. This is magnified in children due to the large bypass circuit surface area and priming volume relative to patient blood volume. Humoral responses include activation of complement, kallikrein, eicosinoid, and fibrinolytic cascades; cellular responses include platelet activation and an inflammatory response, with an adhesion molecule cascade stimulating neutrophil activation and release of proteolytic and vasoactive substances [46–49].

The clinical consequences can include increased interstitial fluid, generalized capillary leak, and potential multiorgan dysfunction. Total lung water is increased with an associated decrease in lung compliance and increase in A-aO_2 gradient; some of these effects can be attenuated by hemofiltration or modified hemofiltration in the operating room (OR) [50, 51]. Myocardial edema results in impaired ventricular systolic and diastolic function. A secondary fall in CO by 20–30% is common in neonates in the first 6–12 hours following the arterial switch operation, contributing to decreased renal function and oliguria [52]. Sternal closure may need to be delayed due to mediastinal edema and associated cardiorespiratory compromise when closure is attempted. Ascites, hepatic congestion, and bowel edema may affect mechanical

ventilation as well as intestinal function (e.g., a prolonged ileus causing a delay in enteral feeding). A coagulopathy post-CPB may contribute to delayed hemostasis. The clinical manifestation of some of these issues may be attenuated with the lower priming volumes and higher hematocrits used on modern bypass circuits (see Chapter 12 for a detailed discussion of the inflammatory response to CPB).

Dysrhythmias

The ECG is an essential component of the initial postoperative evaluation because the CICU team must identify whether the patient is in sinus rhythm early in the recovery period. If the rhythm cannot be determined with certainty from a surface 12- or 15-lead ECG, temporary epicardial atrial pacing wires, if present, can be used with the limb leads to generate an atrial ECG [53]. Also, right and left atrial waveforms are useful in diagnosing atrioventricular synchrony (see Chapter 13). Temporary epicardial atrial and/or ventricular pacing wires are routinely placed in many patients to allow mechanical pacing if sinus node dysfunction or heart block should occur in the early postoperative period. Because atrial wires are applied directly to the atrial epicardium, the electrical signal generated by atrial depolarization is significantly larger and thus easy to distinguish compared with the P-wave on a surface ECG. Sinus tachycardia, which is common and often secondary to medications (e.g., sympathomimetics), pain and anxiety, or diminished ventricular function, must be distinguished from a supraventricular, ventricular, or junctional tachycardia. Any of these tachyarrhythmias can lower CO by either compromising diastolic filling of the ventricles or depressing their systolic function [54, 55]. High-grade second- and third-degree (or complete) heart block can diminish CO by producing either bradycardia or loss of atrioventricular synchrony or both. Third-degree block is transient in approximately one-third of cases. If it persists beyond postoperative days 9–10, it is unlikely to resolve, and a permanent pacemaker is indicated (see Chapter 22) [56].

Low preload

The diagnosis of insufficient preload is usually made by monitoring the mean atrial pressure or central venous pressure. The most common cause in the CICU is hypovolemia secondary to blood loss from postoperative bleeding. Initially after surgery and CPB, the filling pressures may be in the normal range or slightly elevated, but this often reflects a more centralized blood volume secondary to peripheral vasoconstriction and venoconstriction following hypothermic CPB. As the patient continues to rewarm and vasodilate in the CICU, additional intravascular volume may be necessary to maintain an adequate circulating blood volume and preload. There may also be significant third-space fluid loss in neonates and small infants who manifest the greatest systemic inflammatory response following CPB. The "leaking" of fluid from vessels into serous cavities (e.g., ascites) and the extracellular space (peripheral edema that can progress to anasarca) requires that these patients receive close monitoring and volume replacement to maintain an adequate circulating blood volume. Patients with a hypertrophied or poorly compliant ventricle, and those with lesions dependent on complete mixing at the atrial level, also often require additional preload in the early postoperative period.

High afterload

Elevated afterload in both the pulmonary and systemic circulations frequently follows surgery with CPB [52, 57]. Excessive afterload in the systemic circulation (elevated SVR) results in diminished CO and is typically manifest by decreased peripheral perfusion and cool extremities. Treatment of elevated SVR includes recognizing and improving conditions that exacerbate vasoconstriction (e.g., pain and hypothermia) and administering a vasodilating agent. A vasodilator, which can be a phosphodiesterase inhibitor (e.g., milrinone), a nitric oxide donor (e.g., nitroprusside), a calcium channel blocker (e.g., nicardipine), or a peripheral α-receptor antagonist (e.g., phenoxybenzamine or phentolamine), can be added to an inotropic agent such as epinephrine to augment CO. Neonates, who tolerate increased afterload less well than older infants and children, appear to derive particular benefit from afterload reduction therapy [58–60].

Decreased myocardial contractility

Because decreased myocardial contractility occurs frequently after reparative or palliative surgery with CPB, pharmacologic enhancement of contractility is used routinely in the CICU. Before initiating treatment with an inotrope, however, the patient's intravascular volume status, serum-ionized Ca^{2+} level, and cardiac rhythm should be considered. Inotropic agents enhance CO more effectively if preload is adequate, so IV colloid or crystalloid administration should be given if preload is low. If hypocalcemia (normal serum-ionized Ca^{2+} levels are 1.14–1.20 mmol/L) is detected, supplementation with IV calcium gluconate or calcium chloride is appropriate, because Ca^{2+} is a potent positive inotrope itself, particularly in neonates and young infants. Supranormal supplementation of calcium should be avoided, however, as increased levels of diastolic myocardial calcium are potentially cytotoxic [61].

Dopamine is often the first-line agent used to treat either mild hypotension (10–20% decrease in normal mean arterial blood pressure for age) or moderate hypotension (20–30% decrease in normal mean arterial blood pressure for age). This sympathomimetic agent promotes myocardial contractility by elevating intracellular Ca^{2+}, both via direct binding to myocyte β_1 adrenoceptors and by increasing norepinephrine levels. Dopamine is administered by a constant infusion because of its short half-life, and a usual starting dose for inotropy is 5 μg/kg/min. At a dose >5 μg/kg/min, dopamine should ideally be infused through a central venous catheter to avoid superficial tissue damage if extravasation were to occur. The dose is titrated to achieve the desired systemic blood pressure, although some patients, especially older children and adults, may develop an undesirable dose-dependent tachycardia. The challenge with dopamine is its simultaneous effects on β, α, and dopaminergic receptors, often resulting in undesired rhythm disturbances despite maintaining an adequate blood pressure [62]. For this reason, low-dose epinephrine, up to 0.05 μg/kg/min, is also a useful first-line inotropic agent, and it may have fewer

AL Grawany

arrhythmogenic side effects than dopamine in pediatric patients. If a patient does not respond adequately to dopamine up to 10 μg/kg/min or has severe hypotension (more than 30% decrease in mean arterial blood pressure for age), treatment with epinephrine should be considered.

Epinephrine may also be used as a first-line agent to treat mild-to-moderate hypotension. It should be given exclusively via a central venous catheter. A typical starting dose is 0.01–0.05 μg/kg/min with subsequent titration of the infusion to achieve the target systemic blood pressure. At high doses (i.e., ≥0.2 μg/kg/min), epinephrine can produce significant renal and peripheral vasoconstriction, tachycardia, and excessive myocardial oxygen demand (chronotropic and vasopressor effects) [58]. Patients with severe ventricular dysfunction who require persistent or escalating doses of epinephrine >0.15–0.2 μg/kg/min may benefit from opening of the sternum and/or should be evaluated for the possibility of mechanical circulatory support with a ventricular assist device (VAD) or extracorporeal membrane oxygenation (ECMO).

Norepinephrine is a direct-acting α agonist that primarily causes arteriolar vasoconstriction, but it also has positive inotropic actions. At doses of 0.01–0.2 μg/kg/min, it can be considered in patients with severe hypotension and low SVR (e.g., "warm" or "distributive" shock), inadequate coronary artery perfusion, or inadequate pulmonary blood flow with a systemic-to-PA shunt. It is also useful in patients with preserved systemic ventricular function but failing or inadequate RV contractility (PVOD or postoperative TOF with restrictive RV physiology). In patients with normal hearts, variation in afterload is accommodated by varying stroke volumes and contractility; the normal heart works at peak efficiency and contractility exceeds afterload. This increased contractility is also transferred to the RV through the shared intraventricular septum. The increased afterload also improves the filling characteristics of the LV (by shifting of the interventricular septum) and augments RV coronary perfusion (especially in systemic RV pressure where the RV is now dependent exclusively on diastolic aortic root pressure for coronary perfusion). In the failing heart and in patients with limited ventricular reserve, an increase in afterload may not be matched by an increase in contractility, with a resultant fall in CO.

There can be a decrease in responsiveness to increasing doses of catecholamines over time; vasopressin at a dose of 0.1–0.5 mu/kg/min is a potent vasopressor that may help improve the hemodynamics in advanced shock without compromising cardiac function or other adverse sequelae [63].

A combination of epinephrine at lower doses (e.g., <0.1 μg/kg/min) or dopamine with an IV afterload reducing agent, such as milrinone, can help support patients with significant ventricular dysfunction accompanied by elevated afterload. Milrinone inhibits cyclic nucleotide phosphodiesterase III, thereby increasing cAMP, which results in an increased intracellular calcium concentration. In addition to acting as a positive inotrope, increased cAMP relaxes the systemic vasculature, leading to a decrease in afterload as well as a decrease in PVR [59]. The use of milrinone after neonatal and pediatric cardiac surgery has increased significantly over the past 15 years, in part due to the results of a double-blind, placebo-controlled multicenter trial that demonstrated a significant decrease in the incidence of LCOS (milrinone dose 0.75 mcg/kg/min) compared to placebo after infant and pediatric corrective heart surgery [42]. A more recent meta-analysis evaluating the use of prophylactic milrinone in children undergoing surgery for congenital heart disease found that while there is some evidence it may lower the risk for LCOS, there is currently insufficient evidence to conclude that milrinone helps prevent LCOS or mortality [64].

Patients who have the clinical features of relative adrenal insufficiency may benefit from stress steroid therapy [65, 66]. This is primarily a clinical finding of poor vascular tone with persistent hypotension and volume requirement that is refractory to increasing inotrope and/or vasopressor support. The serum cortisol level may be low or show a limited response to adrenocorticotropic hormone stimulation testing [67]; however, the ranges of normal have not been established for pediatric patients after cardiac surgery, in particular for newborns and infants. There is no consistent correlation between serum cortisol level and the incidence of LCOS; nevertheless, stress doses of hydrocortisone (50 mg/m^2/day) have been associated with increased systemic blood pressure and lower inotrope scores, although they have not been definitively demonstrated to improve eventual survival. A recent randomized controlled clinical trial also demonstrated that prophylactic, postoperative hydrocortisone infusion reduces the prevalence of LCOS after neonatal CPB [68]. The increased risk for infection and poor wound healing associated with stress dosing of steroids has led to a recommendation for shorter periods of administration (e.g., over 3–5 days) rather than continuing with a long taper [69].

Hypothyroidism is another cause for a persistent LCOS after cardiac surgery. Triiodothyronine (T_3) levels have been demonstrated to be low after CPB and may remain low for up to 5 days after surgery, particularly if a sick euthyroid state develops and there is decreased conversion of thyroxine (T_4) to the biologically active T_3 in peripheral tissues [70, 71]. A pediatric randomized controlled trial evaluating protocolized treatment with T_3 (two doses of 0.4 μg/kg during surgery and three doses of 0.2 μg/kg at 3, 6, and 9 hours after cross-clamp release) demonstrated improvements in ejection fraction and time to extubation, specifically in patients younger than 5 months [72].

Delayed sternal closure

Sternal closure following cardiac surgery can restrict cardiac function and also interfere with efficient mechanical ventilation. This is particularly important for neonates and infants, in whom considerable capillary leak and edema can develop following CPB, and in whom cardiopulmonary interactions have a significant impact on immediate postoperative recovery. In the OR, mediastinal edema, unstable hemodynamic conditions from both systolic and diastolic dysfunction, and ongoing bleeding are indications for delayed sternal closure, although it may also be considered semi-electively for patients in whom hemodynamic or respiratory instability is anticipated in the immediate postoperative period (e.g., following a modified Norwood procedure for HLHS). Urgent reopening of the sternum in the CICU following surgery is associated with higher mortality compared with leaving the sternum open in the OR [73], and successful sternal closure

can be achieved for most patients by postoperative day 4 with a low risk of surgical site infection [74]. Patients in whom this cannot be achieved and who have additional risk factors (e.g., neonate, need for ECMO, modified Norwood procedure) have an 11% superficial sternal infection (SSI) rate and significantly greater mortality [75]. Additional discussion of hemodynamic management is presented in Chapter 21.

KEY POINTS: MYOCARDIAL DYSFUNCTION AND HEMODYNAMIC MONITORING

- Low CO may be related to residual lesions, myocardial dysfunction, or a systemic inflammatory reaction related to bypass.
- LCOS may result from adverse effects on rhythm, preload, afterload, or myocardial contractility.
- Restoration of circulating volume and vasoactive agents are the first-line therapies. Corticosteroids and thyroid supplementation are the second-line adjuncts.

Cardiopulmonary resuscitation in the cardiac intensive care unit

Pediatric in-hospital cardiac arrest (IHCA) has been a rapidly evolving field of research over the past two decades. Compared to studies in the early 2000s, more recent results show that survival after pediatric IHCA has improved from ~15 to ~40%, largely highlighting an improvement in pediatric resuscitation care. Specifically, the factors contributing to this progress include the following: 1) clinical practice guidelines focused on vigilance and monitoring in the ICU setting, allowing for earlier recognition and prompt initiation of resuscitation efforts; 2) an increase in institutional and national quality improvement efforts surrounding resuscitation care; 3) a focus on cardiopulmonary resuscitation (CPR) quality metrics; and 4) the increased utility of extracorporeal-CPR (E-CPR) to achieve return of circulation [76]. Recognition of the high likelihood for cardiac arrest (CA) and need for CPR are among the primary reasons for creating specialized cardiac units (CICUs) and teams (e.g., ones led by pediatric cardiac intensivists). Although rates of CA remain higher in the CICU compared to the noncardiac pediatric ICU (PICU) population (3.1 vs. 1.8%) [77–79] and SC (those in the CICU following cardiac surgery) patients demonstrate higher rates of CA, they have improved outcomes compared to noncardiac groups. Furthermore, SC patients also have improved CA rates and outcomes when compared to MC (those in the CICU without preceding cardiac surgery) patients [78–80]. Improved outcomes in SC groups are believed to be related to the likelihood of more invasive monitoring in the postoperative CICU setting, younger age of SC groups at the time of arrest (greater age-related chest wall compliance allowing for better CPR quality), lower likelihood of preexisting conditions, noncardiac organ dysfunction, and an increased likelihood of E-CPR deployment during CPR [80, 81].

The ability to rescue a patient from a decompensation event is often used as a metric of unit, team, and system performance, and it requires the thorough exchange of information, high-quality monitoring and resuscitative measures, and specific resources immediately available to facilitate resuscitation such as E-CPR. However, perhaps a better metric may be the ability of a team to anticipate and/or recognize an evolving clinical picture of decompensation and prevent a critical event from occurring in the first place. Ongoing quality improvement initiatives among CICUs across the United States in recent years have facilitated improved outcomes after cardiac surgery in the CICU through data-sharing and collaborative learning models [82].

A CPR event often progresses through five phases. It is important to recognize the phase of care at any given moment, as a vital therapeutic action in one phase may be detrimental in a subsequent phase.

Prearrest phase: monitoring and event risk reduction

The first role of critical care teams is to identify patients at risk for decompensation and cohort them in the ICU where continuous anticipatory monitoring is possible. This is straightforward for most postoperative SC patients, but it becomes challenging for those patients who require interhospital transport or for those patients in the emergency department or hospital acute care units. A rapid response team (RRT) or medical emergency team (MET) that is based out of the ICU is a useful resource to allow transition of a critically ill child to the ICU prior to a CA [83–86]. Invasive (central venous and arterial blood pressure) hemodynamic monitoring combined with pulse oximetry and continuous ECG monitoring are the basics for any critically ill patient (medical or surgical). The importance of hemodynamic trends (e.g., progressive tachycardia and a narrowing pulse pressure) and frequent confirmation by physical examination cannot be overemphasized. A low invasive arterial blood pressure in a patient with poor central and peripheral pulses on clinical examination is likely to be real, and these findings should not be attributed to a technical problem with the monitoring system [87]. Additional monitoring by blood gas, lactate, and central venous oxygen sampling coupled with echocardiography allow static and dynamic trend assessments, which can support the impression provided by physical examination and basic monitoring [88–90]. NIRS does not rely on pulse detection, and it is thus useful in patients with a low CO state who are at increased risk for CA [91].

The use of capnography to monitor end-tidal CO_2 ($ETCO_2$) is especially valuable in patients with marginal CO or tenuous pulmonary blood flow dependent on an aortopulmonary shunt. Dramatic reductions (or loss) in $ETCO_2$ signals/tracings can be the first indicator of the prearrest state or critical shunt obstruction [87].

Although LCOS can often be managed preemptively using inotropic agents (see earlier sections), patients at risk for rapid deterioration often benefit from having low-dose IV boluses of either epinephrine (1 mcg/kg or 0.1 mL/kg of 1 : 100,000 solution) or phenylephrine (5 mcg/kg), followed by initiation of vasoactive infusions. Provision of these agents, which can be premixed and kept at the bedside for

AL Grawany

urgent administration per established indications, may rescue a patient with an acutely failing circulation and prevent a CA, thereby allowing time for other interventions such as sternal reopening or commencement of mechanical circulatory support before the need for CPR.

Formation of formal resuscitation teams with clearly defined leadership, structure, roles, and expectations with a focus on CPR quality metrics and compliance with CPR guidelines is an important prerequisite in any critical care environment. Frequent simulation of resuscitation events is another key component to prearrest and arrest performance [92–94].

Arrest phase: no-flow and low-flow states

The arrest phase consists of the "no-flow" phase of untreated CA and the "low-flow" phase during which CPR is initiated to achieve coronary and cerebral perfusion via administration of chest compressions and code-dose IV epinephrine (0.1 mg/kg of 1 : 10,000 solution) [95]. The goal is to recognize a loss of perfusing rhythm early in the event. Although the presence of an arterial pressure waveform and capnographic tracing can imply some amount of CO, the absence of palpable pulses is the *sine qua non* of CA. Uncertainty or vagueness with pulses should lead the team to err toward rapid, appropriate administration of CPR.

Maneuvers indicated in the arrest phase follow Pediatric Advanced Life Support (PALS) guidelines [96] that include, but are not limited to, the following: (i) securing an advanced airway (if not already present) while minimizing interruptions to chest compression [97]; (ii) provision of appropriate levels of supplemental oxygen; (iii) reducing over-ventilation to limit intrathoracic pressure increases and optimize cardiac preload during chest recoil; (iv) providing hard and fast cardiac compressions while allowing appropriate chest recoil, with the goal of maintaining diastolic blood pressure targets (if invasive blood pressure monitoring is already available) of 25 mmHg in infants and 30 mmHg in children over 1 year and an $ETCO_2$ of 20 [98]; (v) administering appropriate pharmacologic therapies, including early administration of code-dose epinephrine [99]; (vi) evaluating and intervening for inadequate lung (pneumothorax) or cardiac (tamponade) filling with needle thoracentesis and pericardiocentesis, respectively; and (vii) assessing for shockable rhythms early in resuscitation [100]. These therapies are continuously considered while assessing the response to interventions from objective monitoring (invasive arterial waveforms and quantitative $ETCO_2$) while minimizing interruptions in CPR.

There are unique differences compared to the PALS guidelines in the conduct of CPR in patients with specific types of CHD. This is particularly the case in patients with single ventricle physiology and a cavopulmonary connection. Sufficient time during chest recoil is needed to allow for pulmonary and cerebral blood flow. Even optimal closed-chest CPR results in cerebral blood flow that only approaches 25–30% of normal [101]. In children with pulmonary hypertension due to elevated PVR experiencing IHCA, ventilating with inhaled nitric oxide during CPR should be strongly considered to promote both forward flow/CO and gas exchange during resuscitation. Patients with significant atrioventricular valve regurgitation, semilunar valve regurgitation, outflow tract obstruction, and restrictive cardiac physiology may still not achieve adequate coronary and cerebral perfusion despite high-quality CPR [102, 103]. For patients in whom the likelihood of achieving high-quality CPR for specific cardiac lesions is low, and return of spontaneous circulation (ROSC) is not achieved early in resuscitation, early mobilization and deployment of E-CPR should be considered. Its use has been associated with improved outcomes when compared to conventional CPR in the CICU population [103–105]. Other advanced interventions, such as sternal reopening in SC patients early after sternotomy, also need to be considered. When mobilized early, open chest CPR can result in improved cerebral and coronary blood flows, and it has been associated with reasonable neurologic outcomes in survivors [106–108].

Postresuscitation phase: patient-focused care

After attaining hemodynamic stability, the goal of this phase is to optimize systemic oxygen and nutrient delivery (e.g., placing chest/pericardial drains; pacing the atria, ventricles, or both to achieve a desired heart rate and rhythm; optimizing vasoactive agents; replacing lost blood volume; and initiating mechanical support, if indicated) while minimizing systemic oxygen consumption requirements (e.g., adequate sedation, muscle relaxation, avoidance of hyperthermia). Based on the degree of global cerebral ischemic insult suspected, the institution of neuroprotective measures (such as normothermia, euglycemia, $PaCO_2$ goal of 35–40 mmHg, hypernatremia [serum Na > 140 mEq/L], appropriate cerebral perfusion pressures for age, seizure control, and electroencephalogram [EEG] monitoring) may be indicated to achieve the best possible neurologic outcome. Central nervous system (CNS) imaging (e.g., cranial ultrasound and brain CT and/or magnetic resonance imaging [MRI]) is typically performed and may assist in neurologic prognosis and further management postarrest [96, 109–111].

A vital part of this phase is to assess the cause for the arrest and initiate measures to prevent a recurrence. The event may have been predictable based on a difficult postoperative course and consideration given early for resuscitation with ECMO. In contrast, the event may have been unanticipated and further investigation is required, such as by a cardiac catheterization or return to the OR. It is important to discuss the appropriateness of potential interventions and, in some cases, to recognize situations that have become futile. These are not only appropriate discussions to have with relevant members of the medical/surgical team and subspecialty consultants, if involved, but also the child's parents/guardians [112–114].

Postresuscitation phase: team debriefing

Once a patient is stabilized and a care plan is devised and implemented, a postresuscitation team debriefing of the CA event is recommended in the resuscitation guidelines in order to improve future resuscitation team performance [103, 115]. This debriefing can be easy to overlook in a busy intensive care environment, but it is very important to include it as

part of the resuscitation effort. Its purposes are to provide feedback on areas for individual and team improvement for future events and to identify areas for quality improvement in an institution's resuscitation process. The ability to recognize any deficiencies, improve performance, and prevent future CAs is contingent on providing this systematic debriefing process with the team members in a safe and collegial environment [116–120]. Key aspects for broader dissemination (including process, personnel, and communication issues) should be documented (anonymously) in an effort aimed at continual performance improvement.

With the use of surveillance, team coaching through simulation, early detection of the prearrest state, establishment of rapid response services, optimizing team dynamics and performance during an arrest event, instituting mechanical circulatory support options early, if indicated, providing appropriate post-ROSC care, and performing periodic quality reviews of resuscitation events, a CICU can achieve improvements in rates/responses/outcomes of CA events. See Chapter 25 for additional detailed discussion of CA and resuscitation.

Management of postoperative complications

One of the most common features of the early postoperative course in the CICU is LCOS. Most often, the nadir of CO occurs at ~9–12 hours postoperatively, and it is precipitated by a mismatch in oxygen delivery and demand in the setting of post-bypass myocardial dysfunction, systemic inflammation, ischemia–reperfusion injury, electrolyte derangements, possible residual cardiac lesions, and derangements of the neurohormonal axis [121]. Therapies for LCOS generally involve inotropic agents, lusitropic agents, volume resuscitation, hydrocortisone administration, and minimizing oxygen demand while optimizing oxygen delivery [68, 122, 123]. Early postoperative bleeding can be another complication with varying etiologies related to preoperative and intraoperative factors; it requires close monitoring in the early postoperative period and replacement with blood products (e.g., packed red blood cells, fresh-frozen plasma, cryoprecipitate) if it exceeds designated threshold rates [124, 125]. Advanced procoagulant therapies (e.g., fibrinogen concentrate, anti-inhibitor coagulant complex, recombinant factor VII) and reopening of the sternum can also be considered after discussing the details with the cardiac surgeon and weighing the risks/benefits of procoagulant therapy for the patient's specific underlying cardiac anatomy/physiology (e.g., clotting risk can be increased with aortopulmonary shunts, cavopulmonary anastomoses). Chylothorax can also complicate the postoperative course and has been associated with specific traumatic and nontraumatic processes (e.g., single ventricle operations, aortic arch operations, Down/Noonan/Turner syndromes). If significant and prolonged, it may require lymphatic interventions to control [126–128]. Early postoperative arrhythmias, healthcare-associated infections, and central line-associated thromboses can also complicate the postoperative period [129–133]. All these postoperative complications can lead to prolonged mechanical ventilation days, ICU LOS, and increased postoperative morbidity and mortality. Such complications are often apparent early, but their impacts can be masked by expert management until de-escalations of support result in obvious clinical deterioration. Other common postoperative complications can affect the process of ventilator weaning or recovery to hospital discharge. Some of the more common postoperative complications seen in the CICU, their etiologies, and potential interventions are listed in Table 36.7.

The unanticipated postoperative course requires critical review. Based on the anatomical diagnosis, the preoperative risk profile, and the intraoperative course (technical performance of repair, any residual lesions of significance), one should be able to predict the major themes of the postoperative course. Recent data from the Residual Lesion Score (RLS) multicenter study of 1,250 infants undergoing surgery for TOF repair, complete atrioventricular septal defect repair, arterial switch operation for D-TGA, aortic arch/VSD repair, or the modified Norwood operation reported an incidence of RLS 3 (major residual lesions on echocardiography or residual lesion requiring reintervention before discharge) of 15–35% [134] (Figure 36.7). RLS 3 vs. 1 (no or trivial residual lesions) was a risk factor for fewer days alive and out of hospital ($p < 0.008$) and longer postoperative hospital stay ($p < 0.02$) for all operations. RLS 2 (minor residual lesions) was not consistently associated with outcomes. If the course is different than expected, it is incumbent on the CICU team to look actively for explanations. Initial evaluation of early postoperative complications may involve the use of ECG, echocardiography, ultrasonography, CT angiographic imaging, or cardiac MRI. However, more invasive evaluations such as cardiac catheterization can be required. Cardiac catheterization may be indicated to evaluate hemodynamics and obtain angiograms. These can guide decisions about the need for catheterization-based interventions or a return to the OR for surgery to address residual cardiac lesions. Recent studies support the safety and efficacy of early postoperative cardiac catheterization; low rates of complications are typical, and the results often guide changes in medical and/or surgical management when performed in the appropriate cohort of postoperative CICU patients [135–137]. Reopening of the sternum should also be considered for multiple etiologies: (i) to alleviate restrictive intrathoracic physiology from capillary leak syndrome, (ii) to alleviate cardiac tamponade, (iii) to improve pulmonary compliance and promote adequate gas exchange, and (iv) to prepare for initiation of mechanical circulatory support [138]. Patients with higher filling pressures, high vasoactive/inotropic support requirements, acute kidney injury (AKI) with worsening fluid balance, and higher early postoperative lactates have been identified in one study as at-risk groups that may require sternal reopening [138].

All pediatric cardiovascular programs, and specifically CICUs, should establish a process through which recognition and routine discussion of postoperative complications can occur. This allows identification of the patient who is not following an anticipated course and provides a forum for suggestions for evaluation and potential therapy. It also gives the care team an opportunity to review key themes from a quality perspective, ensuring critical attention to relevant processes for areas of improvement.

AL Grawany

Table 36.7 Postoperative Complications, Etiologies, and Interventions

Postoperative Complications	Etiologies	Intervention(s)
Low cardiac output syndrome	Myocardial dysfunction, systemic inflammation, ischemic-reperfusion injury	Inotrope/vasoconstrictor infusions, lusitropic agents, volume resuscitation, hydrocortisone, increasing DO_2, decreasing VO_2
Bleeding	Intra-op blood administration, inadequate intra-op hemostasis, dehiscence of suture lines, coagulopathy	Product administration (PRBCs, FFP, cryoprecipitate, fibrinogen concentrate, recombinant factors, anti-inhibitor coagulant complex), sternal reopening with exploration and source control
Arrhythmias	Junctional ectopic tachycardia (VSD patch closure) Complete heart block (damage to AV node) Supraventricular tachyarrhythmias (interventions on atria) Ventricular tachyarrhythmias (right ventriculotomy, coronary artery interventions, heart transplantation)	Temporary pacing wires (rapid atrial pacing, overdrive pacing, atrial or dual-chamber pacing) Antiarrhythmics (i.e. procainamide, amiodarone, lidocaine, esmolol) sedation, muscle relaxation, cooling, minimizing pro-arrhythmic pharmacologic therapies Electrophysiology study +/- ablation
Infections	Surgical site infection, central-line associated infection, ventilator-associated infection, sepsis, infective endocarditis, catheter-associated urinary tract infection	Targeted antibiotic therapy Imaging modalities to identify source (echocardiography, ultrasound, CT, MRI) Source control (removal of nidus of infection)
Chylothorax	Thoracic duct injury, abnormal lymphatic vasculature	NPO, antibiotics, fat-free diet, octreotide, methylprednisone, beta blockade, mTOR inhibitors, MEK inhibitors, magnetic resonance lymphangiogram, thoracic duct ligation, pleurodesis, pleuroperitoneal shunts
Central venous thrombosis	Central line placement, inadequate anticoagulation with foreign material in vascular structures, abnormal vascular anatomy	Anticoagulation, mechanical thrombectomy (surgical, catheterization), removal of intravascular catheters from vessel in question
Vocal cord injury	Intubation, recurrent laryngeal nerve injury	Bedside flexible bronchoscopy, therapies at discretion of otorhinolaryngology service
Diaphragm paralysis/paresis	Phrenic nerve injury	Evaluation with fluoroscopy or ultrasound (preferentially off invasive or noninvasive positive pressure ventilation), prolonged noninvasive positive pressure ventilation, diaphragmatic plication
Seizures	Intra-op ischemic insult, embolic stroke, intracranial hemorrhage	EEG, ultrasound or CT, anti-epileptic medications
Intestinal ischemia/ necrotizing enterocolitis	Limitation of cardiac output or systemic steal (i.e. single ventricle, shunt physiology, truncus, TGA), abnormal vascular pathology (i.e. mid-aortic syndrome, vasculopathy)	NPO, abdominal radiograph and ultrasound, pediatric general surgery consultation, optimizing DO_2, antibiotics
Sedation/analgesia withdrawal	Prolonged intubation and ICU length of stay, rapid weaning of pharmacologic therapies	Slow sedation drip weans, transitioning to enteral analgesic/anxiolytic/central alpha agonist therapies, monitoring withdrawal assessment tool (WAT) scores
Delirium	Sedation practices, related to intensive care stay	Environmental changes (restructuring sleep-wake cycles), melatonin, neuroleptic medications (risperidone, haloperidol), clustering bedside cares, monitoring of Cornell Assessment of Pediatric Delirium (CAP-D) scores
Feeding intolerance	Post-operative ileus, pre-operative intolerance of feeds, intestinal ischemia, reflux	Proton pump inhibitors, H_2-blockers, post-pyloric feeds, gut rest, assessment for adequate cardiac output, GI anatomic abnormalities assessment (i.e. malrotation, volvulus, intestinal strictures, Hirschsprung's)

DO_2 – oxygen delivery, VO_2 – oxygen demand, PRBC – packed red blood cells, FFP – fresh frozen plasma, VSD – ventricular septal defect, AV – atrioventricular, CT – computerized tomography, MRI – magnetic resonance imaging, NPO – *nil per os*, mTOR – mechanistic target of rapamycin, MEK – mitogen-activating protein kinase, EEG – electroencephalography, TGA – transposition of great arteries, ICU – intensive care unit, GI - gastrointestinal

Patient safety and quality improvement in the cardiac intensive care unit

Vigilance and structured processes are vital to reduce or eliminate the risk of preventable harm. Critically ill patients require many decisions and processes to be efficiently delivered, and the environment is a key interface between human factors and technology. Although we are continually striving to improve the quality of care, every change in the system, despite capable team members and/or advanced technology, has the potential to adversely affect patient safety. The following general principles are fundamental to improving patient safety:

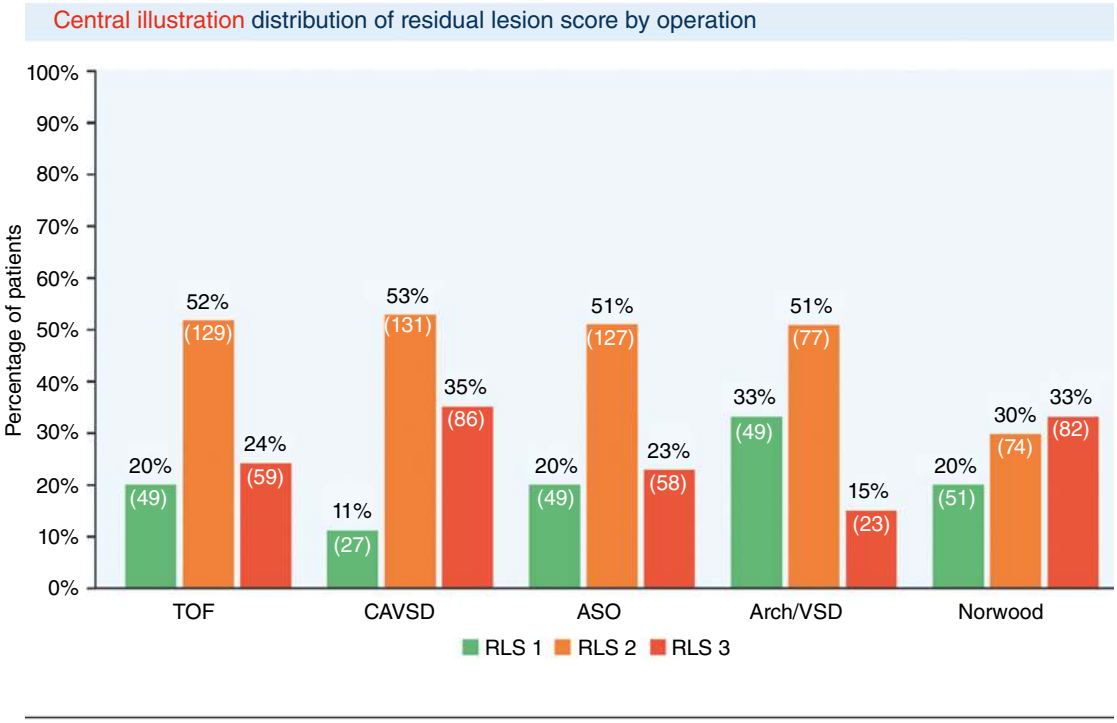

Figure 36.7 Residual lesion score figure. (Source: Nathan et al. [134]. Reproduced with permission of Elsevier.)

- Create a culture of transparency and respect.
- Measure performance continuously and provide timely data feedback to all team members in a relevant format.
- Insist on clear, direct, and closed-loop communication.
- Limit interruptions during focused activities as much as possible.
- Insist on systematic handovers during care transitions.
- Declare timeouts before invasive procedures.
- Ensure forced functions through appropriate human factor engineering of the environment (e.g., infusion pumps, alarm limits/silencing).
- Ensure read-backs and double checks when patient identification is key (blood products administration, transfer to OR).
- Create an anonymous, easy-to-use process for event reporting, review, and resolution.

Essential to any environment that values patient safety is a culture of accountability, openness, and teamwork. One must balance the value of creating a blame-free environment (essential for recognizing mistakes) with ownership of the mistake as a team (and as the intensivist). The latter is key to creating accountability that results in measurable change when needed. Accountability also requires prompt disclosure of significant error(s) to the patient's parents/guardian by the responsible attending intensivist. If these errors occurred outside the CICU (e.g., OR), the intensivist often plays a key role in facilitating disclosure by the appropriate individual(s).

Communication among care provider teams is paramount to safe patient care. Pertinent patient information sharing begins preoperatively, often with cardiac surgical case conferences, where the CICU team is a key stakeholder and participant. A structured, collaborative, and comprehensive transfer of care from the OR to intensive care team has been shown to be associated with fewer preventable complications [139]. Ensuring adequate time for handover, with minimal interruptions and use of structured communication tools, is essential.

Furthermore, there has been a concerted effort to improve postoperative care for all patients. In the adult population, the development and adoption of ERAS (Enhanced Recovery After Surgery) has been an international project to optimize patient outcomes and delivery of efficient care; nearly all surgical specialties are involved, including cardiac. The development of bundles and guidelines, audits, and team feedback has been a cornerstone of standardized, consistent care [140]. Data sharing and collaborative learning through multicenter initiatives such as the Pediatric Cardiac Critical Care Consortium (PC^4) have been organized to develop meaningful outcome analysis and benchmarking aimed at improving the care of complex pediatric cardiac surgical patients [82]. See Chapters 3 and 4 for further discussion of Quality and Outcomes, and Team Functioning.

Mechanical support of the circulation

Mechanical assist devices serve an important role in the care of children with critical myocardial failure, providing stable circulatory support for patients who have become refractory to aggressive medical management. Support may be required for only a short period, allowing for recovery from a self-limited process (e.g., acute viral myocarditis or postcardiotomy

myocardial failure), or it may be needed for long-term support to bridge a patient to cardiac transplantation. Historically, venoarterial (VA) ECMO has been the most common mode of mechanical support for patients in the CICU, and it continues to be a valuable tool secondary to its flexibility in cannulation strategy, ability to support both cardiac and pulmonary function, and ease of bedside deployment. Over the past decade, there has been a dramatic increase in the use of ventricular assist devices (VADs), as device manufacturers have begun to create miniaturized pumps that can reliably support pediatric patients [141]. The experience with the Berlin Heart EXCOR® VAD, in particular, has demonstrated that younger and smaller pediatric patients can be successfully bridged to heart transplant with results that are comparable with the adult VAD experience [142]. Despite improvements in device design and increased clinician experience with these devices, significant morbidity and mortality still occur in patients supported with mechanical assist devices, underscoring the need for further research to improve the care of this complex and high-risk patient population.

Extracorporeal membrane oxygenation

VA-ECMO is the most widely used mode of mechanical cardiopulmonary support for children with CHD. It fully supports heart and lung function similar to CPB and requires significant levels of systemic anticoagulation to maintain circuit performance. While VA-ECMO is the most commonly employed support strategy in CHD patients owing to its cardiac support, venovenous ECMO is occasionally utilized when cardiac patients with primary respiratory failure have preserved cardiac function. Figure 36.8 depicts a standard VA-ECMO circuit. Cannulation for VA-ECMO may be accomplished with venous drainage via the internal jugular vein, femoral vein, or centrally in the right atrium, while arterial input is via the carotid artery, femoral artery, or centrally in the aorta.

Over the past two decades, there has been a progressive increase in the use of ECMO for cardiac indications, as increasingly complex surgical interventions are being performed in younger patients. Currently, there are over 500 children/year, worldwide, who receive ECMO for cardiac support [143, 144]. The majority of these patients are placed on ECMO for postcardiotomy support, but other indications for ECMO include primary myocardial dysfunction secondary to cardiomyopathy or myocarditis, management of refractory arrhythmias, respiratory failure, refractory hypoxemia secondary to right-to-left intracardiac shunting, pulmonary hypertension, and for support during interventional cardiac catheterization or electrophysiology procedures in patients with unstable circulations. Overall survival to discharge is 40–65% in this heterogeneous group of patients, with certain subgroups demonstrating better outcomes [145–148]. Despite growing provider experience with ECMO, survival has remained largely unchanged over the past decade, although some centers report improving survival rates [149]. Further refinements in patient selection, timing of deployment, and creation of more biocompatible circuits are needed to increase successful outcomes.

ECMO has an important role in the resuscitation of critically ill patients following cardiac surgical intervention (i.e., postcardiotomy support). The best outcomes are seen in patients with a self-limited process, such as secondary myocardial failure post-CPB [150]. These patients typically demonstrate recovery of myocardial function within 48–72 hours, as evidenced by the return of pulsatility on invasive arterial blood pressure monitoring and improved systolic performance on echocardiography. VA-ECMO may also be an effective rescue therapy to bridge patients through correction of a reversible process, such as acute aortopulmonary shunt thrombosis [151]. In patients who do not follow this pattern, further investigation, such as a comprehensive echocardiogram and/or cardiac catheterization, should be undertaken to search for potential residual defects, as early identification and intervention may improve survival [152, 153]. Although not without potential hazard, cardiac catheterization can be safely undertaken in this high-acuity population [135, 154, 155]. The outcome of patients who require ECMO secondary to an inability to wean from CPB in the OR is particularly poor, with reported survival rates of only 10–30% [156, 157]. Despite isolated case reports describing myocardial recovery following prolonged periods of support, several studies in the postcardiotomy population have demonstrated that survival is <10% in ECMO runs longer than 10–12 days [158].

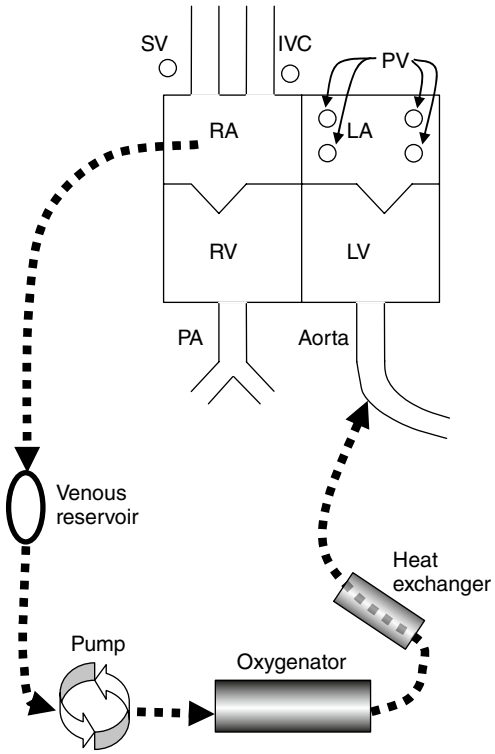

Figure 36.8 Extracorporeal membrane oxygenation (ECMO) circuit. The dashed lines represent flow through a venoarterial ECMO circuit. Blood is drained from the right atrium by direct atrial cannulation, or from an SVC catheter advanced into the right atrium. When using a roller pump, the blood is first drained to a small venous reservoir; with a centrifugal pump, a reservoir is not used. Blood then passes through a membrane oxygenator and heat exchanger before returning to the ascending aorta, which is cannulated directly or via the right carotid artery. IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

Support of the single ventricle patient can be problematic and merits further discussion. Outcomes in neonates with HLHS supported with ECMO following Norwood palliation are lower than other subpopulations, with hospital survival of 30% [159]. However, patients cannulated for severe hypoxemia, primarily caused by aortopulmonary shunt thrombosis, have better survival than patients supported for CA or myocardial failure [151]. Moreover, interstage mortality and progression to subsequent surgical palliations for infants who survive an ECMO course are comparable to infants not requiring ECMO after Norwood palliation [160]. Patients with systemic-to-PA shunts require unique management when supported by ECMO, as runoff through the shunt into the lung vessels will limit systemic blood flow and can lead to impaired end-organ perfusion. Strategies for managing this circulation include increasing ECMO flow into the range of 150–200 mL/kg/min to provide increased systemic output or to occlude the shunt partially to limit pulmonary runoff. Complete shunt occlusion is not recommended and has been associated with worse survival [161]. ECMO support in patients with a cavopulmonary connection has also been associated with poor outcomes. One case series reported 17% survival for patients with a bidirectional Glenn circulation and a strong association with severe neurologic injury [162]. Neurologic injury likely occurs because of the development of cerebral venous hypertension and impaired cerebral perfusion during low CO and/or CPR. That same case series report and a subsequent review of the Extracorporeal Life Support Organization (ELSO) registry for outcomes in Fontan patients revealed a 35% survival rate [162, 163]. Patients who demonstrated evidence of Fontan failure immediately after surgery had better outcomes compared with patients who required ECMO for progressive myocardial failure. Patients with a cavopulmonary connection may require the insertion of an additional venous cannula in the upper body to optimize venous drainage, particularly if a primary femoral cannulation strategy is instituted. A recent single-center review of 57 single ventricle patients (41 stage I palliation, 11 bidirectional Glenn, and 5 Fontan) reported that 53% were weaned off support, but only 33% survived to hospital discharge [164]. This outcome is consistent with broader data suggesting that the post-stage I circulation is a high-risk subset in which to apply support with a VAD.

ECMO support for patients with acute fulminant myocarditis is associated with the highest survival rates in children requiring ECMO for cardiac indications [165]. Survival rates of 60–80% are reported in this subpopulation [166]; these better results are likely attributable to the typically reversible nature of the myocardial dysfunction and the shorter periods needed to bridge to recovery. Myocardial recovery typically occurs within 2 weeks, and in those patients who continue to demonstrate severe myocardial dysfunction, conversion to a VAD for long-term support should be considered if cardiac transplantation is an option.

ECMO may also be used to bridge patients to cardiac transplantation, but its role in this indication has been usurped by VADs in the current era. Survival to transplant in patients utilizing ECMO as a bridge has been reported to be 40–60%, compared with 70–80% in patients bridged with VAD support [167, 168]. Given the limited number of available organs and relatively prolonged waiting list times, especially for the youngest patients, ECMO as a bridge strategy has major limitations in pediatric patients. Prolonged support with ECMO is associated with increasing complications, including bleeding, neurologic injury, end-organ failure, and sepsis.

Survival after pediatric IHCA is poor and reported to be 25–33% [169]. ECMO as part of CPR (i.e., E-CPR) is increasingly used as a procedure to rescue children who do not recover spontaneous circulation during standard CPR. Initiation of E-CPR is typically undertaken if there has been inadequate recovery with standard CPR following 10–15 minutes of resuscitation, provided there are no contraindications to mechanical support. Cannulation can be through either the chest, neck, or groin depending on the particular patient. A "clear" or asanguinous primed circuit allows for more rapid deployment, but some centers use banked O-negative blood that is stored within the CICU for rapid circuit priming. A review of the ELSO registry reported a 38% hospital survival rate for E-CPR, with patients who had an underlying cardiac diagnosis demonstrating more favorable outcomes [170]. There was no relationship between the type of cannulation strategy and survival. Interestingly, single-center reports of E-CPR outcomes demonstrate better survival, suggesting that the development of experienced teams with structured protocols can yield improved results [171]. Long-term neurologic outcome data are limited, but several studies report favorable neurologic outcomes in the majority of surviving patients [172–175]. Some patients, however, may develop significant neurocognitive morbidity [176].

A brief review of ECMO management principles follows. If time allows, blood is typically used to prime the ECMO circuit, but an asanguinous prime may be needed in the case of emergent deployment for E-CPR. Traditionally, perfusionists have primed the ECMO circuit, but many centers now have trained ECMO specialists (nurses, respiratory therapists, or physicians) who develop this skill set. Initially, the patient is supported with ECMO flows approaching full CPB flow (i.e., 100–150 mL/kg/min for patients in the range of 10 kg). This flow strategy allows for significant unloading of the myocardium and provides adequate perfusion to end organs to allow time for recovery. Inotropic agents are discontinued or minimized to decrease myocardial oxygen demand and to prevent downregulation of adrenergic receptors in the myocardium and peripheral vasculature. Vasodilator agents may be necessary to control systemic hypertension in order to prevent bleeding and cerebrovascular events. A left atrial vent may be required in those two-ventricle patients who have an intact/restrictive atrial septum and do not demonstrate any native systemic ventricular ejection, as left atrial hypertension, pulmonary edema, and subsequent pulmonary hemorrhage typically ensue [177, 178]. Ventilator support is adjusted to maintain FRC and minimize oxygen toxicity or barotrauma.

Anticoagulation is typically maintained with a heparin infusion beginning at 10–20 units/kg/hour, and it is titrated to maintain an activated clotting time (ACT) of 180–200 seconds. A lower ACT strategy may need to be utilized in recent postoperative patients with significant ongoing bleeding. More recently, some centers are using heparin activity levels to assist with their anticoagulation monitoring. A newer strategy is to use a bivalirudin infusion (a direct thrombin

AL Grawany

inhibitor) instead of heparin as the primary anticoagulant [179, 180]. Bleeding and coagulopathy are common, and blood products must be readily available for infusion into the circuit. The need for surgical exploration is also common, particularly among postcardiotomy patients, with prior sites of surgical intervention and the cannulation sites themselves being the most likely sources of bleeding. Typically, a goal platelet count >100,000, hematocrit >35%, and a prothrombin time within the normal range are maintained in these patients. Epsilon-aminocaproic acid (EACA) has been shown to be effective at reducing blood loss and transfusion in cardiac ECMO [181]. Recombinant factor VII has also demonstrated efficacy in reducing blood loss, but it can be associated with increasing thrombus burden in the circuit and thrombotic events [182]. Central nervous system (CNS) bleeding is a catastrophic complication and should be suspected whenever there is clinical and/or laboratory evidence of sudden decrease in hematocrit without another explanation for blood loss. Cranial ultrasonography is a commonly used screening tool among infants (via an open fontanelle) supported on ECMO. Portable CT for bedside brain imaging is a helpful tool to increase diagnostic yield, but it is not available in all hospitals.

Inadequate ECMO circuit volume is indicated by excessive negative pressure readings on the venous side of the circuit and an inability to maintain target flows and mean arterial pressures. Pre- and post-oxygenator pressures are monitored to assess both oxygenator function and distal resistance to flow. An increasing gradient between the pre- and post-oxygenator pressures in association with deteriorating gas exchange is an indication that oxygenator thrombosis has occurred. Increases in both pre- and post-oxygenator pressures indicate elevated distal resistance to flow secondary to mechanical issues with the arterial cannula or systemic hypertension.

Renal insufficiency and fluid overload can be managed by placement of a hemofilter in the circuit for continuous hemofiltration. If greater solute clearance is desired, hemodialysis can be run in tandem with the ECMO circuit. The development of acute renal failure while on ECMO has been associated with an increased risk for mortality [183, 184]. However, the use of continuous renal replacement therapy (CRRT) does not appear to confer risk for the development of chronic renal failure in the ECMO population [185, 186].

Infectious complications are prevented by meticulous sterile technique, and broad-spectrum antibiotics are initiated if sepsis is suspected. Sedation, analgesia, and, frequently, paralysis are required for these patients to optimize patient comfort and minimize risk for cannula site bleeding and disruption. Nutritional support is frequently delivered parentally while on ECMO, although enteral nutrition may be provided in the absence of splanchnic hypoperfusion.

ECMO support is weaned when the compromised myocardium has recovered, with the time course for recovery varying from as little as 24–48 hours to several weeks. Echocardiography (transthoracic, epicardial, or transesophageal) can be used to assess myocardial contractility both on full support and as support is weaned [187]. Before weaning flow, inotropic agents are typically restarted or increased, intravascular volume status is optimized, and ventilator support is increased. As ECMO flow is progressively reduced, additional titration of cardiovascular and ventilator support will be required with frequent assessments of clinical CO. If repeated attempts at weaning are unsuccessful, the team and the parents/guardians must decide if support should be withdrawn or if further pursuit of long-term mechanical support (i.e., a VAD) and cardiac transplantation is appropriate.

Ventricular assist devices

The application of VAD technology has increased dramatically in the pediatric population over the past decade [188]. Historically, VAD use was uncommon in children because of technical limitations, including device size and increased risk of device thrombosis secondary to use of flows that were outside the typical device operating range (lower due to smaller patient size). Short-term devices were primarily used; these devices required patients to be sedated and supported with mechanical ventilation, limiting opportunities for rehabilitation. Currently, short-term VAD support is most often used in postcardiotomy patients with an ischemic myocardium secondary to an anomalous left coronary artery from the pulmonary artery (ALCAPA), patients with late repair of D-TGA and an intact ventricular septum who develop LV failure following arterial switch, or for temporary support of RV failure following orthotopic heart transplantation or left ventricular assist device (LVAD) implantation [189].

With the arrival of the Berlin Heart EXCOR pump and the creation of miniaturized continuous flow devices, smaller pediatric patients can now be supported for longer periods and successfully bridged to cardiac transplantation. Long-term VAD support can be divided into paracorporeal pneumatic devices, such as the Berlin Heart EXCOR, or intracorporeal continuous flow devices, such as the HeartWare HVAD® and HeartMate III®. Given the compact design of the HVAD, it has become the most widely used continuous flow VAD in children. The HVAD is most commonly implanted in children with cardiomyopathy, but it has also been used with some success in children with CHD, including those with single ventricle physiology [190–192]. A recent study from ACTION, a collaborative pediatric VAD quality improvement network, demonstrates promising results related to HVAD use in children, with a 96% survival rate at 1 year and only 4% occurrence of stroke [193]. As of June 2021, the HVAD device was removed from the market after the U.S. Food and Drug Administration (FDA) advised healthcare providers to stop implanting the device due to a higher frequency of neurological events and patient deaths compared to other devices [194]. The SynCardia Total Artificial Heart® is an intracorporeal pneumatic device that provides biventricular support, but its use has been limited to larger adolescents secondary to its larger size. The Berlin Heart EXCOR VAD is the only one of these devices that has been specifically designed for a pediatric application and can support infants. There have been ongoing efforts as part of the National Institutes of Health-sponsored PumpKIN Program to create a durable continuous flow VAD that can support infants and small children. The Jarvik 2015 is the only remaining device from this program, signifying the challenges in creating pediatric-specific devices [195]. Unlike the previously described short-term VADs, children with these devices can be weaned off sedation, extubated, and

ambulate, allowing for pretransplant rehabilitation. Larger patients whose BSA permits implantation of the intracorporeal continuous flow devices can be discharged from the hospital following intensive training in the daily maintenance of their device.

Despite relatively recent introduction into practice in the United States over the past decade, a large body of experience has developed with the Berlin Heart EXCOR device. As compared with ECMO, patients can be supported for longer periods and more successfully bridged to transplant. The Berlin Heart investigational device exemption (IDE) trial reported that 88–92% of patients (two patient groups based on BSA) were successfully bridged to transplant or recovery [142]. Serious adverse events, including bleeding, infection, and stroke, occurred in 29% of the patients. A follow-up investigation examining all patients implanted with the Berlin Heart during the same study period as the IDE trial reported 75% survival to transplant or recovery [196]. Neurologic dysfunction occurred in 29% of the patients and was the leading cause of death. However, more recent data suggest that the incidence of stroke is decreasing [197]. Smaller patient size, end-organ dysfunction preimplantation, and biventricular support were all associated with increased risk of death while on VAD support. These findings underscore the importance of careful patient selection and timing of implantation.

Small infants and children with single ventricle physiology remain particularly problematic patient populations to support with VADs [191]. Smaller patient size, in particular those weighing <5 kg, was identified as an important risk factor for mortality in the Berlin Heart EXCOR bridge to heart transplantation study [196]. Whether this risk is related to patient-specific factors, such as immature hematologic function, or device-related issues remains unclear. Recognizing the difficulties related to supporting small infants with pulsatile devices, some groups have advocated for the use of short-term continuous flow devices such as the PediMag™ [198]. While survival with a VAD following Fontan palliation can reach 95%, survival after stage 1 and stage 2 procedures is much lower (30 and 40%, respectively). Success of VAD therapy in single ventricle patients is much lower compared to non-CHD patients, with higher mortality and a lower rate of effective bridge to transplantation [199]. For stage 1 and/or shunted patients, the need to support both the systemic and pulmonary circulations (i.e., two COs with one device) presents a unique challenge. If unable to achieve adequate decompression, the systemic venous and intracardiac pressures may increase as well as the amount of atrioventricular valve regurgitation.

Another important concept is the need to limit pulmonary blood flow in some manner, in order to decrease the risk of steal from the systemic circulation. For patients with Glenn physiology, VAD cannulation strategy is systemic ventricle (or atrial if the RV is heavily trabeculated) to ascending aorta. While the failing ventricle is volume unloaded compared to shunted physiology, the VAD may also need to support collateral circulation. Additional considerations include ensuring adequate intracardiac decompression to prevent failure of the Glenn circulation with development of a low-flow state in the systemic venous and pulmonary circuits. Continuous flow devices may better support this physiology; however, patient size is a major limitation in using an intracorporeal continuous flow device unless the patient is an older, school-aged child. Patient selection for VAD placement in failing Fontan physiology is important. Fontan patients with elevated ventricular filling pressures may be the better candidates compared to those with progressive end-organ injury and/or those with Fontan failure related to protein losing enteropathy or plastic bronchitis.

A brief discussion of VAD management follows, but a more in-depth review can be found in Chapter 37. For the pneumatic devices, stroke volume is fixed and thus output is adjusted by titrating the beat rate of the device to provide an adequate clinical CO and blood pressure. In continuous flow devices, the pump speed is titrated to achieve goal clinical CO and mean arterial pressure. Intravascular volume status and device filling can be monitored via central venous pressure and direct inspection for the paracorporeal devices, or via device parameters in the intracorporeal devices. Systemic anticoagulation is necessary to prevent device thrombosis, but at a lower level than that required for ECMO. Patients are initially treated with heparin infusions and then transitioned to low-molecular-weight heparin or warfarin once they have recovered from device implantation and achieved stable VAD settings. Platelet inhibition with aspirin, dipyridamole, and/or clopidigrel may also be required to prevent thrombus formation, usually based on the manufacturer's recommendations. For patients receiving LVAD support alone, medical support for the RV is critical for optimizing postimplant care. Inotropic support and inhaled nitric oxide for RV afterload reduction are helpful adjuvants to assist with RV function. If the RV is unresponsive to medical therapy, mechanical RV support may be necessary with either a short-term or long-term device. This decision is frequently made either in the OR during LVAD implantation or within the first postoperative hours in the CICU.

KEY POINTS: MECHANICAL SUPPORT OF THE CIRCULATION

- ECMO is the most common mode of mechanical cardiac support utilized in the CICU secondary to its flexibility in cannulation strategy, ability to support both cardiac and pulmonary function, and ease of deployment.
- ECMO is most effective in patients with myocarditis, reversible postcardiotomy myocardial failure, or shunt thrombosis. Prolonged support with ECMO is associated with increasing complications, including bleeding, neurologic injury, end-organ failure, and sepsis.
- ECMO may be used as an adjunct to assist with resuscitation of patients who do not recover spontaneous circulation during standard CPR. Long-term neurologic outcome data are lacking for this high-risk patient group.
- Increasing experience with VAD use has improved the care of patients with terminal heart failure who are awaiting cardiac transplantation. Patient selection and timing of device implantation are critical in optimizing patient outcomes.

AL Grawany

Hemostasis

The risk of postoperative bleeding in the pediatric cardiac surgical patient is multifactorial. Delayed hemostasis can be partly related to the deleterious inflammatory and hematologic effects of CPB, which include hemodilution from the bypass circuit prime, stimulation of the intrinsic coagulation pathway resulting in coagulation factor consumption, and platelet activation and aggregation leading to platelet loss and dysfunction [200]. Priming the bypass circuit with reconstituted whole blood has been demonstrated to be beneficial in neonates and infants undergoing cardiac surgery to reduce post-bypass bleeding [201]. Patient-specific factors identified as risks for postoperative bleeding include low CO with tissue hypoperfusion and associated disseminated intravascular coagulopathy, hepatic immaturity or dysfunction, the preoperative use of anticoagulants and antiplatelet agents, a history of prior cardiac surgery, the presence of extensive suture lines, and chronic cyanosis.

Prompt identification and control of surgical bleeding are essential in preventing the complications associated with massive transfusion. Categories of postoperative bleeding by volume and management strategies are listed in Table 36.8. Transfusion of platelets, plasma, cryoprecipitate, and/or fibrinogen concentrate to correct coagulopathy is an important initial intervention. In critically ill children with hemorrhagic shock, consensus guidelines suggest product ratios of 2 : 1 : 1 to 1 : 1 : 1 of red cells, plasma, and platelets, respectively, until the bleeding is no longer life-threatening [202]. Normalization of body temperature and correction of hypocalcemia can be helpful adjuncts in achieving hemostasis. Evidence of a prolonged partial thromboplastin time (PTT) with a normal heparinase-treated sample suggests the presence of residual heparin and can be corrected with an additional dose of protamine. Antifibrinolytic agents such as EACA and tranexamic acid (TXA) are used intraoperatively to reduce bleeding, but may also be effective in the CICU if coagulopathy and fibrinolysis persist [203]. These agents bind to plasminogen, rendering it incapable of binding to lysine residues on fibrin and thus inhibiting plasmin generation.

Table 36.8 Volumetric approach to postoperative bleeding

Evaluation	Laboratory assessment • INR, PTT, platelet count • Consider ACT, PTT with heparinase, TEG, ROTEM. Measure chest tube output
Chest tube output	Considerations
<5 mL/kg/hour	Review labs Monitor, usually resolves spontaneously
5–10 mL/kg/hour	Review labs Blood product replacement Volume resuscitation Consider protamine if residual heparin effect found on lab testing
>10 mL/kg/hour	Prompt communication with surgeons Consider chest re-exploration Review labs Ongoing blood product and volume replacement

INR – international normalized ratio, PTT – partial thromboplastin time, ACT – activated clotting time, TEG – thromboelastogram, ROTEM – rotational thromboelastometry

Critically ill children with heart disease are at risk for both bleeding and thrombosis [204]. Goal-directed therapy with factor concentrates has been used successfully in adult cardiac surgery patients, but data in children are limited [205]. Fibrinogen concentrate has been shown to be equivalent to cryoprecipitate in children undergoing cardiac surgery [206]. Off-label use of recombinant activated factor VII (rFVIIa) as a rescue agent for cases of refractory postoperative bleeding has been employed. However, recent studies have demonstrated that high-dose rFVIIa (>90 mcg/kg) is associated with significant thrombotic complications [207, 208]. The use of prothrombin factor concentrates (PCCs) in pediatric cardiac surgical patients has also gained interest. Similar to rVIIa, limited data for pediatric patients exist, and the thrombotic risk remains an issue [209, 210].

Irrespective of management strategies, post-bypass bleeding increases the risk of adverse outcomes such as need for postoperative dialysis and ECMO, and in-hospital mortality, especially in neonates [211]. Ongoing research with high-quality studies and comparable outcomes, focusing on monitoring tests, pharmacologic treatments, and development of clinical practice guidelines, are needed. Chapter 16 has an extensive presentation of bleeding and hemostasis in CHD surgery.

KEY POINTS: HEMOSTASIS

- Patients in the CICU are at risk for bleeding complications from exposure to inflammatory and hematologic effects of bypass, the presence of end-organ dysfunction related to LCOS, and the use of anticoagulants/antiplatelet agents.
- Postoperative bleeding associated with chest tube output of 5–10 mL/kg/hour requires aggressive medical management with blood product replacement and correction of coagulopathy. Output > 10 mL/kg/hour may require chest re-exploration.
- Adjuvant agents, such as EACA or TXA, rVIIa, and PCC, may be helpful in controlling postoperative bleeding, but their use can be associated with thrombotic events. Careful risk–benefit assessment must be done prior to use.

Infection control

Hospital-acquired infections are an important source of morbidity and mortality in ICUs, and they cause increased healthcare expenditure [212, 213]. Patients in CICUs are particularly vulnerable secondary to the high incidence of surgical procedures, exposure to the inflammatory and immunomodulatory effects of CPB, and the routine use of invasive devices. Bloodstream infection and surgical site infection (SSI) are the most common, followed by ventilator-associated pneumonia and urinary tract infection [214, 215].

Studies examining risk factors for nosocomial infection frequently identify younger age, higher disease complexity (e.g., based on RACHS-1 and PRISM scores), and the presence of delayed sternal closure as factors that convey increased risk [214–216]. An analysis of central line-associated bloodstream infection (CLABSI) in the PC[4] collaborative demonstrated a 70% prevalence of central line use in almost 20,000 admissions [133]. The median duration of use was 4 days, and there was a 2% incidence of central line-associated thrombosis and a 1% incidence of CLABSI with medical admissions; younger age, greater surgical complexity, and greater number of catheter days were risk factors for both. Table 36.9 lists factors associated with CLABSIs in cardiac surgical patients.

Reviews of SSIs identify younger age, inappropriate timing of prophylactic antibiotics, excessive bleeding in the immediate postoperative period, and prolonged CPB as important risk factors [217, 218]. In the setting of delayed sternal closure, multiple episodes of delayed sternal closure and ECMO use have been identified as independent risk factors for SSI [75].

Efforts at limiting the occurrence of nosocomial infection have focused on staff education, good hand hygiene, creation of central line insertion and maintenance bundles, daily evaluations of the need for all indwelling devices (e.g., central venous line, Foley catheter, ETT), and regular audits of staff compliance. When trialed, these maneuvers have proved successful and led to decreasing rates of infection [219]. In addition, quality improvement projects following the PLAN-ACT-STUDY-DO model have proven highly effective in reducing nosocomial infections [220]. Maneuvers to minimize SSI have included a preoperative chlorhexidine bath prior to the day of surgery, standardizing intraoperative skin preparation and antibiotic timing, standardization of dressing care, early removal of pacing wires, and utilization of sterile technique for transthoracic echocardiograms in fresh postoperative patients [217]. Given the previously identified risks of steroid use and exposure to blood products, future studies may investigate the efficacy of limiting these interventions in CICU patients.

Table 36.9 Factors associated with an increased risk for catheter-associated bloodstream infection in patients with congenital cardiac defects before and after surgery

- Younger age
- Higher STAT category
- Total catheter days
- Multiple catheters in place
- History of cardiac catheter intervention
- Cardiac arrest
- Use of mechanical circulatory support
- Chylothorax
- Prior infection
- Open chest
- Unplanned reintervention
- History of thrombosis

Neurologic monitoring/assessment and complications

Surgical mortality for patients with CHD has progressively declined over the past several decades, yielding a growing population of survivors who display an incidence of neurologic, developmental, and psychiatric disabilities that are notably greater than normal healthy children [221]. In particular, children who undergo repair or palliative procedures as neonates and infants appear to be the group at greatest risk [222]. These emerging data reinforce the importance of further refining preoperative, intraoperative, and postoperative care to minimize potential neurologic insults to the developing brain.

Historically, children with CHD but no identified associated genetic disorder were believed to have normal brain development. This precept has been challenged over the past decade with new studies utilizing advancements in MRI technology. MRI studies have demonstrated the presence of brain immaturity and white matter abnormalities prior to any surgical intervention [223]. These findings have been documented most consistently in patients with D-TGA and severe LV outflow obstruction, particularly HLHS and its variants [224]. Changes in fetal circulation secondary to the presence of these congenital heart lesions may contribute to these abnormalities, although future research is necessary to confirm causality [225]. In addition, fetal cardiac and brain development are linked, so genetic abnormalities that lead to CHD may also cause abnormal brain development [226, 227].

Although patients with CHD may have coexisting CNS abnormalities, they are also at risk of acquired neurologic injury throughout the perioperative period. These injuries may occur due to periods of hypoxia/ischemia, CNS hemorrhage, and embolic phenomenon. Premature infants are at additional risk for intraventricular hemorrhage. Older patients, particularly those with chronic cyanosis, are at risk for injury secondary to cerebral abscess and stroke, the latter related to venous or arterial thrombosis from erythrocytosis. In light of data illustrating the presence of preexisting brain injury, attempts to mitigate damage related to these perioperative insults take on even greater importance.

A large body of research over several decades has contributed to advances in intraoperative management with the goal of decreasing brain injury related to bypass, circulatory arrest, and surgery. These include the application of deep hypothermia to minimize injury during periods of ischemia/circulatory arrest, controlling the rate of body cooling and rewarming, optimizing perfusion pressure and flow via bypass, minimizing periods of circulatory arrest or avoiding it altogether with regional brain perfusion, optimizing hematocrit, adjusting pH and $PaCO_2$ during periods of hypothermia (pH stat strategy), and refining bypass circuit technology to minimize the risk for particulate or air emboli [228–230]. Choreoathetosis is historically a complication that could develop following cardiac surgery in children, particularly in older infants. Contributing factors to its development include inadequate brain cooling, rapid rate of cooling, α-stat blood gas strategy during cooling, and the presence of systemic-to-PA collateral vessels [231, 232]. Fortunately, this potentially devastating complication is uncommon in the current

AL Grawany

era where antegrade cerebral perfusion has become a more standard practice. In addition, intraoperative monitoring with NIRS to assess regional cerebral oxygen saturation has assisted in avoiding prolonged episodes of hypoxia/ischemia, particularly during periods of circulatory arrest or regional cerebral perfusion [233]. Some centers may also use transcranial Doppler assessment during regional perfusion to assess adequacy of bypass flow [234, 235].

Postoperative monitoring and care in the CICU also contribute to the avoidance of neurologic insults. Postoperative factors contributing to neurologic injury are related mainly to the development of persistent LCOS with depressed cerebral perfusion and potential progression to cardiovascular collapse. Assessment of CNS function may prove difficult, particularly in patients receiving sedation and/or neuromuscular blockade. The extension of the intraoperative practice of monitoring cerebral oximetry via NIRS to the CICU has allowed for a further portal into assessing the interplay between hemodynamics and the CNS. Several studies have demonstrated that sustained periods with low postoperative cerebral oxygen saturation (below a range of 45–55% by oximetry) are associated with poor outcomes, particularly in the HLHS population [236–238]. Some institutions have instituted protocols to alert providers when these threshold values are reached; interventions are then initiated, such as volume resuscitation, increased inotropy, modulation of afterload/vascular resistance, and increased sedation to minimize oxygen demand [239]. Further studies are needed to validate the efficacy of these protocols. Additional factors in patient management may play an important role in avoiding neurologic injury, including minimizing hyperventilation (to prevent reduction in cerebral blood flow) and avoiding hyperthermia. Post-bypass hyperthermia may develop from low CO with associated peripheral vasoconstriction or from aggressive rewarming practices. The avoidance of hyperthermia following pediatric traumatic brain injury is important, as early hyperthermia is associated with worse neurologic status [240]. Data from a neonatal porcine model of circulatory arrest also demonstrated the detrimental effect of hyperthermia on neurologic outcome [241]. Avoidance of hyperthermia in the postoperative period may help attenuate neurologic injury associated with circulatory arrest and periods of low output in the CICU [242]. The use of therapeutic hypothermia has been implemented to positive effect in neonatal hypoxic–ischemic brain injury and in adults following witnessed CA due to ventricular fibrillation [243, 244]. Its use has been extended to pediatric patients following CA, but there is currently no clear evidence demonstrating its benefit [245]. A recent randomized controlled clinical trial also did not demonstrate survival benefit of therapeutic hypothermia as compared to normothermia after pediatric IHCA [109]. Postarrest therapeutic hypothermia in patients with CHD may decrease the incidence of seizures, but it did not show additional benefits [246].

Historically, seizures were the most frequently observed neurologic complication following deep hypothermic circulatory arrest (DHCA), with a reported incidence of 4–25% [247]. Both focal and generalized seizures have been described, usually occurring on the first or second postoperative day. Status epilepticus was uncommon, and the occurrence of postoperative seizures did not increase the risk for seizures later in life. Because epilepsy rarely developed, these limited postoperative seizures were initially not thought to be of significant concern. However, the Boston Circulatory Arrest Study demonstrated that early postoperative seizures are a marker for worse neurodevelopmental outcome [248]. In recent years, postoperative seizures have become an uncommon event, with an incidence of 4%; the reduced incidence is likely secondary to improved techniques for neurologic protection as described earlier [249]. Other potential inciting events for postoperative seizures include embolic phenomenon and CA with development of severe hypoxic–ischemic injury. As stated previously, clinical detection of seizures in the CICU can be impaired by the presence of sedation and paralysis, necessitating careful assessment of autonomic manifestations such as sudden onset of tachycardia, hypertension, and pupillary dilation, although the cause of these signs can be difficult to distinguish from other hemodynamic causes. Acute declines in cerebral oximetry may also be noted, but as this technique assesses regional oxygen saturation, it may not reliably detect seizure activity in areas distant from the frontal cortex. EEG monitoring is a useful adjunct in the diagnosis of seizures; in particular, 24-hour video EEG monitoring can be helpful in assessing subtle or clinically-silent seizure activity (nonconvulsive status epilepticus) [250]. Imaging with head CT and/or MRI may be helpful, particularly if the seizures are focal in nature, suggesting the presence of a localized lesion such as an intracerebral hemorrhage or infarct. Treatment of postoperative seizures includes first-line IV administration of a benzodiazepine, typically lorazepam, followed by IV administration of fosphenytoin for persistent seizure activity [251]. Additional agents, including phenobarbital, levetiracetam, and a continuous midazolam infusion, may also be employed for refractory status epilepticus.

Stroke is another neurologic complication seen in the CICU. Awareness of this clinical entity has been heightened, as mechanical support with VADs has become the standard of care for most patients with end-stage heart failure. Other potential risk factors for stroke include the presence of intracardiac thrombus in association with ventricular dysfunction and arrhythmia, right-to-left intracardiac shunt, chronic cyanosis with associated erythrocytosis, mechanical valves, anticoagulant/antiplatelet use, and inherited or acquired thrombophilia [200]. A thorough history and physical examination are important to establish timing of the event, potential contributing risk factors, and the nature/severity of the neurologic deficits. Parents are often astute observers of subtle changes in their children, and their insights should be elicited. Initial signs and symptoms are age-dependent, with infants less than 6 months of age typically demonstrating nonspecific signs such as altered mental status (persistent irritability or depressed level of consciousness) and seizures. Older children may display focal neurologic findings, such as hemiparesis, which are associated with specific vascular territories in the brain. Cerebral venous thrombosis typically yields nonspecific findings across all age groups, with depressed mental status, headache, vomiting, and seizures being typical manifestations. Subsequent management includes neurodiagnostic imaging with head CT and brain MRI to assess for hemorrhage (CT) or focal areas of

ischemia/infarction. Cerebrovascular imaging may add further diagnostic information. Treatment involves efforts to restore or optimize perfusion to affected areas, modify risk factors, if possible, and deliver additional supportive care (e.g., institute mechanical ventilation if the airway cannot be protected and maintain appropriate cerebral perfusion pressure). The use of thrombolytics and anticoagulation is guided by a careful analysis of the risk–benefit ratio of these therapies, including risk for hemorrhage into a recently infarcted area.

Delirium, defined as an acute and fluctuating state of neurologic dysfunction, is becoming an increasingly recognized and important issue in the CICU patient population [252, 253]. Recent studies suggest a high prevalence of delirium in pediatric CICU patients, anywhere from 50 to 65%, with the majority in the postcardiotomy subpopulation [252, 254, 255]. Currently identified risk factors for development of delirium in the pediatric CICU population include the following: younger age (less than 2 years), developmental delay, higher severity of illness, longer CPB time, cyanotic disease, poor nutritional status, mechanical ventilation, and benzodiazepine use. Importantly, delirium has been found to be an independent predictor of prolonged CICU LOS. Delirium has also been shown to be an independent predictor of pediatric in-hospital mortality [256]. Given that delirium may contribute to increased ICU LOS, as well as possible as yet unrecognized long-term morbidities and mortality, screening is of utmost importance so that the CICU team can address modifiable risk factors and consider institution of pharmacologic treatment.

There are three main types of delirium: hypoactive, hyperactive, and mixed. Clinical guidelines recommend screening for delirium at least once a nursing shift [257]. There are two validated screening tools for pediatric delirium: the Pediatric and Preschool Confusion Assessment Method for the ICU (pCAM-ICU, psCAM-ICU) [258, 259] and the Cornell Assessment of Pediatric Delirium (CAPD) [260]. If a patient screens positive for delirium, the first steps should be to assess for underlying medical causes (e.g., infection, hypoxia, metabolic derangement, new neurologic insult), minimize iatrogenic risk factors (e.g., choice of sedative medications, use of restraints), and optimize the ICU environment (e.g., promote circadian rhythm, allow for soothing techniques and familiar items from the home environment, encourage family involvement at the bedside). If these interventions are not sufficient, then pharmacologic intervention, typically in the form of an atypical antipsychotic, may be considered. However, data on the use and efficacy of antipsychotics for pediatric delirium are lacking, and many centers appropriately consult a pediatric psychiatry team to help with medication management. A retrospective study found that the use of an atypical antipsychotic (quetiapine) in PICU patients was safe [261]. If an atypical antipsychotic is used, the QTc interval should be monitored closely, especially if the patient is receiving other QTc-prolonging medications.

A brief discussion about the potential impact of analgesia and sedative medication on brain development follows (see Chapter 10 for additional discussion). There is a growing body of work devoted to understanding the effects of volatile anesthetics and sedative agents in pediatric anesthesia which may help inform thoughtful sedation practices in the CICU. Animal models have demonstrated detrimental effects of sedative medications, such as midazolam and morphine, which can trigger neuroapoptosis [262, 263]. The jury is still out, however, regarding long-term effects of these medications in human infants and children. Although there is concern that they could have negative neurocognitive effects, some studies do not support this hypothesis. For example, a prospective study examining the neurodevelopmental outcomes in infants following exposure to sedative and analgesic drugs for complex cardiac surgery found no association between sedation/analgesia and mental, motor, or vocabulary delay [264]. Interestingly, dexmedetomidine (a CNS α2-adrenergic receptor agonist) has been found to have neuroprotective properties, and a recent retrospective study found that it may improve neurodevelopmental outcomes and protect against adverse effects of general anesthesia in infants with CHD [265]. It will be important to continue research in this field and modify CICU sedation/analgesia practices based on findings from future studies in this fragile patient population.

Longitudinal follow-up of neonates and infants who have undergone cardiac surgery demonstrates that the risk of long-term neurodevelopmental abnormalities is most likely the result of an interplay among preexisting brain injury, perioperative risk factors, and patient-specific factors (e.g., type of congenital heart lesion, socioeconomic status, gestational age, presence of genetic abnormalities). Prolonged LOS in the CICU has also been associated with worse cognitive outcomes, even when adjusting for perioperative events and sociodemographic variables [266]. Moreover, postoperative infants with CHD have impairments in autonomic, motor, attention, and state regulation [267]. CICU providers are becoming more cognizant of the disruptive and unnatural environment in an ICU and are beginning to focus on providing developmentally-appropriate and family-focused care [268]. Neurodevelopmental abnormalities appear to be most pronounced in the single ventricle population, especially those with HLHS [221, 269]. Motor deficits are significantly worse than cognitive deficits at 1 year of age. More sophisticated neuropsychological testing can be performed in older patients, and detailed follow-up of the Boston Circulatory Arrest Study group in adolescence revealed impairments in memory, visual–spatial skills, executive function, attention, and social integration [270]. A significant proportion of these patients also required academic and behavioral services, with 33% receiving tutoring and 25% receiving special education. Children with repaired congenital heart defects, in later infancy and childhood, have had more encouraging neurodevelopmental results, with one study demonstrating test results within the population normative range [271]. These long-term assessments of neurodevelopment underscore the need for the creation of integrated support systems, including physical/occupational/speech therapy, academic support, and psychological counseling to assist these at-risk children following hospital discharge. Organizations, such as the Cardiac Neurodevelopmental Outcome Collaborative, have been created to study and optimize neurodevelopmental outcomes in patients with CHD. Chapter 14 has an extensive discussion of neurological monitoring and outcomes.

AL Grawany

KEY POINTS: NEUROLOGIC MONITORING/ ASSESSMENT AND COMPLICATIONS

- Children who undergo surgical intervention as neonates and young infants appear to be at the greatest risk for the subsequent development of neurologic, developmental, and psychiatric disabilities.
- Neonates with CHD, particularly those with D-TGA and severe LV outflow tract obstruction, frequently demonstrate evidence of brain immaturity on MRI.
- Prolonged LOS in the CICU is associated with worse cognitive outcomes, even when adjusted for perioperative events and sociodemographic variables.
- The clinical manifestations of stroke are age dependent, with infants typically demonstrating altered mental status and seizures, while older children display focal neurologic deficits associated with specific cerebrovascular territories.

Fluid management and renal dysfunction

Fluid overload and renal dysfunction are important sources of morbidity and occasional mortality in the CICU. Data from the general pediatric critical care population reveal that increasing degrees of fluid overload are an independent predictor of pulmonary dysfunction, increased length of hospitalization, and mortality [272–275]. Subsequent evaluations in the postoperative cardiac population demonstrate similar findings, with fluid overload associated with longer exposure to inotropes and mechanical ventilation, longer hospital stays, development of AKI, and mortality [273, 276–280]. AKI in postoperative cardiac surgery patients has been shown to be associated in one study with younger age (particularly infants), higher surgical complexity, cyanotic lesions, longer CPB times and use of DHCA, and higher postoperative vasoactive-inotrope scores [281–283]. Two large, single-center reports also indicate that single ventricle physiology is an independent risk factor for AKI [284, 285]. Fluid overload and AKI in the cardiac surgical population are influenced by both intraoperative factors (e.g., ischemia–reperfusion injury and hypothermia from CPB, maladaptive inflammatory response to oxidative stress with capillary leak and interstitial fluid accumulation) and postoperative factors (e.g., endothelial dysfunction and capillary leak, LCOS, nephrotoxic medication administration, volume resuscitation, vasomotor instability) [281, 286, 287]. Early postoperative fluid overload is also compounded by volume replacement with crystalloid, colloid, and/or blood products in the CICU in response to progressive hemodynamic compromise from intravascular depletion secondary to capillary leak. The youngest patients, particularly neonates and young infants, who tend to have longer CPB support times, are the population at greatest risk for the development of capillary leak syndrome [288]. Subsequent development of an LCOS and increased secretion of antidiuretic hormone also contribute to fluid overload and AKI by means of renal dysfunction and delayed water clearance, which may progress to renal failure if LCOS persists. Most patients develop mild degrees of AKI by postoperative day 1 and recover within 2–3 days. Patients with increasing severity of AKI are more likely to have prolonged ventilation days and longer ICU/hospital stays [282–284]. In addition, children undergoing multiple cardiac surgeries have higher odds of developing AKI with subsequent surgeries, especially if AKI developed with earlier surgeries [289]. Long-term evaluations of children who developed postoperative AKI demonstrate an increased incidence of chronic kidney disease and hypertension at 5-year follow-up [290].

Management of fluid overload begins in the OR through the initiation of ultrafiltration. Ultrafiltration is a technique that removes low-molecular-weight solutes and plasma water through convection using hydrostatic forces to filter these substances across a semipermeable membrane. The use of conventional ultrafiltration during CPB as well as modified ultrafiltration after CPB cessation has been shown to reduce fluid accumulation in the early postoperative period, improve early postoperative hemodynamics including measured CI, decrease postoperative blood loss and blood product use, improve lung compliance with decreased duration of mechanical ventilation, improve ventricular function, and decrease ICU LOS [291–297]. Intraoperative glucocorticoids have also been used for many years to blunt the inflammatory effects of CPB; although decreased laboratory evidence of inflammation is achieved, this intervention has not been proven to result in significant improvement in clinical outcomes [298].

Fluid management post-CPB in the CICU commences with restriction of maintenance IV fluids to 50–75% of full maintenance and is coupled with judicious use of fluid replacement and vasoactive/inotropic support titrated to appropriate filling pressures and hemodynamic response. Once the patient has achieved greater hemodynamic stability and any capillary leak process has subsided, IV diuretics are instituted to accelerate fluid removal and assist with the reduction in mechanical ventilator support. Furosemide (1 mg/kg IV every 6–8 hours) is a commonly-prescribed loop diuretic that must be excreted into the renal tubular system before producing diuresis. Low CO, therefore, reduces its efficacy. Bolus dosing may result in a significant diuresis over a short period, leading to intravascular depletion and the potential for hypotension. A continuous furosemide infusion (0.1–0.3 mg/kg/hour) after an initial loading dose as a bolus may provide a more consistent and sustained diuresis without inducing sudden fluid shifts and hemodynamic lability. Chlorothiazide (5–10 mg/kg IV or PO every 6–12 hours) is also an effective diuretic, particularly when used in conjunction with loop diuretics (with chlorothiazide preceding furosemide administration by ~30 minutes when administered as intermittent dosing). Low-dose dopamine (3–5 mcg/kg/min), in addition to supporting CO, may increase renal blood flow and promote diuresis. Fenoldopam (0.1–0.5 mcg/kg/min), a selective dopamine-1 receptor agonist, may also assist in optimizing diuresis by reducing renal vascular resistance and enhancing renal perfusion; however, results of its effects on urine output and fluid balance status in young children after CPB are mixed [299, 300]. Nesiritide (0.005–0.03 mcg/kg/min), a recombinant form of brain natriuretic peptide (BNP) identical to endogenous BNP, has

been approved to treat adult acute decompensated heart failure. It can be added to the diuretic regimen as an adjunct to encourage diuresis. Its cardiac effects include increased lusitropy through a reduction in cytosolic calcium, leading to cardiac myocyte relaxation. In the kidney, it promotes diuresis through afferent arteriolar vasodilation and efferent arteriolar vasoconstriction. The limited reports of its use in the pediatric population suggest that it can be used safely in the pediatric heart failure population to promote diuresis [301–303]. However, caution is advised with the use of nesiritide, as administration has been associated with worsening renal function and risk for mortality in adults with decompensated heart failure. This has led to a rapid decline in its use overall and associated reduction in its use in pediatrics in the setting of insufficient data [304, 305].

AKI occurs commonly in the CICU, with a reported incidence of 15–60% [281–285, 306]. This wide range of reported incidence is likely due to use of differing criteria to define AKI, as well as examination of different study populations. The most commonly used criteria to define AKI are the pediatric RIFLE (pRIFLE), AKIN, and KDIGO criteria (Table 36.10). The pRIFLE criteria were developed as a pediatric application of the adult RIFLE criteria, an acronym standing for risk, injury, failure, loss, and end-stage kidney disease [307, 308]. Patients are grouped into three categories (corresponding to AKI) based on progressive declines in urine output and estimated Cr clearance via the Schwartz equation. The AKIN criteria define three stages based on progressive increases in serum Cr from baseline, with a minimum increase of 0.3 mg/dL, and it categorizes any patient receiving renal replacement therapy (RRT) as failure [309]. The KDIGO criteria, which was created in 2012 by harmonizing the adult RIFLE, pRIFLE, and AKIN criteria with validation in both pediatrics and adults, rely on rise in serum Cr and changes in urine output. It is defined in three stages based on the degree of serum Cr rise above baseline and extent of urine output [310].

While serum Cr has traditionally been used as the gold standard for the assessment of renal function, assessments of AKI based on increases in serum Cr may delay diagnosis and render interventions ineffective, as renal injury occurs well before changes in Cr levels are reflected in serum measurements. Extensive basic and translational science research has yielded the discovery of several emerging biomarkers that may allow for a more rapid diagnosis of AKI. The best-described biomarkers include neutrophil gelatinase-associated lipocalin (NGAL), cystatin C, interleukin-18 (IL-18), IL-8, liver fatty acid-binding protein (L-FABP), and kidney injury molecule-1 (KIM-1). All of these biomarkers have been studied in the post-CPB population, and single-center studies have been shown each to be independent predictors of AKI [311–316]. When these same biomarkers were evaluated in prospective, multicenter observational studies, they did not perform as well, particularly in discriminating mild AKI, but they were predictive of more severe degrees of AKI [317, 318]. Further research is ongoing regarding the use of biomarkers in the diagnosis of AKI and their potential for the evaluation of therapeutic interventions.

There are currently no recognized medical therapies for the treatment of AKI in the pediatric population. *N*-acetylcysteine (NAC) has known antioxidant properties and has been used historically to prevent or attenuate renal injury related to IV contrast exposure for radiologic studies. Multiple randomized, placebo-controlled studies in adults have failed to demonstrate any clear benefit of NAC in the prevention of AKI, and its use for this purpose in the pediatric population has not been reported [319]. Aminophylline in a single-center retrospective study has been reported to improve renal excretory function and augment urine output in CICU patients with oliguric AKI [320]. A comparative retrospective study between diuretic and aminophylline intraoperatively for oliguria showed similar urine output at 48 hours after surgery with no difference in AKI; less RRT use occurred in the aminophylline group [321]. A randomized, double-blinded, placebo-controlled study examining aminophylline use in the postoperative pediatric cardiac population found no difference in rate or severity of AKI, fluid balance, or urine output [322].

When AKI progresses to renal failure, RRT may be indicated to treat fluid overload, severe electrolyte or metabolic derangements, and symptomatic uremia and to address fluid restriction, which limits the delivery of adequate nutritional support. A peritoneal dialysis (PD) catheter may be placed intraoperatively or postoperatively for either simple drainage with the goal of reducing intra-abdominal pressure or the institution of true PD. Reports on prophylactic placement of PD catheters with early institution of dialysis in the immediate postoperative period to relieve fluid overload have shown shorter time to achievement of negative fluid balance, decreased duration of mechanical ventilation, and decreased inotrope scores [323]. A randomized clinical trial of PD versus furosemide for the prevention of fluid overload in postoperative cardiac patients showed the PD group to have a lesser degree of fluid overload, shorter inotrope use duration, and fewer electrolyte imbalances, but there were no differences in mortality [324]. Earlier PD initiation has been shown to be associated with better clinical outcomes and survival advantage in one study [325]. Complications of PD catheter placement and use include infection and injury to abdominal organs, but PD use is generally safe with minimal rate of adverse events [324, 326, 327]. It is important to note that a persistent communication between the peritoneum, mediastinum, and/or pleural cavities early following surgery may limit the effectiveness of PD. A more recent meta-analysis suggests that PD use may be associated with increased odds of mortality, indicating that further evaluation of the efficacy of PD use in postoperative pediatric cardiac surgical patients is indicated [328].

Double-lumen, large-bore catheters may also be inserted into a large systemic vein to institute intermittent hemodialysis or CRRT. As postoperative cardiac patients frequently will not tolerate the larger fluid shifts generated through intermittent hemodialysis, CRRT is typically the modality of choice and is more efficient than PD in both fluid and solute removal. Complications related to this therapy include infection, catheter-related venous thrombosis, and potential hemodynamic instability related to fluid shifts. In the general pediatric intensive care population, an association between mortality and increasing degrees of fluid overload prior to CRRT initiation is reported, suggesting that earlier initiation of this therapy may be beneficial [329]. For pediatric cardiac patients, data suggests that the risk of requiring CRRT is higher in children undergoing cardiac surgery, and that the need for CRRT after cardiac surgery is associated with higher

mortality. Similar to the experience of PD, earlier initiation of CRRT may lead to lower mortality when compared to later use [330, 331]. In addition, with the development of CRRT devices that can be used in neonates and infants as small as 2.5 kg (central venous catheter sizes ranging from 4 to 7 Fr), the application of CRRT to younger and smaller patients may be on the horizon [332, 333].

Aquapheresis is another modality for patients needing only fluid removal and not solute clearance. It has been used in adult heart failure patients and can be deployed in children with smaller catheters and a smaller module with lower extracorporeal volumes; this reduces blood product exposure because a blood prime is no longer required [334]. Thus far, data on aquapheresis use in pediatrics and pediatric cardiac patients are limited, thus warranting further evaluation [335–337]. A prospective registry study looking at the utility and safety profile of aquapheresis in pediatric populations is currently underway.

KEY POINTS: FLUID MANAGEMENT AND RENAL DYSFUNCTION

- Neonates and young infants who have been exposed to longer CPB times are the population at greatest risk for the development of capillary leak syndrome and AKI.
- Patients with AKI after cardiac surgery are more likely to require prolonged support with mechanical ventilation, longer hospitalizations, and increased inotropic support, and their risk of mortality is increased.
- Several emerging biomarkers that may allow for a more rapid diagnosis of AKI, including NGAL, cystatin C, IL-18, L-FABP, and KIM-1, have recently been described.
- Fluid restriction and diuretic therapy continue to be the primary treatments to reduce postoperative fluid overload in the CICU.
- PD and hemodialysis should be considered in patients with fluid overload refractory to diuretic therapy, severe electrolyte or metabolic derangements, symptomatic uremia, and inadequate nutrition.
- Although the need for CRRT in the postoperative period for pediatric cardiac surgery patients is associated with overall worse outcomes, early initiation of CRRT appears to mitigate this effect to some extent, and newer devices allow CRRT to be applied safely in children weighing 5 kg or less.

Nutrition and gastrointestinal complications

Adequate delivery of nutrition is a vital component in the care of critically ill children. Several studies in the pediatric and adult critical care population have underscored the importance of nutritional therapy by demonstrating its role in reducing the incidence of infection, duration of mechanical ventilation, and length of hospital stay [338–340]. Despite the importance of optimizing nutritional intake, there are often multiple barriers to the delivery of adequate calories to patients in the CICU. These barriers include dynamic changes in energy expenditure, particularly in the early postoperative period, and the need for postoperative fluid restriction. Parenteral nutrition (PN) is frequently employed in the early postoperative period secondary to concerns regarding systemic or splanchnic hypoperfusion and feeding intolerance. However, a recent multicenter trial has shown that withholding PN for up to 1 week has been clinically superior with respect to infection rate and length of mechanical ventilation when compared with the strategy of providing early PN [341].

These data have put into question the current paradigm of early PN in postoperative pediatric cardiac patients, as this study showed greater risk for nosocomial infection in the early PN group. The duration of mechanical ventilatory support was shorter, and the likelihood of being weaned alive earlier from mechanical ventilation was higher among patients receiving late PN than among those receiving early PN. This may be due to the fact that earlier PN makes fluid management more challenging and overestimates caloric needs. In fact, a recent systematic review demonstrated that indirect calorimetry-guided energy delivery prevented the well-known risks of under- and overfeeding and reduced short-term mortality in critically ill patients [342]. It is likely that a subset of early postoperative patients may have reduced total energy expenditure, similar to hibernation, and thus standard calculations of total energy expenditure may overestimate energy requirements and thus impose an unnecessary ventilatory load.

As in the critically ill adult population, stress ulceration and gastritis can occur in pediatric patients; historically, universal stress ulcer prophylaxis (SUP) has been recommended. Recently, however, this paradigm has been reassessed, and the risk of harm from SUP has been demonstrated in pediatric and adult ICU patients. The SUP ICU trial was a multicenter trial that demonstrated no mortality benefit between IV pantoprazole and placebo, despite a reduction in clinically significant gastrointestinal (GI) bleeding [343]. In pediatric patients, the data are observational, but they demonstrate that clinically significant bleeding is rare, multiagent prophylaxis common, and complications are frequently associated [344]. In addition, a number of meta-analyses have demonstrated risks with SUP for ventilator-associated pneumonia in enterally fed adult [345] and PICU patients [346].

Postanesthesia nausea and vomiting are frequent in the early postoperative period, particularly in patients who have been fast-tracked to extubate either in the OR or within several hours of arriving in the CICU. The use of antiemetics, such as 5-HT_3-receptor antagonists, H_1-histamine receptor antagonists, benzodiazepines, anticholinergics, and dexamethasone, may be helpful in mitigating this response.

Early resumption of enteral nutrition is encouraged to reduce the risk of nosocomial pulmonary and bloodstream infections by preventing bacterial overgrowth and to minimize complications associated with the delivery of parental nutrition, including catheter-related infection and liver injury or cholestasis. The use of feeding algorithms (one example is shown in Figure 36.9) has been demonstrated to improve the introduction of enteral nutrition following cardiac surgery [347, 348], although no one specific algorithm has been demonstrated to be superior. Unfortunately, the introduction of enteral nutrition can be compromised by the presence of splanchnic hypoperfusion due to LCOS or from low diastolic pressure in patients with runoff from systemic-to-PA shunts or a large PDA in the preoperative period. Clinical

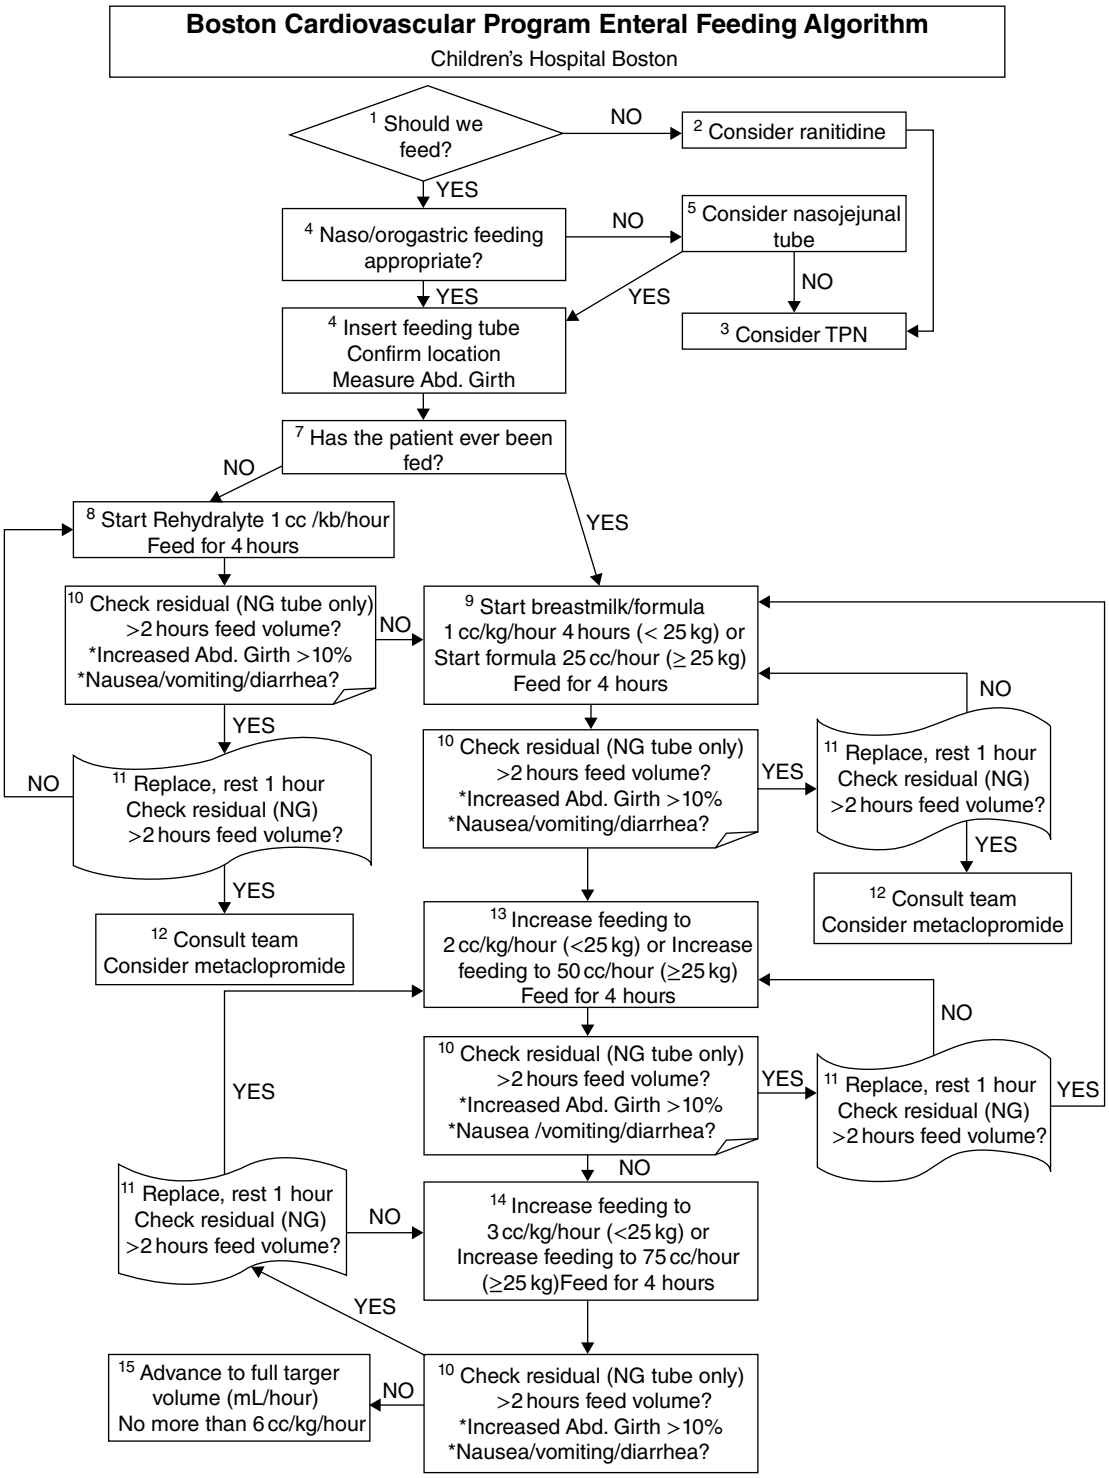

Figure 36.9 Feeding algorithm. (Source: Braudis et al. [347]. Reproduced with permission of Wolters Kluwer Health, Inc.)

manifestations of splanchnic hypoperfusion range from feeding intolerance and ileus to necrotizing enterocolitis [349]. The onset of abdominal distension, bloody stool, and pneumatosis intestinalis on abdominal radiograph suggests necrotizing enterocolitis. Severe cases may also demonstrate signs of abdominal wall cellulitis, sepsis, hemodynamic instability, and gut perforation. Initial treatment includes discontinuation of enteral feeds, support with PN, and broad-spectrum IV antibiotics [350]. Hemodynamic support may be necessary, and occasionally laparotomy if perforation occurs or hemodynamic instability persists.

Other causes of feeding intolerance in the pediatric cardiac population include bowel edema following CPB, delayed gastric emptying secondary to opioid use for perioperative analgesia, gastroesophageal reflux, vocal cord dysfunction, and small bowel obstruction secondary to malrotation,

particularly in the heterotaxy population [351, 352]. Patients with decreased ventricular function may be unable to increase their CO sufficiently to meet the metabolic demand associated with oral feeding and the absorption of food. Coexisting respiratory problems such as tachypnea may also restrict oral intake. Placement of an enteral feeding tube is helpful to ensure adequate nutritional intake in these circumstances. Transition from nasogastric to transpyloric feeding may also be considered in patients with delayed gastric emptying, respiratory compromise requiring noninvasive PPV with accompanying gastric insufflation, and severe gastroesophageal reflux. In addition, progressive increases in the caloric density of enteral feeds (e.g., from 20 to 28–30 calories/oz) are frequently required to meet patient metabolic demands and prevent fluid overload. Consultation with a registered dietician, assessment of somatic growth by measuring serial weights, analysis of nutritional status via biochemical markers (i.e., albumin, prealbumin, and transferrin), and consideration of indirect calorimetry to assess resting energy expenditure can assist in ensuring the adequate delivery of calories [353].

Liver dysfunction may also occur in CICU patients. It is typically related to a persistent LCOS causing ischemic hepatitis or complications related to CPB, including inadequate venous drainage from the lower body and low perfusion pressure. Patients following a Fontan procedure may be at particular risk because of hepatic venous congestion from persistently elevated central venous pressure. Marked elevations in liver transaminases may be detected within hours of surgery and remain elevated for 2–3 days before gradually returning to normal. These patients typically have elevated prothrombin time and PPT as well and are thus at increased risk of bleeding complications. However, fulminant hepatic failure is uncommon.

Finally, the presence of chylothorax can pose a significant challenge to establishing adequate nutrition and enteral feeding. Chylous effusions tend to be milky in appearance, have a cell count of predominantly lymphocytes (>80%), and test positive for triglycerides. Standardized diagnostic criteria and subsequent management strategies are lacking, further exacerbating compromised nutritional status in these complex patients. Generally, initial steps involve transitioning to a medium-chain triglyceride or low-fat diet. For persistent, high-output losses (>10 mL/kg/day), cessation of feeds, and initiating total PN are subsequent steps; NPO periods may last anywhere from 5 to 21 days. Additional treatment interventions vary among institutions and availability of expertise and resources [354].

KEY POINTS: NUTRITION AND GASTROINTESTINAL COMPLICATIONS

- Patients in the CICU are often malnourished from the catabolic state induced by CHF and postoperative stress, as well as fluid restriction secondary to capillary leak and renal dysfunction.
- Enteral nutrition may be compromised by splanchnic hypoperfusion due to low CO or from low diastolic pressure in patients with runoff systemic-to-PA shunts.
- The use of feeding algorithms has been demonstrated to improve the introduction of enteral nutrition following cardiac surgery.
- Postoperative chylothorax further compromises nutritional challenges.

SARS-CoV-2 infection and multisystem inflammatory syndrome in children

Since its emergence late in 2019, the coronavirus disease 2019 (COVID-19), caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has caused a global pandemic resulting in the loss of millions of lives, significant and persistent health complications in those who survive severe infection, and disruption of the global economy and geopolitical climate [355–358]. In April 2020, reports began to emerge of a new clinical entity affecting children associated with SARS-CoV-2 in different regions of the world. The clinical presentation was similar to the hyperinflammatory responses described in Kawasaki disease (KD), toxic shock syndrome (TSS), and hemophagocytic lymphohistiocytosis/macrophage activating syndrome (HLH/MAS) and occurred following prior exposure to/infection with SARS-CoV-2 [357, 359–361]. The term "Multisystem Inflammatory Syndrome in Children" (MIS-C) has since been given to this newly documented and distinct condition.

The case definition for MIS-C includes the following: (i) age <21 years, (ii) fever ≥38 °C for ≥24 hours *or* subjective fever lasting ≥24 hours, (iii) lab evidence of inflammation (e.g., abnormal C-reactive protein, erythrocyte sedimentation rate, fibrinogen, D-dimer, ferritin, lactate dehydrogenase, procalcitonin, IL-6), (iv) severe illness requiring hospitalization with ≥ two organ system involvement (e.g., cardiac, renal, respiratory, hematologic, GI, dermatologic, neurologic), (v) no alternate plausible diagnosis, and (vi) current or recent SARS-CoV-2 infection by polymerase chain reaction (PCR)/serology/antigen test *or* exposure to suspected/confirmed COVID-19 case within the previous 4 weeks prior to onset of symptoms [362–364]. MIS-C is thought to be a post-viral inflammatory response resulting in organ dysfunction (e.g., decreased myocardial performance) and not secondary to unremitting infection [363]. Although the majority of children infected with SARS-CoV-2 experience mild-to-minimal disease, severe disease in children has been noted [363–365]. As more cases of both severe infection in children with SARS-CoV-2 requiring hospitalization and MIS-C arise, additional data support that differences do exist between these two entities [365]. In MIS-C, serologic antibody testing is frequently positive while PCR may be negative, the median age is older for MIS-C than in children hospitalized with severe COVID-19 infection, there is an increased incidence of MIS-C in children of African/Afro-Caribbean descent, and those with MIS-C are more likely to have cardiorespiratory or isolated cardiovascular involvement with myocardial dysfunction and shock as presenting symptoms [365]. The degree of cardiovascular involvement, older age at presentation, and elevated cardiac enzymes and BNP along with a higher degree of inflammatory markers can also help distinguish MIS-C from KD. Cardiovascular involvement in MIS-C includes LV systolic dysfunction of varying degrees, arrhythmias, pulmonary edema secondary to elevated left heart filling pressures from diastolic dysfunction, coronary artery aneurysms (CAAs), elevated serum troponin and BNP levels, and cardiovascular collapse requiring CPR and ECMO [365, 366]. GI symptoms are also common in those with MIS-C. In children with either potential or diagnosed MIS-C, early consideration of admission to an ICU (preferably a CICU with experience in

managing myocarditis and cardiogenic shock) should be considered.

Although a significant amount of literature exists on respiratory management strategies in adults with severe SARS-CoV-2 infection requiring mechanical ventilation, data and consensus guidelines on respiratory management in children with severe SARS-CoV-2 infection are currently lacking. This is due, in large part, to minimal-to-mild illness in most pediatric patients infected with SARS-CoV-2. Initial large-scale adult clinical data utilized a higher degree of PEEP use for hypoxemia and increased utility of prone positioning along with successful use of noninvasive ventilatory support [367]. Over time and with more experience using different ventilation strategies in patients with SARS-CoV-2 and severe respiratory involvement, treatment approaches have changed to promote noninvasive ventilatory support and less emphasis on institution of early invasive mechanical ventilation. In addition, high empiric PEEP strategies for hypoxemia in otherwise fairly compliant lungs are no longer considered favorable due to significant hemodynamic impairment secondary to high PAP [368]. In children with severe respiratory involvement with SARS-CoV-2, the pediatric acute respiratory distress consensus guidelines appear to be beneficial. These include early consideration of noninvasive PPV, permissive hypercapnia, tidal volumes 5–8 mL/kg, moderately elevated PEEP, inspiratory plateau pressure <32 cmH_2O, alveolar recruitment maneuvers, SpO_2 levels >88%, goal-directed fluid management, and minimizing systemic metabolic demand while optimizing systemic oxygen delivery [369].

MIS-C with cardiovascular or cardiorespiratory involvement should be treated similarly to children presenting with myocarditis. Achieving appropriate gas exchange while maintaining lung volumes at FRC may require NIV or invasive ventilation strategies. Although children commonly present as comfortably tachypneic, intubation and invasive mechanical ventilation may be indicated for progressive hypoxemia, altered mental status, or failure to improve respiratory distress despite initiation/escalation of noninvasive PPV. The use of personal protective equipment (PPE) during the aerosol-generating process of intubating a patient with known SARS-CoV-2 infection or patient under investigation (PUI) for SARS-CoV-2 infection is of paramount importance. This includes at a minimum a properly fitted N95 mask and sufficient eye protection, as well as gown and double gloves. Under some conditions, this may result in the need for higher levels of protection, such as a powered air-purifying respirator. This process requires adherence to specific institutional polices regarding essential staffing so that provider exposure inside and outside the patient room is minimized, appropriate donning/doffing techniques for PPE are used, and a closed ventilator circuit with ventilator filters is maintained [370]. Procedures in which the ventilator system must be opened to the environment should be minimized as much as possible, as this increases the risk of aerosolizing potentially infectious viral particles.

In children presenting with MIS-C and LV systolic dysfunction complicated by pulmonary congestion due to heart failure, PPV may both re-recruit collapsed alveoli and improve respiratory distress. Furthermore, PPV in this setting will also decrease LV afterload, increase LV stroke volume, and lower myocardial oxygen demand. Myocardial dysfunction culminating in cardiogenic shock occurs commonly in MIS-C [366], and the initiation of inotropic and/or inodilator support (e.g., epinephrine, dopamine, dobutamine, and milrinone) is recommended to improve CO and systemic oxygen delivery. If a child is presenting instead in distributive shock secondary to the immune-dysregulated response associated with MIS-C, peripheral vasoconstricting agents can be administered (e.g., norepinephrine, vasopressin). If IV volume expansion is indicated to support an adequate blood pressure, providing gentle resuscitation with small volume boluses in 5 mL/kg aliquots with frequent reevaluation of the CO examination and respiratory examination is suggested to reduce the likelihood of creating fluid overload in the setting of systolic and/or diastolic heart failure.

After an initial evaluation measuring serum troponin and BNP levels, trending these values through the hospitalization should be considered. An ECG and echocardiogram should be performed early in cases of diagnosed or suspected MIS-C to document the cardiac rhythm and conduction and assess the degree of myocardial injury/ischemia, myocardial dysfunction, and the appearance of the coronary arteries (both their dimensions and to look for aneurysms). Continuous ECG monitoring and telemetry are warranted due to the incidence of arrhythmias in children with MIS-C [365, 366]. Similar to classic myocarditis, the presence of arrhythmias in MIS-C should be closely monitored and treated in consultation with cardiac electrophysiology consultants; arrhythmias may serve as a marker for significant myocardial dysfunction/irritability, which can lead to clinical decompensation. The severity of LV systolic dysfunction can vary in MIS-C [365, 366], while RV systolic dysfunction appears to be quite rare [366]. However, studies to date report that the vast majority of patients have a normalization of LV systolic function over time [365, 366]. As MIS-C and KD share a vasculitis component caused by a postviral inflammatory response as a possible etiology, CAAs have been described in MIS-C, and they warrant treatment with high-dose intravenous immune globulin (IVIG) along with high-dose aspirin. Close monitoring during and after the hospitalization to evaluate for regression of CAAs should be performed similar to treatment guidelines for KD [371].

As our understanding of MIS-C develops further, treatment options are likely to evolve over time. At the time this chapter was updated, high-dose IVIG (2 g/kg), methylprednisolone, and low-dose aspirin remain the most commonly accepted therapeutic treatments [357, 362–364, 366] for MIS-C, with IVIG and glucocorticoids being used either alone or in combination. One study suggests that recovery from MIS-C did not differ after primary treatment with IVIG alone, glucocorticoids alone, or IVIG+glucocorticoids; however, differences in outcomes may emerge as additional data accrues [372]. Additional therapies that can be considered in consultation with appropriate subspecialty services include IL-2 receptor antagonists and IL-6 receptor antagonists. The presence of a variety of potential treatments emphasizes that we do not yet have a specific treatment regimen that is clearly documented to be effective in changing the course of MIS-C. Careful consideration should be given to the use of high-dose IVIG, as this constitutes a large IV volume load that may not be well tolerated in the setting of myocardial dysfunction. Mitigation tactics for this risk include administration of IVIG slowly or using lower volume aliquots along with the addition of diuretic therapy. As the inflammatory response in MIS-C can result in

AL Grawany

a prothrombotic state, anticoagulation with heparin or enoxaparin and antiplatelet agents is strongly recommended [357].

A multidisciplinary approach to management of the child presenting with MIS-C is of paramount importance, and the involvement of cardiology, infectious diseases, and rheumatology services is recommended. The role of the cardiac intensivist in coordinating the evaluations and considerations of these and other subspecialty services (e.g., hematology, nephrology, gastroenterology, neurology, dermatology) in MIS-C cases will optimize the support and treatment strategies offered to the child admitted to the CICU. The use of ECMO in children with MIS-C with refractory cardiogenic shock or those who experience IHCA is supported by the limited published literature, and the outcomes in MIS-C patients supported with ECMO have been reassuring to date [365, 366]. Currently, no guidelines exist that clearly support the use of cardiac catheterization to obtain endomyocardial biopsies in the prognostication or risk stratification of MIS-C; however, follow-up cardiac MRI may be useful for that purpose [357]. Cardiac catheterization to assess hemodynamics and consider interventions (e.g., BAS while supported on peripheral VA-ECMO) may be considered by the cardiac intensivist if the general course of myocarditis is not following an improving trajectory.

Institutional practices in the evaluation and management of children with MIS-C may vary, and the reader is advised to refer to the MIS-C guidelines in use at their respective institution/practice. One example of an institution-specific MIS-C pathway can be found in Figure 36.10. This pathway, which was developed at Lucile Packard Children's Hospital Stanford and last updated in May 2021, highlights inclusion criteria, laboratory testing, indications for admission, indications for treatment, treatment options, diagnostic and consultation considerations, anticoagulation therapy, and respiratory/cardiogenic shock management considerations. As we continue to learn more about the impact of SARS-CoV-2 active infection and the postinfectious inflammatory response that constitutes MIS-C and its place along a continuum with KD/TSS/HLH/MAS, therapies and optimal practice patterns will continue to be revised and improved. The reader of this section is strongly advised to evaluate the most up-to-date literature regarding SARS-CoV-2 infection in children and MIS-C when caring for patients with these newer disease processes.

Background, introduction, and history

The successful use of extracorporeal membrane oxygenation (ECMO) in children began in the late 1970s when Bartlett et al. applied this technology to term newborn infants with respiratory failure [1]. In 1973, Soeter et al. described the ECMO use for cardiorespiratory failure after tetralogy of Fallot repair [2]. Later in 1987, Kanter et al. reported the first series of 13 patients with postoperative cardiac failure treated with ECMO [3]. The utilization of ECMO for cardiac support has increased steadily since the 1980s. Improved perfusion and anticoagulation techniques make the support safer so that it may be initiated earlier and not as a last resort. Data from the Extracorporeal Life Support Organization (ELSO) reveal an increase in ECMO support of 24% from 2009 to 2015, with overall survival of 62% [4]. Neonatal cardiac, neonatal, and pediatric extracorporeal life support (ECLS) to support cardiopulmonary resuscitation (CPR) have lower survival rates.

The first successful use of a left ventricular assist device (LVAD) as a bridge to heart transplant in an adult was reported by Cooley et al. in 1969 [5]. The first description of ventricular assist device (VAD) use in children was 20 years later, and the authors concluded that, as adults, VAD bridge to transplantation in children is possible [6]. In the 1990s, LVAD use in children was sporadic. However, VAD implantation in children has grown exponentially [7, 8].

Indications for mechanical support

Mechanical support can be considered for children with potentially reversible cardiac failure, respiratory failure, pulmonary hypertension (PHTN), and cardiorespiratory arrest. When used for cardiac failure, the primary goal is to rest the myocardium to allow recovery of function (bridge to recovery, BTR). Sometimes is difficult to estimate myocardial recovery, especially amid organ failure. In this situation, mechanical support can stabilize the patient before making a

AL Grawany

long-term decision (bridge to decision, BTD). In the absence of recovery of the myocardium, the patient may be transitioned to long-term mechanical support while awaiting a heart transplant (bridge to transplant, BTT) [9]. Adult patients can have a permanent mechanical device to support the circulation for the remainder of their lives (destination therapy, DT) if they are not heart transplant candidates (e.g. 70 years, malignancy, or severe comorbidities) [10]. Recently, several reports of DT in the pediatric population have been published [11]. The goal is not only to improve survival but also to improve the quality of life [12]. As with adults, pediatric patients, non-transplant candidates, such as those with muscular dystrophy, malignancy, comorbidities (e.g., severe obesity), or high allosensitization could be offered VAD as DT.

The indications for mechanical circulatory support (MCS) in children are often divided into two groups: those related and those unrelated to cardiac surgery (Box 37.1).

As a general principle, ECMO could potentially be used for all the indications in Box 37.1, and VAD is only considered in the absence of PHTN or respiratory dysfunction. There are pros and cons of VAD and ECMO devices, and sometimes, they are used in sequence. However, either device can be used as BTR, BTD, or BTT. The choice depends on the acuity of illness, comorbidities, the recovery potential, and anticipated duration of support [13]. In addition, if there is a choice between ECMO and VAD, a LVAD is preferable if patients are suspected of needing longer than 2 weeks of circulatory support and if the support is intended as a bridge to transplant. As ECMO has become safer, it is generally agreed that mechanical support should be initiated early before circulatory collapse to avoid prolonged periods of low cardiac output state (LCOS) and organ hypoperfusion. Patients with cardiac dysfunction after cardiopulmonary bypass (CPB) have a better prognosis when ECMO is initiated in the operating room (OR), rather than waiting for deterioration in the pediatric intensive care unit (PICU). In one study of 81 children, those placed on ECMO in the OR had a survival rate of 64%, whereas those put on ECMO in the PICU had a 29% recovery [14]. Pediatric patients who failed to wean off CPB requiring ECMO are a high-risk population with a mortality of 55% [15].

Box 37.1: Indications for mechanical support in neonates, infants, and children

Indications related to cardiac surgery
- Preoperative stabilization and support
- Postoperative support
  - Failure to wean from cardiopulmonary bypass
    - Low cardiac output state
    - Respiratory failure
    - Severe hypoxemia (occluded shunt or right-to-left shunt)
    - Cardiac arrest

Indications unrelated to cardiac surgery
- Respiratory failure (oxygenation and/or ventilation failure)
- Septic shock
- Cardiovascular indications
  - Myocarditis
  - Cardiomyopathy
  - Intractable arrhythmias
  - Instability during cardiac catheterization
  - Pulmonary hypertension
  - Intoxicants
  - Bridge to organ donation
  - Cardiac arrest

Preoperative stabilization and support

Occasionally, neonates with severe cyanosis or cardiogenic shock require preoperative mechanical support for stabilization before cardiac surgery. There are many case reports of successful use of ECMO in this context [16]. At Royal Children's Hospital and Texas Children's Hospital, we have numerous successful anecdotal examples of preoperative ECMO use. At the Children's Hospital, Boston, a retrospective review over 13 years demonstrated the use of ECMO in 26 patients with acute cardiorespiratory deterioration and unrepaired congenital heart disease (CHD) as a bridge to palliative or definitive surgery. Sixteen out of 26 patients survived to discharge. [17] Despite no studies showing superiority of this approach, it is reasonable to conclude that preoperative ECMO may be a useful rescue modality to allow cardiopulmonary and other end-organ recovery as well as a bridge to surgery. Specifically, however, it is noted that neonates with obstructed total anomalous pulmonary venous return (TAPVR) are poor candidates for this approach as the pulmonary pressures remain unacceptably high despite mechanical support and surgery should be performed promptly [17, 18]. Despite this, however, preoperative ECMO can still be lifesaving in patients with obstructed TAPVR.

Failure to wean from CPB or LCOS after cardiac surgery

Failure to wean from CPB after congenital heart surgery is the most common cardiac indication for mechanical support and it is estimated that 2–5% of all children require ECMO after congenital heart surgery [4, 19]. Extracorporeal cardiac life support may be required after CPB due to an LCOS, respiratory failure or severe hypoxemia (due to right-to-left shunt or occluded systemic-to-pulmonary artery shunts). The etiology of an LCOS after CPB may be anatomical (and must be excluded by echocardiography or sometimes catheterization), ventricular dysfunction (often due to long CPB and cross-clamp times), arrhythmias, or PHTN [20]. Mechanical support could be required immediately on attempted separation from CPB or may be required later and used as rescue in intensive care. If mechanical support is initiated in the OR, the cannulas are often placed in the right atrium and aorta via the sternotomy.

Criteria for considering ECMO or VAD in patients with LCOS include a progressive increase in inotrope or vasopressor dosage with evidence of poor end-organ perfusion, such as reduced mixed venous oxygenation <40%, reduced cerebral saturation (>20% below baseline), oliguria, or metabolic acidosis with increasing lactate. Again, initiation of early mechanical support in these situations shows better outcomes [9].

Patients with single-ventricle physiology or cyanotic heart disease are more likely to require mechanical support after CPB. According to the ELSO registry 2015, the most frequent CHD requiring ECMO in neonates is hypoplastic left heart

syndrome (HLHS), with 33% survival of stage 1 palliation surgery, although generally those who require ECMO for hypoxia (often an occluded shunt) have a better outcome than those who require support for low cardiac output [21]. A recent systematic review and meta-analysis of ECMO after CHD repair showed the most common reason for ECMO was left ventricular (LV) dysfunction with LCOS. About 60.3% were able to wean from ECMO and the overall in hospital mortality was 56.8%. Single-ventricle physiology and renal failure were the only independent risk factors for in-hospital mortality [22].

Resuscitation of cardiac arrest

Resuscitation of children with ECMO during CPR for cardiac arrest was first described in 1992. del Nido et al. reported on the use of veno-arterial ECMO (VA-ECMO) for 11 children with a witnessed sudden cardiac arrest [23]. Ten out of 11 patients were centrally cannulated, and seven patients survived to hospital discharge. Using extracorporeal support for management of cardiac arrest is termed "extra-corporeal cardiopulmonary resuscitation" (ECPR). Rapid VA-ECMO for patients suffering in-hospital cardiac arrest (IHCA) has been used increasingly in pediatrics since then [18, 24, 25].

The American Heart Association (AHA) 2010 resuscitation guidelines state, "There is increasing evidence that extracorporeal cardiac life support (ECLS) can act as a bridge to maintain oxygenation and circulation in selected infants and children with cardiac arrest if they are transplant candidates or have a self-limited or treatable illness" [24]. When compared with CPR alone, it appears that ECPR improves survival by 12–23% in children [26]. This is consistent with a multivariate analysis of an observational registry study which showed higher rates of survival to hospital discharge for those managed with ECPR [27]. From analysis of the same registry, ECPR was associated with better neurological outcomes in patients with IHCA of any etiology [28]. After longer-term follow-up, overall, about one-third of pediatric patients have good neurobehavioral outcomes 1 year after ECPR for IHCA [29]. The AHA pediatric resuscitation guidelines of 2020 recommend "ECPR may be considered for pediatric patients with cardiac diagnoses with IHCA in settings with existing ECMO protocols, expertise and equipment" [25, 27, 28]. ECPR is typically only effective when arrest occurs in a highly monitored environment (such as the intensive care); the AHA cautions that there is insufficient evidence for or against for the use of ECPR in out of hospital cardiac arrest or IHCA in patients with noncardiac disease [25]. The AHA (2010) states that there is no good evidence for an upper limit as to the length of CPR after which ECPR should be considered futile; it is known that long-term survival is possible after >50 minutes of CPR [30].

A recent review of the ELSO registry for term and premature neonates receiving ECPR from 1998 to 2010 revealed 39% survived to discharge, however, gestational age, corrected gestational age, and birth weight correlated inversely with stroke and death. Of those born before 34 weeks, the survival was 21%. As expected, if dysrhythmia was the primary diagnosis, the odds of death were significantly lower than those with single-ventricle physiology. Overall, the survival rate was like that of older children receiving ECPR [31]. The April 2021 ELSO report also revealed an overall 42% survival to discharge or transfer in neonatal and pediatric patients receiving ECPR [21]. Chapter 25 presents more information about cardiac arrest and resuscitation in CHD.

Respiratory failure and lung transplantation

When considering mechanical support for respiratory failure, neonatal patients are typically differentiated from (older) pediatric patients due to different etiologies and pathophysiology. With neonates, the conditions requiring ECMO are either acquired at birth or congenital in origin, such as meconium aspiration, pulmonary hypoplasia (possibly with congenital diaphragmatic hernia (CDH)), pneumonia/septicemia, and persistent PHTN of the newborn [32]. Of these neonatal causes, CDH and meconium aspiration syndrome (MAS) are the two most common reasons for the use of ECMO. The specific criteria for ECMO in neonates with respiratory disease vary depending on etiology and on location of providers [33, 34]. However, the general principle is to refer for ECMO due to failure to improve on optimal medical management (lung protective strategies, pulmonary vasodilators, surfactant, and high-frequency ventilation) and the desire to avoid ventilator-associated lung injury. The optimal timing, however, may be difficult, since ECMO is no longer seen as a last-ditch attempt, so that, intervention is aimed at reducing morbidity as well as mortality [35]. Outcome is dependent on multiple factors, including etiology and underlying associated conditions; the 2016 ELSO registry suggests that neonates with CDH requiring ECMO have a 51% survival whereas those with MAS requiring ECMO have an overall 94% survival [4, 35].

The use of ECMO in the neonatal population decreased in the 1990s due to advances in ventilation strategies (including high-frequency oscillation) and medical management, such as nitric oxide (NO) [36]. However, the rate of ECMO use for persistent PHTN and CDH has remained steady. Currently, in total, approximately, 800 neonates require ECMO support annually [4].

Older pediatric patients require ECMO because of acquired conditions, such as pneumonia (bacterial, viral, or fungal), aspiration, acute respiratory distress syndrome (ARDS), or acute respiratory failure from other causes [4]. Of these, infection is the leading cause of respiratory failure requiring ECMO [37]. Today, many pediatric patients requiring ECMO have significant comorbidity, such as renal, lung, and heart diseases. In an ECMO registry review, 19% of these patients had comorbidities in 1993, compared with 47% in 2007 [38]. Because of a lack of randomized controlled trials, the use of ECMO as a treatment modality has been slowly accepted, and recent evidence demonstrates accelerated interest from new advances in equipment/technique [39]. For example, veno-venous cannulation has reduced the need for carotid puncture and therefore reduced the risk of neurological complications [38]. Veno-venous ECMO (VV-ECMO) has had a higher survival to discharge compared with VA-ECMO [37]. During the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic, a minority of pediatric patients with multisystem inflammatory syndrome in children

(MIS-C) required ECMO support. A systematic review of reported cases fulfilling the WHO criteria of MIS-C showed that the need for ECMO was 4% in 783 patients [40]. The ELSO supports the early use of VV-ECMO in ARDS due to SARS-CoV-2 in patients that other measures have failed, especially prone positioning [41].

Technically, ECMO could be used as a bridge to lung transplantation; however, long waiting times on ECMO are associated with morbidity and mortality from bleeding at the cannulation or surgical entry sites, hemolysis and coagulopathy, sepsis, and multiorgan failure. It is known that the survival of pediatric patients having ECMO as a bridge to heart transplant is significantly better than for lung or heart–lung transplant [42]. ECMO is therefore not favored for long-term use as a bridge to lung transplant. New machines, such as the pumpless lung assist devices (described later) may alter the risk–benefit assessment of mechanical support in these patients. After lung transplant, patients who develop primary graft dysfunction may require extracorporeal support. Both VV-ECMO and VA-ECMO can be used, allowing the lungs to recover from the acute injury with an overall rate of survival to discharge of 42% [43, 44].

Sepsis

The updated definition of sepsis in adults is "life threatening organ dysfunction caused by a dysregulated host response to infection" and the definition of septic shock is "a subset of sepsis in which underlying circulatory and cellular/metabolic abnormalities are profound enough to substantially increase mortality" [45]. The definition of sepsis in children is currently being re-examined, but is likely to include risk factors, clinical criteria, and illness severity scores to identify those at high risk of developing sepsis-associated organ dysfunction and mortality [46]. In the meantime, the old definition of severe sepsis is being used in children and refers to the presence of organ dysfunction, hypoperfusion, or hypotension [47].

Sepsis is one of the leading causes of mortality and morbidity worldwide and severe infections kill more than 4.5 million children every year [48]. In Australia and New Zealand from 2007 to 2013, invasive infections, sepsis, and septic shock were responsible for 765 (26·4%) of 2,893 pediatric deaths in ICUs [48]. Overall mortality for invasive infections was 3.9%, sepsis was 5.6%, and septic shock was 17%. Identification of those children at highest risk of mortality is therefore of paramount importance.

Septic shock may be the primary reason requiring mechanical support, or sepsis could be a coexisting problem in a patient with respiratory or cardiac failure. This causes classification difficulties, which can pose a problem for extracting meaningful outcome data. Despite this, sepsis was historically considered a contraindication for ECMO; however, it is now accepted that ECMO is a viable therapy in neonates and children. In neonates, the survival rates are over 80%, whereas, in older children, it is lower, but it has improved lately to 75% for refractory shock and 90% for refractory pneumonia [49]. A recent systematic review of ECMO in children with sepsis was consistent with this whereby overall pooled survival was 65% with neonatal survival the highest group at 73% [50]. Gram-positive organisms were the most common among those requiring ECMO, although many underlying bacterial, viral, and fungal organisms can be implicated [51].

More recently, a sepsis mortality prediction model has been used to assess the effectiveness of VA-ECMO in pediatric septic shock; in patients with a predicted mortality higher than 47.1%, the measured mortality was reduced by 16.1%, whereas in patients with a lower predicted mortality had a higher measured mortality by 16.8% [51, 52]. Some questions remain unanswered from this study, for example, the mortality prediction tool did not consider the different hemodynamic profiles of sepsis in children [53]. In addition, the mode of ECMO was not consistent; 71% provided central ECMO with higher flows compared with 29% with peripheral ECMO. There is some evidence that there is survival benefit from using ECMO with higher than 150 mL/kg/min flows [54]. The American College of Critical Care Medicine has issued a consensus statement on the management of children with septic shock, suggesting that ECMO be considered when a child is deteriorating from hypotension, rising lactate, or progressive multiorgan dysfunction despite high doses of vasoactive/inotrope medications, aggressive fluids, and appropriate medical management [50]. During this assessment, the rate of progression of shock with associated physiological decline is more important than the absolute amount of inotropic support [47].

Myocarditis, cardiomyopathy, and cardiac transplantation

In children without CHD, viral myocarditis is the commonest cause of acute heart failure. ECMO is the initial modality of choice for MCS, because of ease of application, biventricular support, and relatively few complications [55]. Once on mechanical support, ECMO can be used as a bridge to VAD, transplant, or recovery. ECMO in this population was first reported in 1999 with an 80% survival [55]. In the 2016 ELSO registry report, the survival rate for myocarditis requiring ECMO was higher than CHD in neonates and children [4]. Pediatric patients with myocarditis have the highest survival rate of 76%.

ECMO is also used in children with dilated or restrictive cardiomyopathy to BTT. Although VA-ECMO has traditionally been the standard management strategy for myocardiopathy, several reports have shown better survival with VAD [56]. In a prospective, multicenter, single-group cohort study, children who underwent implantation of the Excor® Pediatric VAD as a BTT were compared with a historical control group of children who received circulatory support with ECMO [57]. The patients supported with VAD had longer survival rates than those supported on ECMO but with a high incidence of complications (e.g. bleeding, infection, and stroke). Of note, children who are on ECMO at the time of listing for cardiac transplant have a worse outcome (50% 12-month survival) compared with those on a VAD at listing (76%) [58].

ECMO is also used for patients with early and late ventricular dysfunction after cardiac transplant. In a retrospective chart review of 100 pediatric orthotopic heart transplant recipients, 15 patients required 17 episodes of ECLS. Ten of these episodes were early (<1 month after transplant), and

seven were late (>1 month). Of the 10 with premature graft failure, 8 were weaned from support with graft function recovery, 1 was retransplanted, and 1 died [59]. Late failure was due to acute rejection and had a 50% mortality. ECMO is usually the initial mode of support because of the speed of application and familiarity, as well as the ability to manage circulations with right ventricular (RV) dysfunction and high pulmonary vascular resistance (PVR) [42]. Recently, the temporary use of LVAD support via miniature axial flow pumps (Impella®) solo or combined with VA-ECMO has been successfully used after cardiac allograft failure due to acute rejection [60].

Arrhythmias with hemodynamic compromise

Short-term mechanical support for malignant arrhythmias is a temporizing measure while medical management is optimized, or ablation performed. Etiology includes postcardiotomy arrhythmia, myocarditis, or coronary ischemia. Most patients had supraventricular tachycardia (69%) that needed mechanical support to stabilize. Thirty-three percent underwent transcatheter ablation while on ECMO, while the rest received medical treatment. The long-term survival was 59% [61].

Cardiac catheterization instability

Improvement in skills and equipment has led to a significant number of younger, sicker patients presenting for complex interventional procedures in the catheterization laboratory. ECMO has been used as rescue therapy after a critical event (e.g. failure to wean from bypass, cardiac arrest, severe cyanosis) or prophylactically to manage an LCOS. A single-center 15-year retrospective review found the most common indications for cardiac catheterization while on ECMO were purely diagnostic, atrial septostomies, and stenting of vessels or shunts [20].

Patients at greatest risk include those <1 month of age with poor cardiovascular performance. Four high-risk hemodynamic variables include: high end-diastolic pressure, low systemic arterial saturations, low mixed venous saturations, and high pulmonary artery pressures [62]. In one reported series, 57% of children receiving ECPR in the catheterization survived to discharge [63].

Pulmonary hypertension

Three groups of patients with PHTN candidates for ECMO support. The first group is perioperative patients with reversible PHTN, for example, neonates with total anomalous pulmonary venous drainage that PVR will improve with time after surgical correction. The second group is the severe PHTN patients at high risk of an acute pulmonary hypertensive crisis from intervention or intercurrent illness. Before the PHTN crisis, the suitability of rescue ECMO is discussed. Even centers with an expert mechanical support team report low survival with ECPR in these patients [64]. The third group includes patients with severe medically refractory PHTN who require VA-ECMO as a bridge to heart–lung or lung transplant; however, the likelihood of survival with this approach is quoted as "minimal" and should be made on a case-by-case basis. A recent retrospective analysis of pediatric patients on ECMO with PHTN allowed the development of mortality models. The pre ECMO poor prognostic clinical features are (age <6 months, age >5 years, absence of pneumonia, and pH <7.12). The ECMO-related poor prognostic markers are ECPR, neurological complications, pulmonary hemorrhage, renal replacement therapy, and metabolic acidosis [65].

Novalung® (Novalung GmbH, Hechingen, Germany) has recently developed a paracorporeal pumpless interventional lung assist device that uses a low-resistance hollow-fiber oxygenator. This device has been applied to patients with cardiogenic shock from PHTN, with cannulas placed via sternotomy in the pulmonary artery and left atrium. High pulmonary pressures drive the blood through the oxygenator, without the need for a mechanical pump, removing CO_2 and improving oxygenation. Pulmonary pressures are reduced, which offloads the failing right ventricle, potentially allowing RV recovery [65]. Most of the research with this device has been in the adult population, but there is a need for application in pediatrics.

Intoxicants

ECMO can support both adults and children who have severe toxin exposure [66]. A recent literature review identified 46 reports from 1996 to 2012 where ECMO rescued adult and pediatric patients with ARDS or circulatory shock from poisoning. The most common intoxicants cited were beta-blockers and calcium channel blockers. However, other drugs mentioned were ibuprofen, tricyclic antidepressants, colchicine, and chloroquine. A recent retrospective review of the ELSO registry identified 28 children who required ECMO due to toxin exposure. The in-hospital mortality was 32%. The following features were associated with higher mortality: preECMO use of NO, lower pH, elevated pCO_2 or inotrope requirement while on ECMO [67].

Mechanical support to assist organ donation

There is a worldwide shortage of organs, and significantly fewer cadaveric donors exist for any given child when compared to adults [68]. ECMO provides the potential to improve organ perfusion and increase the availability of viable organs suitable for transplant. Small case series in adults and adolescents have been reported [69].

Cultural, religious, and legal barriers differ depending on the country. ECMO could represent a violation of donor autonomy [70]. However, ECMO has been supported in this setting by ethicists and theologians [71]. Mechanical support improves viable organ retrieval in both brain-dead donors and donation after cardiac death (DCD) [69, 72]. Brain-dead donors supported with ECMO after suffering cardiac arrest or severe cardiovascular or respiratory dysfunction before organ retrieval increase the pool of donors. The timing of implementing ECLS for DCD, before or after the declaration of circulatory death, depends on the institution. The aim is to reduce warm ischemia time and improve the chance of graft survival. Firm conclusions regarding organ outcomes using this technique are challenging to draw in this population at this stage.

KEY POINTS: INDICATIONS FOR MECHANICAL SUPPORT

Mechanical circulatory support should be initiated early before organ injury from a low cardiac output state. Criteria include:

- Progressive increase in inotropes or vasopressors with continued poor tissue perfusion
  - Mixed venous oxygen saturation <40%
  - Cerebral saturation <20% below baseline
  - Oliguria
  - Metabolic acidosis

The American College of Critical Care Medicine states that ECMO should be considered in the treatment of children with septic shock unresponsive to inotropes and fluid management.

Contraindications to mechanical support in children

It is difficult to provide absolute numerical "cut-offs" as to who should categorically not be offered mechanical support. Progressively over the years, the list of absolute contraindications has been shrinking [73]. Contraindications are related to either futility treatment or high risk of death or severe long-term morbidity. As medical equipment and techniques evolve, the risk–benefit balance changes. It is, therefore, wise to consider the suitability of individual patients on their own merits. For example, infants with HLHS were once regarded as inferior candidates for ECLS, but now, this is the most common congenital heart lesion requiring mechanical support of the circulation [74]. A temporizing approach is the "bridge to decision" process for patients with acute circulatory failure. The patient is supported to assess cardiogenic shock and the end or organ damage for 24–72 hours. Thus, transitioning to a long-term MCS device in patients, either transplant candidates or deemed to recover [75].

The futility of mechanical support refers to the presence of a lethal anomaly, either cardiac or noncardiac in origin. Futility includes fatal chromosomal disorders, severe irreversible brain damage, or unrecoverable cardiac or respiratory injury. Of course, "unrecoverable" is patient- and organ-specific, and the definition of futility in the context of ECMO remains very difficult [76].

Malignancy has also been considered under this "futile" category in the past, although the outcome of children with cancer is quite good; however, patients with neutropenic sepsis following bone marrow transplantation have a dismal prognosis. Despite this, a recent report described the successful use of ECMO in a few of these children [77]. Another group considered to be "futile" are those with advanced multiorgan failure. However, McLaren et al. describe 23 children at high risk of death from septic shock, of whom 22 had damage to at least three organ systems. All were cannulated centrally through the chest to obtain higher flow rates, and 17 patients (74%) survived to discharge. This high-flow technique appears to confer more remarkable survival than with conventional ECMO [78].

Neonates pose a particular difficulty in defining contraindications. The ELSO registry shows that neonates have good survival for all diagnoses. However, certain neonatal subsets pose a specific risk when considered for ECMO; data from the ELSO registry indicate overall premature (<37 weeks) neonatal survival from ECMO is 31% compared with 41% in term infants [79]. Survival falls to 19% for neonates <33 weeks of gestational age [79].

Much of the concern with premature neonates and ECMO is because of the risk of developing or worsening intracranial hemorrhage (ICH), i.e. low birth weight, extreme prematurity, and pre-existing ICH. Those with low gestational age (<32–34 weeks) are at the greatest risk. Most bleeds occur in the first 72 hours after birth, so in theory, the risk of ICH and hemorrhage extension may be less after the infant is 3 days old. Grade 3 ICH (blood causing enlargement of the ventricles) and grade 4 ICH (blood extending into the brain parenchyma) confer a poor long-term prognosis [80]. ECMO increases the risk of extension of pre-existing ICH, and most ECMO exclusion criteria include those with ICH grade 3 or 4. Although neonates with ICH < grade 3 have the potential for hemorrhagic extension, it is feasible to manage these patients without worsening their ICH, provided there is imaging and diligent monitoring of their coagulation status [81]. In the absence of good long-term developmental follow-up data, many would currently consider birth weight <1.6 kg as a valid contraindication to ECMO. Regression analysis suggested that 1.6 kg was the lowest threshold weight to achieve a 40% survival in noncardiac ECLS [82]. Although some have suggested ECLS to be beneficial in neonates >32 weeks of gestational age, many consider a gestational age <34 weeks to be a relative contraindication to ECMO. As data emerge, these thresholds change; preterm and neonates <2.5 kg still demonstrate mortality rates after cardiac surgery greater than larger neonates [83]. Examining ECPR in neonates, the survival was 21% for those <34 weeks of gestational age and 20% for those <2 kg. Yet, these findings do not support a strict age cut-off for ECPR [31]. With the above caveats in mind, a list of contraindications is presented in Box 37.2.

Futile treatment in the context of repeated or prolonged ECMO is a problematic issue. The probability of ECMO survival in children with respiratory failure reduces with the number of days on support. We also know that myocardial recovery is rare after 12 days of ECMO support after pediatric cardiac surgery. Despite this, prolonged ECLS has produced

Box 37.2: Contraindications for mechanical support in neonates, infants, and children

Neonatal population

- Severe irreversible CNS injury
- Lethal congenital abnormality (cardiac or noncardiac anomaly)
- Intraventricular hemorrhage grade 3 or 4
- Gestational age <34 weeks
- Very low birth weight, for example, <1.6 kg
- Uncontrollable coagulopathy

Infants and older children

- Severe irreversible CNS injury
- Incurable malignancy
- Advanced multisystem organ failure
- Irreversible organ damage if not suitable for transplantation

CNS, central nervous system.

Note that extreme prematurity and very low birth weight are risk factors for intracranial hemorrhage on mechanical support.

remarkable outcomes in children, so that, delineating "futility" is poorly defined. Therefore, repeat ECMO should not be offered unless the mechanical support was initially withdrawn prematurely or considered a new treatment modality [83]. Poor prognostic features include hyperkalemia in the context of hypothermic arrest. Hyperkalemia indicates irreversible cell damage, potassium leakage, and a poor chance of recovery [84].

Devices

Extracorporeal membrane oxygenation (ECMO)

At Royal Children's Hospital (RCH), our ECMO program began by keeping on CPB overnight patients unable to be weaned. This effort was the last opportunity for the patient to either limp off CPB or die. Unfortunately, most failed to wean and died. Understanding how the ECMO service began gives us insight into where we are now and where we will be tomorrow. Due to the needed change in our service, a small team visited major US pediatric cardiac programs in 1988 and put together a peculiar system that was an adaptation of the CPB machine. The new design used a roller pump, silicone membrane oxygenator with a bladder on the venous line that on collapse would cause an alarm; however, not the pump to stop. The new ECMO system required perfusion bedside 24/7 assistance during all the mechanical support. Later, we modified the ECMO system using a Biomedicus centrifugal pump with pressure monitoring of the venous inlet and arterial outlet. Subsequent, in 1989, Dr Roger B. Mee implanted a modified version of the ECMO system without oxygenator configuring an LVAD in an infant post anomalous left coronary artery from the pulmonary artery (ALCAPA) repair with isolated LV dysfunction who was unable to wean off CPB [85]. The patient was well supported for 7 days and then successfully weaned. This infant was the first pediatric patient assisted LVAD as a BTR. The next step in improving the ECMO system was to adopt centrifugal pumps, which significantly improved their ease of management. However, the high-resistance silicone oxygenator was still an Achilles heel of the circuit requiring high pump revolutions per minute (RPMs) to overcome the afterload. These resulted in high shear forces and cellular dysfunction, which promoted bleeding.

The Pump (Figure 37.1)

Active development of improved centrifugal pumps occurred through the 1990s, with Deutschen Herzzentrum München developing the Jostra Rotaflow, a partially magnetic

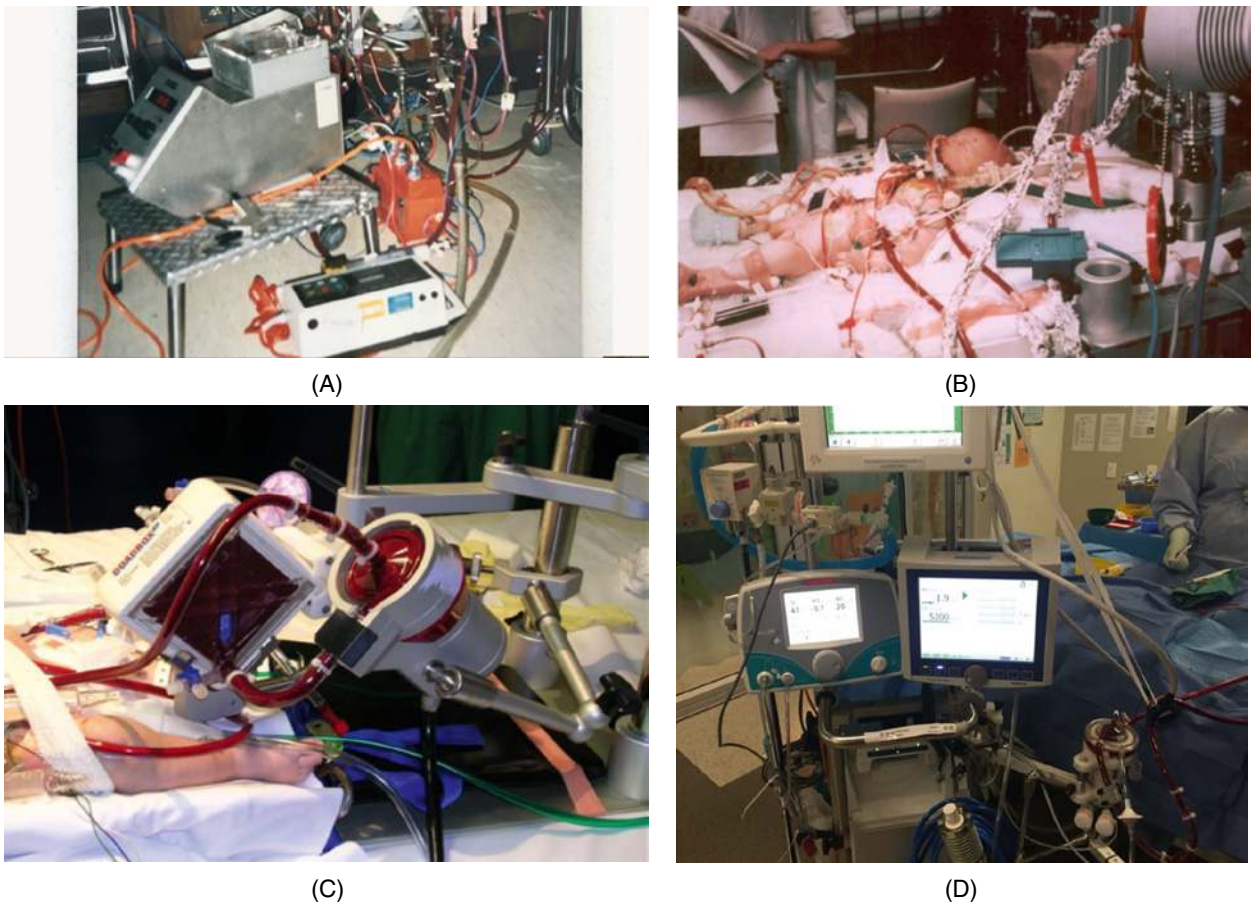

Figure 37.1 (A) First ECMO circuit crafted with a roller pump and a silicone membrane oxygenator; (B) LVAD circuit in an ALCAPA patient using a BioMedicus (Eden Prairie, MN) centrifugal pump; (C) Jostra Rotaflow® (Maquet AG, Hirrlingen, Germany) centrifugal pump with the Quadrox D oxygenator; (D) Medos Deltastream DP3 (Medos Medizintechnik AG, Stolberg, Germany) with the NO delivery system incorporated in the ECMO circuit.

suspended centrifugal pump. This highly efficient device removed the requirement for an axle and seals, which were prone to thrombose and fail after 5 days, such as the Biomedicus Biopump® (Medtronic Corp., Minneapolis, MN, USA). In 1992, a trial comparing the Biomedicus Biopump (Medtronic Corp., Minneapolis, MN, USA) with a conventional roller pump found that the roller pump produced notably more hemolysis [86]. However, by day 5 of use, the Biomedicus acutely begins to cause cell trauma approaching the severity of the roller pump at 7 days. This trial confirmed the clinical experience at RCH of electively replacing the Biomedicus at day 5 as a precautionary measure or earlier if indicated. We adopted the Jostra Rotaflow (Maquet AG, Hirrlingen, Germany) in the late 1990s, which removed the need for elective pump changes. The pump rotor is suspended and driven by a radial permanent magnetic field that stabilizes the impeller in four of the six spatial degrees of freedom. It also allows it to be top-spun on a single blood flushed pivot bearing with minimal load and friction. This pump has a small internal volume, and surface and passage time demonstrate excellent hydraulic efficiency. It can provide 10 L/min of pump flow rate against 400 mmHg of total head pressure, indicating high performance. In long-term ECLS, or prolonged *in vivo* experiments, centrifugal pumps show superior blood handling characteristics if inlet pressures are monitored and do not become excessively negative [87]. Anecdotally, we have found that sub-atmospheric pressures more than –20 mmHg (measured at the cannula) potentiate hemolysis. The concept of integrating a pump and oxygenator into a single device that can monitor core vitals become available for adults as the Cardiohelp system but did not have a pediatric equivalent [88]. The developed pediatric ECMO circuit alternatives were the PediVAS (Levitronix Technologies LLC, Waltham, Massachusetts, USA) and the Medos Deltastream DP3 (Medos Medizintechnik AG, Stolberg, Germany). The PediVAS is a fully suspended centrifugal pump designed as a midterm VAD that some centers in Europe had adopted into their ECMO circuits. However, the disposables were 20 times more expensive than the Rotaflow, which would have created too significant a financial burden in an extensive ECMO program. Our service elected to transition to the Medos Deltastream DP3 (Medos Medizintechnik AG, Stolberg, Germany) oxygenator systems. The entire circuit from Medos was approximately half the cost of the PediVAS pump head, with the potential benefits of being able to provide pulsatile flow with a more sophisticated pump controlling system. Medos provided several oxygenator sizes in a wound polymethylpentene (PMP) fiber configuration. The pump is a diagonal hybrid rotary type that rotates at approximately two times the rate of the Rotaflow to achieve the same flow. Thus, potentially making it more hemolytic if a thrombus occurs on the pump impeller. We undertook a study comparing the hemolysis rate across the three top-performing centrifugal pumps Rotaflow (Maquet AG, Hirrlingen, Germany), Medos Deltastream DP3 (Medos Medizintechnik AG, Stolberg, Germany), and PediVAS (Levitronix Technologies LLC, Waltham, Massachusetts, USA) [89]. The analysis showed no difference between the DP3 and Rotaflow, but the PediVAS fared significantly better causing less hemolysis.

The oxygenator

Several companies released versions of their CPB hollow-fiber oxygenator for ECMO use with the drawback that plasma leaked after several hours, necessitating urgent exchange. The Quadrox D oxygenator adoption finally found a device that could last for most of a potential ECMO run without failing [90]. This device was developed as a low inflammatory activating oxygenator for long CPB runs using a polymethyl pentene plate fiber rather than a spiral wind polypropylene fiber. The pores were logarithmically smaller such that wet out did not occur. Even volatile gases would not cross. The device was exceptionally good at removing even large air emboli; however, the most significant advantage was low resistance, which resulted in immediate improvement of managing anticoagulation, with significantly fewer blood products requirements during ECMO. However, this device was only available for adults, so that, initial use with neonates required a more extensive than necessary oxygenator running at lower than optimal flow, which was still significantly better than the others on the market. To reduce time to support, we also introduced leaving our circuits primed with Plasmalyte® for 4 weeks after ensuring no microbial growth or significant drop in membrane efficiency. Other companies have produced PMP oxygenators, for example, the Medos Hilite® (Medos Medizintechnik AG, Heilbronn, Germany) 7,000 LT (275 mL priming volume), 2,400 LT (95 mL priming volume), and 800 LT (55 mL priming volume). In addition, Medtronic has the Nautilus, while Spectrum is evolving their Quantum platform for ECMO.

Thromboresistant surfaces

The aim is to inhibit activation of the inflammatory and coagulation systems from blood exposure to the foreign surface of the ECLS. To this end, the materials composing circuits either should be inert or hemocompatible. Hemocompatibility refers to those properties that allow ECLS circuits to maintain contact with flowing blood without producing a coagulopathy. Hemocompatibility is related to material's surface, extrinsic conditions (e.g. cannulation sites), blood contact duration, local hemodynamic status (e.g. pulsatile vs. nonpulsatile), flow length, and diameter of tubes). For example, when surfaces feature peaks or valleys (average height or depth = 9 μm), the number of platelets adhering to polyvinylchloride (PVC) surfaces is increased three-fold, compared with polished surfaces [91, 92].

Anticoagulation is challenging, with further improvements still required. Before, we had adopted using heparin-coated technologies in the pursuit of reducing circuit thrombosis, which to our surprise, we found increased with its use. Unfortunately, we used tip-to-tip coating until a patient on VAD support developed a significant thrombus, which resulted in him dying from valve incompetence after several days of successful support. This prompted us to stop using any heparin surface coating and undertake a study investigating potential differences with heparin bonding, only to conclude that postprotamine made this technology prothrombotic [93].

Anticoagulation management has formed the most recent significant advances with less reliance on heparin as the sole mechanism. Since the 2000s, we have used prostacyclin (dose

5 ng/kg/min) as an adjunct and, more recently, NO (20 ppm) into the sweep gas of the oxygenator. These adjuncts have significantly reduced the number of circuit changes per 1,000 hours of ECMO but, more importantly, meant that patients are much less coagulopathic, meaning more stable support [94]. NO and prostacyclin have a synergistic effect on reducing platelet activation from exposure to the ECMO circuit. This reduction in circuit changes results from fewer coagulopathic patients on ECMO, resulting in stable patients requiring fewer interventions.

Ventricular assist devices

The advantages of VAD circuits over ECMO are reduced priming volume from the lack of an oxygenator, shorter tubing, and minor trauma to blood cells. In addition, VADs lessen the ventricular work. VAD circuits are composed of inflow and outflow cannulas, a pump (intracorporeal or paracorporeal), a driving line power source, and a system controller (Figure 37.2) [95, 96]. The inflow cannula attaches to the atrium or the ventricle and transports blood from the left or right heart to the VAD. In left-sided VAD, the outflow cannula connects to the ascending aorta; and in right-sided VAD, the outflow cannula connects to the pulmonary artery. With the optimal placement of inflow cannulas, ventricular cannulas achieve superior unloading of the heart, reducing wall stress, allowing better ventricular recovery, and having a lower incidence of thrombosis. However, endocardial trabeculations can obstruct the inflow cannula in small ventricles (e.g. noncompaction cardiomyopathy). Therefore, these patients may require left atrial cannulation or LV cavity myectomy before ventricular cannulation.

The length of planned support divides VADs into those for short-term use (typically <2 weeks) and those for long-term use (>2 weeks) (Table 37.1, Figure 37.3). They are also classified based on the mechanism that propels blood. For example, ventricular ejection occurs with a rotational device (e.g. centrifugal pumps), a pneumatic pusher plate (e.g. Berlin Heart), or via axial flow (e.g. HeartMate III®).

Impella (Abiomed, Danvers, MA, USA) (Figure 37.4) is a micro axial flow device with three different pump sizes, at 2.5, 5, and 5.5 L/min [97]. The smaller pump provides partial left ventricle support in adults during high-risk cardiac catheterizations (e.g., ablation procedures and urgent catheterizations for acute coronary syndrome). But in pediatrics, this smaller pump can also offer full left ventricle support. The Impella 5 and 5.5 L/min provide full left ventricle mechanical support for adolescents and adults. The main indication is BTR, BTD, or bridge to a permanent support device. The Impella is inserted retrograde through a femoral or axillary artery. The device inlet zone is resting in the left ventricle cavity, where blood is collected and propelled into the aorta. The deployment is performed under direct vision by fluoroscopy and echocardiography. Like many devices initially designed for adults, the Impella will have limited use in younger patients because of its size. The 2.5 L/min pump has a 12 F motor in diameter and requires a 13 Fr peel-away introducer for delivery. Morray et al. in a magnetic resonance

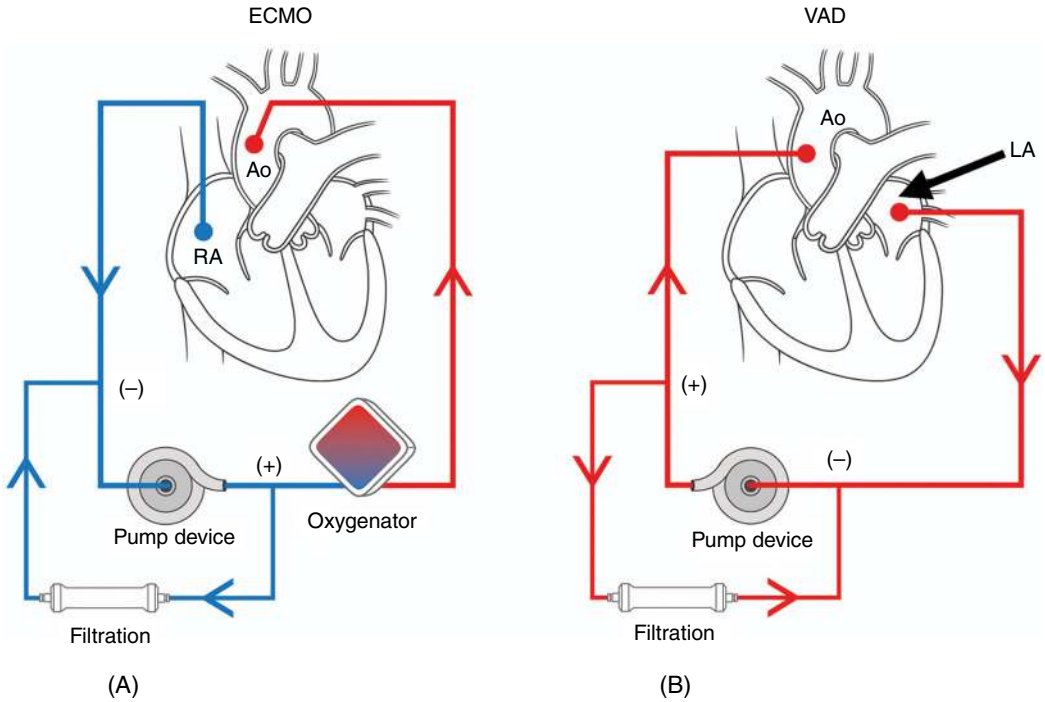

Figure 37.2 Illustration of the (A) ECMO circuit draining deoxygenated blood (negative pressure) from the RA to the pump (positive pressure) through the oxygenator back to the patient through the aortic cannula. Note the ultrafiltration through the venous side beyond the pump; (B) VAD circuit draining oxygenated blood (negative pressure) from the LA to the pump (positive pressure) back to the patient through the aortic cannula. Note the ultrafiltration beyond the pump. Abbreviations: RA, right atrium; Ao, aorta; LA, left atrium.

Table 37.1 Ventricular assist device systems available in the United States

	Pump/flow type	Stroke volume (mL)/ pump speed (rpm)	Flow range (L/min)	BSA range (m^2)	Device type
Short term (<14 days)					
Rotaflow	Centrifugal/nonpulsatile	0–4,500 rpm	0–9.99	No minimum[a]	Rotational
Impella 2.5[b]	Centrifugal/nonpulsatile	0–50,000	0–2.5	>0.9–1.1[c]	Axial
Impella 5	Centrifugal/nonpulsatile	0–33,000	0–5	>1.1[c]	Axial
Impella 5.5	Centrifugal/nonpulsatile	0–33,000	0–5.5	>1.1[c]	Axial
Long term (> 14 days)					
Pneumatic pulsatile ventricular assist devices					
Berlin heart EXCOR	Pulsatile	12, 15, 25, 30, 50, 60 and 80 mL	Variable[d]	>0.2	Pusher plate
SynCardia total artificial heart	Pulsatile	50 and 70 mL	Up to 9.5	>1.7–2.5	Pneumatic-driven chambers
Continuous-flow ventricular assist devices					
HeartMate III	Axial	3,000–9,000 rpm	0–10	>1.4	Axial
HeartWare®	Centrifugal/nonpulsatile	1,800–4,000	0–10	>1.4–2.6	Axial

See text for complete details.

[a] Smaller patient reported 1.9 kg neonate.

[b] 2.5 L/min flow needs a 17 F arterial cannula; 4 L/min flow needs a 15 F arterial cannula.

[c] The Impella is a partial support device which enhances the patient cardiac output – the limitation in pediatrics is the vascular access needed for the size of the cannulas.

[d] Depends on pump size and set rate.

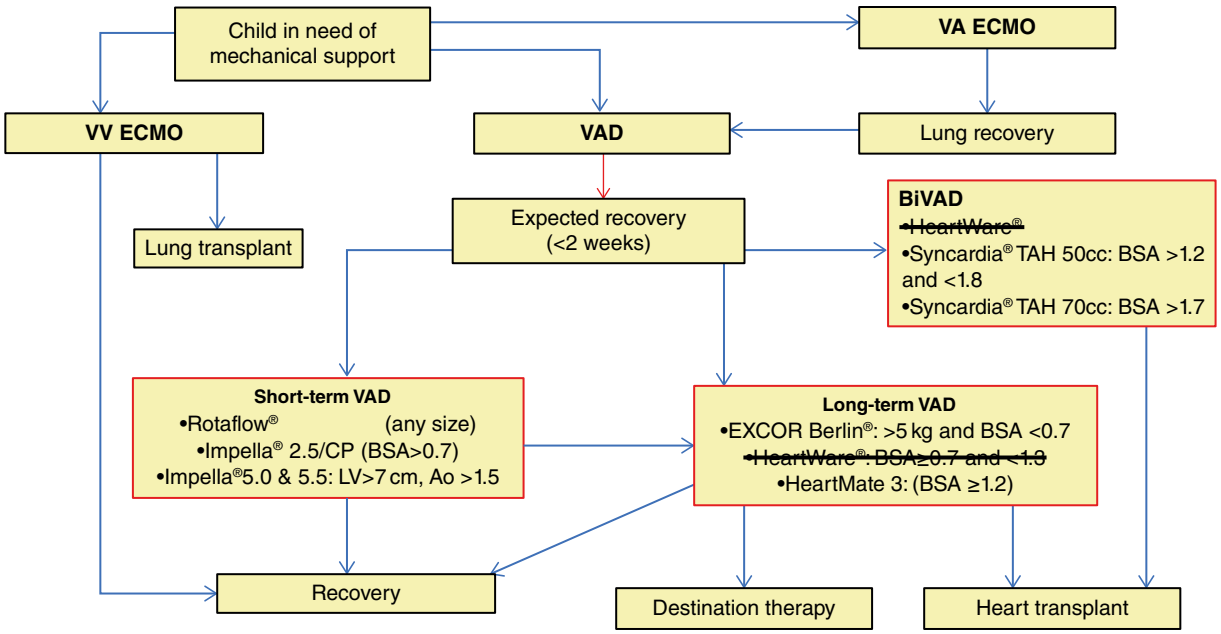

Figure 37.3 Algorithm of MCS used at Texas Children's Hospital. The recall of the HeartWare Ventricular Assist System by the FDA leaves a gap in the patients with BSA ≥0.7 and <1.3. Abbreviation: BSA, body surface area; FDA, Food and Drug Administration; MCS, mechanical circulatory support.

imaging (MRI) and echocardiographic study, define minimum size parameters that are necessary for the correct placement of the Impella 2.5 L/min catheter. The device needs a 7.5 cm LV catheter length achieved when the patient height is 122 cm, the weight of 23 kg, and body surface area (BSA) of 0.89 m^2 [98]. The 5.0 L/min pump is a 21 F motor in diameter, requiring a femoral cutdown for delivery. The 5.5 L/min motor is 18 F in diameter, requiring axillary cutdown. The 5.5 L/min pump does not have a pigtail at the end of the catheter and is shorter (70 vs. 135 cm). Finally, another Impella, the Impella RP, is designed to provide support to the right ventricle. The indication for the Impella RP is to support the failing right ventricle percutaneously implanted RV assist device (RVAD). It is inserted in the femoral vein via a 23-French sheath, and the

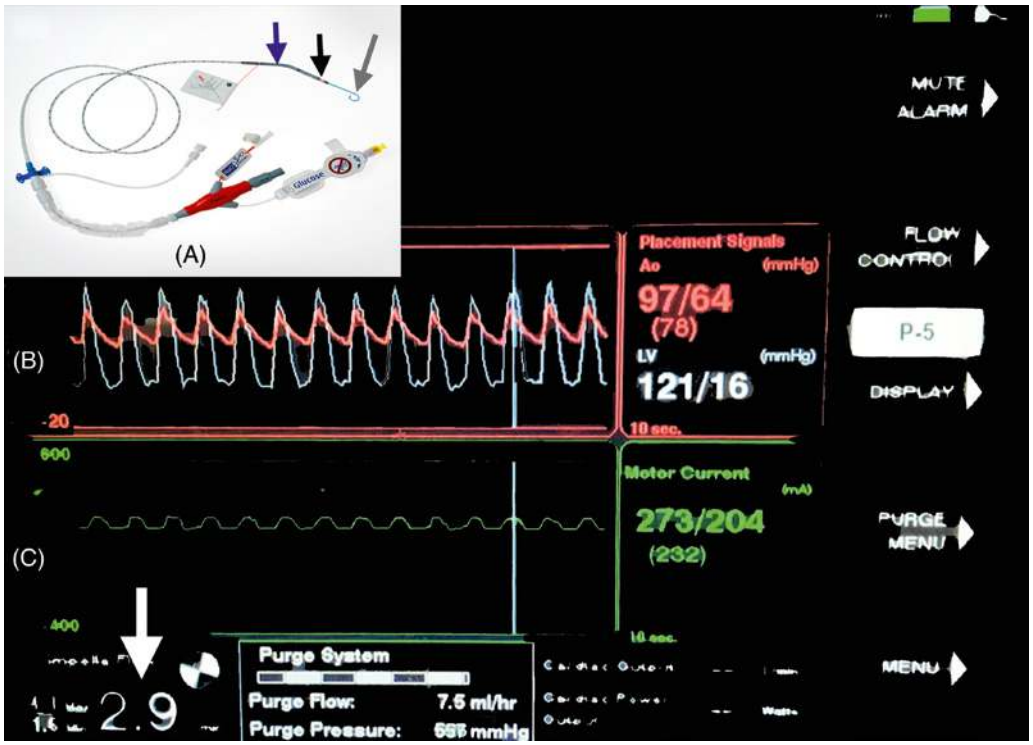

Figure 37.4 (A) Impella 2.5 L/min catheter showing the pig tail end (grey arrow), the blood inlet area (black arrow) and the blood outlet area (blue arrow); (B) Impella console placement signal in red aortic pressure and in white left ventricular pressure; and (C) Green trace showing the motor current in MA, the device flow is 2.9 L/min (white arrow).

motor has a 22 F diameter. Recently, Qureshi et al. published their experience with the Impella RP in adolescents with RV failure reporting an 83% survival to hospital discharge [99].

The Berlin Heart VAD (EXCOR) (Figure 37.5) is a pulsatile, paracorporeal device suitable for all pediatric patients, including neonates [100]. It is available in several sizes (10–60 mL). Most miniature pumps are appropriate to support neonates and infants (weight 3–8 kg), and the 25- and 30-mL pumps will support children weighing up to 20–25 kg. It provides pulsatile flow delivered through a pneumatically driven thin membrane pump. In diastole, blood enters the pusher-plate polyurethane chamber through an inlet valve, and negative pressure aid the pump filling. The blood-filled pump is compressed from an air-filled chamber in systole, creating pulsatile systolic flow ejected through the outlet valve to the aorta. Mechanical valves direct the flow, and there is no direct contact between the pumping mechanical parts and blood. The maximum systolic positive pressure generated is 350 mmHg, and the maximum negative driving pressure is –100 mmHg. High pressures are sometimes needed to overcome the resistance of small pediatric cannulas. The pump allows rates between 30 and 150 beats/min and the systolic time between 20 and 70% of the cycle; these parameters can all be monitored and adjusted on the external driving unit. The blood pump is transparent, allowing visual inspection of filling, emptying, and thrombus formation. The pump exchange is indicated if there is thrombus formation in the pump or cannulas to avoid systemic embolization. The blood-contacting surfaces of the pump, including the polyurethane valves, are covered with Carmeda® bioactive heparin coating to prevent thromboembolic complications. The EXCOR has silicon cannulas with a Dacron covering that works as a biological barrier against ascending infections.

Patients supported with this device often do not require mechanical ventilation; they can eat normally and ambulate, making intensive care unit (ICU) discharge possible [97, 98] The EXCOR can be used for biventricular support using two pumps (right VAD [RVAD] and LVAD) controlled by the same external driving unit. The one prospective trial from the USA comparing the EXCOR with ECMO as a bridge to transplantation showed better survival rates with the VAD than with ECMO in two different BSA cohorts (cohort 1, <0.7 m^2; cohort 2, 0.7–<1.5 m^2) [57]. Unfortunately, the incidence of serious adverse events was high in both groups, including major bleeding (42 and 50%, respectively), infection (63 and 50%, respectively), and stroke (29 and 29%, respectively) [57]. In addition, the need for pump exchanges due to thrombosis was frequent. The higher-risk patients in the US pediatric experience had a smaller size, renal dysfunction, hepatic impairment, and required biventricular assist. ECMO before implantation and CHD was not associated with worse outcomes in this study population. In the German experience with 122 implantations, the overall median duration of support was 63.6 days (range 1–841). Fifty-six (45.9%) were transplanted, 18 (14.7%) patients recovered and weaned, 43 (35.2%) patients died, and five remain on the device. In addition, pump exchange due to thrombus (35 patients) and re-exploration due to bleeding (22 patients) were common complications [101].

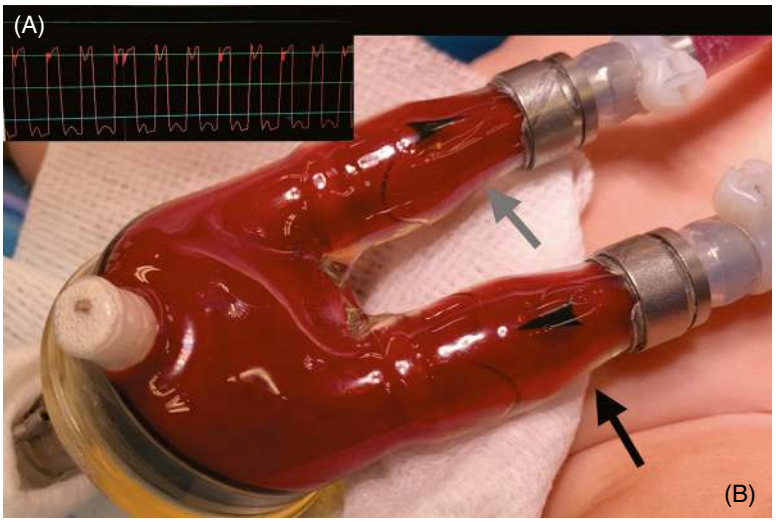

Figure 37.5 (A) Picture of the Berlin Heart console showing: left pump settings (systolic pressure 180 mmHg, diastolic pressure – 30 mmHg, rate 65 bpm and percentage of systole of the cycle 40%). (B) Picture of a Berlin Heart LVAD. The black arrows show the blood entering the VAD from LV (LVAD) and the grey arrow show the blood leaving the VADs to the aorta (LVAD).

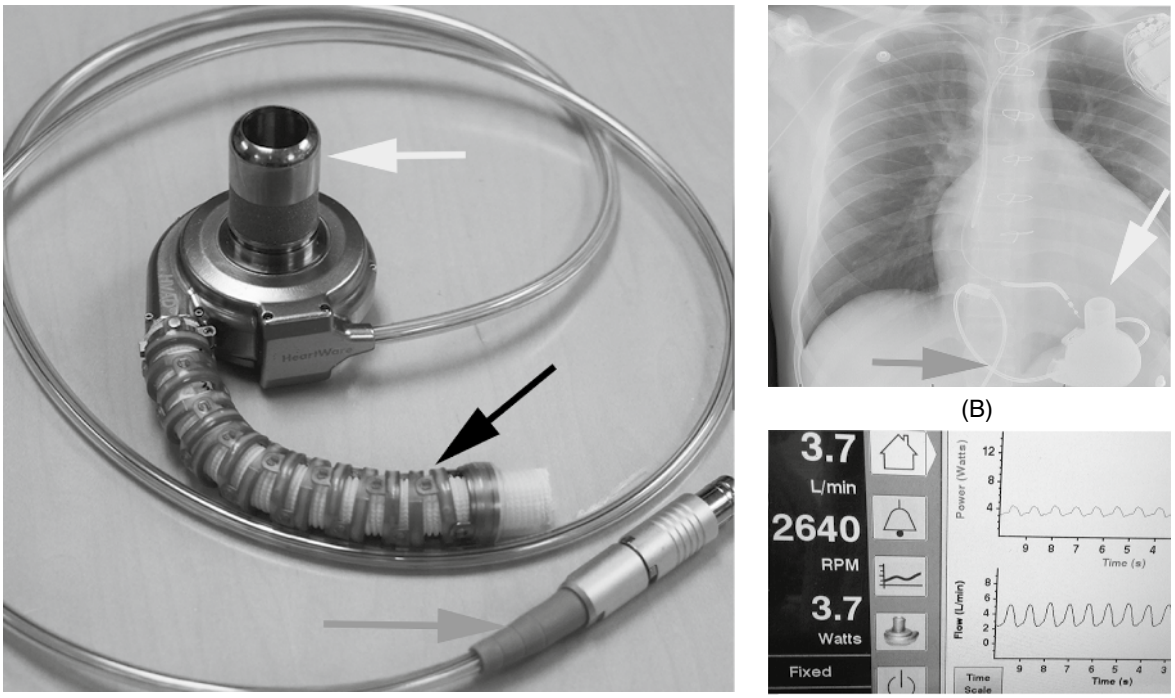

Figure 37.6 (A) Photograph of the HeartWare Ventricular Assist System (total height 58 mm, diameter 49 mm) displaying the drive line (4.2 mm, grey arrow), inlet cannula (diameter 20.5, length 25 mm, white arrow) and outlet cannula (10 mm, black cannula); (B) Postoperative anterior–posterior chest x-ray showing the implanted HeartWare Ventricular Assist System with drive line (grey arrow) and inlet cannula (white arrow), the outlet cannula is not observed because is not radiopaque, in addition an automatic implantable cardioverter defibrillator (AICD) and leads are observed; and (C) HeartWare Ventricular Assist System monitor displaying cardiac output (liter/minutes), device rpm, power (watts) and the graphs (power/time and flow/time).

The HeartWare Ventricular Assist System® (HVAD) (HeartWare, Inc., Miami Lakes, FL) [102] (Figure 37.6) is a small intrapericardial centrifugal flow pump with a rotating impeller, forcing blood through the device using hydrodynamic and centrifugal forces. The displacement volume is 50 mL and can flow up to 10 L/min. The inflow cannula is integrated within the device and is inserted into the left ventricle apex by an adjustable sewing ring – the 10 mm outflow graft anastomoses to the ascending aorta [103]. An external console controls the pump, regulates power, monitors performance, and displays alarms. The pump is connected to the console by a subcutaneous driveline through

the patient's abdominal wall. For safety reasons, two of three different sources power the HVAD: rechargeable lithium batteries, alternating current (AC) power, or a 12 V DC power source. The worldwide experience with the HVAD in 205 pediatric patients (<18 years) showed a low mortality (10.7%) and successful BTT (65%). In addition, a small number of patients (3.2%) recovered function and were explanted. However, right heart support and pump exchange were mortality risk factors [104]. June 3rd, 2021, the US Food and Drug Administration (FDA) alerted the medical community that Medtronic stopped the sale and distribution HVAD system. The recall was due to the increased risk of neurological adverse events and mortality associated with the internal pump. In addition, there is a potential for the internal pump to stop and fail to restart.

The HeartMate III (HM3) (Abbott Cardiac Arrhythmias and Heart Failure, Plymouth, MN) is a new centrifugal VAD characterized by a fully levitated rotor lacking mechanical bearings [105] (Figures 37.7 and 37.8). The HM3 design has a short and wide inflow that decreases shear stress and provides a reliable blood flow pattern supply (Figure 37.8B). In addition, HM3 incorporates a "pulsatility" feature wherein the rotor drops below the set speed and immediately increases above the set speed generating a pulse (~30 cycles per minute). The purpose of "pulsatility" is to allow ejection through the aortic valve reducing stasis and thrombosis. The HM3 insertion is intrapericardial, like the HeartWare® HVAD. Therefore, the modular driveline replacement in the event of malfunction does not need a complete pump exchange. The control screen consists of four boxes displaying pump flow, pump speed, pulsatility index (abbreviated on-screen as pulse index), and pump power. The HM3 allows a wide range of working speeds accomplishing flows between 2.5 and 10.0 L/min. The pump flow is a calculated value. The pulsatility index value is inversely proportional to the support given. The higher the pulsatility index, the lesser the VAD support. The HM3 power ranges between 0.0 and 25.5 W. Five life-threatening warnings display on the system monitor, including pump off, driveline disconnection, low flow × min, low voltage, and no external power. Low-level speed is considered fewer than 3000 rpm. The miniaturized pocket-size controllers and 17 hours battery pack life supports an ambulatory lifestyle. The pediatric experience with HM3 is limited. However, recently O'Connor et al. published the first pediatric HM3 series (40% of the patients < 60 kg), including a few with CHD (mostly Fontan circulation) who presented a low incidence of mortality and adverse events [107]. The smaller patient implanted in this series was 19 kg (BSA 0.78 m^2). There are two limitations to its pediatrics use one is the safest lowest flow (2–2.5 L/min) and the inflow cannula (25 mm) that seats inside the LV chamber [108]. The traditional anticoagulation regime for HM3 includes Coumadin (INR target 2.0–3.0) plus antiaggregation with aspirin (100–200 mg daily). The MAGENTUM 1 trial showed that low-intensity anticoagulation with Coumadin to a lower INR target (1.5–1.9) and aspirin was adequate [109]. The risk

of thromboembolic complications after the stabilization period (6 weeks) did not increase.

SynCardia Total Artificial Heart. (SynCardia Systems Inc., Tucson, Ariz) (Figure 37.9). It is a pneumatically driven pulsatile biventricular device with two prosthetic polyurethane ventricles (70 mL each) [110]. Each ventricle has two mechanical valves providing unidirectional inflow and outflow from the ventricle. The valves are single-leaflet Medtronic-Hall (Minneapolis, MN), 27 mm for the inlet and 25 mm for the outlet. The SynCardia Total Artificial Heart (STAH) has the most significant inflow, and shortest distance of blood traveled of all available VADs. The large valves and short blood path provide very little resistance, decreasing stasis and thrombosis [111]. The prosthetic ventricles coupled with silicone cuffs to two atrial connectors and two connectors on the end of the grafts sewn to the aorta and pulmonary artery. The external console displays the pressure waveform of each cardiac cycle and has two independent controllers for emergency backup. Compressed air powers the device. Two separate wire-reinforced conduits connected to the right and left prosthetic ventricles. The indication of the STAH are patients unable to be supported by VAD, such as those who require biventricular support or have PHTN (>4.5 Wood units). Successfully used after catastrophic intraoperative heart damage, failing Fontan, refractory arrhythmias, or irreversible cardiac rejection after transplantation have been reported. Pediatric use is limited because the device needs a distance between the sternum and the 10th anterior vertebral body of >10 cm. The recommended BSA is >1.7 m^2, but it has been used successfully in patients with a BSA of 1.5–1.7 m^2. The smaller 50 mL device is recommended for patients with a BSA of 1.2–1.7 m^2 [112]. Morales et al. published the worldwide experience with STAH in 43 patients under 21 years old [113]. Most of the patients were older and received the 70 ml pump. Twenty-five patients (58%) were successfully bridged to transplantation with a mean duration of support of 146 days.

KEY POINTS: DEVICES

- Roller pumps produce a linear increase in hemolysis that is not observed with centrifugal pumps.
- Centrifugal pumps are generally used for short-term ventricular support (less than 2 weeks)
- Impella either percutaneous or surgically has become the most used temporary ventricular assist device
- The Berlin Heart EXCOR device:
  - Has several sizes of pumping chambers versatile in pediatrics
  - Allows patients to be extubated, ambulate, and eat normally
  - Can be used as an LVAD, RVAD or BiVAD;
- HeartWare Ventricular Assist System is currently of the market but is still implanted in several patients
- HeartMate III fully levitated rotor lacking mechanical bearings
  - "Pulsatility" feature wherein the rotor drops below the set speed and immediately increases above the set speed generating a pulse (~30 cycles per minute).
- SynCardia Total Artificial Heart biventricular support or sever pulmonary hypertension (>4.5 Wood units).

Role of echocardiography in mechanical support

Extracorporeal membrane oxygenation

Transthoracic echocardiography (TTE) or transesophageal echocardiography (TEE) helps detect complications during ECMO [114]. Before initiating ECMO, echocardiography rules out reversible causes of cardiogenic shock. In addition, it detects anatomic variations that affect cannula insertion in

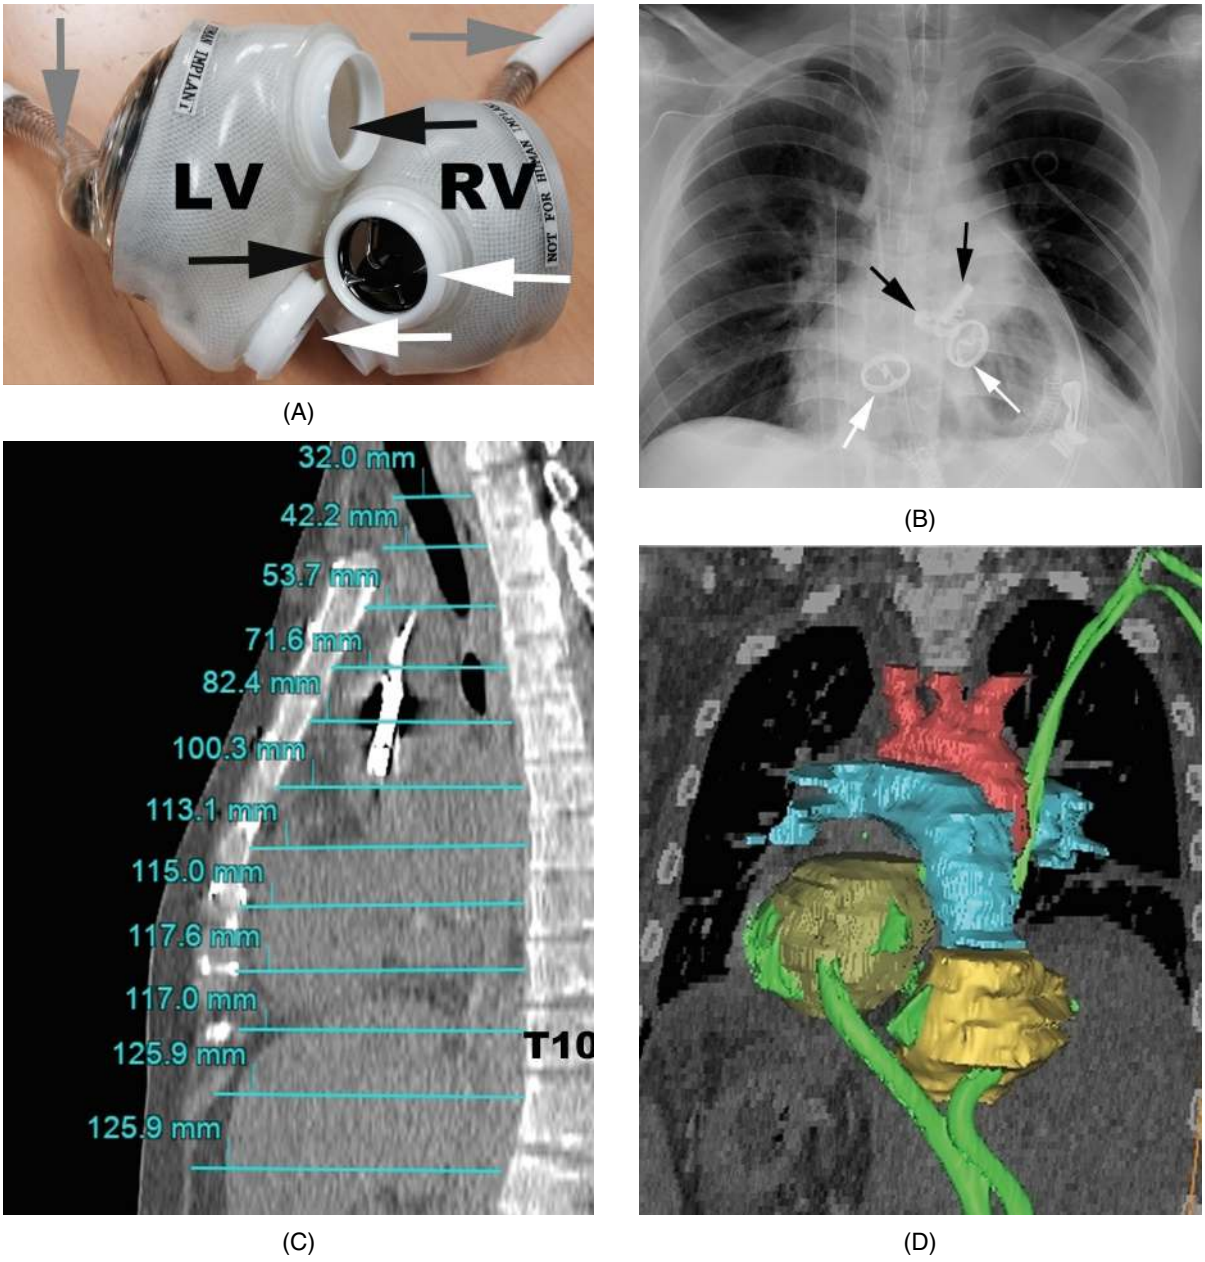

Figure 37.9 (A) Image of the Syncardia TAH showing the LV and RV pump, drive line (grey arrows), inlet valves (white arrows), and outlet valves (black arrows); (B) antero-posterior chest x-ray of an implanted Syncardia TAH displaying inlet valves (white arrows) and outlet valves (black arrows); (C) preoperative chest computed tomography (CT) performed towards placement of Syncardia TAH, the anterior posterior dimensions of the thoracic cavity at T-10 level is 117 mm (minimum for implantation is 100 mm at that level); and (D) preoperative three-dimensional CT reconstruction of Syncardia TAH for surgical implantation exhibiting drive line (green), Syncardia TAH (yellow), pulmonary artery (blue), and aorta (red). Abbreviations: TAH, total artificial heart; LV, left ventricle; RV, right ventricle; CT, Computer Tomography; T-10, 10th thoracic vertebrae.

the right atrium, such as a prominent Chiari network or an aneurysmal atrial septum. If central cannulation through sternotomy is required, TEE is a better choice, as most TTE windows are not available. Kuenzler et al. analyzed the echocardiography of 193 pediatric patients supported with ECMO, detecting a 17.8% incidence of cannula malposition. With echocardiography, the incidence reduced to 3.3% [115]. After the initiation of ECMO, echocardiography assesses the LV unloading and the potential need for left atrial venting via surgical or balloon atrial septostomy [114]. In addition, echocardiography monitors the aortic valve opening because limited aortic ejection increases the risk of blood stasis, leading to thrombosis. Conversely, increasing aortic valve opening during ejection indicates LV recovery when decreasing the ECMO. Echocardiography is used to periodically evaluate cannula positioning and thrombi formation, chamber filling and function, and cardiac compression from pericardial effusion. Tamponade physiology is typically not evident until the patient is off ECMO [116].

AL Grawany

Ventricular assist devices

The American College of Cardiology, AHA, and American Society of Echocardiography consider TEE to be a class 1 indication for the insertion of a VAD (Table 37.2) [116–119]. Before initiating VAD support, TEE is helpful to rule out conditions that jeopardize VAD function. These conditions include mitral stenosis, endocardial trabeculations, and aortic insufficiency. These conditions limit the filling of the device and impede LV unloading. Mitral regurgitation and aortic stenosis do not affect device function. Mitral regurgitation

Table 37.2 Role of transesophageal echocardiography in VAD insertion

Prebypass period	**Tee windows**	**Comments**
Monitor:		
LV size, filling and function	ME4Ch, TGSAX, TG2ch	LVEDD
RV size, filling and function	ME4Ch, MERVIO	Need for RVAD placement RVEDD and L/R ratio calculation
Diagnose:		
Right-to-left shunting (PFO, ASD, VSD)	ME4Ch, MEBC, TGSAX	Causes of severe hypoxemia with LV unloading Agitated bubble study Avoid Valsalva maneuver in patients with marginal physiology
Aortic regurgitation	MELAX, DTG5Ch, DALAX	Increases LVAD preload and LV dimension – impeding LV rest
Mitral stenosis (rare)	ME4Ch, basal TG	Impedes device filling MV commissurotomy
Endocardial trabeculations (noncompaction cardiomyopathy)	ME4Ch, MELAX, TGLAX	Obstruct inflow cannula Resect subvalvular apparatus
Tricuspid regurgitation	ME4C, MERVIO, MEmodBC	Assess the need for TVR Calculate PASP = V_{peakTR}^{2} + CVP
LV Thrombi	ME4Ch, TG SAX	LV thrombectomy before VAD placement
Pulmonary regurgitation	MERVIO, MEAASAX	Rule out before RVAD placement
On bypass period	**Tee windows**	**Comments**
Monitor:		
Cannula alignment		
Inlet	ME4Ch, MELAX	CWD peak velocity <1.2 m/s
Outlet	MELAX	CWD peak velocity 1.0–2 m/s
Deairing	ME4Ch, MELAX	Need for aortic venting Trendelenburg position
Degree of decompression	ME4Ch, TG SAX	Too much LV unloading could shift the interventricular septum causing TF
Diagnose:		
Residual right-to-left shunting	ME4Ch, MEBC, TGSAX	Severe hypoxemia with LV unloading
Rule out aortic regurgitation	MELAX, DTG5Ch, DALAX	Increases LVAD preload and LV dimension – impeding LV rest
Postbypass period	**Tee windows**	**Comments**
Monitor:		
Pericardial effusion / Cardiac Tamponade	ME4Ch, TG SAX	Most common cause of hemodynamic instability and reoperation (20–30%)
Aorta (ascending)	MELAX	Aortic dissection
RV size, filling and function	ME4C, MERVIO	Need for RVAD placement (Transient VS Permanent)
Tricuspid regurgitation	ME4C, MERVIO, MEmodBC	Too much LV unloading could shift the interventricular septum causing TR
Decompression of LV and LA	ME4Ch, MELAX, TGSAX	
Air entrainment	ME4Ch, MELAX	Need for aortic venting Trendelenburg position

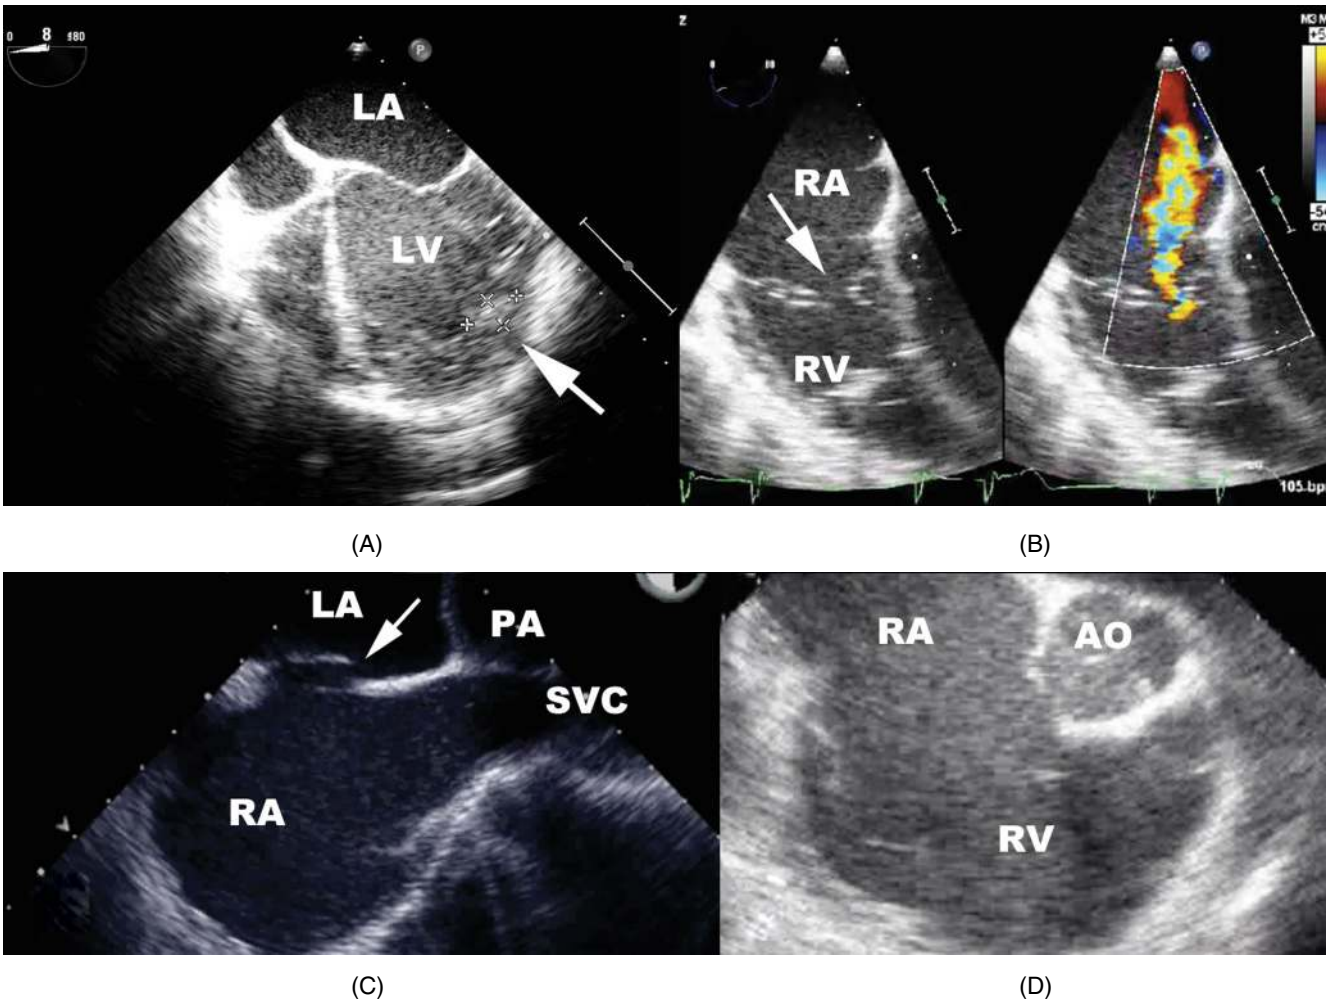

Figure 37.10 Preoperative TEE displaying common procedures performed during LVAD placement, such as: (A) 2-D image at midesophagus four chamber view (0°) on patient with a dilated cardiomyopathy showing a dilated LV with an intra-cavitary thrombus (white arrow) requiring surgical thrombectomy; (B) 2-D and color Doppler images at midesophagus four chamber view (0°) exhibiting an area of noncoaptation (white arrow) and severe TR by color flow Doppler needing TV repair; (C) 2-D image at midesophagus bicaval view (90°) showing a PFO (white arrow) needful of surgical closure to avoid hypoxemia once LVAD support started due to unloading of LV and LA chambers; and (D) 2-D image at midesophagus RV inflow and outflow tract view displaying a severely dilated RA and RV that might require RVAD support in addition to the LVAD placement. Abbreviations: 2-D, two-dimensional; Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium, RV, right ventricle; SVC, superior vena cava; TEE, tranesophageal echocardiography; TV, tricuspid valve; TR, tricuspid regurgitation.

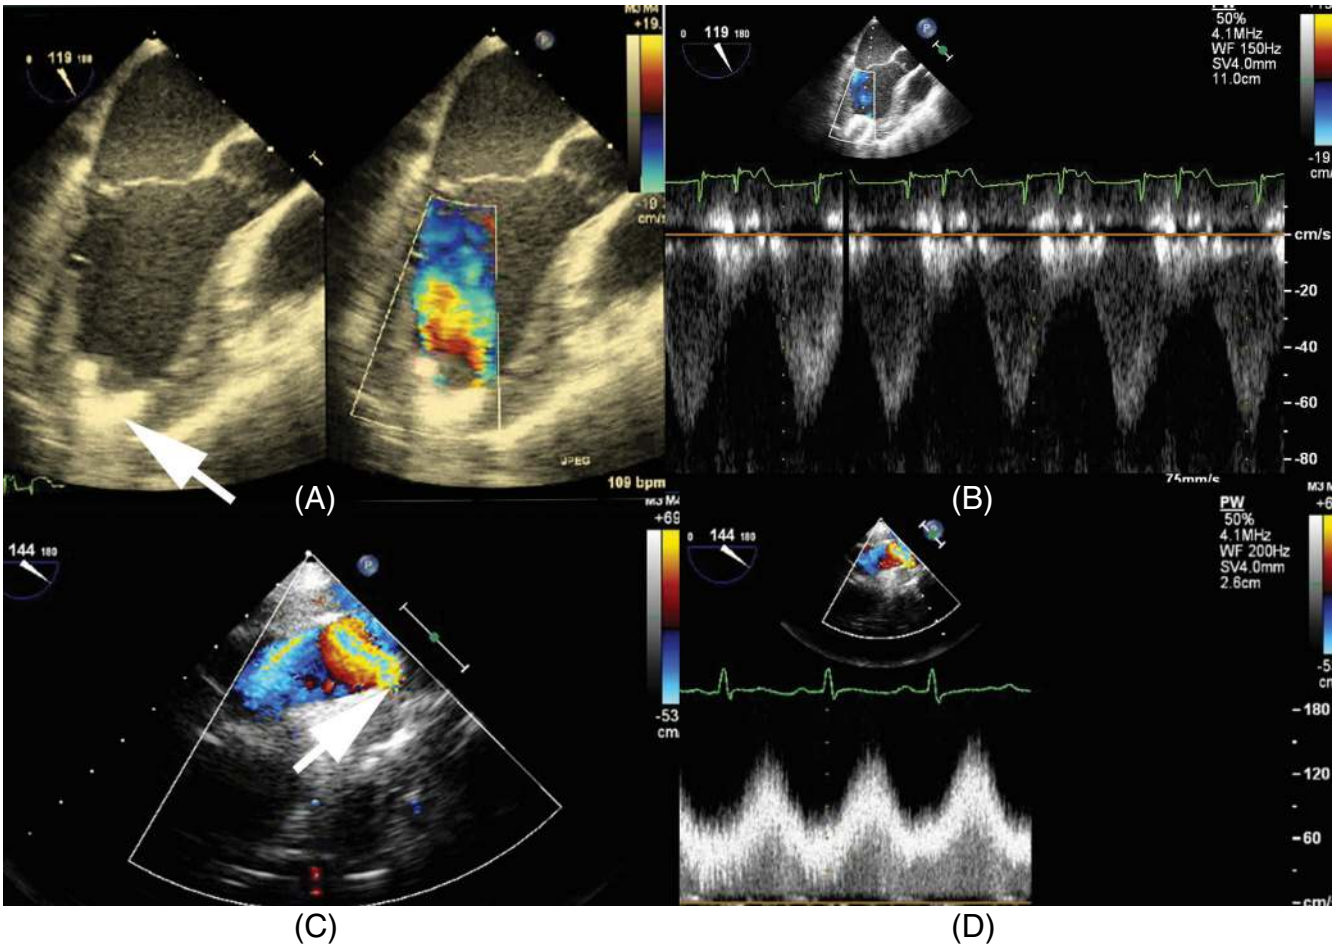
generally improves from LV unloading by reducing left ventricle chamber size and mitral annulus size. Preoperative echocardiography should screen for septal defects (Figure 37.10). Unrepaired atrial or ventricular communications should be closed before VAD insertion. Unloading the left-sided chambers produces significant oxygen desaturation. Echocardiography screens for potential intracardiac thrombi, as thromboembolic events are common and potentially devastating. Intraoperative measures of RV function, such as tricuspid annular plane systolic excursion, tricuspid annular systolic velocity, and RV strain have not been helpful to predict RV failure after LVAD implantation [120]. As RV function commonly has significant improvement from unloading the left ventricle in children. Real-time visualization of RV function should be performed by intraoperative TEE as LVAD support is initiated. Devices placed on CPB should undergo interrogation of the inflow and outflow cannulas before weaning. The inflow should be laminar with a velocity <2 m/s. A peak flow velocity >2.3 m/s along with the turbulent flow indicates inflow cannula obstruction and an indication for surgical revision (Figures 37.11 and 37.12). The normal outflow has a low velocity (peak velocity 1.0–2.0 m/s). Continuous monitoring of RV function and the detection of air is crucial for early intervention. Air may enter through suture lines if the left ventricle completely collapses, and sub-atmospheric intra-device pressures develop. While weaning from CPB, echocardiography determines RV function and guides (RVAD) implantation, if needed (Figure 37.13). Severe septal shifting to the left is an indicator of right-sided heart failure and the need for RVAD. A temporary RVAD can be used when rapid RV recovery is anticipated. Once LVAD support starts and CPB flows decrease, TEE quantifies left ventricle decompression and the degree and direction of movement of the interventricular septum.

AL Grawany



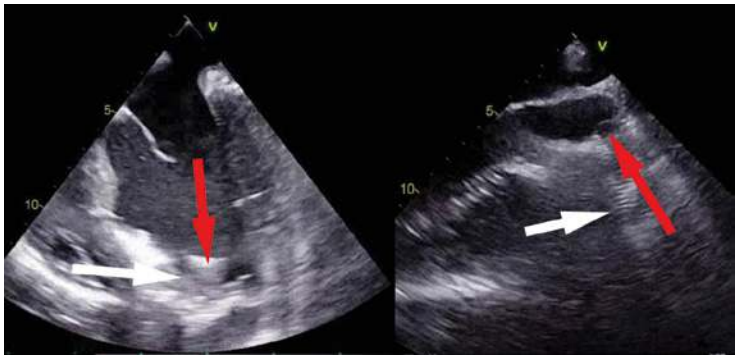


Figure 37.11 Postoperative TEE images showing (A) 2-D and color Doppler images at midesophagus long-axis view (110°) of the HeartWare inflow cannula at the apex of the heart (white arrow); (B) pulse wave Doppler interrogation at the same location showing unobstructed inflow (<70 cm/s); (C) Color Doppler image at the aortic long-axis view (140°) of a HeartWare outflow cannula (white arrow) unobstructed flow is seen in the ascending aorta; (D) pulse wave Doppler interrogation at the same location showing unobstructed outflow (<150 cm/s). Abbreviation: TEE, transesophageal echocardiography.

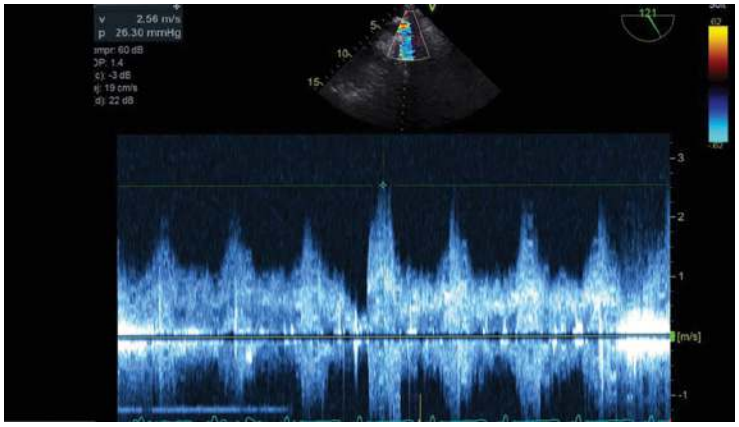
TEE monitors the interventricular septum shift, sufficient LV unloading and ensures that the aortic valve opens periodically. Aortic dissection distal to outlet cannula insertion site is a potential complication. Finally, after chest closure, a final scan is performed to exclude the possibility of kinking of the cannulas or RV compression. Echocardiography is helpful to guide the percutaneous VAD placement (e.g. Impella) (Figure 37.14) [121]. TEE helps to monitor the correct positioning. In long-axis midesophageal aortic valve view, the device inlet should be 3.5 cm below the aortic valve and the outlet above the aortic valve. In the transgastric long-axis LV view, the device positions away from the mitral valve toward the LV apex. Improper deployment of the Impella includes device too far into the left ventricle (e.g., inlet >3.5 cm from the aortic valve or outlet across the aortic valve), outlet too far into ascending aorta, or pigtail in the subvalvular apparatus of the mitral valve. Echocardiography imaging of the STAH is technically challenging due to artifacts caused by the device and its valves. TEE helps diagnose right-to-left shunting, distortion, and compression of systemic and pulmonary venous return to the native atrium, all of which affect STAH function. TEE also guides the de-airing procedures by imaging the ascending aorta. Once the device is functioning, the Medtronic-Hall valves (tilting disc) in the atrioventricular position can be interrogated to assure adequate function [122].



Weaning from circulatory support

ECMO weaning

Patients are weaned from ECMO when their cardiac function recovers, and their lungs can support adequate oxygenation and ventilation using conventional mechanical ventilation. When the myocardium has an acute insult, such as acute myocarditis or ischemia from a prolonged period of CPB, ECMO can usually be weaned 72 hours after the initiation of support. Echocardiographic criteria associated with successful ECMO weaning include LV ejection fraction >35%, LV outflow tract velocity–time integral >10 cm, lack of ventricular dilatation, and no pericardial effusion [123]. In anticipation of ECMO weaning, optimal inotropic support restarts and full ventilation resumes. There is a gradual reduction in the ECMO flow while carefully evaluating the patient's

AL Grawany

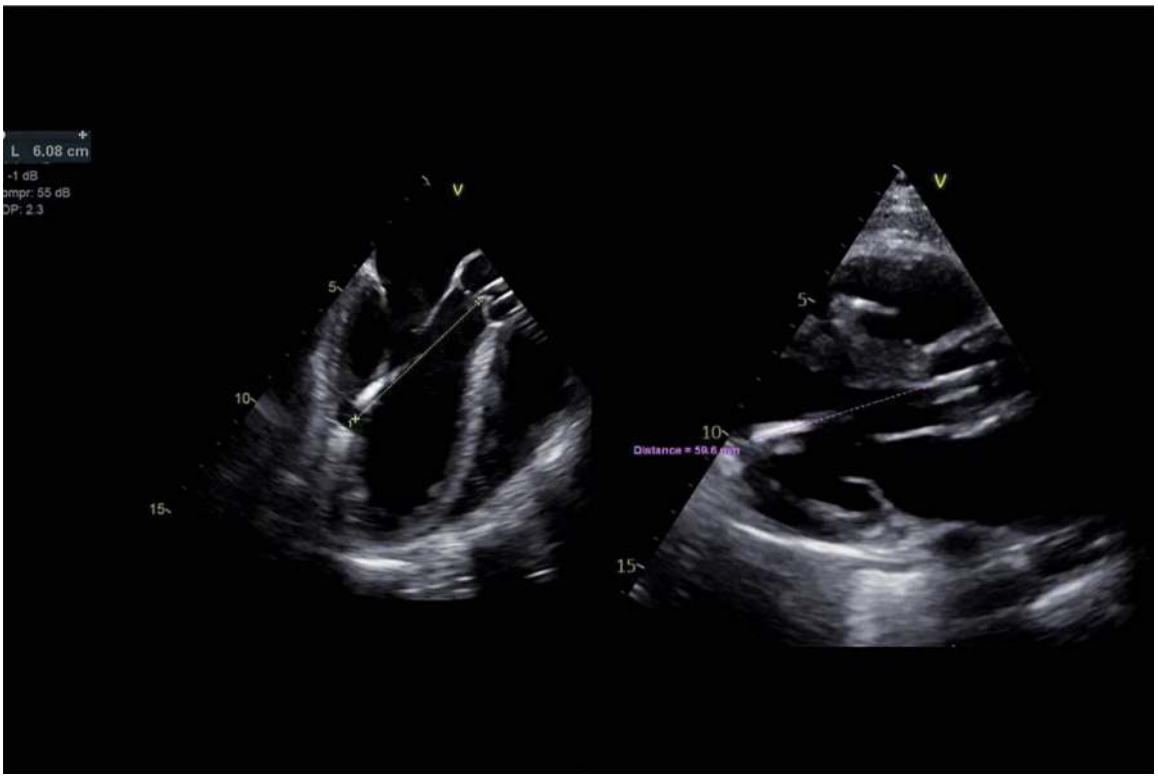

Figure 37.14 Echocardiography images of Impella 5.5 catheter inserted via the left subclavian artery (A) Midesophageal long-axis view with the Impella "motor" positioned against the lateral left ventricle wall below the mitral valve apparatus and papillary muscles. The final distance from the mid-portion of the Impella "motor" to the aortic valve was 6.1 cm; (B) Parasternal long-axis view of the same patient with the Impella motor 5.96 cm below the valve and the outlet in the ascending aorta (white arrow).

hemodynamics (heart rate, blood pressure, arterial waveform, SpO_2, central venous pressure, and pulmonary artery pressure). Tissue perfusion with serum lactate levels and cerebral/somatic oximetry trends. Once flow rates reduce to 25% of full support, a connection (bridge) between the arterial and venous cannulas opens to allow blood to recirculate in the ECMO circuit and avoid thrombosis. The chest is not closed if the cardiac function is marginal after weaning from ECMO until cardiac and pulmonary function recovers [124]. Prolonged cardiac ECMO support (>14 days) and failure to wean from ECMO is associated with high mortality and potential transplant candidates should therefore be transitioned to a VAD when their lung function has recovered, and PHTN controlled [125, 126].

VADs: weaning from CPB to VAD

Intracardiac air complicates LVAD placement. Infield CO_2 insufflation reduces air emboli. However, air can get trapped in the cannulas or the device and is dislodged once the blood flows. Air can have devastating effects if it reaches the coronary or cerebral circulation. As the right coronary artery is the most anterior, it is the most common site for air emboli and will worsen RV function. Therefore, continuous electrocardiogram with ST monitoring and TEE is mandatory while on CPB after ventilation is resumed. De-airing is accomplished by placing the patient in the Trendelenburg position, increasing the mean arterial pressure, and using an aortic vent until all air is removed [127]. Optimal oxygenation and ventilation are mandatory before attempting to wean of CPB. NO decreases the afterload of the RV starting at 20 ppm if there is a concern for RV failure. In addition, the RV function is supported with milrinone (0.375–0.75 mcg/kg/min) and low-dose epinephrine (0.02–0.05 mcg/kg/min). We attempt to maintain a hematocrit of >30% during CPB weaning to optimize oxygen delivery and to anticipate the dilutional effect from other nonred cell blood products transfusion. The CPB flows decrease in a stepwise fashion during the VAD support increase. Pulsatile VAD has a fixed systolic volume determined by the size of the pump, and cardiac output adjusts only by changing the pump rate. Continuous flow VAD output can be increased by increasing the device RPM and modifying the afterload. If VAD is functioning well with favorable hemodynamics, we reverse heparin with protamine. Blood products administration depends on the point of care testing (e.g. ROTEM) and clinical judgment. Careful volume administration to avoid overdistension of the RV. CPB wean is achieved successfully by reducing CPB flows while increasing the LVAD flows and using TEE surveillance of the RV function, LV volume, and the interventricular septal position. With LVAD support, the LV output increases, thereby increasing

Table 37.3 Ventricular assist device troubleshooting[a]

Clinical finding	Echo	Etiology	Treatment
Hypotension	Normal LV chamber filling	Vasoplegia	Stop vasodilators Phenylephrine Vasopressin
	Incomplete LV chamber filling	Hypovolemia[b] (e.g., postoperative bleeding)	Fluid administration
	RV dilation TV regurgitation Incomplete LV filling	RV Failure	Optimize ventilation Nitric Oxide Milrinone ± Epinephrine

Abbreviations: CFD, continue flow device; LV, left ventricle; PFD, pulsatile flow devices; RV, right ventricle.

[a] Berlin Heart EXCOR® as a paracorporeal device can be inspected directly.

[b] PFD are more preload sensitive than CFD.

RV function preload. The RV function output depends on the relationship between the RV function compliance, the septal shift, and the RV function afterload. Ideally, one observes improved RV function after the left ventricle is supported and the pulmonary capillary pressure decreases [124, 128]. Table 37.3 displays the hemodynamic changes and interventions of the long-term MCS devices.

VADs: weaning from VAD to recovery

Unloading the LV with a VAD leads to reverse remodeling of the heart. Some patients will normalize the cytoskeleton integrity by decreasing neurohumoral and cytokine activation. The reverse remodeling process has been described in patients with DCM. During the VAD support, optimization of heart failure medical treatment takes place with angiotensin-converting enzyme inhibitors (ACE-Is), β-blockers (preferably carvedilol), and aldosterone antagonists. Also, patients should undergo extensive physical therapy and nutritional support to maintain and improve their strength. The criteria used for myocardial recovery and candidacy for LVAD explantation are sinus rhythm, trivial mitral regurgitation, LV ejection fraction ≥45%, and LV end-diastolic diameter ≤ one standard deviation below mean for age (≤55 mm for adult-sized patients) along with serum brain natriuretic peptide (BNP) < 100 pg/mL. In a report, including pediatric and adult patients with DCM, 8.8% of patients weaned to recovery. In this study, patients were more likely to be weaned to recovery if they were younger and had a pulsatile VAD [129]. Several case reports or case series of children recovering from acute myocarditis after VAD support have been published [130]. Younger patients (<2 years) and with myocarditis have the highest chance of recovery.

Anesthesia, analgesia, and sedation for mechanical support

Patients who require ECMO or VAD support due to failure to wean from CPB have been under general anesthesia for the surgical procedure. The sedation should continue during the insertion of the long-term MCS system. In addition, plans should continue for sedation and analgesia to smooth the transition of care in the ICU. Patients requiring ECMO in the ICU are already intubated, have invasive pressure monitoring, and receive infusions for sedation and analgesia. If a patient needs the airway secured before initiation of ECMO, the surgical team should be immediately available in preparation for circulatory collapse after the induction of anesthesia. There are specific pharmacological considerations when anesthetizing children receiving mechanical support of the circulation.

Drug disposition changes on mechanical support

Critically ill patients have poorly predictable drug pharmacokinetics secondary to altered hepatorenal perfusion and function, drug interactions, reduced protein binding, and renal replacement therapy. The patient on ECMO will have additional pharmacokinetic changes related to the volume of the circuit, the polymer components, and the altered perfusion and drug elimination. On initiation of ECMO, the fluid in the membrane oxygenator and tubing adds 200–300 mL to the circulating volume, depending on the circuit. This effect is relatively insignificant for drugs with a high volume of distribution (V_d), such as fentanyl, which shows relatively little change in plasma concentration, following ECMO initiation, drugs will diffuse back into the plasma from the tissues.

Pharmacokinetics alteration on ECMO is common and affects about 70% of the drugs used in children [131]. Drugs with lower V_d, (e.g., gentamicin, vancomycin, and nondepolarizing neuromuscular blockers) have a larger dilutional effect. Therefore, a higher loading dose is needed, but the dosing interval should be the usual [132, 133]. The hemodilution of ECMO also associates with a reduction in plasma protein concentration, increasing the free fraction of highly protein-bound drugs (e.g., teicoplanin or ceftriaxone). The increased free fraction of the drug will cause a transient increase in clinical effect, but there will also be an increase in

AL Grawany

drug diffusion to the tissues and, hence, a reduction in plasma concentration. The addition of albumin to the pump circuit will reduce this effect.

Another pharmacokinetic ECMO effect is the absorption by the circuit. Absorption can occur on the large surface area of tubing or the membrane oxygenator of the ECMO circuit, further increasing the V_d. Conversely, sequestered drugs are released back into the circulation, which adds further unpredictability of drug disposition and may prolong the drug's effect [134]. The degree of sequestration depends on the materials used in the ECLS circuit and the nature of the drug. ECLS PVC tubing and the membranes may comprise several biomaterials, including silicone rubber, polypropylene, PMP, or PVC [135]. In general, drugs are more likely to adhere to the PVC if they are highly lipophilic, such as opioids, propofol, and benzodiazepines. *in vitro* studies show that morphine has more negligible adsorption from PVC than fentanyl, 40% for morphine vs. 86% for fentanyl [136]. Most of this adsorption is onto the tubing itself rather than the membrane oxygenators, although newer modified surface-coated PVC tubing still sequesters approximately 40% of fentanyl and 35–58% of morphine [136].

Multiple factors in a heterogeneous patient population make an accurate prediction of drug doses extremely difficult. Nevertheless, appreciation of the issues helps the clinician to make sensible drug management decisions, particularly when initiating ECLS and changing the circuit. Appropriate sedative and analgesic dosing can be difficult, running the risks associated with under-and over-sedation. Under-sedation is associated with pain, ventilator desynchrony, and inadvertent line removal. Alternatively, oversedation is associated with prolonged ventilation and hospital-acquired infections. Vigilant clinical monitoring is therefore mandatory. Prolonged analgesic infusions with fentanyl and morphine are associated with tolerance; however, the long duration of action makes morphine the preferred analgesic. Careful drug monitoring should always be employed where possible (e.g., gentamicin) to guide dosing regimens.

KEY POINTS: ANESTHESIA AND ANALGESIA FOR MECHANICAL SUPPORT

- Pharmacokinetics of medications can be significantly altered by ECMO or VAD.
- V_d is increased, and drugs with low V_d, such as nondepolarizing neuromuscular blockers, will have a lower concentration and require a higher loading dose.
- Hemodilution may reduce plasma proteins, which would increase the free fraction of highly protein-bound drugs.
- Lipophilic medications, such as opioids, benzodiazepines, and propofol will bind to the circuit with the following consequences:
  - Lower plasma levels are seen when initiating the medication.
  - There may be continued release of the medication from the circuit after the drug is discontinued.

Anesthesia, analgesia, and sedation for mechanical support patients undergoing NonCardiac surgery

Technological improvements have allowed MCS to expand to the pediatric population. However, because heart transplantation continues to be limited by organ availability, the number of patients having MCS as DT continues to increase, representing 73% in the Intermacs 2020 Annual Report [137, 138]. This has, in turn, increased the incidence of these patients presenting for noncardiac procedures, currently being between 20 and 50% [139]. For this reason, it is imperative to have a comprehensive understanding of the device characteristics and the perioperative anesthetic implications.

Preoperative management

Preoperatively, it is important to know the type of MCS device, its baseline parameters, and any additional inotropic support. Besides the formal review of systems, coagulation status is usually affected by anticoagulation and antiplatelet aggregation agents. Although there is a lack of standardized guidelines, each MCS device will have goal international normalized ratio (INR) manufacturer recommendations. The perioperative bridging strategy will also institution dependent. Ultimately, the anticoagulation strategy is tailored to the patient's history, surgery type, and urgency [140]. Additionally, it is crucial to consider these patients may have some degree of liver dysfunction resulting in factor deficiency. Acquired von Willebrand disease (vWD) type 2A in the setting of a high-shear continuous-flow VADs may also generate platelet dysfunction [141]. It is of paramount importance to assess the RV function to determine the LV/MCS preload. These patients are commonly on ACE-Is, angiotensin-receptor blockers (ARBs), beta-blockers, and nitrates, all of which may have significant effects on intraoperative hemodynamic management. Because of the high incidence of cardiac arrhythmias in these population, it is frequent to have implantable cardioverter defibrillators (ICDs) [134]. Consequently, it is essential to address the presence of such devices, their characteristics, the patient's dependency on them, and the need for interrogation and deactivation before the procedure. Noncardiac procedures in this patient population should be performed in a tertiary center. A multidisciplinary team is needed, including VAD coordinators, cardiologists, cardiothoracic surgeons, anesthesiologists, and intensivists. Recent studies comparing noncardiac vs. cardiac fellowship-trained anesthesiologists have shown similar techniques and outcomes during low-risk noncardiac procedures and surgeries [135].

Intraoperative management

It is essential to connect the MCS to a power source. Backup batteries, inotropes, vasopressors, and inhaled NO may be required. Regarding intraoperative monitoring, the pulsatility index may vary when managing patients on VADs, depending on the speed, afterload, and native LV contractility. Therefore, essential monitors, such as the pulse oximeter and noninvasive blood pressure (NIBP) cuff may be unreliable [136]. In this sense, near-infrared spectroscopy (NIRS) will aid in assessing regional oxygenation, while using an NIBP

cuff with a Doppler or an arterial catheter will help obtain accurate blood pressure measurements [142]. A central venous catheter or TEE may help assess RV function and volume status. The surgical approach may have significant hemodynamic effects. Thoracic or abdominal procedures requiring cavitary insufflation or extreme positioning (e.g. reverse Trendelenburg) decrease the preload, increase the afterload, and increase the $PaCO_2$, negatively affecting the VAD hemodynamics [143]. Finally, appropriate adjustment of mechanical ventilation, preventing arrhythmias, and volume-overload in nonvolume responsive states is of paramount importance [144].

Postoperative management

Patients with MCS devices recovering from noncardiac surgery need to be in a unit with personnel familiar with their management. It is essential to prevent hypoxia and hypercarbia during anesthesia recovery, increasing PVR and worsening VAD function. Moreover, bucking and vomiting should also be avoided, increasing intrathoracic pressure and RV afterload. Consequently, postoperative nausea and vomiting (PONV) prophylaxis are mandatory. Resuming anticoagulation should be discussed with the surgical and cardiology team. The AICD needs to be restored to its baseline settings. Recently, the AHA published guidelines for CPR in patients with VAD [145]. The challenge in this population is to promptly diagnose circulatory arrest in a clinical setting which is misleading due to VAD physiology. The first step is to assess perfusion. Patients lacking perfusion suggest primary device failure (e.g., disconnection, driveline breakage, or driver failure). First, rule out nonVAD causes of arrest. Bedside point of care echocardiography helps to identify reversible arrest causes. If the VAD is nonfunctioning, it should be restarted after inspection of the power source and driveline. If the circulatory failure is not attributable to VAD failure, the guideline recommends CPR with chest compressions. The only exception is with STAH patients in which CPR and inotropes are detrimental.

Anticoagulation, antifibrinolytics, and platelet antiaggregation therapies

Blood exposure to the ECMO circuit causes cellular activation of complement, coagulation, fibrinolysis, and inflammation. These effects are more pronounced in neonates and infants because of their lower blood volume than the circuit size [146]. Anticoagulation is mandatory when initiating ECMO. Thus, the challenge is to achieve adequate anticoagulation without producing hemorrhagic complications. Unfractionated heparin (UFH) is the first-line drug to achieve anticoagulation on ECMO. Before ECMO cannulation, a bolus of UFH of 100 units/kg is administered to achieve an activated clotting time (ACT) of more than 180–200 seconds. ACT is a real-time bedside test that measures whole blood clotting (platelets, red cells, and clotting factors) after exposing the blood to activators (kaolin or celite). The ACT does not correlate well with activated partial thromboplastin time (aPTT) or antifactor Xa in heparinized neonates receiving. [197] Postcannulation UFH drip is started with the aim of keeping the ACT between 180 and 220 seconds followed by an infusion of 8 units/kg/hour (range 6–60 units/kg/hour) and adding heparin to the pump prime. Neonates have higher heparin needs secondary to faster heparin clearance and volume of distribution (higher water content). During ECMO, the primary source of heparin clearance is inactivation in the circuit. Therefore, we transfuse platelets to keep platelet count >100,000/mm^3 and cryoprecipitate to keep fibrinogen over 150 mg/dL. In patients with heparin-induced thrombocytopenia, direct thrombin inhibitors have been used in pediatric ECMO [147]. The selected use of factor VII helps in refractory bleeding on ECMO, but it has also been associated with life-threatening thrombosis [148]. The ATIII levels should be checked and kept above 70% to avoid thrombotic complications.

Point of care testing is use in ECMO and VAD placement. The most important parameter to follow is maximal graph amplitude (MA in TEG®) or maximum clot firmness (MCF in ROTEM®). It is measured in millimeter and reports the maximal clot firmness through the increase in fibrin polymerization, platelets and FXIII. The use of FIBTEM or functional fibrinogen can differentiate between the platelets or fibrinogen contribution to the clot firmness. It is our practice to send a two channel ROTEM (HEPTEM with heparinase and FIBTEM) upon rewarming of CPB [149] (see Table 37.4).

Our philosophy is that anticoagulant agent(s) should start once the coagulation profile is normal postVAD insertion. In most of the cases, patients are in a "hypocoagulable" state early after surgery (<48 hours postoperative). The etiology of bleeding includes low platelet counts, platelet dysfunction, or inadequate coagulation factors, such as fibrinogen. Therefore, initiation of anticoagulation occurs typically 24–48 hours postoperatively. Currently, most of the institutions follow the Edmonton antithrombotic protocol once the patient is discharged from the ICU. This protocol involves a three-drug regimen: antiplatelet agent (e.g., aspirin clopidogrel, or dipyridamole), and either warfarin (≥12 months)

Table 37.4 ROTEM normal values

	CT (sg)	α-angle (°)	CFT (sg)	A10 (mm)	MCF (mm)	LI30 (%)	ML (%)

APTEM	38–79	63–83	34–160	43–65	50–72	94–100	0–15

Abbreviations: A10, amplitude 10 minutes after CT; CFT, clot formation time; CT, clotting time; LI30, lysis index 30 min after CT; MCF, maximun clot firmness; ML, maximum lysis; mm: millimeters; n.d.: no data; sg: seconds.

or enoxaparin (<12 months) [148]. Platelet aggregation studies are used to follow the platelet function and guide the administration of aspirin and dipyridamole. Infection will increase the risk of clotting, and anticoagulation monitoring should increase in frequency when infection is suspected.

Anti-infective therapy

Bleeding and infections continue to be the leading cause of adverse events in patients with VADs [137]. The incidence of MCS infections varies between 13 and 80%, depending on the definition [150]. Bacteria represent the primary etiology of early and late infections, with fungi representing <10% of the time. *Staphylococcus aureus* and *Staphylococcus epidermidis* cause more than 50% of the infections. The most common gram-negative bacteria is *Pseudomonas aeruginosa* (22–28%). Candidemia (caused by *Candida albicans* in 70% of the cases) is the most common fungal infection (1.3–9.7% of cases), with a 15–25% mortality rate [151]. The most common risk factors for infection in MCS are pulsatile devices, older age, comorbidities, intravascular lines, open sternum, prolonged ICU stay and duration of MCS support. There are currently no randomized controlled trials studying the optimal perioperative antimicrobial prophylaxis regimen for MCS implantation. However, the International Society for Heart and Lung Transplant (ISHLT) MCS consensus expert panel recommends always targeting *Staphylococcus* species and, in colonized patients or centers with high methicillin-resistant *S. aureus* (MRSA) prevalence, coverage for MRSA. The duration of the antimicrobial prophylaxis should not exceed 48 hours after the procedure. Routine broad-spectrum gram-negative prophylaxis and antifungal prophylaxis are not required unless guided by local institutional epidemiology data. In case of MCS infections, it is based on identification of the specific pathogens, infection location site (pump, cannula, pocket or drive-line), infection type (infective endocarditis, bloodstream infection, and mediastinitis) and transplant candidacy status (BTT vs. DT). Frequently, surgical debridement, collection drainage, device exchange, or even urgent heart transplant may be necessary. Patients with severe MCS-related infection or sepsis may have increased short-term mortality rates and are ineligible for transplantation [152].

Outcomes and complications of extracorporeal support

The number of all age-group cases requiring ECMO and the number of reporting centers have been increasing significantly over the past 15 years [37]. The outcome depends on the age, deployment timing, comorbidity, indication for support, and severity of illness. In children, results of ECMO for CHD are generally worse than for respiratory disease. However, it must be remembered that although the overall rate of ECMO in congenital heart surgery centers has remained constant at 2–3%. But the demographic of children requiring ECLS has changed in recent years, including more complex patients. Children undergoing ECPR, transplants, and complex congenital heart surgery (e.g., stage 1 hypoplastic left heart) are represented in the figures with increased frequency [36]. The ECMO survival to hospital discharge in children with heart disease is 40–45%, which is lower than the survival rate in children with respiratory disease. However, most outcome data are based on the ELSO registry, which has collected over 50,000 patients since 1984. Unfortunately, cardiorespiratory function, neurodevelopmental outcomes, and quality of life are not collected by ELSO [36]. In addition, until 2013, there was no severity of illness scoring within the registry, so that, specific data have so far been difficult to interpret; for example, VA-ECMO for neonates with respiratory failure has a mortality of 29%, but with VV-ECMO, the mortality is 16%. Without knowing the illness severity, we cannot ascertain what impact the mode of ECLS has on these figures.

Critically ill patients requiring central or peripheral mechanical support are at risk of serious complications, most of them related to organ hypoperfusion, bleeding, coagulopathy, systemic inflammatory response, embolic events (air or thrombus), hemolysis, and sepsis. In addition, the design of the mechanical support carries an inherent risk. Oxygenators run the risk of red cell damage, and the tubing and multiple connectors risk clot formation and gas embolization. The frequencies of mechanical and patient-related complications are summarized in Tables 37.5 and 37.6. We see that overall mechanical failure is relatively uncommon but is associated with significant mortality. Of the patient-related complications, bleeding from the cannula and surgical sites remains a considerable risk that carries a high mortality. Unfortunately, there is a lack of data on the long-term consequences of ICH.

ECMO for cardiac support

Cardiac failure and sequelae of low cardiac output are the most common causes of mortality after ECMO for cardiac reasons [15, 36, 37]. For postcardiotomy patients, outcomes vary due to specific indication and deployment techniques. In these patients, if an arterial pulsatile waveform does not return after 72 hours of ECMO or VAD support, the prognosis is dismal, and transplantation or withdrawal is considered. Other prognostic indicators for ECMO, but not VAD, include urine output, renal function, and pH at 24 hours.

Overall, the rate of survival of ECMO in neonatal patients with cardiac disease is 42%, with pediatric survival of 51% [33]. Neonates following cardiac surgery for stage 1 palliation for HLHS represent the most common subgroup; 17% of patients require ECMO. Unfortunately, this group has a high early mortality of 57% [126]. Pediatric patients in all age groups with acute fulminant myocarditis requiring ECMO have a better prognosis than postcardiotomy patients; 60–80% survive to discharge [153]. The natural history for myocardial recovery is different in this group, and recovery can take days up to years. However, according to the ELSO registry, this survival figure is worse in neonates with enteroviral myocarditis at 33% [154].

These patients should transition to VAD from ECMO if there are no signs of recovery after 2 weeks [155]. There is a 57–61% survival rate and new VAD technology appears to reduce transplant waiting list mortality compared with long-term ECMO support [57].

Postcardiac transplantation ECMO requires ECLS commonly (14–17%). Acute graft dysfunction is the most common

Table 37.5 Mechanical complications of extracorporeal life support

Complication	Age group	Cohort	Number of cases (%)	Survival (%)
Oxygenator failure	Neonatal	Respiratory	1,529 (6)	53

Patient-related complications of extracorporeal life support (ECLS) divided into age group and cohort. Pediatric refers to the age range 1 month to 16 years. Respiratory cohort refers to those with a respiratory indication for ECLS. Cardiac cohort refers to those with a cardiovascular indication for ECLS.

reason for early survival is approximately 60% since the natural history is for many grafts to recover [36]. Long-term mortality after hospital discharge in children with cardiac disease is becoming appreciated; a recent study suggests 6% late mortality, often related to the severity of the cardiac condition or comorbidity; this was like the findings of a 5-year follow-up study from Canada [156, 157].

ECMO for respiratory support

The introduction of ECMO programs for neonates with respiratory failure produced significant improvement in outcome, 82% survival vs. 72% for historical controls [158]. Of the 51,000 patients requiring ECMO recorded to the ELSO Registry through 2016, 50% were for neonatal respiratory support, with 74% survival to discharge in this population

[33]. As always, however, the specific indication for ECMO impacts survival rates; neonates with CDH requiring ECMO have a 51% survival, whereas those with MAS requiring ECMO have an overall 94% survival [33]. Survival depends on preECLS factors (e.g., primary diagnosis, age, hypoxemia, acidosis), ECLS factors (e.g. cannulae, complications, duration), and postECLS status. Late mortality is primarily related to comorbidities [159].

The most common indication for ECMO for respiratory disease outside the neonatal period is viral pneumonia (20%) [37]. Overall pediatric hospital survival is approximately 57%. However, outcomes depend on both diagnosis (e.g., 83% survival for asthma, 23% for fungal pneumonia) and comorbidity (e.g. 59% for chronic lung disease, 5% for hematopoietic stem cell transplant) [160]. Survival declines with increasing time on mechanical support. In a study of 3213 children supported on ECMO, those requiring <14 days of support had 61% survival compared with 38% in those supported for more than 21 days. Male gender increased inotrope infusion and acidosis were independently associated with increased odds of death [161]. Age >10 years is associated with lower survival (50%) compared with infants and toddlers (57, 61%) [162]. Overall survival rates appear to have shown only small improvements over the last 10 years. However, the increased frequency of children with significant comorbidity offered ECMO is likely to have reduced the improvement in survival [163]. Despite improvement in ventilatory strategies, preECMO ventilation time of >2 weeks has worse hospital survival [164].

ECMO complicated by sepsis

Sepsis is a critical complication of ECMO, and its presence is a poor prognostic marker and increases the overall mortality [165]. Potential sources of sepsis include ventilator-associated pneumonia (VAP), bloodstream or cannula infections, mediastinitis, infections related to urinary catheters or other invasive lines, infected pressure sores, and *Clostridioides difficile* diarrhea [159, 165]. Mechanical support involves long-term invasive cannulas and access ports for sampling in critically ill patients who may be immunosuppressed, placing patients at significant risk of infection. Examination of the ELSO registry from 1998 to 2008 found that infections occurred in 11.7% of patients on ECMO. For adult, pediatric, and neonatal groups, the rates were 30.6, 20.8, and 10.1 infections per 1,000 ECMO days. Neonates and children have infections complicating their ECMO in 5.8 and 16.8%, respectively [33]. VA-ECMO was associated with the highest rate of infection in each group. As expected, the prevalence of infectious disease increases with time on mechanical support: 6.1% infection rate for <7 days ECMO, 30.3% in those requiring ECMO for >14 days [166].

The most common organisms were coagulase-negative staphylococci in the neonatal group (15.9% of all patients) and *Candida* in the older pediatric and adult groups (12.7% of all patients). *P. aeruginosa* was grown in 10.5% and *S. aureus* in 9.4%. Overall, those with culture-positive infections on ECMO had longer ECMO runs and a higher rate of death (57.6% infected vs. 41.5% noninfected). Even though fungal infections during extracorporeal support increase mortality, the presence of a fungal infection before ECMO does not contraindicate support [167]. Similar strategies may reduce these infections to those for central line infections and VAP [166].

ECMO and renal function

Renal function in the context of ECMO or CPB may be adversely affected due to hemodynamic impairment, ischemia–reperfusion injury, inflammation, and oxidative stress. Definitions of acute kidney injury (AKI) vary, and the ELSO registry data collection uses a high threshold of serum creatinine for their criteria (>1.5 mg/dL) [168]. With this definition, younger patients may be missed, and single-center reports of AKI differ from the ELSO registry data. Data extracted from ELSO for neonates and older children are presented in Table 37.7. These results reported in 2012 were like

Table 37.7 Renal injury during extracorporeal life support

Age group	Indication for support	Degree of acute kidney injury (AKI)	Number reported with AKI (% of total)	Survival number (% of total)	Cohort survival to discharge or transfer (%)
Neonatal	Respiratory	$[Cr]_{serum}$ 1.5–3 mg/dL	1,782 (7)	914 (51)	75
		$[Cr]_{serum}$ >3 mg/dL	345 (1.3)	126 (37)	
		Renal support required	5,067 (20)	2552 (50.3)	
	Cardiac	$[Cr]_{serum}$ 1.5–3 mg/dL	617 (12.7)	138 (22)	39
		$[Cr]_{serum}$ >3 mg/dL	92 (1.9)	24 (26)	
		Renal support required	2,038 (42)	476 (23.3)	
Pediatric	Respiratory	$[Cr]_{serum}$ 1.5–3 mg/dL	521 (9.9)	162 (31)	56
		$[Cr]_{serum}$ 1.5–3 mg/dL	242 (4.6)	69 (29)	
		Renal support required	2297 (43.6)	909 (39.5)	
	Cardiac	$[Cr]_{serum}$ 1.5–3 mg/dL	684 (11.8)	195 (28.5)	48
		$[Cr]_{serum}$ >3 mg/dL	261 (4.5)	79 (30)	
		Renal support required	2,215 (38.3)	761 (34.3)	

Source: Data from Thiagarajan et al. [37].

The association of AKI with extracorporeal life support (ELSO) stratified according to neonates <30 days old and pediatrics (1 month to 16 years). Renal replacement therapy refers to those requiring dialysis, hemofiltration or continuous arteriovenous hemodialysis.

a recent systematic review and meta-analysis of kidney injury on ECMO in children, whereby the overall incidence of AKI was 61.9, and 40.9% required renal replacement therapy. The increased hospital mortality related to AKI and AKI requiring renal replacement therapy showed an odds ratio of 1.7 and 3.64, respectively. Note that the incidence of AKI in the cardiac ECMO groups is higher than those in the respiratory groups. In a neonatal single-center study, NO ventilation and younger age at ECMO cannulation predictors acute kidney injury [169]. In this study, 64% had acute kidney injury, 30% classified as "risk," 23% as injury, and 11% as failure [170]. In addition to mortality, neonates with acute kidney injury associated with ECLS treatment are risk factors for developing chronic kidney disease. For example, in one study of neonatal ECLS survivors, 32% had signs suggestive of chronic kidney disease at median 8.2 years of follow-up, as defined by proteinuria, hypertension, or reduced glomerular filtration rate (GFR). The presence of AKI was the predictor, although maybe of minimal clinical significance [170].

Overall long-term survival

It would be shortsighted to restrict our focus on hospital discharge, as the combination of mechanical support and underlying disease will have a longer-lasting effect on the child's health [171]. Data are starting to reveal that the incidence of late death is significant. In a study of 741 children requiring ECMO, 469 survived the past 90 days. Of these survivors, 46 (10%) subsequently died. Of the children alive at 90 days, the highest survival was for MAS (97.9%), and the lowest survival was for CDH (73.6%). Congenital and acquired heart disease also carried a significantly increased risk of late death compared with MAS. The most common cause of late death was a cardiac failure in these cardiac patients, although some deaths were due to neurological injury, respiratory and renal failure. Other reports show consistent results; in a single-center study of children receiving ECMO for respiratory failure from 1987 to 2013, those who survived 90 days had a 93% survival in neonates and 89% in the pediatric population; the highest survival groups were due to meconium aspiration, trauma, and infectious disease. Patients who received VV-ECMO had significantly higher 10-year survival compared with VA-ECMO. This observation is probably related to the increased risk of complications with VA-ECMO, such as systemic ventricular wall tension and thrombosis, as well as the underlying conditions requiring VA-ECMO compared with VV-ECMO [172]. The late deaths were primarily related to underlying disease. This study did not focus on functional outcomes and quality of life. For children receiving ECMO for cardiac disease, the long-term outcome is worse. For example, a single-center long-term follow-up study showed despite 43% survival to hospital discharge, only 33% of patients were alive at median 6-year follow-up.

ECLS for CHD had an estimated five-year survival after ECMO of 32.3%. Surprisingly, some late deaths were in children with an underlying diagnosis of myocarditis who had been successfully weaned from ECMO after the acute illness [173]. As expected, in those who required ECLS for respiratory disease, the causes of late deaths were primarily due to respiratory failure or PHTN. Many of the other deaths were due to complications of prematurity [173]. Therefore, we can conclude that for cardiac and respiratory indications for ECMO, almost all the late deaths were related to the primary underlying disease rather than complications of the mechanical support itself.

Neurological outcome

Brain injury is common in children receiving mechanical support. A nationwide study in the Netherlands reviewed ultrasound images over 20 years on all neonates (>2 kg and >34 weeks' gestation) who received ECMO. The overall incidence of injury was 17.3%, of which 8.8% had a primary hemorrhage. Stroke occurred in 5% and lobar hematoma in 2.2%. Survival of patients without brain injury was 75.5% compared with 54.7%, and the incidence of brain injury in preterm neonates was 31.5% compared with those born at term (14.5%). As expected, three-quarters of the premature brain injury was primary hemorrhage. Notably, the prevalence of brain injury did not differ over the 20 years, despite alterations in the technical management of the ECMO circuit [174]. Much of the longer-term neurological outcome data available involves neonatal follow-up – particularly for respiratory disease. Overall, 5–10% of neonates who survive ECMO for respiratory illness have severe neurological impairment. The remaining survivors are at risk of more subtle neurodevelopmental problems. Long-term follow-up has demonstrated intelligence is generally comparable to previously healthy children [175]. However, a relatively high number of ECMO survivors attended special education compared with the general population. Neuropsychological testing has shown despite a comparable IQ, a large group of previous ECMO patients exhibits selective attention deficits, working memory impairment, reduced operating speed, and the need for extra help at school [175–177]. Children on ECMO for CDH had lower IQ and worse neuropsychological outcomes than other respiratory diagnoses [176]. Motor function development is generally favorable in neonatal ECMO. Survivors measured in the preschool phase of growth. However, more complex task deficits become apparent at an older age. For example, at 1 year of age, normal motor function is identified as standard in 84%, whereas only 43% are average at 7 years of age [178]. Seizures are common in children treated with ECMO, and recent evidence suggests that we may be underestimating the true incidence. In one small study of 19 non-neonatal pediatric patients, four children had seizure activity, of which three were nonconvulsive. Although the seizures were not associated with mortality, the abnormal EEG activity often occurred without associated clinical findings. This seizure activity may indicate CNS injury although the neurological outcome in this population was unknown. However, it is known that neonates treated with ECMO who had seizures have a higher risk of developmental delay. A single-center 6-year follow-up of ECMO for cardiac disease showed high morbidity, including over 50% had seen a neurologist and nearly 20% having ongoing neurology follow-up. Nearly, 50% of survivors had some degree of learning disability, although the time-course and the exact nature of these disabilities are unclear [172]. Approximately, one-third of survivors needed ongoing physiotherapy, occupational therapy, or speech pathology.

The recommendations for long-term neurodevelopmental follow-up depend on neurological comorbidity, the nature

and extent of the underlying disease, and ECMO indication [179]. Sensorineural hearing loss has been reported in patients after ECMO. Risk factors include prolonged ECMO, ICH, sepsis, and seizures. In 136 neonatal ECMO survivors followed up to 5–12 years of age, the incidence of bilateral sensorineural hearing loss >20 dB was 3.7%; however, median intelligence and language development were normal. Risk factors were related to the premorbid condition and other therapies, such as aminoglycosides rather than the ECLS treatment [180].

Quality of life

Neurological injury is common during ECMO, as is long-term cardiac and respiratory dysfunction. Despite the inherent difficulties in defining quality of life, assessment tools are becoming available to measure quality of life in children, including disease, psychosocial impact, and dynamic environment [181]. Limitations of acquiring meaningful data still exist, however, such as difficulty in assessing children's quality of life under 8 years of age and delineating the effects of ECMO from those of the underlying disease. In addition, there are the practical difficulties of interpreting data where there is invariably a low proportion available for study at long-term follow-up (<50%). Most studies studying the quality-of-life measurements have occurred in children receiving ECMO for cardiac disease and are single-center studies.

With these caveats in mind, results have been variable. Follow-up of patients receiving ECMO for cardiac disease in one 4-year follow-up study demonstrated mean pediatric quality of life summary scores were significantly lower than nonECMO children with chronic health conditions and CHD [182]. Another study examining those who received mechanical support as a bridge to transplant showed physical and psychosocial scores to be equivalent [183]. Recently, a longer-term (11–24 years) follow-up study of 20 neonates and children receiving ECMO used a self-reporting pediatric quality of life questionnaire. Ninety percent had no disability with complete standard quality of life, and 95% had no cognitive impairment [184].

In neonates receiving ECMO for primarily respiratory disease, one study concluded that they had a significantly worse quality of life at 5 years of age than a reference group based on maternally reported health-related quality of life scores. Delayed neuromotor development, cognitive and behavior problems, and a disabled maximum exercise capacity affected the outcome [185]. Another study looking at pediatric cardiac ECMO survivors also found their maternal reported health-related quality of life to be lower than that of the controls but like children with complex cardiac disease. In contrast, the psychosocial quality of life was like the general population. Interestingly, the children old enough to report on their questionnaire suggest their quality of life is equal to or better than their peers [186]. It is consistent with a more recent study of 22 patients median 5 years of follow-up where parents reported reduced quality of life compared to healthy children. However, those over 12 years old able to self-assess showed scores comparable with healthy controls [187]. Overall, regardless of the range of psychosocial and physical disabilities, long-term survivors of CHD requiring ECMO report their quality of life to be quite good [188].

Comparing outcomes and complications of VAD and ECMO

Given their differing roles, timing, indications, and practicalities, it is not always possible to directly compare outcomes after ECMO with VAD. ECMO is more familiar and more commonly used in children because VAD cannot provide respiratory support or be used for PHTN. VAD advantages include lower prime volume, less hemolysis, reduced anticoagulation requirement, and fewer bleeding complications. The VAD circuit has fewer access ports, which reduces the chance of infection, and the patient can ambulate and go home. In addition, the time-dependent increase in complications seen with ECMO does not seem to be as evident with VAD [57]. Long-term support with VAD is therefore associated with fewer ECLS-related complications while bridging to recovery or transplant. In a larger, less selective multicenter trial, children supported for 1–435 days showed a 12-month survival of 75%, which comprised 64% successfully transplanted, 6% recovered and explanted, and 5% with device in situ at 12 months. The most common cause of death on EXCOR was a respiratory failure (50% of deaths), while 33% were due to neurological injury, with thromboembolic strokes being more common than hemorrhagic strokes. Smaller patient size (and age) was also associated with early mortality. Mortality appeared to reduce in centers with higher implantations; however, this difference was not significant when adjusted for other baseline characteristics [189].

Although no extensive studies compare ECMO and VAD used as a bridge to transplantation, this study reveals improved survival for children >5 kg supported by EXCOR compared with outcomes of long-term ECMO. The survival for children <5 kg in the study was poor; 21 out of 33 died, so the advantage over ECMO seen in larger children has yet to be demonstrated in this group [189]. One center studied children requiring mechanical assistance for primary graft failure following heart transplantation and had 44 patients requiring continuous flow VAD or VA ECMO. VAD needed longer bypass time to insert and was associated with more bleeding complications requiring exploration ($p = 0.0047$), a higher incidence of renal replacement therapy ($p = 0.0045$), higher in-hospital mortality ($p = 0.16$), and higher 3-year mortality ($p = 0.13$) [190]. From the physiological point of view, a study in piglet models comparing ECMO with pulsatile and continuous-flow VADs showed an improved LV blood supply/demand ratio in both VAD and ECMO groups. In addition, LV filling pressures and LV workload were similarly reduced in the pulsatile VAD and ECMO groups. However, VAD demonstrated an improved global myocardial blood supply/demand ratio compared with ECMO [188]. It is not known whether these cardiovascular changes induced by VAD would lead to improved reversed ventricular remodeling of the myocardium.

Other outcome issues

Volume of cases

A retrospective study of 7,322 pediatric patients supported with ECMO found that after adjusting for case-mix, surgery complexity, and year of treatment, the low-volume centers (average <20 cases/year) had significantly higher odds of

death compared with the medium- and higher-volume centers. The minimum annual caseload associated with lower mortality was 22 [191]. It is consistent with more recent studies suggesting a similar pattern of lower mortality is true in both neonates and adults in those centers with a higher age-specific volume of cases [192]. Interestingly, the trend was not seen in this study in the pediatric population. However, a more recent survey of US pediatric centers found lower risk-adjusted mortality in those centers with more than 30 ECMO runs per year in all pediatric ages [193].

Parental outcomes

A study of the parents of children who were successfully bridged to recovery demonstrated that 20% suffered symptoms of post-traumatic stress disorder. This issue has potential implications for the information we deliver to parents. Therefore, screening and developing service interventions for parents suffering from these symptoms are advised [194].

KEY POINTS: COMPLICATIONS AND OUTCOMES OF MCS

- Survival after ECMO is significantly better when used for respiratory support than when used for cardiac support.
- Survival among patients requiring cardiac support is significantly better for cardiomyopathy than for post-cardiotomy patients.

The future

Tomorrow ECMO

Over the last few years, technology in the pediatric field has not progressed significantly; there is still no pediatric Cardiohelp™ (Maquet Cardiopulmonary AG, Hirrlingen, Germany), available even though is available for adults a decade ago. Companies are reticent to spend significant research and development on new products with limited demand or significant regulatory hurdles. Spectrum is evolving its Quantum platform so that the ECMO system can potentially integrate more effectively with the electrical medical record. The efficiency of devices will be incrementally improved, allowing for rapid, simple ECMO initiation; however, no significant technological leap is on the horizon. Improvement allowing stable long-term ECMO support will result from using a less traumatic cannula, such as Berlin Heart cannula & anticoagulation regimens that use a cocktail rather than relying on heparin alone. NO, prostacyclin and bivalirudin will be the vanguard of maintaining anticoagulation. Heparin niche will be as a "fine control" (e.g., < 10 units/kg/min). NO has many other benefits which should result in better organ perfusion during ECLS with less morbidity (e.g., improved neurological sequelae and kidney function). Donor blood has no nitrosothiol levels resulting in poor organ perfusion even in high PaO_2 and high hemoglobin resulting in organ ischemia. Future devices will have NO eluting surfaces or use systems whereby NO is generated from room air via a plasma arc (Beyond Air), enabling routine NO use without the high cost [94, 195].

Tomorrow VAD

The future of VAD in children will continue growing in the next few years. The reason for this growth is the expanding indications, improved safety profile, and technological improvement. In addition, the use of pediatric VAD as DT, such as muscular dystrophy and failing single ventricle [12]. Thus, prospects of pediatric VADs are undoubtedly encouraging due to technological adaptations, such as continuous flow device miniaturization [196]. Finally, the expanded VAD use in children will bridge the gap between a stable pool of heart transplant donors and an increasing end-stage heart failure pediatric population.

4 Barbaro RP, Paden ML, Guner YS, et al. Pediatric extracorporeal life support organization registry international report 2016. ASAIO J 2017;63(4):456–63. This report is to describe the international growth, outcomes, complications, and technology used in pediatric extracorporeal life support (ECLS) from 2009 to 2015 as reported by participating centers in the Extracorporeal Life Support Organization (ELSO). Since 2009 21,907 received ECLS with an overall survival to hospital discharge rate of 61%.

23 del Nido PJ, Dalton HJ, Thomson AE et al. Extracorporeal Membrane Oxygenator rescue in children during cardiac arrest after cardiac surgery. Circulation 1992;86:II 300–4. This is the first article to demonstrate the benefit of ECMO as rescue for cardiac arrest, termed ECPR. Overall early survival was seven of 11 (64%), with one patient requiring heart transplantation due to irreversible cardiac dysfunction. One child died late (1 month) after ECMO support. There were no long-term sequelae in the survivors.

Critical Care Med 2017 Jun;45(6):1061–93. The new recommendation consider de use of a "recognition bundle" for rapid identification of patients with septic shock, "resuscitation and stabilization bundle" to adherence to best practice, and a "performance bundle" to identify and overcome perceived barriers.

95 Tume SC, Conway J, Ryan KR, et al. Developments in pediatric ventricular assist device support. World J Pediatr Congenit Heart Surg 2019;10(6):759–68. The author presents a focused review of the inpatient critical care environment. They discuss the recent field

developments and focus on challenging patient populations, the emergence of temporary support, management of anticoagulation, and diagnostic approach to stroke in VAD support.

98 Morray BH, Dimas VV, McElhinney DB, et al. Patient size parameters to guide use of the Impella device in pediatric patients. Catheter Cardiovasc Interv 2019;94(4):61. The authors define anthropomorphic and anatomic measurements in a creative study to guide providers in patient selection for MCS using the Impella devices.

106 Mehra MR, Naka Y, Uriel N, Goldstein DJ, Cleveland JC, Colombo PC, et al. A fully magnetically levitated circulatory pump for advanced heart failure. N Engl J Med 2017;376(5):440–50. In this randomized study of patients with advanced heart failure, the authors compared either the new centrifugal continuous-flow pump or a commercially available axial continuous-flow pump. The fully magnetically levitated centrifugal-flow pump was associated with better outcomes at six months than was the implantation of an axial-flow pump, primarily because of the lower rate of reoperation for pump malfunction.

157 Iguchi A, Ridout DA, Galan S, et al. Long term survival outcomes and causes of late death in neonates, infants and children treated with extracorporeal life support. Pediatr Crit Care Med 2013;14:580–6. A total of 741 children with 272 early deaths (36.7%) and 46 late deaths (6.2%) were included. Median follow-up time in survivors was 7.1 (interquartile range, 3.0–11.9) years. There was increased risk of late death in congenital diaphragmatic hernia, CHD, and acquired heart disease ($P < 0.001$, $P < 0.01$, $P = 0.01$) in comparison with the risk in meconium aspiration syndrome.

174 Raets MMA, Dudink J, Ijsselstijn H, et al. Brain injury associated with neonatal extracorporeal membrane oxygenation in the Netherlands: a nationwide evaluation spanning two decades. Pediatr Crit Care Med 2013;14:884–92. Brain abnormalities were detected in 17.3%: primary hemorrhage was most frequent (8.8%). Stroke was identified in 5% of the total group, with a notable significant preference for the left hemisphere (in 70%). Lobar hematoma (prevalence 2.2%) was also significantly left predominant.

Appendix: Pediatric Cardiovascular Anesthesia Drug Sheet (September 2022)

Drug doses and treatments are those commonly recommended; each patient's treatment must be individualized, drug doses double-checked for accuracy, and drug concentrations and modes of administration used according to local guidelines. The information here is current at the time of publication; however, the practitioner must always be aware of new recommendations and remains responsible for determining the best course of treatment. Consult the textbook, hospital formulary, or authoritative internet resources for a complete listing of indications, contraindications, interval dosing schedules, and side-effects of these drugs and treatments. All drugs are intravenous, unless otherwise noted. Drugs denoted with an asterisk (*) are not approved by the US Food and Drug Administration (FDA) as of May 2021. Many drugs are not specifically labeled for pediatric use by the US FDA; however, the physician may choose to administer these drugs for specific indications, if in their judgment the drug will be safe and effective. The source for dosing information is the Texas Children's Hospital formulary, current as of May 2021, except as otherwise noted in the references.

AL Grawany

Vasoactive infusions		
Clevidipine [1]	0.5–7 μg/kg/min	Loading: 10–15 μg/kg
Dobutamine	2–20 μg/kg/min	
Dopamine	2–20 μg/kg/min	
Epinephrine	0.03–1 μg/kg/min	
Esmolol	200–1000 μg/kg/min	Loading: 100–500 μg/kg
Fenoldopam	0.1–0.8 μg/kg/min	
Isoproterenol	0.03–1 μg/kg/min	Maximum dose 2 μg/kg/min
Levosimendan [2]*	0.05–0.1 μg/kg/min	Loading: 6–12 μg/kg over 1 hour
Liothyronine (Triostat®,T_3) [3, 4]	0.05–0.15 μg/kg/hour	
Milrinone	0.25–0.75 μg/kg/min	Loading: 50 μg/kg over 10–60 minutes
Nesiritide	0.01 μg/kg/min; at intervals of 3 hours, dosage may be increased by 0.005 μg/kg/min to the maximum of 0.03 μg/kg/min	
Nicardipine	0.5–2 μg/kg/min	
Nitroglycerine	0.25–3 μg/kg/min	
Nitroprusside	0.3–3 μg/kg/min	
Norepinephrine	0.03–1 μg/kg/min	
Phenylephrine	0.05–0.5 μg/kg/min	
Prostaglandin E1	0.01–0.1 μg/kg/min	
Vasopressin	0.01–0.04 units/kg/hour	
Vasoactive bolus drugs		
Atropine	IV: 0.01–0.02 mg/kg IM: 0.02 mg/kg	
Calcium chloride	10 mg/kg IV	
Calcium gluconate	30 mg/kg IV	
Enalaprilat	5–10 μg/kg/dose IV Q8–24H; max. 5 mg/dose	
Ephedrine	0.1 mg/kg IV max. 5 mg	
Epinephrine	0.5–10 μg/kg IV	
Hydralazine	0.1–0.2 mg/kg IV	
Labetalol	0.2–1 mg/kg IV	
Methylene blue [5–7]	1–2 mg/kg IV	
Phenoxybenzamine	0.25–1 mg/kg IV	
Phentolamine	0.05–0.2 mg/kg IV	
Phenylephrine	0.5–3 μg/kg IV	
Antiarrhythmic agents		
Adenosine	First dose: 0.1 mg/kg IV (max 6 mg) Second dose: 0.2 mg/kg IV (max dose 12 mg)	
Amiodarone	10–15 mg/kg/day	Loading: 2.5–5 mg/kg or a maximum of 300 mg IV over 5–10 minutes. Additional boluses of 5 mg/kg or a maximum of 150 mg IV push may be given with a maximum total dose not to exceed 25 mg/kg or 2.2 g in 24 hours
Lidocaine	20–50 μg/kg/min	Loading: 1 mg/kg; repeat if the dose infusion is initiated more than 15 minutes after initial bolus
Procainamide	20–80 μg/kg/min (max 2 g/day)	Loading: 3–6 mg/kg/dose over 5 minutes, not to exceed 100 mg/dose; may repeat every 5–10 minutes to the maximum total loading dose of 15 mg/kg; do not exceed 500 mg in 30 minutes
Verapamil	0.1–0.3 mg/kg/dose (max. 5 mg) Repeat dose 30 minutes after the initial dose as needed (max second dose 10 mg)	

Pulmonary hypertension medications		
Inhaled nitric oxide	1–20 PPM	
Epoprostenol [8]	Intravenous: 1–2 ng/kg/min initial infusion; increase by 1–2 ng/kg/min every 4–8 hours to 25–40 ng/kg/min; must be given in dedicated intravenous line Inhaled: 20–50 ng?kg/min continuous infusion	
Iloprost [9]	Inhaled: Initial: 0.5 mcg/kg over 10 minutes Subsequent Dosing: 1–2 mcg/kg over 10 minutes	
Sildenafil [10, 11]	0.067 mg/kg/hour; loading: 0.4 mg/kg over 3 hours	
Treprostinil	0.625–1.25 ng/kg/minute; must be given in dedicated intravenous line	
Anesthetic/analgesia agents		
Acetaminophen	10–15 mg/kg IV Q6 H	
Dexmedetomidine	0.25–0.75 µg/kg/hour	Loading: 0.25–1.0 µg/kg over 10 minutes
Etomidate	0.2–0.3 mg/kg	
Fentanyl	1–10 µg/kg	Infusion: 1–10 µg/kg/hour
Hydromorphone	0.005–0.015 mg/kg	Maximum single dose: 2 mg
Ibuprofen	10 mg/kg IV Q6–8H	
Ketamine	IV: 1–2 mg/kg IM: 5–10 mg/kg	
Ketorolac	0.5–1 mg/kg IV; 0.5 mg/kg/dose every 6 hours (max 30 mg/dose; 120 mg/day)	
Midazolam	0.03–0.1 mg/kg IV	
Morphine	0.05–0.2 mg/kg IV	
Remifentanil	0.025–2 µg/kg/min	Loading: 0.5–1 µg/kg IV
Sufentanil	0.1–0.3 µg/kg/hour	Loading: 1–2 µg/kg IV
Muscle relaxants (intubation dose) and reversal of neuromuscular blockade		
Atracurium	0.4–0.5 mg/kg IV	
Cisatracurium	0.1 mg/kg IV	
Pancuronium	0.1 mg/kg IV	
Rocuronium	0.6–1.2 mg/kg IV	
Succinylcholine	1–2 mg/kg IV; 4 mg/kg IM	
Vecuronium	0.08–0.1 mg/kg IV	
Neostigmine	50–70 µg/kg IV	
Glycopyrrolate	10–14 µg/kg IV (with neostigmine)	
Sugammadex [12]*	Immediate reversal of rocuronium: 16 mg/kg Deep block (1–2 post-tetanic counts and prior to the second twitch following train-of-four stimulation): 4 mg/kg Moderate block (after appearance of the second twitch following TOF stimulation): 2 mg/kg	
Antibiotics		
Ampicillin	50 mg/kg IV (max 2 g)	
Cefazolin	25–30 mg/kg IV (max 1 g)	
Cefuroxime	25–50 mg/kg IV (max 1.5 g)	
Clindamycin	10–13 mg/kg IV (max 900 mg)	
Gentamicin	1–2.5 mg/kg IV (max 120 mg)	
Nafcillin	37.5–50 mg/kg IV (max 2 g)	
Piperacillin/tazobactam	50–100 mg/kg IV piperacillin component (max 16 g piperacillin component/day)	
Vancomycin	10–15 mg/kg IV (max 1 g)	

Antiemetics	
Dexamethasone	0.15–0.5 mg/kg IV
Metaclopromide	0.1–0.2 mg/kg/dose IV every 6–8 hours as needed (max. 10 mg)
Ondansetron	0.1 mg/kg IV (max. 4 mg)
Corticosteroids	
Dexamethasone	Airway edema: 0.25–0.5 mg/kg IV
Hydrocortisone	Adrenal insufficiency (stress dose): 50–100 mg/m^2/dose IV Anaphylaxis 0.5–2 mg/kg (max 250 mg)
Methylprednisolone	20–30 mg/kg IV bolus or to bypass circuit
Diuretics	
Bumetanide	0.1 mg/kg/dose (IV or PO)
Furosemide	0.5–1 mg/kg IV (max 20 mg)
Mannitol	0.25–2 g/kg IV
Antifibrinolytics	
Tranexamic acid [13, 14]	Neonate 0–2 mo.: 15 mg/kg bolus; 20 mcg/mL of CPB prime; 2.5 mg/kg/hour. infusion. Infant 2–12 mo.: 9 mg/kg bolus; 20 mcg/mL of CPB prime; 2 mg/kg/hour infusion. Child > 12 mo.: 4 mg/kg bolus; 20 mcg/mL of CPB prime; 2 mg/kg/hour infusion.
Aprotinin[a]	28,000–60,000 KIU/kg bolus; 28,000–60,000 KIU/kg to CPB prime, 3,500–7,000 KIU/kg/hour infusion
Epsilon aminocaproic acid [15]	Neonate 0–2 mo.: 40 mg/kg bolus; 0.1 mg/ml of CPB prime; 30 mg/kg/hour infusion. Infant 2–12 mo. and child > 12 mo.: 75 mg/kg bolus; 75 mg/kg for CPB prime; 75 mg/kg/hour infusion.
Anticoagulants and reversal	
Bivalirudin [16, 17]	For bypass: 1 mg/kg IV bolus; additional bolus of 0.1–0.5 mg/kg for subtherapeutic ACT; 50 mg to bypass circuit; infusion 2.5 mg/kg/hour For ECMO or VAD: 0.1–0.2 mg/kg bolus; infusion 0.03–0.3 mg/kg/hour; monitor PTT hepzyme
Heparin	300–400 units/kg (3–4 mg/kg) for CPB; 100 units/kg (1 mg/kg) for heparinization for non-CPB cases (e.g. coarctation of the aorta, systemic-to-pulmonary artery shunt)
Protamine	1–1.3 times heparin dose in mg
Electrolytes	
Sodium bicarbonate	1 mEq/kg; dilute 1 : 1 with sterile water for neonates
THAM (tromethamine)	1 mL/kg IV of 0.3 M solution; subsequent dosing based on blood gas result
Potassium chloride	0.5–1 mEq/kg IV over 1 hour
Magnesium sulfate	25–50 mg/kg IV over 1 hour
Dextrose	For the treatment of hypoglycemia D_{10}: 3–5 mL/kg IV for neonates D_{25}: 1–2 mL/kg IV for age 3 months to 2 years D_{50}: 0.5–1 mL/kg IV for age > 2 years
Miscellaneous drugs	
Diphenhydramine	For acute hypersensitivity 1–2 mg/kg IV (max. 50 mg/dose)
Flumazenil	1–5 µg/kg IV; repeat as necessary
Levoalbuterol	4–8 puffs MDI through ETT; may repeat
Naloxone	1–10 µg/kg IV; repeat as necessary
Ranitidine	1 mg/kg IV

Oral/intranasal premedications	
Dexmedetomidine	Intranasal: 2 μg/kg
Ketamine	Oral: 5–10 mg/kg
Midazolam	Intranasal: 0.2 mg/kg over 15 seconds, may repeat in 5–15 minutes (max 15 mg) Oral: 0.5–1 mg/kg
Pentobarbital	Oral: 3–5 mg/kg

Maximum doses of local anesthetics[b]

Drug	Spinal	Caudal/Lumbar epidural	Peripheral	Subcutaneous
Chlorprocaine	NA	8 mg/kg	8 mg/kg	8 mg/kg
Chlorprocaine with epinephrine 1 : 200 K	NA	10 mg/kg	10 mg/kg	10 mg/kg
Tetracaine	0.2–0.6 mg/kg	NA	NA	NA
Lidocaine (0.5–1% infiltration), (1–2% peripheral, epidural, subcutaneous), (5% spinal)	1–2.5 mg/kg	5 mg/kg	5 mg/kg	5 mg/kg
Lidocaine with epinephrine 1 : 200 K	1–2.5 mg/kg	7 mg/kg	7 mg/kg	7 mg/kg
Bupivacaine (0.125–0.5% infiltration), (0.25–5% peripheral, epidural, subcutaneous)	0.3–0.5 mg/kg	2 mg/kg	2 mg/kg	2 mg/kg
Bupivacaine with epinephrine 1 : 200 K	0.3–0.5 mg/kg	3 mg/kg	3 mg/kg	3 mg/kg
Ropivacine (0.2–0.9% peripheral, epidural)	NA	2 mg/kg	2 mg/kg	2 mg/kg
Ropivacine with epinephrine	NA	3 mg/kg	3 mg/kg	3 mg/kg
Prilocaine (1–2% peripheral), (2–3% epidural)	NA	5 mg/kg	5 mg/kg	5 mg/kg
Liposomal Bupivacine 1.3%	NA	NS	NA	3 mg/kg

Local anesthesthetic toxicity treatment	
20% Lipid emulsion [18]	Under 70 kg: Bolus 1.5 mL/kg over 2–3 minutes, start infusion at 0.25 mL/kg/hour; If patient remains unstable, repeat bolus and double infusion rate, max dose 12 mL/kg Over 70 kg: Bolus 100 mL over 2–3 minutes, infuse 250 mL over 15–20 minutes; If patient remains unstable, repeat bolus and double infusion, max dose 12 mL/kg

Blood products and volume expanders	
Albumin 5%	10–20 mL/kg IV
Anti-inhibitor coagulant complex (FEIBA®; activated prothrombin complex concentrate) [19, 20]	50–100 units/kg; maximum rate of infusion 2 units/kg/min 10 units/kg IV, may repeat dose
Cryoprecipitate	15 mL/5–10 kg IV
Fibrinogen concentrate [21]	60–70 mg/kg when fibrinogen level is not known; when fibrinogen level is known Dose (mg/kg) = [100 (mg/dL) – measured level (mg/dL)] divided by 1.7
Fresh frozen plasma	10–20 mL/kg IV
Packed red blood cells	10–15 mL/kg IV
Platelets	1 random unit/5 kg will increase platelet count by 50,000; 1 pheresis unit = 6 random units
Prothrombin complex concentrate (Octaplex®, Kcentra®)	Pretreatment INR 2- < 4: Administer 25 units/kg (max dose 2,500 units); Pretreatment INR 4–6: Administer 35 units/kg (max dose 3,500 units); Pretreatment INR > 6: Administer 50 units/kg (max dose 5,000 units)

Recombinant factor VIIa [19]	40–60 µg/kg IV; may repeat dose q 1–2 hours (max. Three total doses)
Whole blood	10–15 mL/kg IV
DC defibrillation/synchronized cardioversion	
Internal defibrillation	2 J, increase to 5 J, 10 J
External defibrillation	2–5 J/kg; increase if ineffective to max 200 J
External synchronized cardioversion	0.5 J/kg; increase if ineffective to 1 J/kg

[a] Aprotinin was not available in the USA as of December 2007.
