Anesthesia for Congenital Heart Disease

Anesthesia for Congenital Heart Disease

Fourth Edition

EDITOR-IN-CHIEF

Dean B. Andropoulos, MD, MHCM
Anesthesiologist-in-Chief Texas Children's Hospital
Burdett S. Dunbar, MD, Chair in Pediatric Anesthesiology
Texas Children's Hospital Department of Anesthesiology Perioperative and Pain Medicine
Professor, Anesthesiology and Pediatrics
Vice Chair, Department of Anesthesiology
Baylor College of Medicine
Houston, TX, USA

EDITORS

Emad B. Mossad, MD
Division Chief, Arthur S. Keats Division of Pediatric Cardiovascular Anesthesiology
Vice Chief for the Heart Center
Texas Children's Hospital – Department of Anesthesiology Perioperative and Pain Medicine
Professor, Anesthesiology and Pediatrics
Baylor College of Medicine
Houston, TX, USA

Erin A. Gottlieb, MD, MHCM
Chief, Pediatric Cardiac Anesthesia
Dell Children's Medical Center of Central Texas
Associate Professor of Surgery and Perioperative Care
Dell Medical School
University of Texas at Austin
Austin, TX, USA

Contents

List of Contributors, vii

Preface to the Fourth Edition, xiii

List of Abbreviations, xv

About the Companion Website, xix

Part I History, Education, Outcomes, and Science

1 History of Anesthesia for Congenital Heart Disease, 1
Katherine L. Zaleski and Viviane G. Nasr

2 Education for Anesthesia in Patients with Congenital Cardiac Disease, 16
Viviane G. Nasr and Nina Deutsch

3 Quality, Outcomes, and Databases in Congenital Cardiac Anesthesia, 29
Lisa A. Caplan, Ehrenfried Schindler, and David F. Vener

4 Multidisciplinary Collaboration, Team Functioning, and Communication in Congenital Cardiac Care, 44
Dean B. Andropoulos

5 Informatics and Artificial Intelligence in Congenital Heart Disease, 70
Eric L. Vu, Craig G. Rusin, and Kenneth M. Brady

6 Development of the Cardiovascular System, 83
Barry D. Kussman, Amy E. Roberts, and Wanda C. Miller-Hance

7 Nomenclature and Anatomic Evaluation in Congenital Heart Disease, 116
Wanda C. Miller-Hance and Barry D. Kussman

8 Genetic Syndromes and Associations in Congenital Heart Disease, 131
Erin A. Gottlieb, Andrew Matisoff, and Dean B. Andropoulos

9 Physiology and Cellular Biology of the Developing Circulation, 166
Dean B. Andropoulos, Koichi Yuki, and Sophia Koutsogiannaki

10 Anesthetic Agents and Their Cardiovascular Effects, 190
Chinedu G. Otu, Dean B. Andropoulos, and Emad B. Mossad

11 Cardiopulmonary Bypass, 211
Ralph Gertler, Dean B. Andropoulos, and Ashraf Resheidat

12 Multiorgan Effects of Congenital Cardiac Surgery, 244
Gina Whitney, Nicholas Houska, Megan Albertz, Brian Donahue, and Suanne Daves

Part II Monitoring

13 Vascular Access and Monitoring, 272
Kenji Kayashima, Shoichi Uezono, Maricarmen R. Rodriguez, Koichi Yuki, and Dean B. Andropoulos

14 Neurological Monitoring and Outcome, 305
Kenneth M. Brady, Chandra Ramamoorthy, R. Blaine Easley, and Dean B. Andropoulos

15 Transesophageal and Epicardial Echocardiography in Congenital Heart Disease, 331
Annette Vegas and Wanda C. Miller-Hance

16 Coagulation, Cardiopulmonary Bypass, and Bleeding, 377
Laura A. Downey and David Faraoni

17 Point-of-Care Ultrasound for Congenital Heart Disease Patients, 409
Alan F. Riley, Kriti Puri, and Adam C. Adler

Part III Preoperative Considerations

18 Preoperative Evaluation and Preparation, 425
Emad B. Mossad, Rahul Baijal, and Rajesh Krishnamurthy

19 Approach to the Fetus, Premature, and Full-Term Neonate, 448
Lee P. Ferguson, Annette Y. Schure, Peter C. Laussen, and Kirsten C. Odegard

20 Anesthesia for Adults with Congenital Heart Disease, 466
Jane Heggie, Catherine Ashes, Andrea Girnius, and Pablo Motta

Part IV Management

21 Hemodynamic Management, 494
Mirela Bojan and Philippe Pouard

22 Arrhythmias: Diagnosis and Management, 527
Santiago O. Valdes, Jeffrey J. Kim, and Wanda C. Miller-Hance

23 Airway and Ventilatory Management, 558
Loren D. Sacks, Gregory B. Hammer, and Stephen A. Stayer

24 Early Tracheal Extubation, Enhanced Recovery After Pediatric Cardiac Surgery, Regional Anesthesia and Postoperative Pain Management, 578
Alexander Mittnacht

25 Cardiopulmonary Resuscitation in the Patient with Congenital Heart Disease, 599
Javier J. Lasa, Daniel Stromberg, Sai S. Raju, and Timothy P. Welch

Part V Anesthesia for Specific Lesions

26 Anesthesia for Left-to-Right Shunt Lesions, 624
Scott G. Walker

27 Anesthesia for Left–sided Obstructive Lesions, 650
James P. Spaeth and Andreas W. Loepke

28 Anesthesia for Right-Sided Obstructive Lesions, 674
Michael L. Schmitz, Destiny F. Chau, R. Ryan Das, Lorraine L. Thompson, and Sana Ullah

29 Anesthesia for Transposition of the Great Arteries, 710
Valentine Woodham, Mariepi Manolis, Lucy Hepburn, and Angus McEwan

30 Anesthesia for the Patient with a Single Ventricle, 741
Laura Diaz-Berenstain, Rania K. Abbasi, Lori Q. Riegger, James M. Steven, Susan C. Nicolson, and Dean B. Andropoulos

31 Anesthesia for Miscellaneous Cardiac Lesions, 781
Ian McKenzie, Maria Markakis Zestos, Stephen A. Stayer, Edward Kaminski, Paul Davies, and Dean B. Andropoulos

32 Anesthesia for Cardiac and Pulmonary Transplantation, 832
Glyn D. Williams, Chandra Ramamoorthy, Anshuman Sharma, and Manchula Navratnam

33 Anesthesia for Pulmonary Hypertension, 869
Mark D. Twite and Robert H. Friesen

Part VI Anesthesia Outside the Cardiac Operating Room

34 Anesthesia for the Cardiac Catheterization Laboratory, 890
Premal M. Trivedi, Philip Arnold, Aarti Shah, and Athar M. Qureshi

35 Anesthesia for Noncardiac Surgery and Magnetic Resonance Imaging, 934
Andres Bacigalupo Landa, Anthony Zapata, Stephen A. Stayer, and Erin A. Gottlieb

36 Cardiac Intensive Care, 958
Gary Dhillon, Elizabeth Herrup, Paula Holinski, Peter C. Laussen, V. Ben Sivarajan, Stephen J. Roth, and Justin C. Yeh

37 Mechanical Circulatory Support, 996
Stephen B. Horton, Adam Skinner, Andres Bacigalupo Landa, Iki Adachi, Stephen A. Stayer, and Pablo Motta

Appendix: Pediatric Cardiovascular Anesthesia Drug Sheet (September 2022), 1026
Lisa A. Caplan and Erin A. Gottlieb

Index, 1032

List of Contributors

Rania K. Abbasi MD, FASA
Associate Professor of Clinical Anesthesia, Division of Pediatric Cardiac Anesthesia
Program Director, Pediatric Cardiac Anesthesia Fellowship
Riley Hospital for Children/Indiana University School of Medicine
Indianapolis, IN, USA

Iki Adachi MD
Associate Surgeon, Congenital Heart Surgery
Texas Children's Hospital
Clayton Endowed Chair in Cardiac Transplant and Mechanical Support
Director, Mechanical Circulatory Support, Texas Children's Hospital
Associate Professor, Department of Surgery and Pediatrics,
Baylor College of Medicine
Houston, TX, USA

Adam C. Adler MD, MS, FAAP, FASE
Associate Professor of Anesthesiology
Department of Anesthesiology, Perioperative and Pain Medicine
Texas Children's Hospital
Baylor College of Medicine
Houston, TX, USA

Megan Albertz MD
Division of Pediatric Cardiac Anesthesiology
University of Colorado School of Medicine and Children's Hospital Colorado
Aurora, CO, USA

Dean B. Andropoulos MD, MHCM
Anesthesiologist-in-Chief, Texas Children's Hospital
Department of Anesthesiology, Perioperative and Pain Medicine
Baylor College of Medicine
Houston, TX, USA

Philip Arnold MBBS
Department of Cardiac Anaesthesia
Alder Hey Hospital
Royal Liverpool Children's NHS Trust
Liverpool, UK

Catherine Ashes MBBS
Consultant Anesthetist
St. Vincent's Hospital
Sydney, New South Wales, Australia

Rahul Baijal MD
Staff Anesthesiologist, Texas Children's Hospital
Associate Professor, Department of Anesthesiology
Baylor College of Medicine
Houston, TX, USA

Mirela Bojan MD PhD
Congenital Cardiac Unit
Department of Anesthesiology
Hôpital Marie Lannelongue, Groupe Hospitalier Paris-Saint Joseph
Le Plessis Robinson, France

Kenneth M. Brady MD
Division Head, Cardiac Anesthesia; Intensivist, Regenstein Cardiac Care Unit
Gracias Family Professor in Cardiac Critical Care
Lurie Children's Hospital of Chicago
Professor, Department of Anesthesiology and Pediatrics
Northwestern University Feinberg School of Medicine
Chicago, IL, USA

Lisa A. Caplan MD
Staff Cardiovascular Anesthesiologist
Arthur S. Keats Division of Pediatric Cardiovascular Anesthesiology
Associate Professor, Department of Anesthesiology
Baylor College of Medicine
Houston, TX, USA

Destiny F. Chau MD
Professor of Anesthesiology
Director, Pediatric Cardiothoracic Anesthesiology Fellowship
Arkansas Children's Hospital, University of Arkansas for Medical Sciences
Little Rock, AR, USA

R. Ryan Das MD
Associate Professor of Anesthesiology
Arkansas Children's Hospital
University of Arkansas for Medical Sciences
Little Rock, AR, USA

Suanne Daves MD
Chief, Pediatric Cardiac Anesthesia
University of Oklahoma College of Medicine
Oklahoma, OK, USA

Paul Davies MBBS

Department of Anaesthesia and Pain Management
The Royal Children's Hospital
Melbourne, Victoria, Australia

Nina Deutsch, MD

Associate Chief, Anesthesiology
Associate Chief, Academic Affairs
Children's National Hospital
Professor of Anesthesiology and Critical Care Medicine
George Washington University School of Medicine and Health Sciences
Washington DC, USA

Gary Dhillon MD

Clinical Assistant Professor
Department of Pediatrics (Cardiology)
Cardiovascular Intensive Care
Stanford University School of Medicine
Lucile Packard Children's Hospital Stanford
Palo Alto, CA, USA

Laura Diaz-Berenstain MD

Professor of Clinical Anesthesiology
Division of Pediatric Cardiac Anesthesiology
Cincinnati Children's Hospital Medical Center
Cincinnati, OH, USA

Brian Donahue MD, PhD

Division of Pediatric Cardiac Anesthesiology
Vanderbilt University School of Medicine
Nashville, TN, USA

Laura A. Downey MD

Assistant Professor, Departments of Anesthesiology and Pediatrics
Emory University School of Medicine
Children's Healthcare of Atlanta
Atlanta, GA, USA

R. Blaine Easley MD

Department of Pediatrics,
Anesthesiology, and Critical Care
Texas Children's Hospital
and
Baylor College of Medicine
Houston, TX, USA

David Faraoni MD, PhD

Professor, Department of Anesthesiology, Perioperative and Pain Medicine
Texas Children's Hospital
Baylor College of Medicine
Houston, TX, USA

Lee P. Ferguson MBChB

Associate in Cardiac Anesthesia
Boston's Children's Hospital
Assistant Professor in Anaesthesia
Department of Anesthesiology, Critical Care and Pain Medicine
Harvard Medical School
Boston, MA, USA

Robert H. Friesen MD

Professor Emeritus of Anesthesiology
University of Colorado School of Medicine
Department of Anesthesiology
Children's Hospital Colorado
Denver, CO, USA

Ralph Gertler MD

Department of Anaesthesiology and Intensive Care
HELIOS Klinikum Munchen West
Teaching Hospital of the Ludwig-Maximilians-Universitat
Munchen, Germany

Andrea Girnius MD

Assistant Professor of Clinical Anesthesiology
Division Director, Obstetric Anesthesia
University of Cincinnati Medical Center
Program Director, Obstetric Anesthesia Fellowship
University of Cincinnati College of Medicine
Cincinnati, OH, USA

Erin A. Gottlieb MD, MHCM

Division of Pediatric Cardiac Anesthesiology
Department of Surgery and Perioperative Care
The University of Texas at Austin
Dell Children's Medical Center of Central Texas
Associate Professor of Surgery and Perioperative Care
Dell Medical School
Austin, TX, USA

Gregory B. Hammer MD

Attending Physician, Cardiovascular Intensive Care Unit and Pediatric Cardiac Anesthesia
Lucill Packard Children's Hospital
Professor of Anesthesiology, Perioperative and Pain Medicine
Professor of Pediatrics - Critical Care
Stanford University School of Medicine
Stanford, CA, USA

Jane Heggie MD, FRCP

Medical Director Cardiovascular Intensive Care Unit
Peter Munk Cardiac Center
Staff Cardiovascular Anaesthesiologist, Toronto General Hospital
Associate Professor, University of Toronto
Toronto, Ontario, Canada

Lucy Hepburn MBBS

Department of Anaesthesia
Great Ormond Street Hospital for Children NHS Foundation Trust
London, UK

Elizabeth Herrup MD

Assistant Professor
Pediatric Cardiac Critical Care Medicine
UPMC Children's Hospital of Pittsburgh
Pittsburgh, PA, USA

Paula Holinski MD, FRCPC

Clinical Assistant Professor of Anesthesiology
Department of Pediatric Anesthesia and Pediatric Cardiac Intensive Care
University of Alberta, Stollery Children's Hospital
Edmonton, Alberta, Canada

Stephen B. Horton PhD, CCP(Aus), CCP(USA), FACBS

Associate Professor, Director of Perfusion
Faculty of Medicine
Department of Paediatrics
The University of Melbourne
Cardiac Surgery, Royal Children's Hospital
Melbourne, Victoria, Australia

Nicholas Houska MD

Division of Pediatric Cardiac Anesthesiology
University of Colorado School of Medicine and Children's Hospital Colorado
Aurora, CO, USA

Edward Kaminski MD

Department of Anesthesia
Children's Hospital of Michigan
Wayne State University
Detroit, MI, USA

Kenji Kayashima MD

Department of Anesthesiology
Japan Community Health Care Organization
Kyushu Hospital
Fukuoka, Japan

Jeffrey J. Kim MD

Section of Cardiology, Electrophysiology and Pacing
Department of Pediatrics
Texas Children's Hospital
Houston, TX, USA

Sophia Koutsogiannaki PhD

Assistant Professor in Anaesthesia, Harvard Medical School
Research Associate, Cardiac Anesthesia Division
Department of Anesthesiology, Critical Care and Pain Medicine
Boston Children's Hospital
Boston, MA, USA

Rajesh Krishnamurthy MD

Radiologist-In-Chief, William E. Shiels Chair of Radiology
Nationwide Children's Hospital
Clinical Professor of Radiology
Ohio State University
Columbus, OH, USA

Barry D. Kussman MBBCh, FFA(SA)

Department of Anesthesiology, Perioperative and Pain Medicine
Boston Children's Hospital
Department of Anaesthesia
Harvard Medical School
Boston, MA, USA

Andres Bacigalupo Landa MD

Department of Pediatrics and Anesthesiology
Baylor College of Medicine
Arthur S. Keats Division of Pediatric Cardiovascular Anesthesiology
Texas Children's Hospital
Houston, TX, USA

Javier J. Lasa MD

Attending Physician, Cardiovascular Intensive Care Unit
Texas Children's Hospital
Assistant Professor of Pediatrics
Baylor College of Medicine
Houston, TX, USA

Peter C. Laussen MBBS, FANZCA, FCICM

Executive Vice President of Health Affairs
Boston Children's Hospital
Professor of Anaesthesia, Harvard Medical School
Boston, MA, USA

Andreas W. Loepke MD

Cardiac Anesthesiology
Children's Hospital of Philadelphia
Philadelphia, PA, USA

Mariepi Manolis MBBS

Department of Anaesthesia
Great Ormond Street Hospital for Children NHS Foundation Trust
London, UK

Andrew Matisoff MD

Cardiac Anesthesiologist
Children's National Medical Center
Associate Professor, Anesthesiology and Critical Care Medicine
Associate Professor of Pediatrics
George Washington School of Medicine and Health Sciences
Washington, DC, USA

Angus McEwan MBBS

Department of Anaesthesia
Great Ormond Street Hospital for Children NHS Foundation Trust
London, UK

Ian McKenzie MBBS

Department of Anaesthesia & Pain Management
The Royal Children's Hospital
Melbourne, Victoria, Australia

Wanda C. Miller-Hance MD

Arthur S. Keats Division of Pediatric Cardiovascular Anesthesiology
Department of Anesthesiology, Perioperative and Pain Medicine;
Section of Cardiology, Department of Pediatrics
Baylor College of Medicine
Texas Children's Hospital
Houston, TX, USA

Alexander Mittnacht MD

Department of Anesthesiology
Westchester Medical Center
Valhalla, NY, USA

Emad B. Mossad MD

Division Chief and Vice Chief for the Heart Center
Arthur S. Keats Division of Pediatric Cardiovascular Anesthesiology
Texas Children's Hospital
Professor of Anesthesiology
Department of Anesthesiology
Baylor College of Medicine
Houston, TX, USA

Pablo Motta MD, MS

Staff Cardiovascular Anesthesiologist
Service Lead, Adult Congenital Cardiac Anesthesiology
Arthur S. Keats Division of Pediatric Cardiovascular Anesthesiology
Texas Children's Hospital
Associate Professor of Anesthesiology
Department of Anesthesiology
Baylor College of Medicine
Houston, TX, USA

Viviane G. Nasr MD, MP

Associate Professor of Anaesthesia
Harvard Medical School
Senior Associate in Cardiac Anesthesia
Department of Anesthesiology, Critical Care and Pain Medicine
Boston Children's Hospital
Boston, MA, USA

Children's Hospital of Michigan,
Wayne State University, Detroit, MI, USA

Preface to the Fourth Edition

In the 17 years since the first publication of *Anesthesia for Congenital Heart Disease*, each successive edition has seen a significant expansion in the material in the book due to the ongoing rapid advances in the field of congenital heart disease (CHD). The Fourth Edition marks the greatest number of changes since the conception of this book, and the new chapters and content, including thorough chapter updates and the addition of many more figures and tables that illustrate the myriad of changes in this field, are designed to further enhance the knowledge of the anesthesiologist and others caring for CHD patients. The continued participation of a number of international authors contributes to the many perspectives represented in congenital cardiac anesthesia care; it truly is a world-wide field. Chapter 4 is a new chapter entitled, "Multidisciplinary Collaboration, Team Functioning, and Communication in Congenital Cardiac Care." This chapter emphasizes the unique nature of an often large, multidisciplinary team that must work together to make complex patient care decisions, and then perform the procedures and care that result in the best possible patient outcomes. It also focuses on the role of the Congenital Cardiac Anesthesiologist, not only to provide patient care but also to make substantive contributions to clinical decision-making and leadership in the Heart Center. Another new chapter is Chapter 5, "Informatics and Artificial Intelligence in Congenital Heart Disease," which presents an overview of this crucially important field of medicine, which has a number of applications in Congenital Cardiac Anesthesia and Critical Care, and CHD in general. Chapter 8 is entirely devoted to Genetic Syndromes in CHD; an increasingly recognized and important aspect in the care of patients with CHD; it seeks to inform the anesthesiologist about the genetic underpinnings of many syndromes in CHD, their multisystem involvement, and the ethical principles of providing care for this complex population. Chapter 17 presents Point of Care Ultrasound in CHD, which has become an increasingly important skill for the Congenital Cardiac Anesthesiologist, not only to assist in vascular access procedures but also to assess the heart and lungs during procedures and emergencies to guide diagnostic and therapeutic choices. Finally, Chapter 25 is dedicated to Cardiac Arrest and Resuscitation in CHD, which has many unique features as a result of the anatomy and pathophysiology of these patients. The Key Points and Selected References are again included in all chapters, to enhance the reader's learning and provide an opportunity for further knowledge.

We are pleased to welcome as Editor Erin A. Gottlieb, M.D., M.H.C.M., our former Texas Children's Hospital colleague who is now Chief of Pediatric Cardiac Anesthesia at Dell Children's Medical Center, and the University of Texas Dell Medical School in Austin, Texas. Two editors from the Third Edition, Drs. Stephen Stayer and Wanda Miller-Hance, have retired from this role, and we wish to thank them for their many contributions to previous editions, and for their ongoing work as chapter authors for the Fourth Edition.

We would like to dedicate this edition of the book to Dolly D. Hansen, M.D. who passed away in 2021. Dr. Hansen came to Boston Children's Hospital (BCH) in 1971 for a Pediatric Cardiac Anesthesia Fellowship and spent the remainder of her career there until her retirement in 2001. Among the many firsts that Dr. Hansen was an integral part of was the establishment of the neonatal arterial switch operation as the preferred surgical strategy, the first Stage I Palliation for Hypoplastic Left Heart Syndrome, the first deep hypothermic circulatory arrest case at BCH, and landmark studies of high-dose opioid anesthesia and survival in neonatal cardiac surgery. Dr. Hansen was not only an outstanding clinician, but she also had a profound effect as a teacher of a very large group of anesthesia fellows at BCH. As one of the first female Pediatric Cardiac Anesthesiologists, Dr. Hansen paved the way for many to follow in her footsteps. Dr. Hansen was awarded the inaugural Congenital Cardiac Anesthesia Society Lifetime Achievement Award in 2021, a richly deserved honor for a singular career. She will be missed by all.

The COVID-19 pandemic has profoundly affected society and has caused more than 1 million deaths in the United States and over 6 million deaths worldwide as of the time of this writing. COVID-19 has also affected care in CHD, and a new disease, Multisystem Inflammatory Syndrome in Children, often has cardiac involvement with some patients requiring inotropic and even mechanical support of the circulation. The high number of COVID-19 positive pediatric patients in many parts of the world has led to widespread screening for infection with SARS-CoV2, and alteration of many aspects of anesthetic care, including personal protective equipment and airway protocols. Elective cardiac surgeries at times have been delayed due to overwhelming COVID-19 caseloads straining hospital resources. Education, patient care conferences, and even inpatient and outpatient care have been profoundly affected, with many functions now being conducted over videoconferencing to maintain

social distancing protocols. This Fourth Edition addresses COVID-19 and its effect on CHD care in several chapters: Chapter 8: Multidisciplinary Collaboration, Team Functioning, and Communication in Congenital Cardiac Care; Chapter 18: Preoperative Evaluation and Preparation; Chapter 32: Heart and Lung Transplantation; Chapter 36: Cardiac Intensive Care; and Chapter 37: Mechanical Support of the Circulation. We hope that this new information will be useful to the reader; but our greatest hope is that the COVID-19 pandemic will soon be brought under control through a worldwide effort to heed advice from experts in Medicine, Public Health, Science, and Epidemiology with widespread vaccination and other proven approaches.

Caring for patients with congenital heart disease requires a team of dedicated professionals that include congenital cardiac anesthesiologists, congenital heart surgeons, pediatric and adult congenital cardiologists, cardiac intensivists, cardiac interventionalists and imaging specialists, nurses, perfusionists, respiratory therapists, technicians, child life and social workers, and interpreters, among many others. We greatly appreciate the passion and commitment of the people in these disciplines, without whom we could not do our work. Finally, the patient and family are the focus of the team, and their courage and goodwill in the face of serious and complex illness always amaze and inspire us. It is to our patients and their families that *Anesthesia for Congenital Heart Disease*, Fourth Edition, is also dedicated, in the hope that the knowledge contained in these pages will contribute to better outcomes for them.

It is the purpose of this, our Fourth Edition of *Anesthesia for Congenital Heart Disease*, to contribute to the fund of knowledge in our field, to help prepare the next generation of congenital cardiac anesthesiologists, and to enhance the care of children and adults with congenital heart disease by individuals from various disciplines worldwide.

List of Abbreviations

α_2M	α_2-macroglobulin
AA	aortic atresia
ABC	Aristotle Basic Complexity
ABO-C	ABO-compatible
ABO-I	ABO-incompatible
ACE	angiotensin-converting enzyme
ACGME	Accreditation Council for Graduate Medical Education
ACHD	adult congenital heart disease
ACT	activated clotting time
ACTH	adrenocorticotropic hormone
AEG	atrial electrogram
AI	aortic insufficiency
AICD	automatic internal cardiac defibrillator
AIDS	acquired immunodeficiency syndrome
AKI	acute kidney injury
Akt	protein kinase B
ALCAPA	anomalous left coronary artery arising from the pulmonary artery
ALI	acute lung injury
ANF	atrial natriuretic factor
ANH	Acute normovolemic hemodilution
APAF-1	apoptotic protease activating factor 1
APERP	accessory pathway effective refractory period
APOE	apolipoprotein E
APRV	airway pressure release ventilation
aPTT	activated partial thromboplastin time
APW	aortopulmonary window
AR	adrenergic receptor
ARCAPA	anomalous right coronary artery from the pulmonary artery
ARDS	acute respiratory distress syndrome
ARF	acute renal failure
ASD	atrial septal defect
ASE	American Society of Echocardiography
ASO	arterial switch operation
AT	atrial tachycardia
ATIII	antithrombin III
ATP	adenosine triphosphate
AUC	area under the curve
AV	atrioventricular
AVC	atrioventricular canal
AVNRT	atrioventricular nodal re-entry tachycardia
AVSD	atrioventricular septal defect
BAV	bicuspid aortic valve
Bax	B-cell lymphoma-2-associated X protein
BCAS	The Boston Circulatory Arrest Study
BCL-2	B-cell lymphoma-2
BCL-xL	B-cell lymphoma-extra large
BCPC	bi-directional cavopulmonary connection
BDNF	Brain-derived neurotrophic factor
BiVAD	biventricular ventricular assist device
BNP	brain natriuretic peptide
BOS	bronchiolitis obliterans syndrome
BPA	branch pulmonary artery
BPD	bronchopulmonary dysplasia
BSA	body surface area
BSID	Bayley Scales of Infant Development
BUN	blood urea nitrogen
C3PO	Congenital Cardiac Catheterization Project on Outcomes
CABG	coronary artery bypass grafting
CALM	congenital atresia of the left main coronary artery
cAMP	cyclic adenosine monophosphate
CAV	coronary artery vasculopathy
CAVC	complete atrioventricular canal
CAVF	coronary arteriovenous fistula
CBF	cerebral blood flow
CBG	corticosteroid-binding globulin
CCA	common carotid artery
CCAN	Congenital Cardiac Anesthesia Network
CCAS	Congenital Cardiac Anesthesia Society
CCB	calcium channel blocker
CCTGA	congenitally corrected transposition of the great arteries
CF	cystic fibrosis
cGMP	cyclic guanosine monophosphate
CHARM	Catheterization for Congenital Heart Disease Adjustment for Risk Method
CHD	congenital heart disease
CHF	congestive heart failure
CICU	cardiac intensive care unit
CIED	cardiovascular implantable electronic device
CIRCI	critical illness-related corticosteroid insufficiency
CL	cardiolipin
CLAD	chronic lung allograft dysfunction
CMR	cardiac magnetic resonance
$CMRO_2$	cerebral metabolic rate for oxygen consumption
CMV	cytomegalovirus

CO	carbon monoxide
CO	cardiac output
CoA	coarctation of the aorta
COP	colloid osmotic pressure
COx	cerebral oximetry index
CPAP	continuous positive airway pressure
CPB	cardiopulmonary bypass
CPVT	catecholaminergic polymorphic ventricular tachycardia
CRBSIs	catheter-related bloodstream infections
CRMDs	cardiac rhythm management devices
CSA	cross-sectional area
CSOR	cerebral–splanchnic oxygen ratio
CT	computed tomography
CUF	conventional ultrafiltration
CVC	central venous catheter
CVVH	continuous veno-venous hemofiltration
CVVH/D	continuous veno-venous hemofiltration and dialysis
DBD	donation after brain death
DCD	donation after cardiac death
DCM	dilated cardiomyopathy
DCRV	double-chambered right ventricle
DHCA	deep hypothermic circulatory arrest
DIC	diffuse intravascular coagulation
DIVA	difficult intravenous access
DLCO	diffusing capacity for carbon monoxide
DLT	double-lumen tube
DNA	deoxyribonucleic acid
DO_2	oxygen delivery
DORV	double outlet right ventricle
D-TGA	dextro-transposition of the great arteries
DVT	deep vein thrombosis
EA	Ebstein's anomaly
EACA	ε-aminocaproic acid
EACTS	European Association for Cardio-Thoracic Surgery
EAT	ectopic atrial tachycardia
EBV	estimated blood volume
ECG	electrocardiogram
ECMO	extracorporeal membrane oxygenation
ECPR	extracorporeal cardiopulmonary resuscitation
EDA	end-diastolic area
EDV	end-diastolic volume
EEG	electroencephalogram
EF	ejection fraction
EFE	endocardial fibroelastosis
EJV	external jugular vein
ELSO	Extracorporeal Life Support Organization
EMA	European Medicines Agency
EMI	electromagnetic interference
EP	electrophysiological
EPDCs	epicardially derived cells
EPO	recombinant human erythropoietin alpha
ERA	endothelin receptor antagonist
ERK	extracellular signal-regulated kinase
ESA	end-systolic area
ESV	end-systolic volume
ET-1	endothelin-1
$EtCO_2$	end-tidal CO_2
ETT	endotracheal tube
FAC	fractional area change
FDA	Food and Drug Administration
FEV_1	forced expiratory volume in 1 second
FFP	fresh frozen plasma
FHF	first heart field
FiO_2	fraction of inspired oxygen
FOB	fiberoptic bronchoscope
FRC	functional residual capacity
FTR	failure to resuscitate
FV	femoral vein
FVC	forced vital capacity
dATP	deoxyadenosine triphosphate
FVL	Factor V Leiden
GABA	γ-aminobutyric acid
GDP	guanosine diphosphate
GFR	glomerular filtration rate
GI	gastrointestinal
GLUTs	glucose transporters
Gp	glycoprotein
GSK-3β	glycogen synthase kinase-3β
GTP	guanosine triphosphate
HAT	heparin-associated thrombocytopenia
HCII	heparin cofactor II
Hct	hematocrit
HEAL	Health Education Assets Library
HFOV	high-frequency oscillatory ventilation
HIT	heparin-induced thrombocytopenia
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HLHS	hypoplastic left heart syndrome
HPA	hypothalamic–pituitary–adrenal axis
HPAH	heritable pulmonary artery hypertension
HPV	hypoxic pulmonary vasoconstriction
HR	heart rate
HTK	histidine-tryptophan-ketoglutarate
HUS	head ultrasound
IAA	interrupted aortic arch
IABP	intra-arterial blood pressure
IAS	interatrial septum
ICE	intracardiac echocardiography
ICH	intracranial hemorrhage
ICU	intensive care unit
IE	infective endocarditis
IgG	immunoglobulin G
IJV	internal jugular vein
IM	intramuscular
INR	international normalized ratio
iNO	inhaled nitric oxide
IO	inflow occlusion
IPAH	idiopathic pulmonary artery hypertension
IPCCC	International Pediatric and Congenital Cardiac Code
ISHLT	Scientific Registry of the International Society for Heart and Lung Transplantation
IU	international unit
IV	intravenous
IVC	inferior vena cava
IVH	intraventricular hemorrhage

JCAHO	Joint Commission for the Accreditation of Hospital Organizations
JET	junctional ectopic tachycardia
KIM-1	kidney injury molecule-1
LA	left atrium
LAA	left aortic arch
LAA	left atrial appendage
LAP	left atrial pressure
LAS	lung allocation score
LBBB	left bundle branch block
LBW	low birth weight
LBWN	low-birth-weight neonate
LCOS	low cardiac output syndrome
LDLLT	living donor lobar lung transplant
LE	lower esophageal
L-FABP	liver fatty acid-binding protein
LiDCO	lithium dilution CO
LMA	laryngeal mask airway
LMWH	low-molecular-weight heparin
LPA	left pulmonary artery
LQTS	long QT syndrome
LSVC	persistent left superior vena cava
L-TGA	levo-transposition of the great arteries
LV	left ventricle, left ventricular
LVEDP	left ventricular end-diastolic pressure
LVEDV	left ventricular end-diastolic volume
LVNC	left ventricular non-compaction
LVOT	left ventricular outflow tract
MAC	minimum alveolar concentration
MAP	mean arterial pressure
MAS	meconium aspiration syndrome
MAT	multifocal atrial tachycardia
mBTS	modified Blalock – Taussig shunt
MCS	mechanical circulatory support
MDI	Mental Development Index
MMF	mycophenolate mofetil
MOD	method of discs
MPA	main pulmonary artery
mPAP	mean pulmonary artery pressure
MPTP	mitochondrial permeability transition pore
MR	mitral regurgitation
MRI	magnetic resonance imaging
MRSA	methicillin-resistant *Staphylococcus aureus*
MSOF	multisystem organ failure
mTOR	mammalian target of rapamycin
MUF	modified ultrafiltration
MV	mechanical ventilation
NAC	*N*-acetylcysteine
NEC	necrotizing enterocolitis
NGAL	neutrophil gelatinase-associated lipocalin
NICU	neonatal intensive care unit
NIRS	near-infrared spectroscopy
NMDA	*N*-methyl-D-aspartate
NOS	nitric oxide synthase
OB	obliterative bronchitis
OEF	oxygen excess factor
OER	oxygen extraction rate
OHT	orthotopic heart transplantation
OPTN	Organ Procurement and Transplant Network
OR	operating room
$p75^{NTR}$	p75 neurotrophic receptor
PA	pulmonary artery
PA	pulmonary atresia
PA/IVS	pulmonary atresia with intact ventricular septum
PAA	pharyngeal arch arteries
PAC	premature atrial contraction
$PaCO_2$	partial pressure of carbon dioxide in arterial blood
PAD	preoperative autologous donation
PAH	pulmonary arterial hypertension
PAH-CHD	pulmonary arterial hypertension associated with congenital heart disease
PAI	plasminogen activator inhibitor
PAO_2	alveolar oxygen tension
PaO_2	partial pressure of oxygen in arterial blood
PAPVC	partial anomalous pulmonary venous connection
PAPVD	partial anomalous pulmonary venous drainage
PAPVR	partial anomalous pulmonary venous return
PASP	pulmonary artery systolic pressure
PBF	pulmonary blood flow
PC	protein C
pCAS	pediatric cardiopulmonary assist system
PCC	prothrombin complex concentrate
PCWP	pulmonary capillary wedge pressure
PD	peritoneal dialysis
PDA	patent ductus arteriosus
PDC	peritoneal drainage catheter
PDE	phosphodiesterase
PDE-5	phosphodiesterase-5
PDEIs	phosphodiesterase inhibitors
PEEP	positive end-expiratory pressure
PEO	proepicardial organ
PF4	platelet factor 4
PFO	patent foramen ovale
PG	pressure gradient
PGE_1	prostaglandin E_1
PH	pulmonary hypertension
PHT	pulmonary hypertension
PI	pulmonary insufficiency
PICC	peripherally inserted central catheter
PIP	peak inspiratory measurement
PI-PLC	phosphatidylinositol-specific phospholipase C
PKA	protein kinase A
PKC	protein kinase C
PLC	phospholipase C
PMP	poly-(4-methyl-1-pentene)
POCA	Pediatric Perioperative Cardiac Arrest Registry
PPL	polypropylene
PPS	postpericardiotomy syndrome
PPV	positive pressure ventilation
PRA	panel reactive antibody
pRIFLE	pediatric modification of the RIFLE (**Pediatric Risk, Injury, Failure, Loss, End Stage Renal Disease**) score
PRISM	Pediatric Risk of Mortality
PS	protein S
PS	pulmonary stenosis

PS/IVS	pulmonary stenosis with intact ventricular septum
PT	prothrombin time
PTLD	post-transplant lymphoproliferative disorder
PTT	partial thromboplastin time
PV	pulmonary valve
PVCs	premature ventricular contractions
PVD	pulmonary vascular disease
PVP	pulmonary valve perforation
PVR	pulmonary vascular resistance
PVRI	pulmonary vascular resistance index
Qp	pulmonary blood flow
Qs	systemic blood flow
RA	right atrium
RAA	right aortic arch
RACHS-1	Risk Adjustment for Congenital Heart Surgery 1
RAP	right atrial pressure
RBBB	right bundle branch block
RBC	red blood cell
RCP	regional cerebral perfusion
RDS	respiratory distress syndrome
rFVIIa	recombinant activated factor VIIa
RIFLE	risk, injury, failure, loss, and end-stage renal disease
RIPC	remote ischemic preconditioning
ROS	reactive oxygen species
RPA	right pulmonary artery
RV	right ventricle, right ventricular
RVDCC	right ventricle-dependent coronary circulation
RVOT	right ventricular outflow tract
RVOTO	right ventricular outflow tract obstruction
RVSP	right ventricular systolic pressure
SAN	sinoatrial node
SaO_2	arterial oxygen saturation
SCA	Society of Cardiovascular Anesthesiologists
SCPA	superior cavopulmonary anastomosis
SCV	subclavian vein
$ScvO_2$	central venous oxygen saturation
SERCA	sarcoplasmic reticulum Ca^{2+}-ATPase
SF	shortening fraction
SGOT	serum glutamic oxaloacetic transaminase
SHF	second heart field
SIRS	systemic inflammatory response syndrome
$SjvO_2$	jugular bulb venous oximetry
SLV	single-lung ventilation
SPA	Society for Pediatric Anesthesia
SpO_2	pulse oximeter saturation
SR	sarcoplasmic reticulum
SSI	surgical site infection
STAT	Society of Thoracic Surgeons–European Association for Cardio-Thoracic Surgery Congenital Heart Surgery mortality score
STS	Society of Thoracic Surgeons
STS-CHSD	Society of Thoracic Surgeons Congenital Heart Surgery Database
subAS	subvalvular aortic stenosis
SV	stroke volume
SVAS	congenital supravalvular aortic stenosis
SVC	superior vena cava
SvO_2	percentage of oxygen saturation of mixed venous blood
SVR	systemic vascular resistance
SVRI	systemic vascular resistance index
SVT	supraventricular tachycardia
T3	triiodothyronine
T4	thyroxine
TA	tranexamic acid
TA	tricuspid atresia
TAFI	thrombin-activatable fibrinolysis inhibitor
TAPVC	total anomalous pulmonary venous connection
TAPVR	total anomalous pulmonary venous return
TCAD	transplant coronary artery disease
TDI	tissue Doppler imaging
TEE	transesophageal echocardiography
TEG	thromboelastography
TF	tissue factor
TFPI	tissue factor pathway inhibitor
TGA	transposition of the great arteries
TGC	tight glycemic control
TI	tricuspid valve (TV) insufficiency
TLC	total lung capacity
TNF-alpha	tumor necrosis factor-alpha
TOF	tetralogy of Fallot
TOR	target of rapamycin protein
tPA	tissue plasminogen activator
TPTD	transpulmonary thermodilution
TR	tricuspid regurgitation
TRALI	transfusion-related acute lung injury
TTE	transthoracic echocardiography
TV	tricuspid valve
UFH	unfractionated heparin
UNOS	United Network for Organ Sharing
URI	upper respiratory tract infection
V/Q	ventilation/perfusion
VA	ventriculoarterial
VAA	volatile anesthetic agent
VAC	video-assisted cardioscopy
VAD	ventricular assist device
VATS	video-assisted thoracoscopic surgery
VF	ventricular fibrillation
VMI	visual-motor integration
VO_2	oxygen consumption
vPEO	venous proepicardial organ
VSD	ventricular septal defect
VT	ventricular tachycardia
VTI	velocity time integral
vWF	von Willebrand factor
WHO	World Health Organization
WMI	white matter injury
WS	Williams syndrome
WUS	Wake Up Safe Database

Introduction

Over the last 80+ years, congenital cardiac anesthesia has developed as a subspecialty of pediatric and/or cardiac anesthesia, depending on one's perspective. It is impossible to describe the evolution of congenital cardiac anesthesia without simultaneously referring to developments in the surgical and interventional management of congenital heart disease (CHD) due to the great interdependency of these fields. As pediatric anesthesia developed, surgical treatments and percutaneous interventions for children with CHD began to be devised, starting with the simple surgical ligation of a patent ductus arteriosus (PDA). Over the years, the continual development and refinement of surgical and interventional techniques has led to the introduction of staged palliations, increasingly sophisticated repairs of complex intracardiac lesions requiring cardiopulmonary bypass (CPB) and circulatory arrest, and most recently, of complex biventricular repairs. These advances were accompanied by concurrent changes in anesthetic management that overcame the technical challenges and mitigated the perioperative morbidity associated with these novel techniques.

This chapter will be organized primarily around the theme of how anesthesiologists met these new challenges using the anesthetic armamentarium that was available to them at the time. The secondary theme running through this history is the gradual shift from a purely intraoperative focus to one with a view of the entirety of the perioperative period. Not surprisingly, the drastic decreases in surgical mortality have led to an increased interest in the reduction of perioperative morbidity. The final theme is the progressive and ongoing expansion in the age range of patients routinely presenting for congenital cardiac surgery.

The first years: 1938–1954

The first successful operation for CHD was performed in August 1938 when Robert E. Gross ligated the PDA of a 9-year-old girl. The operation and the postoperative course were smooth, but because of the interest in the case, the child was kept in the hospital until the 13th postoperative day. In the report of the case, Gross mentions that the operation was done under cyclopropane anesthesia, and continues: "The chest was closed, the lung being re-expanded with positive pressure anesthesia just prior to placing the last stitch in the intercostal muscles." A nurse using a "tight-fitting" mask delivered the anesthetic. There was no intubation and, of course, no postoperative ventilation. The paper does not mention any particular pulmonary complications, so it cannot have been much different from the ordinary postoperative course of the day [1].

In 1952, Dr. Gross published a review of 525 PDA ligations where many, if not all, of the anesthetics were administered by the same nurse anesthetist, under surgical direction [2]. Here he states: "Formerly, we employed cyclopropane anesthesia for these cases, but since about half of the fatalities seemed to have been attributable to cardiac arrest or irregularities under this anesthetic, we have now completely abandoned cyclopropane and employ ether and oxygen as a routine." It is probably correct that cyclopropane under these circumstances with insufficient airway control was more

Anesthesia for Congenital Heart Disease, Fourth Edition. Edited by Dean B. Andropoulos, Emad B. Mossad, and Erin A. Gottlieb.

likely than ether to cause cardiac arrhythmias. An intralaryngeal airway was used, which also served "to facilitate suction removal of any secretions from the lower airway" (and, we may add, the stomach). Dr. Gross claims that the use of this airway reduced the incidence of postoperative pulmonary complications. Without a modern, rigorous review of this series, it is hard to know what other particular anesthetic challenges were confronted by the anesthetists, but we may assume that intraoperative desaturation from the collapsed left lung, postoperative pulmonary complications, and occasional major blood loss from an uncontrolled, ruptured ductus arteriosus were high on the list.

The next operation to be introduced, the systemic to pulmonary artery (PA) shunt, was billed as "corrective" for the child with cyanotic CHD. The procedure was proposed by Helen Taussig as an "artificial ductus arteriosus" and was first performed by Albert Blalock and the surgical technician Vivien Thomas at the Johns Hopkins Hospital in 1944. In a very detailed paper, Drs. Blalock and Taussig described the first three patients to undergo the Blalock–Taussig shunt operation, recently recognized as Blalock-Thomas-Taussig shunt. Dr. Harmel anesthetized the first and third patients, using ether and oxygen in an open drop method for the former and cyclopropane through an endotracheal tube for the latter. The second patient was given cyclopropane through an endotracheal tube by Dr. Lamont. Whether the first patient was intubated is unclear, but it is noted that in all three cases, positive pressure ventilation was used to reinflate the lung [3]. Interestingly, in this early kinder and gentler time, the surgical and pediatric authors reporting the Blalock–Taussig operation acknowledged by name the pediatricians and house officers who took such good care of the children postoperatively, but still did not acknowledge the contribution of the anesthesiologists, Lamont and Harmel. Although intubation of infants was described by Gillespie as early as 1939, it is difficult to say precisely when intubations became routine [4].

Drs. Harmel and Lamont reported in 1946 on their anesthetic experience of 100 operations for congenital malformations of the heart "in which there is pulmonary artery stenosis or atresia." They reported 10 anesthetic-related deaths in the series, so it is certain that they encountered formidable anesthetic problems during these surgical procedures [5]. In 1952, Damman and Muller reported a successful operation in which the main PA was reduced in size and a band was placed around the artery in a 6-month-old infant with a single ventricle (SV). They state that morphine and atropine were given preoperatively, but no further anesthetic agents are mentioned. At that time, infants were assumed to be oblivious to pain, so we can only speculate on what was used beyond oxygen and restraint [6].

Over the next 20 years, many palliative operations for CHD were developed and a number of papers describing the procedures and their anesthetic management appeared in the literature. In 1948, McQuiston described the anesthetic technique used at the Children's Memorial Hospital in Chicago [7]. This is an excellent paper for its time, however, a number of the author's conclusions are erroneous. The anesthetic technique for shunt operations (mostly Potts' anastomosis) is discussed in some detail but is mostly of historical interest today. McQuiston explained that he had no experience of anesthetic management used in other centers, such as the pentothal–N_2O–curare used at Minnesota or the ether technique used at the Mayo Clinic. McQuiston used heavy premedication with morphine, pentobarbital and atropine, and/or scopolamine; this is emphasized because it was important "to render the child sleepy and not anxious." The effect of sedation with regard to a decrease in cyanosis (resulting in making the child look pinker) is noted by the authors. They also noted that children with severe pulmonic stenosis or atresia do not decrease their cyanosis "because of very little blood flow," and that these children have the highest mortality. McQuiston pointed out that body temperature control was an important factor in predicting mortality and advocated the use of moderate hypothermia (i.e., "refrigeration" with ice bags), because of a frequently seen syndrome of hyperthermia. McQuiston worked from the assumption that hyperthermia is a disease in itself, but did not explore the idea that the rise in central temperature might be a symptom of low cardiac output with peripheral vasoconstriction. Given what we now know about shunt physiology, it is interesting to speculate that this "disease" was caused by pulmonary hyperperfusion after the opening of what would now be considered as an excessively large shunt, stealing a large portion of systemic blood flow.

In 1950, Harris described the anesthetic technique used at Mount Zion Hospital in San Francisco [8]. He emphasized the use of heavy premedication with morphine, atropine, and scopolamine. The "basal anesthetic agent" was Avertin (tribromoethanol) administered rectally and supplemented with N_2O/O_2 and very low doses of curare. Intubation was facilitated by cyclopropane with FiO_2 titrated according to cyanosis throughout. Bucking or attempts at respiration were thought to be due to stimulation of the hilus of the lung and were treated with "cocainization" of the hilus [8].

In 1952, Dr. Robert M. Smith discussed the circulatory factors involved in the anesthetic management of patients with CHD [9]. The anesthetic agents recommended were mostly ether following premedication. He pointed out the necessity of understanding the pathophysiology of the lesion and also "the expected effect of the operation upon this unnatural physiology." That is, he recognized that the operations were not curative. While most of the previous papers had been about tetralogy of Fallot (TOF), Dr. Smith also described the anesthetic challenges of surgery for coarctation of the aorta, introduced simultaneously in 1945 by Dr. Gross in the United States and Dr. Craaford in Sweden. He emphasized hypertension following clamping of the aorta and warned against excessive bleeding in children operated on at older ages using ganglionic blocking agents. This bleeding was far beyond what anesthesiologists now see in patients operated on at younger ages, before the development of substantial collateral arterial vessels [9].

The heart–lung machine: 1954–1970

From 1954 to 1970 the development of what was then called the "heart–lung machine" allowed for the surgical repair of complex intracardiac congenital heart defects.

Early CPB technology was associated with significant morbidity and mortality, especially in smaller children weighing less than 10 kg. In Kirklin's initial report of intracardiac surgery utilizing a mechanical pump–oxygenator system at the Mayo Clinic, the only reference to anesthetic management was a brief remark that ether and oxygen were given [10]. In Lillehei's description of direct vision intracardiac surgery in humans using a simple, disposable artificial oxygenator, there was no mention of anesthetic management [11]. What strikes a "modern" cardiac anesthesiologist in these two reports is the high mortality: 50% in Kirklin's series and 14% in Lillehei's series. All of these patients were children with CHD ranging in age from 1 month to 11 years.

Anesthetic challenges multiplied rapidly with the introduction of CPB and early attempts at intracardiac repairs. At that time, most anesthetics were performed by nurses under the supervision of the surgeon utilizing ether (first with open drop ether administration and later using various non-rebreathing systems) or cyclopropane. In most early textbooks, cyclopropane was the recommended drug for pediatric anesthesia despite the fact that it was both explosive and difficult to use. CO_2 absorption was necessary with cyclopropane in order to avoid hypercarbia and acidosis, which might precipitate ventricular arrhythmias. The use of a Waters' absorber, however, could be technically difficult, especially as tracheal intubation was considered to be dangerous to the child's "small, delicate airway."

In all of the early reports, it is noted or implied that the patients were awake (more or less) and extubated at the end of the operation. In the description of the postoperative course, respiratory complications were frequent, in the form of either respiratory insufficiency or airway obstruction. The former problem was likely related to the morbidity of early bypass technology on the lung, while the latter problem was probably because "the largest tube which would fit through the larynx" was often used and/or that the red rubber tube was not tissue tested.

Arthur S. Keats, who worked with Denton A Cooley at the Texas Heart Institute and Texas Children's Hospital starting in 1955, had significant experience with congenital heart surgery and anesthesia and provided the most extensive description of the anesthetic techniques used in this era. He described anesthesia for congenital heart surgery without bypass in 150 patients, the most common operations being PDA ligation, Potts' operation, atrial septectomy (Blalock–Hanlon operation), and pulmonary valvotomy [12]. Patients were administered a generous premedication of pentobarbital or chloral hydrate along with meperidine or atropine. Endotracheal intubation was utilized, and ventilation was assisted using an Ayres T-piece, to-and-fro absorption system, or a circle system. Cyclopropane was used for induction, and a venous cutdown provided vascular access. A succinylcholine bolus and infusion were used to maintain muscle relaxation. Light ether anesthesia was used for maintenance until the start of chest closure, at which point 50% N_2O was used as needed. Electrocardiogram (ECG), ear oximeter, and intra-arterial blood pressure (IABP) recordings were used for monitoring during this period, as were arterial blood gases and measurements of electrolytes and hemoglobin. The following year, he published his experiences with 200 patients undergoing surgery for CHD with CPB, almost all of whom were children [13]. Ventricular septal defect (VSD), atrial septal defect (ASD), TOF, and aortic stenosis were the most common indications for surgery. The anesthetic techniques were the same as described earlier, except that D-tubocurare was given to maintain apnea during the bypass.

Perfusion rates of 40–50 mL/kg/min were used in infants and children, and lactic acidemia after bypass (average 4 mmol/L) was described. No anesthetic agent was added during the bypass procedure, and "patients tended to awaken during the period of bypass," but apparently without recall or awareness. Arrhythmias noted ranged from frequent bradycardia with cyclopropane and succinylcholine to junctional or ventricular tachycardia, ventricular fibrillation (VF), heart block, and rapid atrial arrhythmias. Treatments included defibrillation, procainamide, digitalis, phenylephrine, ephedrine, isoproterenol, and atropine. Eleven out of 102 patients with VSD experienced atrioventricular block. Epicardial pacing was attempted in some of these patients but was never successful. Fresh citrated whole blood was used for small children throughout the case, and the transfusion of large amounts of blood was frequently necessary in small infants. The mortality rate was 13% in the first series (36% in the 42 patients less than 1-year-old) and 22.5% in the second series (47.5% in the 40 patients less than 1-year-old). Causes of death included low cardiac output after ventriculotomy, irreversible VF, coronary air emboli, postoperative atrioventricular block, hemorrhage, pulmonary hypertension, diffuse atelectasis, and aspiration of vomitus. No death was attributed to the anesthetic alone. Reading these reports provides an appreciation of the daunting task of providing anesthesia during these pioneering times. In 1957, in addition to ECG, IABP, and oximeter, Dr. Digby Leigh noted the importance of capnography in cardiac surgery. He described the effect of pulmonary blood flow on end-tidal CO_2 ($EtCO_2$) and the decrease in $EtCO_2$ after partial clamping of the PA during the Blalock–Taussig shunt procedure. However, it was not until 1995 that Smolinsky et al. reported the importance of $EtCO_2$ during PA banding [14–16].

Tracheostomy after cardiac operations was not unusual, and in some centers, it was done "prophylactically" a week before the scheduled operation. These practices were certainly related to primitive (relative to the present) techniques and equipment used for both endotracheal intubation and CPB. Postoperative ventilatory support did not become routine until later when neonatologists and other intensive care specialists had proven that it could be done successfully. Successful management of prolonged respiratory support was first demonstrated in the great poliomyelitis epidemics in Europe and the United States in 1952–1954 [17].

Halothane was introduced into clinical practice in the mid-1950s and rapidly became the most popular agent in pediatric anesthesia as it allowed for a smoother induction. Halothane was also widely used for pediatric cardiac

anesthesia despite its depressive effect on the myocardium and its significant risk of arrhythmia. During this period, adult cardiac anesthesiologists, following the practice reported by Edward Lowenstein in 1970 [18], began to use opiate-based intravenous anesthesia. Initially, morphine in doses up to 1 mg/kg was given with 100% oxygen and this technique became the anesthetic of choice for adult cardiac patients, but vasodilation and hypotension associated with its use slowed the incorporation of this technique in pediatric cardiac anesthesia until synthetic opiates became available.

Both prior to the development of CPB and during its early implementation, a number of modalities were utilized to improve outcomes in infants. Inflow occlusion (IO) was an elegant technique that required close cooperation between the entire operating room team, but most especially between the surgeon and the anesthesiologist. The technique was as follows: The chest was opened in the midline. After pericardiotomy, a side clamp was placed on the right atrial (RA) free wall and an incision made in the RA, or proximal on the PA, prior to placing the vascular clamps used to occlude caval return. Before application of the clamps, patients were hyperventilated with 100% O_2. During IO, the superior vena cava (SVC) and inferior vena cava (IVC) inflow were occluded, ventilation held, and the RA or PA clamp released. The heart was allowed to empty and the septum primum was excised or the pulmonic valve dilated. After excision of the septum or valvotomy, one caval clamp was released to de-air the atrium. The RA side clamp or the PA clamp was then reapplied and the other caval clamp was released. The heart was resuscitated with bolus calcium gluconate (range 30–150 mg/kg) and bicarbonate (range 0.3–3 mEq/kg). Occasionally, inotropes were administered, most often dopamine. It was important to titrate the inotropes so as not to aggravate rebound hypertension caused by endogenous catecholamines. The duration of the IO was between 1 and 3 minutes – terrifying minutes for the anesthesiologist, but quickly over.

Another modality used to try to improve the survival after shunt operations, PA banding, and atrial septectomy was to operate in the hyperbaric chamber, thereby benefiting from the increased amount of physically dissolved oxygen [19] (Figure 1.1). It was a cumbersome affair operating in crowded, closed quarters. There was only room for two surgeons, two nurses, one anesthesiologist, and one baby, as the number of emergency oxygen units limited access. Retired navy divers ran the chamber and kept track of how many minutes the personnel had been in the hyperbaric chamber in the previous week. Help was not readily available because the chamber was buried in a sub-basement and people had to be sluiced in through a side arm that could be pressurized. The chamber was pressurized to 2–3 atmospheres so it was unpleasantly hot while increasing the O_2 pressure and cold while decreasing the pressure. People with glasses were at a disadvantage. Providing anesthesia was also a challenge. Infants were anesthetized with ketamine and nitrous oxide. As the pressure in the chamber increased, the concentrations of N_2O had to be decreased to avoid hypotension and bradycardia. The hyperbaric chamber did not seem to improve survival and was abandoned around 1974.

It was also during this era that the first infant cardiac transplant was performed by Kantrowitz in 1967 [20]. The recipient was an 18-day-old, 2.6 kg patient with severe Ebstein's anomaly, who had undergone a Potts' shunt on day 3 of life. The donor was an anencephalic newborn. The anesthetic technique is not described, and the infant died of pulmonary dysfunction 7 hours postoperatively.

AL Grawany

Deep hypothermic circulatory arrest and the introduction of PGE_1: 1970–1980

Sometime around 1970, the physiological repair of CHD, or "correction," began to come of age. Children were still treated as "small adults" because major physiological differences were not yet well appreciated, particularly as related to CPB morbidity. CPB was rarely employed during surgery on pediatric patients weighing less than 9 kg due to the very high morbidity and mortality experienced during the early years. The notion of repairing complex CHD in infancy was gaining attention but was hindered by the limitations of surgical, CPB and anesthetic techniques in infants. Theoretically, physiological repair early in life provides a more normal development of the cardiovascular and pulmonary systems and may altogether avoid palliative procedures and their adverse sequelae (e.g. anatomic distortions secondary to shunt and/or banding procedures and/or PA hypertension secondary to pulmonary vascular occlusive disease following Waterston and Potts' shunts). Furthermore, parents could be spared the anxiety of repeated operations and the difficulties of raising a child with a partially palliated heart and abnormal physiology.

The perceived need for early repair, together with the high mortality of CPB procedures in infants and small children, led to the introduction of deep hypothermic circulatory arrest (DHCA). First practiced in Kyoto, Japan, the use of DHCA then spread to pediatric centers in Russia and the United States. The first description of DHCA in the English surgical literature was published by Horiuchi in 1963 [21]. This involved a simple technique of surface cooling and rewarming during resuscitation, using ether as the anesthetic agent without intubation. In 1972, Mori et al. reported details of a technique for cardiac surgery in neonates and infants using deep hypothermia [22]. The infants were surface-cooled with ice bags and rewarmed on CPB. The anesthetic was maintained with halothane/N_2O combined with muscle relaxant and CO_2 was added to the anesthetic gas during cooling and rewarming (pH-stat) in order to improve cerebral perfusion. Another paper from Toronto described an anesthetic regime with atropine premedication occasionally combined with morphine [23]. Halothane and 50% N_2O were used, combined with D-tubocurarine or pancuronium. CO_2 was added to "improve tissue oxygenation by maintaining peripheral and cerebral perfusion." The infants were cooled with surface cooling (plastic bags with melting ice) and rewarmed on CPB. It was noted that 6 of the 25 infants had VF when cooled below 30 °C.

Surprisingly, given the enormity of the physiological disturbances and challenges presented by DHCA, very few articles describing an anesthetic technique for DHCA were published in the anesthesia literature, perhaps because DHCA and early surgical repair were not widely accepted. The material that was published about these techniques was restricted to surgical journals and was largely unknown to cardiac and pediatric anesthesiologists. Given the lack of scientific data to guide the anesthetic management of such cases, a very simple technique with ketamine–O_2–N_2O and curare supplemented by small amounts of morphine (0.1–0.3 mg/kg) was used at Boston Children's Hospital. Palliative cardiac surgical procedures were performed in the hyperbaric chamber. The infants were surface-cooled in a bathtub filled with ice water to a core temperature of approximately 30 °C. The bathtub consisted of a green plastic bucket (for dishwashing) bought at a Sears-Roebuck surplus store, keeping things as simple as possible [19] (Figure 1.2). This method was used in hundreds of infants over the next couple of years and only one infant developed VF, secondary to a coronary air embolus either from a peripheral IV or during an attempted placement of a central venous line, rather than the cooling itself (Figure 1.3).

During the first year of using DHCA in Boston, it was noticed that a number of the infants had "funny, jerky" movements of the face and tongue. A few also had transient

seizures during the postoperative period, but as they had normal electroencephalograms (EEGs) at 1-year follow-up, it was felt that significant cerebral complications were not a problem. In view of the knowledge developed subsequently, these clues to neurological damage occurring during and after pediatric cardiac surgery involving DHCA were overlooked. In hindsight, it is perhaps more accurate to say that these clues were ignored, and as a result, a great opportunity to study this problem was delayed for almost two decades. The issue of neurological damage with DHCA was raised repeatedly by surgeons such as John Kirklin, but was not intensively studied until the group at Boston Children's Hospital led by Jane Newburger and Richard Jonas systematically followed a cohort of infants who had undergone the arterial switch operation in the late 1980s using DHCA techniques [24]. In the late 1980s and early 1990s, Greeley et al. at Duke performed a series of human studies delineating the neurophysiological response to deep hypothermia and circulatory arrest [25]. These studies provided crucial data from which strategies for cooling and rewarming, length of safe DHCA, blood gas management (pH-stat versus alpha-stat during hypothermic CPB), and perfusion (DHCA with hypothermic low-flow perfusion, hematocrit in the perfusate) were devised in order to maximize cerebral protection.

From the beginning of this period, surgical results as measured by mortality alone were excellent, with steady increases in raw survival statistics. Because anesthetic techniques were evolving over this period of time, it was difficult to definitively ascribe any outcome differences to different anesthetic agents. A 1984 study of 500 consecutive cases of cardiac surgery in infants and children looked at anesthetic mortality and morbidity. Both were very low – so low in fact that they were probably not universally believed [26].

As new synthetic opioids such as fentanyl and sufentanil were developed, they replaced morphine to provide more hemodynamic stability in opiate-based anesthetic techniques for cardiac patients. This technique slowly and somewhat reluctantly made its way into pediatric anesthesia [27], replacing halothane, ketamine, and morphine, which had previously been the predominant choice of pediatric anesthesiologists dealing with patients with CHD. In 1981, Gregory et al. first described the use of "high-dose" fentanyl 30–50 μg/kg combined with pancuronium in 10 infants undergoing PDA ligation [28]. It is noteworthy that transcutaneous oxygen tension was measured as part of this study. This paper was, in fact, the introduction of high-dose narcotics in pediatric cardiac anesthesia [28]. The technique was a great success. One potential reason for this was determined several years later by Anand et. al. who demonstrated that fentanyl attenuated the stress response in infants undergoing PDA ligation [29].

In the years from 1983 to 1995, a number of papers were published showing the effect of different anesthetic agents on the cardiovascular system in children with CHD. Ketamine, nitrous oxide, fentanyl, and sufentanil were systematically studied. Some misconceptions stemming from studies of adult patients were corrected, such as the notion that N_2O combined with ketamine raises PA pressure and pulmonary vascular resistance (PVR) [30]. On the other hand, increased $PaCO_2$ and lower pH were shown to cause higher PVR immediately postoperatively [31]. A number of studies done at this time demonstrated (in a controlled fashion) the earlier clinical observation by Harmel and McQuiston in the late 1940s. [5, 32] that in cyanotic patients the O_2 saturation would rise during the induction of anesthesia, almost irrespective of the agent used [33]. These events only serve to reinforce the value of acute clinical observation and provide an example of how the interpretation of such observations may well change as new knowledge is discovered.

It was also during this decade that the "team concept" developed at larger centers, with cardiologists, cardiac surgeons, and anesthesiologists working closely together in the OR and the intensive care unit (ICU). These teams were facilitated by the anesthesiologists' "invasion" of weekly cardiology/cardiac surgery conferences where the scheduled operations for the week were discussed. Dr. Castaneda, the chief surgeon at Boston Children's Hospital, was a leader in the creation of the cardiac team concept for pediatric cardiac surgery.

PDA and the introduction of PGE_1

The medical and surgical management of PDA presents an interesting story. In 1938, Dr. Robert Gross became the first to successfully correct a CHD lesion when he surgically ligated a PDA in a 9-year-old girl. [1]. Fifty years later, it would also be the first CHD lesion to be corrected in the catheterization laboratory [34]. In the intervening years, several discoveries were made that turned out to be of great clinical significance to the pediatric cardiac anesthesiologist and the entirety of the cardiac team. During this time, pharmacological treatment of PDA was developed, and perhaps more importantly, it was discovered that the intravenous infusion of PGE_1 prevented the closure of the ductus arteriosus [35]. As the critical role of the ductus arteriosus in the pathophysiology and management of cyanotic and acyanotic CHD was increasingly appreciated, clinicians sought methods of maintaining ductal patency or achieving ductal closure, depending on the type of CHD encountered.

As neonatal intensive care advanced and the understanding of the physiology of this patient population expanded, the survival rates of very small and increasingly premature infants improved. It became apparent that in many of these infants, the ductus arteriosus would remain patent rather than undergo normal closure and that this continued patency had a deleterious effect on mechanical ventilation. In the 1970s, this appreciation led to the institution of medical therapy using aspirin (and later indomethacin, ibuprofen, and acetaminophen) in order to promote ducal closure. When such pharmacologic attempts at closure failed, it was increasingly understood that necrotizing enterocolitis (NEC) in the premature neonate was associated with decreased mesenteric blood flow secondary to the "steal" of systemic blood flow into the

pulmonary circulation through a PDA. Thus, in cases when the PDA failed to close in premature infants, the need for operative treatment of the PDA arose as prophylaxis for necrotizing enterocolitis.

Pediatric and cardiac anesthesiologists were then faced with the task of anesthetizing these tiny patients safely. As the decade progressed, issues such as temperature, maintenance fluid, and the prevention of secondary injury arose and were addressed emerged and were addressed. In 1980, Neuman described the anesthetic management of 70 such infants using an O_2/N_2O muscle relaxant anesthesia technique with no mortality [36]. Low FiO_2 was used to reduce the risk of retrolental fibroplasia and precautions were taken to prevent heat loss. In those days, 40% of the infants received a blood transfusion. Interestingly, the question of whether to operate in the neonatal intensive care unit (NICU) or the OR for closure of the PDA was debated at that time and remains unsettled even today.

Presently, if surgical closure is necessary, it is often done using a minimally invasive, thoracoscopic video-assisted technique [37]. Thoracoscopy has the benefit of using four tiny incisions to insert the instruments, avoiding an open thoracotomy, and limiting dissection and trauma to the left lung. At the same time, this latest development of surgical techniques required the anesthesiologist once again to change the anesthetic approach to these patients. Unlike adult anesthesiologists, who can use double-lumen endotracheal tubes for thoracoscopic procedures, pediatric anesthesiologists caring for 1–3 kg infants undergoing PDA ligation do not have the luxury of managing the left lung [37]. Another problem posed by thoracoscopic PDA ligation in the infant is the emerging need for neurophysiological monitoring of the recurrent laryngeal nerve's innervation of the muscles of the larynx to avoid injury, a known complication of PDA surgery [38]. The last issue is tailoring the anesthetic so that the children are awake at the end of the operation, extubated, and spend an hour or so in the post-anesthesia care unit, bypassing the cardiac ICU. In fact, in 2001, a group led by Hammer at Stanford published the first description of true outpatient PDA ligation in two infants aged 17 days and 8 months [39]. These patients were managed with epidural analgesia, extubated in the OR, and discharged home 10 hours postoperatively. This report brings PDA closure full circle from a 13-day hospital stay following an ether mask anesthetic for an open thoracotomy to a day surgery procedure in an infant undergoing an endotracheal anesthetic for a thoracoscopic PDA ligation.

Maintaining the patency of the PDA using PGE_1 is probably now of considerably greater importance than its closure. The introduction of PGE_1 suddenly improved the survival rate of a large number of neonates with ductal-dependent CHD. It also drastically changed the clinical practice of pediatric cardiac surgeons and anesthesiologists as frequent, middle-of-the-night shunt operations with extremely cyanotic infants almost immediately became a thing of the past. These operations were particularly daunting when one realizes that these procedures were most commonly performed before the availability of pulse oximetry – the only warning signs of impending cardiovascular collapse were the very dark color of the blood and preterminal bradycardia. To get an arterial blood gas with a PaO_2 in the low teens was not uncommon and PaO_2 measurements in single digits in arterial blood samples from live neonates during such surgical procedures were reported. PGE_1 also dramatically improved the care of the neonate with critical post-ductal coarctation. Prior to PGE1, these infants were extremely acidotic, with a pH of 7.0 or less at the start of the procedure (if it was possible to obtain an arterial puncture); they looked mottled and almost dead below the nipples. With the advent of PGE_1 therapy, they were resuscitated medically in the ICU and could be operated on the following day in substantially better condition than was previously the case.

But the introduction of PGE_1 had an effect that was not clearly foreseen except possibly by few astute cardiologists. An increasing number of neonates with severe forms of CHD that had hitherto been considered a "rare" pathological diagnosis were now surviving and presenting for care. Foremost among these were the infants with hypoplastic left heart syndrome (HLHS) and some forms of the interrupted aortic arch. As further experience was gained, it became obvious that these forms of the disease were not so rare, but that infants who had survived with those forms of CHD were.

The story of HLHS: 1980–1990

As mentioned in the previous section, the introduction of PGE_1 brought major changes to the practice of pediatric cardiac anesthesia, solving some problems but at the same time, introducing new challenges. New diagnoses of CHD were recognized and presented for treatment while, as did some that had previously been known but until then had presented insurmountable obstacles to effective therapy. One of these latter types of lesions was HLHS.

HLHS had been accurately described in 1958 by Noonan and Nadas, but only as a pathological diagnosis [40]. In the beginning, most of the infants were misdiagnosed as having sepsis, and few babies reached a tertiary center without a telltale Band-Aid®, indicating a lumbar puncture. HLHS is a ductal-dependent lesion, with 100% mortality within a few days to weeks as the ductus undergoes physiological closure. HLHS was therefore of no practical interest from a therapeutic standpoint until ductal patency could be maintained. When this became possible with PGE_1, these neonates rapidly became a problem that could not easily be ignored. Even with the ability to diagnose the defect in a live neonate temporarily kept alive with a PGE_1 infusion, the outlook was not much better as there was no palliative operation yet devised. In some centers, such neonates were kept viable on a PGE_1 infusion for weeks or even months in the (usually) vain attempt to get them to grow large enough for a surgical procedure to be attempted. Those were also the years during which President Ronald Reagan's Baby Doe regulations were in effect. Anyone who thought an infant was being mistreated (i.e. not operated upon) could call a "hotline number" that was posted in all neonatal ICUs to report the physicians' "mistreatment" of the infant. Fortunately, these regulations died a quiet death after a few chaotic years [41].

In subsequent years, several centers tried different approaches with ingenious conduits, attempting to create an outlet from the right ventricle to the aorta and the systemic circulation. The search for a palliative operation was spurred by the increasing success of the Fontan operation, which had been introduced in 1970 [42]. This meant that there now was a theoretical endpoint for HLHS as well as for other forms of the SV physiology. It was William Norwood at Boston Children's Hospital who was the first person to devise a viable palliation and also to complete the repair with a Fontan operation the following year [43]. The publication of this landmark paper spurred considerable discussion. Many cardiologists and surgeons took the position that this operative procedure represented experimental and unethical surgery and that these infants "were better off dead."

The current approach to these infants varies somewhat by center, but is most commonly a multistage palliation culminating with a Fontan operation. Another, albeit historical at present, alternative is neonatal transplantation as proposed by the group at Loma Linda in California [44]. Throughout the years, some cardiologists continued to be advocates of conservative "comfort care" for neonates with HLHS; however, with survival rates of about >70% being achieved in many centers, these infants are no longer being written off as untreatable. Now the question is more about the quality of survival, especially intellectual development. It is also recognized that many have both chromosomal and non-chromosomal anomalies that affect the cerebral and gastrointestinal systems [45].

As was the case from the beginning of pediatric cardiac surgery, this new patient population presented a new management dilemma for the anesthesiologist that required a solution before acceptable operative results could be achieved. Patients with HLHS were hemodynamically unstable prior to CPB because of the large volume load on the heart coupled with coronary artery supply insufficiency. The coronary arteries in HLHS are supplied by the PDA in a retrograde fashion through a hypoplastic ascending and transverse aorta that terminates as a single "main" coronary artery. A common event at sternotomy and exposure of the heart was VF secondary to mechanical stimulation. This fibrillation was sometimes intractable, necessitating emergent CPB during internal cardiac massage. This was not an auspicious beginning to a major investigational open-heart procedure.

It was during these years that there was a transition from morphine–halothane–N_2O maintenance to a high-dose narcotic technique (fentanyl or sufentanil) combined with 100% oxygen. This technique seemed to provide some protection against sudden VF events compared with historical controls [46]. Despite this modest progress in getting patients successfully onto CPB, it soon became painfully clear that not much progress was made in treating this lesion when trying to wean the patients from bypass. The infants were still unstable coming off bypass and severely hypoxemic, and it took some time before we discovered a way to deal with the problem.

A chance observation led to a solution. Infants who came off bypass with low PaO_2 (around 30 mmHg) after the HLHS repair often did well, while those with immediate "excellent gases" ($PaO_2 \geq 40$–50 mmHg) became progressively unstable in the ICU a couple of hours later, developing severe metabolic acidosis and dying within the first 24 hours. This observation, combined with discussions with the cardiologists about PVR and systemic vascular resistance (SVR), led to attempts to influence these resistances to assure adequate systemic flow. In retrospect, infants with low PaO_2 after bypass had smaller aortopulmonary shunts and adequate systemic blood flow, while those with larger shunts and higher initial PaO_2 levels after weaning from bypass tended to "steal" systemic blood flow through the shunt. This would occur in the postoperative period, as the PVR that initially remained elevated as a result of CPB returned to more normal levels. These observations led to the technique of lowering the FiO_2 (sometimes as low as 0.21) and allowing hypoventilation in order to increase PVR in patients with larger shunts so as to supply adequate systemic blood flow [46]. A different technique used at other institutions to deal with this problem was to add CO_2 to the anesthetic gas flow, increasing PVR and continuing to use "normal ventilation" in children who had excessive pulmonary blood flow in the setting of larger shunts [47]. Both techniques represented different approaches to the same problem: finding ways to deal with the need to carefully balance PVR and SVR after bypass in a fragile parallel circulation where dynamic changes in ventricular function were taking place.

These observations, and the subsequent modifications in anesthetic and postoperative management, improved the survival for the stage I palliation (Norwood procedure). It should be noted that the pediatric cardiac anesthesiologist was a fully contributing partner in the progressive improvement in the outcome of this very complex and challenging lesion. More importantly, the techniques developed and the knowledge gained in this process also simplified the management of other patients with parallel circulation and SV physiology. The obvious example is truncus arteriosus, where the "usual" ST-segment depression and frequent VF that occurred intraoperatively can almost always be avoided. Any decrease in PVR during anesthesia in a child with unrepaired truncus arteriosus can lead to pulmonary "steal" of systemic blood flow and decreased diastolic pressure through the common trunk to the aorta and PA, resulting in hypotension and insufficient systemic blood flow expressed initially as coronary insufficiency and ST depression (or elevation).

During the same decade, the surgical treatment of transposition of the great arteries (TGA) underwent several changes. The Mustard variant of the atrial switch operation was feared due to the risk of SVC obstruction. The arterial pressure during bypass and in the immediate post-bypass period in the OR tended to be low and the pressure in the SVC high. Following a Mustard procedure, it was not uncommon to see a child with a grotesquely swollen head having to be taken back to the OR for immediate reoperation. Venous hypertension in the internal jugular veins and SVC led to low cerebral perfusion pressure during CPB with many of these children suffering brain damage, especially when reoperation was delayed. The extent and prevalence of such damage were never systematically studied. An article from Great Ormond Street in London

AL Grawany

demonstrated arrested hydrocephalus in Mustard patients [48]. The Senning operation (another variant of the atrial switch approach to TGA) was better but traded pulmonary venous obstruction for systemic venous obstruction. When the diagnosis was not promptly made and intervened upon, these infants were often quite sick by the time they came to reoperation.

The successful application of the arterial switch operation (ASO) as described by Jatene in 1975 revolutionized the surgical management of TGA [49]. The ASO eliminated the risk of pulmonary and systemic venous obstruction seen with atrial level switches. It also diminished the incidence of the subsequent sick sinus syndrome, a later complication thought to result from the extensive atrial suture lines required by these earlier repairs. The introduction of the ASO again heavily involved anesthesiologists. At many institutions, the learning curve was very steep with the initial ASOs performed resulting in a substantial number of infants with severe myocardial ischemia or frank infarcts. This was due to a variety of problems with the coronary artery transfer and reimplantation onto the "switched" aorta that had been moved to the left ventricle outflow tract. Pediatric cardiac anesthesiologists gained extensive experience with intraoperative pressor and inotropic support as well as nitroglycerin infusions. They were expected by surgeons to provide the support necessary to get infants through what later turned out to be iatrogenic myocardial ischemia. As surgeons refined coronary artery transfers, these problems largely disappeared, along with the need for major pressor and inotropic support as well as for nitroglycerin infusions inappropriately directed at major mechanical obstructions in the coronary arterial supply. At many centers, the ASO is now largely considered to be a "routine" procedure which presents, for the most part, no unique anesthetic challenges.

It was also during this period that a randomized controlled study of the stress response in infants undergoing cardiac surgery while anesthetized with high-dose sufentanil was performed. It showed that a high-dose narcotic technique suppresses but does not abolish stress responses. It also demonstrated a reduction in morbidity and possibly mortality [50]. However, when the study was refined 10 years later using only high-dose narcotic anesthesia techniques, no mortality differences were seen between various high-dose narcotic techniques. It must be pointed out that the patient population was older and the bypass technique had undergone some refinement [51].

Fontan and the catheterization laboratory: 1990–2000

As the neonatal palliation of HLHS and other SV lesions improved and became more commonplace, a growing number of patients became candidates for the Fontan operation. The Fontan operation, HOWEVER, became somewhat problematic as it was applied to younger patients with an increasing variety of SV CHD. Although many of the patients had technically perfect Fontan operations, they developed low cardiac output with massive pleural and pericardial effusions postoperatively in the cardiac ICU. Many died in the postoperative period. Their course over the first 24–48 hours was relentlessly downward and could only be reversed by taking them back to the OR, reversing the Fontan operation, and reconstructing a systemic to PA shunt. It was hard for the caretakers of these infants to accept the loss of children they had known from birth. Various treatment modalities were tried to avoid this sequence of events, from early extubation to the use of a G-suit to improve venous return to the heart. In some centers, a large balloon was placed tightly around the child's lower body and intermittently inflated by a Bird respirator asynchronous with ventilation.

After a couple of years, two innovations changed both management and prognosis. Both were linked to the understanding that a major limitation of the Fontan operation was the need for a normal or near-normal PVR to allow survival through the postoperative period and that CPB, when used, causes a marked elevation of PVR in the early postoperative period through the release of inflammatory mediators and cytokines. This bypass-related increase in PVR was associated with younger age (<2 years old) at the time of Fontan completion – the higher baseline PVR of the infant made the bypass-related increase in PVR worse. This resulted in inadequate pulmonary blood flow and (single) ventricular filling in the early postoperative period, leading to a cycle of low cardiac output, pulmonary and systemic edema, further increases in PVR, acidosis, and death.

One solution was to interpose a bidirectional (Glenn) cavopulmonary anastomosis as the second stage of palliation 6–12 months before completion of the Fontan. This procedure and the related operation known as a "hemi-Fontan," directed only half of the systemic venous return through the lungs at a time when the infant's PVR had not yet fallen to normal levels. By doing so, it preserved an alternative pathway for (single) ventricular filling by the systemic venous return not routed through the lungs. This enabled the patients to maintain reasonable cardiac output, although they were a bit "blue" during the early postoperative period when the PVR was elevated by CPB. The other innovation was the "fenestrated" Fontan where a small fenestration in the atrial baffle allowed systemic venous return to bypass the lungs as a right-to-left shunt, thereby maintaining ventricular filling and systemic cardiac output during the early postoperative period of high PVR. Over time, the fenestration closed as PVR fell and shunting decreased. Alternatively, a device delivered during an interventional cardiac catheterization could close the fenestration [52]. The process of testing the applicability of the Fontan principle and its various modifications involved a great deal of collaborative work among anesthesiologists, surgeons, and cardiologists, the net result of which was that the prognosis for a patient with HLHS, and indeed for all children with SV defects, greatly improved. As these improvements spread and were amplified by work done in other centers, local improvement became national and international.

Within institutions, this multidisciplinary collaborative effort spread naturally to the cardiac catheterization laboratory. Previously, nurses sedated children, operating under the supervision of the cardiologist performing the

[c] Includes pulmonary vein stenosis repair, cardiac tumors.

catheterization procedures. In many institutions, this involved high volumes of cases sedated by specially trained nurses, while in others with smaller pediatric caseloads, the practice of using general anesthesia for children undergoing cardiac catheterizations had been routine. As pediatric cardiologists began to develop interventional procedures, the need for greater control and support of hemodynamics and respiratory function became apparent. The interventional cardiologists increasingly turned to pediatric cardiac anesthesiologists to help manage these patients while the cardiologists themselves dealt with the complex demands of carrying out interventional procedures in infants and children with CHD. As was the case with the newly devised pediatric cardiac surgical procedures, the development of interventional procedures for CHD in the cardiac catheterization laboratory posed a novel set of challenges for the pediatric cardiac anesthesiologist. Not the least of these was providing anesthesia and hemodynamic support in the dark, foreign environment of the cardiac catheterization laboratory. The introduction of increasingly complex (e.g. vessel and valve dilations, miniaturized closure devices, transcatheter valves) and hemodynamically significant procedures placed progressively greater demands on the anesthesiologists, who became more integrally involved in these procedures.

The application and expansion of interventional electrophysiology procedures in the pediatric patient population further illustrate the progressive complexity encountered by anesthesiologists. When radiofrequency ablation procedures were exclusively employed in the management of paroxysmal atrial tachycardia (PAT) in healthy teenagers with structurally normal hearts, the anesthesia care was straightforward. Now, in contrast, many of these procedures are performed in children (or adults) with complex CHD (unrepaired, repaired, or partially palliated) and varying levels of cyanosis and cardiac output.

AL Grawany

Despite these innovations, the defects encountered have remained largely the same (Table 1.1). Two notable exceptions are the decrease in PDA ligations (neonates as small as 700 gm are now candidates for catheter-based closure) and the increase in biventricular repairs that likely represent shifting treatment paradigms and changing referral patterns [53]. As Helen Taussig remarked in her paper about the global distribution of cardiac diagnoses, only surgical interventions change the numbers [54].

Emergence of new technology – imaging (TEE, MRI) and ECMO: 2000–2010

The first decade of the 21st century saw numerous changes driven by the availability of new imaging technology, including transesophageal echocardiography (TEE) and cardiac MRI. The utility of TEE in congenital heart surgery was first demonstrated in the late 1980s by several groups in Japan and the United States, including Russell and Cahalan at the University of California, San Francisco. The use of two-dimensional echocardiography, as well as three-dimensional echocardiography, improved diagnosis both within and outside the OR. Utilizing TEE to interpret the anatomy of complex CHD and to judge the adequacy of intraoperative repairs is considerably more challenging in pediatric patients with CHD than in adults with acquired heart disease. Many centers have called upon pediatric echocardiographers to make such judgments, rather than make the pediatric cardiac anesthesiologist responsible for TEE imaging as well as the management of the patient in the post-bypass period. The use of TEE has also expanded to the cardiac catheterization laboratory where it is used in parallel with fluoroscopy for device closure of septal defects and transcatheter valve placement, allowing for confirmation of the placement and location of the device [55]. It has likewise been useful in guiding the implantation of mechanical support devices, especially the ventricular assist device (VAD), confirming cannula placement and the absence of obstruction [56]. The main concerns for the anesthesiologist while using TEE remain oropharyngeal and/or esophageal trauma, airway obstruction, left atrial pressure alternation, and inadvertent extubation of the child in the middle of an operation "under the drapes."

Similarly, the emerging availability of cardiac MRI (cMRI) and its expanded use for the diagnosis and follow-up of CHD patients continue to challenge the congenital cardiac anesthesiologist. Although seen by many on the multidisciplinary care team as a simple, non-invasive procedure, cMRIs involve relatively long anesthetics in a magnetic field with limited patient access and are often performed in patients with severe, complex CHD.

The early 2000s also saw increased utilization of another technical innovation of great importance to pediatric cardiac anesthesia – extracorporeal membrane oxygenation (ECMO) (Figure 1.4). First described in pediatric cardiogenic shock (2-year-old s/p Mustard) and neonatal respiratory failure in 1974 and 1976, respectively, ECMO use increased during the early 2000s due to expanded pediatric inclusion criteria as well as increased use in children with CHD, during extracorporeal cardiopulmonary resuscitation (ECPR), during failure to wean from CPB, and a bridge to transplantation [57–62]. In the history of the development of pediatric cardiac anesthesia, we have come a long way from the baby in the ice bath being prepared for DHCA to the complex technology necessary for ECMO resuscitation.

Figure 1.4 Infant on extracorporeal membrane oxygenation in the cardiac intensive care unit.

The surgical and interventional management of CHD continues to evolve as surgeons and interventional cardiologists further develop and refine treatment approaches that cross the boundaries of traditional CHD care. Two such novel treatment modalities, intrauterine fetal cardiac catheter intervention (see Chapter 19) and the hybrid stage I Norwood palliation (see Chapter 30), were first described in humans in the early 2000s. The hybrid stage I palliation in the catheterization laboratory requires the anesthesiologist to anticipate and treat significant hemodynamic perturbations, blood loss, and arrhythmias while managing neonatal SV physiology without CPB and providing an anesthetic technique that offers the possibility of early tracheal extubation [63, 64]. Hybrid surgical procedures are increasing in the catheterization laboratory and include VSD closure, HLHS management, and percutaneous valve implantation. They require a multidisciplinary approach and the availability of cardiac interventionists, cardiac surgeons, and anesthesiologists [65].

2011–2021 and the future

With the understanding that certain cardiac lesions are progressive in nature, prenatal intervention is believed to halt the process *in utero* and improve the postnatal outcome of these patients. Since the initiation of fetal cardiac interventions, the number of these procedures has been increasing and includes valvuloplasty of the aortic and

pulmonary valve, balloon atrial septostomy for restrictive or intact interatrial septum in cases of HLHS and TGA, and fetal pacing in complete heart block. Improving delivery of oxygenated blood to the brain *in utero* may affect neurodevelopmental outcomes of patients with congenital disease – an area of interest and research [66, 67]. Pediatric cardiac anesthesiologists have an integral role in planning for and carrying out these procedures. Fetal cardiac intervention for aortic valve stenosis or HLHS with intact atrial septum requires the anesthesia team(s) to provide anesthesia for the pregnant mother and the fetus with the fetus monitored by ultrasound throughout [68]. The success of the intrauterine procedures potentially allows for the growth of the hypoplastic ventricle such that a biventricular repair is possible during infancy. Although the reported success of these procedures is promising, the number of cases and series published is small and does not allow us to conclude superiority over neonatal surgeries or to discuss long-term outcomes at this time [69, 70]. Studies comparing anesthetic techniques are likewise limited with most having been done in animal models. Prospective clinical trials in human fetuses would have multiple limitations, including the limited number and type of procedures, their associated complications, the maternal condition, and the lack of time to assess the fetal outcomes during the procedure itself [71].

In the past decade, extracorporeal life support (ECLS) has also evolved. Although ECMO remains the most widely used type of ELCS across centers, additional ventricular support devices have been introduced as a bridge to transplant, leading to an increase in the number of patients listed for pediatric cardiac transplant [72]. The EXCOR® pediatric VAD (Berlin Heart GmbH, The Woodlands, TX, United States) was approved by the US Food and Drug Administration in December 2011. A database study from 2007 to 2011 (the date of approval of the device) compared the 1-year post-transplant survival between patients who underwent heart transplant without VAD support and those who were bridged with EXCOR to transplant; it showed that the pediatric patients supported with EXCOR have similar survival rates to Open Procurement and Transplantation Network status 1A patients supported on either inotropes or ventilator [73]. Pre-transplant mechanical support with a VAD has been shown to offer a post-transplant survival advantage when compared to support with ECMO [74]. Children with ECLS awaiting cardiac transplantation may present for multiple procedures while awaiting transplantation. Periprocedural challenges include perioperative anticoagulation management, appropriate monitoring, and the maintenance of hemodynamic stability [75–77]. It is imperative that the care team is familiar with the device, the patient's settings, and how the adjustment of the settings affects hemodynamics. A team approach, including a surgeon, intensivist, anesthesiologist, and mechanical support team, is of the utmost importance.

As survival has dramatically improved over the years, attention has gradually shifted from the reduction of mortality to the reduction of perioperative and long-term morbidity. Recent concerns about the effect of anesthetic agents on the developing brain have prompted extensive efforts to study the magnitude and mechanism of the effect as well as whether alternative agents or protective strategies are warranted [78]. Neonatal cardiac surgery occurs at a particularly vulnerable age and exposes the patient to a number of potentially injurious factors including cyanosis, CPB, inflammation, low cardiac output, and/or mechanical support devices. The neurodevelopmental outcome was found impaired in approximately one-third of children who underwent surgery at a neonatal age [79]. It has been shown that 23–40% of neonates presenting with a complex cardiac defect show evidence of cerebral injury on preoperative MRI [80–84]. Postoperatively, 36–73% of patients have evidence of new cerebral lesions on MRI [80–86]. Cardiac anesthesiologists may play a key role in the minimization of perioperative neurologic injury and have been involved in research to identify risk factors and ameliorate their deleterious effects on neurodevelopmental outcomes [87–89]. The American Heart Association/American Academy of Pediatrics guidelines on the evaluation and management of neurodevelopmental outcomes in children with CHD now identify brain biomarkers and EEG measurements that could be useful in managing patients during the perioperative period [90, 91].

Quality improvement and perioperative cost reduction have also come under the purview of the congenital cardiac anesthesiologist, providing new challenges and opportunities for the current generation of anesthesiologists. The development and adoption of Enhanced Recovery After Surgery (ERAS) protocols for cardiac surgery, and more specifically, for pediatric cardiac surgery, have generated a great deal of interest in recent years [92]. These protocols generally include minimization of *nil per os* (NPO) time, incorporation of multimodal analgesia regimens, and clinical optimization for early extubation, mobilization, and ICU discharge. Such changes in care have associated risks that will require careful, ongoing assessment considering the advantages achieved with postoperative ventilation and sedation. For example, the incidence of arrhythmias and cardiac arrest following endotracheal suctioning in the ICU postoperatively was greatly diminished with the use of heavy sedation with fentanyl that prevented major swings in PA pressure [93, 94]. Careful selection of patients for early extubation and judicious use of shorter-acting anesthetic agents may allow lengths of stay to be shortened without increasing risks. Other advances, such as limiting the total dose of anesthetic agents by developing ways to monitor the depth of anesthesia, so as to give sufficient doses to prevent awareness but still attenuate the stress response to CPB, are being explored, but remain elusive [95].

In recent years, there has been an increasing call for the regionalization of CHD care, both in the United States and around the world [96, 97]. CHD care within the United States is highly fragmented and there exists a high degree of variability in staffing, program structure, care processes, case volumes, and outcomes. At present, within the United States, there is no national mandate for the regionalization of pediatric cardiac care. A regionalization simulation by Welke et al. suggested that the consolidation of care from 153 hospitals with varying case volumes to 37 hospitals with case volumes

AL Grawany

of >300 cases/year would increase mean travel distance by 31 miles, but lead to a decrease of 263 deaths, 124,602 hospital days, and 1,504 major complications over a 4-year period [98]. Challenges such as changes to staffing, revenue generation considerations, effects on post-graduate medical education, and care coordination will have to be better understood before regionalization could become a viable tool for quality improvement.

Another area of growing interest is the development of cross-center collaboration in order to share data and expertise so as to help establish best practices, reduce practice variation, and shift the mean toward better outcomes. Numerous organizations, consortiums, and collaboratives [Society of Thoracic Surgeons (STS), Pediatric Cardiac Critical Care Consortium (PC^4), Congenital Cardiac Anesthesia Society (CCAS), Pediatric Acute Care Cardiology Collaborative (PAC^3), the American College of Cardiology's IMPACT Registry®, National Pediatric Cardiology – Quality Improvement Collaborative (NPC-QIC), Pediatric Interagency Registry for Mechanical Circulatory Support (Pedimacs), Extracorporeal Life Support Organization (ELSO), Pediatric Heart Transplant Society (PHTS), Cardiac Neurodevelopmental Outcome Collaborative (CNOC), Advanced Cardiac Therapies Improving Outcomes Network (ACTION)] have been established to maintain multicenter registries of pediatric cardiovascular data. Collaborative projects have the potential to lead to profound improvements in outcomes as well as reduced costs. Since 2010, the CCAS has maintained an anesthesia database, and currently, more than 60 centers submit anesthetic data, and there are more than 100,000 anesthetics represented in the data. Together with the 120 centers submitting surgical data, this collaborative approach has led to publications about airway management and extubation practices, dexmedetomidine usage, bleeding and thrombosis, and vascular access practices [99–104]. Benchmarking by individual centers in comparison to all contributing centers for adverse outcomes is also made possible by this collaboration as a quality and outcomes tool.

Congenital heart disease – a growing specialty from the fetus to the adult patient

Tempora mutantur et nos in illis – "Time changes and we develop with time." It has been over 80 years since Robert Gross first ligated a PDA and we have seen amazing developments in the treatment of CHD. Indeed today, surgical ligation of PDAs is increasingly uncommon as devices and approaches for percutaneous PDA occlusion have developed even for the smallest premature infants [105]. Concomitantly, anesthesiology has evolved and slowly defined pediatric anesthesia, and then cardiac anesthesia, and now, in the past two decades, pediatric cardiac anesthesia has developed as a distinct and separate area of subspecialization. Freisen documents the landmark publications from the 1930s to 2010s that have documented and disseminated the new knowledge that has continuously advanced the field [106].

In 2005, the Congenital Cardiac Anesthesia Society (CCAS; www.pedsanesthesia.org/ccas) in the United States was formed and now has more than 1,300 members. It provides a forum for subspecialized educational meetings, a national database of congenital cardiac anesthesia cases (see Chapter 3), and recommends standards for training. Starting in 2010, leaders of the CCAS proposed a curriculum for a 12-month fellowship in pediatric cardiac anesthesia, defined case numbers in 2012, in 2014 further refined the curriculum, and in 2018 proposed a detailed set of milestones for training in the field [107–109]. These efforts culminated in the recognition of the postgraduate training in pediatric cardiac anesthesia by the Accreditation Council for Graduate Medical Education in the United States in 2021 [110] (see Chapter 2). CCAS is a society organized within the larger Society for Pediatric Anesthesia, indicating that this specialty has chosen to align itself more closely with pediatric anesthesiology than with adult cardiac anesthesiology, although there are important common interests and principles in all three of these specialties caring for patients with CHD.

As part of the trend of increasing long-term survival, the patient care group growing most rapidly at most centers is the adult with CHD. The prevalence of adults in the year 2000 was 49% of patients with CHD [111]. This is the somewhat unexpected result as care in childhood improves and more and more of these patients survive to adulthood and even into old age. At many institutions, special programs have been created to treat these patients and the problems they face. These problems include complications, reoperations, and socioeconomic barriers to normal education, employment, and the creation of families. The question of pregnancy and anesthetic management of delivery for these patients is also evolving. It is unclear who is most qualified to provide anesthesia for such patients during labor and delivery. But suddenly the pediatric cardiac anesthesiologist may find themselves having to care for adults [112–114] (see Chapter 20).

Although there has been much progress in pediatric cardiac anesthesia in providing safe anesthetic care and improving the outcome of treatment of CHD in the OR and catheterization laboratory for patients of all ages, much remains to be done. One can say with certainty that the intimate connection between advances in therapy, surgical or medical, and the anesthesia support services required to make those therapeutic advances possible will continue to present new challenges to the pediatric cardiac anesthesiologist (Figure 1.5). The pediatric cardiac anesthesiologists will, in turn, meet those challenges and in the process find ways to make yet more improvements. Thus, we progress in our art and science.

Acknowledgments

We would like to acknowledge Dolly D. Hansen MD and Paul A. Hickey MD for their excellent contributions to previous editions of this chapter as well as for their enormous contributions to the field of congenital cardiac anesthesiology.

Introduction

Pediatric cardiac anesthesiology has developed as a sub-subspecialty of anesthesiology over the past 50 years. It has been practiced since the first patent ductus arteriosus (PDA) was ligated by the cardiac surgeon Dr. Robert Gross in 1938. Initially, in the 1970s and 1980s, anesthesiologists interested in practicing pediatric cardiac anesthesia would spend additional months during residency training or as a staff member gaining experience in anesthesia care for these patients, the apprenticeship model. With further advances in surgical and catheter-based interventions and technologies in patients with congenital heart disease (CHD), pediatric cardiac anesthesiology has evolved in parallel with pediatric cardiac surgery and pediatric cardiology as a distinct field. The evolution of this specialty has led to the establishment in 2005 of a dedicated professional society, the Congenital Cardiac Anesthesia Society (CCAS).

Before the advent of CCAS, there were very few resources in terms of providing training and experience in the specific field of pediatric cardiac anesthesia. The board of directors along with other pediatric anesthesiologists addressed the lack of training criteria in congenital cardiac anesthesia and have developed the resources that we have today culminated in recognition by ACGME [1].

Why teach and learn congenital cardiac anesthesia?

Pediatric cardiac anesthesiology encompasses the care of neonates, infants, children, and adults with CHD and pediatric patients with acquired heart disease. Initially, practitioners interested in the field used to spend varying amounts of additional training time during their anesthesiology residency or as faculty members. However, the fields of congenital cardiac surgery and congenital cardiology have made significant strides which required ever-increasing advances in the anesthetic care of these patients. While the subspecialty initially grew in concert with pediatric anesthesiology and adult cardiac anesthesiology programs, pediatric cardiac anesthesiology is now a distinct field which requires a unique fund of knowledge and skillset beyond that possessed by either the pediatric anesthesiologist or adult cardiac anesthesiologist alone.

In order to successfully care for patients with CHD and pediatric patients with acquired heart disease, it is necessary to gain expertise in the perioperative care of all forms of CHD from the simple to the most complex, and the pediatric acquired heart lesions. This includes a comprehensive understanding of congenital and acquired cardiovascular anatomy and pathophysiology. In addition, mastery of patient care along the continuum of care from the preoperative planning

AL Grawany

period, through the operative procedure itself, and through the postoperative recovery must be appreciated. In light of the wide spectrum of congenital cardiovascular anomalies and each condition having unique management considerations, the pediatric cardiac anesthesiologist must be adept at developing and executing an individualized perioperative anesthetic plan. Importantly, pediatric cardiac anesthesiologists must also master complex procedural skills to care for these patients with abnormal anatomy and physiology which go beyond those used to care for the patient with a normal cardiovascular system.

Today, an estimated 40,000 live births/year in the United States are affected with CHD [2]. These patients present for cardiac and noncardiac procedures. Given the increasing demands for well-trained pediatric cardiac anesthesiologists, it is essential that a cohort of comprehensively trained practitioners of this craft be consistently produced. This is the only viable pathway to further advance the key objectives of providing improved clinical care and enhanced patient safety [3–5].

The current model

In 2010, leaders in pediatric cardiac anesthesiology in the United States recognized the need for a standardized educational approach to the training of pediatric cardiac anesthesiologists, and accordingly several program guidelines were developed [6]. In 2014, the Pediatric Anesthesia Leadership Council (PALC) in conjunction with the CCAS recognized the need for a formalized training pathway [7]. They specifically recommended that pediatric cardiac anesthesiology be an additional 12-month second-year advanced fellowship following pediatric anesthesia. This recommendation clearly recognizes that attaining skills to become a competent pediatric cardiac anesthesiologist requires training beyond a standard pediatric anesthesia fellowship. In 2018, specific training milestones required during fellowship training were established by the CCAS leadership [8].

At present, the total number of 12-month positions offered is 28. Figure 2.1A and B represent the number of programs and trainees over time. While the structure of these fellowship programs mostly follows the published guidelines as noted above, it is acknowledged by CCAS leadership, program directors, and individual pediatric cardiac anesthesiologists that central oversight of program quality is needed for educational and training consistency. Hence, as cardiology and cardiac surgery have done previously, the subspecialty has moved forward, aiming for a standardized approach to fellowship training with ACGME oversight (Figure 2.2).

Pediatric cardiac anesthesia training

Curriculum development should employ a logical, systematic approach linked to specific healthcare needs. The Kern model of curriculum development for medical education could be used to develop a curriculum to teach and learn congenital cardiothoracic anesthesia [9]. This has a six-step approach and consists of the following:

1. Problem identification and general needs assessment
2. Targeted needs assessment
3. Goals and objectives
4. Educational strategies
5. Implementation
6. Evaluation and feedback.

Problem identification and general needs assessment

This comprises identification and characterization of the healthcare problem:

- Whom does it affect?
- What does it affect?
- What is the qualitative and quantitative importance of the effects?

As detailed above, education in anesthesia for CHD covers a wide range of lesions – uncorrected, corrected, and palliative therapies. The trainee needs to be educated in all aspects of the six core competencies related to these topics.

The following points should be addressed to obtain adequate needs assessment:

- What proficiencies (cognitive, affective, and psychomotor skills) currently exist among learners?

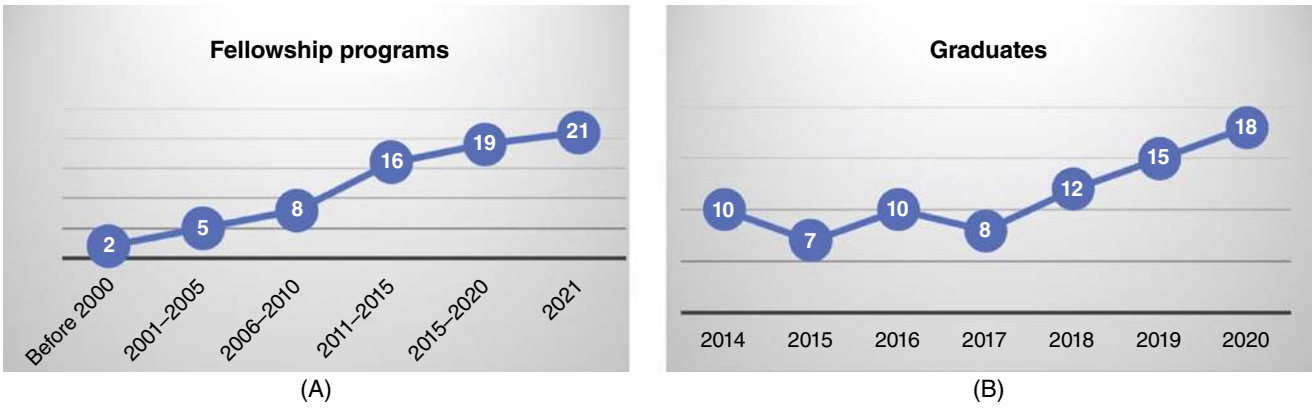

Figure 2.1 (A) Number of pediatric cardiac anesthesia programs over time; (B) number of graduating 12-month fellows per year over time.

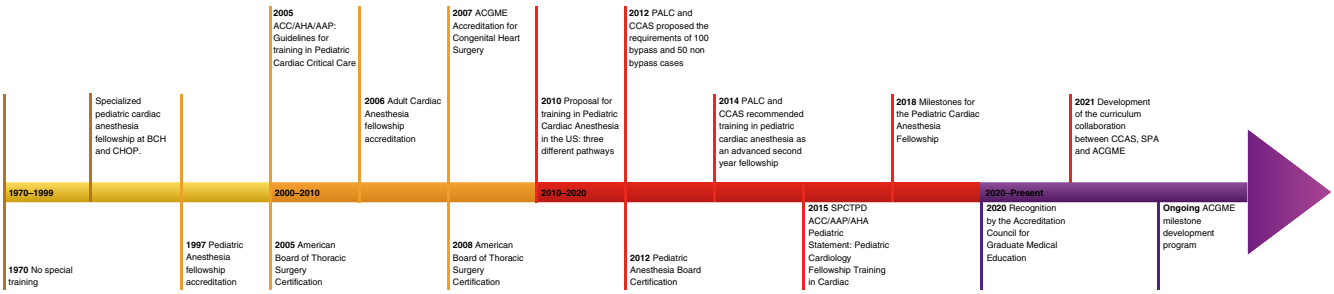

Figure 2.2 Timeline of major milestones in education and training in CHD. AAP, American Academy of Pediatrics; ACC, American College of Cardiology; ACGME, Accreditation Council for Graduate Medical Education; AHA, American Heart Association; BCH, Boston Children's Hospital; CCAS, Congenital Cardiac Anesthesia Society; CHOP, Children's Hospital of Philadelphia; PALC, Pediatric Anesthesia Leadership Council; SPA, Society for Pediatric Anesthesia; SPCTPD, Society of Pediatric Cardiology Training Program Directors; US, United States.

AL Grawany

- Previous training and experiences of fellows and residents in congenital cardiac anesthesia
- Current training and experiences already planned for trainees
- Resources available to learners (patients and clinical experiences, information resources, computers, audiovisual equipment, role models, teachers, mentors)
- Perceived deficiencies and learning needs
- Characteristics of the learners and barriers to learning and teaching.

The current state of the pediatric cardiac anesthesia training in CHD was most recently characterized in an email survey performed in 2019 addressed to program directors (n = 19). The number of pediatric cardiac anesthesia programs in the United States offering pediatric cardiac anesthesiology training has continually grown from 2 in 2000 to 8 in 2010 and to 19 in 2020 (Figure 2.1A). Similarly, the number of 12-month fellows graduating each year has increased (Figure 2.1B).

Following graduation, the majority of trainees (75%) work either exclusively as a pediatric cardiac anesthesiologist or divide their time as a general pediatric anesthesiologist and as a pediatric cardiac anesthesiologist. Seven percent work in combined pediatric cardiac and adult cardiac anesthesia programs. The remaining 15% work in a combination of anesthesia and critical care, adult cardiac anesthesia, or other settings.

Targeted needs assessment

For the needs assessment to be an accurate reflection of what is required, it must involve the current trainees (learners) in pediatric cardiac anesthesia. Attempts should be made to assess the current strengths and weaknesses in knowledge, skills, and performance [10]. The environment in which education is currently happening needs to be evaluated as well. Is the operating room (OR) conducive to the education of some of the complex physiology or should the initial education happen in a simulated environment where the stress level of all concerned is much lower? It is vital that all the stakeholders (trainees, program directors, cardiologists, intensivists, and pediatric cardiac surgeons) are involved in the development at an early stage. Barriers and reinforcing factors that affect learning should be identified early on. Faculty development programs may be necessary to improve the quality of teaching and education in congenital cardiac anesthesia. Needs assessment should also include what resources are currently available to the trainees to facilitate learning in congenital cardiac anesthesia.

There is a dedicated body of science, knowledge, and skills related to the unique field of pediatric cardiac anesthesiology. There are chapters on the practice of pediatric cardiac anesthesia in every major anesthesia textbook, every major pediatric anesthesia textbook, and in several major cardiac surgical and pediatric interventional catheterization/electrophysiology textbooks. More importantly, there are numerous textbooks devoted entirely to the practice of pediatric cardiac anesthesia. In addition to textbooks and journals, dedicated pediatric cardiac anesthesia faculty at all the different respective programs constitute a body of knowledge and a source of education for the fellows in the field.

The case mix in the training programs, multidisciplinary faculty educators, and access to online journals and educational materials, including the availability of audiovisual equipment, are vital to the success of curricular delivery. The value of the hidden and informal curriculum that is currently in place should not be underestimated.

Goals and objectives

Goals and objectives must, by necessity, be specific and measurable. They should measure the knowledge (cognitive), attitude (affective), and competence (psychomotor) of the learners. The goals and objectives are currently being developed by a task force which is comprised of ACGME leadership, a pediatric anesthesiologist, an adult cardiac anesthesiologist, and representative from the Society for Pediatric Anesthesia and CCAS. The goals and objectives should reflect the relationship of the educational process to the degree of participation of the learners, as well as the faculty response to the developed curriculum. To achieve goals, the program must be structured to ensure optimal patient care while providing trainees with the opportunity to develop skills in clinical care, judgment, teaching, and research. Consideration should be given to the use of learning goal-scoring rubrics. Meyerson et al. performed needs assessment for an errors-based curriculum on thoracoscopic lobectomy and structured the curriculum based on their observations using a standardized checklist [11].

The following goals and objectives are valuable in the OR to achieve competency in congenital cardiac anesthesia:

- The subspecialist in congenital cardiac anesthesiology should be proficient in providing anesthesia care for both pediatric and adult patients undergoing congenital cardiac and vascular surgery as well as anesthesia for non-cardiac surgery.
- The subspecialist should demonstrate and conduct a preoperative patient evaluation; and demonstrate the ability to interpret imaging, cardiovascular, and pulmonary diagnostic test data.
- The subspecialist should be able to evaluate and understand the anesthetic management of patients undergoing non-operative diagnostic and interventional cardiac, thoracic, and electrophysiological procedures. Examples include angiography, arrhythmia mapping and ablation, stent placements, and device closures.
- The clinical curriculum should include competency and demonstrate cognitive proficiency in the management of cardiopulmonary bypass (CPB), pharmacological and mechanical hemodynamic support as well as extracorporeal circulation.
- The subspecialist should be able to create a plan for postoperative critical care, including ventilatory support, extracorporeal circulatory support, and pharmacologic hemodynamic support, as well as understand the implications of pain management.
- The subspecialist should demonstrate effective communication skills in obtaining informed consent from families, discussing any complications that may have occurred as well as providing consultations as and when necessary.
- The subspecialist should demonstrate skills in preparing materials and presenting at multidisciplinary conferences to allied health professionals.

- The subspecialist must demonstrate professionalism in the work environment as evidenced by the ability to show compassionate care to the patient and their diverse needs, respecting other providers, as well as complying with program, department, and institutional policies and procedures.
- The subspecialist should understand the value of multidisciplinary teams, be able to evaluate errors, and find solutions, thereby enhancing patient safety and improving outcomes for their patients.

The didactic curriculum provided through lectures, conferences, and workshops should supplement clinical experience as necessary for the fellow to acquire the knowledge to care for cardiothoracic patients with CHD and conditions outlined in the guidelines for the minimum clinical experience for each fellow. The didactic components should include the areas in the following list, with an emphasis on how cardiothoracic diseases affect the administration of anesthesia and life support to cardiothoracic patients with CHD.

These represent guidelines for the minimum didactic experience for each fellow:

- Embryological and morphological development of the cardiothoracic structures; nomenclature of CHD
- Pathophysiology, pharmacology, and clinical management of patients with all adult and pediatric CHD, including single ventricle lesions, septal defects, defects of semilunar and atrioventricular valves, left- and right-sided obstructive lesions, transposition of the great vessels, defects of systemic and pulmonary venous return, cardiomyopathies, vascular rings, and tracheal lesions
- Pathophysiology, pharmacology, and clinical management of patients requiring heart, lung, and heart-lung transplantation, including immunosuppressant regimes and selection criteria
- Non-invasive cardiovascular evaluation: electrocardiography, echocardiography, cardiovascular computed tomography (CT), and magnetic resonance imaging (MRI)
- Cardiac catheterization procedures and diagnostic interpretation; invasive cardiac catheterization procedures, including balloon dilatations and stent placement; device closure of septal defects, PDA and baffle leaks, and arrhythmia ablation
- Pre-anesthetic evaluation and preparation of pediatric and adult cardiothoracic patients
- Pharmacokinetics and pharmacodynamics of medications prescribed for medical management of pediatric and adult cardiothoracic patients
- Peri-anesthetic monitoring methods, both non-invasive and invasive, including use of ultrasound guidance: intra-arterial, central venous, mixed venous saturation, cardiac output determination, transesophageal and epicardial echocardiography, neurological monitoring, including near-infrared cerebral oximetry, transcranial Doppler, and processed electroencephalograms
- Pharmacokinetics and pharmacodynamics of anesthetic medications prescribed for cardiothoracic patients. Pharmacokinetics and pharmacodynamics of medications prescribed for the management of hemodynamic instability: inotropes, chronotropes, vasoconstrictors, vasodilators
- Extracorporeal circulation (including CPB, low-flow CPB, deep hypothermic circulatory arrest, antegrade cerebral perfusion, extracorporeal membrane oxygenation (ECMO)), myocardial preservation, effects of extracorporeal circulation on pharmacokinetics and pharmacodynamics, cardiothoracic, respiratory, neurological, metabolic, endocrine, hematological, renal, and thermoregulatory effects of extracorporeal circulation and coagulation/anticoagulation before, during, and after extracorporeal circulation
- Circulatory-assist devices: left and right ventricular assist devices and biventricular assist devices
- Pacemaker and automated internal cardiac defibrillator (AICD) insertion and modes of action
- Perioperative ventilator management: intraoperative anesthetic and critical care unit ventilators and techniques
- Postanesthetic critical care of pediatric cardiothoracic surgical patients
- Pain management of pediatric and adult cardiothoracic surgical patients. Post-anesthetic critical care of pediatric and adult cardiothoracic surgical patients
- Research methodology and statistical analysis
- Quality assurance and improvement
- Ethical and legal issues
- Practice management

What is the minimum level of anesthesia training required?

- Subspecialty training in congenital cardiac anesthesiology should begin after satisfactory completion of a residency program in anesthesiology accredited by the ACGME or other training judged suitable by the program director and
- Trainees should complete an ACGME-accredited pediatric anesthesia fellowship of 12 months' duration after anesthesia residency.
- Alternatively, the trainees could enter the training following completion of an ACGME-accredited adult cardiac anesthesia fellowship of 12 months' duration after anesthesia residency if they have completed additional pediatric anesthesia rotations.

What are the ideal duration, case quantity, and scope of training?

The following represent suggested cases for the minimum clinical scope and duration of training:

- Nine months of clinical anesthesia activity caring for patients with congenital cardiac problems in the OR, the cardiac catheterization laboratory, and other locations.
- This experience should include a minimum of 100 anesthetic procedures, the majority of which must require CPB. At least 50 of these patients should be infants from birth to 1 year of age and should include at least 25 neonates (≤1 month of age). The trainee should also care for at least 25 adults (≥18 years of age).
- This experience should also include a minimum of 50 patients undergoing diagnostic procedures (cardiac catheterization, echocardiography, MRI, etc.), as well as

AL Grawany

therapeutic procedures in the catheterization laboratory (arrhythmia ablation, pacemaker insertion, septal defect closure, and valve dilatation, etc.)
- Suggested case numbers for specific lesions are described in Table 2.1 [12]
- Adequate experience should be obtained in the preoperative evaluation of pediatric and adult cardiothoracic patients.
- The fellow should understand how to use information from diagnostic studies and how to recognize when additional studies and/or consultations are indicated.

It is important to note that formal guidelines and case numbers are currently being developed by the ACGME task force. They will be available by end of 2021.

Table 2.1 Suggested case numbers for Anesthetic Management of Surgical Repairs and Diagnostic and Interventional Procedures

Surgical cases bypass	**Case numbers**
Hypoplastic left heart syndrome	3
Transposition of great arteries	3
Total anomalous pulmonary venous return	1
Common atrioventricular canal	6
Tetralogy of Fallot	5
Ventricular/atrial septal defect	10
Bidirectional Glenn	5
Fontan	4
Left ventricular assist device	1
Right-sided valvular lesions	15
Left-sided valvular lesions	15
Heart/lung transplant	2
Interrupted aortic arch	1
Truncus arteriosus	1
Surgical cases without bypass	**Case numbers**
Blalock-Taussig shunt	3
Aortic coarctation	3
Patent ductus arteriosus	3
Vascular ring	2
Diagnostic and interventional (catheterization laboratory and imaging)	**Case numbers**
Hemodynamic catheterizations	20
Pulmonary artery dilations	7
Pulmonary vein dilations	5
Endomyocardial biopsy	5
Transcatheter valve placement	2
Device closure (atrial septal defect/ventricular septal defect/PDA)	2
Emergency cath cases (neonatal AS or PS, balloon atrial septostomy, stenting of Blalock-Taussig/Sano shunts)	3
Electrophysiology studies	10
Cardiac magnetic resonance imaging/chest tomography	2
Sedated transthoracic or transesophageal echocardiography	5
Cases with extracorporeal support (extracorporeal membrane oxygenation)	2

Relationship to other anesthesiology programs

The congenital cardiac anesthesiology program should function in direct association with one of the following ACGME-accredited programs, preferably within the same institution: core anesthesiology, adult cardiothoracic anesthesiology, or pediatric anesthesiology. A congenital cardiac anesthesiology program may be conducted in either a general hospital or a children's hospital. The division of responsibilities between trainees in the core anesthesiology program and an associated fellowship program(s) in adult cardiothoracic anesthesiology and/or pediatric anesthesiology must be clearly delineated. The presence of congenital cardiac anesthesiology fellows must not compromise the clinical experience and number of cases available to pediatric anesthesiology fellows and/or core anesthesiology residents. There must be close cooperation between the core anesthesiology program, the adult cardiothoracic anesthesiology program and/or the pediatric anesthesiology program, and the congenital cardiac anesthesiology program.

Educational strategies

Educational strategies involve the content of materials to be delivered in the setting of the curriculum as well as the instructional methodology to be used to deliver the content. It will be beneficial to have the fellows involved in the planning of the educational activity. Consideration should be given to forming a committee of responsible faculty members to ensure that the best possible content is delivered.

Content of the curriculum

The driving force here is the learning objectives that have been created in the goals and objectives section. The program director should consider the development of a syllabus that includes learning objectives for the lectures, locations of the lectures, any readings that may have to be completed prior to arrival at the educational activity as well as additional resources for the educational activity. All of this information could be made available on a departmental intranet so the fellows have access to it at all times of the day (example: Open Pediatrics; https://www.openpediatrics.org).

Educational methodology

To thrive in today's technologically complex and information-laden clinical environment, pediatric cardiac anesthesiology trainees must become self-directed learners who are able to engage in self-reflection and assessment of their learning needs. To facilitate self-directed learning, program directors and trainees should work together to develop individualized educational plans, learning contracts, and milestone timelines. Here is a list of suggested educational strategies that may be used to address the cognitive, affective, and psychomotor objectives of the curriculum:
- Strategies for achieving cognitive objectives
  - Readings
  - Lectures or large group interactive discussions
  - Audiovisual materials

- Small group discussions
- Self-study modules or web-based learning materials
- Online discussion forums
- Podcasts or streaming video
- Fellow-led didactic sessions
- Systematic reading of stored transesophageal echocardiogram (TEE) clips, if included in the curriculum

- Strategies for achieving objectives effectively
  - Exposure to, and discussion of, challenging clinical and ethical situations
  - Simulated-learning and cross-training experiences with facilitated debriefing to gain experience in leadership, communication, task delegation, and team development skills
  - Facilitation and modeling of openness, introspection, and reflection through the establishment of a safe learning environment
  - Observation of role models, and serving as a role model for anesthesiology residents
  - Standardized patients and role plays
- Strategies for achieving psychomotor objectives
  - Regular supervised clinical experiences with feedback
  - Simulations: partial task trainers, full-body manikins, virtual reality simulators
  - Audiovisual reviews of skills
  - Expert-derived checklists of procedural competence.

In the digital age, there are several tools available to deliver content to the learners. However, all the different methods available may not be suitable for the various objectives to be achieved. The use of self-directed readings, lectures, programmed learning, small group discussions, problem-based discussions, and learning projects is helpful to advance cognitive knowledge. Team-based training, problem-based learning, and participation in learning projects all help to cultivate problem-solving skills. However, to teach some of the affective objectives, reflective exercises, discussions, and observing role models in the OR may be helpful. To teach skills or competency objectives, the trainee may be taught using simulations, using standardized patients, supervised clinical experiences, artificial models, and role playing. All these methods of teaching have pros and cons. They have to be adapted for each individual program and only serve as a guide for program directors. The ideal methodology will encourage active learning, provide immediate feedback to the trainee, promote learning from experience, provide a safe learning environment, facilitate learning of higher cognitive objectives, and promote trainee motivation and responsibility. The utilization of low-cost and less resource-heavy methodologies is also more likely to succeed. Consideration should be given to faculty development if new instructional methodologies are to be utilized.

Conferences should be regularly attended by the trainee, including lectures, interactive conferences, hands-on workshops, morbidity and mortality conferences, cardiac catheterization conferences, echocardiography conferences, cardiothoracic surgery case review conferences, journal reviews, and research seminars. While the faculty members should be the leaders of the majority of the sessions, active participation by the fellow in the planning and production of these conferences is essential. Attendance at multidisciplinary conferences, especially in cardiovascular medicine, pulmonary medicine, cardiothoracic surgery, vascular surgery, and pediatrics relevant to cardiothoracic anesthesiology, should be encouraged. Provision of an opportunity for fellows to participate in research or other scholarly activities is vital to the success of the educational strategies employed. The fellows must be encouraged to complete a minimum of one academic assignment. Projects may include grand rounds presentations, preparation and publication of review articles, book chapters, and manuals for teaching or clinical practice, clinical research investigation, or similar scholarly activities. A faculty supervisor must oversee each project.

In the context of practice-based learning and improvement, trainees should be encouraged to participate in audits of their own patient care and be involved in critical appraisal of clinical practices and the literature. Trainees should be encouraged to develop learning portfolios as well as to create a learning plan for themselves. Learner-driven teaching methodologies are likely to be more successful.

Congenital cardiac anesthesia lends itself nicely to education in the various aspects of systems-based practice and teamwork. Trainees should be involved with quality improvement and attend case conferences focused on cost-effectiveness, patient safety, and quality of care as part of a multidisciplinary team. *In situ* team training has been associated with improved patient outcomes in the setting of pediatric emergencies.

Explicit education in professionalism in the cardiothoracic OR should be promoted by educating the trainees using faculty role models, trainee participation in writing professionalism goals and objectives, and trainee participation in ethics rounds in the intensive care unit (ICU) as part of a multidisciplinary team.

The use of the Internet to share educational materials is becoming the norm. As the number of physicians training to be providers of anesthesia for CHD is small, this option is attractive to allow for sharing of information between programs. Interesting case discussions, sharing of echocardiographic images, and recent articles pertaining to this area could be posted on the Internet as well. The MedEdPORTAL (https://www.mededportal.org), Health Education Assets Library (HEAL) (https://mwdl.org/collections/HealthEducationAssetsLibraryHEAL.php), Open Pediatrics (https://www.openpediatrics.org), CCAS website (https://pedsanesthesia.org/partner-organizations-sections/ccas), and Multimedia Educational Resource for Learning and Online Teaching (https://www.merlot.org/merlot) are some currently available resources that could house the curricular material related to congenital cardiac anesthesia. However, given this wealth of potential educational resources, it is important to keep in mind that the learner should be physically and mentally involved in the learning process.

The use of simulation in medical education continues to grow. Simulation allows complex clinical tasks to be broken down into their parts. Simulation-based medical education can contribute considerably to improving medical care by boosting medical professionals' performance and enhancing patient safety. Many surgical specialties are looking to simulation as a method for teaching and learning as well as evaluation. There is a role for simulation in learning procedural skills, especially in the climate of decreasing clinical exposure. A recent meta-analysis of the use of simulation in

anesthesia training showed inconsistency in the measurement of non-technical skills and consistency in the (ineffective) design of debriefing [13]. More recent studies have demonstrated that adjunctive simulation-based curriculum enhances learners' management of clinical scenarios [14]. There is also evidence in the surgical literature that virtual reality training can improve OR performance. In a recent meta-analysis, a simulation-based airway management curriculum appeared superior to no intervention and non-simulation intervention for important educational outcomes. Consideration should be given to the use of a clinical skills laboratory to pre-teach some of the skills necessary in the management of a complex patient population [15]. Leaders in pediatric anesthesiology also advocate the use of a shared simulation-based curriculum to improve education opportunities for fellowship programs, especially in light of the small size of many of them [16].

Anesthesia for CHD is a high-risk, low-error tolerance field. The fundamental knowledge and skills that congenital cardiac anesthesiologists will need to master if they are to increase their capacity to attain higher levels of performance are considerable. A clinical microsystems model may prove useful to facilitate the development of this fundamental knowledge and skills using the action-learning theory and sound education principles to provide the opportunity to learn, test, and gain some degree of mastery.

Implementation

Once a curriculum has been developed, it is the role of the program director to oversee its successful implementation. Success is achieved through insightful leadership, transparency and constant communication, forethought and general administration of the program, continuous quality improvement efforts, and establishment and maintenance of a stable educational environment. The program director must possess the requisite specialty expertise and have the relevant training and/or clinical experience in providing anesthesia care for congenital cardiac surgical patients that meet or exceed that associated with completion of a 1-year congenital cardiac anesthesiology fellowship program. To implement a new curriculum, the program director must possess the necessary administrative and educational knowledge and skills to:

- Identify necessary materials and resources
- Obtain administrative and, if necessary, financial support
- Identify and recruit qualified faculty members
- Provide faculty development and teacher training
- Develop administrative mechanisms to support the curriculum
- Identify appropriate teaching space (e.g. in the OR, simulation center, or other appropriate clinical venues)
- Anticipate and address barriers.

Above all else, the program director is responsible for keeping faculty, learners, and staff informed about plans for implementing a new curriculum. Individuals who are expected to support, teach, or participate in a program must be made aware of the program's design, educational strategies, and assessment methods in order to ensure its smooth execution. The program director should also present curricular updates, especially any successes or milestones achieved, to identified stakeholders. Stakeholders are people with an interest in the program and its evaluation and may include the pediatric anesthesia department chair, cardiothoracic anesthesia division chief, anesthesia residency program director, other anesthesia subspecialty fellowship directors, funding agencies, and/or hospital administrators (e.g. the Vice President for Quality and Safety).

While the program director is responsible for overseeing the curriculum, this does not have to be done in isolation. There are a number of faculty and staff members who can provide support and advice regarding the design and teaching of a curriculum. As an added benefit, those involved at the front end of a program's design and implementation are more likely to want to participate in teaching and assessing the curriculum. A junior faculty member with expertise in congenital cardiac anesthesiology and interest in medical education may be eager to help develop and present a curriculum. Pediatric anesthesia faculty members with previous curriculum development experience as well as clinician educators committed to anesthesiology training in CHD may be recruited as educational consultants and then asked to teach in the program. Involving other faculty members in the development and implementation of a curriculum also ensures a program's continuity, stability, and sustainability.

There are several key decisions that must be made, and steps that must be taken, before implementing a congenital cardiac anesthesia curriculum. First, the program director needs to decide whether to introduce the curriculum as a pilot program, in stages or to present it in its entirety. There are arguments both for and against each approach; however, if stakeholders are wary of a new curriculum's educational benefit, it is best to introduce a pilot program in order to collect evidence of its value and then gain support for its full implementation. Recruiting faculty members and then developing them to teach in the program are further essential steps. To present a successful and sustainable curriculum, there must be a sufficient number of faculty members with documented qualifications to instruct and adequately supervise all anesthesia fellows in the program. Although the number of faculty members involved in teaching will vary, there should be at least three, and these should be equal to or greater than two full-time equivalents, including the program director. A ratio of no less than one full-time equivalent faculty member to one subspecialty fellow must be maintained. The anesthesia faculty must possess the requisite congenital cardiac anesthesia specialty expertise, competence in clinical care, and teaching abilities, as well as documented educational and administrative abilities and experience in their field. There must be evidence of active participation by qualified physicians with training and/or expertise in congenital cardiac anesthesiology beyond the requirement for completion of a core anesthesiology residency. The faculty members should have training and experience that would generally meet or exceed that associated with the completion of a 1-year congenital cardiac anesthesiology program. Faculty members in cardiology, cardiothoracic surgery, pediatrics, intensive care, and pulmonary medicine can provide teaching in multidisciplinary conferences. The responsibility for establishing and maintaining an environment of inquiry and scholarship of discovery, dissemination, and application rests with the program director and the faculty, and an active research component must be included in each program.

Equally important to recruiting qualified faculty members with the appropriate expertise and training in congenital cardiac anesthesiology is the development of their ability to teach the curriculum. It is a common error to assume that faculty members with the necessary clinical skills, knowledge and specialized expertise are also qualified to teach. They are rarely required to provide documentation of their teaching experience or evidence of teacher training, even for the most basic skills such as assessing and providing feedback to learners, leaving many ill-prepared for their teaching responsibilities. The core components of a faculty development program in training congenital cardiac anesthesiology fellows should include:

- Communication of curricular goals and objectives
- Discussion of qualities that characterize effective and respected clinical educators
- Suggestions of how to apply adult learning principles to congenital cardiac anesthesia clinical venues
- Assurance that faculty members can effectively assess trainees and provide useful feedback on their performance
- Review of best teaching practices for common educational strategies such as procedural teaching as well as large and small group facilitation skills
- Specialized training sessions to teach faculty members how to communicate and explain clinical decision-making; make teaching in the OR a priority; maintain a balance between supervision and autonomy; promote critical thinking skills; and provide clear, constructive, and developmental feedback.

Evaluation and feedback

Evaluation and feedback are essential for the continuous improvement and development of a curriculum. The purpose of evaluation in medical education is to determine if the curricular goals and objectives have been met. In addition, an evaluation can determine if the time, resources, and effort spent producing the curriculum are merited. Evaluation results can be used to identify educational outcomes, assess teaching effectiveness, determine areas of strength and needed improvement, and make decisions about the level of support necessary to sustain or further develop a curriculum. "Feedback" is defined as the provision of information regarding an individual's or program's performance to trainees, faculty, stakeholders, and accrediting agencies. While the terms "evaluation" and "assessment" are often used interchangeably when measuring both individual learner and program outcomes, it is best to distinguish between them, adopting the term "evaluation" in relation to the measurement of the curriculum, and "assessment" in relation to the measurement of learners. As learner assessment often comprises a significant portion of a program's evaluation, making this distinction will help to avoid confusion when planning and presenting results [17].

The process of curriculum evaluation and feedback

To conduct a comprehensive evaluation of a congenital cardiac anesthesiology program, multiple sources of data must be sought, which requires a systematic information collection process involving learners, faculty, other healthcare providers, and, in some cases, external evaluators. Data and information should be collected at the start of a curriculum, -its midpoint, conclusion, and subsequent to completion (e.g. 6–12 months post-fellowship). A program director's effort in collecting evaluation data at the program's mid- and end-points will be less challenging if the requisite time and effort are put into creating specific and measurable learning objectives at the start of a curriculum, and into assessing the fellows' knowledge, skills, and performance levels in congenital cardiac anesthesiology up-front. With the appropriate administrative support, a program director can institute an iterative "plan–do–check–act" methodological approach to continuous curriculum improvement. This method involves *planning* (the curriculum development steps 1 through 4 – problem identification through educational strategies); *doing* (the implementation step); *checking*, in which data are collected to determine what is going well and what needs to be improved moving forward; and *acting*, in which the program director addresses identified curricular problems by determining their causes and applying countermeasures, standardizes what is working well, and communicates decisions, new standards and improvements to be made.

Kirkpatrick [18] described four levels to focus program evaluation, which Curran and Fleet [19] later adapted for use in medical education evaluation:

- Reaction – this level of evaluation is intended to evaluate how well participants liked a program. It generally provides data concerning participants' perceptions, and satisfaction with objectives, content, instruction, delivery, and/or instructors.
- Learning outcomes – this level of evaluation involves some form of assessment of changes in skills, knowledge, or attitudes among learners; it is most commonly conducted through pre-and post-test study designs.
- Performance improvement – this level of evaluation provides information on the extent to which learning has influenced the post-learning behavior or performance of learners in their practice setting. Evaluating at this level attempts to answer the question: Are the newly acquired skills, knowledge, or attitudes being used in the everyday environment of the learner?
- Patient/health outcomes – this level of evaluation is concerned with measuring tangible results which are influenced by the performance of the learner as a result of participation in the educational activity. These tangible results can be transferred to a health perspective (e.g. improving patient health or improving efficiencies). Evaluation at this level is challenging given the variety of uncontrollable variables a learner encounters when he or she leaves an educational program.

A program director needs first to determine the intention of the curriculum evaluation as well as the audience reviewing the results in order to choose which level(s) to focus his or her time and effort on. For example, if a department chair is mostly interested in whether the fellows are better able to perform advanced TEE in the OR, then evaluation results should report on learning outcomes. If, however, the Vice President of Healthcare Quality is interested to report to the board on the reduction of anesthesia-related complications post-CHD surgery, then the focus should be on patient/health outcomes.

Learner assessment methods

With the adoption of outcomes-based training requirements in 2002, the focus of learner assessment for all residency programs has been on the ACGME's six core competencies. The goal of competency-based assessment is for trainees to meet discreet, transparent, achievable objectives at developmentally appropriate stages in training. The challenge for program directors of congenital cardiac anesthesia training programs is to ensure that the curriculum's goals and objectives match the intended competencies.

Learner assessment should be thought of in terms of formative and summative purposes. Formative assessment should be provided consistently throughout a fellowship program, as it provides trainees with feedback on their performance towards defined educational objectives. It also steers learning towards desired outcomes and can focus high-achieving learners towards more rapid skill advancement. The summative assessment determines how well learners achieved competency of specific objectives at developmentally appropriate stages in their training. These are conducted at the end of a rotation or program.

For formative and summative learner assessment to be considered reliable, performance data must be obtained from the predominant clinical units where congenital cardiac anesthesia trainees work and learn. Multidisciplinary cardiothoracic team members, including supervising anesthesiologists, surgeons, nurses, and other staff members in the OR or ICUs, should use multiple assessment methods and tools (e.g. standardized checklists, performance audits, case logs), in combination with the trainee's own self-assessment, to create a comprehensive performance appraisal system required in a competency-based training model.

Learner assessment methods can be categorized as cognitive, affective, or psychomotor appraisals. Cognitive learner assessment methods are used to determine and provide feedback about trainees' acquisition and application of biomedical, clinical, epidemiological, and social-behavioral sciences knowledge, as well as their ability to problem-solve, reason through clinical challenges, and use critical thinking skills. Methods include:

- Written or computer-interactive tests – multiple-choice, essay-type questions
- Oral examinations
- Questionnaires
- Individual interviews
- Procedural, operative, or case logs
- Chart stimulated recall
- Review of scholarly projects and research
- Observation of a fellow's ability to apply data from advanced monitoring devices.

Affective learner assessment methods are used to appraise and provided feedback about trainees' attitudes, feelings, motivations, and decisions. Methods include the following:

- Standardized patient exercises
- Questionnaires
- Written reflections and essays
- Rating and forced ranking forms
- Patient and family surveys
- Teamwork exercises
- Peer assessment of professionalism
- Case-based discussions that involve clinical uncertainty or ethical dilemmas
- Individual interviews
- Self-report of adverse events and near misses related to pediatric cardiothoracic and vascular anesthesia rotations
- Root cause analyses of medical errors or complications of patients under the fellows' care.

Psychomotor learner assessment methods are used to appraise and provide feedback on trainees' physical skills or the performance of actions. There are numerous methods to use for psychomotor assessment. Methods must be criterion-based, anchored using demonstrable behaviors, and developmentally appropriate. The most common methods are as follows:

- Simulation exercises
- Portfolios of videotapes
- Direct observation of discrete procedural skills (such as intubation or line placement)
- Objective structured clinical examinations
- Objective structured assessment of technical skills
- Mini-clinical evaluation exercise
- Clinical encounter cards
- Clinical work sampling
- Practice metrics scoring using data collected as part of routine care via an existing perioperative information management system (e.g. central line insertion and temperature management).

The assessment process for congenital cardiac anesthesia trainees should emphasize learning, inspire confidence in the trainee, enhance the trainee's ability to self-monitor, and drive the institutions toward self-assessment and curricular change when necessary. The primary endpoint should be the ability to demonstrate trainee competence in the care of their patients in accordance with the ACGME's six core competencies – patient care, medical knowledge, systems-based practice, professionalism, interpersonal and communication skills, and practice-based learning and improvement.

In 2018, the CCAS published a consensus statement for the milestones of the ACGME based on the six core competencies [8] (Table 2.2). Milestones are "specialty specific achievements that residents are expected to demonstrate at established intervals as they progress through training" [20, 21].

Program evaluation methods

Curriculum developers perform an evaluation of an educational program to make judgments about its successes and deficiencies; decide about resource allocation, administrative support, and material management; determine teaching performance; uncover influencing attitudes regarding the curriculum's educational value; pinpoint areas that are effective and that are in need of improvement, conclude whether the curriculum met its intended learning goals and objectives and should continue to be incorporated into a training program.

A core component of the program evaluation process is to conduct and collect data from formative and summative learner assessment methods. The faculty must evaluate in a timely manner the fellows whom they supervise. In addition, the fellowship program must demonstrate that it has

Table 2.2 Core competencies and milestones for the pediatric cardiac anesthesia fellowship

Six core competencies and milestones
Patient care [4]
Perioperative assessment, planning and management
Technical/Procedural Skills
Understanding cardiovascular surgical procedures
Understanding cardiac catheter-based therapeutic procedures and electrophysiologic studies
Medical knowledge [4]
Congenital and acquired cardiovascular anatomy, physiology and pathophysiology
Pharmacology
Cardiopulmonary bypass, extracorporeal circulation and circulatory assist device principles
Understanding cardiac diagnostic procedures (e.g., echocardiography, magnetic resonance imaging, cardiac catheterization, computerized tomography)
Systems-based practice [3]
Coordination of care
Incorporation of patient safety and quality improvement into clinical practice
Understanding of health care economics; cost awareness and cost-benefit analysis
Practice-based learning and improvement [2]
Self-directed learning and scholarly activity
Education of team members and other health care providers
Professionalism [3]
Commitment to institution, department and colleagues
Receiving and giving feedback
Responsibility to maintain personal, emotional, physical and mental health
Interpersonal and communications skills [2]
Communication with patients and families
Interprofessional communication and transitions of care

an effective mechanism for assessing fellow performance throughout the program and utilizes the results to improve fellow performance. At the minimum, faculty members responsible for teaching must provide a critical assessment of the six ACGME core competencies for each fellow at the end of 6 and 12 months of training. Learner assessment should include regular and timely performance feedback to fellows that includes at least semi-annual written evaluations. Such evaluations should be communicated to each fellow in a timely manner and be maintained in a record that is accessible to each fellow. The program director or designee must inform each fellow of the results of the evaluations at least every 6 months during training, advise the fellow of areas needing improvement, and document the communication. Assessments should include the fellows' fund of knowledge, clinical judgment and clinical psychomotor skills, patient management skills, and the ability to critically analyze complex clinical situations. Periodic evaluation of patient safety and teamwork is mandatory. Evidence of the congenital cardiac anesthesiology fellows' scholarly projects and research, including those pertaining to continuous quality improvement and risk management, should be reviewed and summarized by designated faculty mentors.

The program director should conduct a final evaluation for each fellow who completes the program. This evaluation must include a review of the fellow's performance during the final period of education and should verify that the fellow has demonstrated sufficient professional ability to practice competently and independently. Documentation of the congenital cardiac anesthesiology fellows' successful completion of the program as well as subsequent training or career plans should be kept up to date, as this information will help to inform future program evaluation efforts. A program director should also maintain a listing of all graduating fellows' scholarly activities as well as aggregate feedback from the ACGME's resident fellow surveys. This survey provides feedback on the duty hours, faculty supervision and instruction, fellow evaluation processes, educational content and resources, patient safety and teamwork, as well as overall reflections on the quality of the training program.

Faculty members

As part of a comprehensive curriculum evaluation effort, faculty members should be evaluated on their congenital cardiac anesthesia teaching performance and supervisory capabilities. Clinical teaching assessment instruments should produce valid and reliable results and any findings should be provided to faculty members in a clear and concise format. The faculty members should be assessed on their medical knowledge, clinical competence, teaching effectiveness, scholarly activities, and professional attributes. Lombarts et al. found that existing tools could be adapted for the systematic evaluation and support of faculty members involved in residency programs. They suggest basing faculty evaluation on qualities established by the well-known Stanford Faculty Development Program instrument. These qualities include the establishment of an effective learning climate, professional attitudes towards trainees, communication of goals, evaluation of trainees, and quality of feedback provided. Moreover, Baker's study of resident assessment of educators in anesthesiology provides data about the positive impact that trainee evaluation can have in motivating clinicians to become better teachers [22].

Overall program effectiveness

Summative program evaluation provides information on the degree to which a curriculum has met its intended objectives and at what cost. It can also document the curriculum's success in engaging and motivating its learners and faculty as well as associated subspecialty anesthesiology training programs. In addition to quantitative data, summative program evaluation may include qualitative information about educational barriers and unanticipated obstacles as well as means to streamline curriculum implementation. The results of summative program evaluations are often disseminated to stakeholders to obtain or maintain time, administrative support, funding, and other resources. The educational

AL Grawany

effectiveness of a program must be evaluated at least annually in a systematic manner.

Representative program personnel (at a minimum the program director, representative faculty, and one fellow) must be organized annually to review program goals and objectives, and the effectiveness with which they are achieved. In the evaluation process, the group must take into consideration written comments from the faculty, the most recent report of the graduate medical education committee of the sponsoring institution, and the fellows' confidential written evaluations. If deficiencies are found, the group should prepare an explicit plan of action, which should be approved by the faculty and documented in the minutes of the meeting.

The program should use fellow performance and outcome assessment in its evaluation of the educational effectiveness of the fellowship program. The performance of program graduates in the certification examination should be used as one measure of evaluating program effectiveness. The program should maintain a process for using assessment results together with results of other program evaluations to improve the fellowship program.

Curriculum maintenance and enhancement

Once a curriculum in congenital cardiac anesthesia has been developed, the next challenge is curriculum maintenance. A successful curriculum is continually developing by responding "to evaluation results and feedback, to changes in knowledge base and the material requiring mastery, to changes in resources (including faculty), to changes in its targeted learners, and to changes in institutional and societal values and needs". Areas for curricular enhancement may include a review of the written or intended curriculum, assessment of the environment/setting of the curriculum, and determination of learner assessment methods to meet new accrediting agency requirements (such as the ACGME's milestones). The following data can be collected and utilized to assess how well a curriculum is functioning:

- Program evaluation
- Learner/faculty/patient questionnaires
- Patient quality metrics
- Objective measures of learners' skills and performance
- Focus group of learners, faculty, staff, and patients
- Other systematically collected data
- Regular/periodic meetings with learners and faculty
- Special retreats and strategic planning sessions
- Site visits
- Informal observation of curricular components, learners, faculty, and staff
- Informal discussions with learners, faculty, and staff

Congenital cardiac anesthesia is a subspecialty in which there are significant interactions between anesthesiologists and cardiac surgeons, cardiologists, radiologists, and other pediatric subspecialists. Close alliance between these disciplines is vital to the growth and development of the subspecialty. Furthermore, curriculum enrichment is dependent on both intra- and inter-subspecialty collaboration as well as combined faculty development efforts.

Dissemination

There is a need for an international comprehensive curriculum in congenital cardiac anesthesia. Local adaptation of a core curriculum will be necessary to overcome technological and cultural care delivery obstacles. The following issues should be considered when considering the dissemination of core curriculum material:

- What material should be disseminated?
- How should the material be disseminated (publications, presentations, multi-institutional interest groups or academic societies, educational clearing houses, online learning systems, digital communication, instructional videotapes or audiotapes, and/or instructional computer software)?
- What resources are required (time and effort, personnel, equipment/facilities, funds)?
- How can dissemination and impact be measured?

Dissemination of a curriculum can be a valuable process, benefiting many other congenital cardiac anesthesia trainees. A coherent strategy must be determined on what should be disseminated, appropriate methods of dissemination, and the best use of limited time and administrative resources.

Role of professional societies

At present, the CCAS, in conjunction with the Society for Pediatric Anesthesia (SPA), has taken the lead in developing a core curriculum for fellowship training in congenital cardiac anesthesia. Collaboration with the ACGME and Residency Review Committee (RRC) is ongoing as the subspecialty matures to the point where it becomes a board-certifiable specialty in its own right. As many children with CHD survive to adulthood and develop the adult cardiothoracic disease, the American Heart Association as well as the American College of Cardiology may be able to provide significant input into developing a holistic approach to the care of this complex patient population. A significant proportion will go on to become pregnant, and hence, both the American College of Obstetricians and the Society for Obstetric Anesthesia and Perinatology will need to contribute to the development of a curriculum.

Conclusion

Developing durable new curricula will be challenging in the highly specialized area of congenital cardiac anesthesia. The use of a systematic approach to its development will facilitate efficient teaching and learning in this complex discipline. It is important to develop programs that give faculty members the necessary skills to develop curricula and that provide mentoring. Collaboration with ACGME for the development of the program requirements and the Milestones development program is ongoing. Finally, the challenge of transitioning trainees from fellow (learner) to the faculty member (provider and teacher) in congenital cardiac anesthesia will continue. The trainees should be encouraged to create a learning portfolio, preferably web-based, that is a record of participation and achievement, career goals and professional development, physical evidence, and reflective writing.

Acknowledgments

We would like to acknowledge Sugantha Sundar MD, Lori Newman, MD, PhD, and James A. DiNardo, MD for their contributions to previous editions of this chapter.

Introduction

Patient safety in the operating room (OR) and beyond has long been a driving force in anesthesia care. Technical innovations such as pulse oximetry and capnography, combined with better trainee and practitioner education have dramatically increased safety for our patients and the quality of our anesthesia care. Additionally, newer medications, technologies, and monitoring modalities continue to advance the field. As a result of these systematic changes, anesthesia-related patient morbidity and mortality have steadily declined across all patient populations. Non-technical attempts to reduce perioperative complications such as perioperative time-outs and checklists have become another major focus of various organizations such as the World Health Organization (WHO) and the Joint Commission, formerly the Joint Commission for the Accreditation of Hospital Organizations (JCAHO).

Efforts to delineate the frequency of complications related to anesthesia in patients undergoing congenital cardiac surgery and procedures in the cardiac catheterization laboratory and elsewhere have been difficult. This is due to the relatively low frequency of this surgery compared with other surgeries on children and the uncommon incidence of anesthesia-related complications today. Busy cardiac anesthesia services at major North American pediatric institutions will each have contact with 2,000–3,000 congenital cardiac patients/year, and the majority of these cases are non-surgical, such as diagnostic and therapeutic catheterizations and radiology procedures. The recognition of the need to systematically quantify and study outcomes in pediatric cardiac surgery, anesthesiology, cardiac critical care, and cardiology has led to the development of a variety of multi-institutional and multinational efforts to systematically document and study this population.

Educational content reviewed by this chapter will include: (i) A discussion of errors and outcomes in surgery and anesthesia, emphasizing communication and teamwork; (ii) A discussion of systems for prospective risk assessment in pediatric cardiac surgery; (iii) An analysis of closed malpractice claims in anesthesia focusing on pediatric cardiac anesthesia, morbidity, and mortality; and (iv) Database initiatives in congenital cardiac anesthesia, surgery, and interventional catheterization.

Errors and outcomes in surgery and anesthesia

The perioperative management of patients with congenital heart disease (CHD) is fraught and there are occasions when even small decision-making errors can have catastrophic outcomes. James Reason has popularly described the "Swiss cheese model" for evaluating patient complications due to

Anesthesia for Congenital Heart Disease, Fourth Edition. Edited by Dean B. Andropoulos, Emad B. Mossad, and Erin A. Gottlieb.
© 2023 John Wiley & Sons Ltd. Published 2023 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/andropoulos/congenitalheart

human errors [1]. For a complication to occur, all the "holes" in the cheese have to line up – that is, there is a sequential failure of various defense mechanisms in place to prevent, recognize, and/or treat unwanted physiologic changes (Figure 3.1). Many "anesthesia" complications are multifactorial in origin, and it can be difficult to assign the relative contributions of different clinical services. For example, failure to successfully separate from cardiopulmonary bypass may be due to issues such as technical difficulty (surgery and perfusion), residual lesions or bleeding (surgery), inotrope management or mistaken infusion pump programming (anesthesia and surgery), ventilator management (anesthesia), or underlying patient physiology such as intractable pulmonary hypertension (patient). These system factors are further exacerbated if there are communication difficulties between the various parties, including surgeons, anesthesiologists, perfusionists, cardiologists, and the pre- and postoperative medical and nursing teams [2].

In a landmark study, de Leval and colleagues investigated the impact of human factors and teams on surgical outcomes in congenital cardiac patients, focusing on the neonatal arterial switch operation (ASO) as the prototype for complex, high-risk surgery [3]. Patient and procedural data were collected on 243 operations performed by 21 cardiac surgeons in the United Kingdom in 16 centers over 18 months. Of these 243 patients, case study data were collected on 173 ASOs by two human factors researchers who followed each case from the time of induction of anesthesia until care was transferred to the intensive care team. The observed adverse events were subsequently divided into major and minor events depending on their impact on the safety of the patient. Analyses determined that, after adjustment for patient factors, the total number of minor and major events per case were both strong predictors of the probability of major morbidity or death or "near-misses" ($P < 0.001$). The authors concluded that minor events go largely unnoticed by the OR team and are therefore left uncompensated. A subsequent examination of the same data suggests that minor events impede the OR team's ability to compensate for future major events [4]. This investigation only included perioperative care and did not begin to address patient care prior to surgery or after handoff to the intensive care team, which would have added even more events into the calculations.

In addition to the organizational factors, pediatric cardiac surgery procedures have a low error tolerance. The Bristol Royal Infirmary Inquiry and the Manitoba Inquiry reports both recognized the importance of human factors and systems research in improving pediatric cardiac surgical outcomes [5, 6]. The report of the Manitoba Pediatric Cardiac Surgery Inquest found that "serious organizational and personnel problems experienced by the Health Sciences Center's Pediatric Cardiac Surgery Program during 1993 and throughout 1994 contributed to the deaths of these children."

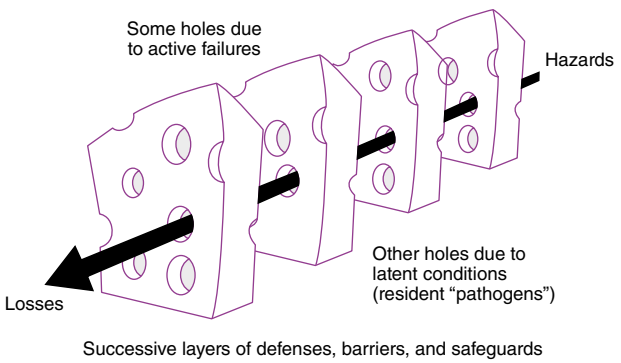

Figure 3.1 The "Swiss cheese" model of accident causation. (Source: Reason [1]. Reproduced with permission of Cambridge University Press.)

Galvan et al. published an observational study on complications in this complex patient population and recorded an average of 1.8 major compensated and nine minor compensated complications per case [7]. These complications were observed during the surgeries but were all recognized and treated by the medical team before injury resulted – all the "holes" in the Swiss cheese did not line up because one or more of the various systems in place to prevent patient injury worked appropriately. Barach et al. reported on a comprehensive process map in which they outlined the multiple steps involved in congenital cardiac anesthetic care and identified the potential sites for safety interventions [8]. They observed 108 open cardiac surgeries and found that communication failures were the most common underlying cause of major events. Examples of the organizational and human factors challenges that Barach et al. observed include:

- Unplanned transfusion of blood products correlated with a breakdown of communication between the anesthesia team, the nurses, and the perfusionist.
- Failure to identify a non-functioning infusion pump was directly related to poor communication between the anesthesia attending physician and the resident who was performing several tasks simultaneously.
- Detection of increased chest tube bleeding was delayed and may have been related to suboptimal communication between residents and the attending physician.

"Near-misses" are important as they are 10–100 times more common than documented adverse events and yet share the same organizational and cognitive sources of error as major adverse events. Determining the frequency and nature of these events is potentially far more important than just looking at system failures resulting in patient injury, a process typically conducted in various quality improvement forums after the events. However, "near miss" analysis is difficult as it requires a trained, independent observer to accompany the patient through the entire care continuum – something that is clearly impractical except in very specific research settings.

Outcome transparency has become a key component of programmatic evaluation. For example, news articles have either disclosed or triggered congenital cardiac surgical program closures possibly related to adverse patient outcomes compared with their cohorts, while other institutions have made the decision to publicly release their pediatric heart surgery outcome data on a regular basis in an attempt to provide the most accurate data possible and fend off any accusations of a program intentionally obscuring their outcomes [9–11]. Although there is currently no mandatory reporting for congenital cardiac surgical or anesthesia programs in the United States, the Society of Thoracic Surgeons (STS) provides "Star" ratings on its website for adult heart surgery outcomes in isolated coronary artery bypass grafting or aortic valve replacement operations [12]. One "Star" programs have risk-adjusted outcomes greater than expected, two

AL Grawany

"Stars" have risk-adjusted outcomes equal to expected, and three "Star" programs have outcomes better than expected based upon the procedure being performed and the patient's underlying preoperative risk factors. Attempts to utilize this same "Star" system in the STS Congenital Heart Surgery Database (STS-CHSD) have not been as successful because of a large number of factors relating to appropriate risk adjustments and the wide variety of case types in CHD.

The STS-CHSD has implemented a voluntary public reporting system that the vast majority of participants in the U.S. participate in. The STS-CHSD public site reports 4-year outcomes stratified by age grouping and adjusted for center case-mix and complexity [13]. In Great Britain, congenital cardiac program mortality is reported publicly for all programs through the central cardiac audit database [14]. To date, there has been no similar effort to publish anesthesia morbidity and mortality, both because it is so infrequent and because of the absence of a national clearing house and the lack of risk adjustment.

KEY POINTS: ERRORS AND OUTCOMES IN SURGERY AND ANESTHESIA

- Reason's Swiss cheese model has widely been cited in explaining patient complications in complex systems.
- The total number of minor and major adverse events during complex congenital heart surgery were strong predictors of morbidity and mortality in de Leval's study.
- "Near-miss" events are 10–100 times more common than adverse events yet they share the same sources of error.

The six "Cs": communication and teamwork

In complex environments like pediatric cardiac ORs or catheterization laboratories, errors cannot entirely be avoided. In his publication, *Normal Accidents*: *Living With High-risk Technologies*, Perrow has postulated that even the best teams cannot eliminate every error [15]. What they can achieve at best is to prolong the time interval between errors. Therefore, it is of great importance for successful hospitals to create a culture of safety similar to the culture that the aviation industry promulgated to minimize the risk of human errors. More than a decade was required before hospitals were able to embed the concepts of checklists, team time-outs and sign in/sign out procedures as components of daily safety procedures. In commercial aviation, one must realize that computers in modern airplanes have taken over the human function of checking lists. These computers are checking the lists themselves automatically because analysis of the human practice of using a checklist a hundred times reveals that this is a source of error in itself. The effort in the aviation industry now is focused more on team performance, simulation, and reducing errors due to hierarchy and authority issues. The six "Cs" – Communication, Cooperation, Coordination, Cognition (simulation and cross-training), Conflict (managing disruptive behavior), and Coaching (team-training) – are the key goals for successful working interdisciplinary teams. A comprehensive summary of this topic is presented by Wahr et al. [16].

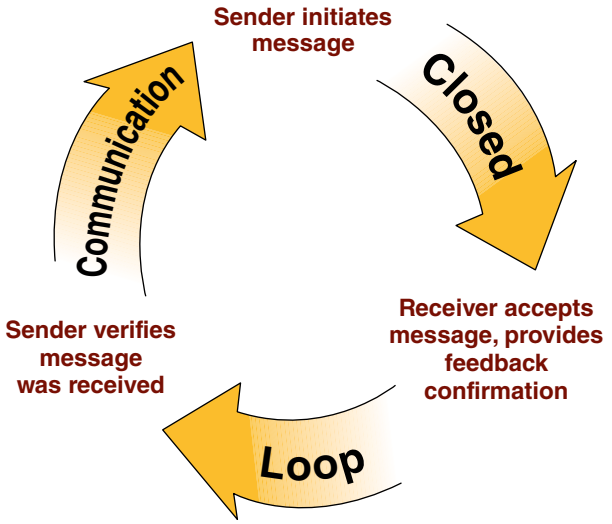

Figure 3.2 Closed-loop communication. (Source: Agency for Healthcare Research and Quality [18].)

The Joint Commission and WHO have both advocated instituting a time-out system prior to procedures to minimize the risk of preventable complications such as wrong-site surgery and failure to administer antibiotics in a timely manner [17]. In addition, "closed-loop" communication has been encouraged to minimize system errors (Figure 3.2) [18]. This particular technique is very helpful in the OR environment, where there can be a wide variety of distractions from background noise, music, cellular telephones, computers, monitors, conversations, and alarms. Shaw and colleagues reviewed much of this literature in their chapter, "Operating room safety, communication and teamwork" in *Gregory's Pediatric Anesthesia* [19]. There are a variety of additional techniques to maximize communication in the OR (or any other procedural location) as well as documenting the flow patterns that may lead to adverse events [17].

KEY POINTS: COMMUNICATION AND TEAMWORK

- Six Cs: Communication, Cooperation, Coordination, Cognition, Conflict management, and Coaching are key goals for interdisciplinary teams.
- Checklists and timeout procedures are now accepted as mandatory components of complex systems such as congenital cardiac surgery.
- Closed-loop communication is an accepted strategy to minimize system errors.

Databases in pediatric cardiac surgery and anesthesiology

Pediatric and congenital cardiac care databases are among the most commonly utilized multicenter areas of study and are in place worldwide in surgery, cardiology, anesthesia,

critical care medicine, hospital-based care, outpatient care, echocardiography, and more [20]. These take the form of either clinical datasets, administrative datasets, or a combination of the two. Many, if not most, of the databases have settled upon a universal set of terms to define the spectrum of congenital heart defects and repairs, the International Paediatric and Congenital Cardiac Code (IPCCC) [21]. The IPCCC has been widely adopted and is now incorporated into the World Health Organization's International Classification of Diseases (ICD), version 11 [22].

In order to better quantify both the incidence of adverse events and the outcomes of surgical procedures, the Society of Thoracic Surgeons' database committee established a nationwide (and now international) voluntary and anonymized registry of congenital cardiac cases and outcomes in the 1990s [23]. This includes almost every congenital cardiac center in the United States and three in Canada. As of the Spring 2019 report, the STS Congenital Heart Surgery Database (STS-CHSD) held information on over 515,659 patient surgical procedures. The European Association for Cardio-Thoracic Surgery (EACTS) has developed a transnational system for congenital cardiac surgery throughout the European continent and the UK. The EACTS utilizes a shared nomenclature for both lesions and complications with the STS that allows pooling of the two datasets to create an even larger picture of worldwide congenital cardiac surgery and outcomes. Other databases in pediatric cardiac surgery worldwide either use the common STS-EACTS nomenclature or similar tools.

The STS-CHSD serves as an important resource for determining United States outcomes on a given congenital cardiac lesion and benchmarks by which individual hospitals and surgeons can compare their results against aggregate results on a lesion-by-lesion, complexity, risk, and age-adjusted basis. Both public and private payers have begun to incorporate these data in evaluating programs. The state of Florida, for example, has mandated participation in this type of database as a requirement for participation in state-run insurance programs such as Medicaid [24]. In New York and Pennsylvania states, the Departments of Health publish outcomes data on every program in their respective states, including whether they fall above or below 95% confidence intervals for expected outcomes after risk adjustment [25]. The private health insurer, United Healthcare, has established "Centers of Excellence" to facilitate referrals within their systems and to maximize their patient outcomes and satisfaction while minimizing the added expense of complications [26, 27]. Demonstration of superior outcomes through benchmarking is one element of the requirements for consideration as a preferred referral center, and the popular US News and World Report Hospital and Specialty annual rankings include database participation and benchmarking in their ranking algorithm [28].

Other important efforts that have come out of the STS-CHSD include working groups that have established the consensus guidelines for defining lesion nomenclature, morbidity, and mortality [29]. All of these efforts have been coordinated internationally with other groups such as the EACTS to allow the free flow of comparative data across national boundaries.

Unlike many countries around the world that utilize a national insurance program and patient registry, the U.S. has not developed a patient identification system that accurately allows tracking of an individual throughout their lifetime and across both state and hospital boundaries. Utilization of something like a Social Security number is impractical due to privacy restrictions and, in the case of the Social Security number, availability at the time of admission, particularly for newborns or for international patients being treated within the United States. At this time, efforts to link the various congenital cardiac surgical and non-surgical databases are relatively limited and rely upon post-hoc linkage of various unique identifiers such as date and place of birth, patient gender at birth, and maternal name. Cardiac Networks United is a consortium of various specialty groups attempting to bridge this gap but its functionality is currently limited by the absence of surgical data from the STS-CHSD [30].

Denmark might serve as a role model because the combined health registers with social registers on an individual level by a unique personal identification number called CPR which is used in all Danish national registers. In 2009, they established The National Centre for Register-based Research [31]. This institution set up a register database in 2010 combining all available registers in Denmark open to researchers. Up to now, the database contains a detailed description of over 45 Danish registries [32].

One well-recognized weakness of single-site reporting systems is that a patient undergoing a procedure at one institution is completely separated from the same individual being cared for at a different institution subsequently, a circumstance which happens frequently with congenital heart care. In the case of an adverse event, the receiving facility becomes the center that reports the morbidity in their statistics, while the initial treating institution may not necessarily report the event. The STS-CHSD is attempting to address this flaw by extending the mandatory follow-up period from 30 days to 1-year post-procedure and through changes in the data collection form which reflect transfers and "salvage" care.

The Congenital Cardiac Anesthesia Society (CCAS) was incorporated in 2005 and one of its first initiatives was to approach the STS about developing anesthesia information to be included in the STS dataset [33]. The first iteration of this collaboration went "live" in January 2010 and has been updated regularly since then. The CCAS work with the STS subsequently served as a model for the Society of Cardiovascular Anesthesiologists (SCA) Adult Cardiothoracic Anesthesia Database, which is now working in conjunction with the appropriate STS dataset. The adult SCA database that began entering patient data in 2013 tends to focus more on patient diagnostic and therapeutic elements rather than outcomes or adverse events [34]. The CCAS is now working with the American College of Cardiology's Improving Pediatric and Adult Congenital Treatment (IMPACT) registry, which collects information about pediatric interventional cardiology and electrophysiology procedures, to include an expanded number of data elements relative to anesthesia including anesthesia type and anesthesia-related adverse events in its next update.

A major benefit of utilizing an annual data submission process across multiple institutions is that it allows for a more contemporaneous examination of patient outcomes. Publications from two centers with a long history of anesthesia data collection, the Boston Children's Hospital and the Mayo Clinic, illustrate the difficulties with single-center record-keeping [35, 36]. Their data, critically important as it is, represents time periods ranging from 6 years (Boston Children's Hospital) to 17 years (Mayo Clinic). During these time spans multiple factors may shift that significantly alter

patient outcomes and potential complications. For example, personnel changes and experience (physician, nursing, and ancillary staff), surgical technique modifications, pharmacology, technical advances with better monitoring and equipment, and more sophisticated complication detection and tracking all impact patient outcome statistics.

In examining low-frequency events, the only way in which to accurately estimate their occurrence is to investigate large numbers of patients. No single center can provide sufficient patients as a denominator in a relatively short period of time; therefore, it is necessary to either lengthen the epoch studied (with the weaknesses mentioned earlier) or increase the denominator by expanding the patient base by making the data multi-institutional, recognizing that by increasing the sites participating one may decrease the relative consistency and accuracy of the data collected. One goal of the STS–CCAS collaboration is specifically to do the latter.

KEY POINTS: DATABASES IN PEDIATRIC CARDIAC SURGERY AND ANESTHESIOLOGY

- The STS Congenital Heart Surgery Database (CHSD) is the most widespread multi-institutional effort to gather data on practice and outcomes in congenital heart surgery.
- The EACTS has also developed a similar database for congenital heart surgery.
- Cardiac anesthesia databases have been initiated by the CCAS and the SCA, appended to the surgical databases.

Prospective risk assessment in pediatric cardiac surgery and cardiology

It is intuitive that different pediatric cardiac surgical procedures will have radically different long-term outcomes related to the underlying severity of the defect(s) (including *in-utero* effects on blood flow patterns), the complexity of the operative repair, and the co-morbidities found in a given patient as well as non-defect related elements such as patient socio-economic factors, racial disparities, parental education levels and insurance status [37].

In order to best estimate these potential outcomes, initial efforts were made at developing risk categories based upon "best guess" techniques in which groups of cardiac surgeons and cardiologists sat down in a room and assigned each individual operative procedure to a risk category pool based upon their collective years of experience. The most widely adopted categorization schema utilizing this technique is the Risk Adjustment for Congenital Heart Surgery (RACHS-1) scoring system developed by Jenkins and colleagues [38, 39]. The Aristotle Basic Complexity (ABC) score is another attempt at preoperative risk assessment utilizing expert consensus based upon values being assigned to three components: the potential for perioperative mortality, the potential for perioperative morbidity, and the technical difficulty of the proposed repair [40]. The ABC system expanded the number of procedures evaluated, as compared with the RACHS-1 system, but the RACHS-1 appears to better discriminate at predicting mortality when the two are compared against each other [41]. The weakness of both these systems is that they are based upon a consensus estimation of experts in the field. The STS-CHSD, in conjunction with the EACTS, subsequently developed a risk model developed from empirical outcome data from two large databases, the Society of Thoracic Surgeons–European Association for Cardio-Thoracic Surgery Congenital Heart Surgery (STAT) mortality score. The initial STAT mortality scores were modeled utilizing over 70,000 records from the two societies and the pediatric cardiac surgical procedures were divided into five levels of mortality categories ("strata"); however, these are based upon the observed outcomes rather than *a priori* assignment by expert opinion and this process was then validated by comparison to a larger sample set of over 111,000 pediatric cardiac surgical cases in both the STS and EACTS registries [42]. This STAT mortality score has recently been updated, incorporating more procedures and frequent combination procedures and updated based upon more current outcome data solely from the STS-CHSD [43]. Each STAT mortality category was created so that the inter-category differences were sufficient to warrant assignment to either a lesser or a greater score category. Table 3.1 contains a listing of the newest STAT-assigned procedures or procedure combinations and their respective categories. The STAT, RACHS-1, and ABC scores are all based upon in-hospital mortality rates and do not fully account for either in-hospital morbidity or out-of-hospital mortality, such as inter-stage deaths that occur more than 30 days after the procedure or either hospital discharge, whichever is later. Another major component that is not fully accounted for in these systems is preoperative morbidity, such as prematurity, genetic abnormalities, or co-existing diseases. Post-operative mortality after hospital discharge, and residual surgical lesions are also not captured. Work is progressing on each of these issues as they relate to patient outcomes. Concerns within the STS-CHSD related to differences in surgical outcomes based upon the patient's underlying diagnosis have also led to ongoing research examining the impact of diagnosis-procedural (D-P) combinations. For example, the modified Blalock-Taussig shunt palliative procedure may be performed for a very heterogeneous group of underlying anatomic diagnoses with inadequate or abnormal pulmonary artery blood flow. Ongoing research efforts using complex large machine-learning models are currently underway to determine if these D-P combinations impact patient mortality estimates differently than a purely procedure-based model such as the current STS-CHSD utilizes. This work has now shown that except for helping discriminate between very high risk procedures, the addition of diagnosis to the procedure did provide additional benefit in predicting post-operative mortality [44, 45].

Pasquali et al. have drawn extensively from work done in adult cardiovascular surgery to determine the relevance of "failure to resuscitate" (FTR) as a marker for programmatic quality [46]. The authors start with the hypothesis that complications and morbidity will always occur in any complex system such as the surgical repair of congenital heart defects. A single-site retrospective analysis by Agarwal and colleagues found an incidence of identified adverse events of 43% (126 of 325 patients); this was in a retrospective chart review, not in the type of prospective observational study performed years earlier by de Laval and Barach, which might identify more subtle minor events that occur without being recorded [3, 8, 47]. What distinguishes high-performing programs from lesser-performing ones is not the incidence of adverse events *per se*, but the response to them.

Table 3.1 Society of Thoracic Surgeons – European Association for Cardio-Thoracic Surgery Congenital Heart Surgery (STAT) Mortality Score categories

STS expected hospital discharge mortality rate (95% confidence interval)				
Mortality category 1 (0.20–1.33%)	**Mortality category 2 (1.43–2.94%)**	**Mortality category 3 (3.01–6.82%)**	**Mortality category 4 (6.88–13.00%)**	**Mortality category 5 (13.45–38.68%)**
Aortic stenosis, subvalvar	Valvuloplasty, mitral	Coarctation + VSD repair	Unifocalization, bilateral complete	ASO + VSD + aortic arch repair
Valve replacement, pulmonic	Valvuloplasty, Aortic – converted to AVR	Pulmonary artery aneurysm repair	TAPVC repair	Unifocalization, bilateral, incomplete
ASD repair, patch +PAPVC	Atrial fenestration closure	MAPCA unifocalization	ASD + aortic arch + VSD	Shunt, Potts' type
ASD repair, Patch	Arrhythmia surgery, ventricular	Systemic venous stenosis repair	Ross–Konno	Valve replacement, common AV valve
AVC repair, intermediate	Annular enlargement procedure	ASD partial closure	Fontan revision or conversion	Truncus + interrupted aortic arch
ASD repair, primary	PA reconstruction, Branch, Central	ccTGA, VSD closure	Ross–Konno, valvuloplasty converted to aortic valve replacement	Norwood
Conduit reoperation	Valve closure, semilunar	DORV repair	Senning	Unifocalization MAPCAs + Central shunt
PAPVC, baffle (Warren)	Glenn (unidirectional)	MAPCA occlusion	TOF – AVC repair	Hybrid stage 1
AAOCA repair	Glenn (bidirectional)	Aortic arch repair	Valvuloplasty converted to a replacement, common AV valve	ASD partial closure + pulmonary venous repair
DCRV repair	PA band adjustment	Hepatic vein to azygous graft	Valve closure, tricuspid	Hybrid stage 1 + bilateral PA bands + PDA stent
Vascular ring repair	Arterial switch + aortic arch repair	TOF, RV-PA conduit	Glenn + AV valvuloplasty	Ebstein's repair + PDA closure
TOF, ventriculotomy, nontransannular	Shunt, ligation and takedown	Fontan, atrio-pulmonary	PDA + modified BT shunt	Shunt, modified BT + DKS
Fontan, lateral tunnel, fenestrated	ASD + TOF repair, no ventriculotomy	ASD repair, common atrium	Yasui	Ross–Konno + valve replacement, mitral
PFO, primary	Mitral stenosis, supravalvar ring	Hybrid approach, transcardiac device placement	Aortic root replacement, homograft	Valvuloplasty, tricuspid + Norwood + RV-PA conduit
VSD repair, patch	Conduit placement, RV to PA	Mustard procedure	VSD + ASD + PAPVC	PA Banding + valvuloplasty, common AV valve
PAPVC repair	PAPVC, Scimitar	Valvuloplasty converted to a replacement, Pulmonic	Cardiac tumor resection	Hybrid stage 1 + bilateral PA bands
TOF, no ventriculotomy	Coronary artery fistula ligation	Aortic root translocation	Pulmonary venous stenosis repair	TAPVC + shunt, systemic – pulmonic
Aortopexy	Anomalous coronary from the pulmonary artery	Coronary artery bypass	PA reconstruction (central) + modified BT shunt	TAPVC + shunt, systemic – pulmonic + PDA closure
Valvuloplasty, pulmonic	VSD creation/enlargement	Pericardial drainage procedure	Valvuloplasty converted to a replacement, tricuspid valve	
Ross procedure	LV to aorta tunnel repair	Valve replacement, aortic, homograft	Central shunt	
AVC repair, partial	PDA closure, surgical	TOF, ventriculotomy, transannular patch + vascular ring repair	Shunt, reoperation	
Pacemaker procedure	Pulmonary atresia-VSD repair s/p unifocalization	Transplant, heart	PA banding	
VSD repair, primary	ASD repair, device	Valve replacement, mitral	Central shunt, Mee type	

AL Grawany

Aortic root replacement, bioprosthetic	Bilateral bidirectional Glenn	Valvuloplasty converted to replacement, mitral	PA reconstruction + heart transplant
RVOT procedure	ASD + PV replacement	Interrupted aortic arch repair	Transplant, lungs
Valve replacement, Aortic	ASD + PAPVC	Valvuloplasty, aortic + valvuloplasty, mitral	Aortic dissection repair
Valvuloplasty, Tricuspid	VSD repair + conduit	VSD patch + AVC repair	Truncus arteriosus repair
AS repair, subvalvar with myectomy	PA reconstruction, Branch, peripheral	Coarctation, subclavian flap	ASD + pulmonary atresia/VSD repair, including TOF pulm atresia
Valvuloplasty, aortic	VSD multiple, repair	Ventricular septation	Unifocalization + conduit placement
Pulmonary sling repair	Glenn + PA plasty	Ventricular septum fenestration	TOF – absent PV
Sinus of Valsalva aneurysm repair	VSD + valve replacement, pulmonic	REV	HLHS biventricular repair
PA reconstruction, main trunk	Conduit placement, Ventricle to aorta	Pulmonary embolectomy, chronic	Conduit, RV – PA + aortic root replacement
Valvuloplasty, Truncal valve	Removal of transcatheter delivered device from heart	Valve replacement, Tricuspid	AVC repair, complete + coarctation end-end
Rastelli procedure	Batista procedure	Arterial switch + VSD	RV – PA conduit + PDA closure
Explantation of pacemaker	Valvuloplasty, common AVV	Unifocalization, MAPCAs	Hybrid stage 2 + aortic arch repair
Coarctation repair, end-to-end	PA debanding	Fontan, external, hepatic veins to PA, fenestrated	Pulmonary artery sling + tracheal repair
Aortic aneurysm repair	Anomalous systemic venous connection	Tricuspid valve excision without replacement	
Hemi-Fontan	VSD repair, device	Hybrid stage 2 without aortic arch repair	
ASD, primary + VSD repair, patch	Arterial switch operation	Fontan, external conduit, fenestrated + pacemaker	
Aortic root replacement, valve sparing	Valve excision, pulmonary	Fontan, external, hepatic veins to PA, nonfenestrated	
Coarctation repair, patch	Acute pulmonary embolectomy	Hybrid, transcardiac	
Valve replacement, Aortic, mechanical	Ligation, pulmonary artery	Damus-Kaye-Stansel	
1 1/2 Ventricular repair	Sternotomy wound drainage	ccTGA, atrial switch + Rastelli	
AICD Implantation	VSD – MAPCA, single stage repair	Shunt, modified BT	
Coarctation repair, interposition graft	Atrial baffle procedure	AVC + vascular Ring	
Arrhythmia surgery	Pericardiectomy		
Fontan, external conduit, nonfenestrated	Aortic stenosis repair, supravalvar		

(*Continued*)

Table 3.1 (Continued)

STS expected hospital discharge mortality rate (95% confidence interval)				
Mortality category 1 (0.20–1.33%)	**Mortality category 2 (1.43–2.94%)**	**Mortality category 3 (3.01–6.82%)**	**Mortality category 4 (6.88–13.00%)**	**Mortality category 5 (13.45–38.68%)**
Aneurysm repair, right ventricle	ccTGA, double switch repair			
Pacemaker implantation, permanent	cc TGA, LV to PA conduit			
Fontan + AV Valve repair	DOLV repair			
Hemitruncus repair	Pulmonary AV fistula repair			
Fontan, external conduit, fenestrated	Conduit reoperation + AVR			
Kawashima operation	Pulmonary atresia – VSD repair			
Cor triatratum repair	Fontan, intra/extracardiac repair, nonfenestrated			
AP window repair	Cardiac tumor resection			
Fontan, intra/extracardiac, fenestrated	Aortic arch + VSD repair			
	Valve replacement, truncal			
	Fontan takedown			
	Glenn takedown			
	Vascular stent removal			
	ASD creation/enlargement			
	Konno procedure			
	Aneurysm repair, LV			
	Ebstein's repair			
	Conduit, LV to PA			
	Atrial baffle, Mustard or Senning			
	Pulm valve replacement + pacing explant			
	Pulmonary atresia – VSD MAPCA s/p unifocalization			
	VSD + PAPVC			

AICD, automated internal cardiac defibrillator; AP, aortopulmonary; ASD, atrial septal defect; ASO, arterial switch operation; AVC, atrioventricular canal; AVR, aortic valve replacement; ccTGA, congenitally corrected transposition of the great arteries; DCRV, double-chambered right ventricle; DKS, Damus–Kaye–Stansel; DOLV, double outlet left ventricle; DORV, double outlet right ventricle; HLHS, hypoplastic left heart syndrome; IAA, interrupted aortic arch; LV, left ventricle; MAPCAs, major aortopulmonary collateral arteries; PA, pulmonary artery; PAPVC, partial anomalous pulmonary venous connection; PDA, patent ductus arteriosus; PFO, patent foramen ovale; PVR, pulmonary valve replacement; REV, reparation a l'étage ventriculaire (REV procedure); RV, right ventricle; RVOT, right ventricular outflow tract; TAPVC, total anomalous pulmonary venous connection; TCPC, total cavopulmonary connection; TOF, tetralogy of Fallot; TVR, tricuspid valve replacement; VSD, ventricular septal defect.

Interventional cardiologists have also addressed predictive outcomes analysis. In 2007 the Congenital Cardiac Catheterization Project on Outcomes (C3PO) registry was created to establish standardized and comparable metrics across 15 pediatric cardiac catheterization laboratories, utilizing an internet-based tool on all cardiac catheterization cases [48]. *Post hoc* analyses utilizing multivariate modeling then determined four discrete procedural risk categories based upon the age of the patient and the type of procedure being performed (diagnostic, valvuloplasty, device or coil closure, angioplasty, stent placement, stent redilation, and others). Adverse events were categorized on a scale of 1–5, with 1 being no adverse event noted, and 5 catastrophic (i.e. resulting in death or emergent surgical intervention to prevent death). The risk scoring method was called the Catheterization for Congenital Heart Disease Adjustment for Risk Method (CHARM). The purpose of the C3PO and CHARM project is to allow for appropriate risk adjustments to be made when comparing outcomes at a given center with expected outcomes for their specific patient population. Over a 2-year-period approximately 10,000 cases were analyzed to develop predictors of adverse events which included hemodynamic parameters such as cardiac index, right ventricular pressures, and the right ventricular to systemic pressure ratio [49]. The C3PO-QI database evolved from this endeavor in 2013 to address quality improvement issues in the catheterization laboratory. This prospective data registry includes over 13,000 cases and aims to improve standards of care in pediatric cath labs, including initiatives on radiation exposure [50]. This is a critical part of the quality improvement process that must occur at every institution.

Similarly, the IMPACT Registry was created in 2011 with the aim of creating risk stratification among common pediatric cath lab cases, and tracking outcomes comparing high versus low performing centers [51]. In order to achieve this, IMPACT created learning collaboration with the National Pediatric Cardiology-Quality Improvement Collaborative (NPC-QIC). The NPC-QIC's focus is to reduce themortality rate and improve the quality of life for small children with hypoplastic left heart syndrome in the interstage period between the Norwood and Glenn Procedures. The key drivers of this quality improvement initiative extend beyond the pediatric cath lab and include factors such as nutritional status, discharge coordination, and home medical surveillance. This quality improvement collaborative was able to demonstrate a 44% reduction in interstage mortality amongst the participating centers.

KEY POINTS: PROSPECTIVE RISK ASSESSMENT IN PEDIATRIC CARDIAC SURGERY AND CARDIOLOGY

- The STAT score is a risk model developed from empiric outcome data and is the most accurate method for estimating mortality risk preoperatively.
- The CHARM and IMPACT projects estimate the risk of adverse outcomes according to the complexity of the interventional cardiac catheterization procedure.

Closed claims analysis in anesthesia

The American Society of Anesthesiologists has sponsored multiple investigations using a "closed claims" analysis method to identify areas of concern for anesthesiologists, including claims for death and brain injury, central venous line injuries, nerve injury, and airway injury [52–56]. These reports have not generally examined the effects of age or type of surgery and do not have a denominator that is needed to determine the incidence of injury. Jimenez et al. used the closed claims data to investigate pediatric anesthesia liability and segregated the data by type of surgery [57]. This report found that thoracic and cardiac surgeries accounted for slightly less than 10% of all claims that were settled. This figure probably represents a disproportionately high number because of the relatively small number of thoracic and cardiac surgeries compared with all surgeries performed on pediatric patients. In general, malpractice data are a very insensitive tool for determining the incidence or causality of complications, as many different factors apart from medical error determine whether or not a claim is initiated or settled. The denominator of pediatric patients undergoing surgical and diagnostic procedures with anesthesia in the United States is not measurable with any accuracy due to the lack of a central reporting mechanism. Examining the caseload at children's hospitals is insufficient because many procedures are performed in mixed adult–pediatric general hospitals, ambulatory surgical centers, or physicians' offices. In addition, many adult congenital heart procedures are performed by adult cardiac surgeons and cardiologists and never entered into any congenital databases. For example, bicuspid aortic valve stenosis is very frequently treated in adult facilities but is widely acknowledged to be a congenital structural defect rather than an acquired disease, particularly when presenting at younger ages compared to acquired aortic valvular disease.

Pediatric and congenital cardiac anesthesia morbidity and mortality

Numerous anesthesia-related manuscripts concerning cardiac arrest in children have been published, some of which focused on children with CHD, with others focusing on children undergoing all types of surgical and non-surgical procedures [35, 36, 58, 59]. The pediatric perioperative cardiac arrest (POCA) registry was a multi-institutional effort in which participants anonymously reported all episodes of cardiac arrest in children aged 18 and younger that resulted in chest compressions or death at the time of surgery or within 24 hours. This project was begun in 1994 and data collection and analysis continued through 2004, at which time further data collection was put on hold. Subsequent examination of the detailed data forms allowed the investigators to assess the relative contribution of anesthesia to the cardiac arrest or death. A subsequent publication from the POCA group was a follow-up to their original publication in 2000 and focused the analysis on arrests in patients with heart disease [60, 61]. The authors reported that cardiac arrests in these patients were more likely to be in unrepaired patients

(59%) or palliated patients (26%) than in patients with repaired cardiac lesions (15%). Finally, in 2010, Ramamoorthy et al. re-examined the POCA data, specifically assessing children with congenital heart defects [62]. Overall, they found that of the 373 anesthesia-related cardiac arrests, 127 (34%) patients had congenital or acquired heart disease – a number, not surprisingly, far out of proportion to the incidence of heart disease in the pediatric population (0.8%). Patients with single ventricle physiology were those most likely to suffer a cardiac arrest, while those with aortic stenosis and cardiomyopathy were associated with the highest mortality rates.

Building on the scope of the POCA Registry, Wake Up Safe (WUS) was established in 2008 with the aim of improving perioperative processes and care for children receiving general anesthesia [63]. An initiative started by the Society for Pediatric Anesthesia (SPA), the mission of WUS is to provide ongoing monitoring of very rare adverse events under general anesthesia across multiple institutions, and to use these data to uncover ways to prevent them from recurring. Centers participating in WUS have grown from the initial 19 participating pediatric hospitals in the United States to 34 as of the time of this writing [64]. In order to study these events, WUS created an organized multicenter detailed voluntary registry to record serious adverse events during the perioperative period [65]. Data collected by WUS not only consist of cardiac arrest events like POCA but also includes "near miss" events such as acute lung injury, musculoskeletal injury, spinal cord injury, or surgery on the wrong patient/site. Because of the way in which the WUS initiative is structured, it should be possible to determine the incidence of these events and not just record their existence. Limitations to this database include reporting bias, as this is a voluntary non-audited registry and the membership of a proportionately small number of US academic institutions. WUS does not reflect the events that may occur at ambulatory surgery centers, private offices (e.g. dental operatories), and general community hospitals; locations where the majority of pediatric anesthetics are provided in the United States.

Since the WUS project began, statements have been published on the WUS website concerning hyperkalemia, preventing wrong-site procedures, and decreasing the risks of intravenous medication errors. In 2014, WUS published their first database analysis of adverse events from 2008 to 2013: of 736,365 pediatric anesthetics of all subspecialties in the database, there was a serious adverse event rate of 1.4/1,000 anesthetics (0.05%), with respiratory events most common (254 of 740) and cardiac arrest the next most frequent (241) [65]. Five years later, the event data from the 19 original institutions was examined along with a root cause analysis on the anesthetics performed from 2010 to 2015 [64]. Compared to the previous study, 0.104% of the 1,964,211 children receiving an anesthetic experienced an adverse event. Consistent with most studies, the incidence of adverse events was higher in neonates/infants and those with ASA status of IV or higher. The most commonly reported adverse events in this study were cardiac (31.6% total events, 3.3/10,000), respiratory (29.2% of total events, 3/10,000), medication (16.9% of total events, 1.8/10, 000), and perioperative death (8.5% of total events, 0.9/10, 000). However, after root cause analysis, events judged to be primarily caused by anesthesia demonstrated medication events as the most common (31.9%), followed by respiratory (24.1%), and finally cardiac arrest (18.5%). The findings of this study suggest that QI efforts aimed at the reduction of medication events would be the most impactful.

The investigators at Boston Children's Hospital have been collecting anesthetic data on their own patients since January 2000, both for internal quality and for state reporting requirements in Massachusetts. The publication of this data through December 31, 2005 from their cardiac ORs represents a significant single-site effort to determine contemporary complications specific to pediatric cardiac anesthesia-related morbidity [35]. One of the difficulties associated with determining causality in this patient population is the interdependent nature of anesthesia, surgery, and patient physiology. The authors examined each incident with a panel of three pediatric cardiac anesthesiologists, with a subsequent review by a pediatric cardiac surgeon, before assigning causality. Boston Children's Hospital reported that in their series of 5,213 cardiac surgical patients from 2000 to 2005, there were 41 cardiac arrests in 40 patients for an overall frequency of 0.79%, with anesthesia playing a significant role in 11 of the 41 cases; in other words, 21.1 cardiac arrests/10,000 anesthetics were reported. This compares with their previously reported anesthesia-related incidence of 2.7 cardiac arrests or death/10,000 anesthetics in all pediatric patients during roughly the same period [66].

In 2013, the investigators from Boston Children's Hospital again reviewed their institution's database to examine the incidence of cardiac arrest in children with CHD undergoing cardiac catheterization and to describe potential risk factors for anesthesia [58]. In total, 7,289 catheterization procedures were performed between January 1, 2004 and December 31, 2009, and were classified as either a biopsy (19%), diagnostic (23%), or interventional catheterization (58%) [58]. Seventy procedures were associated with a cardiac arrest, with a reported frequency of 0.96/100 cardiac catheterizations. The authors acknowledge that although the frequency of arrest is higher than other multi-institutional reports, it is comparable to the results of their prior study on the incidence of arrest in the cardiac OR. The incidence of cardiac arrest in the population studied was found to be statistically significantly higher for children undergoing interventional procedures and those who were younger at the time of the procedure ($P < 0.001$). These authors concluded that these high-risk patients should be managed by an anesthetic team familiar with the pathophysiology, cases, environment, and perioperative staff, in order to facilitate communication and prompt resuscitation should the need arise. There also appeared to be an overall decline in the incidence of cardiac arrest when sedation and anesthesia were provided more routinely by a dedicated pediatric cardiovascular anesthesia team in the latter half of the data collection period.

Another institution with a long history of anesthesia data collection, the Mayo Clinic in Rochester, MN, also reviewed their experience with cardiac arrests in children [36]. A consistent factor in all of these studies is that children with underlying congenital cardiac defects are at a much higher risk of cardiac arrest than children without these defects. The incidence of cardiac arrest at the Mayo Clinic for children during non-cardiac procedures was 2.9/10,000, as compared

with 127/10,000 for children undergoing cardiac procedures, a 30-fold increase in risk. Sub-analysis related to causality, age, and the type of surgery further stratified their data. Of their 92,881 patients, 4,242 were for cardiac procedures. Within the 54 children who suffered a cardiac arrest or death undergoing a cardiac procedure, age played a significant role, with neonates having the highest risk. Anesthesia was not identified as a causative factor in any of the cardiac surgical arrests or death. At the Royal Children's Hospital, Melbourne, Australia, van der Griend and colleagues examined anesthesia-related mortality in 101,885 anesthetics administered to 56,263 children from January 1, 2003 through August 2008 [59]. They, too, utilized an expert review panel of three senior anesthesiologists, examining the record of every patient who died during this period but who had received an anesthetic in the preceding 30 days. Overall anesthesia-related mortality was found to be 1 in 10,188 cases (0.98/10,000). All 10 deaths where anesthesia was found to be a contributing factor had significant pre-existing conditions, with pulmonary hypertension present in 50%. There were no anesthetic-related morbidities in children without underlying medical problems. Overall mortality was significantly higher in children <30-days old and those with cardiac disease (particularly after 30 days of life).

Recently, a group of collaborators coming from the European Pediatric Anesthesia community started two large Pan-European studies funded by the European Society of Anaesthesiology Clinical Trial Network (ESA CTN) and supported by the European Society for Paediatric Anaesthesia (ESPA) to investigate the incidence of severe critical events in children and neonates undergoing general anesthesia in Europe. The main finding of the Incidence of Severe Critical Events in Paediatric Anesthesia (APRICOT) study was that the incidence of perioperative severe critical events was 5.2% (95% CI 5.0–5.5) with an incidence of respiratory critical events of 3.1% [67]. This was independent of the type of anesthesia administered. In the APRICOT study, 30,784 children from 33 countries, mainly from Europe, were included. Besides the main findings, the study revealed that the standard operating procedures differ enormously within not only the countries but also participating centers. One could observe more than 40 combinations for premedication, at least 100 different methods for anesthesia induction, and more than 40 different types of crystalloid infusions combined with or without glucose. Only 1.6% of anesthetics were cardiac surgery or catheterization, and the incidence of congenital heart disease in the entire group was not specifically reported. Cardiac surgery conferred a relative risk (RR) for cardiac severe critical events of 16.92 (95% CI 13.67–20.93, $p<0.0001$), and cardiac catheterization a RR of 3.20 (95% CI 1.71–5.85, $p<0.0001$). The NEonate and Children AudiT of Anaesthesia PRactice IN Europe (NECTARINE) study was of a similar design but the age group was neonates and infants up to 60 weeks' postmenstrual age in 165 centers in 31 European countries [68]. A total of 6,542 anesthetics were performed; 12.7% of patients had congenital heart disease, which was not specifically analyzed as a risk factor for the entire group. Of 5,200 surgical procedures, 439 (8.4%) were for cardiac surgery, which was the second most common operation after inguinal herniorrhaphy. Cardiac surgery was consistently the highest risk factor for morbidity at 30 days (51.6%, RR 3.08, 95% CI 2.65–3.57, $p<0.01$) and 30- and 90-day mortality (9.45%, RR 2.67, 95% CI 1.61–4.42, $p = 0.002$). The findings of the two large multicenter, Pan-European studies give important information regarding how to set up studies or databases within different countries. Moreover, in an accompanying editorial Lerman pointed out that the multivariate analysis revealed that senior anesthesiologists had 1% fewer critical respiratory events per year of experience [69]. Additionally, the frequency of critical events from centers that reported these events was inversely associated with the number of children anesthetized.

As is evident from the most recent data, even the busiest of programs only infrequently have anesthesia-related cardiac arrests or death because of the low incidence of these events. As a consequence, it is necessary to harvest data over many years to collect any meaningful numbers, during which time major changes in patient management may occur. For example, the initial POCA study attributed many arrests to the use of the anesthetic agent, halothane, a known cardiac depressant [61]. By the time of the follow-up publication 7 years later, halothane had been replaced almost entirely in North America by sevoflurane, an anesthetic agent with significantly less cardiotoxicity at the typically administered doses.

KEY POINTS: PEDIATRIC AND CONGENITAL CARDIAC ANESTHESIA MORBIDITY AND MORTALITY

- The POCA Registry reported that 34% of cardiac arrests under anesthesia had heart disease as a factor.
- The Boston Children's Hospital registry has reported a cardiac arrest rate of 0.79% for cardiac surgery, and 0.96% for cardiac catheterization.
- The Mayo Clinic study reported a 30-fold increase in the risk of cardiac arrest with cardiac surgery vs. non-cardiac surgery in pediatric patients.
- The Royal Children's Hospital study reported that pulmonary hypertension was a factor in 50% of anesthesia-related deaths.
- The APRICOT and NECTARINE studies from Europe reported that cardiac surgery or catheterization was the highest risk factor for critical events, morbidity, or death with relative risk 2.6–16.9 times other procedures.

Congenital Cardiac Anesthesia Society and the Congenital Cardiac Anesthesia Network

The Congenital Cardiac Anesthesia Society was formed in 2005 by representatives drawn from many of the busiest congenital cardiac surgical programs in North America. It is a subsidiary of the Society for Pediatric Anesthesia and its work is closely coordinated with that organization. Membership is open to all individuals providing anesthesia-related care for children with heart defects or an interest in the field and it currently has almost 1,300 members both

from the US and international programs. In addition to educational programs at its conferences and as a sponsor of other educational efforts, a major function of the organization is the development of a data registry linked to the STS-CHSD. In the UK and Ireland, the Congenital Cardiac Anaesthesia Network (CCAN) is an informal organization of pediatric cardiac anesthetists numbering 70–80 physicians, which sponsors an annual meeting for presentation of timely topics and discussion/debate about clinical practices. CCAN also sponsors a mailing list for regular updates.

Joint CCAS–STS database initiative

The Joint CCAS-STS Congenital Cardiac Anesthesia Database is a collaborative project developed over the last decade by multiple parties interested in capturing anesthesia-related information on these high-risk patients. The process by which this project came about is described previously [8]. Anesthesia-related data fields for the database are selected by a database committee of the CCAS in coordination with the existing fields in the STS-CHSD. For an additional fee, STS-CHSD participating centers may elect to submit their anesthetic data to be pooled anonymously with the other participating centers during their annual data harvest.

The interdependent relationship between congenital cardiac surgery and congenital cardiac anesthesia supports the creation of a common database for these subspecialties. Multiple potential benefits are being realized through the development of this joint database:

- Minimization of data entry burden
- Minimization of costs associated with data entry
- Minimization of the cost associated with database maintenance
- Utilization of common nomenclature based on the International Pediatric and Congenital Cardiac Code [70].
- Utilization of common database fields
- Utilization of common database definitions
- Utilization of common database standards
- Development of common strategies to report outcomes
- Development of common quality improvement initiatives.

The Joint CCAS-STS Congenital Cardiac Anesthesia Database began collecting data in January 2010. The data are harvested semi-annually, though the STS is currently moving to a continuous harvest process with semi-annual reporting and analysis. The most recent report from the STS-CHSD was published in 2020 containing data for the 4-year period ending June 30, 2019[71]. Reviewing only cardiac surgery procedures either with or without cardiopulmonary bypass (excluding minor procedures, ECMO or VAD or non-surgical procedures), there were 66,655 cases in the dataset. Of these, 50,633 included bypass and 15,318 were non-bypass cases such as repair of coarctation of the aorta or pacemaker placement. Adverse events were reported overall in 1,653 of the 66,655 (2.5% or else 2.47%) These data were derived from over 60 anesthesia reporting sites.

The STS-CHSD, including the anesthesia component, is updated approximately every 3 years. The most recent update went live on July 1, 2021. The CCAS Database Committee has made several modifications to the data being collected, including multiple additions to the adverse outcome reporting options. The committee has also worked with the STS to consolidate and clarify duplication of data entry items, such as blood transfusion categories, and added additional medication and blood product categories to reflect newer pharmacologic options. The complete data collection forms are available on the STS website, as is information about how to become a participating center [71]. Table 3.2 lists the adverse events being collected by the CCAS–STS-CHSD.

Table 3.2 Congenital Cardiac Anesthesia Society–Society of Thoracic Surgeons Database Adverse Event Fields (as of January 1, 2021)

Event	Definition
None	No anesthesia-related adverse events noted in the perioperative period
Cardiac arrest events	
Cardiac arrest – anesthesia-related	Cardiac arrest requiring CPR during anesthesia care not related to surgical or catheter manipulation
Cardiac arrest – not anesthesia-related	Cardiac arrest requiring CPR during surgical or catheter manipulation
Airway–related events	
Difficult intubation/reintubation	Unplanned difficult intubation or reintubation
Unplanned extubation	Unplanned extubation (except if TEE-related – see below)
Bronchospasm	Wheezing requiring medical intervention other than suctioning
Endotracheal tube malposition	Endotracheal tube needing to be repositioned in ICU on arrival chest X-ray
Stridor/subglottic stenosis	New-onset stridor noted after extubation requiring intervention
Oral/nasal injury – bleeding	Bleeding noted in oropharynx or epistaxis, dental, lip, or nasal injury
Laryngospasm requiring medication	Laryngospasm requiring medical intervention other than positive pressure
Hemoptysis/pulmonary hemorrhage	Bleeding either from the endotracheal tube or postoperative hemoptysis
Respiratory arrest	Need to intervene in airway management in an unplanned way (i.e. converting from the cannula to ETT or LMA to ETT)
Airway injury	Barotrauma/pneumothorax secondary to positive pressure ventilation

(*Continued*)

AL Grawany

Table 3.2 (Continued)

Event	Definition
Medication-related events	
Protamine reaction	Significant reaction to protamine requiring intervention other than slowing administration
Anaphylaxis/anaphylactoid reaction	Suspected anaphylactic/anaphylactoid reaction requiring intervention for either hemodynamic support or respiratory intervention
Medication dosage	Wrong dosage of correct medication
Medication administration	Wrong medication administered
Non-allergic drug reaction	A nonanaphylactic reaction such as "red man" syndrome or hypotension
Malignant hyperthermia	Suspected or confirmed malignant hyperthermia reaction requiring dantrolene
Vascular access events	
Arrhythmia – CVL placement	Arrhythmia therapy needed other than withdrawing wire or catheter
Myocardial injury – CVL placement	Myocardial perforation
Vascular compromise – CVL placement	Extremity ischemia or compromise with CVL placement
Pneumothorax – CVL placement	Pneumothorax during placement of CVL
Vascular access	Inability to obtain desired vascular access within 1 hour of induction anesthesia (PIV/Aline/CVL)
Hematoma requiring relocation of the catheter	Significant hematoma that requires changing the site of desired access
Arterial puncture	Inadvertent arterial puncture during CVL placement
Intravenous/intra-arterial air embolism	Air embolism causing hemodynamic change or ischemia
Arterial line placement – extremity ischemia	Extremity ischemia or compromise with the arterial line placement
Intravenous Infiltration	Peripheral or central IV infiltration
TEE-related events	
TEE-related esophageal bleeding/injury	TEE-related esophageal bleeding noted during or after TEE removal
Esophageal chemical burn	TEE-related injury to esophageal mucosa due to TEE cleaning chemicals
TEE-related airway compromise	TEE-related compromise of ventilation or oxygenation requiring removal of TEE
TEE-related extubation	TEE-related inadvertent extubation of the patient
Positioning-related	
Complications during patient transfer	Any event occurring during movement of the patient into/out of the procedure, such as loss of IV or arterial line, airway compromise, disconnection of lines
Peripheral nerve injury due to positioning	Temporary or permanent nerve injury noted postoperatively due to positioning during the procedure
Integument injury under anesthesia	Skin breakdown or dehiscence or alopecia noted postoperatively due to positioning during the procedure
Ocular injury (corneal abrasion or injury)	Ocular injury noted postoperatively, such as corneal abrasion
Regional anesthetic events	
Bleeding – regional anesthetic site	Bleeding at the site of regional anesthetic placement
Intrathecal puncture – regional	Inadvertent intrathecal puncture during caudal or epidural placement
Local anesthetic toxicity – regional	Systemic evidence of local anesthesia toxicity (ECG changes, CNS changes)
Neurologic injury – regional	Injury to the peripheral nerve during regional nerve block
Miscellaneous	
Anesthesia equipment malfunction/failure	Any anesthesia equipment malfunction or failure during the procedure
Unplanned need to remain intubated due to anesthesia	Need to remain intubated at the conclusion of the procedure due to anesthesia factors (oversedation, muscle relaxation)
Hypercyanotic episode ("Tet" spell)	Hypercyanotic episode (decrease in SpO_2 > 20% from baseline) requiring intervention other than establishing airway ("Tet" spell)
Pulmonary hypertensive crisis	Probable or definite PH crisis requiring intervention
Postoperative nausea/vomiting	PONV requiring unplanned admission
Vomiting / Aspiration	Vomiting or aspiration of gastric contents at either induction or emergence of anesthesia
Intraoperative recall	Recall of intraoperative events
Emergence delirium requiring medication	Emergence agitation or delirium requiring medication
Other	Any event related to anesthesia care not otherwise listed

Aline, arterial line; CNS, central nervous system; CPR, cardiopulmonary resuscitation; CVL, central venous line; ECG, electrocardiogram; ETT, endotracheal tube; ICU, intensive care unit; LMA, laryngeal mask airway; PH, pulmonary hypertension; PIV, peripheral intravenous catheter; PONV, post-operative nausea/vomiting; SpO_2, pulse oximeter oxygen saturation; TEE, transesophageal echocardiography; TOF, tetralogy of Fallot.
Source: Data fields are from Vener et al. [26].

International efforts

Efforts are ongoing to make this database initiative a global project. Initial collaborative discussions have taken place about the possibility of linking this initiative with the European Association of Cardiothoracic Anaesthesiology and Intensive Care [72]. The final selection of database fields will be made through a collaborative effort involving surgeons and cardiologists from Europe and North America, as well as other continents. It is certainly possible and desirable that the STS-CHSD has an identical anesthesia module in the congenital heart database of EACTS and The European Congenital Heart Surgeons Association. These European and North American congenital heart surgery databases have functioned as sister databases with identical nomenclature and database fields and definitions [73, 74]. The incorporation of anesthetic data into the effort should follow a similar strategy. This project should also ideally spread beyond North America and Europe. Efforts to involve Africa, Asia, Australia, and South America are necessary and already underway, under the leadership of The World Society for Pediatric and Congenital Heart Surgery [75].

The creation of a joint cardiac surgery and anesthesia database is another step toward the ultimate goal of creating a database for CHD that spans both geographic and subspecialty boundaries and can potentially capture a patient's lifetime of cardiac care regardless of their location. The Pediatric Heart Network, a research consortium of major congenital cardiac centers, has recognized this need and is supporting the creation of linkage between various registries such as the CCAS, STS, EACTS, Congenital Heart Surgeons' Society, the ACC IMPACT Interventional Cardiology registry, and the Pediatric Cardiac Critical Care Consortium (PC^4) ICU registry, as well as others [76].

Measuring outcomes has become a critical component of all facets of medical practice today. It is important for anesthesia and, in particular, for practitioners of pediatric cardiac anesthesia because of the extremely high-risk nature of this practice. Regular review of both caseload and outcomes in a structured manner through quality improvement conferences, mortality and morbidity, and individual case reviews can help to educate anesthesia departments and individuals and perhaps minimize future adverse outcomes. Open lines of communication with our surgeons, cardiologists, and intensive care physicians are a key component of this process, along with the recognition that adverse events are inevitable in such a system and our job is to always be vigilant and ready to act on the patient's behalf.

KEY POINTS: NETWORKS AND DATABASES

- A major database effort has been initiated by CCAS in conjunction with the STS Congenital Heart Surgery Database.
- Both cardiac surgical and non-cardiac surgical anesthetics can be entered, and 66,655 anesthetics from over 60 US programs have been analyzed as of 2020.

Introduction

Caring for the patient with congenital heart disease (CHD) has become an increasingly complex endeavor, with the rapid increase in knowledge about each condition, and the diagnostic and therapeutic options available. Previously unimaginable procedures, such as a Stage I Palliation procedure for hypoplastic left heart syndrome (HLHS) being performed interventionally in the cardiac catheterization laboratory without surgery, are being contemplated and will be attempted soon [1]. Congenital cardiac care now encompasses the entire lifespan from the fetus and neonate to the adult with CHD [2]. The explosion of knowledge in pediatric and CHD makes it impossible for one practitioner, or a small group of caregivers, to possess the requisite knowledge about every condition to make an informed decision for the best care of the patient. Newer procedures such as transcatheter pulmonary and aortic valve replacement, stenting or occlusion of the patent ductus arteriosus (PDA) in small infants, and a variety of new short- and long-term mechanical support devices have radically changed the older approaches to many lesions and clinical scenarios which formerly had been well established [3, 4]. There is a profusion of outcome studies of all of these new approaches published every year, and it is infeasible to be well versed in all of these new data. Over the past several decades, the development of pediatric and congenital cardiac anesthesiology, with a more formal and complete knowledge base, dedicated teams in many centers, and organized fellowship training now culminating in Accreditation Council for Graduate Medical Education (ACGME) certification in the United States, has given impetus for anesthesiologists to be formally involved in patient care decision-making and leadership roles in systems of care [5]. The idea of multidisciplinary collaboration, where many experts discuss and contribute to patient care decisions and reach a consensus, has evolved as the desired model for many institutions, given the profound implications for outcomes and quality of life for patients. In addition, collaborative shared leadership for strategic and operational planning has emerged as a desired model in congenital cardiac care for many programs.

This chapter will review the concept of a Center for care in congenital cardiac disease from the perspective of the Texas Children's Hospital (TCH) Heart Center as an example of one possible approach to multidisciplinary collaboration of a large number of providers from many disciplines, and its evolution over 25+ years. Undoubtedly, there are many varied paths

AL Grawany

taken by different institutions to achieve their current CHD programs, and TCH is but one example [6, 7]. The congenital cardiac anesthesiologists' essential role as not only caregivers, but also as contributors to patient care decision making, and TCH Heart Center leadership, will be highlighted. Then, important issues in communication and team functioning in the periprocedural areas will be discussed, focusing on the anesthesiologist's role in the cardiac surgical operating rooms (OR) and catheterization laboratories, and in the handoff of information postprocedure, to the intensive care unit (ICU) caregivers. Next, additional examples of multidisciplinary programs and teams will be described. Finally, a brief discussion of the COVID-19 pandemic on team functioning in congenital cardiac care is presented.

Texas Children's Heart Center multidisciplinary approach

Over the past 25+ years, Texas Children's Hospital congenital cardiac care has evolved from a small team of one surgeon, one anesthesiologist, three perfusionists, two OR nurses, and 10–15 cardiologists (many of whom doubled as cardiac intensivists), performing 450 surgeries and 500 cardiac catheterizations per year, to the current large system of seven surgeons, 14 anesthesiologists, 60 cardiologists, and 25 cardiac intensivists performing more than 1,000 surgeries, and 1,500 cardiac catheterizations annually. What formerly was essentially 2–3 possible personnel combinations for cardiac surgery, with great familiarity of the same team working together at least several times a week, has evolved into an almost infinite number of caregiver combinations where the same team is only infrequently together. The TCH Heart Center has developed a robust system of leadership, care, and communication that has enabled this evolution, from a simple system to a large complicated organization, and now to a very large complex organization, where all personnel strive to provide a consistent, high-quality level of care to all patients. The concept of complex adaptive systems in health care is being realized [8], where the focus is on interactions of interdisciplinary team members with each other, rather than on the characteristics of individual team members, in their ability to adapt to the many changing conditions and challenges to the organization [9].

Heart Center leadership structure

The TCH Heart Center Executive Committee (HCEC) consists of two Co-Directors, the Service Chiefs of Congenital Heart Surgery, and Pediatric Cardiology. Additional members include the Service Chiefs of Congenital Cardiac Anesthesiology (CCA) and Cardiac Intensive Care. Finally, a Nursing Lead, Physician Business Development lead, Hospital Administrative Director, and several Leads for Philanthropy and Public Relations complete the Committee (Table 4.1). This committee meets monthly or more often as needed, to set strategic directions and respond to current challenges. Of note, CCA has a major role "at the table" for all of these meetings and has an opportunity to contribute to all major questions facing the HCEC. The HCEC has a reporting relationship to a TCH Senior Leadership team consisting of the In-Chiefs of the six hospital medical staff departments, and Executive Vice Presidents. Reporting to the HCEC are six multidisciplinary teams, each with representation from all major disciplines, that encompass the major priorities of the TCH Heart Center: clinical operations, research operations, teaching operations, data operations, patient and family experience, and marketplace competition.

Table 4.1 Texas Children's Heart Center multidisciplinary leadership structure

Heart Center executive committee members:
- Chief of Pediatric Cardiology, Co-Director
- Chief of Congenital Heart Surgery, Co-Director
- Chief of Congenital Cardiac Anesthesiology
- Chief of Cardiac Intensive Care
- Business Development Lead (Physician)
- Nursing Lead
- Hospital Administrative Lead
- Philanthropy Lead
- Marketing/Public Relations Lead

Multidisciplinary distributive leadership teams:
- Clinical operations
- Teaching operations
- Research operations
- Patient and family experience
- Marketplace competition
- Data operations

Clinical decision-making

The TCH Heart Center has made a commitment that every patient presenting for a potential intervention, whether surgery or cardiac catheterization, should be presented before a wide audience of Heart Center members, and the clinical decision-making conferences are open to all members of the TCH Heart Center. The only exception is an emergency case where time does not permit broad discussion or simple diagnostic catheterization cases that are scheduled per protocol such as myocardial biopsies. There is formal Heart Center time every day, Monday through Friday, to present new cases in need of a timely decision about surgery, catheterization, or complex medical care.

Presurgical planning conference

Presurgical planning conferences have remained a key component of congenital cardiac care for well over 50 years and are a familiar feature of most pediatric cardiology/cardiac surgery programs [10]. Traditionally this approach involved only cardiology and surgery; for example, in the author's experience at the University of California, San Francisco, during Pediatric Residency training in the 1980s, a Cardiology Fellow would present the history and physical examination findings, and the additional data such as ECG, chest radiograph, cardiac catheterization angiograms and physiologic calculations, and laboratory data. In later years, echocardiography, computed tomography (CT), and magnetic resonance imaging (MRI) results were added to the data presented. After this presentation, a surgical plan was made after discussion among the (usually senior) cardiologists and surgeons. The junior

members of the team were reluctant to speak and rarely did so. Duignan and colleagues prospectively evaluated clinical decision-making in 107 consecutive patients in a joint Pediatric Cardiology-Cardiac Surgery Conference, deeming 50% of the cases as complex [11]. Among these patients, Duignan and colleagues identified occasional patients with the same data sets that had different clinical decisions, some instances of the same complex patient being revisited, and two different treatment plans resulting. Anchoring bias (tendency to recommend procedures within one's own field, i.e. surgery or interventional catheterization) was identified in several cases, and the lack of validated decision-making algorithms in the field of congenital cardiac care was noted. The TCH Heart Center has attempted to minimize these issues with the following approaches.

At TCH, Surgical Case Conferences reviewing upcoming cases for the week have involved anesthesiologists, intensivists, nurses, consultants, radiologists, trainees in all disciplines, and any other interested clinician in the Heart Center for over 25 years; and in pre-COVID 19 pandemic times often over 100 people gathered in the Helen B. Taussig Auditorium to discuss and confirm, and at times alter, the surgical plan (Figure 4.1). A structured template, with a clinical presentation by the cardiology, surgery, or intensive care fellow, followed by the display of pertinent imaging findings by an echocardiographer, or cardiac MRI/CT specialist dedicated for the conference and prepared in advance, is followed by proposed surgical plan and discussion, confirming or at times changing the plan. Ninety minutes on Monday morning is allotted to the presentation of approximately 15–20 patients; requiring presentation and discussion to be efficient and accomplished in 3–5 minutes for the straightforward patients. In the COVID-19 pandemic era, this and all large Heart Center Conferences have been converted to a videoconference format (Figure 4.2). In both settings, all attendees are encouraged to voice their opinions about the proposed plan for a case, even if they are a member of the junior faculty or trainee groups.

Figure 4.1 Texas Children's Hospital surgical case conference. (A) Pediatric cardiology fellow presenting the history and physical exam findings of a neonatal patient scheduled for cardiac surgery. (B) View of the surgical case conference audience, with chest radiograph displayed. (C) Large-scale high-resolution digital screens allow accurate review of angiograms from the Cardiac Catheterization Laboratory. (D) Cardiac magnetic resonance imaging is presented.

AL Grawany

Figure 4.2 Desktop computer view during urgent case presentation of the neonate with hypoplastic left heart syndrome requiring surgery. The echocardiogram is being discussed via videoconference during the COVID-19 pandemic era.

New patient case conferences

Additional clinical decision-making opportunities exist for new patients, and existing patients requiring decisions about the next steps in clinical care. Further, 90 minutes each on Monday and Wednesday afternoons are allotted to two such conferences, where primary cardiologists present to representatives from Cardiac Surgery and Catheterization Laboratory, to decide on a treatment plan.

A specialized conference for Adult Congenital Heart Disease (ACHD) patients is held once a week for 60 minutes, where a multidisciplinary group discusses the unique needs of this patient group, including medical, catheter, and surgical therapy. Representatives from surgery, ACHD cardiology, ACHD ICU, anesthesia, and nursing are present in these weekly conferences. As with the other patient decision-making conferences, the entire Heart Center is invited to attend these conferences.

Morning report

In addition to these formal conferences, each day starts with a morning report where the entire Heart Center can attend; after a brief review of the inpatient Heart Center census and planned admissions and discharges there is an opportunity to present newly admitted patients, or patients otherwise in need of clinical treatment decisions urgently (within 24–48 hours) who cannot wait for the formal case conferences (Figures 4.2 and 4.3). As with the formal planning conferences, any attendee is encouraged to speak up and voice their views on a proposed treatment plan, and at the end of the presentation, a consensus is reached about the planned treatment. These presentations often result in cases added to the surgical or catheterization schedule the same day as the presentation. For example, on the day of this chapter writing, an infant with tetralogy of Fallot, and PDA stent with cyanotic spells was presented in morning report, and dilation of PDA stent vs. surgery was discussed, the consensus was for surgery and successful repair was accomplished that day.

Data, validation, and consistency in clinical decision-making

This system of clinical decision-making has evolved as the TCH Heart Center has grown in numbers of cases handled and personnel available, so that every patient has the advantage of the collective experience and wisdom of the entire Heart Center through a transparent process striving to attain consistency in decision-making, e.g. all patients with the same condition will receive the same or similar treatment plan, that is data and outcomes-driven and widely known to all who have an interest. The above-noted Surgical Case Conference is an opportunity for a second review to confirm the surgical plan before the patient enters the OR and occasionally results in a change in the plan. Periodically, through additional Heart Center quality conferences noted below, outcome data for major lesions or other lesions of interest are reviewed, both for local cases, for large databases such as the Society of Thoracic Surgeons' Congenital Heart Surgery Database, and recently published literature. Through this process, a consensus is reached to change approaches to specific lesions. Two recent examples include the decision to move to primary stenting of the PDA for most neonates with right-sided obstructive lesions in need of a stable source of pulmonary blood flow instead of a Blalock-Taussig-Thomas shunt; and transcatheter occlusion of the PDA in premature and other small neonates instead of ligation by thoracotomy.

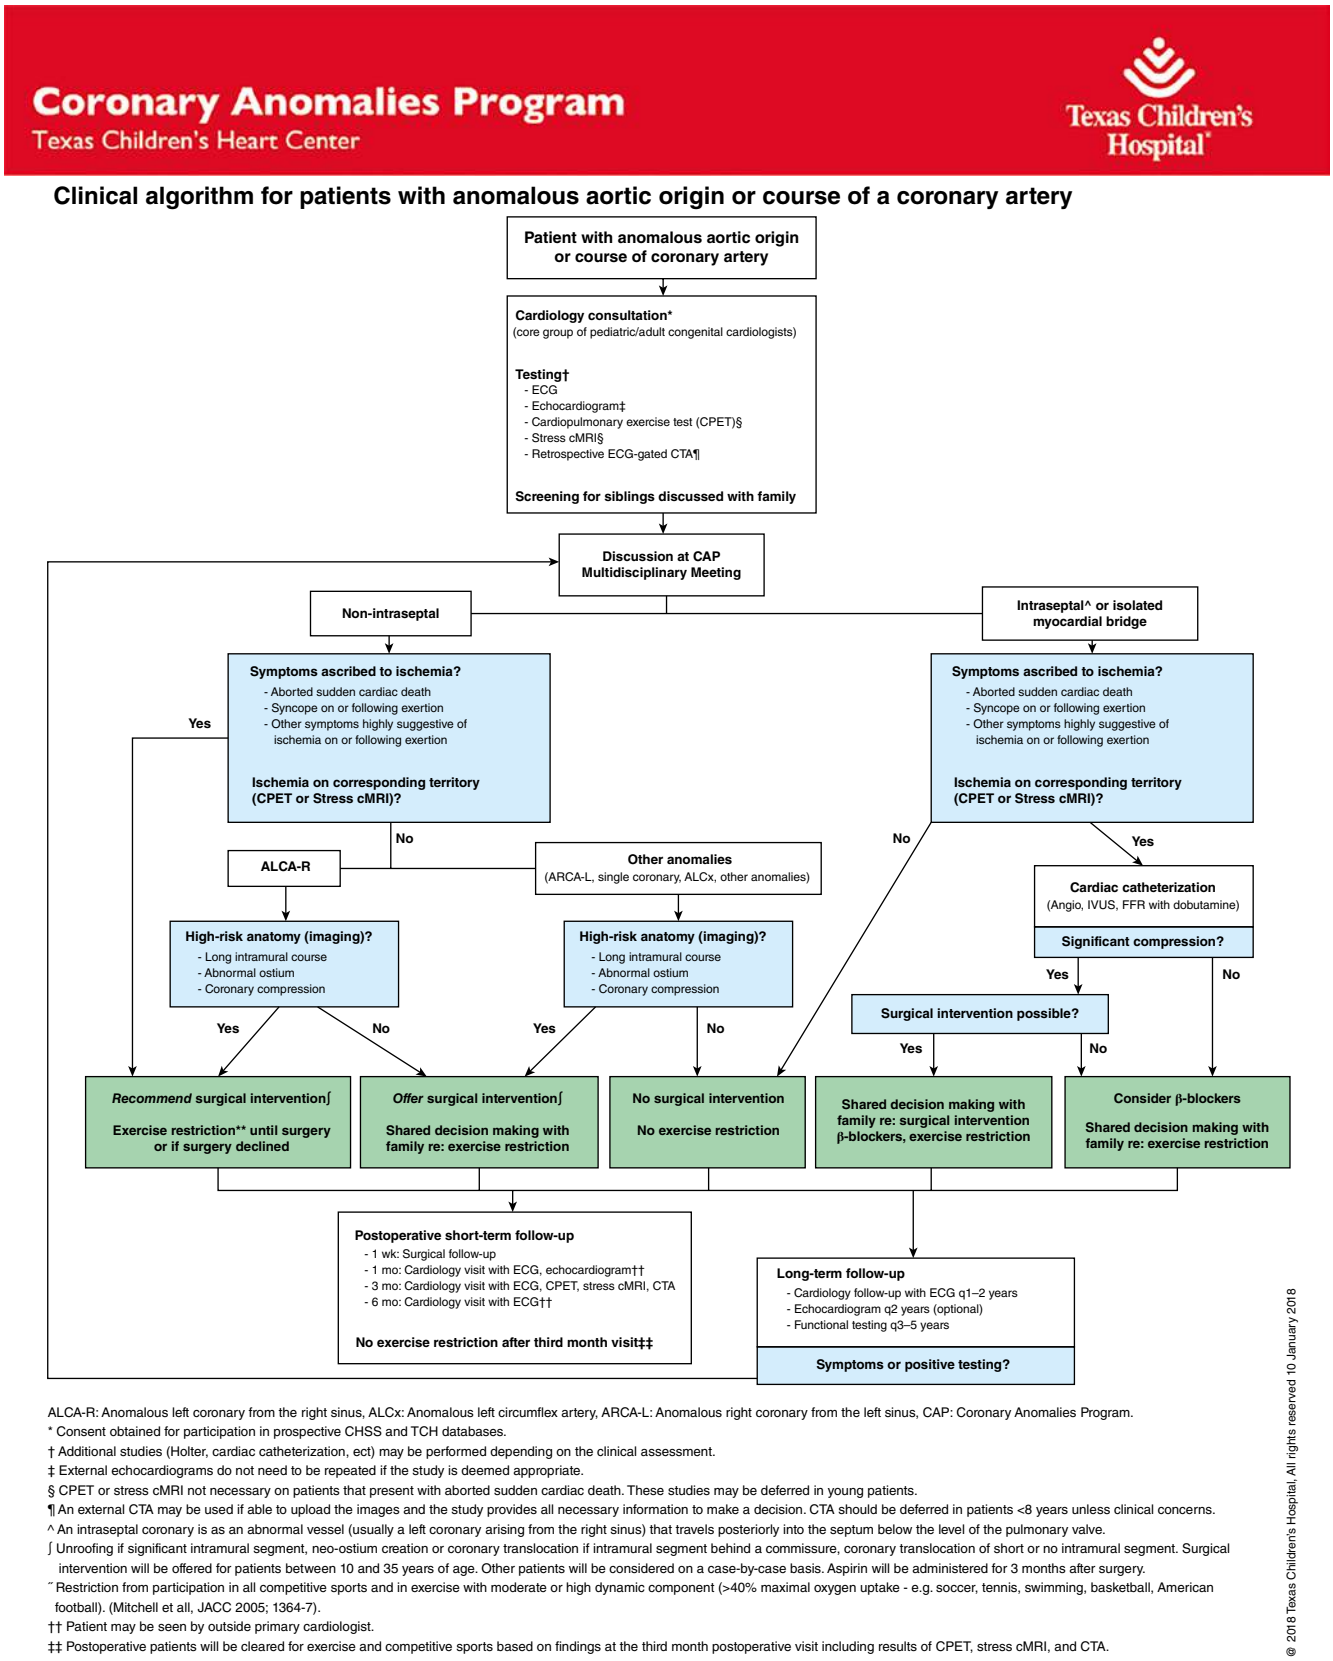
Figure 4.3 Morning report. (A) An overview of heart center census and non-scheduled admissions. ACHD, adult congenital heart disease unit; AS, aortic stenosis; ASD, atrial septal defect; AVSD, atrioventricular septal defect; CICU, cardiac intensive care unit; CoA, coarctation of aorta; CPCU, cardiology-cardiac surgery inpatient ward; CVOR, cardiovascular operating rooms; DORV, double-outlet right ventricle; EC, emergency center; FTT, failure to thrive; GI, gastrointestinal; HIE, hypoxic-ischemic encephalopathy; ICD, implantable cardioverter-defibrillator; MIS-C, multisystem inflammatory syndrome in children associated with COVID-19; PVS, pulmonary valve stenosis; PDA, patent ductus arteriosus; RRT, rapid response team; SOB, shortness of breath; TGA, transposition of the great arteries; VSD, ventricular septal defect (B) Anticipated admissions and discharges to inpatient units, and scheduled clinic visits. CHS, congenital heart surgery; ECHO, echocardiography laboratory; OP, outpatient; SDA, same-day admission.

AL Grawany

Although the field of validated decision-making algorithms in CHD is relatively new, one example is an approach developed at TCH for Anomalous Aortic Origin of the Coronary Arteries (AAOCA), where the three treatment strategies are: observation without exercise restriction; exercise restriction; and surgical intervention [12]. Using decision analysis, a formal quantitative approach that analyzes different management strategies under conditions of uncertainly, an algorithm was developed utilizing outcomes from the published literature, and individual patient characteristics such as age and symptomatology. Life expectancy and quality-adjusted life expectancy were the outcomes, and a cohort of 10,000 hypothetical identical patients underwent a first-order Monte Carlo simulation, with further sensitivity analyses. Surgery was the preferred management strategy for most patients under 30 years of age for anomalous left coronary artery; and for patients <25 years of age for anomalous right coronary. Utilizing the principles proposed in this algorithm, 47 of 163 patients with AAOCA underwent surgery; 82% of the entire group was allowed unrestricted sports exercise activity; and of the surgical patients, 3 (6.4%) are restricted from sports exercise activity(Figure 4.4) [13]. All patients in the cohort were alive, whether they underwent surgery or not, during the follow-up period. The formation of a multidisciplinary team, with support from clinical data science specialists, is key to the success of this program.

Multidisciplinary Surgical Patient ICU Rounds



Because of the early start to the surgical cases and the additional early morning conferences, the practice of rounding on surgical patients in the Cardiac ICU (CICU) at 6:15 AM Monday–Friday has been practiced for many years. This has resulted in a large group of surgeons, surgical trainees, advanced practice providers, CICU physicians and trainees, nursing leadership, the bedside nurse, and even the parents present in (or mostly outside in the hall) the CICU, traveling from patient to patient. A brief, standardized presentation by the ICU, surgical, and nursing providers for the patient was followed by surgical plans, i.e. removal of the chest tubes, pacing wires, sternal closure, etc. for the day. It was typical to have limited sight and hearing lines to the presenter, the patient, the displayed radiographs, and the physiological monitors. The COVID-19 pandemic has prevented the gathering of large groups near the bedside and given rise to some novel methods to present the patient's data to a multidisciplinary group. At the time of this writing, Surgical Rounds are conducted over videoconferencing with all participants (20–40 on most days) logged in at their respective desks. The presenters communicate the data, while the chest radiograph and real-time physiologic monitoring data are displayed on the screen (Figure 4.5). Joint decisions are made about surgical and major ICU issues, with all participants able to see and hear all the data, and with the ability to speak up to allow their perspectives to be communicated. The process is also more efficient in this manner, with as many as 30–40 active surgical patients presented in the allotted 45 minutes. The entire Heart Center is invited to these rounds, as with all of the other major patient care conferences.

Heart Center Quality Improvement Conferences

The TCH Heart Center has several patient care Quality and Outcomes Improvement Conferences, which are protected in a legal framework from disclosure and outside discovery, allowing detailed and frank discussion of quality issues. Most of these conferences include the entire Heart Center on the invitation list.

Performance Rounds

Once per week a 60-minute meeting is devoted to Performance Rounds, where selected patients from surgery or the catheterization laboratory are presented in a standardized, visual, infographic time-based format where the horizontal axis is time (days) and the vertical axis is the perceived risk level to the patient, from threats, errors, unintended clinical states and their linkage; risk increases with the intensity of the activity and decreases with the de-escalation of care (Figure 4.6). Increased risk is conferred during surgery, generally the highest risk state in a patient's journey, and decreased with tracheal extubation, sternal closure, weaning off inotropes, discharge to ward, and discharge to home. Data is collected from electronic medical records, bedside data, adverse event reporting mechanisms, and staff interviews. This approach was described by Hickey and colleagues, who reported on 524 patient care "flights" surrounding a surgical procedure [14]. In 12% of flights the patients failed to de-escalate sequentially, and in the timeframe expected, through the risk levels. Failed de-escalations were strongly associated with errors (426 in 257 flights, $p < 0.0001$). More serious errors were associated with the 29% rate of failed de-escalation, vs. 4% in flights with no consequential error ($p < 0.0001$). Using this process at the TCH Heart Center, outcomes data for the major procedures have been developed, both internal center-specific outcomes, and from national databases such as the Society of Thoracic Surgeons' Congenital Heart Surgery Database. A team of outcome specialists develops the infographics and presents the data, and the entire Heart Center staff is invited. In recent years interventional cardiac catheterization procedures have been added to Performance Rounds. Before these rounds, the themes of psychological safety (see below), and confidentiality of the privileged patient care information are emphasized. Surgeons', cardiologists', and anesthesiologists' names are listed on the infographic, and they are encouraged to explain any unexpected events for the benefit of the entire Heart Center, with the goal of collective learning, communication, and improving patient care, and not to direct blame to the individual practitioner. Themes and issues that are identified, i.e. communication errors, delayed care, technical errors, decision-making errors, etc., are discussed, and if emerging patterns are perceived over multiple patients, they are referred formally to the Quality and Outcomes Team for a deeper dive into causes and solutions. These issues are brought back to the Heart Center for updates on changes to processes and outcomes. Routine simple surgery or catheterization laboratory cases, without unexpected progress in de-escalation, are presented in a list format but not otherwise discussed.

ALCA-R: Anomalous left coronary from the right sinus, ALCx: Anomalous left circumflex artery, ARCA-L: Anomalous right coronary from the left sinus, CAP: Coronary Anomalies Program.
* Consent obtained for participation in prospective CHSS and TCH databases.
† Additional studies (Holter, cardiac catheterization, ect) may be performed depending on the clinical assessment.
‡ External echocardiograms do not need to be repeated if the study is deemed appropriate.
§ CPET or stress cMRI not necessary on patients that present with aborted sudden cardiac death. These studies may be deferred in young patients.
¶ An external CTA may be used if able to upload the images and the study provides all necessary information to make a decision. CTA should be deferred in patients <8 years unless clinical concerns.
^ An intraseptal coronary is as an abnormal vessel (usually a left coronary arising from the right sinus) that travels posteriorly into the septum below the level of the pulmonary valve.
∫ Unroofing if significant intramural segment, neo-ostium creation or coronary translocation if intramural segment behind a commissure, coronary translocation of short or no intramural segment. Surgical intervention will be offered for patients between 10 and 35 years of age. Other patients will be considered on a case-by-case basis. Aspirin will be administered for 3 months after surgery.
¨ Restriction from participation in all competitive sports and in exercise with moderate or high dynamic component (>40% maximal oxygen uptake - e.g. soccer, tennis, swimming, basketball, American football). (Mitchell et all, JACC 2005; 1364-7).
†† Patient may be seen by outside primary cardiologist.
‡‡ Postoperative patients will be cleared for exercise and competitive sports based on findings at the third month postoperative visit including results of CPET, stress cMRI, and CTA.

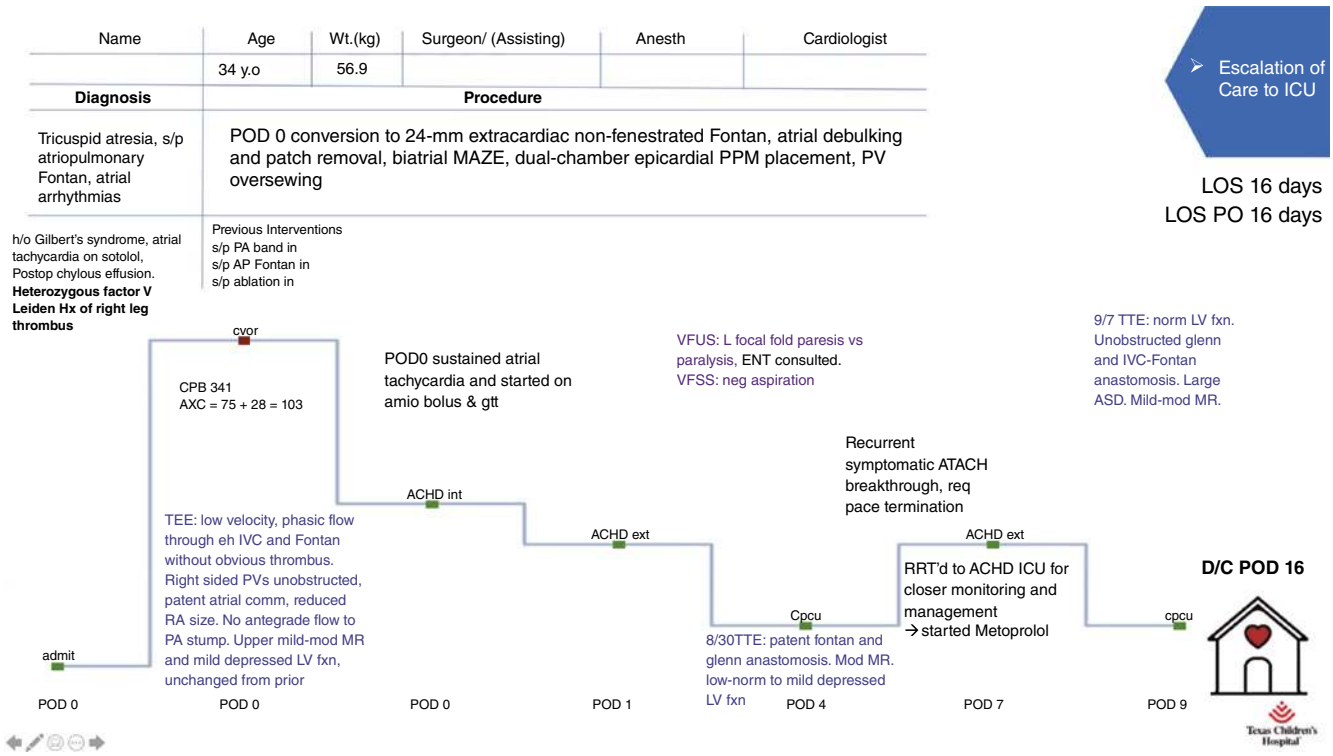

Figure 4.6 Performance rounds infographic. Time in days is displayed on the horizontal axis; risk level on the vertical axis; and details of the operative course are reported. The upper right-hand corner displays the major event prompting discussion; in this case, an arrhythmia requiring readmission to ICU which was recognized and treated appropriately. Note the stepwise decrease in risk level until postoperative day 7.

Heart Center Quality Conference

Once per week a 60-minute conference is devoted to quality and outcomes data and reports from each of the clinical disciplines in the Heart Center, on a rotating basis. This includes a Surgical Morbidity and Mortality conference, Catheterization Laboratory Quality Conference, CICU Quality and Outcomes presentation, Cardiovascular Anesthesiology Quality Presentation, and presentations from Nursing, Adult CHD, Outpatient Cardiology, Echocargiography, and other components of the Heart Center clinical enterprise.

Multidisciplinary meeting

Every Friday early morning, 45 minutes are devoted to a Quality and Outcomes Multidisciplinary Meeting, where only the attending physicians from Surgery, Anesthesiology, and CICU, plus a Nursing and Perfusion leader, are invited, for a discussion of each surgical case done in the past week, to review the immediate perioperative course and outcomes, communicate common important issues to the group, and give each member an opportunity to discuss their decision-making process and how it may have contributed to the outcome. The surgeon starts by briefly presenting the case, and then the anesthesiologist and intensivist have an opportunity to add to the discussion. The smaller group is conducive to frank discussions about opportunities for improvement; identifying significant issues that affect the entire perioperative team that then can be assigned an individual to lead more data collection and solutions to the problem. Great successes are also discussed and celebrated, and those involved in the case can enlighten the group, again for the benefit of future patients.

Figure 4.7 displays the calendar of the weekly multidisciplinary meetings in the TCH Heart Center.

Heart Center Wide Communication Activities

Heart Center Town Hall

With a very large group of practitioners and supporting staff that now numbers greater than 500 individuals, it can be challenging to communicate important events, announcements, initiatives, and strategies to all Heart Center members. Quarterly Heart Center Town Halls, 60 minutes in length, are held, with the Heart Center Executive Committee leadership leading the agenda and introducing additional speakers; there are always at least 15–20 minutes left for comments and questions, and unanswered questions are addressed separately by email (Figure 4.8).

Heart Center annual retreat

Once every year, non-emergent patient care is paused for 4 hours, and the entire Heart Center participates in a "retreat" – in reality on site at TCH. During these retreats, a theme is prepared, and after Heart Center leadership presentations, speakers from the Heart Center, or outside speakers make presentations followed by questions and comments from the audience. Once again, all Heart Center members at any level of seniority are encouraged to ask questions and make comments, for the benefit of the entire group. Some annual retreat themes have included: improving communication across silos, integrating teams and processes, transparency, psychological safety, shared decision-making, patient/family experience, partnerships with external providers, and shared common purposes [15, 16]. In the pre-pandemic era, several hundred people gathered in a large auditorium and enjoyed well-prepared content, for example, presentations on psychological safety from a well-regarded Rice University School of Business professor with substan-

tive research in this area (Figure 4.9). In the current pandemic era, this activity is conducted by videoconference; with participants encouraged to write questions, or ask live if they prefer.

Anesthesiologist involvement in patient care and leadership activities

TCH Heart Center anesthesiologists are often busy starting cases for the early 7–8 AM conferences and cannot attend all, but all conferences have anesthesiology representation for those without scheduled cases at that time. The anesthesiologists very often contribute to the discussion and the decision-making process for all of these conferences and are valued full-time members of the Heart Center team, whose opinion is often requested and is always respected. Presence and visibility at these conferences for the Anesthesiologists give them complete access and exposure to the broader Heart Center, increasing respect and affording opportunities, rather than being limited to surgeons in the operating room and interventional cardiologists in the catheterization laboratory. Having a full-time division whose sole clinical activity is in the Heart Center also increases the reputation and trust of CCA, and affords leadership, quality, education and research opportunities that facilitate career advancement and satisfaction.

Communication and team functioning in periprocedural areas: surgery and catheterization laboratory

In 2000, de Laval and colleagues published a landmark paper on human factors, errors, near misses, communication, and rescue from negative events in a multicenter study of 193 arterial switch operations (ASO) performed by 21 surgeons in all 16 institutions performing pediatric cardiac surgery in the United Kingdom in the late 1990s [17]. A self-assessment questionnaire regarding performance was filled out at the end of the operation by the surgeon and surgical assistant, the anesthesiologist, perfusionist, and scrub nurse. Each case was independently observed by a human factor researcher, who wrote a detailed description of the operation, including individual and team performance, communication within and between teams, and situational and organizational data. Errors or failures were recorded and classified as minor (minor disruptions in surgical flow without consequences) or major (likely to have serious patient safety consequences) negative events. Events were also deemed compensated, or uncompensated, meaning resolved, or recovered after appropriate action by the perioperative team. There were 16 hospital deaths for mortality of 6.6% with 43 near misses (17.7%). The number of uncompensated major events per case conferred the strongest risk of death at an odds ratio of 13 (95% CI 2.1–83, $p = 0.006$), and for each uncompensated major event, estimated odds of death increased by a factor of 5.7, and odds of death plus near miss were increased by a factor of 40. Interestingly, the self-report questionnaires were not successful in capturing human factors in predicting outcomes. The finding that failure to rescue from complications was strongly associated with poor outcomes is consistent across medical specialties. The list of observed major and minor events in this paper details a number of team performance problems, e.g. not communicating significant deterioration during cannulation, delay in the administration of heparin, delay in recognition of myocardial ischemia post-CPB, incorrect interpretation of serious deterioration during transport to ICU, failure to achieve sufficient vascular access, the inappropriate delegation of anesthetic tasks to inexperienced juniors, and many others (Table 4.2). This widely cited study described in great detail the gaps in performance during a highly complex, but very reproducible operative procedure. The study serves as a roadmap to better team functioning and communication and has contributed to the ability not only to rescue from errors but even more important to prevent them from occurring in the first place.

Table 4.2 List of observed major and minor events during the arterial switch operation

Stage (No.)	Description and examples
Major events Preoperative (4)	Serious errors and problems that are experienced before anesthetic induction for surgery, e.g. cardiac perforation during balloon atrial septostomy(BAS)
Anesthesia (8)	Errors and problems experienced during anesthesia and insertion of lines • Failure to gain sufficient vascular access • Pincushioning during insertion of lines, leading to a serious cardiac event • Delayed diagnosis of a major deterioration in the patient's condition • Lack of monitoring delaying diagnosis of a serious event
Prebypass (27)	• Hemodynamic instability of the patient due to rough surgical manipulations • Surgical errors, e.g. laceration of the ductus arteriosus before bypass • Serious cannulation problems • Severe unrecognized deterioration in the patient's condition (low ABP and SaO_2) before bypass caused by cognitive tunnel vision on surgical tasks and/or lack of monitoring • Delay in the administration of heparin
Bypass (44)	• Decision-making errors in deciding how to reimplant a difficult CAP (inexperienced surgeons) • Technical errors: aortic tear during the administration of the cardioplegic solution, accidental injury to a major coronary artery, malrotation of the main pulmonary artery, twisting the pulmonary artery during the Lecompte maneuver, damage to the neo-aortic valve, tear during the closure of the ductus arteriosus, severe laceration of a pulmonary arterial branch requiring patch repair • Major perfusion problems • Anesthetic problems: failure to cool the cardioplegic solution, failure to flush the cardioplegia-infusion set resulting in massive coronary air embolism
Postbypass (84)	• Serious ischemic event: delay in diagnosis, incorrect interpretation, inappropriate strategy in the event of a serious ischemic event • Ventilation errors by consultant anesthetist • Surgical omissions; omission of pacing wires in a patient who has severe arrhythmias, omission of securing indwelling catheters such as the left atrial line • Delayed diagnosis; incorrect interpretation of a serious deterioration of the patient during the transfer from the operating theater to the ICU
Minor events Preoperative (17)	• Coordination problems with the blood bank, problems with the availability of ICU beds • Communication problems between the ward and the theater team, scheduling of cases • Poor fasting policy

AL Grawany

Table 4.2 (Continued)

Stage (No.)	Description and examples
Anesthesia (67)	• Cognitive tunnel vision on insertion of lines to the neglect of monitoring the ECG screen (where no major event results) • Inappropriate delegation of anesthetic tasks to an inexperienced junior • Equipment problems: failed alarm systems, incorrect ECG readings, or unavailability of equipment • Human resource problems, e.g. no junior anesthetic assistant available, no technical assistance
Prebypass (144) and bypass (732)	• Positioning and tension error(s) by the surgical assistants • Instrument handing errors by the scrub nurse • Distracters: internal and external • Inappropriate task delegation (surgical, anesthetic, perfusion) to an inexperienced assistant • Problems with theater equipment • Communication errors: problems with passing information between theater teams • Absence of a senior team member in theater at safety-critical times • Surgical tunnel vision, where the surgeon(s) focus(es) exclusively on the surgical aspects of the procedure at the expense of monitoring the ECG screen (but no serious problems develop); this usually occurs when closing the sternum • Perfusion problems: air locks, poor visibility because of unsatisfactory blood aspiration
Postbypass (73)	• Positioning, tension, and instrument handing errors, communication errors, surgical tunnel vision, and equipment problems • Anesthetic problems: e.g., adjustment of ventilating parameters, not starting inotropic support and vasodilators at an appropriate time • Communication problems during hand-over to ICU • Lack of seniority during transfer or in the team admitting the patient to ICU • Absence of monitoring for an excessive period of time during transfer to the ICU

ABP, arterial blood pressure; BAS, balloon atrial septostomy; CAP, coronary artery pattern; ECG, electrocardiograph; ICU, intensive care unit; SaO_2, arterial oxygen saturation.

Communication in the operating room

A brief preoperative conversation between the anesthesiologist and surgeon is advisable before the patient is brought to the OR for induction of anesthesia. This is an informal "check-in" to communicate unique aspects of the case that affect anesthetic and surgical approaches, and can include issues such as planned sites of vascular access, (i.e. are two arterial lines needed for an aortic arch repair?); are there special plans for CPB such as regional cerebral perfusion; of the surgical options listed on the consent form which is most likely, risk of cardiac or vascular injury during re-entry sternotomy and plans for emergency bypass, high-risk induction of anesthesia and need for the surgeon to be present and CPB circuit primed and ready, and other details about the case that often are not decided until the patient has had a detailed preoperative examination and individual plan made. This conversation can be the day before, or the morning of, surgery, and ensures that concerns about the case are communicated beforehand, and not only at the time of surgical timeout (see below) so that preparations can be made before entering the operating room. This conversation can help avoid unexpected requests or procedures that are only known during, or even after, the surgical timeout.

Surgical safety checklist

The effectiveness of a surgical safety checklist (SSCL) gained wide recognition after Gawande and colleagues conducted a study of eight hospitals in diverse settings and populations that instituted a process that required a pre-induction checklist of patient identification, basic monitors, surgical and anesthetic factors; a time out before surgical incision introducing the team and role, re-identifying the patient, and reviewing surgical and anesthetic procedures; and a sign out before the patient leaves the operating room reviewing sponge and instrument counts, disposition of the patient, and whether any concerns were identified [18]. Surgical mortality and complications were recorded in 3,733 patients before the institution of the SSCL, and in 3,955 after its introduction, and mortality decreased from 1.5% before to 0.8% after ($p = 0.003$), and inpatient complications decreased from 11.0 to 7.0% ($p < 0.001$). At TCH, the SSCL was introduced in 2009 and has gone through a number of iterations for various operating rooms and types of cases in the institution. The current version for cardiac surgery cases with bypass is displayed in Figure 4.10. Institutional lessons learned in the evolution of the approach are numerous, perhaps most important that during each phase of the SSCL, all other activity is ceased and all involved are completely attentive to the checklist, and the checklist is read like a script and not recited from memory.

The preoperative briefing is initiated by the anesthesiologist and involves the anesthesia team, circulating nurse, patient, and parents and the parents are encouraged to listen and ask questions. Any questions are resolved, and the patient proceeds immediately to the operating room. The surgical timeout is initiated by the surgeon and occurs with the patient prepared and draped, and all surgical personnel scrubbed and in position for the operation, immediately before the incision. A crucial point is that all other activity is ceased, any extraneous noise such as music is silenced, and all in the operating room introduce themselves. If the patient needs attention due to instability the timeout is delayed.

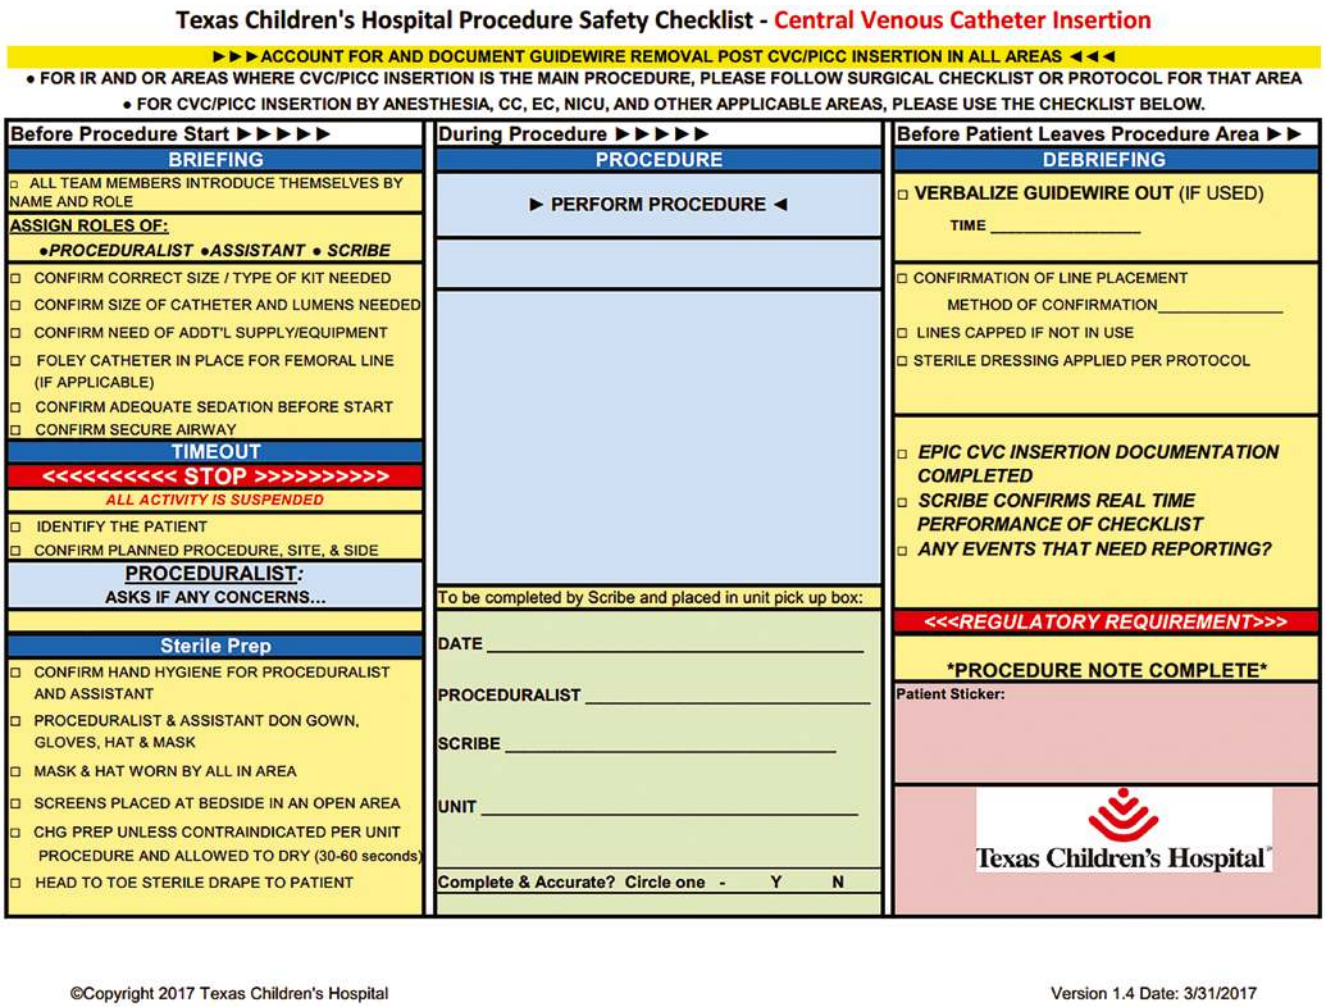
Figure 4.10 Texas Children's Hospital surgical safety checklist for cardiac surgery cases with bypass.

All personnel in the room, including the echocardiographers, all anesthesia personnel, any students or observers, are also part of the process. The timeout script is read so that no elements are missed, and any unexpected issues i.e. equipment or implant needs, are immediately addressed so they are ready when needed. Only when the checklist is completed, and the surgeon has asked about any concerns and any questions are resolved, does the operation commence. The SSCL, and particularly the surgical timeout, are observed and graded by a neutral observer periodically for correct and complete process and these data are reported regularly in the quality improvement efforts of the Heart Center.



The surgical debriefing occurs in the OR after the attending surgeon has broken the scrub, and before the patient leaves the room; any issues or problems are verbalized, along with plans for disposition of the patient, i.e. extubation in the OR. The surgeon, anesthesiologist, and circulating nurse perform this activity in person.

Anesthesiology-specific checklists

The anesthesia team performs a number of complex procedures at the beginning of a cardiac surgical case; simultaneously managing the time pressure of starting the case and the often complex pathophysiology of an unstable patient. Distraction from best procedural practices is possible during this often intense period of anesthetic care. Central venous access is achieved by the anesthesiology team in nearly every cardiac surgical case, and in order to ensure best practices are followed for prevention of central line-associated bloodstream infection, and issues such as a retained guidewire, a checklist was introduced, to be reviewed once the anesthesiologist has scrubbed, gowned, gloved, and the patient is prepared and draped for the procedure (Figure 4.11). The anesthesiologist and the circulating nurse perform this checklist, and only when completed does line placement proceed. An important feature of the checklist is to announce when the central line guidewire has been removed, with the goal of preventing the rare but consequential complication of a retained guidewire.

Regional anesthesia is increasingly utilized in cardiac and thoracic surgical cases in congenital heart disease, and a checklist has been instituted to be completed before the procedure starts [19]. Of particular importance besides the site and laterally of the block or catheter, is the local anesthetic drug and dose, and any adjuvants such as opioids or alpha receptor agonists. A regional block may be performed by a team other than the primary anesthetic team, so this checklist is particularly important. Chapter 24 contains a detailed presentation of regional anesthesia techniques for congenital cardiac surgery.

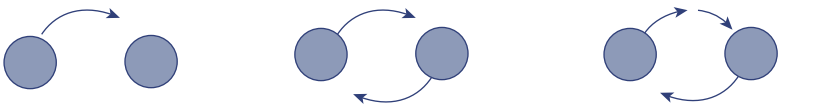
Figure 4.11 Central venous catheter insertion checklist.

In the period after induction and before sterile preparation of the patient, many simultaneous procedures occur for patient positioning and padding, application of monitors such as backup pulse oximeter probes, near-infrared spectroscopy probes, defibrillation pads, and many others. To avoid the omission of any of these elements and the necessity to institute them after the patient is draped and interrupt the flow of the surgical case, a "Pre-Flight" anesthesia checklist was developed that was to be completed by the circulating nurse and anesthesiologist (Table 4.3).

Communication during the operation

Few procedures in medical practice are as complicated as congenital heart surgery, where the interdependence of surgical action, patient pathophysiology, anesthetic procedures, perfusion approaches, and surgical assistant and scrub personnel support depend on precise coordination and communication to achieve the goals of the operation, recognize and prevent adverse patient states, and rescue from such states, as they inevitably occur with significant frequency. The complexity of the surgical procedure flow demands consistent, clear communication, and omitting standardized elements of communication during cardiac surgery can lead to errors and adverse outcomes. With as many as 8–12 personnel directly involved in the care of the patient, consistency, protocols, and scripts are crucial, as well as a sense of when to communicate, and in what tone and frequency, i.e. anesthesiologist to the surgeon during periods of hypotension from surgical manipulation, and other events. For example, is the hypotension likely to be very short-lived and easily recoverable when retraction by the surgeon on the right ventricle for placement of inferior vena cava purse string sutures for cannulation stops? Or, is this a surgically-induced cardiac rhythm change resulting in hypotension that needs immediate action in the form of synchronized internal cardioversion? Congenital heart surgery cases each have a number of these moments, and the experience of the anesthesiologist with the surgical team will help determine the optimal frequency and level of communication, striking a balance between "needing to know" and changing the surgical flow, vs. "not needing to know" and keeping the flow of the surgery going. The intense concentration required by the surgeon argues for a quiet, calm operating room with minimal extraneous noise and conversation during the surgery. The concept of a "sterile cockpit," borrowed from the aviation industry, means that during safety-critical periods of the operation that unnecessary conversation is stopped,

Table 4.3 Texas Children's Hospital Cardiovascular Anesthesiology "Pre-Flight" Checklist



To be completed by circulating nurse and anesthesiologist immediately prior to patient preparation. The nurse asks the questions, anesthesiologist responds "Yes/No" (not indicated, or will correct now)

- Extremities, sacrum, and occiput positioned and padded properly?
- Vascular access connections and sites secure, padded, and lines are functioning?
- Five-lead ECG in place and functioning, displaying multiple leads?
- Two pulse oximeter probes in place and functioning?
- Extra backup pulse oximeter probes in place for infants?
- Blood pressure cuff in place and functioning on different extremity than an arterial line?
- Bilateral NIRS probes in place and functioning?
- Three temperature probes (nasopharyngeal, rectal, skin) in place, properly labeled, and functioning?
- TEE probe in place and not compressing oral structures?
- Urinary catheter secured and draining clear urine?
- Surgical rack (for drapes) in place and secure?
- Defibrillation pads, if indicated, in place, and connected to the defibrillator, with ECG synchronization leads in place and functioning?
- Electrocautery pad in place and connected to the unit?
- Forced-air warming blanket in place and functioning?
- Pacemaker box present and functioning?
- Adequate blood products in the operating room and checked?

NIRS, near-infrared spectroscopy; TEE, transesophageal echocardiography.

standardized terminology for communication is used, and instructions given by the surgeon are "read-back" when tasks are completed, i.e. heparin administered [20]. The idea of creating shared mental models among the disciplines in the cardiac operating room, to agree on critical points during the operation and methods of communication during these important junctures, can improve the quality and efficiency of information exchange [21].

van Wijngaarden and colleagues performed a video recording study of six coronary artery bypass graft (CABG) surgeries, and by personal interviews and focus group meetings with surgeons, anesthesiologists, and perfusionists, arrived at 64 items to be critical to communicate for safe CABG surgery [22]. These items were classified as to which subteams were involved, and type of communication, i.e. open loop, call-back, closed loop, and series (Figure 4.12); and exchange types classified by purpose (Table 4.4). Quality, consistency, frequency, timeliness, and appropriateness of communications were graded by viewing the videos, with the goal of developing a quality standard for the critical verbal exchanges between surgeons, anesthesiologists, and perfusionists. There was an average of 219 sequences of exchanges per operation, with the surgeon initiating 45%; perfusionist 33%, and anesthesiologist 21%. The most common types of exchanges were "status" – shared understanding of the current state; followed by "direction" – command an action to transition to a new state. Of the 64 critical events, on average 60 (94%) were consistently verbalized during the same phase of surgery. Quality of communication was graded as "substantive," e.g. specific information in a call back (e.g. "heparin is in" in response to "give heparin"), as opposed to insubstantive (e.g. "yes" or "OK" in response to "give heparin"). Substantive communication is less prone to error and was present in 40% of exchanges, instubstantive communication in 33%, and no call back (open loop communication not requiring a call back) in 27%. This study demonstrated that optimal high-quality communication could be improved and provided an important patient safety standard for intra-team communication during CABG operations.

Open-loop communication **Call-back communication** **Closed-loop communication**

	2 subteams		3 subteams	
Open loop	A	Protamine is at one third		
Call-back	S	Heprin may be administered	P	And the pump is empty
	A	Heparin administered	A	Yes
			S	Good
Closed loop	S	How much do you have [perfusionists]?	P	Breathing is also (...)?
			S	Yes sure
	P	About 100	A	Yes
	S	Oh, ok	P	Ok
Series	S	[anesthetist], should I stay here, because the pressure is 75	P	Off bypass
			A	Yes, I heard you
	A	Stay there?	S	Off bypass?
	S	At half a liter, or... Do you agree that it's going to fast/	A	Yes
			S	Wonderful
	A	No, fine, let's go off bypass (...)		
	S	Yes		

Figure 4.12 Loop types and examples per number of subteams involved. Open loops are exchanges without call-back and only involve one subteam. Call-backs are exchanges with call-backs from 1 or 2 subteams and in closed loops, the initiator fully "closes" the exchange loop with a final call after the receiver gave a call-back. Series involve more sequences between 2 or 3 subteams. A, anesthetist; P, perfusionist; S, surgeon. (Source: de Lind van Wijngaarden et al. [22] / Elsevier / CC BY 4.0.)

Congenital heart surgery possesses many similarities to the events specified in this important study, but there are unique aspects such as different perfusion techniques (deep hypothermic circulatory arrest, regional cerebral perfusion) utilized more commonly in CHD; assessment of intracardiac air by TEE before aortic unclamping; and others. Each institution should develop a consistent approach to communication that is specific to the procedures practiced locally. The potential for adverse clinical states is greater for congenital heart surgery, with complex anatomy and physiology, small patient sizes and equipment increasing the risk for cannula malposition impairing perfusion and venous return, and a smaller margin of error given increased metabolic rates and frequent arterial desaturation. The anesthesiologist, surgeon, and perfusionist, in particular, must work together to troubleshoot and communicate these abnormal states, for example, cerebral oxygen desaturation during bypass, and use a standardized system of clear communication to achieve these goals [23]. Particularly in a large system where there are multiple possible combinations of intraoperative personnel, a standardized approach to communication will minimize the risk of errors. Another crucial aspect of communication is that if any member of the team has a question, concern, or is uncertain about what was communicated or intended, they must speak up for clarification, for the benefit of the patient. This includes junior members of the team or those on the lower end of the authority gradient; i.e. a scrub technician with a concern or question directed at a senior surgeon. The concepts of psychological safety discussed

previously apply to the OR; senior physicians, in particular, must pay attention to including the contributions of all members of the team in a non-threatening manner, and voicing appreciation for their contribution to the optimal care of the patient. On the extreme end of the scale, the disruptive physician has severely detrimental effects on patient safety and should not be tolerated on the congenital heart surgery team [24].

In addition to the standardized approach to communication during surgery, at TCH the surgeon wears a lightweight, high-definition camera on their headlight that reproduces exactly what they are viewing, so that caregivers, and learners in the room but not directly involved in the surgical team, can see accurately what phase of the surgery is ongoing, and have a better understanding of the surgical procedure (Figure 4.13). This view is displayed on multiple high-definition monitors around the OR that produce a magnified image of the surgeon's field of view. The advantage of this system over a fixed, overhead camera integrated into a surgical light source is the exact view that changes with the surgeon's position, and is not obscured by the surgical team itself. Particularly important beneficiaries of this system are the perfusionist and the anesthesiologist.

Communication during emergencies

During congenital heart surgery, emergencies occur with some regularity that, while not unexpected, can catch the unprepared team off guard and lead to a disorganized or delayed response that can increase patient risk and result in adverse outcomes. One such event is massive bleeding during re-entry sternotomy requiring an emergency institution of CPB. For higher-risk patients, i.e. aortic position immediately behind and adjacent to the sternum, preparations such as the site of emergency cannulation, selection of emergency cannulas, assessment of femoral vessels preoperatively by ultrasound or other imaging, are crucially important. When the actual emergency occurs, it is also important to institute an approach consistent with the "sterile cockpit," as noted above. The surgeon takes over communication, gives clear instructions which are read back and carried out, all extraneous noise and activity stops, and the entire team focuses on resuscitating the patient, instituting bypass as quickly as possible, and controlling the source of the bleeding. Development of protocols, and simulation scenarios of the emergent institution of CPB, especially for new team members, can facilitate team performance during actual emergencies [25, 26]. Cognitive aids can also facilitate team performance during sudden unexpected emergencies, to ensure that all necessary steps are carried out; one such cognitive aid has been developed for massive systemic air embolism on bypass [27] (Figure 4.14).

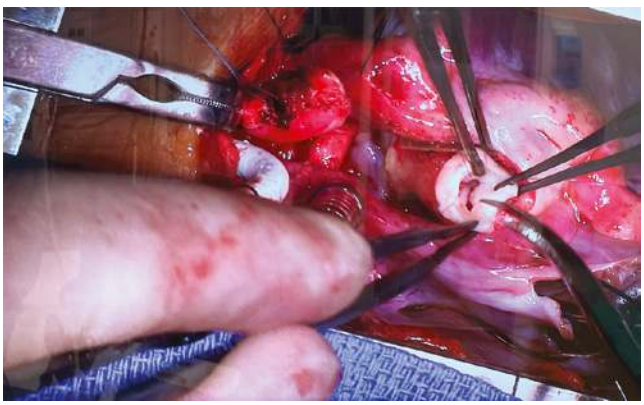

Figure 4.13 View from the surgeon's headlight camera displaying a high-definition magnified image of repair of supravalvar aortic stenosis. The aorta has been transected and the sinuses of Valsalva are being incised to prepare for autologous pericardial patch augmentation. The aortic cross clamp is seen at the upper lefthand corner of the screen; just below it is the white-colored polytetrafluoroethylene graft sewn to the innominate artery for arterial cannulation.

Other intraoperative multidisciplinary collaborations

Variation in clinical care paradigms, either within an institution or between institutions, are very significant and there is increasing evidence that a standardized approach to similar clinical situations can improve outcomes and control costs of medical care. One such approach is the protocols for early tracheal extubation after congenital heart surgery, i.e. in the operating room or within 6 hours of ICU admission. The Collaborative Learning Project developed a clinical practice guideline for two common lesions, coarctation of the aorta and tetralogy of Fallot repair, among 10 congenital cardiac surgery programs in the Pediatric Heart Network of the U.S. National Heart, Lung, and Blood Institute (NHLBI) [28]. This guideline was developed using collaborative learning techniques that included site visits, and a number of meetings among the multidisciplinary investigators to develop approaches to decrease the time to tracheal extubation using the Delphi method. The principles of anesthetic care included limiting intraoperative opioid (fentanyl) to no more than 10 mcg/kg/hour of surgery; utilizing dexmedetomidine from the beginning of the anesthetic, and utilizing adjunct pain control techniques such as acetaminophen, and regional anesthesia where applicable (Table 4.5 for the TCH approach). Five sites actively instituted this protocol, and five did not change their usual standard of care. The rate of early extubation increased in the active sites from 11.7 to 66.9% ($p < 0.001$) with no change in the reintubation rate. The median duration of postoperative ventilation among active sites decreased from 21.2 to 4.5 hours ($p < 0.001$). The control sites experienced no significant change in these parameters. Implementation of the protocol was also associated with a significant decrease in intraoperative opioid and benzodiazepine dosages, with no change in volatile agent exposure. Intraoperative dexmedetomidine usage increased, and postoperatively there was a decrease in opioid, benzodiazepine, dexmedetomidine, and ketorolac dosages [29]. In addition to intraoperative protocols, training and communication to ICU nursing and physician staff are critically important when instituting early extubation protocols so that these staff are prepared to assess and support the airway of the extubated patient they receive from the OR, and intentionally make

2. Systemic Air Embolism

Arterial Line–On Pump

ACTIONS

1. First witness states loud & clear "MASSIVE AIR EMBOLISM EMERGENCY"
   - *A. Ask: "Who will be the crisis manager?"*
   - *B. VOCERA page back-up perfusionist*
   - *C. VOCERA page Attending Anesthesia*
   - *D. Start crisis timer*
2. STOP cardiopulmonary bypass immediately
3. Clamp *Arterial line near cannulation* immediately (*to prevent additional air entry*)

1. ANESTHESIOLOGIST: Place patient in steep Trendelenberg
2. ANESTHESIOLOGIST: Ventilate lungs with 100% FiO2
3. Locate, Confirm, and Control source of air
4. Re-prime Lines
   - Purge air from arterial line (aspirate of refill line)
5. Start CPB and Consider Retrograde Cerebral Perfusion
6. Cool patient on CPB to 25°C, Pack head in ice (30–40 min)
7. If needed, vasopressors to raise perfusion pressure (50–70 mmHg)
8. Complete planned operation
9. Slowly rewarm to 35° C
10. Consider Hyperbaric Oxygen Therapy

DRUG DOSES

Mannitol: 1g/kg IV

Methylprednisolone: 30 mg/kg IV

Dexamethasone: 20 mg IV x1

Retrograde Cerebral Perfusion

1. Purge air and refill CPB arterial line
2. SURGEON: Place retrograde cardioplegia cannula into SVC or insert arterial cannula into SVC
   if bicaval cannulation, connect arterial line to seared SVC cannula
3. Begin retrograde Perfusion with 20°C hypothermia at 1–2 L/min for 1–3 min
   Include period with carotid compression to clear vertebral system
4. Maintain perfusion pressure < 25 mmHg

Sources of Air Emboli

- Surgical [operative] Air
- Pump Circuit (check arterial line, reservoir, cardioplegia delivery system)
- Anesthesia Arterial Line

Figure 4.14 Crisis checklist developed for systemic air embolism while on cardiopulmonary bypass. Troubleshooting directives are on the right, crisis protocol is on the left. (Source: Tarola et al. [27]. Reproduced with permission from IEEE.)

Table 4.5 Texas Children's Hospital Heart Center approach to operating room extubation

Preoperatively:
- Patient at least 3 months old
- Surgery STAT category 1–3
- No preoperative respiratory support or difficult airway
- Stable hemodynamic status not receiving continuous inotropic support

Intraoperative:
- Opioids: limit to no more than 20–25 mcg/kg fentanyl; add incremental morphine 0.025 mg/kg per dose if needed at end of surgery
- Dexmedetomidine 0.5–0.7 mcg/kg/hour started at beginning of anesthetic, ±loading dose
- Volatile anesthetic agent: any agent at any MAC level required for anesthesia/hemodynamic stability
- Benzodiazepines: small doses as premedication/or during bypass only
- Intravenous acetaminophen 15 mg/kg, maximum dose 1,000 mg, post-bypass
- Ondansetron 0.1 mg/kg, maximum dose 4 mg, post-bypass
- Regional anesthesia/catheter at beginning of the case, or local anesthetic wound infiltration at end of the case whenever possible
- Order patient/nurse controlled morphine analgesia in the operating room and bring to ICU bedside
- Stable hemodynamics on minimal vasoactive support; no significant pulmonary hypertension
- No significant bleeding, ACT at or below baseline
- Favorable respiratory mechanics: low ventilating pressures including PEEP, minimal A-a gradient if acyanotic, PaO_2>40 mm Hg on low FiO_2 if cyanotic lesion

Table 4.5 (Continued)

- Full reversal of neuromuscular blockade with sugammadex 4 mg/kg
- The oral airway in place
- Extubation in the OR when adequate spontaneous respiratory rate/tidal volumes achieved with no pressure support ventilation
- Goal: "sedated" extubation with zero end-tidal volatile agent
- Adequate observation time to ensure stable airway; prepared to treat upper airway obstruction/laryngospasm

Intensive care unit:
- Transport to ICU with Jackson-Rees circuit and 100% oxygen by anesthesia facemask to closely monitor ventilation
- Close attention to airway obstruction and ventilation by anesthesia team immediately after arrival to ICU
- Review first ABG and chest radiograph in ICU
- Patient/nurse-controlled morphine analgesia

Abbreviations: A-a, alveolar-to-arterial gradient; ABG, arterial blood gas; ACT, activated clotting time; MAC, minimum alveolar concentration; PEEP, positive end-expiratory pressure; STAT, Society of Thoracic Surgeons-European Association for Cardiothoracic Surgery Risk Category Score.

progress toward early extubation, when the patient is ready no matter what the timing. This approach is consistently applied at TCH, where in the past 4 years, 32% of patients are extubated in the operating room after cardiac surgery [30] (Table 4.6). Additional information about early extubation is discussed in Chapter 24.

Complex congenital cardiac operations consistently have a high rate of significant post-bypass bleeding, and

Table 4.6 Operating room extubations after cardiac surgery at Texas Children's Hospital 2017–2020

Age group	Percent extubated in the operating room, TCH (Number of patients extubated, % of age group)	Percent extubated in the operating room, STS-CCAS database, *N* = 118 programs
Neonates, 0–30 days	0	4%
Infants, 1–12 months	76 (9%)	19%
Children, 1–17 years	669 (60%)	49%
Adults, >18 years	59 (49%)	37%
Cardiac lesion		
ASD closure	97 (85%)	64%
VSD closure	129 (48%)	34%
Tetralogy of Fallot repair	18 (15%)	21%
Atrioventricular canal repair (partial, intermediate and complete)	31 (26%)	13%
Bidirectional cavopulmonary connection	8 (5%)	31%
Fontan operation	142 (92%)	52%
Norwood stage I palliation	0	0
All procedures	32%, *N* = 2,867 procedures	22%, *N* = 119,198 procedures

All procedures include bypass and non-bypass cardiac cases. ASD, atrial septal defect; CPB, cardiopulmonary bypass; STS-CCAS, Society of Thoracic Surgeons' Congenital Heart Surgery, and Congenital Cardiac Anesthesia Society Database; TCH, Texas Children's Hospital; VSD, ventricular septal defect.
[a] In OR, extubation is defined as extubation by the primary anesthesia team either in the OR or immediately upon arrival in the ICU by the anesthesia team without utilizing an ICU ventilator

hypofibrinogenemia is a common cause, especially in neonates and small infants. Cryoprecipitate is frequently utilized in these situations and is often ordered and thawed in advance in anticipation of acute need; but if not needed the unit is wasted, resulting in significant cost to the patient and institution. At Texas Children's Hospital, a multidisciplinary team consisting of anesthesiologists, blood bank coagulation specialists, surgeons, and nurses devised a standardized pathway utilizing rotational thromboelastometry during rewarming on CPB to help anticipate the need for fibrinogen. If indicated and the patient is less than 5 kg; 1–2 units of cryoprecipitate are ordered and thawed. If the patient is greater than 5 kg in weight, then lyophilized fibrinogen (Riastap®) is utilized. The institution of this protocol resulted in the reduction of wastage of cryoprecipitate by 61%, from 37 units/month in the year prior to the protocol, to 14 units/month in the first 5 months of the protocol [31] (Figure 4.15). See Chapter 16 for further discussion of bleeding and coagulation.

Intensive care unit handoffs

Transfer of care from the OR team to the ICU team after congenital heart surgery can be a time of intense activity, with multiple caregivers from a number of disciplines including nursing, respiratory therapy, surgery, anesthesia, intensive care, and involving all of their trainees and advanced practice providers (APP). At times there can be as many as 10–12 caregivers at the bedside in the immediate postoperative period. This can be a time of patient instability, and the interruption in monitoring that occurs can mask a destabilizing state. Delays in the communication of handoff information while the OR team stabilizes the patient can hamper the ability of the ICU team to provide fully informed care. Structured, consistent, clear, and scripted handoffs from the OR to ICU teams, and in many other healthcare settings, reduce technical and informational errors and lead to improved caregiver confidence and satisfaction when assuming care for a complex patient [32, 33].

TCH Heart Center implemented a structured handoff process over 20 years ago, which has been through a number of iterations and is now a standardized, process where the expected elements of communication are communicated in a consistent, efficient approach. The receiving ICU team consists of two bedside nurses, a respiratory therapist, and the ICU attending and fellow/APP. The patient is transported from the OR to ICU by the anesthesia team, surgical fellow, and circulating nurse, fully monitored with emergency drugs, volume expanders, and emergency airway equipment at hand. Upon arrival, and with the anesthesiologist's permission after ascertaining that the patient is stable, the physiologic monitoring module is transferred from the transport monitor to the ICU monitor, a process that results in loss of monitoring for 10–15 seconds. Once this occurs, the respiratory therapist connects the ventilator with the anesthesiologist's specified settings, and adequate ventilation is ascertained by auscultation, observation of chest rise, and ventilator parameters. Then, initial arterial blood gas and other admission laboratory studies are drawn. Vasoactive and sedative infusions are quickly reviewed and double-checked by the nursing and anesthesia teams. Then the handoff begins after ensuring that all necessary personnel are present, and the

AL Grawany

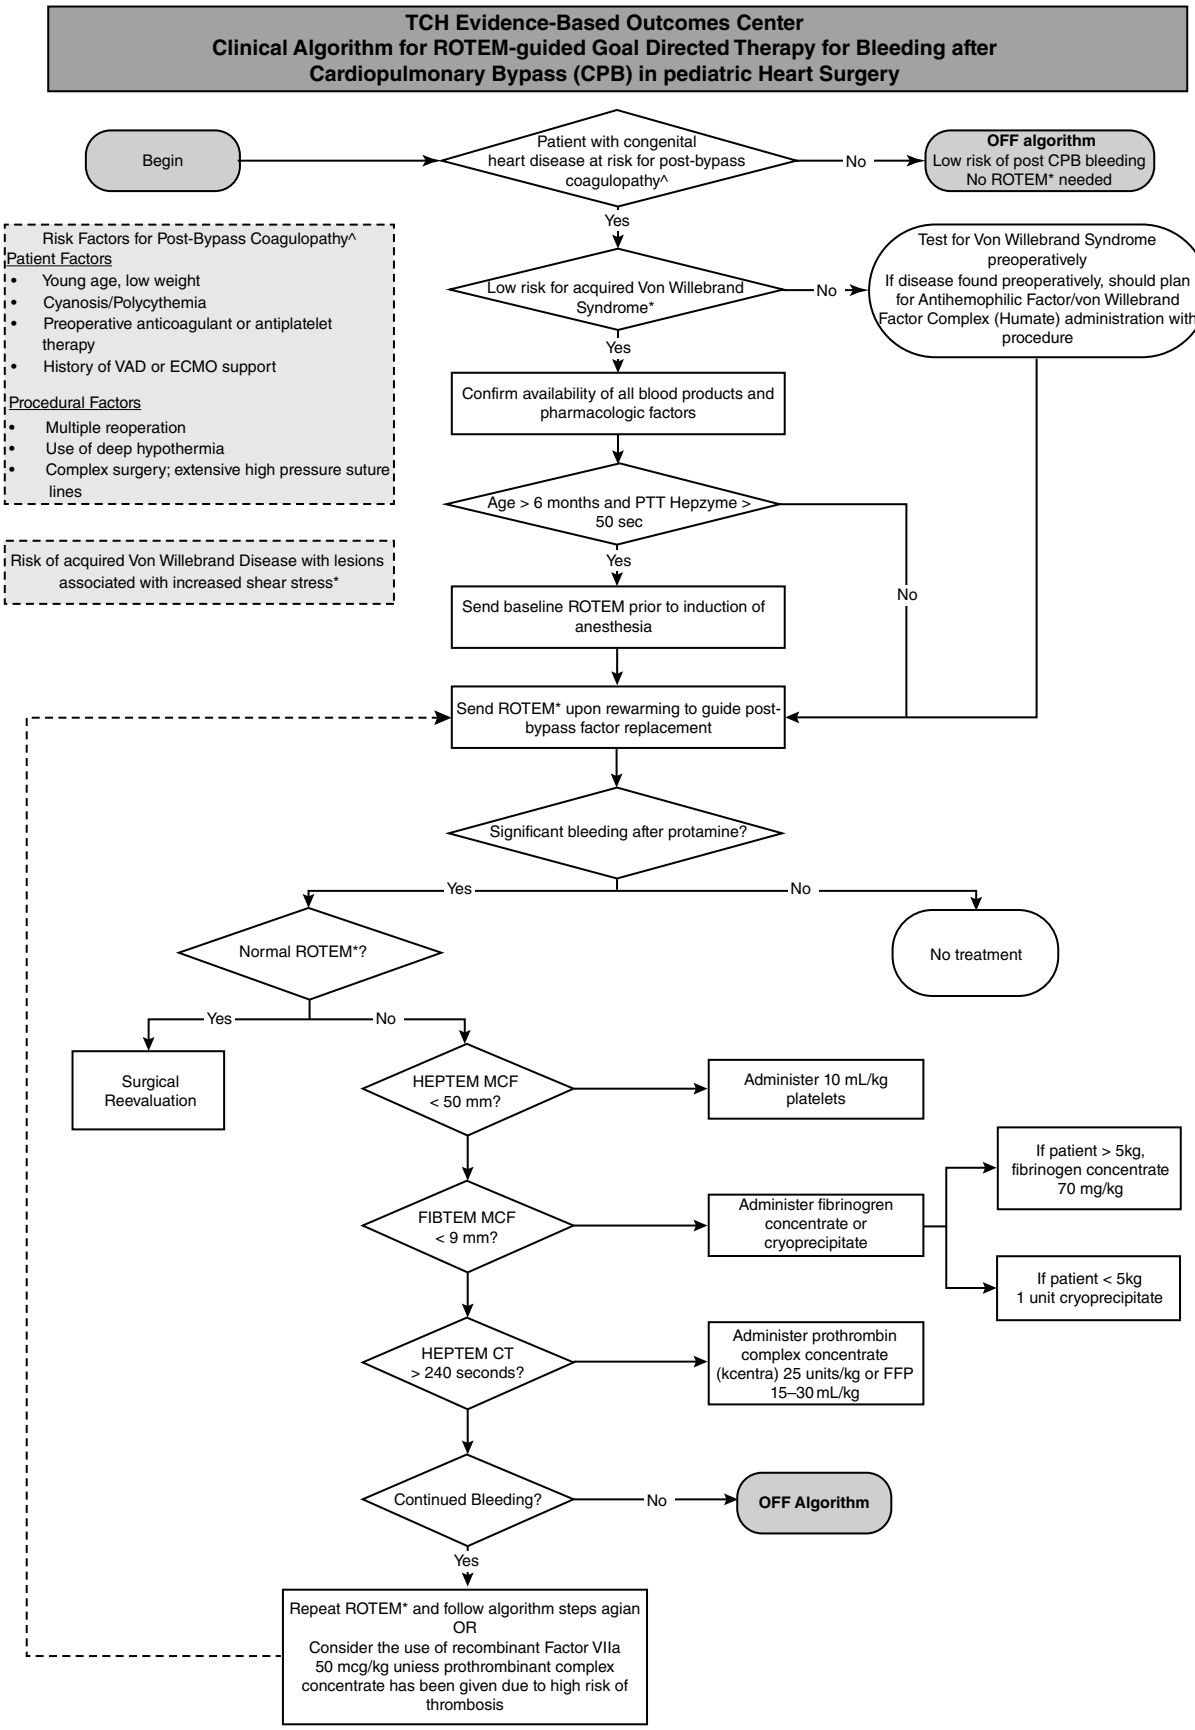

Figure 4.15 Rotational thromboelastometry (ROTEM®) guided goal-directed therapy algorithm for bleeding after cardiopulmonary bypass. CT, clotting time; ECMO, extracorporeal membrane oxygenation; FIBTEM, fibrinogen thromboelastometry; HEPTEM, heparin thromboelastometry MCF, maximum clot firmness; VAD, ventricular assist device.

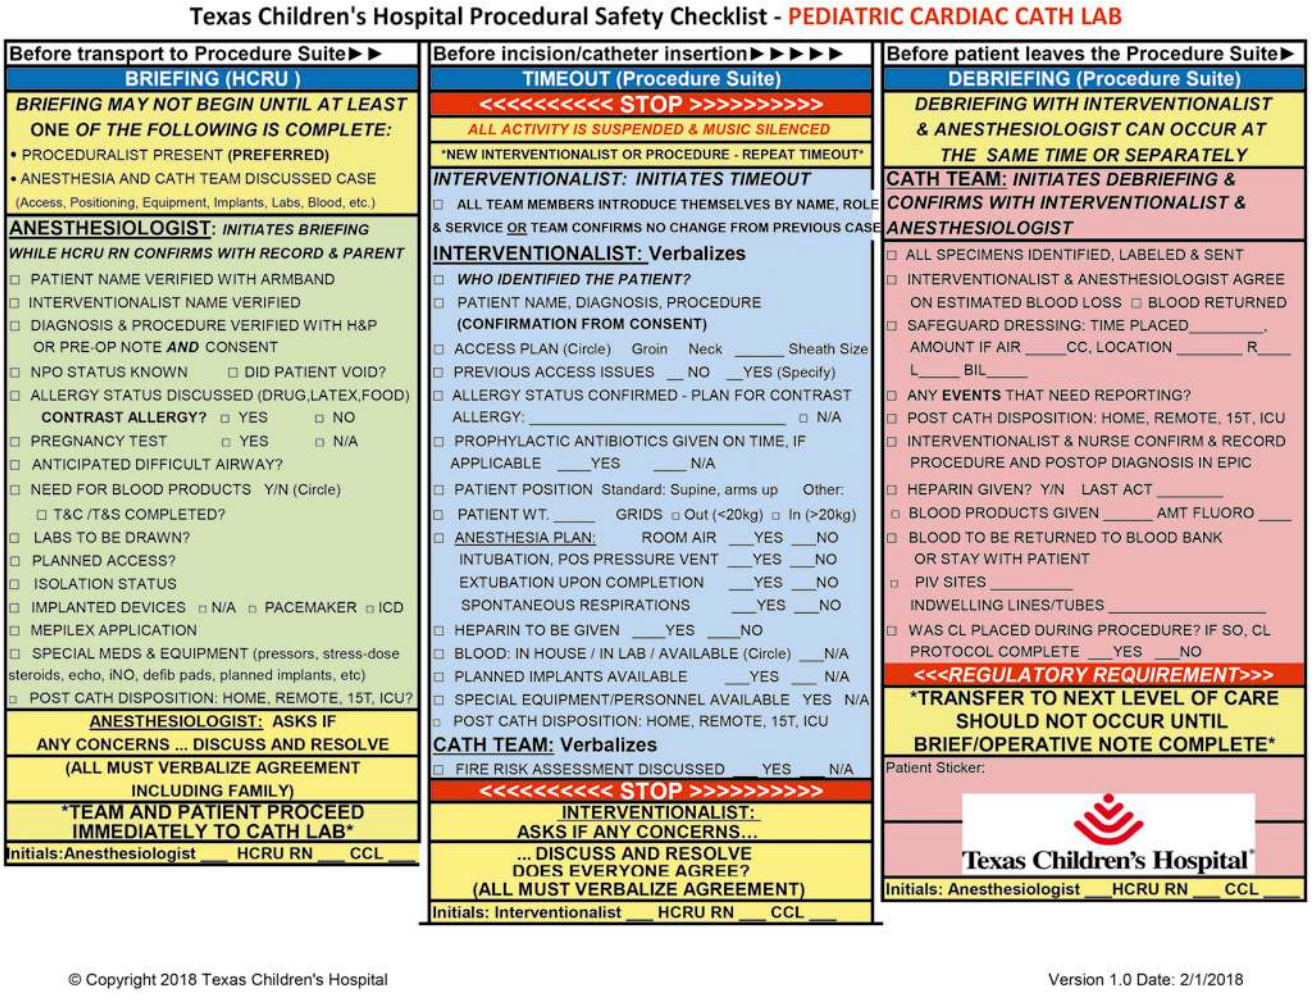
nursing staff can devote their full attention. All activity in the room except direct patient care ceases, and all other conversations are silenced, much like the surgical time out, and the structured handoff process begins. First, the attending surgeon briefly introduces the patient's pertinent demographic details, past surgical history, and preoperative anatomic and physiologic state. Then, s/he details the surgery performed including any change in surgical plan or unexpected findings. Any issues with bypass, or significant issues like bleeding or treatment of arrhythmias, are reviewed. The postoperative echocardiogram is summarized and desired plans for extubation and hemodynamic goals are communicated. Next, the anesthesiologist reports on preoperative medications and allergies and briefly summarizes the induction of anesthesia, any airway issues, and the pre-bypass course. Bypass and aortic cross-clamp times, as well as any CPB issues including neuromonitoring, are communicated. Weaning and post bypass periods are summarized as well as inotropic and vasoactive support, anesthetic drug doses, and blood product administration, as well as adequate filling pressures and systemic blood pressure, current cardiac rate and rhythm including the need for temporary pacing. Arterial blood gases and ventilatory status, as well as last time of administration of antibiotics, and opioids/sedatives/neuromuscular blockade reversal are reviewed. Any problems or unexpected events are communicated. A review of endotracheal tube size and position, central and arterial lines, mediastinal drains, transthoracic lines, and pacemaker wires, along with urine output and bleeding assessment completes the information transfer. Hemodynamic goals and plans for extubation or other therapies are then discussed among the surgical, anesthesia, ICU, and nursing teams. Inventory of blood products available at the bedside is reviewed. Questions are elicited and answered to complete the report. After the transfer of information, the ICU attending physician requests a summary of the immediate postoperative plans from their fellow/APP, and the primary bedside nurse also voices their understanding of the postoperative plans. Finally, the postoperative chest radiograph is performed and reviewed by the team, along with the first arterial blood gas, hematocrit, lactate, and electrolytes. When all are satisfied with the status of the patient and the handoff of information, the care is formally transferred to the ICU team. The handoff process is summarized in Table 4.7. The entire handoff process usually requires no more than 10 minutes, and of necessity must be this efficient in a busy CICU where the team has many other patients and responsibilities, including at times several patients arriving from the ORs at short intervals. See Chapter 36 for an extensive presentation of CICU care.

Table 4.7 Texas Children's Hospital cardiac operating room to cardiac intensive care unit handoff procedure

1. After transfer of physiologic monitors, connection to the ventilator, and blood draw for ABG, electrolytes, hematocrit, lactate, all personnel cease conversation and unnecessary activity to participate in the handoff process
2. Attending surgeon verbal report:
   - Brief demographics, past surgical history, preoperative anatomic/physiologic status
   - Details of surgery, including any change in plans or unexpected findings
   - Issues with bypass, hemodynamics, bleeding, other problems
   - Postoperative echocardiogram
   - Hemodynamic goals and plans for extubation
3. Attending anesthesiologist verbal report:
   - Preoperative concurrent medical problems, medications, allergies
   - Induction of anesthesia including any airway problems
   - Pre-bypass course
   - Bypass period: bypass duration, aortic cross-clamp duration, lowest temperature, special techniques such as regional cerebral perfusion, neuromonitoring
   - Bypass weaning and post-bypass period: inotropic/vasoactive support, ventilation parameters, bleeding and blood product administration, antifibrinolytic/factor administration, urine output
   - Hemodynamics: optimal heart rate, systemic arterial pressure, central venous/right and left atrial pressures, cardiac rhythm/arrhythmias, temporary pacing
   - Anesthetic/sedative doses including last doses, muscle relaxation and reversal, time of the last dose of antibiotics
   - Unexpected events or problems
   - Review of support lines/tubes: endotracheal tube size, depth, cuff; vascular access: arterial/central/transthoracic/peripheral catheters – size, site, lumens; pacing wires, mediastinal/pleural drains, peritoneal dialysis catheter, urinary catheter
   - Inventory of blood products/volume expanders available at the bedside
4. Attending intensivist verbal report:
   - Brief readback of the patient status
   - Summary of early postoperative plans for sedation/analgesia, extubation, hemodynamic goals, bleeding
5. Bedside nurse verbal report:
   - Reads back early postoperative plans for sedation/analgesia, extubation, hemodynamic goals, bleeding
6. Questions/clarifications: any caregiver
7. Chest radiograph, ABG/lab results: all review and order necessary adjustments
8. The formal handover of care to ICU team



AL Grawany

The cardiac catheterization laboratory

The modern cardiac catheterization laboratory (CCL) shares a number of teamwork and communication aspects with the cardiac operating room. The risk of patient instability, need for resuscitation, and adverse outcomes increase with younger age and smaller size of the patient, and complexity of the cardiac anatomy and pathophysiology. The degree of invasiveness of the catheter procedure also correlates with risk to the patient, with procedures such as PDA stent or occlusion in small infants, stenting of the right ventricular outflow tract, balloon dilation of aortic stenosis in infants, pulmonary vein interventions, and pulmonary hypertension studies some of the clinical scenarios conferring the highest risk [3]. In these patients, a preoperative discussion with the interventionalist, and plans for surgical backup, i.e. ECMO if indicated, must be made early, and scheduled appropriately so that the requisite equipment and personnel are available. At Texas Children's Hospital, the Catheterization Safety Checklist has been developed and is closely similar to the SSCL (Figure 4.16). The pre-catheterization timeout is performed before starting the procedure, to ensure that all are aware of the plans for the procedure. Communication among the interventionalist, anesthesiologist, and nursing teams is not usually as frequent or intense as in the cardiac OR, but the same principles of clear, standardized, consistent communication, with readback as necessary, apply. Especially important are the issues of which the team is giving common medications, i.e. heparin, drugs to elicit arrhythmias, etc. Emergency drugs and defibrillation/cardioversion capability must be in the room, with equipment tested regularly for proper function. Chapter 34 presents a detailed discussion of cardiac catheterization anesthesia management.

Enhanced recovery after cardiac surgery

Enhanced Recovery After Surgery (ERAS) programs are multidisciplinary collaborations designed to standardize the approach to patient care for a particular surgery or related surgeries, enhance preoperative preparation and education, intraoperative standardization, and postoperative approach to pain control, early mobility and nutrition, and preventing complications to allow earlier discharge and return to baseline normal activities of daily living. In adult surgery, ERAS programs for colorectal surgery are among the most detailed and advanced, and there is significant evidence that consistent application of such guidelines does

result on average in earlier discharge and return to normal daily functioning [34]. In pediatric surgery, ERAS efforts began later, but the few guidelines that do exist also seem to be efficacious in earlier recovery [35]. Pediatric cardiac surgery would seem to be an appropriate area to study this concept because of the complicated perioperative protocols in place, that have a number of common features despite a variety of cardiac lesions. Roy and colleagues reported on 155 patients eligible for a new Enhanced Recovery After Congenital Cardiac Surgery (ERACS) program [36]. Eligibility criteria included patients 1 month of age or older undergoing lower complexity surgeries, of STAT score (Society of Thoracic Surgeons-European Association for Cardiothoracic Surgery Risk Category) 1–3, with few comorbid conditions that could affect recovery. Patients were identified preoperatively and listed as ERACS patients on the surgical scheduling system. Approaches and protocols were devised by a multidisciplinary group of stakeholders, including surgeons, anesthesiologists, intensivists, cardiologists, perfusionists, nurses, APPs, dieticians, respiratory care, child life, and rehabilitation medicine specialists. Education of perioperative caregivers in the approaches and protocol was undertaken. A graphic depiction of the major components is displayed in Figure 4.17. Adherence to the protocols was variable, ranging from perioperative nausea/vomiting prevention given in OR of 33%, multimodal analgesic regimen given in OR of 57%, ventilation <8 hours in 54%, to cell saver/tranexamic acid use in 97%; and multimodal pain regimen postoperatively in 100%. When compared to a historical matched control group of pre-ERACS patients, major indices such as mechanical ventilation >8 hours, ICU length of stay >1.25 days, and percent of patients with complications, and numbers of complications, were not different. This important initial effort emphasizes both the potential for improvement in ERACS indices if all guidelines were to be followed; but also the complexity and a high number of components to this approach. Further data will be required to understand its benefits, and if simplification and reduction in numbers of the parameters will promote better compliance with ERACS protocols.

TCH handbook

The TCH Heart Center has a number of educational and research conferences, mostly specific to the various disciplines, that will not be further detailed. One important recent multidisciplinary educational effort was the production of the Texas Children's Hospital Handbook of Congenital Heart Disease, created by a collaborative effort of authors from Surgery, Cardiology, Anesthesiology, ICU, Perfusion, Nursing, and other members of the Heart Center team [37]. The handbook is a series of short, informative, practical chapters about the approach to all of the major cardiac lesions at TCH, including the workup, surgical or catheter therapy, and ICU and postoperative care. The handbook has numerous echocardiogram, angiographic, and anatomical figures, and is designed to be a day-to-day source of information for all clinicians in the Heart Center, including trainees in all disciplines, APPs, and faculty level providers. The bedside nursing staff utilizes this resource frequently as well. The handbook is available in paper and electronic format for a nominal cost to the entire Heart Center, as well as to a wider

audience through availability on major electronic platforms. An example from the handbook is displayed in Figure 4.18.

Parent and family involvement in congenital cardiac care

The multidisciplinary nature of congenital cardiac care also involves parents and family, and in the case of adult CHD often involves spouses and partners. This is a crucially important component of the overall care of the patient, and at the TCH Heart Center families are integrally involved in the care of their child; and invited to listen and contribute to patient care rounds in the ICU and wards, and ask questions of the caregiving team [38, 39]. The CICU is designed with sleeping and bathroom space for the family in the actual ICU room, and parents can be present 24 hours/day, with the exception of admission after procedures, or during certain emergencies. After discussion with parents, they are at times allowed to be present during invasive procedures and even resuscitation. Parental presence during induction of anesthesia for cardiac operations and catheterization procedures is not routinely offered but can be arranged in unique cases. Generous use of premedication, distraction with music, storytelling by child life specialists, and electronic devices, and allowing parents to be with the child until immediately before the transfer to the OR results in a smooth separation in almost all cases. Parents are informed of surgical progress every 1–2 hours, either in person by surgical APPs, or by a secure electronic communication system on their mobile phones. The surgeon meets with the family immediately after the surgery, and the parents are reunited with the child as soon as possible after ICU admission, usually within 60 minutes. After catheterization procedures, parents are allowed into the recovery area as soon as the handoff process to the nursing staff is complete. Parents of previous cardiac surgical patients were included in focus groups, and in the design committee for the Heart Center ICU and ward patient care areas.

Heart Center functioning during the COVID-19 pandemic

Prior to March 2020, the TCH Heart Center, as with most around the world, conducted conferences and meetings in

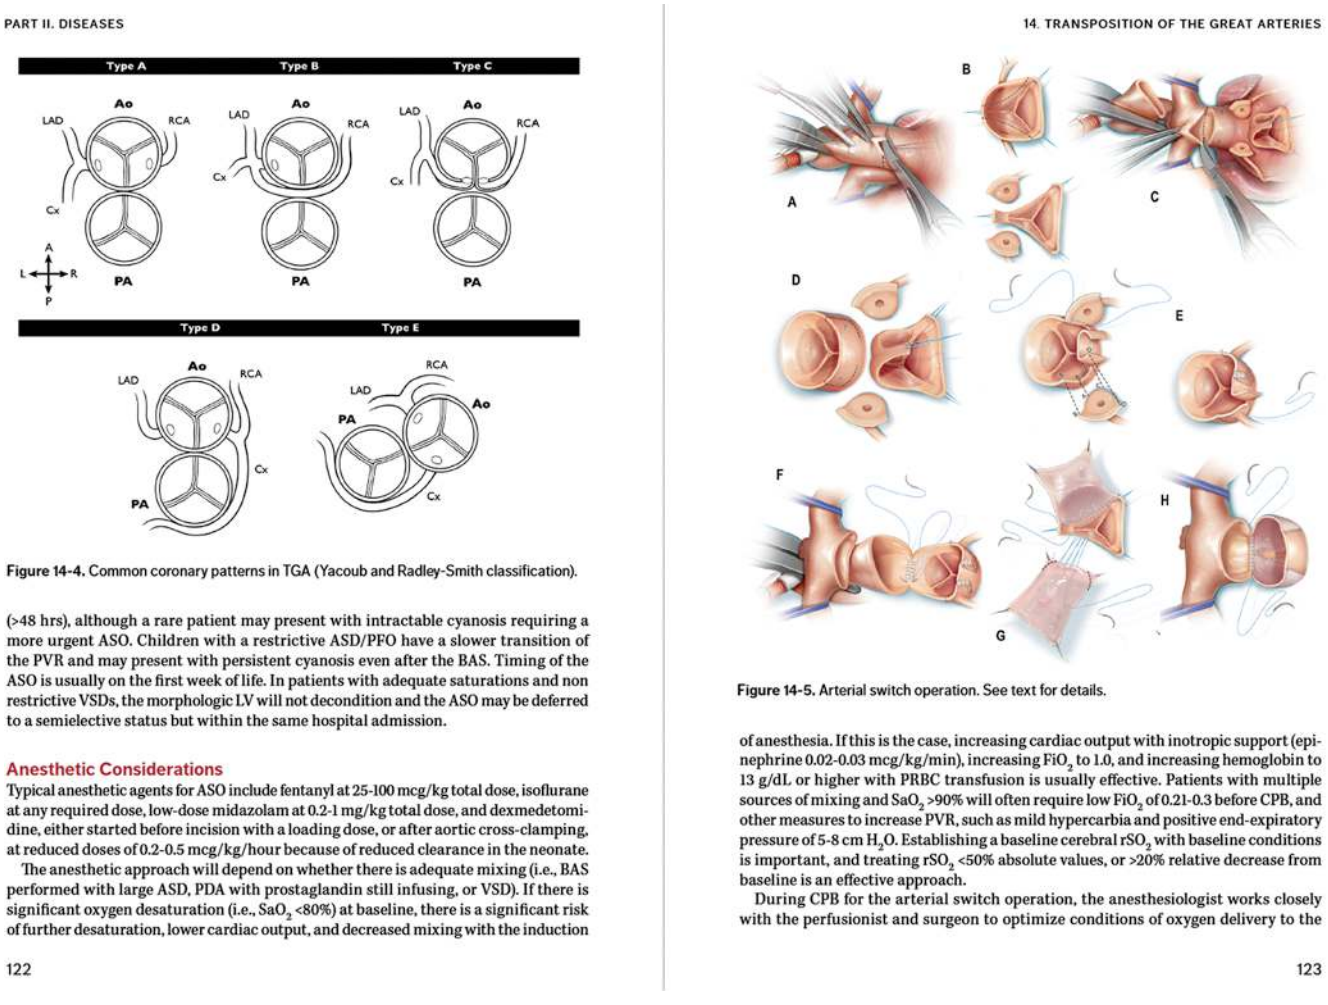

Figure 14-4. Common coronary patterns in TGA (Yacoub and Radley-Smith classification).

(>48 hrs), although a rare patient may present with intractable cyanosis requiring a more urgent ASO. Children with a restrictive ASD/PFO have a slower transition of the PVR and may present with persistent cyanosis even after the BAS. Timing of the ASO is usually on the first week of life. In patients with adequate saturations and non restrictive VSDs, the morphologic LV will not decondition and the ASO may be deferred to a semielective status but within the same hospital admission.

Anesthetic Considerations

Typical anesthetic agents for ASO include fentanyl at 25-100 mcg/kg total dose, isoflurane at any required dose, low-dose midazolam at 0.2-1 mg/kg total dose, and dexmedetomidine, either started before incision with a loading dose, or after aortic cross-clamping, at reduced doses of 0.2-0.5 mcg/kg/hour because of reduced clearance in the neonate.

The anesthetic approach will depend on whether there is adequate mixing (i.e., BAS performed with large ASD, PDA with prostaglandin still infusing, or VSD). If there is significant oxygen desaturation (i.e., SaO_2 <80%) at baseline, there is a significant risk of further desaturation, lower cardiac output, and decreased mixing with the induction

122

Figure 14-5. Arterial switch operation. See text for details.

of anesthesia. If this is the case, increasing cardiac output with inotropic support (epinephrine 0.02-0.03 mcg/kg/min), increasing FiO_2 to 1.0, and increasing hemoglobin to 13 g/dL or higher with PRBC transfusion is usually effective. Patients with multiple sources of mixing and SaO_2 >90% will often require low FiO_2 of 0.21-0.3 before CPB, and other measures to increase PVR, such as mild hypercarbia and positive end-expiratory pressure of 5-8 cm H_2O. Establishing a baseline cerebral rSO_2 with baseline conditions is important, and treating rSO_2 <50% absolute values, or >20% relative decrease from baseline is an effective approach.

During CPB for the arterial switch operation, the anesthesiologist works closely with the perfusionist and surgeon to optimize conditions of oxygen delivery to the

123

person, often with 100+ clinicians and others present and seated adjacent to one another in the main auditorium, and in the smaller but still crowded conference and meeting rooms for smaller groups for in-person meetings. Videoconferencing was occasionally offered to supplement the meetings, but the majority did not have this option. The COVID-19 pandemic forced a rapid change to all meetings converting to videoconferencing because of social distancing protocols, that persists at the time of writing this chapter. Although still encountering many of our colleagues from all disciplines during clinical care and individually in office areas, the camaraderie and opportunity for social exchange and networking within our own Heart Center, before and after the many conferences, has sadly been limited by the current arrangement. However, the excellent visibility of all the data displayed on one's office computer, and the ability to contribute opinions via the chat function in the videoconferencing system, have actually improved the quality of the conferences in these respects. The ability to join conferences from locations outside of the hospital has facilitated attendance and participation. Whether the TCH Heart Center will return to only in-person conferences in the future has not been decided, but some form of hybrid in-person/videoconferencing is likely.

Patient care has also been profoundly affected by the COVID-19 pandemic [40, 41]. Since April 2020, all patients coming for procedures requiring anesthesia have been tested within 72 hours of the procedure for SARS-CoV2 infection via polymerase chain reaction RNA testing and a number of elective procedures postponed because of symptomatic or asymptomatic infection; personal protective equipment protocols for aerosol-generating procedures were instituted and are still in place at the time of this writing [42, 43], and there have been several periods where Heart Center elective procedures have been limited because of high numbers of COVID-19 admissions and the need to care for some of these patients in the CICU because the Pediatric Intensive Care Unit (a separate unit at TCH) itself had no available beds [44]. A number of COVID-19 patients with cardiac involvement have also been a new category of medical admissions to the CICU [45–47]. Telemedicine, although limited in some CHD patients by the nature of their disease and the need to be seen in person, was initiated when appropriate and promises to change the way CHD patients are cared for after the COVID-19 pandemic [48]. Although numbers of surgeries and procedures for non-CHD areas of TCH decreased by as much as 20–30% during the height of the pandemic, CHD procedures in the operating rooms and catheterization laboratories decreased much less and only temporarily, again because of the nature of the diseases involved and the need for ongoing treatment. Finally, the longer-term sequelae of COVID-19 cardiac disease such as coronary artery aneurysms, and a decrease in myocardial function will be a concern for the Heart Center team in this new group of patients [49, 50].

Conclusions

In no field of medicine are multidisciplinary collaboration, team functioning, and communication more important than in CHD. The number, variety, and complexity of available therapies increase continually, as does the patient population served by institutions providing this care. In this chapter, we presented a Heart Center model that has grown and evolved as both provider and patient population have grown at TCH. Each institution will develop its own specific approach, but practicing the principles in this chapter should lead to increased communication and collaboration in a variety of settings. All caregivers in this ever-changing field owe this to the patients and families they serve, in order to maximize not just survival but the quality of life.

Introduction

The amount of patient data which can be leveraged for decision-making in critical care environments, such as operating rooms (ORs) and intensive care units (ICUs), continues to grow at an ever-increasing rate. While working in a data-rich environment has clear clinical benefits, the geometric growth of data generated per patient often leads to increasingly challenging situations for a single individual to manually review and assimilate all the data collected from a given patient with high fidelity. This is often referred to as the "data overload" problem. The field of informatics provides a structured framework for how to overcome this challenge. Applying the tools and technologies of informatics to the data, practices, and use cases inherent to anesthesia and critical care medicine yields powerful ways to enhance physician decision-making and improve patient care and safety. With the development of these tools, there is anticipated improvement in healthcare access, efficiency, quality, and outcomes.

This chapter will provide an overview of the history of medical informatics and emerging technologies. A brief examination of the basics of various data, data types, and common techniques in data mining will be discussed with a focus on their relative strengths and limitations. Finally, clinical examples of advanced analytics for congenital heart disease (CHD) and pediatric critical care medicine will be presented.

History of medical informatics

Biomedical informatics is a multidisciplinary field that studies the effective uses of biomedical data, information, and knowledge for scientific inquiry, problem-solving, and decision-making to improve the medical care and health of patients [1]. The term "medical informatics" first appeared in the 1960s and undoubtedly has historical origin from the first computer, which was developed in 1945. The world's first electronic digital computer was developed at the University of Pennsylvania Moore School of Electrical Engineering. This computer was called the electronic numerical integrator and computer (ENIAC) and was utilized by the United States Army Ballistic Research Laboratory to study thermonuclear weapons and calculate artillery firing tables [2]. ENIAC played a role in the processing of Monte Carlo methods, which are a set of computational algorithms which rely on repeated random sampling to obtain numerical results [3]. The utilization of these methods and computational processing paved the way for applications in simulations, optimization problems, predictive modeling, probabilistic analyses, and applied statistics.

AL Grawany

Machine learning was first described in 1959 by Arthur Samuel in reference to a computer program which could iteratively improve each time it played a game of checkers [4]. What began with programs and algorithms for simple pattern classifications has now grown to a robust field with symbolic methods to analyze data. Over the next few decades, a crossover of computer technology into healthcare emerged. Computer technology began appearing in the 1970s at Veterans Affairs Hospitals and Massachusetts General Hospital [5, 6]. Meanwhile, database and database management continued to evolve from primitive file processing to database management systems from the 1970s to 1980s. This included hierarchical and relational database systems and query languages, such as structured query language (SQL) [7]. In the 1980s, the improvement of computer hardware technology and processing speeds led to improved capabilities to store and process data. With the improvement in the management of more complex data, further integration of heterogeneous data sources, development of advanced data models and queries, and sophisticated database management systems, the landscape of data storage and analysis evolved. By the late 1980s, the business data warehouse was developed by International Business Machines (IBM) researchers Barry Devlin and Paul Murphy [8]. The business data warehouse is a repository of multiple heterogeneous data sources, organized under a schema to facilitate business intelligence and decision-making. The applicability of data warehouses to medicine not only allowed for new techniques and fields to emerge but also created new problems to solve.

Meanwhile, a United States Defense Advanced Research Projects Agency (DARPA)-funded project led to computer networks and the Internet in the 1960s. This system of interconnected computer networks grew to the World Wide Web in the late 1980s and early 1990s [9]. Information retrieval, data mining, and web-based databases (XML or extensible markup language databases) soon became possible. Over the next few decades, the application of database and data warehouse technologies continued to expand from business to medical use.

With the adoption of the Health Information Technology for Economic and Clinical Health (HITECH) Act in 2009, there was a large movement toward the meaningful use of health information technology and the standardization of electronic health records in efforts to improve medical care [10]. The patient data generated on a day-to-day basis in healthcare has led to major advancements in the field of medical informatics, particularly in the perioperative setting and ICU [11, 12]. Modern physiologic monitors can provide more than 20 continuous values at frequencies >200 Hz regarding a patient's status [13]. Similarly, the adoption of electronic health records, databases, and data warehouses has influenced medical informatics. The thoughtful design of these databases and communication standards is essential to ensure interoperability. Communication standards such as Health Level-7 (messaging), Digital Imaging and Communications in Medicine (imaging), and Institute of Electrical and Electronics Engineers/International Organization for Standardization 11 073 (device interoperability) have played a pivotal role in medical informatics [14]. Today, medical informatics is a field which intersects with clinical sciences, medicine, mathematics, computer programming, bioengineering, decision analysis, probability, epidemiology, and statistics.

KEY POINTS: HISTORY OF MEDICAL INFORMATICS

- Biomedical informatics is a multidisciplinary field that studies the effective uses of biomedical data, information, and knowledge for scientific inquiry, problem-solving, and decision-making to improve the medical care and health of patients.
- The development and application of computer technology, databases, and data warehouses in healthcare have led to important advancements in electronic health records, data science, and data mining.

Principles, terminology, and technologies

This section provides an overview of medical informatics by describing basic principles, terminologies, and technologies. Its goal is to provide a framework to begin conceptualizing the use of data science in healthcare.

Friedman's fundamental theorem of informatics states that: "A person working in partnership with an information resource is 'better' than that same person unassisted" (Figure 5.1) [15]. The theorem describes how information technology is capable of augmenting human reasoning, and information resources may provide information, knowledge, or advice to support an individual who is faced with a medical decision. Friedman's fundamental theorem assumes that the resource offers something of benefit that the individual does not know. The interaction between the individual and information resource is critical.

For a technology to be truly useful, data is utilized to create information that the clinician utilizes and integrates with their knowledge. Through the repeated application of such knowledge, wisdom forms. The concept of knowledge

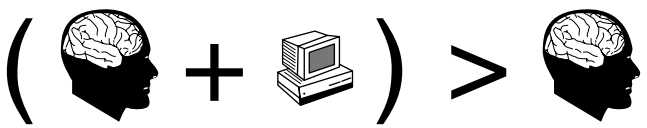

Figure 5.1 Friedman's fundamental theorem of informatics. (Source: Friedman [15]. Reproduced with permission of Oxford University Press.)

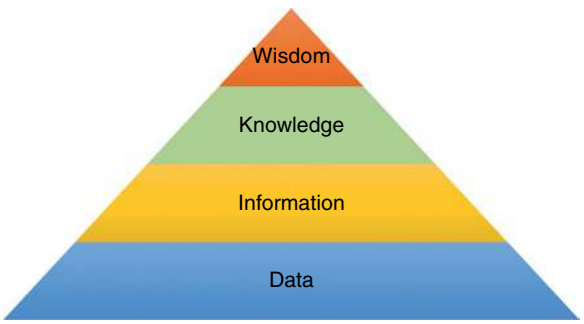

Figure 5.2 Data, information, knowledge, and wisdom hierarchy. Source: Adapted from Ackoff [16].

and wisdom creation from data has been adopted from Ackoff's data, information, knowledge, and wisdom hierarchy (Figure 5.2) [16–18].

- Data includes any number, text, symbol, image, and sound that may be stored and studied. Examples of data include vital signs (heart rate, respiratory rate, blood pressure, pulse oximetry), ventilator parameters, images, diagnoses codes, or free text in medical charts (Figure 5.3).
- Information processed data. An example of this is the interpretation of hypoxia based on pulse oximetry data.
- Knowledge is contextualized information where familiarity is gained by experience. In the perioperative environment, an example is an integration of information (hypoxia and high peak airway pressures) to utilize the knowledge and diagnose a mucous plug.
- Wisdom encompasses testable, consistently successful beliefs and involves the synthesis of knowledge to an elevated and shared understanding that is robust and repeatable. The safe perioperative care of patients with congenital heart disease requires vast knowledge, experience, and understanding of physiology to comfortably treat conditions such as hypoxia.

How to work with big data

Working with data is both an art and a science. Each data science project is unique in its goals and will therefore be unique in its design and execution. However, there are many best practices and frameworks that have been adopted by the data science community to ensure that high-quality and reliable results are achieved. To understand how to work with data, we must first understand how data is represented, measured, collected, organized, and accessed.

How is data represented

All data, from music to images to patient medical records, is ultimately stored as ones and zeros within a computer. These are referred to as bits. The bits are stored in the computer's volatile memory (random-access memory, RAM) or in non-volatile memory (i.e. files on a hard drive which are preserved across reboots of a computer). Typically, sets of 8 bits are grouped together. This grouping is called a byte. Data size is often measured in units of bytes, with ever-increasingly larger prefixes (Table 5.1). There are various systems to encode the data. Two examples include binary, which consists of two digits (0 and 1), or base-10, which consists of 10 digits (0 through 9).

To encode useful information, there are many ways to interpret patterns of bits. Different encoding types have different advantages and disadvantages. The most common data types for data science include the following.

Integers – This data type represents whole numbers (1, 2, 3, etc.). They can be signed or unsigned (i.e. positive or negative). The range of values that integers can have depends on the number of bits that are used to express their values. For example, an unsigned integer that uses 16 bits (or 2 bytes) can represent a number between 0 and 65 535 (2^16 – 1), while an unsigned 8-bit integer can represent a number between –128 and 127. Typical sizes for integers are

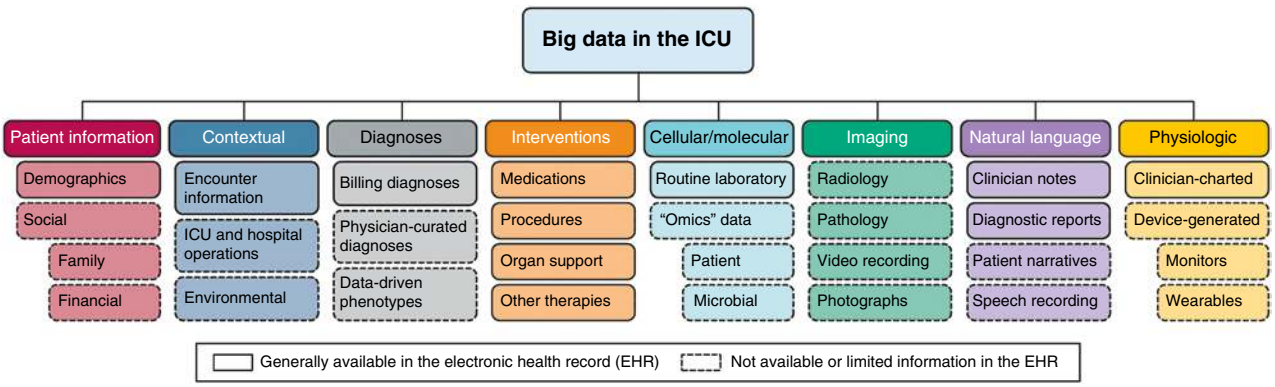

Figure 5.3 Sources of data in the intensive care unit (ICU) setting. (Source: Sanchez-Pinto et al. [21]. Reproduced with permission of Elsevier).

Table 5.1 Units of data

Units	Binary system	Base-10 system	Example
1 Bit (b)	Binary digit	Binary digit	'1' or '0'
1 Byte (B)	8 Bits	8 Bits	1 typed character (i.e. 'A')
1 Kilobyte (kB)	1024 Bytes	1000 Bytes	1 paragraph
1 Megabyte (MB)	1024 Kilobytes	1000 Kilobytes	400-page book
1 Gigabyte (GB)	1024 Megabytes	1000 Megabytes	30 minutes of video. 1 DVD movie is 4–8 GB)
1 Terabyte (TB)	1024 Gigabytes	1000 Gigabytes	500 hours of movies
1 Petabyte (PB)	1024 Terabytes	1000 Terabytes	500 billion pages of typed text or 2000 years of MP3-encoded music
1 Exabyte (EB)	1024 Petabytes	1000 Petabytes	11 million 4k resolution videos

AL Grawany

8, 16, 32, and 64 bits. The disadvantage of integers is that they cannot express a number that contains a decimal or a fraction value.

Floating-point numbers – This data type represents positive and negative decimal numbers. The precision of floating-point numbers is based on the number of representative bits. They are usually represented as a decimal with an exponent (i.e. 2.3456×10^5). A 32-bit floating-point number has eight digits of precision (i.e. seven digits after the decimal), while a 64-bit float (usually called a double float) has 15 digits of precision.

Character arrays, strings, and text – This data type represents text. Usually, 1 or 2 bytes of data are used to represent an individual character, and character encoding maps are used to associate a specific byte value with a letter or pictograph (i.e. a character byte that has a value of 65 represents the letter "A"). The most common encoding maps are American Standard Code for Information Interchange (ASCII) and a universal character encoding standard called UNICODE. Traditionally, a string is terminated with a NULL character (i.e. the byte value of 0).

More complicated data representations are constructed hierarchically from these basic types. For example, a gray-scale image that has a resolution of 600×800 (such as that produced by an X-ray) can be represented using an array of 480 000 integers ($600 \times 800 = 480\,000$), where each integer represents the intensity of the signal at a specific location in the image. An RGB color image is represented using a set of three integers to represent a color for each pixel or location in the image. While there may be complex ways that these data structures are stored (because they can get very large), all complex data structures can be broken down into these fundamental data types for subsequent analysis.

Data types within a hospital

There are four main classes of data within a hospital: text-based records in the electronic medical system (EMR)/electronic health system (EHR), imaging data held in the Picture Archive and Communication System (PACS) system, physiologic time-series data generated by the bedside patient monitoring equipment, and genetic data from patients (-omics data). The most common data on medical data science projects include text-based records from the EMR. Within the EMR, there exists a further dichotomization of data: structured vs. unstructured data.

Structured data is data that has been captured in such a way that an unambiguous result can be ascertained from the user input. Conversely, unstructured data is data that is captured without such a rigorous process in place. For example, the entry of a patient's weight into the EMR using the "weight" field or ordering of a medication from a drop-down "medication list" are examples of creating structured data because there is a specific field on the form that was designed to capture "weight" and "medication name." It is not the nature of the data itself that is structured, but rather the *way* that the data is captured that determines if it is structured data. The limitation of a structured data capture system is that it can only capture data that it is designed to capture and nothing else. The benefit of a structured data capture system is that it facilitates data analyses and the data analysis pipeline (discussed later in this chapter).

Unstructured data is equivalent to the data generated while writing in the free-text portion of a clinical progress note. The free-text nature of unstructured data allows the user flexibility to add whatever information is important. The downside is that unstructured data is significantly more difficult to query than structured data. Imagine if a task is to obtain a list of the medication doses given to a set of patients. If these data were captured in a structured way, a spreadsheet could be generated with the medication name, corresponding dose, time, and patient (how this is done will be addressed later in this chapter). Unstructured data would require a manual chart review of all of the free text in the medical record to obtain the information. This process is time-consuming and may create errors that would potentially invalidate any data analysis. Often the most flexible systems have a mix of both structured and unstructured data. Significant forethought is given to the design of the structured fields to be captured and how the unstructured data will be utilized for analysis.

It is important to note that not all data that is generated in the hospital may be captured for retrospective review and analysis. Just because a piece of data is generated does not mean that it is stored. Oftentimes, there may be temporary storage of data that is purged in the future. A summary of the major data types and sources in an ICU setting is presented in Figure 5.3.

The lexicon of medical informatics and data science broadly encompasses terms related to various types of data, data analytics, and components of machine learning models (Table 5.2).

Table 5.2 Definitions and terminologies in medical informatics and data science

Term	Definition
Big data	Data generated in high volume, variety, and velocity, resulting in datasets that are too large for traditional data-processing systems.
Data science	A set of fundamental principles that support and guide principled extraction of information and knowledge from data.
Data mining	Extraction of knowledge from data via machine learning algorithms that incorporate data science principles.
Domain expertise	The understanding of real-world problems in a given domain (e.g. critical care medicine) that helps frame and contextualize the application of data science to solve problems.
Machine learning	The field of study that focuses on how computers learn from data and on the development of algorithms to make learning possible.
Features	The data elements (independent variables) used to train a model. Features may be raw data, transformations of raw data, or complex transformations of data (such as ones performed by neural networks).
Outcomes	The data elements (dependent variables) which represent the target for training in a supervised learning model. Outcomes may be categorical (e.g. yes/no)

(*Continued*)

Table 5.2 (Continued)

Term	Definition
	or continuous (e.g. length of hospital stay). Binary outcomes are typically represented as Boolean logic (e.g. true/false) or fuzzy logic (e.g. range of probabilities).
Supervised learning	Algorithms used to uncover relationships between a set of features and one or more known outcomes.
Unsupervised learning	Algorithms used to uncover patterns or groupings in data without targeting a specific outcome.
Model training	The process where machine learning algorithms develop a model of the data by learning the relationships between features. In supervised learning, the relationship between a set of features and one or more known outcomes is utilized for training. This is also referred to as model derivation or data fitting.
Model validation	The process of measuring how well a model fits new, independent data. For example, evaluating the performance of a supervised model at predicting an outcome in new data. This is also referred to as model testing.
Predictive model	A model trained to predict the likelihood of a condition, event, or response. The US Food and Drug Administration specifically considers predictive strategies as those geared toward identifying groups of patients more likely to respond to an intervention.
Prognostic model	A model trained to predict the likelihood of a condition-related endpoint or outcome such as mortality. In general, the goal is to estimate a prognosis given a set of baseline features, regardless of what ultimately leads to the outcome.
Overfitting	A phenomenon when an algorithm learns from idiosyncrasies in the training data, usually "noise." The noisy data present in the training dataset do not represent generalizable truth in relationships between features and outcomes. Overfitting will typically lead to poor model performance in an independent validation dataset.
Digitization	The conversion of analog data (e.g. paper documents, printed images) into a digital format (e.g. bits)
Digitalization	The wide adoption of digital technologies by an organization to leverage digitized data with the goal of improving operations and performance. The adoption of electronic health records, picture archiving, and pharmacy management systems are examples of digitalization in healthcare.
Data curation	The process of integrating data from different sources into a structured dataset. It typically involves authenticating data to ensure quality and may involve annotation of data to facilitate use in the analysis.
Structured data	Data (usually discrete or numeric) that are easy to search, summarize, sort, and quantify. Examples include vital signs and laboratory test results (e.g. complete blood count, complete metabolic panel).
Unstructured data	Data that do not conform to a prespecified structure. Unstructured data are usually more difficult to search, sort, and quantify. Examples include clinician notes, written narratives, images, pathology slides, radiology images, video, or audio.

Databases, data organization, and querying data

Structured data can be organized and recorded in databases to enable efficient storage and retrieval of information. While there are many types of databases, the two most common are relational databases and key-value storage systems (also called a NoSQL database or column stores). Relational databases allow a user to define relationships between sets of data so that data integrity and fidelity are rigorously and automatically enforced, while key-value databases provide ways of storing and retrieving large amounts of data without requiring the complexities and overhead associated with these guarantees. For the purposes of this discussion, we will focus on relational databases as these will be the most common databases utilized within the healthcare setting.

The structure of a relational database is called a schema, which is the organization or blueprint of the database. The schema is the database described by a set of one or more tables. A table is similar to a spreadsheet. Each table has its own set of rows and columns. The columns of a table (also called fields) represent the specific aspects of a set of data (i.e. "first name," "last name," and "date of birth"). Each field also has a type (such as integer, float, or text) to allow the database to understand how to interpret the data within each field. The rows of the table (also called records) represent the specific data points that have been recorded (i.e. "John," "Doe," "1-1-1970"). Each table must contain a column that has a unique identifier for each row. This is called the "primary key" field of the table. This is the equivalent of the row number in a spreadsheet. For most tables, this field is called the "record number" and is represented as a 64-bit integer, which allows for the unique identification of hundreds of millions of trillions of rows (or more precisely, 2^64 – 1 records).

The complexity of databases becomes evident when one considers the hundreds or even thousands of tables that need to be managed, linked, and organized. For example, a database associated with an EMR system may have more than 20 000 unique tables, and each table may have hundreds of fields. How is the subset of data located and retrieved in the haystack of tables defined in the database schema? The answer is through relationships. Generally, all tables in a database schema will be related to one another in some way, either directly or indirectly. A relationship between two tables is created by embedding the primary key of one table into a field within a different table. For example, imagine building a database to describe how beds are organized within a hospital ICU. Conceptually, hospital beds are organized into individual units, and each unit has one or more beds. The database schema can be represented using two tables: a "Units" table and a "Beds" table. Each table would have its own primary key and other fields related to the specifics of the table. The "Beds" table might have a field that is "bed name," while the "Units" table might have a field called "unit name." To create the relationship between the units and beds table, a field can be added to the beds' table, called unit ID, which can hold the record number of the record in the unit table that corresponds to the unit the bed is located. Therefore, to lookup what unit a given bed is located in, the following steps are executed:

1. Search the bed table to find the record associated with the name of the bed.
2. Extract the unit ID from the matching bed record.

AL Grawany

3. Search the units table to find the record with a primary key value equal to this unit ID.
4. Extract the unit name from the matching record.

Executing this process manually for dozens or hundreds of relationships between a large number of tables would be very tedious, but computers can be programmed to execute such searches as quickly and efficiently as possible. Computer scientists have created a structured language for querying database tables in order to efficiently search and extract data from databases. This language is called SQL (structured query language). SQL is a standard language that can be used to query data across a wide variety of databases such as MSSQL (Microsoft SQL), Oracle, and PostgreSQL among others. There are many textbooks and online tutorials available for learning how to write SQL queries that the reader can reference for further learning.

Data analysis and processing pipelines

Data processing pipelines are the processes by which heterogeneous data is collected and transformed into a standardized format for subsequent analysis (Figure 5.4). The data processing pipeline allows for the cleaning and integration of data. The process of creating knowledge from data includes the following steps:

1. **Data collection:** Data may be collected via a variety of methods that may include physiological sensors, monitors, or manual entry. This phase also involves data curation, which is the process of integrating data from different sources into a structured dataset. Depending on the size of the dataset, large amounts of data are often stored in databases or data warehouses. Database systems or database management systems are utilized to manage and access data. Data warehouses are a set of databases which hold information collected from multiple sources or locations.
2. **Data selection, feature extraction, and cleaning**: Relevant data is retrieved and may require transformation. Identification of relevant features, attributes, or dimensions of the data is imperative. Another essential process is the removal of noise and inconsistent data. There are techniques to filter, smooth, and estimate missing values by utilization of regression or outlier analyses. This stage also assesses the accuracy, consistency, completeness, interpretability, and believability of data. Occasionally, data integration (or the combination of multiple files, data sources, and databases) is necessary for the creation of a structured dataset.
3. **Analytical processing and algorithms**: Methods and algorithms are designed and then applied to extract data patterns. Descriptive tasks that characterize data can lead to a fundamental understanding of datasets. Predictive tasks can be performed on the dataset to make inferences on future patterns. In this process, elements of pattern evaluation can identify trends that may represent knowledge.
4. **Presentation and knowledge**: In this stage, data is visualized. Examples include data tables, bar charts, or pie charts. The processed data is represented as knowledge.

To ensure meaningful results, this process is often iterative and requires feedback from the data preprocessing or analytical processing steps. In addition, a strong understanding of the dataset via domain expertise is also imperative for meaningful inferences and insights.

KEY POINTS: PRINCIPLES, TERMINOLOGY, AND TECHNOLOGIES

- Friedman's fundamental theorem of informatics states that: "A person working in partnership with an information resource is 'better' than that same person unassisted."
- The data, information, knowledge, wisdom (DIKW) pyramid or hierarchy describes the relationship between data, information, knowledge, and wisdom.
- Common ways to encode data are with integers, floating-point numbers, character strings or text, and complex representations such as images. Various data types which can be studied include text-based records, imaging data, physiologic time-series data, and genetic data.
- Data science is a set of fundamental principles that support and guide principled extraction of information and knowledge from data.
- Relational databases allow for the efficient storage and retrieval of data through the structured query language.
- Data is converted to knowledge via processing pipelines that include data collection, data selection, feature extraction, data cleaning, analytical processing and algorithms, and presentation of knowledge.

Machine learning and artificial intelligence

Machine learning and artificial intelligence have grown from the fields of computer science, applied mathematics, and statistical learning. In general, machine learning is a field of

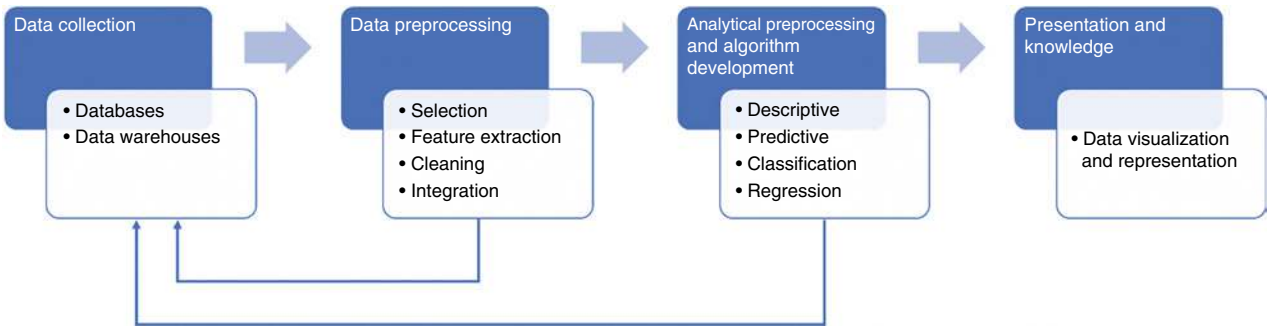

Figure 5.4 Data processing steps and pipeline.

study that focuses on the development of algorithms and methodologies for automating pattern recognition problems [22]. Humans are great at pattern recognition as our brains have had years of training to be able to recognize important aspects of our environment. Computers, on the other hand, have been traditionally poor at pattern recognition tasks.

A pattern recognition task is a task that requires a decision to be made by utilizing previous experiential knowledge of a regularized structure in sets of data. For example, suppose an individual is given a picture of either a cat or a dog and asked to determine which animal is displayed. Even though the exact picture of the cat or dog may not have been seen before, this task can be performed very accurately. Over time, the telltale features that make a cat a cat or a dog and dog have been learned. Using this set of learned, implicit features, the class of animal when a new dog or a cat is encountered may be inferred with a high degree of accuracy. Machine learning is a method for building algorithms that can learn the important "features" embedded within a large set of data and allow a computer to perform pattern recognition tasks automatically without human intervention.

In the field of genetics, molecular medicine, and bioinformatics, these algorithms have fostered discovery through advanced machine learning algorithms, biomedical ontologies, and natural language processing tools. As this field expands into the medical informatics domain, applications to clinical decision-making, methods for reasoning under uncertainty, knowledge representation, and systems integration are critical [23]. A large amount of available patient data has changed the way how we can approach clinical research and medical care [24, 25]. Machine learning is divided into three broad approaches: supervised learning algorithms, unsupervised learning algorithms, and broader, deep learning algorithms.

Supervised learning algorithms

Supervised learning algorithms are utilized to discover clinical features and relationships between variables of interest and outcomes [22]. Each data point is labeled or associated with a category or value of interest. Training data or examples are used to infer these relationships via learning algorithms. A research question addressed by a supervised learning algorithm may involve determining the clinical features that predict mortality in patients after congenital heart surgery (Figure 5.5A). The supervised learning algorithm is applied to a large training dataset to determine the relevant clinical features that predict the outcomes of interest. The goal is for these models to be applied to new patients to predict the pertinent outcome in a specific condition, event, or response.

Examples of supervised learning algorithms include linear regression, logistic regression, naïve Bayes, decision trees, and K-nearest neighbor. Once the algorithm is applied, the parameters of the model may then be adjusted and optimized on a subset/validation dataset. Once the learning algorithm is applied to the training dataset, performance is assessed via a testing dataset.

Unsupervised learning algorithms

Unsupervised learning algorithms are utilized to discover patterns or groupings in datasets without targeting a specific outcome [22]. The outcomes are unlabeled in unsupervised learning algorithms. These algorithms are often used in exploratory data analyses to find similarities in subsets of data. A research question addressed by an unsupervised learning algorithm may be used to determine groups of patients after congenital heart surgery and emerging patterns of clinical outcomes (Figure 5.5B). In this way, the dataset is automatically split into groups based on similarities. The goal of unsupervised learning algorithm is to organize the data to better describe features of the dataset structure.

Examples of unsupervised learning algorithms include hierarchical clustering, centroid-based/k-means clustering, principal component analysis, and latent class analysis. These algorithms are more computationally complex than supervised learning algorithms.

Deep learning algorithms

Deep learning algorithms or neural networks are a unique type of algorithm that consists of connected nodes or neurons, arranged in a series of layers to extract complex and meaningful features from data. Each node receives signal data, processes the data, and passes information to additional nodes. As learning proceeds in the neural network, the relative weights of each connection or edge are adjusted to strengthen the overall network [26]. A research question addressed by a deep learning algorithm may be utilized to extract meaningful diagnoses from patient chest radiographs (Figure 5.5C). The goal of deep learning algorithms is to solve complex medical problems with hierarchical complexity to make useful predictions.

Examples of deep learning algorithms include convolutional neural networks and generative adversarial networks. These algorithms require considerable computing resources and training sets. A summary of machine learning algorithms is presented in Table 5.3.

KEY POINTS: MACHINE LEARNING AND ARTIFICIAL INTELLIGENCE

- Machine learning focuses on how computers learn from data and the development of algorithms and methodologies to make learning possible by leveraging the vast amounts of data available.
- Three broad categories of machine learning algorithms include supervised learning algorithms, unsupervised learning algorithms, and deep learning algorithms.
- Supervised learning algorithms are utilized to discover clinical features and relationships between variables of interest and outcomes. Models are developed through a training dataset and then validated through a testing dataset. Robust models can then be utilized to predict outcomes.
- Unsupervised learning algorithms are utilized to discover patterns or groupings in datasets without targeting a specific outcome. These algorithms are often used in exploratory data analyses to find similarities in subsets of data.
- Deep learning algorithms or neural networks are connected nodes or neurons, arranged in a series of layers to extract complex and meaningful features from data. These algorithms are utilized to solve complex medical problems with hierarchical complexity with the ultimate goal of making useful predictions.

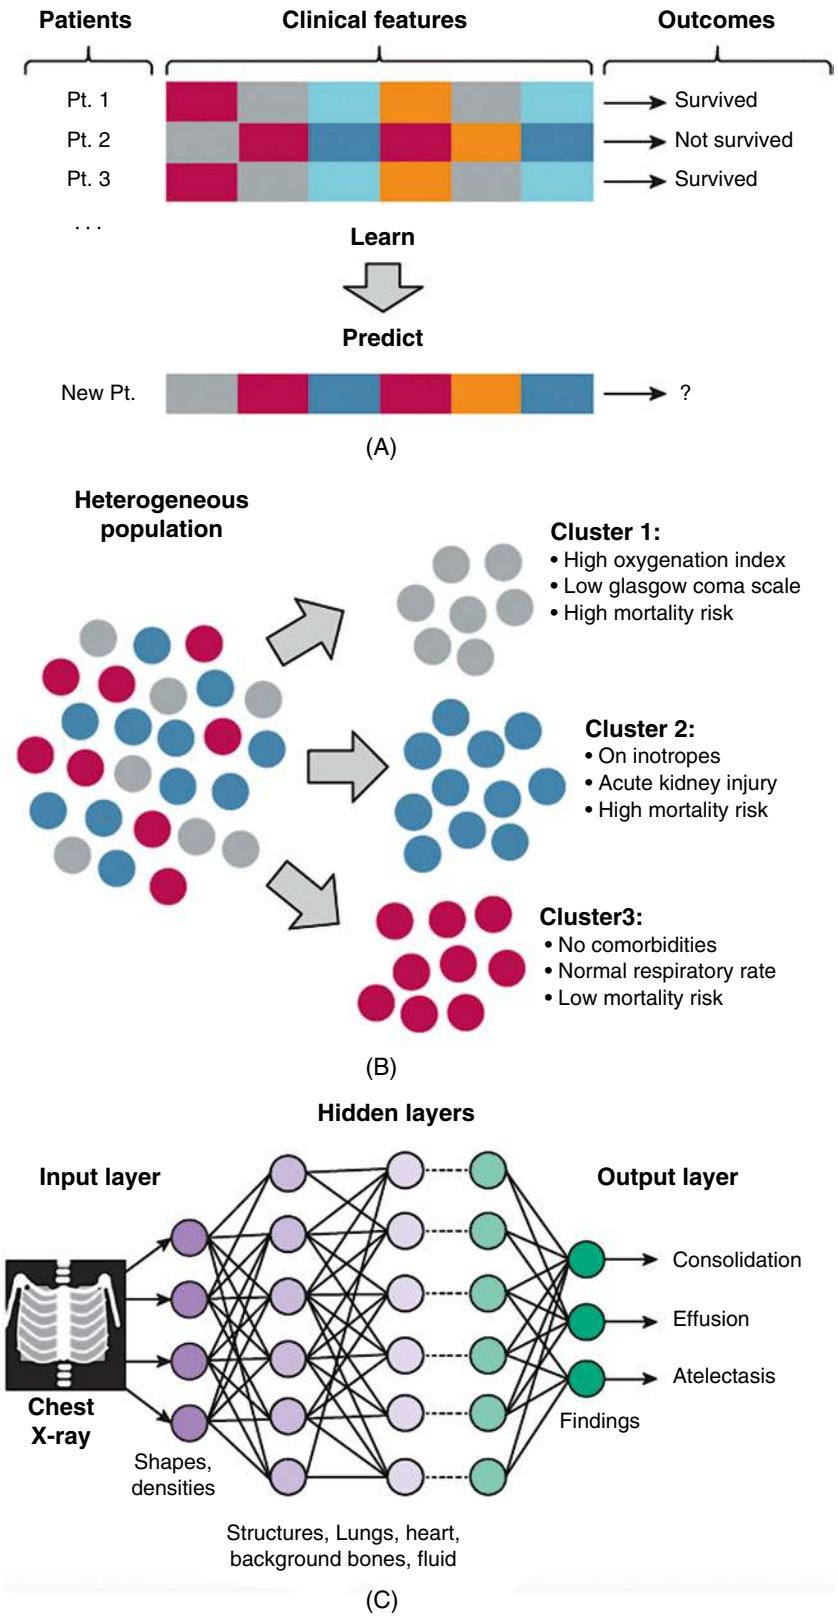

Figure 5.5 Types of machine learning algorithms: (A) supervised learning algorithms; (B) unsupervised learning algorithms; (C) deep learning algorithms. (Source: Sanchez-Pinto et al. [21]. Reproduced with permission of Elsevier).

Table 5.3 Examples of machine learning algorithms

Algorithm class	Examples	Description
Classic regression	Linear regression, logistic regression	Linear regression is a supervised learning algorithm that models the relationship between one or more features and a continuous outcome by fitting a regression line that minimizes the sum of all the residuals (distances between each feature in the training data and the line being fitted to model the data). Logistic regression is a generalization of the linear model that uses the logit function to estimate the probability of a binary outcome. To do this, the fitted sigmoid-shaped curve of the logistic function maps the feature values into a probability between 0 and 1.
Regularized regression	Lasso, ridge regression, elastic net	An extension of the classic regression algorithms in which a penalty is imposed to the fitted model to reduce its complexity and decrease the risk of overfitting.
Tree-based	Classification and regression trees, random forest, gradient boosted trees	A class of supervised learning algorithms based on decision trees. Decision trees are a sequence of "if-then-else" divisions that are derived by iteratively separating data into groups based on the relationship of the features with the outcome. Random forest and gradient boosted trees are examples of ensemble tree models. Ensemble models combine the output of many trained models to estimate an outcome.
Support vector machines	Linear, polynomial, radial basis kernel	A class of supervised learning algorithms that represents the data in a multidimensional feature space and then fits a "hyperplane" that best separates the data on the outcomes of interest. A hyperplane is a space with one dimension less than its space. For example, an n-dimensional space, a hyperplane that separates the space has (n – 1) dimensions.
K-nearest neighbor	K-nearest neighbor	A type of supervised learning algorithm that represents data in a multidimensional feature space and uses local information about observations closest to a new example to predict the outcome for that example.
Bayesian	Naïve Bayes, Bayesian network	A class of supervised learning algorithms that use Bayes' theorem of conditional probability, which is the probability that something will happen given that something else has already occurred. In general, Bayesian algorithms work by iteratively updating the probability of an outcome given new data.
Neural network	Artificial neural network, deep neural network	A class of nonlinear algorithms built using layers of nodes that extract features from the data and perform combinations that best represent the underlying structure, usually to predict an outcome. Neural networks can be shallow (e.g. perceptron with two layers) or deep (multiple layers), which form the basis for the field of deep learning.
Dimensionality reduction algorithms	Principal component analysis, linear discriminant analysis	A class of unsupervised learning algorithms that exploit the inherent structure in the data to describe data using less information. Principal components, for example, summarize a large set of correlated features into a smaller number of representative features.
Latent class analysis	Latent class analysis	A type of unsupervised learning algorithm that identifies unseen subgroups or latent classes, in the data. Class membership is unknown for each example, so the probability of class membership is indirectly estimated by measuring the patterns in the data.
Cluster analysis	K-means, hierarchical cluster analysis	A class of unsupervised learning algorithms that uses the inherent structures in the data to best organize the data into subgroups of maximum commonality based on a distance measure between features.

Advanced monitors in intensive care units and operating rooms

With advancements in medical informatics, computational processors, ICU monitors, and methods of information storage, we have entered an era of data-driven healthcare. The data analytics, algorithms, and methods described earlier in this chapter can be used in the development of new paradigms for the monitoring and treatment of patients with congenital heart disease. At present, monitoring systems are limited in scope for the prediction of adverse events, the opportunity of the development of intelligent monitoring systems is real.

Historical and real-time physiologic patient data can now be synthesized to create an integrated representation of the patient's overall state of health. For example, physiological trend graphs have been used to identify late-onset sepsis in preterm infants with increased accuracy in neonatal ICUs [27]. In future ICU monitors, relevant medical information, including patient-specific alarm conditions, risk-index scores, and suggestions for care, may be displayed in a unified monitor. There is a substantial benefit in the creation of displays that not only integrate the sizable amount of ICU data in a meaningful way but also provide the medical team with a display that allows a patient's clinical trajectory to be followed over time.

In addition to physiologic patient monitors, medical devices in the ICU and OR environments also have interfaces capable of submitting data that can be analyzed, i.e. infusion pumps, ventilators, extracorporeal membrane oxy-

AL Grawany

genation (ECMO) machines, ventricular assist devices, dialysis machines, etc. In addition, EMR data, i.e. problem lists, prior procedures, chronic medications, allergies, etc., can be integrated into the predictive models for a more robust dataset [28, 29]. Besides predicting risk for adverse outcomes, models could be designed to predict readiness to wean from support, i.e. inotropic, mechanical, ventilatory, or renal support [30].

Current pediatric risk and acuity scores include the Pediatric Risk of Mortality, the third version of PRISM (PRISM III) and Pediatric Index of Mortality, second version (PIM II). These scores take discrete physiological values at a moment in time to calculate a risk for mortality and ICU length of stay [31–34]. Consequently, they are limited for real-time analysis compared to high-resolution, physiologic data, which may allow for the development of metrics that may be more specific and sensitive in defining a patient's acute or impending acute condition.

Statistical or machine learning algorithms, such as classification trees, logistic regression, random forest algorithms, neural networks, or probabilistic network models have been utilized to create sophisticated models of disease [35, 36]. Data from the publicly available Physionet database has been utilized in artificial neural networks to create models for the detection of adult ICU patients at high risk of clinical deterioration with improved performance than traditional acuity scores [37, 38]. Neural networks have also been utilized to diagnose arrhythmogenic cardiac arrest, tension pneumothorax, pericardial tamponade, venous air embolism, and exsanguination [39]. In a multicenter study using electronic health record information, Churpek and colleagues have utilized machine learning methods to predict cardiac arrest, ICU transfers, and mortality in an adult hospital ward in a dataset of >250 000 hospital admissions [40].

The pursuit of such real-time analytics and risk prediction is an evolving field. Most modern medical decision support systems, often Internet or software based, utilize an advanced display to allow clinicians to visualize solutions to medical problems [41]. At the University of Michigan, complex network infrastructures capture and link physiologic data from patient monitors, electronic health record data, and anesthesia records to SQL databases, which are then utilized to create patient risk scores and more intelligent alarms in the ICU and OR settings [42] (Figure 5.6). The system was designed to classify patient physiologic states (such as hypotension), generate alerts, and provide notifications to clinicians.

In the CHD population, single ventricle patients have a high risk of interstage mortality and cardiac arrest. Mortality rates have been observed to be 12% described in the Single Ventricle Reconstruction Trial [43]. Additional analyses of the Single Ventricle Reconstruction Trial data have identified mortality rates or need for cardiac transplantation at 12 months to be 36% for patients receiving a modified Blalock-Taussig shunt and 26% for the right ventricle-to-pulmonary artery shunt. Most commonly, mortality was attributed to cardiovascular causes [44]. Rusin and colleagues have utilized continuous, high-resolution, physiologic recordings to develop logistic regression models that predict cardiopulmonary deterioration 1–2 hours prior to the event with a model area under the receiver-operating characteristic curve of 0.91–0.96 [45–47] (Figure 5.7). Ruiz et al. utilized naïve Bayesian models for the prediction of critical events 1–8 hours prior to the event with the area

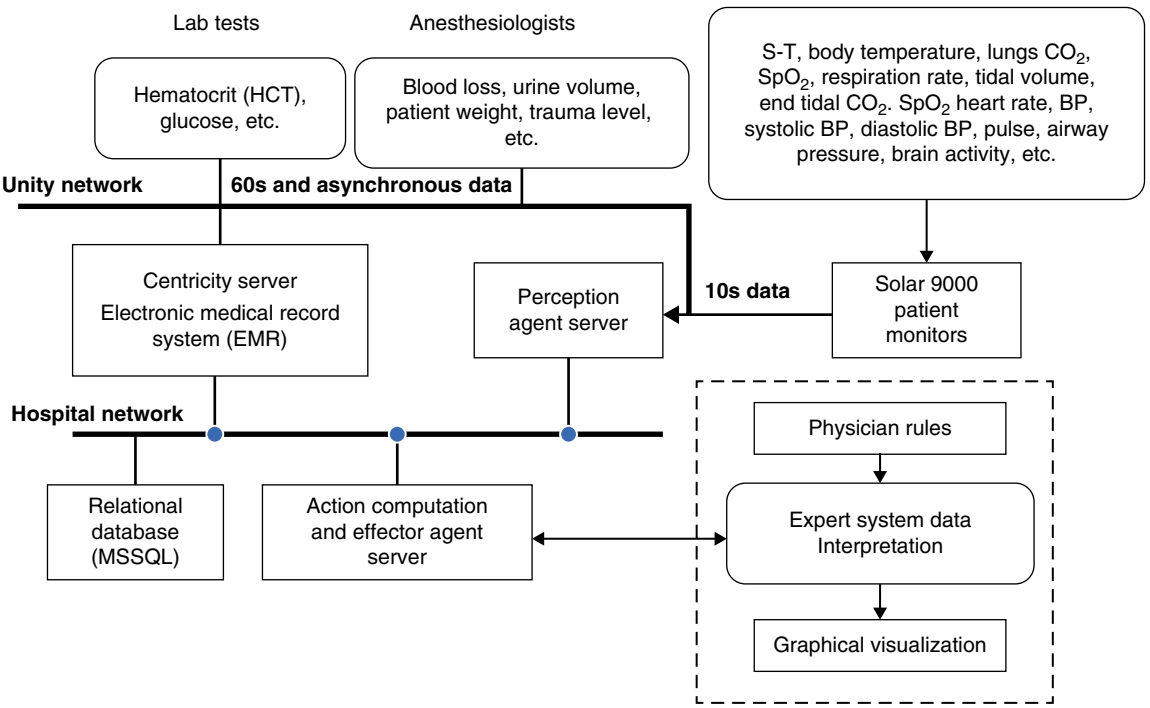

Figure 5.6 Example network architecture and data flow diagram for a clinical decision support system. BP, blood pressure; MSSQL, Microsoft Structured Query Language. (Source: Kruger [42] / The Open Cybernetics & Systemics Journal / CC BY-SA 4.0).

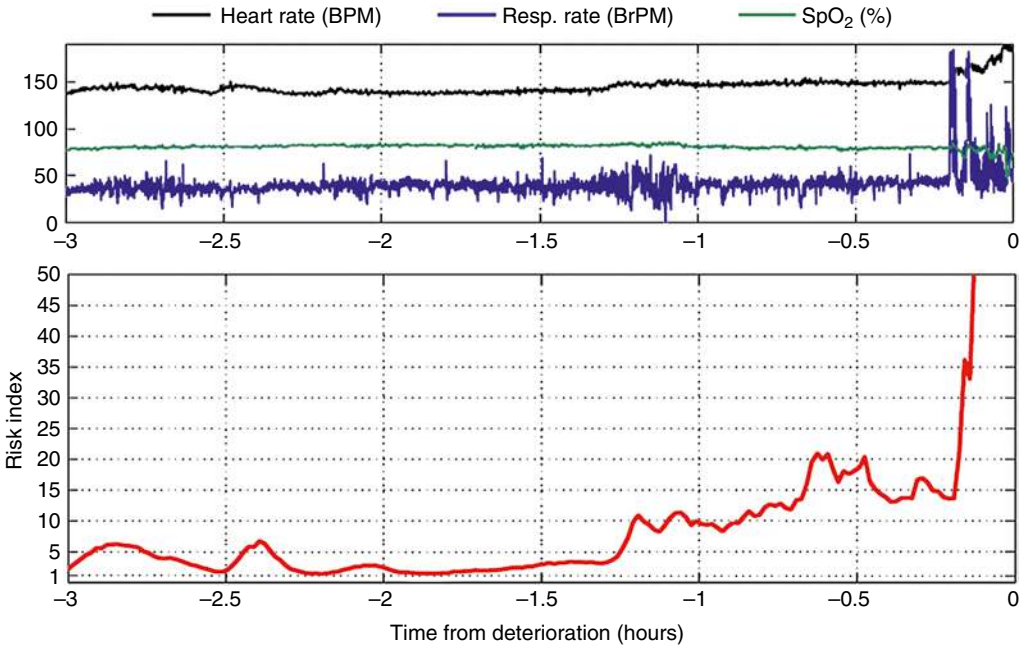

Figure 5.7 Real-time risk index for cardiopulmonary deterioration based on vital sign monitoring. Classification algorithms were applied and optimized to create receiver operating characteristic curves of 0.91. (Source: Rusin [45]. Reproduced with permission of Elsevier).

under the receiver-operating characteristic curves ranging from 0.73 to 0.88 [48]. These results are encouraging and suggest that computational models are able to detect subtle physiological changes in high-risk interstage patients and provide a real-time risk assessment for clinical deterioration. The results of these models are to be tested and validated via further multicenter studies. Early recognition of impending deterioration allows the medical team time for interventions in hopes of reducing patient morbidity and mortality.

The future of monitoring congenital heart disease will continue beyond the OR and ICU environment. In single ventricle patients, home monitoring and telemedicine systems have been proposed to improve outcomes [49–52]. Surveillance through tablet or personal computer-based solutions has been developed to facilitate communication between families and clinicians [53]. However, there are opportunities for growth and improvement as these home monitoring programs consist of basic vital sign monitoring. The expected future growth and expansion of home monitoring technologies and techniques beyond the hospital setting may continue to improve patient outcomes in the high-risk single ventricle patient.

KEY POINTS: ADVANCED MONITORS IN INTENSIVE CARE UNITS AND OPERATING ROOMS

- The data analytics, algorithms, and methods described earlier in this chapter can be used in the development of new paradigms for the monitoring and treatment of patients with congenital heart disease.
- Previous risk index and acuity scores include the Pediatric Risk of Mortality, third version (PRISM III), and Pediatric Index of Mortality, second version (PIM II) that use discrete values to predict mortality risk and ICU length of stay.
- Real-time analytics and risk prediction is an evolving field utilizing advanced data analytics. Logistic regression and naïve Bayes models have been utilized in single ventricle patients in the prediction of critical events such as cardiopulmonary arrest.

Limitations and challenges

With the development of new technologies from the field of medical informatics, there are limitations and challenges not only in the development of the technology but also in the adoption of that new technology. This section will discuss some of the pitfalls with the development of this technology and data mining.

Many advances have been made in medical informatics in the digitalization and integration of medical devices. However, poor integration and interoperability between medical devices remain a challenge for the data scientist when attempting to contextualize vast amounts of data. As the field of medical informatics has grown, the development of domain expertise, which must bridge the areas of computer science, statistics, engineering, and medicine, becomes even more important over the next decades. An understanding of both the data science and clinical applicability is needed to avoid the failures that commonly face new medical technologies. Otherwise, data mining may lead to irrelevant, flawed, or low-quality research [54, 55]. For

example, an issue described earlier in this chapter includes the overfitting of models. A rigorous approach to statistical and data mining methods through validation and testing can be utilized to detect this problem.

The US medical system is burdened with 180 000–440 000 preventable medical errors leading to patient mortality on an annual basis [56, 57]. There are constant pursuits to use the techniques described in this chapter to design advanced monitors for earlier and more reliable detection of adverse patient events. However, the burden of alarm fatigue to the user is a significant challenge in the critical care, OR, and perioperative care settings. In a pediatric ICU study, it was found that 68% of alarms were false and 94% of alarms were clinically unimportant [58]. A national survey among Canadian anesthesiologists found that 58% of 789 respondents routinely deactivated alarms at the start of a case [59]. Simple, rule-based decision support systems have been described for congestive heart failure. However, when the performance of the clinical decision support system was evaluated against manual review of records, the tool had a sensitivity of 79% and a positive predictive value of only 11% [60]. The system failed and was removed from clinical use, but it was able to highlight problems with false negatives, excessive alerts, and lack of physician response to alerts. In the design of clinical decision support systems, alarm management will play an essential role.

The widespread adoption of electronic health records and data warehouses has increased the accessibility of patient information. Information overload is an emerging concern, and the data from multiple devices that the medical provider can process, code, and integrate is finite [13, 61]. An important principle in the design of advanced monitors and clinical decision support tools is in the visual presentation of the information, which must be intuitive to the provider, who may not be familiar with the theory or evidence. The use of human factors science in the design of clinical decision support tools is pivotal to the success of new monitors.

The Gartner Hype Cycle describes a common pattern that arises with new technologies and innovations (Figure 5.8). The innovation trigger begins with a breakthrough and product launch. This is followed by a peak of inflated expectations where the expectations may be greater than the technological capabilities. A trough of disillusionment follows as problems with the technology lead to reduced expectations and slow adoption. Continued work and understanding of technology lead to a slope of enlightenment, and finally, a plateau of productivity forms where the technology finally finds productive and useful value [62]. The Gartner Hype Cycle highlights the challenge in the adoption of new technologies as perceptions and expectations of that technology must align with reality. In this way, the technology finally begins to impact patient care.

KEY POINTS: LIMITATIONS AND CHALLENGES

As medical informatics, machine learning, and artificial intelligence continue to grow in the perioperative and critical care settings, there are challenges in domain expertise, appropriate application of algorithms, model overfitting, and adoption of new technologies.

Future of clinical informatics in congenital heart disease

Though many clinical informatics systems in congenital heart disease are still in early stages of development, they will continue to evolve. As patient data, databases, and data warehouses continue to grow in scope and size, so will the medical system's contextual knowledge base and ability to develop models through advanced computational techniques. Data-driven systems will be transformative in guiding care for complex patient with congenital heart disease.

There have been several developments that have made the growth of medical informatics possible: (i) the increased collection and digitalization of data in medicine, (ii) the extraordinary expansion of computational power, (iii) the growth of the data science movement and its expansion into medical space, and (iv) the increasing availability of educational resources and tools for data science. These tools are a natural

evolution in information technology, and as they continue to grow, so will the next-generation monitors that can provide the medical team with more effective tools for the early recognition of patient conditions to facilitate improved patient care.

This chapter has been designed to provide an overview of data science and machine learning techniques used in the development of future monitors and clinical decision support systems. We encourage further study in this complex field in those interested. Teams of engineers, computer scientists, data scientists, and clinical experts are required as the fields of clinical informatics, machine learning, and artificial intelligence expand in the perioperative setting. As the collection of data continues to grow, the data scientist and clinician can begin to embrace the complexities of congenital heart disease, critical care medicine, and emerging computational technologies [63, 64]. In the future, the multidisciplinary team will be responsible for the design of technologies for intelligent, safe, and effective patient care in patients with congenital heart disease.

Introduction

Congenital heart disease (CHD) is the most common birth defect, occurring in 0.8% of live births and accounting for almost one-third of all major congenital anomalies [1, 2]. The etiology and mechanisms of congenital cardiac malformations are not yet fully understood, and much of our understanding is derived from vertebrate animal models and progress in genomics, proteomics, transgenesis, imaging, and integrative systems biology [3]. CHD is known to have genetic and non-genetic causes, and the multifactorial inheritance of some lesions is probably due to the interactions between several genes, transcriptional programs, and modulating environmental factors, including known teratogens (such as alcohol, isotretinoin, excess vitamin A, thalidomide, anticonvulsants), infectious agents (such as rubella), or maternal diseases (such as diabetes mellitus, obesity, phenylketonuria) [4, 5]. Developmental mechanisms include genetic (somatic or germline variants, chromosomal aneuploidy, copy number variants, point mutations), epigenetic (transcriptional programs, chromatin remodeling factors, histone-modifying proteins), and hemodynamic and contractile forces [4, 6–10]. Furthermore, the understanding of genes and developmental mechanisms producing CHD has provided an insight into adult cell lineages and has opened the door for using regenerative medicine and novel therapies to treat congenital and acquired heart diseases [11]. It must be stated that much of the knowledge and understanding we have regarding cardiovascular development was derived from research in non-human species, which was performed with the hope that the same processes occur in humans.

We have used an anatomical approach to describe the development of the heart and vascular system and to demonstrate the relationships between abnormal development and specific congenital cardiac anomalies. Although a segmental approach is used to describe embryology, cardiovascular development is a three-dimensional, spatiotemporal process with many elements occurring simultaneously.

Contemporary concepts of cardiac development

Up until the 1990s, the conventional view of cardiac development was based on the *segmental model*, in which the primordia of all the future components of the heart were hypothesized to be present in the initial heart tube [12]. Many of the classic concepts have been challenged over the last two decades as advancements have been made in labeling and transgenic fate-mapping techniques. Although the labeling studies performed by Stalsberg, de la Cruz, and Viragh from 1969 onward suggested that cells were added to the poles of the heart from the surrounding mesoderm [13–15], more recent research conducted by Buckingham, Markwald, and others have

confirmed that cells are added to the heart after the initial stage of looping [16–19]. As discussed in detail in the following sections, it is now thought that the primitive heart tube contains little more than the precursors for the left ventricle, parts of the atria, and perhaps the atrioventricular (AV) canal, and that the precursor cells of the other cardiac components are added to both the venous and arterial poles from a second heart field outside the initial heart tube [12, 20]. As stated by Christoffels and Jensen, cardiac development is an iterative process of progenitor cell expansion, intercellular signaling, transcriptional responses, patterning, and differentiation into specialized cell types [20]. Elucidation of the genetic and transcriptional networks regulating cardiac development has provided new insights in that abnormal development not only results in CHD but also influences adult-onset heart disease such as cardiomyopathies, conduction defects, and arrhythmias [21].

Cardiovascular development: normal and abnormal

The human embryo has no heart or vascular system during the first 2 weeks of life. Instead, it relies on diffusion from the uteroplacental circulation. At the end of the second week, the embryo is a bilaminar disc made up of the epiblast and the hypoblast. In vertebrates, the cardiovascular system is the first organ system to develop and function; this begins during the third week of life when diffusion is no longer adequate to meet embryonic nutritional requirements and to remove metabolic waste. The embryo develops into a trilaminar disc by the process of gastrulation, thereby establishing all three germ layers – the ectoderm, mesoderm, and endoderm. Gastrulation involves cells in the epiblast migrating through the primitive streak caudal to the primitive node. These cells detach from the epiblast (invagination), and some displace the hypoblast to create the embryonic endoderm, others come to lie between the epiblast and endoderm to form the mesoderm, and the remaining epiblast cells form the ectoderm (Figure 6.1) [22]. The epiblast is therefore the source of the ectoderm, mesoderm, and endoderm.

Cardiogenic fields

Cardiac progenitor cells are located in the epiblast just lateral to the primitive streak. After gastrulation, these progenitor cells in the lateral plate mesoderm migrate laterally and cranially to locate on either side of the midline under the head folds. The lateral plate mesoderm becomes split by the pericardial coelom into the somatic (dorsal) and splanchnic (ventral) layers (Figure 6.2). Cells in the somatic layer will form the pericardium and cardiac progenitor cells located in the splanchnic layer will form the bilateral cardiogenic or heart fields [24]. These cardiac progenitor fields express the transcription factor *NKX2.5* throughout the left ventricle and atrial chambers, a member of the Homeobox-containing genes that play critical roles in regulating tissue-specific gene expression essential for tissue differentiation and for temporal and spatial patterns of development [25]. The heart fields merge in the midline, cranial to the stomatopharyngeal membrane, to form the *cardiac crescent* (Figure 6.3A,B). There are at least two distinct lineages of cells within the cardiac crescent: one population is referred to as the "first heart field" (FHF), and the other is referred to as the "second heart field" (SHF) [10]. The SHF is contiguous with and located dorsal and medial to the FHF. The FHF will give rise to the linear heart tube and eventually gives rise to the left ventricle (LV) and parts of the right and left atria [27]. Cells from the SHF will be added at the inflow (venous) and outflow (arterial) poles during cardiac looping, ultimately giving rise to the right ventricle (RV), parts of the atria, septum and outflow tract, and base of the aorta and pulmonary trunk. Cardiac cell lineage and specification are shown in Figure 6.4 [27]. Differentiation of the heart field cells into the myocardium is dependent on signals from the neural and dermal ectoderm and adjacent endoderm [28]. The proliferation and differentiation of SHF cells are delayed relative to those of the FHF cells. As discussed in the following sections, the embryonic cells that contribute to cardiac development arise not only from the heart field mesoderm but also from the cardiac neural crest [29] and the proepicardium [30].

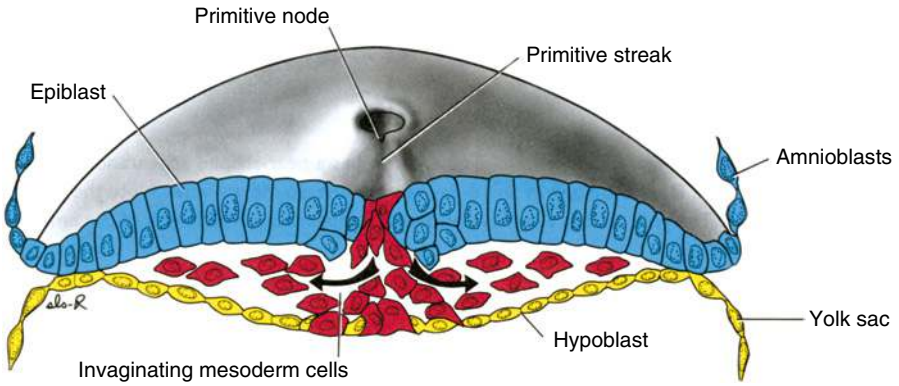

Figure 6.1 Formation of three cell layers. Cross section through the cranial region of the streak at 15 days showing invagination of epiblast cells. The first cells to move inward displace the hypoblast to create the definitive endoderm. Once definitive endoderm is established, inwardly moving epiblast forms mesoderm. (Source: Sadler [22]. KEY POINTS: CARDIOGENIC FIELDS

- Myocardial cells are derived from the bilateral cardiogenic or heart fields in the splanchnic layer of the lateral plate mesoderm.
- The heart fields merge to create a cardiac crescent, giving rise to two lineages of cells referred to as the first and second heart fields.
- Cells that contribute to cardiac development originate from the heart field mesoderm, cardiac neural crest, and the proepicardium.

Formation of the heart tube

The primitive linear heart tube is formed during the fourth week of development from the FHF cells with the folding of the embryo. Contrary to originally held beliefs, the cardiogenic fields do not fuse cranially to caudally in a zipper-like fashion. Folding of the embryo and invagination of the foregut brings the lateral portions of the cardiac crescent together that then fuse at the midline from anterior (cranial) to posterior (caudal) to form the ventral part of the heart tube [20, 26] (Figure 6.2 and Figure 6.3C–G). The medial portions of the cardiac crescent will form the dorsal part of the heart tube, which is open to the ventral foregut endoderm and is suspended from the foregut by the dorsal mesocardium. The myocardium of the heart tube is called primitive or primary because, unlike adult working myocytes, the myocytes of the heart tube have few contractile elements, a poorly developed sarcoplasmic reticulum, a low density of gap junctions, and high automaticity [12]. The heart tube has two caudolateral inlets (venous pole) and one craniomedial outlet (arterial pole) [26, 31].

The endocardium is also derived from the splanchnic mesoderm and develops simultaneously with the myocardium in the cardiac crescent. Adjacent endodermal cells release promoters and antagonists of bone morphogenic protein (BMP), fibroblast growth factor (FGF), and wingless-type (WNT) families of growth factors for differentiation of the cardiac crescent cells into cardiomyocytes (29). T-box transcription factors are key regulators of the fate of cardiomyocytes. *Tbx5* and Tbx20 are activators of the chamber program of gene expression. Antagonists of working myocardium gene expression, TBX2 and TBX3, allow the inflow tract, AV canal, and outflow tract myocardium to develop. Tbx1 is expressed in outflow tract precursors and Tbx18 at the venous pole [26]. There are direct correlations between this specific programming and the variants that alter protein function and lead to CHD in humans. Pathogenic germline variants, for example in *TBX1*, have been reported in tetralogy of Fallot [32]. A distinct population of mesodermal cells in each heart field undergoes *de novo* vasculogenesis into two hollow endocardial tubes that join to form a single tube, which becomes enveloped by the cardiomyocytes. The endocardium becomes contiguous with the endothelium of the developing vasculature.

The cardiac jelly, a thick acellular matrix secreted by the myocardium, lies between the myocardium and endocardium. The initial heart tube is therefore a tubular structure with an inner endocardial layer, a middle layer of cardiac jelly, and an outer myocardial layer.

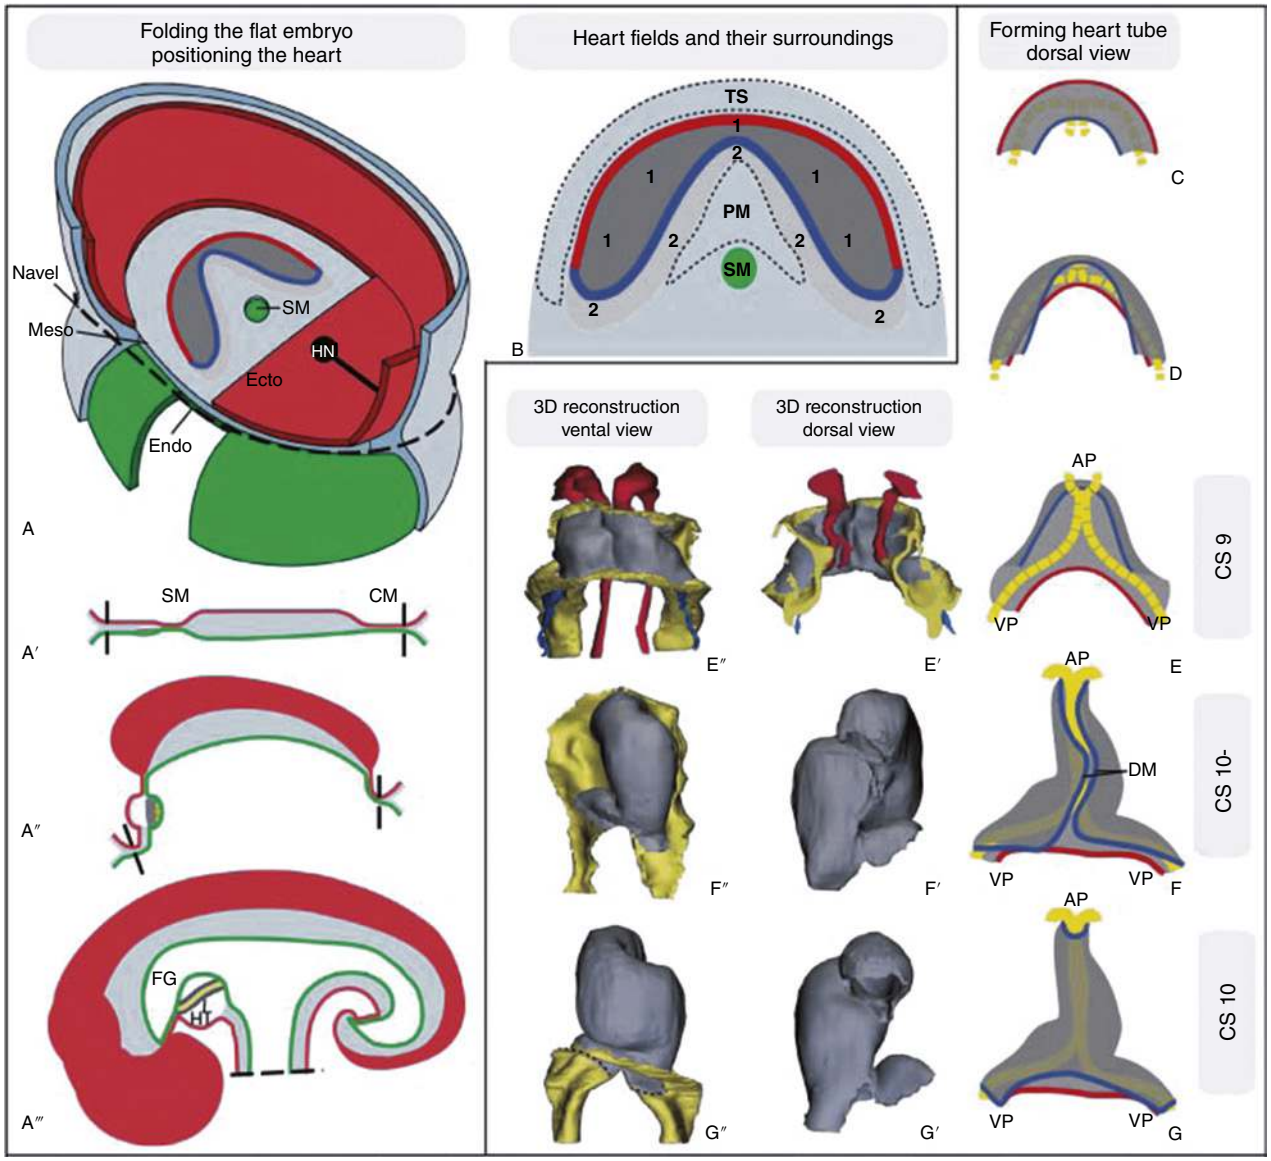

Figure 6.3 Folding of the embryo and formation of the heart tube. (A) The embryo starts as a flat disc containing the three germ layers, the ectoderm (Ecto), mesoderm (Meso), and endoderm (Endo). (A–A‴) With the ongoing folding of the embryo, the embryonic gut that runs from the stomatopharyngeal membrane (SM) to the cloacal membrane (CM) is formed. The heart (HT) becomes positioned ventrally to the foregut (FG), caudally to the head, and cranially to the umbilical cord and transverse septum (TS). HN, Hensen's node or primitive node. (B) Division of the heart-forming field into the first heart field (1), which will give rise to the linear heart tube and the second heart field (2), which will remain in continuity with the first heart field during subsequent development and from which cardiomyocytes are added to the developing heart. In reality, the strict borders drawn here are gradual. PM, pharyngeal mesoderm. (C–G) Formation of the heart tube from a flat horseshoe-shaped cardiac crescent to a tube. Folding of the embryo brings the lateral portions of the cardiac crescent (red line) together to form the ventral part of the heart tube, while the medial portions of the cardiac crescent (blue line) will form the dorsal part of the heart tube, which is suspended from the foregut by the dorsal mesocardium (DM). After the DM closes and the suspension from the foregut is lost, cells of the second heart field can only be added to the heart via the arterial and venous poles (AP and VP, respectively). CS, Carnegie stage (noted along right side of figure). (Source: Sylva et al. [26]. Reproduced with permission of John Wiley & Sons.)

The schematic drawings in older embryology textbooks illustrating the presence of all the cardiac segments in the straight heart tube prior to looping are hypothetical constructions, as most of the segments are added to the primitive heart tube during the looping stages [33].

The primitive atria and ventricles begin to contract around day 22 as the heart tube loops to the right, with circulation through the embryo beginning around day 26. Flow in the valveless heart tube is unidirectional, and because the highest automaticity is found at the venous pole, traveling mechanical waves sweep blood from the venous to the arterial pole [34].

Abnormalities of heart tube formation

Clearly, failure of the heart tube to develop (*acardia*) leads to fetal demise, and as shown in the zebrafish, failure of the bilateral heart fields to fuse results in *cardia bifida* (two separate hearts in lateral positions) [35].

AL Grawany

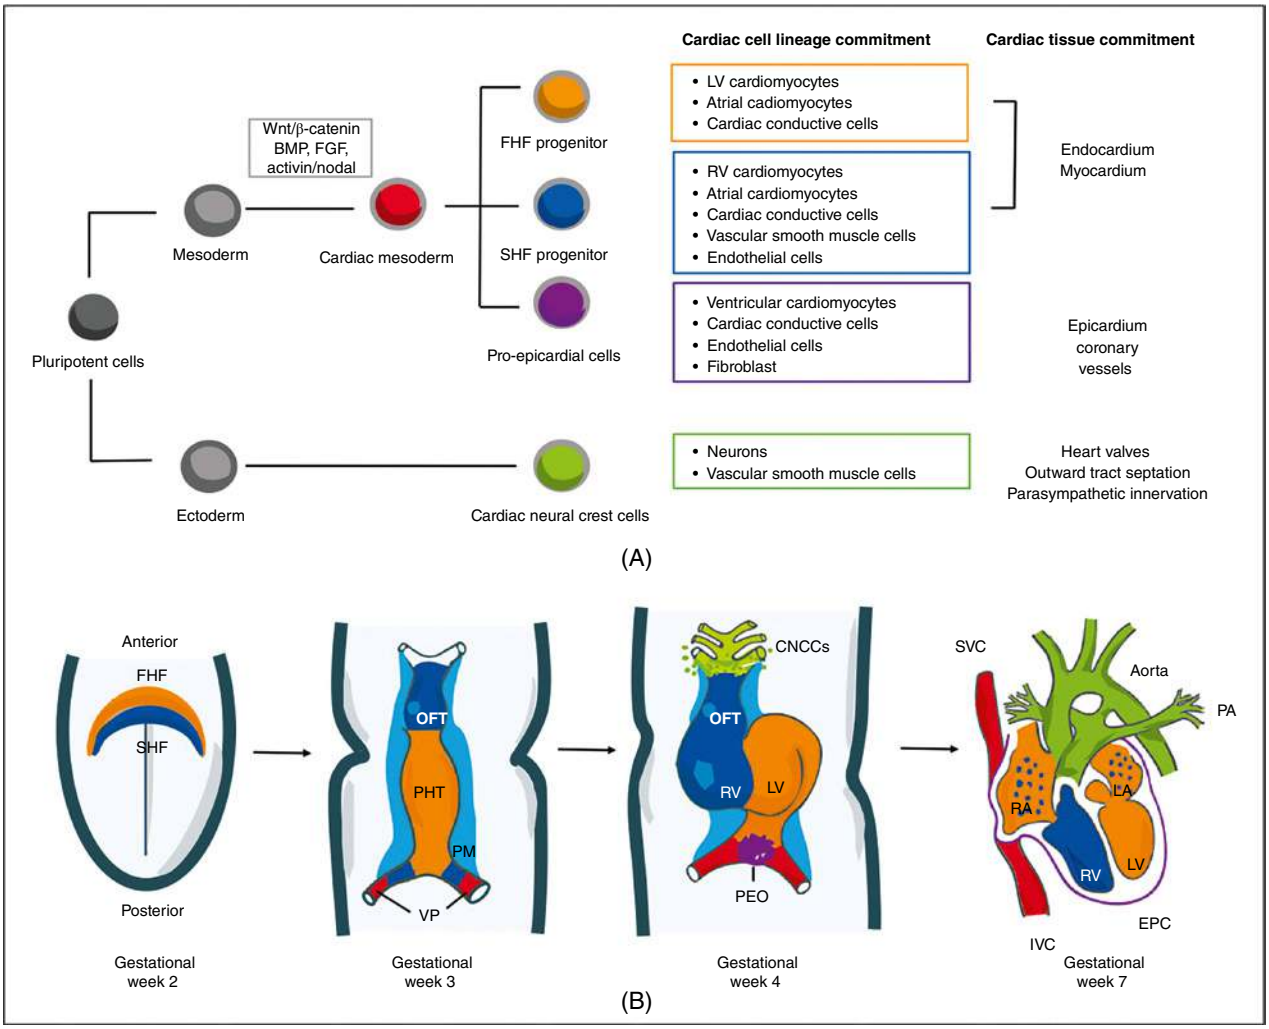

Figure 6.4 Early cardiac development. (A) Cardiac cell lineage and specification during development demonstrate the commitment of pluripotent cells toward mature cardiac cell types within the heart development. (B) Schematic of cardiac morphogenesis in humans. At the second week of gestation, the cardiogenic mesodermal cells migrate toward the anterior side of the embryo to form the FHF or cardiac crescent and SHF that are specified to form specific segments of the PHT, which is patterned along the anteroposterior axis to form the various regions and chambers of the looped and mature heart during weeks 3 and 4. The FHF gives rise to the beating PHT and will eventually give rise to the LV and parts of the right and left atria (RA and LA, respectively). The SHF, located behind the PHT and within the pharyngeal mesoderm by gestational week 3, will contribute to the formation of the RV, parts of the atria and outflow tract, and later to the base of the aorta and pulmonary artery. At gestational week 3, the cells at the venous pole contribute to the formation of the superior and inferior vena cavas (IVC, respectively). By gestational week 4, the cardiac neural crest cells migrate in from the dorsal neural tube, forming smooth muscle cells within the aortic and pulmonary arteries. In addition, the proepicardial organ formed by the proepicardial progenitor cell clusters later contributes to the formation of the epicardium. The four chambers form by the end of week 7. (Source: Tan [27] / S. Karger AG / CC BY 4.0)

KEY POINTS: FORMATION OF THE HEART TUBE

- The primitive heart tube forms during the fourth week of development.
- Contractile activity initiates around day 22 and circulation through the embryo begins around day 26 of development.
- Failure of the heart tube to develop results in fetal demise.

Cardiac looping

Looping is a crucial process in cardiac morphogenesis that brings the tubular configuration of the primitive circulation into the correct conformation for chamber specification, septation, and the creation of systemic and pulmonary pathways [33, 36]. The heart is the first organ not only to function but also to develop a bilateral asymmetric form. Cardiac asymmetry is attained during the process of looping.

At first, the heart tube is straight in the ventral midline with paired venous limbs at its caudal end and a single arterial outlet connected to the aortic sac and pharyngeal

arch arteries at its cranial end (Figure 6.5) [37, 38]. Looping begins with ventral bending (from dorsal to ventral) and the loss of the dorsal mesocardium, which suspends the heart tube from the foregut (ventral pharynx); these changes transform the straight tube into a curved tube (Figure 6.6). This is followed by a rotation around the craniocaudal axis to the right (*dextro-* or *D-looping*), bringing the left side of the tube to a ventral (front) position, which is seen as a C-shaped loop with the convexity to the right in a ventral, two-dimensional view [33]. At this stage, the junction of the inflow and outflow limbs is at the deepest convexity. Externally, the junction corresponds to the bulboventricular groove, and internally it corresponds to the bulboventricular fold [39]. Subsequent looping produces a ventral, two-dimensional, S-shaped loop (Figure 6.7). The heart tube lengthens as cells are added in a continuous stream to the venous (inflow) and arterial (outflow) poles by the addition of myocardium (cardiomyocytes) and endocardium from the SHF in the adjacent pharyngeal mesoderm. The poles are the only entryway for new cells from the SHF [40]. The ventricular bend then shifts caudally from its cranial position above the atria, and the inflow region shifts cranially, thereby resulting in the convergence of the inflow and outflow poles. After looping, there is rotation (untwisting) of the outflow tract, which results in a leftward shift of the outflow tract. The complex process of cardiac looping is shown in schematic form in Figure 6.8. *Wedging* is the process in which the aorta will come to nestle between the mitral and tricuspid valves and behind the pulmonary trunk (Figure 6.9) [36].

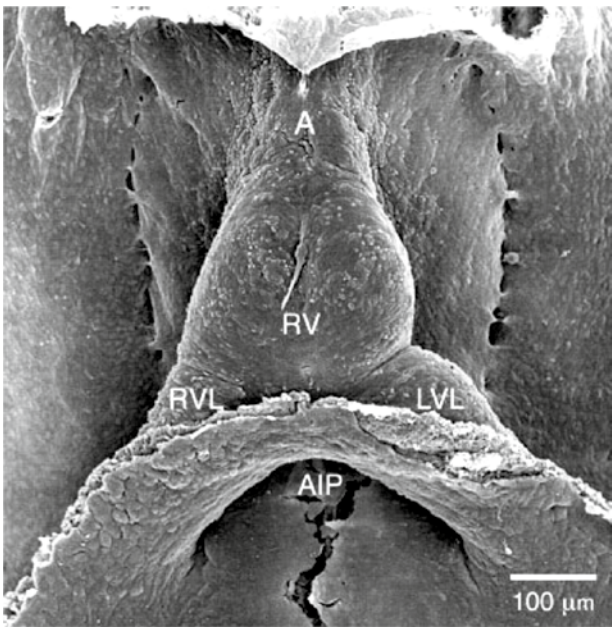

Figure 6.5 Straight heart tube. Scanning electron micrograph of a chick embryo (HH-stage 9), viewed from the front, showing the "straight heart tube" with paired venous limbs at its caudal end and an arterial outlet at its cranial end, which is connected to the aortic sac. A, arterial outlet; AIP, anterior intestinal portal; LVL, left venous limb; RV, primordium of the trabeculated portion of the morphologic right ventricle; RVL, right venous limb. (Source: Männer [33]. Reproduced with permission of John Wiley & Sons.)

When looping is complete, the named segments of the heart (which are extremely variable between authors) are the sinus venosus, common atrium, AV canal, presumptive left ventricle, presumptive right ventricle, conus arteriosus, and truncus arteriosus (frequently referred to as the conotruncus) [41].

Abnormalities of cardiac looping

Cardiac looping is associated with the breaking of the initial bilateral symmetry of the embryo and the establishment of the left-right axis [36, 37]. The left-right axis is established during gastrulation by nodal cilia at the anterior border of the primitive streak. The cilia sweep from right to left, resulting in a leftward flow of extracellular fluid which concentrates a putative secreted factor on the left side of the embryo. Binding of this factor to its receptors triggers asymmetrical gene expression at the node and expression of *Nodal* (a member of the TGFβ family), *Southpaw* and *Lefty2* [25, 42]. The left-sided expression of Nodal is crucial in establishing the left-right axis. Animal models with absent Lefty1 demonstrate thoracic left isomerism and bilateral expression of Nodal, Lefty2, and Pitx2c, implying that Lefty1 restricts expression of Nodal and Lefty2 on the left side and the Nodal and/or Lefty2 signal development [32]. Pitx2c (a member of the homeobox gene transcription factor family) is a key regulator of cardiac left-right patterning that acts downstream of Nodal. PITX2c expression on the left side persists long after Nodal expression [26]. Left ventricle chamber identity is associated with HAND1 expression and right ventricular chamber identity with HAND2 expression [43].

Left-right signaling pathways determine not only the direction of looping and the topology of the future ventricular chambers but also the proper development of the atria, the arterial and venous poles, and the systemic vasculature. Abnormalities in left-right patterning increase the incidence of cardiac malformations in both D- and L-loop hearts; typical examples include mirror imagery, atrial isomerism, discordant connections, and heterotaxy [44]. The left-right signaling cascade is hierarchical because abnormalities high in the cascade result in randomization of situs, whereas abnormalities lower down, which are associated with tissue-specific signaling, produce discordant connections [26].

Normal cardiac looping to the right, referred to as *dextro-looping* or *D-looping*, positions the right ventricle towards the right side and leaves the heart lying predominantly in the left hemithorax with a leftward apex (*levocardia*) (Figure 6.10, left panel). *Situs solitus* refers to normal looping with the liver, stomach, and spleen in their normal positions. Rotation around the craniocaudal axis to the left results in a *levo-loop* (*L-loop*) heart (Figure 6.10, right panel), in this position the right ventricle is positioned toward the left and the left ventricle toward the right. *Congenitally corrected transposition of the great arteries* (CCTGA) arises when the heart (ventricle) loops to the left but the atria and outflow receive correct left-right signals, resulting in both AV and ventriculoarterial (VA) discordance. CCTGA can also occur when the heart loops to the right with inversion of the atria and VA discordance. *Situs inversus totalis* refers to an L-loop heart with mirror-image reversal, which means

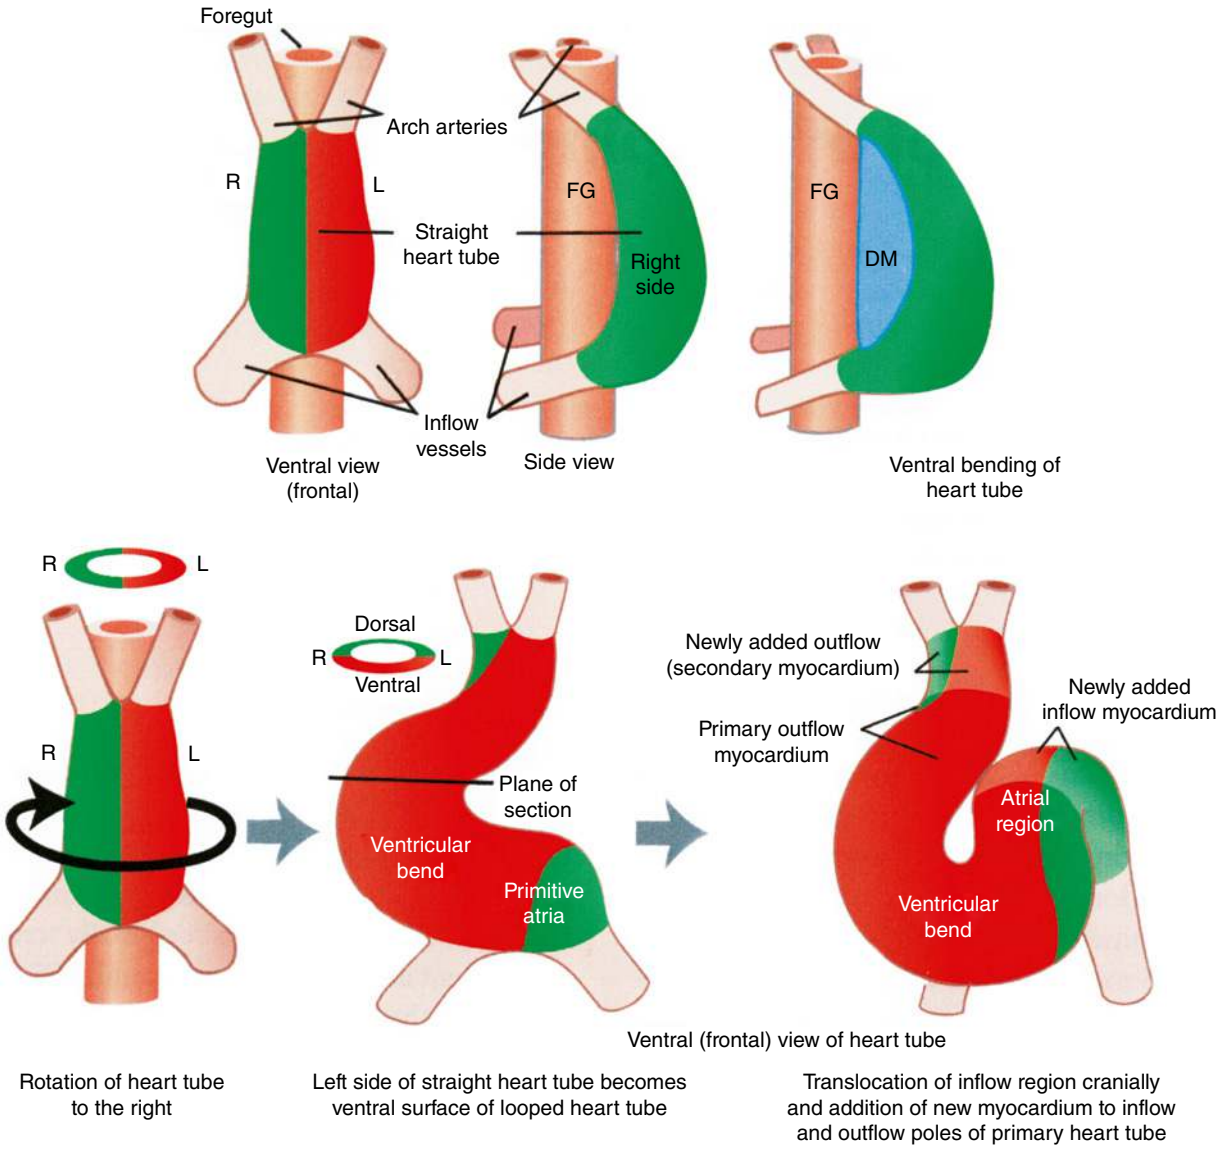

Figure 6.6 Steps in looping of the heart tube. The heart tube forms ventral to the foregut and is open to it at first. Then the heart tube is suspended at its nascent inner curvature from the ventral foregut by the dorsal mesocardium which quickly disappears. Ventral bending occurs first, followed by rotation to the right which brings the left side of the tube to the front and the inner curvature to the left side. Subsequent looping to form the S-shaped loop involves the addition of cells at the inflow and outflow poles. DM, dorsal mesocardium; FG, foregut. (Source: Kirby [23]. Reproduced with permission of Oxford University Press.)

the heart lies predominantly in the right hemithorax with a rightward apex (*dextrocardia*) and there is a mirror-image reversal of the liver, stomach, and spleen. *Mesocardia* refers to a midline heart with the apex pointing inferiorly or anteriorly. Mesocardia and dextrocardia can be associated with a normal or abnormal arrangement of cardiac structures. *Atrial isomerism* refers to a bilaterally symmetrical pattern of the atrial appendages (i.e. bilateral leftness or rightness) and is usually associated with severe complex cardiac malformations. Abnormal PITX2c expression results in both atria developing right atrial appendages, establishing a role of PITX2c in the differentiation of atrial sidedness [45]. *Mixed situs* occurs when some organs, or components thereof, have normal situs and others have situs inversus. This usually results in complex heart defects known as *heterotaxia* or *heterotaxy* syndromes (discussed later in the chapter).

KEY POINTS: CARDIAC LOOPING

- Cardiac looping represents a crucial process in cardiac morphogenesis that determines the shape of the heart.
- The process of cardiac looping is complex, resulting in right-left asymmetry in the embryo.
- Normal cardiac looping is to the right, referred to as dextro- or D-looping; abnormal looping to the left results in Levo- or L-looping.

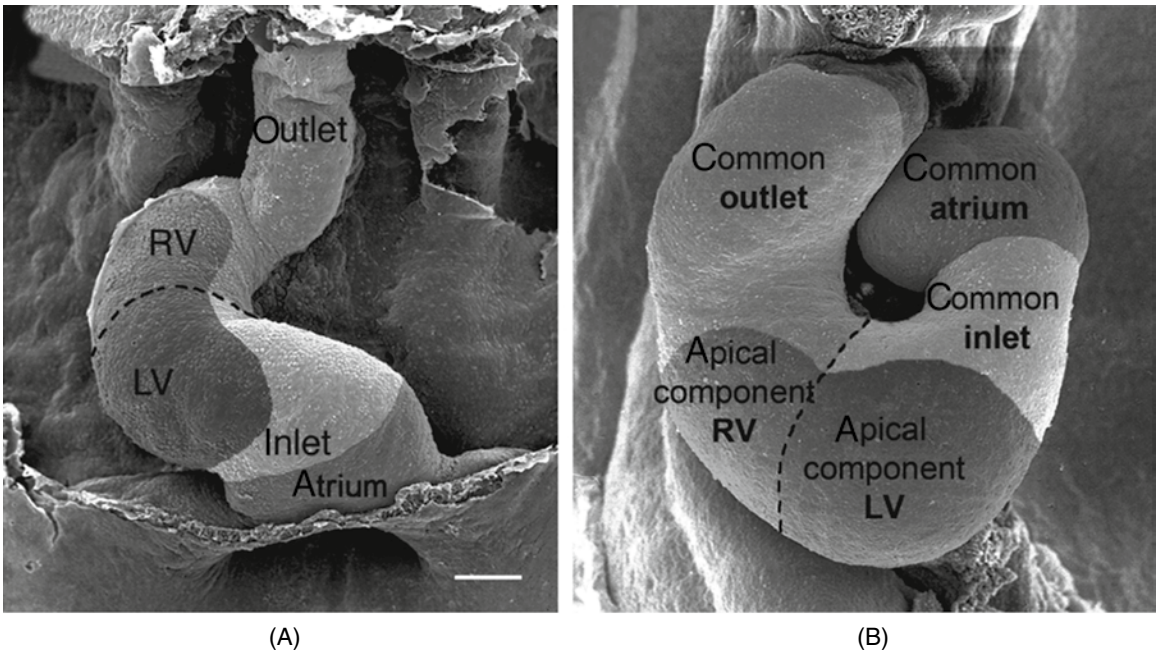

Figure 6.7 Looping morphogenesis. Scanning electron micrographs of embryonic chick hearts, viewed from the front, showing the main positional changes of the developing heart chambers of higher vertebrate embryos during cardiac looping. (A) "C"-shaped loop at early stages (HH-stage 12). (B) "S"-shaped loop at advanced stages (HH-stage 17/18) of cardiac looping. RV, right ventricle; LV, left ventricle. (Source: Männer [37]. Reproduced with permission of Elsevier.)

Cardiac septation

Cardiac septation begins after looping of the heart tube. It consists of four contemporaneous processes that occur between 27 and 37 days of development, dividing the heart into four chambers and creating separate systemic and pulmonary circulations [22]. Septation is attributable to the muscular septa in the atrial and ventricular chambers, the AV endocardial cushions, the outflow tract endocardial cushions, and the dorsal mesenchymal protrusion. *TBX2/3* and *BMP2/4* are important repressors of chamber-specific genes like *ANF* to allow for the development of the nonchamber myocardium [25]. Indeed, deletion of either *Bmpr1a* or *Tbx2* leads to the development of additional myocardial connections [46, 47].

Atrial septation

Atrial septation takes place in phases to maintain right-to-left atrial shunting and involves the septum primum, septum secundum, and AV canal (AVC) septum. The *primary atrial septum* (septum primum) grows as a muscular crescent from the craniodorsal wall of the atrium on the right of the pulmonary

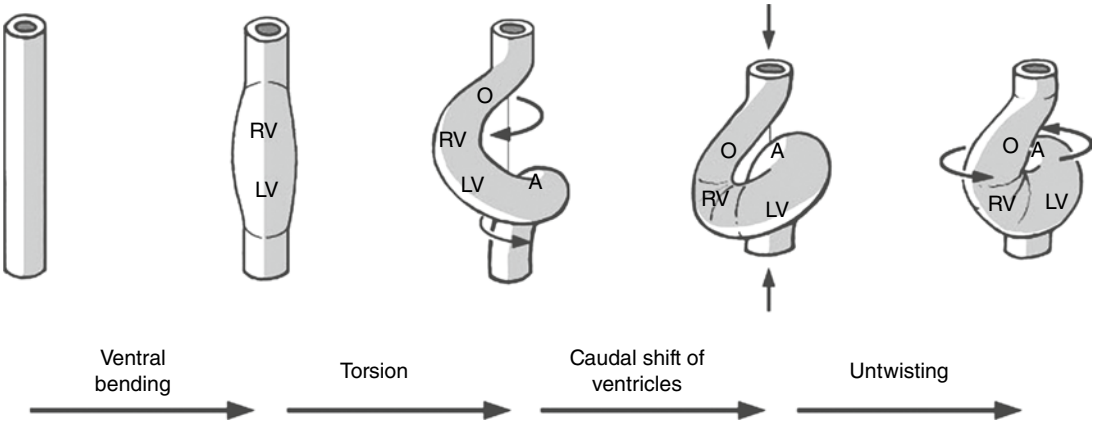

Figure 6.8 Ventricular looping. Schematic drawing (frontal views) of the four components of normal ventricular looping: (1) ventral bending transforms a straight tube into a curved tube whose outer curvature is formed by its ventral wall; (2) torsion around its original cranio-caudal axis transforms a curved tube into a helically wound loop which appears C-shaped in frontal views; (3) caudal shift of the ventricular segment; (D) untwisting is characterized by ventral and leftward shift of the proximal outflow tract, ventral shift of the primitive right ventricle, and rightward shift of the atrioventricular canal. pit toward the AV endocardial cushions (Figure 6.11). The leading edge of the septum primum is covered by a mesenchymal cap produced by the endothelial-to-mesenchymal transformation (EMT) of the endocardium covering the septum [40]. EMT is a complex biologic process whereby endothelial cells lose their specific phenotype and evolve into cells with a mesenchymal phenotype that includes spindle-shaped elongated cell morphology, loss of cell-cell junctions and polarity, and acquisition of functions such as cellular motility, contractility, and invasiveness [48]. This mesenchymal cap is continuous with the protrusion of the dorsal mesocardium (dorsal mesenchymal protrusion) and the dorsal (superior) and ventral (inferior) AV endocardial cushions [26]. The communication between the leading edge of the septum primum and the AV cushions is known as the *primary atrial foramen* (ostium primum), which closes when the septum primum becomes contiguous with the fused dorsal and ventral AV endocardial cushions. Communication between the left and right atria is maintained by the detachment of the septum primum from the roof of the atrial cavity to produce a secondary atrial foramen (ostium secundum) [49]. The *secondary atrial septum* (septum secundum) is formed by the folding of the dorsal wall between the primary atrial septum and the left leaflet of the sinoatrial valve. The septum secundum does not fuse with the AV cushions but remains open as the *foramen ovale*. The cranial portion of the septum primum remains as a flap valve, which fuses with the edges of the foramen ovale after birth to form the fossa ovalis [40]. The muscular septum between the inferior rim of the fossa ovalis and the AV valves is called the AVC septum.

Early in development, the *venous pole* of the heart has two channels (the left and right horns of the sinus venosus), returning blood from the embryo (via the cardinal, vitelline, and umbilical veins) to the sinus venosus and common atrium. During the convergence phase of looping, the common atrium

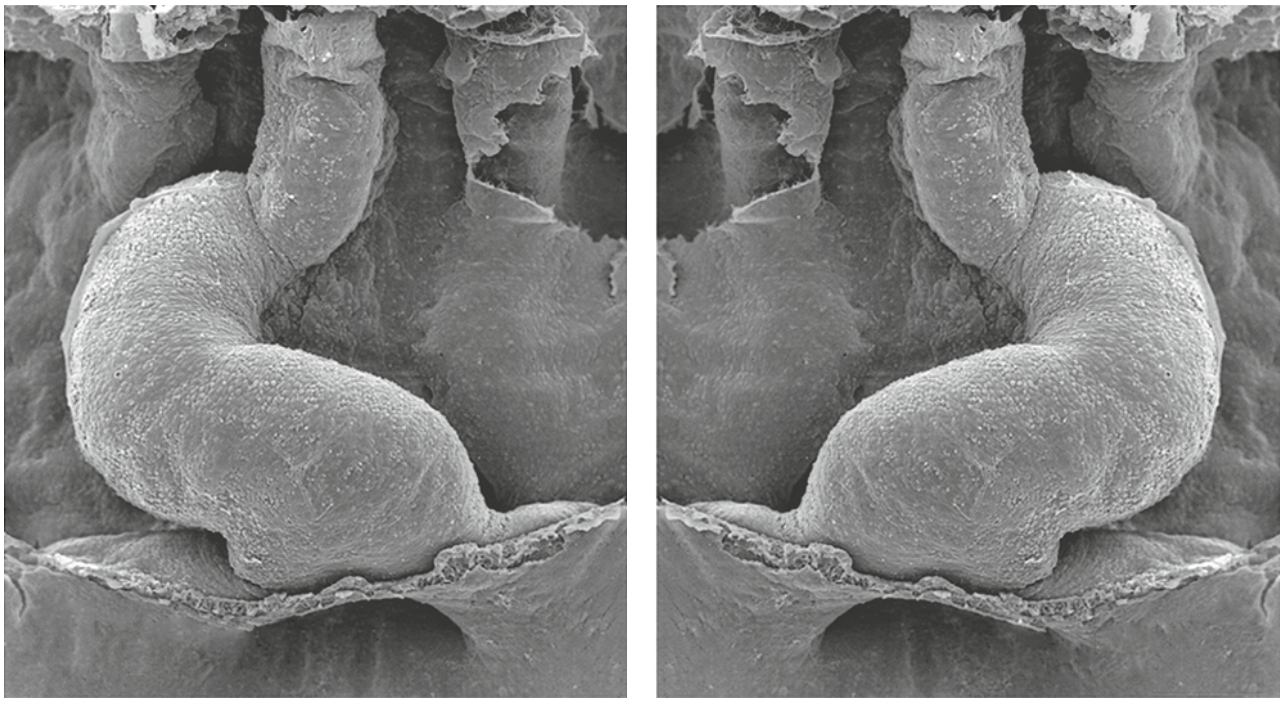

Figure 6.10 Handedness of the cardiac loop. Scanning electron micrographs of embryonic chick hearts, viewed from the front, showing the so-called D-loop (dextral-loop) (A) and L-loop (levo-loop) (B) configurations ("C-shaped" loops; HH-stage 12). Figure 6.11 Schematic drawing illustrating septation of the atria and primary foramen. (A) Chamber-forming heart with the atrioventricular canal (AVC) and outflow tract (OFT) cushions and ridges. The two arrows going down through the AVC into the ventricle represent blood flow during diastole. The two arrows pointing toward the OFT represent blood flow during systole. Note that the primary foramen (PF) is the crossroad of the blood running from the right atrium (RA) to the right ventricle (RV), and the blood running from the left ventricle (LV) to the OFT. (B–F) Sagittal sections at the level of the dotted line in (A). (B) The ventral and dorsal endocardial cushions (1 and 2, respectively) are growing toward each other. (C) The primary atrial foramen (PAF, ostium primum) is closing due to ingrowing of the primary atrial septum (PS, septum primum), with its mesenchymal cap (MC), the dorsal mesenchymal protrusion (DMP), and the endocardial cushions. (C, D) In the PS, small holes appear and merge to form the secondary foramen (SF, ostium secundum). (D–F) The secondary septum (SS, septum secundum) grows to the right side of the PS covering the SF and the rest of the PS, and leaving at the right surface of the atrial septum only the oval fossa (OF) uncovered. A, atrium; LA, left atrium; V, ventricle; 3 and 4, septal and parietal outflow tract ridges, respectively. (Source: Sylva et al. [26]. Reproduced with permission of John Wiley & Sons.)

expands to the right and left, forming two lateral pouches that will become the right and left atrial appendages [33, 50]. Remodeling results in the sinoatrial junction shifting to the right side of the common atrium. The right horn of the sinus venosus and the sinoatrial junction become incorporated into the dorsal (back) wall of the right atrium (Figure 6.12). The sinoatrial junction has left and right craniocaudally oriented valves (venous valves) that meet cranially to form the septum spurium [50]. As the distal portion of the left superior cardinal vein regresses (and thereby absent left superior vena cava), the left horn of the sinus venosus becomes smaller and is incorporated into the developing AV groove to become the coronary sinus. The dorsal (back) wall of the left atrium is also formed by the incorporation of the pulmonary vein and its surrounding myocardium [39, 50].

Defects in atrial septation

The most common cause of an atrial-level shunt is *a secundum atrial septal defect* (ASD), which is located within the region of the fossa ovalis. It is usually due to a deficiency of the septum primum but, in rare cases, it can be caused by the deficiency of the septum secundum [51].

Failure of the septum primum and septum secundum to fuse completely during infancy results in a *patent foramen ovale* (PFO). As long as the left atrial pressure exceeds the right atrial pressure and the flap valve is large enough to cover the boundaries of the fossa ovalis, the foramen remains functionally closed (probe patent foramen).

An *ostium primum defect* results from the failure of the septum primum to fuse with the endocardial cushions. The defect is outside the confines of the fossa ovalis and extends from the inferior limbus of the fossa ovalis to the crest of the interventricular septum. An ostium primum defect is part of the family of AVC defects, also referred to as AV septal and endocardial cushion defects and may occur in isolation or in association with other abnormalities of the AV junction.

A *sinus venosus defect* occurs in the area derived from the embryologic sinus venosus (posterior aspect of the right atrium) so is not strictly a defect in the atrial septum. It is an interatrial communication caused by a deficiency of the common wall between the superior vena cava (SVC) and the right-sided pulmonary veins [52, 53]. The most common location for this defect is between the right upper pulmonary vein and the cardiac end of the SVC type, although in rare cases the right lower and/or middle pulmonary veins and more caudal atrial wall are involved (inferior vena cava [IVC] type) [51].

A *coronary sinus defect* occurs because of unroofing of the normal course of a persistent left anterior cardinal/superior caval vein into the left horn of the sinus venous, i.e. the tissue between the coronary sinus and the left atrium is either partially or completely absent (unroofed) resulting in

AL Grawany

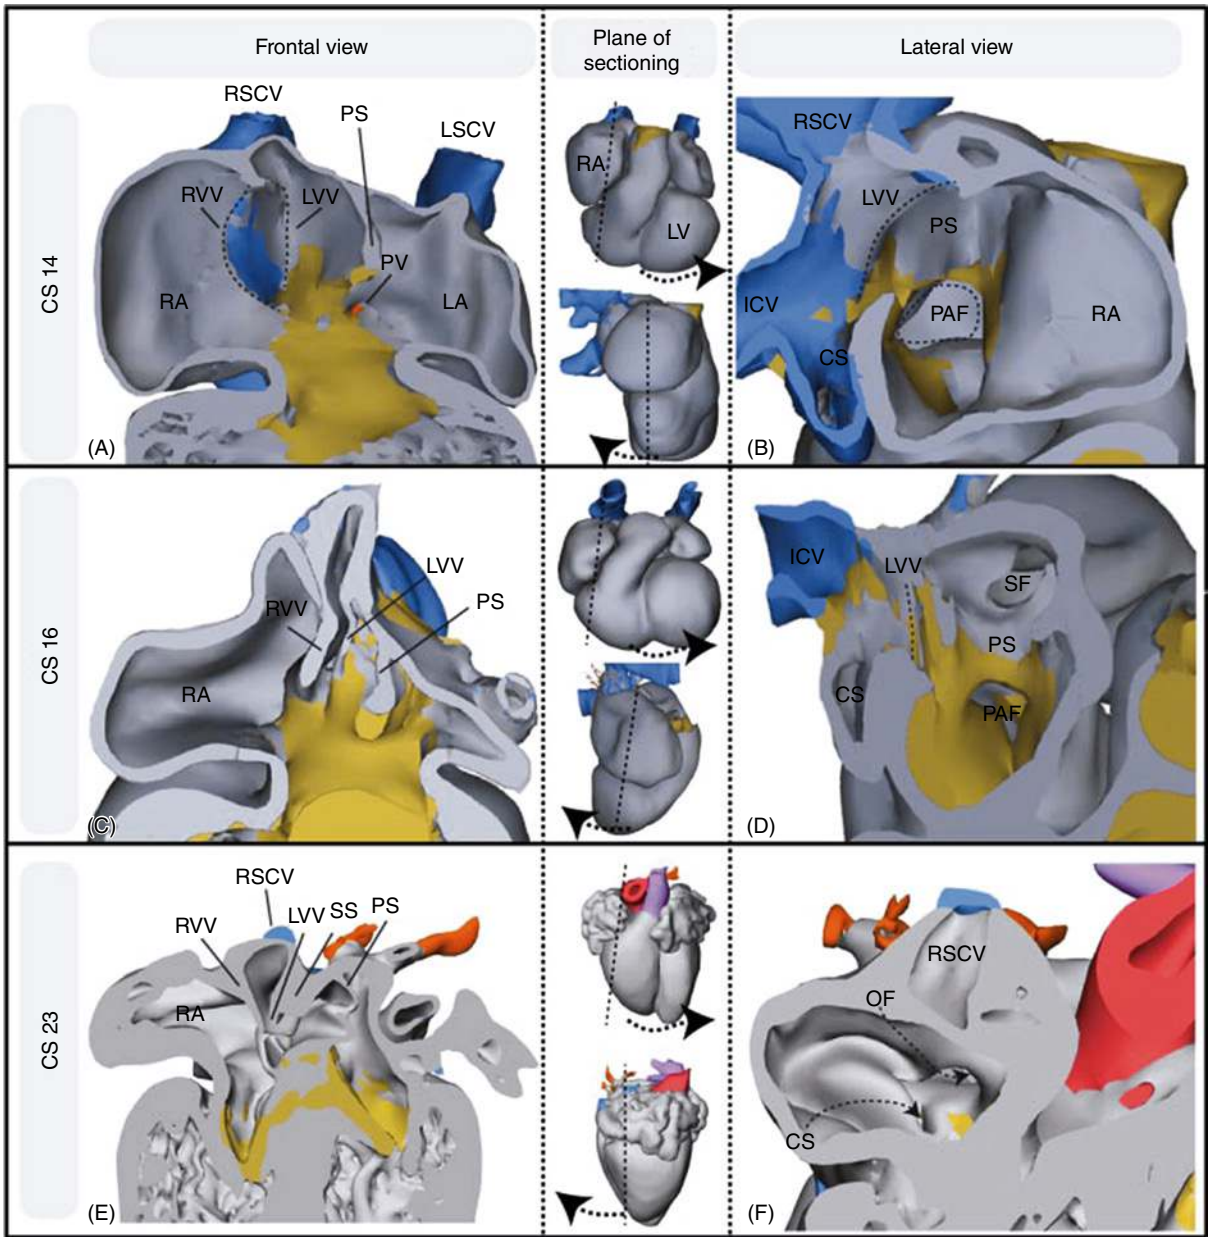

Figure 6.12 Formation of the venous pole. (A–F) Cross-sections of three-dimensional (3D) reconstructions of human hearts (gray, myocardium; blue, systemic veins; orange, pulmonary veins; yellow, cardiac mesenchyme). (A, B) Developing right and left atrium (RA, LA); the RA is connected to both the right superior (RSCV) and inferior caval vein (ICV) as well as the left superior caval vein (LSCV), via the coronary sinus (CS). At this stage, the entire systemic venous pole is connected to the right atrium through one orifice, flanked by the left and right venous valves (LVV and RVV). The primary septum (PS) is growing to the right of the opening of the pulmonary vein (PV). (C, D) The RSCV and CS are still connected to the atrium via a single orifice, which has now been muscularized. The secondary foramen (SF) appears in the primary septum. (E, F) All veins connect separately to the atrium via myocardialized orifices. The primary atrial foramen (PAF) is closed, and the secondary septum (SS) is growing between the PS and the LVV, which is already partially fused to the secondary septum. The RVV can now be separated into a part that flanks the CS and a part that flanks the RSCV, the future Thebesian and Eustachian valves, respectively. OF, oval foramen; CS, Carnegie stage (noted on the left margin of figures). (Source: Sylva et al. [26]. Reproduced with permission of John Wiley & Sons.)

communication between the right and left atria via the coronary sinus orifice [53]. The left-to-right shunt causes enlargement of the coronary sinus orifice.

A *common atrium* is caused by the absence of the septum primum, septum secundum, and atrial portion of the AVC septum and is usually associated with the heterotaxy syndrome [51].

Ventricular septation

After looping of the heart tube occurs, differentiation and re-initiation of cell division by the primary myocardium of the outer curvature cause the ventricles to expand caudally in a pouch-like fashion on either side of the bulboventricular groove (Figure 6.13). De Boer and colleagues [54] have shown that growth of the trabeculae occurs by cellular

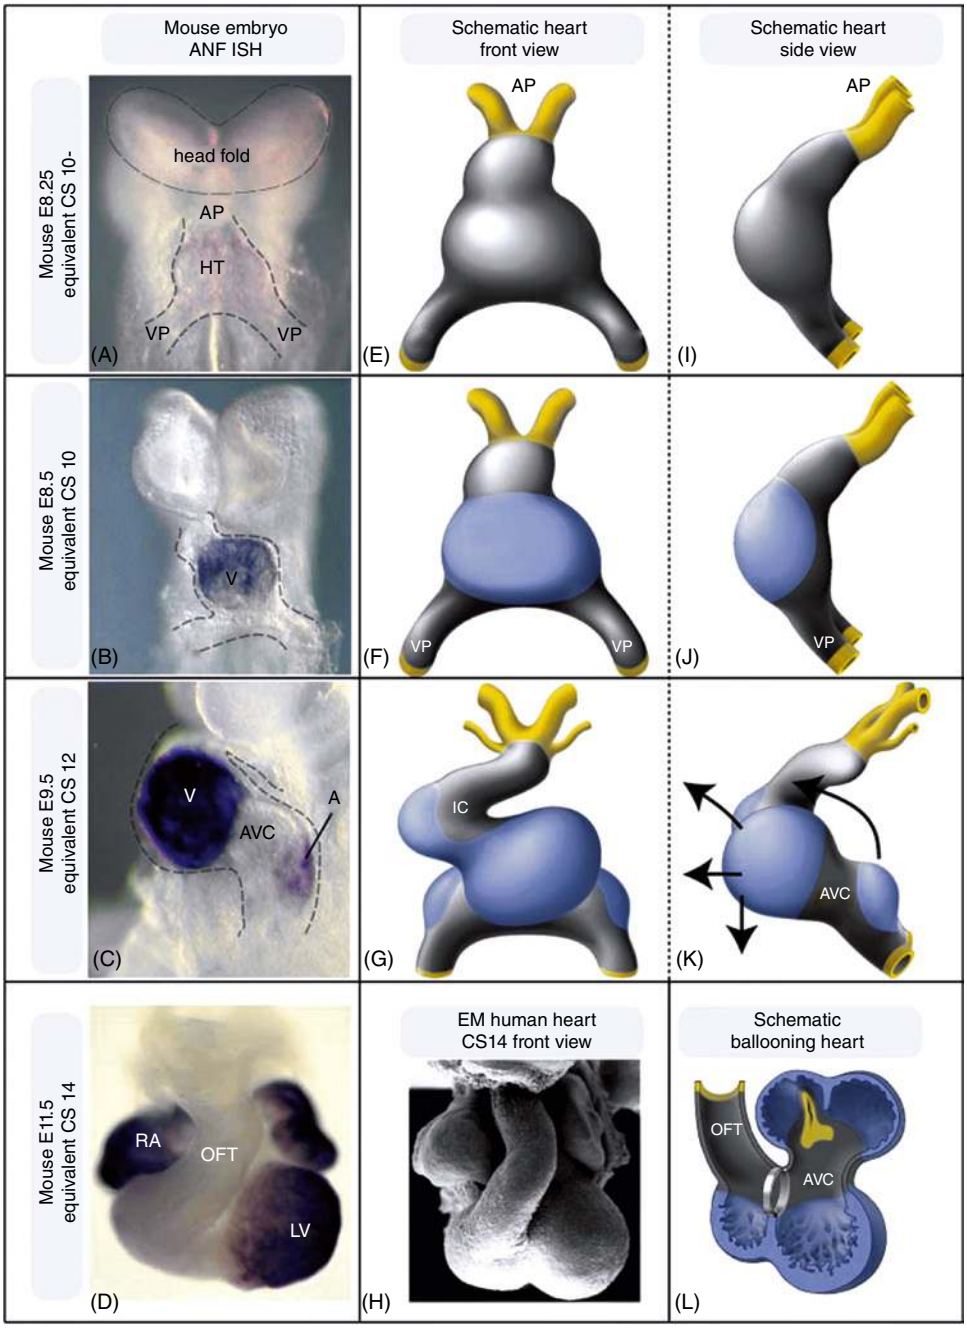

Figure 6.13 Formation of the cardiac chambers. (A–D) Developmental series of mouse embryos. Whole-mount RNA ***in situ*** hybridization for the embryonic chamber marker atrial natriuretic factor (ANF) is used as a marker for differentiation into chamber myocardium. (E–G) and (I–L) Schematic drawings of these chamber-forming hearts. Gray, primary myocardium; blue, chamber-forming myocardium; arrows in K indicate the expansion of the chambers eventually leading to the adult configuration, with the ventricles positioned ventro-caudally to the atria. (H) Electron micrograph of a CS14 human heart, demonstrating the similarity with the mouse E11.5 heart and the schematic shown in (L). For didactic purposes, in the schematic in (L), the outflow tract is hinged toward the right side, ***in vivo*** it is positioned ventrally to the heart, as depicted in (D) and (H). (A, E, I) The heart tube (HT) consists solely of the primary myocardium from the venous (VP) to the arterial pole (AP). (B, F, J) The first chamber to start ballooning is the embryonic ventricle (V) at the outer curvature of the heart. (C, G, K) The heart tube has started to loop and acquire an S shape. An embryonic left and right ventricle are now visible. The atria (A) also start to balloon towards the left and right side. The myocardium of the outflow tract (OFT), inner curvature (IC), and atrioventricular canal (AVC) remain as the primary myocardium. RA, right atrium; LV, left ventricle; CS, equivalent Carnegie stage noted in the left margin of figures. (Source: Sylva et al. [26]. Reproduced with permission of John Wiley & Sons.)

proliferation at the bases, causing the ventricles to expand or "balloon outward" (ballooning model of chamber formation). The disappearance of the cardiac jelly results in the formation of trabeculations on the luminal side, producing a spongy-type myocardium. Compact myocardium forms later when epicardially derived fibroblasts infiltrate the epicardial side, at which time proliferation in the trabeculations ceases.

The *muscular* portion of the interventricular septum is formed by apposition and merger of the medial walls of the expanding ventricles, with cells added mainly from the adjacent left ventricular free wall [22]. The septum represents the least changed part of the lumen of the embryonic heart and the superior portion expresses a transcriptional repressor, TBX3 [55]. It is initially crescent-shaped, extending from the ventral (inferior) AV cushion posteriorly to the dorsal (superior) AV cushion anteriorly. The space between the free rim of the muscular septum and the fused AV cushions is the *primary interventricular foramen*. Although the primary interventricular foramen allows for communication between the primitive left and right ventricles, initially blood from the primitive atrium can only reach the primitive right ventricle via the interventricular foramen (Figure 6.11). It is only after the AV junction develops that the right atrium will communicate directly with the right ventricle. Closure of the interventricular foramen occurs by fusion of three tissue components: the dorsal (superior) and ventral (inferior) AV endocardial cushions, the muscular interventricular septum, and the endocardial cushions of the outflow tract (conal cushions). The septal conal cushion extends deep into the future right ventricle to merge with the dorsal AV cushion and the rightmost edge of the developing muscular septum [56]. The site where these three structures fuse constitutes the *membranous* part of the ventricular septum. The ventricular septum is fully closed at an estimated gestational age of 9 1/7 weeks [57].

Defects in ventricular septation

A ventricular septal defect (VSD) is an opening or hole in the interventricular septum [58]. It may be found in isolation or may co-exist with other congenital cardiovascular anomalies. Because the ventricular septum is composed of three components (muscular, AVC endocardial cushions, and outflow tract [conal] cushions), defects at the ventricular level may result from a deficiency of one or more of these structures and/or from their malalignment. The classification of VSDs can be confusing because of different nomenclatures used by various authors [59].

The most common VSDs are those that occur in the *muscular* portion of the interventricular septum [2]. This type of VSD is surrounded by a rim made completely of muscle. They are often multiple and may be located anywhere in the muscular septum (apical, anterior, mid, or posterior).

The *membranous septum* is a small, translucent structure. It is adjacent to the anteroseptal commissure of the tricuspid valve when viewed from the right side and is located below the noncoronary leaflet of the aortic valve when viewed from the left. Small defects may spontaneously close after birth due to the presence of the surrounding fibrous tissue (also referred to as aneurysmal tissue). Defects that extend beyond the boundaries of the membranous septum are called *para-* or *perimembranous* defects. Membranous VSDs are closely associated with the bundle of His, increasing the risk of causing conduction disturbances and complete heart block during the repair.

A *conoventricular* or *subaortic defect* is situated between the conal and muscular portions of the ventricular septum and is also close to the bundle of His. This defect is often related to malalignment of the muscular and conal portions of the ventricular septum.

A *subpulmonary*, *conal*, *supracristal*, or *doubly committed subarterial* defect is located in the outflow tract (conal septum) just below the pulmonary valve. Fibrous continuity between the aortic and pulmonary valves is frequently present. The aortic valve (right cusp or non-coronary cusp) may prolapse into the defect, which may result in aortic regurgitation.

An *inlet* or *AVC-type VSD* occurs when the inferior endocardial cushion does not fuse with the muscular component of the ventricular septum. The defect is located in the *inlet* portion of the right ventricle beneath the tricuspid valve and may be perimembranous or muscular [59]. The origin of the AV node and the course of the AV bundle (His) differ with respect to the normal heart, increasing the risk of injury during surgical repair.

A *common* or *single ventricle*, defined as the presence of two AV valves with one ventricular chamber or a large dominant ventricle with a diminutive or hypoplastic opposing ventricle may result from various mechanisms. The pathology may be due to the arrest of or a defect in interventricular septation or from poor alignment of the common AV valve with the ventricles [60]. A wide spectrum of functional single ventricles is recognized. These ventricles include double-inlet single ventricle (usually left), defects resulting from atresia or absence of either the right or left AV valves, such as tricuspid atresia, mitral atresia (part of hypoplastic left heart syndrome [HLHS]), those with an atretic semilunar valve (HLHS, pulmonary atresia with intact ventricular septum), unbalanced common AVC defects, and some forms of double-outlet right ventricle.

Atrioventricular canal septation and AV valve development

The cardiac jelly at the AV junction (and outflow tract) forms into mounds by the myocardial synthesis of the extracellular matrix. The endocardial cushions arise from the cells of the endocardium overlying these swellings that invade the cardiac jelly and undergo EMT into fibroblast-like mesenchymal cells [61, 62]. AV canal and outflow tract myocardium produce BMPs that signal through the cardiac jelly to the endocardium. As a result, TGF-beta and Notch signals regulate the EMT of the cushions [63]. Prior to valve formation, the endocardial cushions and underlying myocardium prevent the backflow of blood. Four cushions develop in the AVC: the inferior (ventral) and superior (dorsal) cushions located centrally and two smaller cushions on the lateral walls (left and right). Central fusion of the inferior and superior cushions forms the AV septum, thereby separating the AVC into the left (mitral) and right (tricuspid) orifices [64]. The *atrial portion of the AV septum* extends from the level of the valve annuli to fuse with the primary atrial septum, whereas the *ventricular portion of the AV septum* extends from the level of the valve annuli to form the inlet portion of the interventricular septum. The AVC expands to the right, as does the right ventricle, to allow for direct communication between the presumptive right atrium and the presumptive right ventricle (Figure 6.11).

The septal leaflet of the tricuspid valve and the anterior leaflet of the mitral valve are derived from the fused inferior and superior endocardial cushions, whereas the mural leaflets are derived from the lateral cushions [65]. Mature AV

valves and the subvalvular apparatus are formed by cavitation and remodeling of the cushions and excavation of the underlying ventricular myocardium to form leaflets and chordae tendinae (Figure 6.14) [65, 66]. Late in development, the primitive leaflets undergo lengthening and delamination with the disappearance of the myocardial layer.

After the endocardial cushions have fused, the fibroblast-like cells of the cushions are replaced by myocardial cells in a

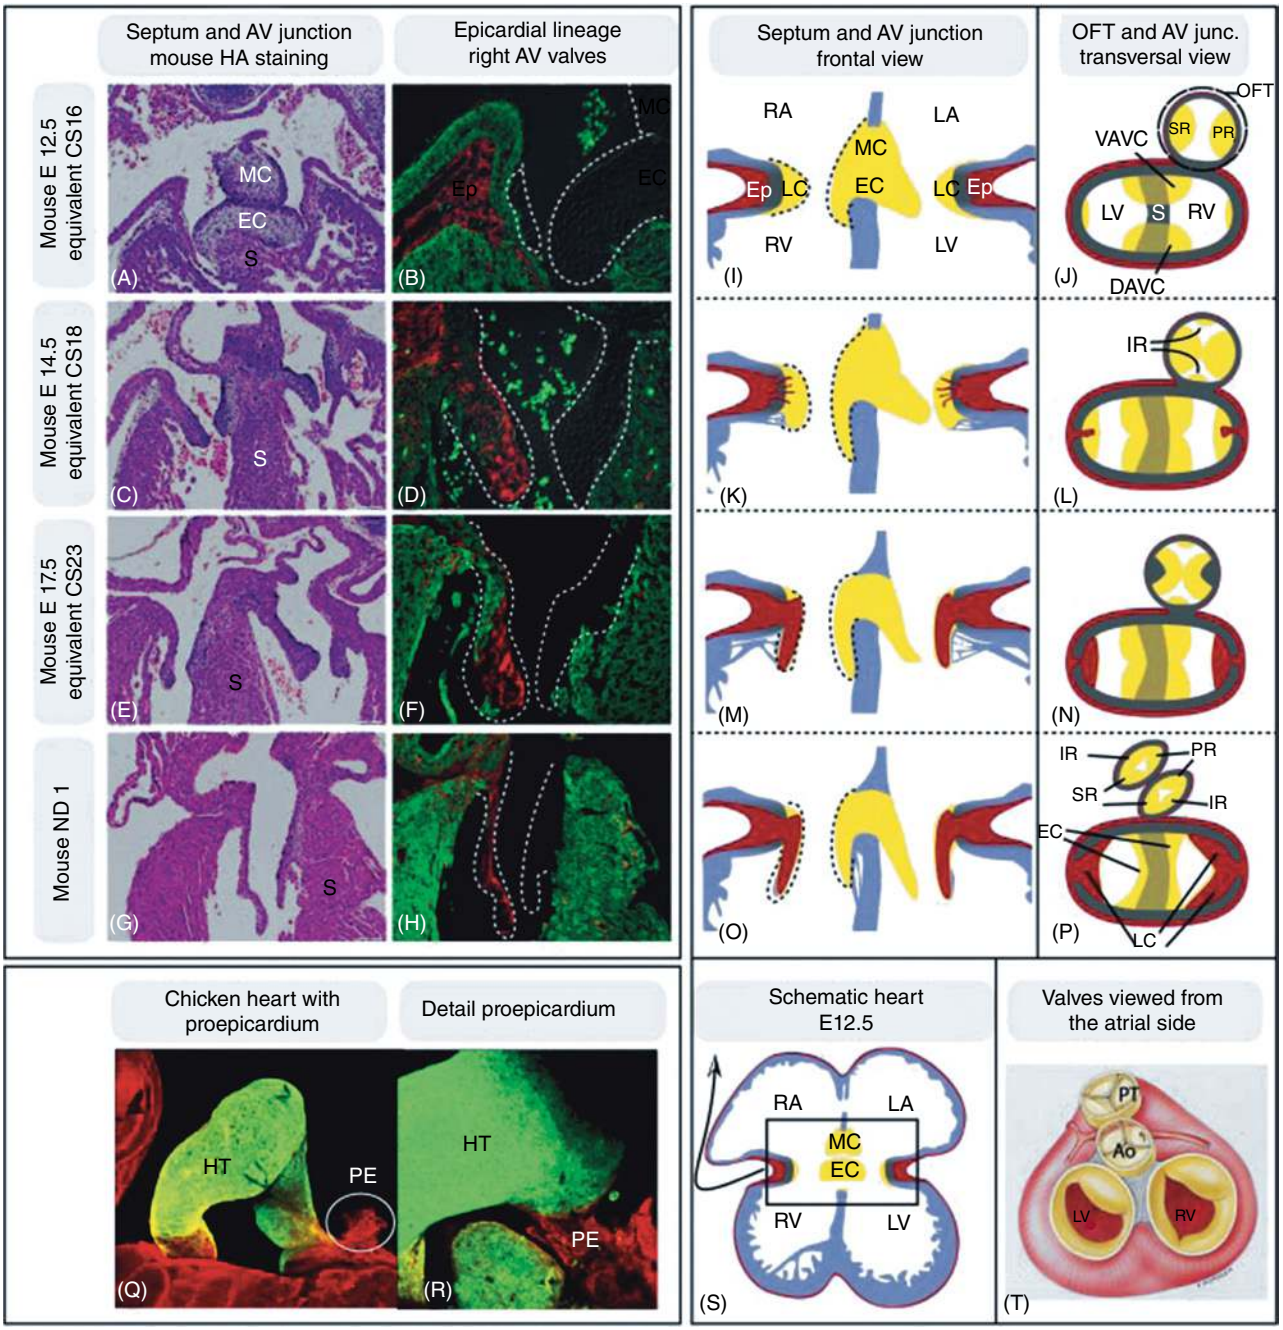

Figure 6.14 Development of the atrioventricular (AV) and outflow tract (OFT) valves and their contributing tissues. process called myocardialization. Fusion of the nonmyocardial mesenchymal cushions and myocardialization create part of the atrial septum, ventricular septum, and conal septum, as well as the substrate for the crux of the heart.

Defects of the AVC

The endocardial cushions of the AVC contribute to the formation of the atrial septum, the ventricular septum, and the mitral and tricuspid valves. They form between the atrium and ventricle in a vascular endothelial growth factor-dependent manner. Variants in vascular endothelial growth factor (VEGF) are implicated as a modifier gene in valvuloseptal CHD [67]. Endocardial cushion-derived structures can have varying degrees of abnormalities producing a spectrum of lesions called endocardial cushion defects (as previously noted, they are also referred to as AVC or AV septal defects). Failure (incomplete or complete) of the endocardial cushions to fuse creates a defect in the AV septum.

A *partial (incomplete)* AVC defect results from incomplete fusion of the superior endocardial cushion with the septum primum and consists of an *ostium primum ASD* with distinct left and right valve annuli, and frequently there is a mitral valve cleft with varying degrees of regurgitation [68]. A *transitional* AVC defect is typically an ostium primum defect with a very small to moderate (restrictive) inlet VSD, which is often occluded by AV valve tissue. Although there are two separate orifices, the valves are abnormal [68]. Lack of fusion of the superior and inferior endocardial cushions leads to a *complete AVC (CAVC)* defect comprising an ostium primum ASD, a non-restrictive VSD just below the AV valve (inlet VSD), and a common AV valve annulus that bridges both the left and right sides of the heart, i.e. the valve leaflets are shared between the left and right ventricles and are not adherent to the crest of the ventricular septum. In the normal heart, the septal leaflet of the tricuspid valve inserts lower (more apical) than the anterior leaflet of the mitral valve and the AV septum is that portion between the hinge points of the tricuspid and mitral valves. With AVC defects, the mitral valve (left AV valve) insertion is at the same level as the tricuspid valve (right AV valve). This displacement of the common hinge plane of the mitral valve towards the apex reduces the inlet-to-apex distance and increases the apex-to-outlet ventricular dimension, resulting in a "gooseneck" deformity of the left ventricular outflow tract with the potential to cause left ventricular outflow tract obstruction [69]. A *balanced* CAVC defect has appropriately sized left and right ventricles and the common AV valve is distributed equally over the ventricular masses. In an *unbalanced* CAVC *defect*, one ventricle is hypoplastic with the other ventricle receiving most of the AV valve tissue and ventricular blood flow because of *straddling* (insertion of chordae in the opposite ventricle) or *override* (insertion of chordae to the crest of the septum or the appropriate ventricle). AVC defects may be isolated or may appear as one element of a more complex lesion or syndrome. Approximately 40% of patients with trisomy 21 (Down syndrome) have AVC defects [66].

Ebstein anomaly is the most important cause of congenital tricuspid regurgitation and is thought to be due to abnormal delamination of the inlet zone of the right ventricle [70]. The septal and posterior leaflets do not attach to the annulus but are displaced downward toward the right ventricular apex. The portion of the right ventricle that extends from the true tricuspid annuls to the level where the septal and posterior leaflets attach is thin due to partial absence of myocardium and is termed the "atrialized" portion, whereas the trabecular and outlet portions make up the functional right ventricle. The anterior leaflet is large ("sail-like") and dysplastic and can obstruct the right ventricular outflow tract. Ebstein anomaly can be associated with abnormalities in left ventricular morphology, such as ventricular non-compaction and increased fibrosis of the wall and septum. Most patients with this anomaly have a PFO, and approximately 50% have an ASD [71]. Downward displacement of the leaflets is associated with discontinuity of the central fibrous body, thus producing a substrate for accessory AV connections and ventricular pre-excitation [70].

Tricuspid atresia is characterized by agenesis of the tricuspid valve and right ventricular hypoplasia. The region normally occupied by the tricuspid valve may be replaced by an atretic membrane, muscular tissue, or fibrofatty tissue, and an ASD is necessary for survival. With normally related great arteries, blood passes to the lungs through a VSD into a small right ventricle and pulmonary artery, whereas with transposition of the great arteries, blood reaches the lungs directly from the left ventricle. Isolated *tricuspid stenosis* is exceedingly rare.

Mitral valve stenosis is most commonly associated with other left-sided obstructive lesions, HLHS being at the most severe end of the spectrum and coarctation of the aorta, aortic arch hypoplasia, and subvalvular or valvular aortic stenosis in Shone's complex occurring with varying severity [72]. *Congenital mitral regurgitation* is more common than mitral stenosis and is usually associated with AVC defects.

Outflow tract septation and semilunar valve development

Cardiac neural crest cells are a subpopulation of the cranial neural crest and are crucial for normal cardiovascular development [29]. Cardiac neural crest cells contribute to the formation and remodeling of the aortic (pharyngeal) arch arteries, outflow tract septation, semilunar valvulogenesis, cap of the interventricular septum, parasympathetic innervation of the heart (neurons and supporting cells of cardiac ganglia), and cardiac conduction system [73, 74].

The outflow tract connects the primitive ventricle to the aortic arch arteries and is traditionally divided into three sections: the conus (proximal), the truncus (middle), and the aortic sac (distal) [75]. Septation of the outflow tract begins with the formation of a shelf of mesenchyme in the dorsal wall of the aortic sac in the area between the fourth and sixth pairs of aortic arch arteries [76]. This shelf, called the aorticopulmonary septum, elongates toward the truncus, thereby dividing the lumen of the aortic sac into the future intrapericardial portions of the aorta and pulmonary trunk. Cardiac neural crest cells delaminate from the cranial portion of the neural tube and migrate into pharyngeal arches 3, 4, and 6, and a subset of these cells migrates into the outflow tract (Figure 6.15). The outflow endocardial cushions are ridges of mesenchyme, formed by EMT of the underlying endocardium, that spiral into the outflow tract. Mesenchymal cells

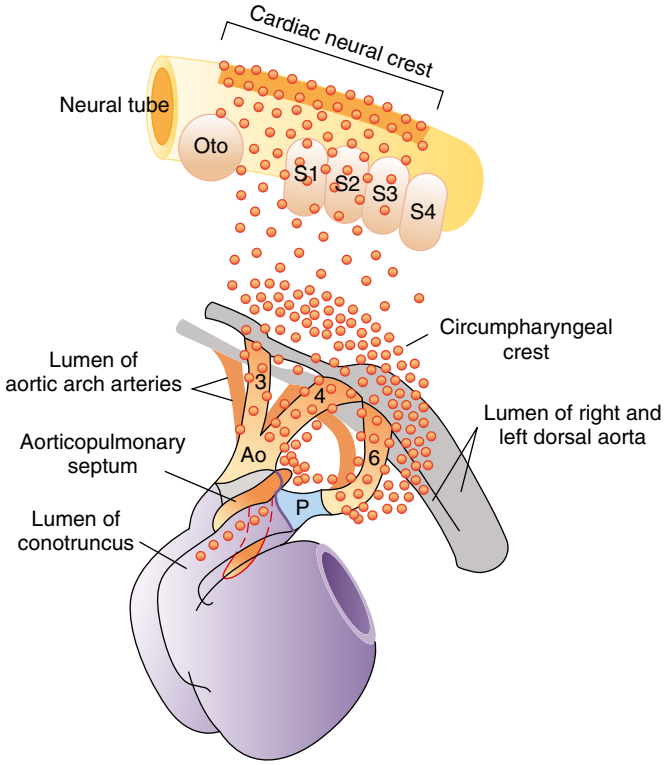

Figure 6.15 Cardiac neural crest. Migration of the cardiac neural crest to the circumpharyngeal ridge, caudal pharyngeal arches (3–6), and outflow tract depicted schematically. S1, S2, S3, S4, somites 1–4. Oto, otic vesicle; Ao, aorta; P, pulmonary artery. (Source: Kirby [23]. Reproduced with permission of Oxford University Press.)

from the pharynx, followed by neural crest cells, invade the truncal cushions to form two centrally placed columns, or prongs, in the shape of an upside-down "U" (Figure 6.16) [78]. These prongs will fuse with the aorticopulmonary septum distally and with the conal cushions proximally. Rotation of the developing pulmonary valve (see later in the chapter) is associated with spiraling of the aorticopulmonary septum and prongs, so that the developing aorta will connect with the rightward and cranial component of the aortic sac and the developing pulmonary trunk will connect with the leftward and caudal component of the aortic sac [79].

The convergence of the inflow and outflow poles during looping combined with the rotation and wedging processes brings the atria and outflow vessels into concordance with the AV valves and ventricles [75, 78]. In the conus, myocardial cells invade the cushions (myocardialization), which then bulge further into the lumen and subsequently meet and fuse in the midline. These conal cushions fuse most proximally with the AV cushion tissue and the crest of the muscular ventricular septum. Muscularization of the central conal cushion tissue and development of the adjacent aortic and pulmonary sinuses produce the *subpulmonary infundibulum* and a plane of space between the infundibulum and aortic root [79].

The developing pulmonary valve is initially posterior to and left of the developing aortic valve. Morphogenetic movement of the pulmonary valve (posterior to anterior, left of the aortic valve) brings it to its final position anterior and lateral to the aortic valve (Figure 6.9) [80]. This movement of the pulmonary valve is thought to be caused by the development of the subpulmonary conus (infundibulum), which also causes the pulmonary valve to be in a superior position relative to the aortic valve. Early in development, both the subpulmonary conus and the subaortic conus are situated above the right ventricle. Following torsion and a leftward shift of the outflow tract, resorption and shortening of the subaortic conus cause the aortic valve to sink inferiorly and posteriorly so that it comes to lie directly over the left ventricle and in fibrous continuity with the mitral valve (Figure 6.9) [81]. The conversion from the primitive, single in-series circulation to the double in-series circulation takes place during the fifth week of development.

Following outflow tract septation, the semilunar valves are formed as the mesenchyme in the outflow cushions is remodeled into the tri-leaflet aortic and pulmonary valves. Initially, three pairs of ridges, consisting of mesenchymal tissue covered by the endocardium, protrude into the lumen on each side of the divided truncus [78]. Valve sinuses are formed by excavation on the arterial (distal) face of the cusps. Thereafter, the leaflets are remodeled by mesenchymal apoptosis, blood flow, and shear stress to produce the delicate fibrous tissue seen in mature valves. Cells from the endocardium are the primary source of semilunar and AV valve fibroblasts, but fibroblasts derived from the epicardium also contribute to valve formation [76]. Cardiac neural crest cells are found at the tip of the leaflets and contribute to remodeling and maturation [74]. The role of cardiac neural crest in coronary vessel formation remains controversial.

AL Grawany

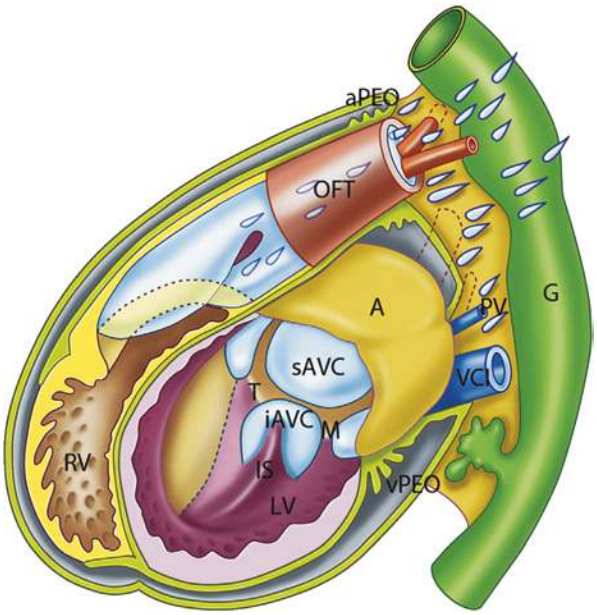

Figure 6.16 Schematic representation of the developing heart. Simplified model of a heart prior to ventricular septation. The roof of the atrium (A, light brown) is closed; therefore, atrial septation is not shown here. The anterior walls of the left ventricle (LV) and right ventricle (RV) are opened to reveal the inside. The interventricular foramen (primary foramen) is present. The inlet septum (IS) is connected to the inferior AV cushion (iAVC). The epicardium (olive green) covers most of the surface of the heart, but the venous proepicardial organ (vPEO; between liver and venous pole) and the arterial PEO (aPEO) surrounding the arterial pole are still present. The second heart field-derived part of the RV is shown in yellow, the endocardial cushions in light blue, neural crest cells in lavender, and the gut (G), including the liver, in green. AVC, atrioventricular canal; M, mitral ostium; OFT, outflow tract; PV, pulmonary vein; sAVC, superior AV cushion; T, tricuspid ostium; VCI, inferior cardinal vein. Abnormalities of outflow tract septation

The loss or dysfunction of cardiac neural crest cells produces a wide spectrum of conotruncal and aortic arch abnormalities that are associated with syndromes linking defects in the heart with craniofacial and glandular (thyroid, parathyroid, and thymus) defects [74]. These include the 22q11 deletion syndromes, such as DiGeorge and velocardiofacial syndromes, CHARGE syndrome, fetal alcohol syndrome, retinoic acid embryopathy, Alagille syndrome, and Noonan and LEOPARD syndromes [75]. The association between thymus, thyroid and parathyroid abnormalities in these syndromes is explained by the fact that the neural crest cells contribute to the connective tissue of these three organs. Additionally, abnormalities of the SHF also produce outflow tract defects [78].

Persistent truncus arteriosus results from a failure in outflow tract septation (conotruncus and aorticopulmonary septum) combined with a virtual absence of the subpulmonary infundibulum and, thus, a VSD [69, 82]. Typically, the aortic and pulmonary valves are fused to form a single semilunar truncal valve. The origin of the pulmonary arteries from the truncal root varies and is dependent on the degree of the septation deficiency [83]. Incomplete outflow tract septation results in an *aortopulmonary window*. Aortoventricular tunnels are thought to result from abnormal excavation and maturation of the outflow cushions during the formation of the semilunar valves [79]. Unequal septation can result in either the aorta or pulmonary artery being *hypoplastic* relative to the other.

Tetralogy of Fallot is thought to result from underdevelopment of the subpulmonary infundibulum (conus) [84]. The smaller infundibulum causes anterior deviation of the conal septum and malalignment of the conal septum with the muscular ventricular septum, producing right ventricular outflow tract obstruction and a subaortic VSD [85]. The pulmonary valve is usually abnormal, and the reduced blood flow contributes, to some degree, to pulmonary artery hypoplasia. Some patients have *tetralogy of Fallot with pulmonary valve atresia (TOF/PA)* and varying degrees of hypoplasia of the main and branch pulmonary arteries.

Theories that have been proposed to explain TGA include resorption of the subpulmonary conus, causing the pulmonary valve to move inferiorly and posteriorly so that it comes to lie above the left ventricle and in fibrous continuity with the mitral and tricuspid valves [80], and failure of the aorticopulmonary septum to spiral [86]. Dextro- or D-TGA refers to TGA with normal looping of the heart to the right, whereas L-TGA refers to looping of the heart to the left. In D-TGA, there is AV concordance and VA discordance. *Congenitally or physiologically corrected TGA* is characterized by TGA and AV discordance (i.e. double discordance). In the more frequent form, referred to as L-transposition, there is levocardia with situs solitus of the atria and L-looping of the heart. The other form is a mirror image of the above with dextrocardia, inversion of the atria (situs inversus), and D-looping of the heart [87].

Persistence of both the subpulmonary and subaortic coni results in a *double outlet right ventricle*, whereas a deficiency of both results in a *double outlet left ventricle* (very rare); in either case, there is almost always a VSD.

Fused or absent pulmonary commissures produce *pulmonary valve stenosis*, in which the valve is typically mobile and dome-shaped with a small and sometimes eccentric orifice [88]. *Critical pulmonary stenosis* is a severe form of pulmonary stenosis in the neonate that is considered a ductal-dependent lesion because a *patent ductus arteriosus* (PDA) is essential for pulmonary blood flow.

Obstruction of the left ventricular outflow tract may occur at the valvular, subvalvular, or supravalvular levels. The most common aortic valve anomaly is a *bicuspid aortic valve* [2]. This malformation is also thought to be the most common cardiac defect (occurring in 1–2% of the population). It may be an incidental finding or may result in a clinical presentation in childhood or adult life, and it can occur in isolation or in association with left-sided obstructive lesions [89]. There are several variants, the most frequent being characterized by commissural fusion (most commonly between the coronary cusps), creating a functionally bicuspid structure, and the far less frequent "true" bicuspid valve. *Critical aortic valve stenosis* in the neonate is a ductal-dependent lesion in that a PDA is necessary for systemic perfusion. The valve is usually unicommisural or bicommisural and incompletely differentiated with thickened, redundant, and rolled cusps and leaflets consisting of immature loose connective tissue (myxomatous) [90]. Dysplastic valves, rather than commissural fusion, obstruct the orifice. Severe aortic stenosis or *aortic atresia* can be part of a spectrum of left-sided obstructive lesions associated

with hypoplasia of the left ventricle, ascending aorta and/or arch, mitral valve stenosis or atresia, and endocardial fibroelastosis of the left ventricle (i.e. HLHS) [64].

Subvalvular aortic stenosis has a number of embryologic etiologies. Malalignment of the conal septum with the muscular interventricular septum results in posterior projection of the conal septum into the left ventricular outflow tract and an associated VSD. This pathology may be seen within the context of an interrupted aortic arch. *Familial hypertrophic cardiomyopathy* is an autosomal dominant developmental abnormality most commonly due to mutations in the contractile protein (sarcomere) genes, but it may also be due to mutations in non-sarcomeric genes that are associated with mitochondrial defects, potassium channel abnormalities, and abnormalities of protein kinase A [91]. A *discrete fibromuscular ridge* or *membrane* below the aortic valve can also cause subaortic stenosis.

Congenital supravalvular aortic stenosis (SVAS) is caused by the deletion of or a loss-of-function mutation in the elastin gene on chromosome 7q11.23. In the majority of cases, SVAS occurs in association with Williams–Beuren syndrome, which is frequently referred to as Williams syndrome (WS) [92, 93]. In other cases, SVAS is inherited as an autosomal dominant disorder or results from sporadic mutations and occurs without mental retardation, elfin facies, distinctive behavioral traits, and neonatal hypocalcemia associated with WS [94]. During the early stages of development, the smooth muscle cells from patients with WS and non-syndromic SVAS express only about 15 and 50%, respectively, of the normal levels of the elastin-precursor tropoelastin [95]. The resultant arterial media has a reduced elastin content, pathologic alignment of the elastin fibers, an increased collagen content, and an increased number of hypertrophied smooth muscle cells. The entire ascending aorta may be narrowed (aortopathy) in about 30% of patients, and up to 80% of patients will have peripheral pulmonary artery stenosis [96].

Heritability and genetic etiologies of non-syndromic left-sided obstructive lesions are highly heritable. First-degree relatives of an individual with a left-sided obstructive lesion have a 20% chance of having CHD (most often a bicuspid aortic valve) [97]. The genetic causes of left-sided obstructive lesions overlap due to genetic heterogeneity (Table 6.1, Figure 6.17) and help explain the phenotypic variability within families with the same genetic variant [98–100].

KEY POINTS: CARDIAC SEPTATION

- Cardiac septation begins after the looping stage with the eventual creation of four chambers and two distinct circulations.
- The process of cardiac septation involves the muscular septa in the atrial and ventricular chambers, the AV and outflow tract endocardial cushions, and the dorsal mesenchymal protrusion.
- Abnormalities in this process can result in septation defects at the atrial and/or ventricular levels, altered AV valve development, abnormalities of outflow tract septation, and semilunar valve pathology.

Epicardium and coronary artery development

After looping of the linear heart tube, the epicardium covers the heart as well as the intrapericardial portion and roots of the great arteries. The epicardium develops from the proepicardial organ (PEO) comprising medusa-like villi that arise from the *splanchnic mesoderm of the ventral pharynx* (Figure 6.16) [26, 30]. The venous PEO (vPEO) is derived from mesenchyme near or in the liver and begins as protrusions of splanchnic mesoderm at the venous pole at the back of the pericardial cavity. The vPEO gives rise to the epicardium that will cover the atria, AVC, and ventricles. Likewise, the splanchnic mesoderm of the ventral pharynx at the arterial pole, which is analogous to the vPEO, gives rise to the arterial PEO (aPEO) that will cover the outflow tract with the epicardium. Gittenberger-de Groot has shown that after the epicardium has invested the myocardium, a subset of cells undergoes EMT and migrates into the subepicardial space [101]. These epicardially derived cells (EPDCs) invade the myocardium and differentiate into fibroblasts, vascular (coronary) smooth muscle cells, endothelial cells, hematopoietic cells, fat cells, and pericytes [102]. The epicardially derived fibroblasts become the interstitial fibroblasts, the annulus fibrosus, and the adventitial coronary fibroblasts. The epicardium is necessary for myocardial growth, and interstitial fibroblasts are crucial to the formation of the thick compact myocardium.

AL Grawany

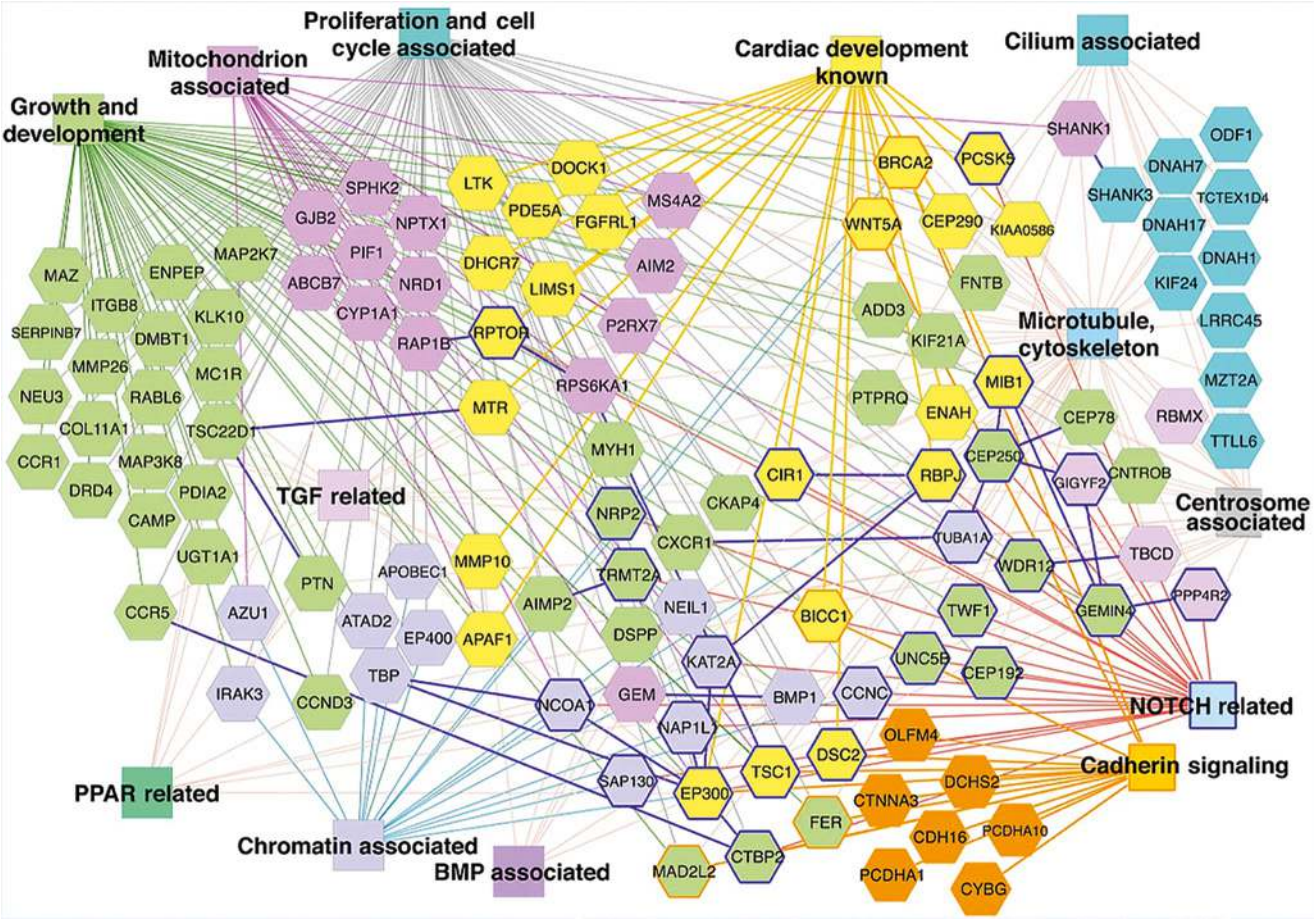

Figure 6.17 Mutations recovered from HLHS patients. ToppCluster-generated interactome network of multi-hit genes recovered from subjects with HLHS and HLHS mutant mice. Genes (hexagons) associated with heart development and various gene ontology biological processes (color rectangles) are shown with corresponding color. Dark blue-outlined hexagons are NOTCH-related genes. Protein-protein interactions are indicated as solid dark blue lines between genes. (Source: Yagi et al. [99]. Reproduced with permission of Springer Nature.).

Nutrient delivery to the myocardium occurs in three sequential and overlapping phases. Although the early myocardium is avascular, the inner trabecular zone of the myocardial wall has venous sinusoids (trabecular channels) lined by the endocardium through which nutrients diffuse. With the formation of the epicardium after cardiac looping, a subepicardial endothelial plexus forms from the EPDCs and undergoes vasculogenesis, angiogenesis, and arteriogenesis [103]. Arteriogenesis is the coating of the initial coronary plexus by smooth muscle cells and pericytes. The coronary plexus penetrates the myocardium, and some of the channels will communicate with the intratrabecular venous sinusoids. The density of the coronary plexus is not uniform across the myocardial wall, being higher on the outer epicardial side than on the inner endocardial side [104]. The subepicardial vascular network later undergoes remodeling to produce the coronary arteries and veins with adult branching characteristics. As reported by Waldo et al. [103] and Smart et al. [105], the final step in the development of the coronary circulation is ingrowth of the peritruncal coronary capillary plexus into the base of the aorta (Figure 6.18). Multiple small vessels penetrate each aortic sinus. In the right and left aortic sinuses the multiple channels coalesce to form the main stems of the right and left coronary arteries, whereas the channels in the remaining (non-coronary) sinus regress.

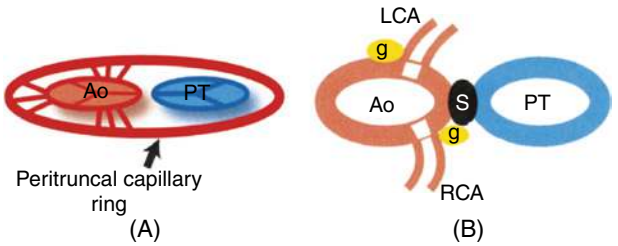

Figure 6.18 Left (LCA) and right (RCA) coronary artery development. (A) Multiple channels penetrate the aortic (Ao) wall in all of the aortic sinuses from the peritruncal ring. (B) Only the ones in the right and left sinuses survive and coalesce to form the main stems of the LCA and RCA. PT, pulmonary trunk; g, cardiac ganglia; S, aorticopulmonary septum. Abnormalities of epicardial development

Normal development of the compact myocardium requires a trophic interaction between the cardiomyocytes and

EPDCs [30]. Abnormal EPDC function results in *ventricular non-compaction*, a cardiomyopathy characterized by a spongy myocardium, and has a predilection for the left ventricle.

Coronary artery fistulae may arise from either the right or left coronary artery and most frequently terminate in the right heart [106]. Fistulae can occur in isolation or in association with other lesions. In some cases of pulmonary atresia with an intact ventricular septum (PA/IVS) and in some forms of HLHS [107], a significant portion of the ventricle may be dependent on blood supply from the hypertensive right (PA/IVS) or left ventricle, respectively. Flow into a lower pressure chamber produces myocardial ischemia by a coronary steal and ventricular volume overload.

Vascular channels from the peritruncal ring normally penetrate the aortic sinuses. However, penetration of the pulmonary artery results in an *anomalous origin of the coronary artery from the pulmonary artery*, the most common form being the left coronary artery from the pulmonary artery (ALCAPA) [108, 109]. Coronary steal can occur, in which the blood flow is reversed into the pulmonary artery due to the lower vascular resistance of the pulmonary circulation and/or the higher pressure of collateral circulation from the normal coronary artery. Also, blood flowing antegrade through the anomalous coronary artery has a lower oxygen content than normal.

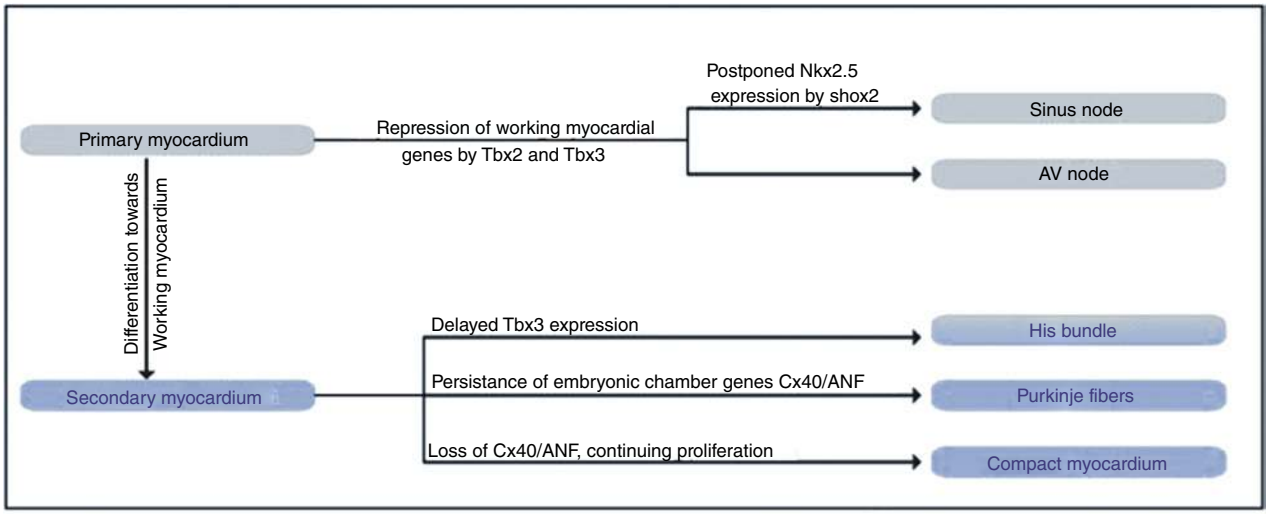
Congenital atresia of the left coronary artery and *anomalous aortic origin of the left or right coronary artery from the right or left coronary sinus*, respectively, are generally rare but have been associated with sudden death [108, 109].

KEY POINTS: EPICARDIUM AND CORONARY ARTERY DEVELOPMENT

- The epicardium is derived from the proepicardial organ which comprises villi that arise from the splanchnic mesoderm of the ventral pharynx at the venous and arterial poles.
- Epicardially derived cells undergo differentiation into fibroblasts, coronary smooth muscle cells, and endothelial and hematopoietic cells.
- The development of the coronary circulation involves various steps, the last one consisting of ingrowth of the peritruncal coronary capillary plexus into the base of the aorta.
- Abnormal epicardial development can result in certain types of cardiomyopathies and anomalies that involve the coronary arteries.

Development of the conduction system

The myocardium of the primitive heart tube has no morphologically distinct conducting cells [110]. The primitive pacemaker (i.e. area with the cells with the fastest intrinsic rate) is located at the junction of the sinus venosus and the primitive atrium. Before the AV and semilunar valves develop, a unidirectional, slowly transmitted, depolarizing impulse (represented by a sinusoidal electrocardiogram) generates a mechanical contraction wave that pushes blood from the venous pole to the arterial pole [34].



With elongation of the heart tube, the myocardial cells of the developing ventricular and atrial chambers differentiate into a *working* (contractile) myocardial phenotype characterized by fast-conducting gap junctions and sarcomere components [111]. Myocardial cells at the venous pole, AVC, and outflow tract differentiate into specialized *conductive* myocardium. Although these cells have elements of working myocardium (including contraction, autorhythmicity, intercellular conduction, and electromechanical coupling), they retain their primary phenotype of sparse gap junctions and slow conduction (Figure 6.19). The cardiomyocytes of the conduction system necessary for the generation and propagation of the electrical impulses for coordinated contraction comprise ~2% of the myocardial mass [112]. With the differentiation of myocytes into working and conductive myocardium, the electrocardiogram resembles that of the formed heart [113].

The *sinoatrial node* (SAN) is detectable at approximately 32 days of gestation. It develops from myocardial cells located at the junction of the right common cardinal vein (which drains into the right horn of the sinus venosus) and the right atrium, ultimately becoming "comma-shaped" with its head at the junction of the SVC and the right atrium and its tail incorporated into the crista terminalis [114]. Normal development of the cardiac conduction system is transcription factor-dependent. TBX3 is expressed in the sinoatrial node and its deletion leads to abnormalities including VSD, Wolff-Parkinson-White arrhythmia, and sinus node dysfunction. It is both a positive regulator of the development of the normal atrioventricular conduction system and a negative regulator of abnormal accessory atrioventricular pathways [115]. Unlike other areas of myocardial development, normal sinus myocardium development (and thus normal sinus node development) depends upon the *absence* of NKX2.5 expression due to suppression by SHOX2. The sinus myocardium is derived from TBX18-positive cells, and the sinus node develops hypoplastically in its absence. Thus, a complex interplay between TBX18, SHOX2, and NKX2.5 is required for normal sinus myocardium and sinus node development [26]. Nodal cells in the left cardinal vein regress to become the ligament of Marshall [110]. It has been established that specific conduction pathways through the atrial myocardium do not exist [116, 117].

The *AV node* (AVN) is detectable at approximately 33 days of gestation. It develops from slow-conducting myocardium within the dorsal AVC. The AVN becomes located in the triangle of Koch, and the cells of the AVN are in direct continuity with the atrial and ventricular myocardium. The AVN retains its primary phenotype of slow conduction so that there is an appropriate AV delay. The development of AV node progenitor cells is dependent upon NKX2.5 transcription factor binding. Pathogenic variants that significantly alter the binding result in AV block, with or without CHD [25].

The *AV (His) bundle, left and right bundle branches* and *Purkinje fibers* develop from fast-conducting ventricular myocardium; the AV bundle from cells in the crest of the interventricular septum, and the bundle branches and Purkinje network from subendocardial myocytes along the ventricular septum [111].

An important step in the development of the conduction system is establishing electrical discontinuity between the atrial and ventricular myocardium at the AV junction.

Reproduced with permission of John Wiley & Sons.)

Epicardial cell-derived fibroblasts in the AV groove invade the AV myocardium inferior to the AVN and make contact with the endocardial cushion mesenchyme to form the *annulus fibrosus*, or crux of the heart. Because the annulus fibrosus insulates the atria from the ventricles, the AV conduction system provides the only myocardial continuity between the atria and ventricles. The complex genetics, transcription factors, and signaling pathways of cardiac conduction system development and function have recently been reviewed [112, 118].

Abnormalities of conduction system development

Normal development of the conduction system is dependent upon a concordance of the atrial and ventricular chambers, correct alignment of the atrial and ventricular septa, and complete closure of the ventricular septum [119]. Thus, from an embryologic perspective, abnormalities of the conduction system would be expected in lesions that involve AV concordance, the AVC, single ventricles, atrial isomerism, or combinations thereof [120, 121].

Congenitally corrected TGA (CCTGA) with L-loop ventricles is associated with displacement of the AVN within the right atrium to an anterior and lateral position beneath the opening of the right atrial appendage [122]. The AV bundle is longer than normal and passes across the anterior surface of the subpulmonary outflow tract to reach the morphologic right ventricle. Infants may be born with complete AV block, but for those born without block, the risk of natural onset

complete AV block increases by 2%/year [123]. In *CCTGA with D-loop ventricles and atrial situs inversus*, the AVN is typically in a left-sided triangle of Koch.

In *AVC defects*, the AVN is displaced posteriorly and inferiorly to lie low in the atrial septum and anterior to the coronary sinus ostium. The AV bundle is displaced posteriorly, is elongated, and courses along the lower rim of the VSD; this gives rise to the superior (left) QRS axis seen on an electrocardiogram [124]. With *perimembranous VSDs*, the AV bundle can be longer and is typically located along the postero-inferior rim of the defect. In *single ventricle* abnormalities, the locations of the AVN and AV bundle can vary widely.

Accessory pathways are accessory bundles of cardiomyocytes that electrically connect the atria and ventricles, providing the substrate for some supraventricular arrhythmias (as occurs in Wolff–Parkinson–White syndrome and Mahaim tachycardia) [124]. Right-sided pathways and some left-sided pathways run subendocardially. The most common right atrial locations in children are the left free wall and the posteroseptal right free wall [119]. Ebstein anomaly is frequently associated with Wolff–Parkinson–White syndrome and other accessory pathways.

Atrial conduction disturbances and arrhythmias are frequently related to sinus venosus myocardium and thus they tend to take place at particular anatomic sites, such as the crista terminalis, ostia of the caval veins, coronary sinus, pulmonary veins, and the ligament of Marshall [124]. The structure of the AVN is complex, both anatomically and electrophysiologically, and in many normal hearts, it provides the substrate (two pathways with different electrophysiological characteristics) for dual AVN physiology and *AV nodal re-entry tachycardia* (AVNRT).

Gene mutations that affect ion channels give rise to *cardiac channelopathies*; the most important of these are long QT syndrome, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia, and short QT syndrome [125, 126].

KEY POINTS: DEVELOPMENT OF THE CONDUCTION SYSTEM

- The primitive pacemaker is located at the junction of the sinus venosus and the primitive atrium.
- The AV node retains its primary phenotype of slow conduction allowing for appropriate AV delay, whereas the AV bundle, left and right bundle branches and Purkinje fibers develop from fast-conducting ventricular myocardium.
- Abnormalities of the conduction system are expected in lesions that alter the AV concordance, proper alignment of the atrial and ventricular septa, and complete closure of the ventricular septum.

Development of the aortic arches

Blood vessels are formed by the aggregation of angioblasts (splanchnic mesoderm that has differentiated into endothelial cell precursors) into small endothelial-lined channels that connect to form vascular networks (vasculogenesis), which grow through the sprouting and branching of vessels (angiogenesis). Depending on the site of the vascular network, cells from the mesoderm, neural crest, or epicardium associate with the endothelial cells to form vascular smooth muscle, thereby stabilizing the vessel wall [127]. The dorsal aortae are bilateral, parallel, longitudinal channels that form in the mesoderm on either side of the notochord, adjacent to the ventral pharyngeal endoderm. The aortic sac is connected to the paired dorsal aortae by the artery of each pharyngeal arch; these vessels are referred to as pharyngeal arch arteries (PAAs) or aortic arch arteries [9]. Pioneering work by Kirby, and later by Poelmann and Gittenberger-de Groot, demonstrated that cardiac neural crest cells migrate into the mesoderm of the pharyngeal arches (3, 4, and 6) and surround the endothelial cells to form the smooth muscle of the PAAs [29, 128–130]. The PAAs are not all present simultaneously but form over time in a symmetric pattern cranially to caudally. The neural crest cells are critical for remodeling, whereby some segments of the aortic arch apparatus and dorsal aortae regress, while other segments transform and persist to produce the mature asymmetric pattern (Figure 6.20).

The dorsal aortae fuse in a caudal-to-cranial direction up to the seventh somite. The seventh somite is supplied by the seventh intersegmental artery, which forms the left subclavian artery and contributes to the formation of the right subclavian artery. The dorsal aortae give off dorsal intersegmental arteries, which supply the spinal cord and developing somites [132]. Longitudinal anastomoses form between the intersegmental arteries, with those from the first to the seventh forming the vertebral artery. The first six intersegmental arteries regress after the vertebral artery is formed, and the vertebral artery arises from the seventh intersegmental artery, which itself forms part of the subclavian artery.

Abnormalities of aortic arch development

Abnormalities of the aortic arch occur when segments of the fourth aortic arch fail to regress or regression occurs at an abnormal site; this can be explained by Edwards' hypothetical double aortic arch model (Figure 6.21) [134]. The aortic arch is referred to as left- or right-sided to indicate which mainstem bronchus the arch crosses over. Congenital variants and aortic arch anomalies have been reviewed by Hanneman and colleagues [135]. The normal left aortic arch (LAA) results from regression of the segment of the right arch between the right subclavian artery and the descending aorta. Conversely, a *right aortic arch* (RAA) with mirror-image branching is produced when the LAA regresses between the left subclavian artery and the descending aorta. An RAA with mirror-image branching is frequently associated with cardiac malformations. A *double aortic arch* results from the persistence of both fourth aortic arches. Regression of the segment between the right carotid and right subclavian arteries results in an LAA with an *aberrant right subclavian artery*, whereas regression of the segment between the left carotid and left subclavian arteries results in an RAA with an *aberrant left subclavian artery*. An *interrupted aortic arch* (IAA) results from the regression of both the right and left fourth aortic arches. The most common type of IAA is type B, in which there is an interruption between the left carotid and left subclavian arteries and normal regression of

AL Grawany

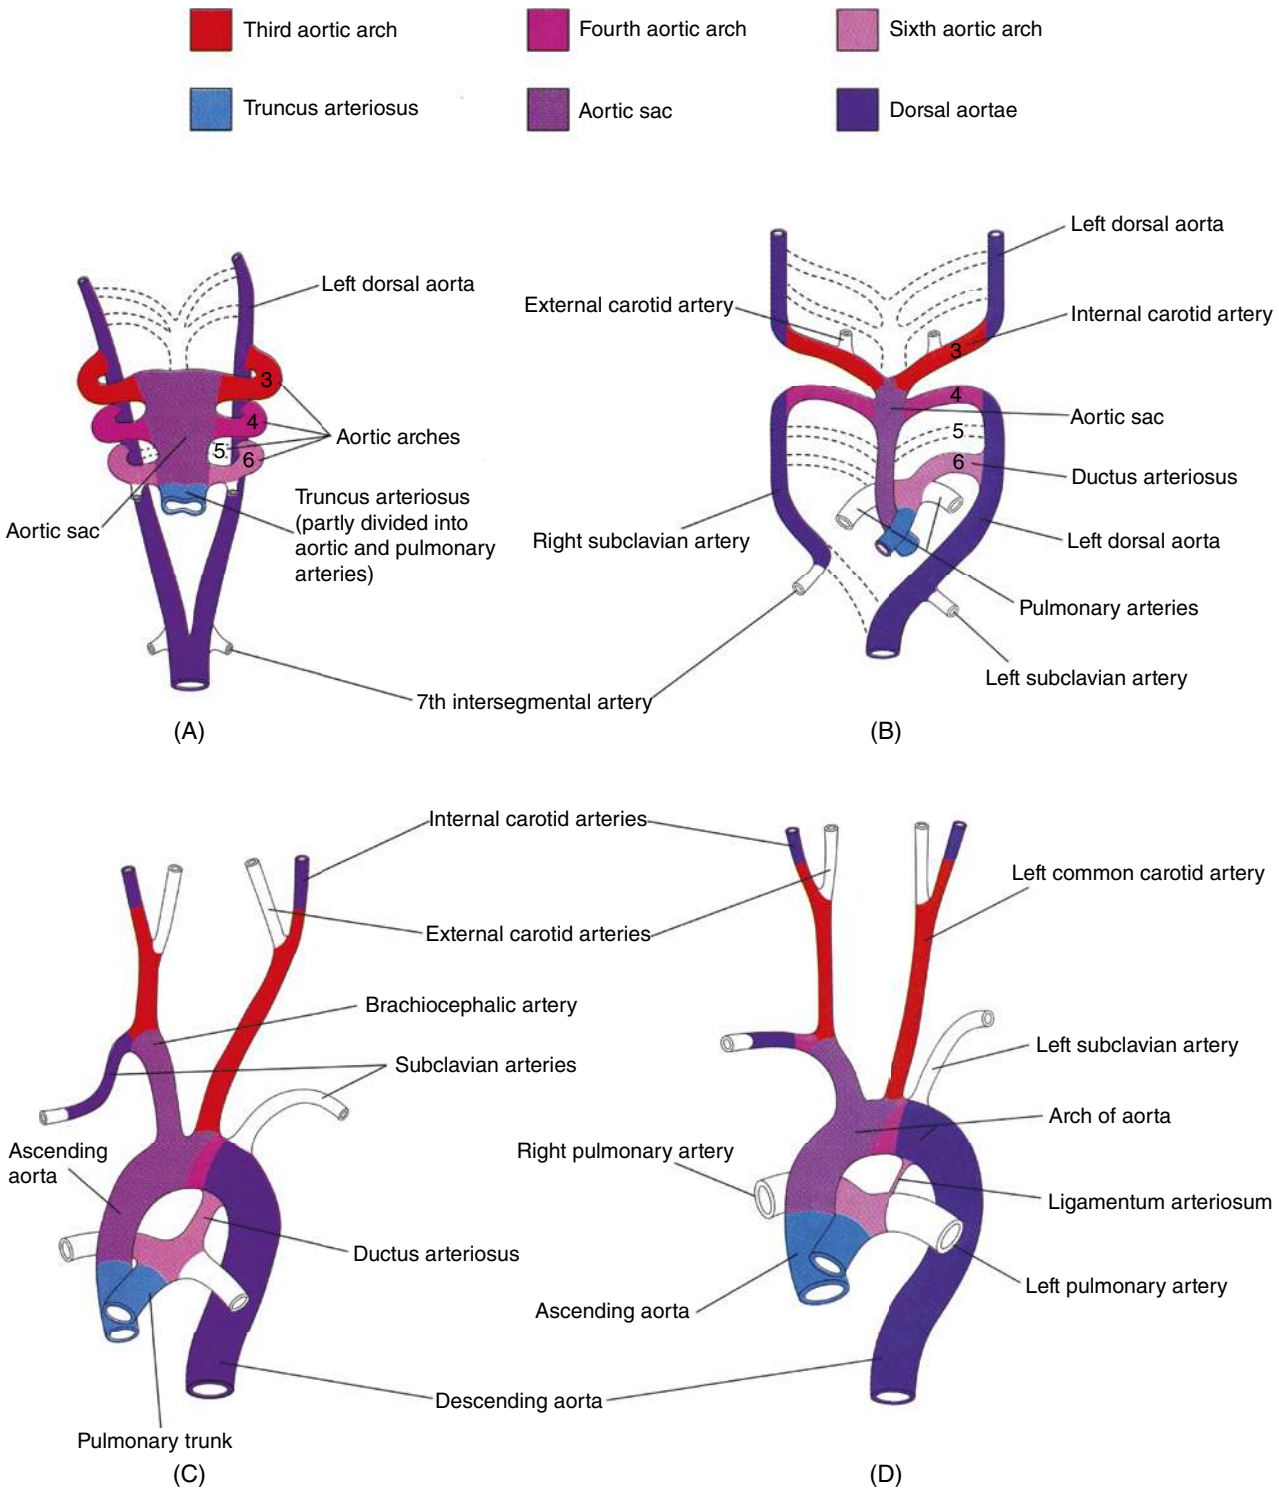

Figure 6.20 Schematic drawings illustrating the arterial changes that result during the transformation of the truncus arteriosus, aortic sac, pharyngeal arch arteries, and dorsal aortae into the adult arterial pattern. The vessels that are not colored are not derived from these structures. (A) Pharyngeal arch arteries at 6 weeks; by this stage, the first two pairs of arteries have largely disappeared. (B) Pharyngeal arch arteries at 7 weeks; the parts of the dorsal aortae and pharyngeal arch arteries that normally disappear are indicated with ***broken lines***. (C) Arterial arrangement at 8 weeks. (D) Sketch of the arterial vessels of a 6-month-old infant. Note that the ascending aorta and pulmonary arteries are considerably smaller in (C) than in (D). This represents the relative flow through these vessels at the different stages of development. Observe the large size of the ductus arteriosus in (C) and that it is essentially a direct continuation of the pulmonary trunk. The ductus arteriosus normally becomes functionally closed within the first few days after birth. Eventually, the ductus arteriosus becomes the ligamentum arteriosum, as shown in (D). (Source: Moore et al. [131]. Reproduced with permission of Elsevier.)

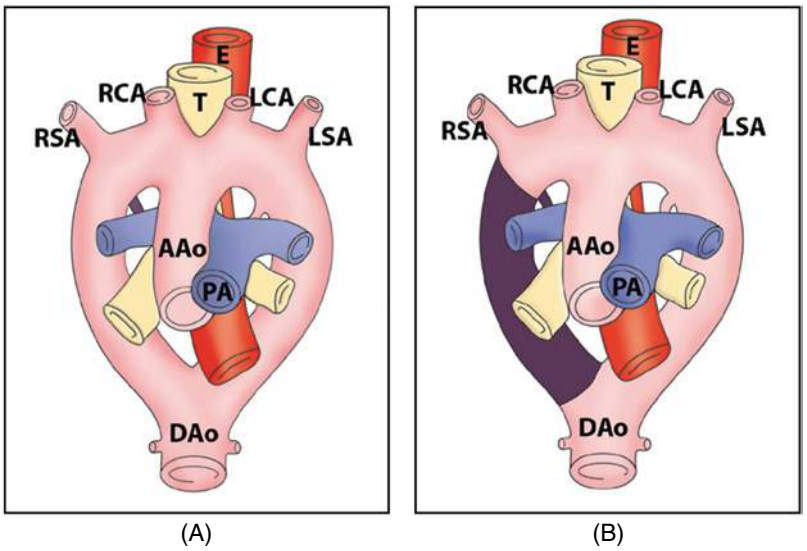

Figure 6.21 Diagram of Edward's developmental model of the aortic arch. (A) Hypothetical double aortic arch system in which there is an aortic arch and ductus arteriosus on each side encircling the trachea (T) and esophagus (E), with the carotid and subclavian arteries arising bilaterally from the respective arches. The descending aorta is in the midline. (B) Normal arch branching results from interruption of the dorsal segment of the right arch between the right subclavian artery and descending aorta with regression of the right ductus arteriosus. AAo, ascending aorta; DAo, descending aorta; LCA, left carotid artery; LSA, left subclavian artery; PA, pulmonary artery; RCA, right carotid artery; RSA, right subclavian artery. (Source: Turkvatan et al. [133]. Reproduced with permission of The Korean Radiological Society.)

the right aortic arch. It is estimated that 50% of cases of IAA type B are due to 22q11.2 deletion syndrome [136]. Smooth muscle differentiation in the outflow tract is dependent upon the histone deacetylase *Hdac3* and its loss in the neural crest of mouse models leads to IAA [137]. A *vascular ring* is an aortic arch anomaly in which the trachea and esophagus are completely encircled by vascular structures, which may be patent or consist of fibrous remnants, such as the ligamentum arteriosum. When the trachea and esophagus are not completely encircled, the abnormality is referred to as a *vascular sling*. Aortic arch anomalies can be associated with tracheobronchial and/or esophageal compression and, in the case of a pulmonary artery sling, malformations of the trachea [138].

Coarctation of the aorta is a focal narrowing of the aorta, usually consisting of a discrete posterior shelf or ridge caused by infolding or thickening of the aortic media with the inner part of the ridge composed of ductal tissue [139]. The site of the coarctation may be preductal, juxta- or paraductal, or postductal. It is most commonly preductal in infants, both pre- and paraductal in young children, and postductal beyond about 15 years of age. The histological architecture does not vary with the location. Coarctation is thought to be due to ductal tissue extending into the wall of the aorta (ductus tissue theory) and an abnormal flow pattern due to lesions resulting in decreased flow into the ascending aorta (hemodynamic theory) [140]. Thus, it is frequently associated with a bicuspid aortic valve, aortic stenosis, hypoplasia of the aortic arch, small left-sided structures, and VSDs.

PDA is an open ductus arteriosus beyond the first three postnatal days, with the incidence being inversely proportional to gestational age at birth [141]. In a preterm infant, a PDA is thought to be due to immaturity of the smooth muscle and oxygen sensing mechanisms. An *isolated PDA* in a full-term infant is most likely a congenital malformation of the vessel wall with different histologic features and a genetic origin [142]. The molecular mechanisms underlying ductal closure and remodeling have recently been reviewed [143]. A PDA may occur in isolation, particularly with prematurity, or in association with almost any other congenital cardiac anomaly. It is lifesaving in some forms of CHD.

KEY POINTS: DEVELOPMENT OF THE AORTIC ARCHES

- During development, the initial arterial pattern becomes modified, and some vessels regress completely, allowing for a transformation into the definitive vascular pattern.
- Neural crest cells are critical for the development of the aortic arches.
- Abnormalities of the aortic arch occur when segments of the fourth aortic arch fail to regress or regression occurs at an abnormal site.

Development of the pulmonary and systemic veins

Pulmonary veins

The lungs and tracheobronchial tree develop from the respiratory diverticulum, a ventral outgrowth from the foregut. Early in development, the lungs have the same venous

AL Grawany

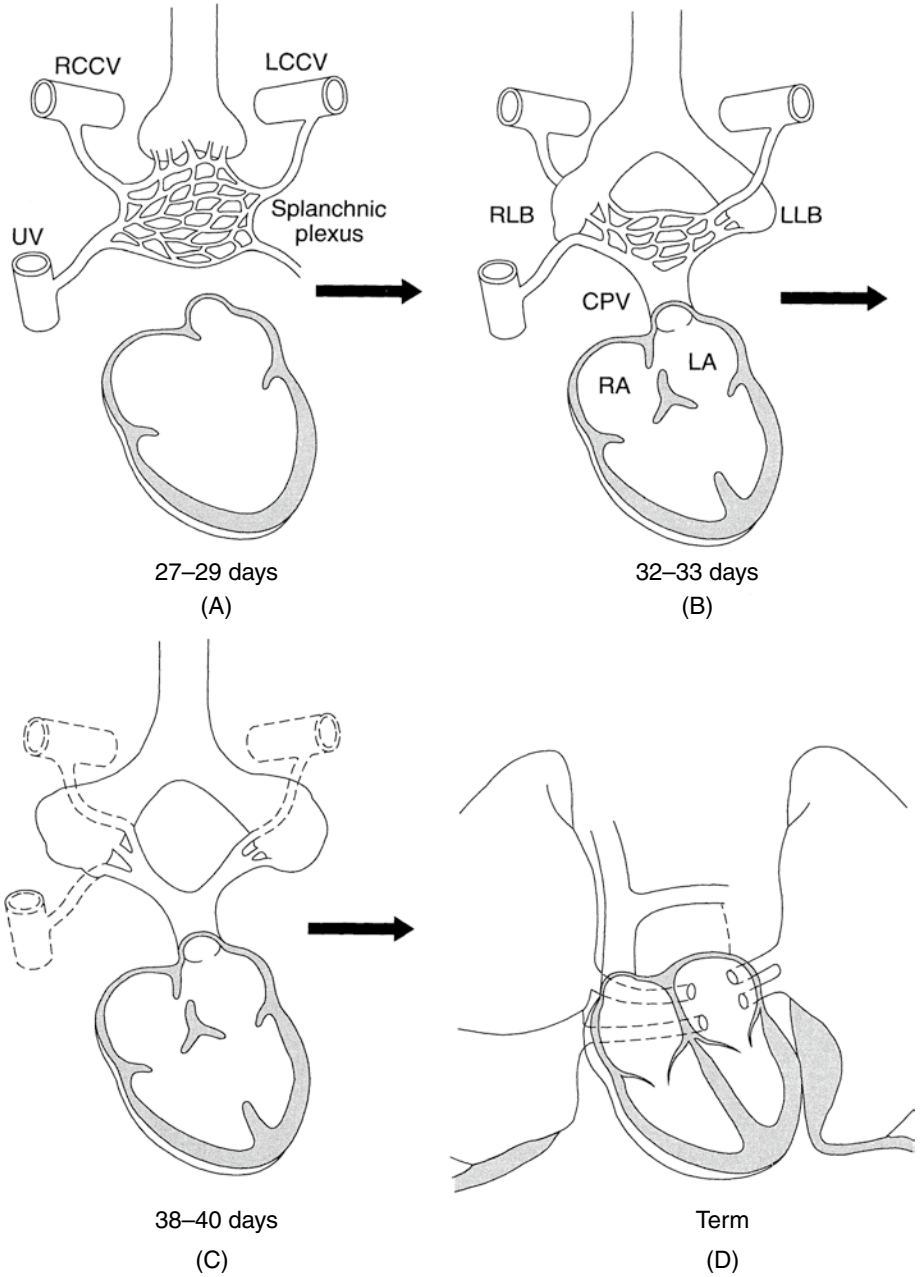

Figure 6.22 Development of the pulmonary veins. (A) At 27–29 days of gestation, the primordial lung buds are enmeshed by the vascular plexus of the foregut (splanchnic plexus). No direct connection to the heart is present at this stage. Instead, multiple connections are present to the umbilicovitelline and cardinal venous systems. A small evagination can be seen in the posterior wall of the left atrium to the left of the developing septum secundum. (B) By the end of the first month of gestation, the common pulmonary vein establishes a connection between the pulmonary venous plexus and the sinoatrial portion of the heart. At this time, the connections between the pulmonary venous plexus and the splanchnic venous plexus are still patent. (C) Subsequently, the connections between the pulmonary venous plexus and the splanchnic venous plexus involute. (D) The common pulmonary vein (CPV) incorporates into the left atrium so that the individual pulmonary veins connect separately and directly to the left atrium. LA, left atrium; LCCV, left common cardinal vein; LLB, left lung bud; RA, right atrium; RCCV, right common cardinal vein; RLB, right lung bud; UV, umbilical vein. (Source: Brown et al. [144]. Reproduced with permission of Wolters Kluwer.)

drainage as the foregut, via the splanchnic plexus into the cardinal and umbilicovitelline (systemic) veins (Figure 6.22).

The primary pulmonary vein develops by canalization within the dorsal mesocardium to form a channel [50]. Endothelial invagination from the left side of the primitive atrium into the dorsal mesocardium delineates the future orifice of the primary pulmonary vein [49]. This invagination is surrounded by ridges of the dorsal mesocardium, forming a pit (pulmonary pit) cephalad to the junction of the left and right horns of the sinus venosus and to the left

of the developing septum primum. Further canalization of the primary pulmonary vein brings it into continuity with the cavity of the developing left atrium, and by the end of the first month of gestation, the primary pulmonary vein has established a connection between the pulmonary venous plexus of the lung bud and the sinoatrial portion of the heart. Once a connection has been established between the primary pulmonary vein and the left atrium, the pulmonary venous plexus loses its connections with the systemic veins. Then, the common pulmonary vein incorporates into the left atrium so that the individual pulmonary veins connect separately and directly to the left atrium. At the connection of the developing pulmonary vein and atrium, pulmonary mesenchymal cells differentiate into pulmonary myocardial cells that form a sleeve of myocardium around the developing pulmonary vein. PITX2c is crucial in the differentiation of the pulmonary vein myocardium. Pitx2c-deficient mice fail to form primary pulmonary myocardial cells and thus the pulmonary myocardial sleeve [145].

Abnormalities of pulmonary vein development

Total anomalous pulmonary venous connection (TAPVC) results from a failure to establish the normal connection between the common pulmonary vein and the pulmonary venous plexus before the connections with the splanchnic venous system regress. All the pulmonary veins join a common horizontal or vertical vein behind the left atrium, which can drain via the supracardiac, cardiac, or infracardiac (infradiaphragmatic) route into the right heart circulation, producing a left-to-right shunt. Atresia of only the right or left portions of the common pulmonary vein before the connections with the splanchnic venous system regress results in *partial anomalous pulmonary venous connection* (PAPVC) with drainage into derivatives of the left or right cardinal systems. Both TAPVC and PAPVC produce a left-to-right shunt and can be associated with pulmonary venous obstruction. Pulmonary veins can also be *hypoplastic* or *atretic*, with the most common variation in the number of pulmonary veins being a *single pulmonary vein* on either the right or left side (prevalence of about 24% in anatomic studies) [146]. *Cor triatriatum* is an oblique fibromuscular membrane that divides the left atrium into two chambers: a postero-superior chamber that receives the pulmonary veins and an antero-inferior chamber that communicates with the mitral valve and left atrial appendage [147]. Cor triatriatum is thought to arise from incomplete incorporation of the common pulmonary vein into the primitive left atrium. *Sinus venosus ASDs* are associated with drainage of some, and less frequently all, of the right pulmonary veins into the right SVC or right atrium and normal connection of the left and other right pulmonary veins to the left atrium. Congenital *pulmonary vein stenosis* typically occurs at the pulmonary vein–left atrial junction but can be progressive in the length and degree of stenosis and number of pulmonary veins affected. The embryologic basis for this anomaly has been postulated to be abnormal incorporation of the common pulmonary vein into the left atrium [148].

KEY POINTS: DEVELOPMENT OF THE PULMONARY VEINS

- The lungs and tracheobronchial tree develop from a ventral outgrowth of the foregut.
- Establishment of a normal connection between the primary pulmonary vein and the left atrium is linked to the loss of the initial connection of the pulmonary venous plexus to the systemic veins.
- Abnormalities of pulmonary vein development result from failure of normal connections between rudimentary pulmonary venous structures to be established before the connections with the splanchnic venous system regress.

Systemic veins

By the end of the fourth week of development, the primitive venous system consists of three bilaterally symmetric systems that each drain into the right and left horns of the sinus venosus: the *vitelline* veins, which drain the yolk sac and gastrointestinal derivatives and will develop into the portal system; the *umbilical* veins, which carry oxygenated blood from the placenta and disappear after birth, and the *cardinal* veins, which drain the head, neck, and body wall and will develop into the caval system (Figure 6.23). The shift of the systemic venous return to the right atrium is associated with regression and remodeling to yield the adult asymmetrical venous pattern.

The vitelline and umbilical veins are altered by the development of the liver in the septum transversum and the formation of the hepatic sinusoids. The vitelline veins pass from the foregut through the septum transversum and developing liver to connect with the hepatic sinusoids (Figure 6.24). When the left horn of the sinus venosus regresses to form the coronary sinus, the proximal (near the heart) left vitelline vein also regresses, causing blood from the left side of the abdominal viscera to be channeled to the right side with subsequent enlargement of the right vitelline vein. The portion of the right vitelline vein between the liver and heart becomes the suprahepatic (terminal) portion of the IVC. During the second and third months of gestation, the right vitelline vein inferior to the liver becomes the portal vein and superior mesenteric vein, and some of the left-to-right vitelline anastomoses become the splenic and inferior mesenteric veins.

The umbilical veins, which initially pass on either side of the liver, become connected to the hepatic sinusoids. The right umbilical vein regresses during the second month of gestation, whereas the left umbilical vein loses its connection to the left horn of the sinus venosus and forms a channel, the ductus venosus, which connects it to the right vitelline vein.

The anterior (superior) cardinal veins, which drain the cephalic part of the embryo, and the posterior (inferior) cardinal veins, which drain the remainder of the embryo, join to form the common cardinal veins, which enter the respective horns of the sinus venosus. During the eighth week of gestation, the proximal (terminal) portion of the right anterior cardinal vein and the right common cardinal vein form the SVC

AL Grawany

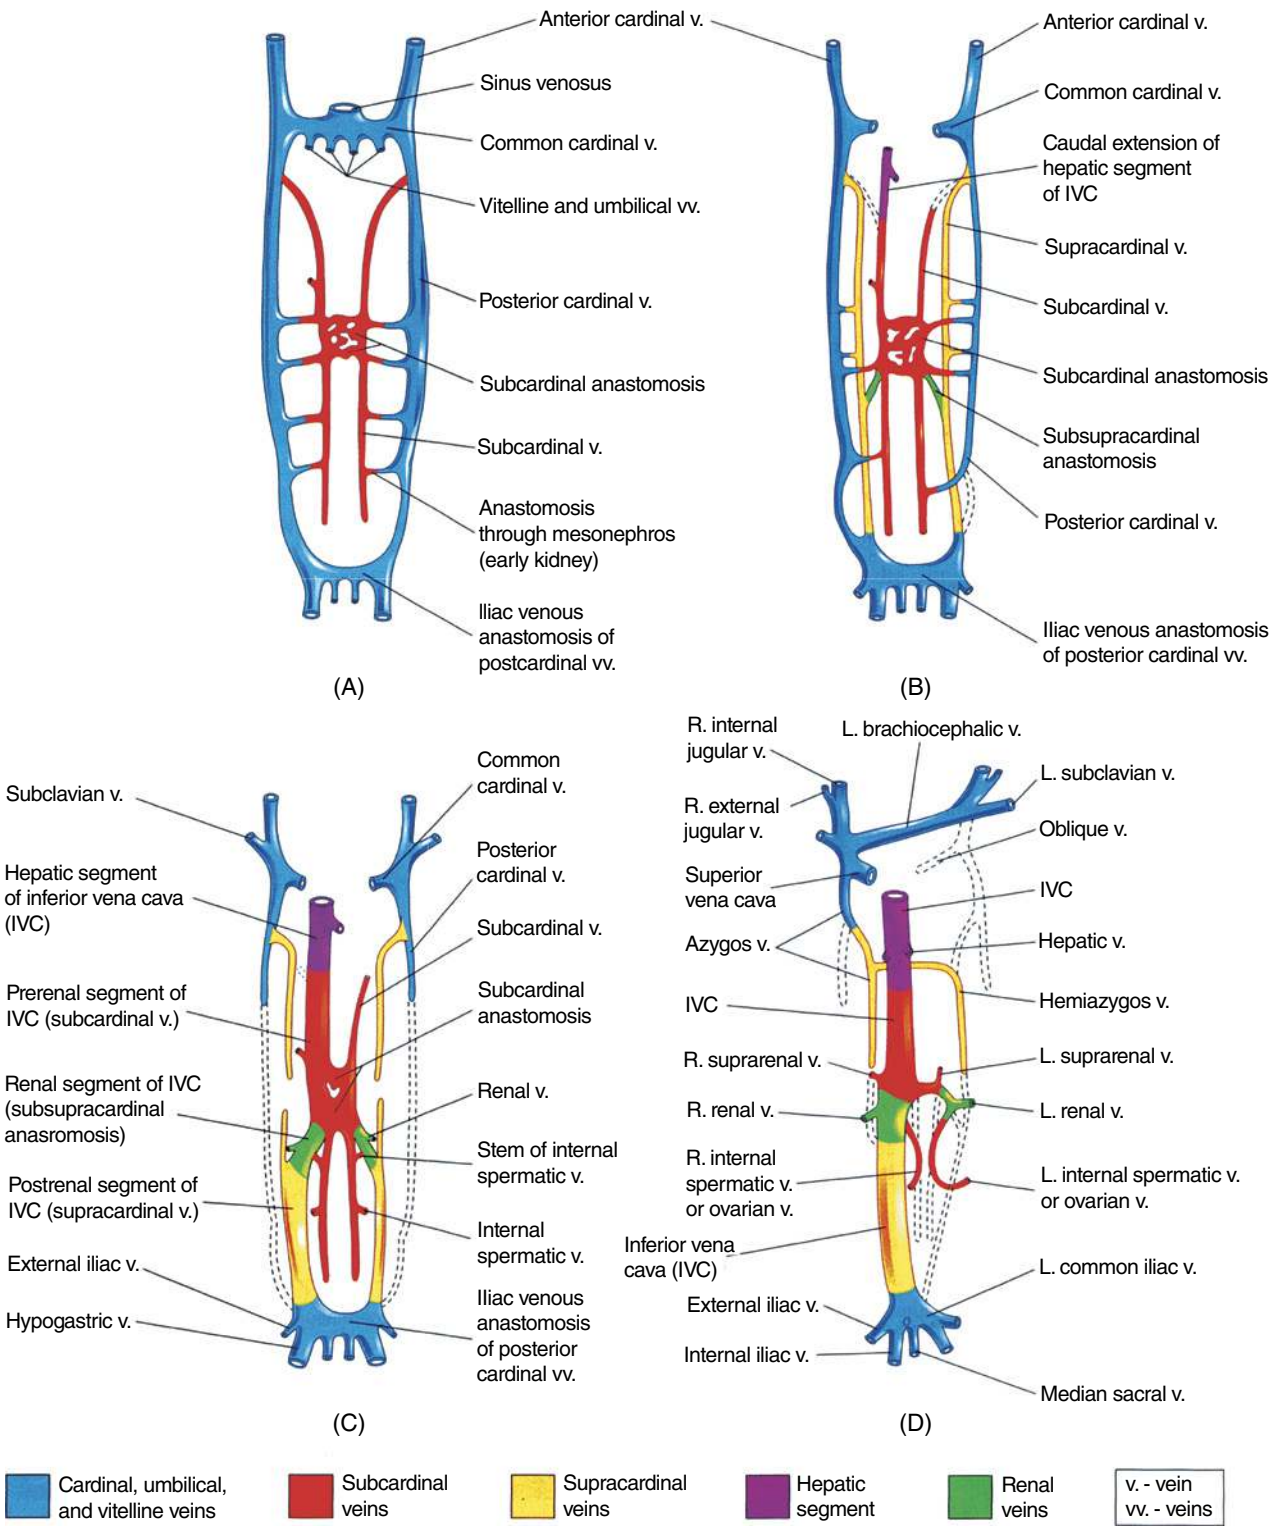

Figure 6.23 Illustrations of the primordial veins of bodies (trunks) of embryos (ventral views). Initially, three systems of veins are present: the umbilical veins from the chorion, vitelline veins from the umbilical vesicle, and cardinal veins from the body of the embryos. Next the subcardinal veins appear, and finally, the supracardinal veins develop. (A) At 6 weeks. (B) At 7 weeks. (C) At 8 weeks. (D) Adult. This drawing illustrates the transformations that produce the adult venous pattern. IVC, Inferior vena cava; L., left; R., right; v., vein; vv., veins. (Sources: Arey [149] and Moore et al. [131]. Figure 6.24 Dorsal views of the developing heart. (A) During the fourth week (approximately 24 days), showing the primordial atrium and sinus venosus and the veins draining into them. (B) At 7 weeks, showing the enlarged right sinus horn and venous circulation through the liver. The organs are not drawn to scale. (C), At 8 weeks, indicating the adult derivatives of the cardinal veins shown in (A) and (B). (Source: Moore et al. [131]. Reproduced with permission of Elsevier.)

(Figure 6.24). An anastomosis develops between the left and right anterior cardinal veins to form the left brachiocephalic (innominate) vein; the portion of the right anterior cardinal vein superior to the anastomosis will become the right brachiocephalic (innominate) vein. The terminal portions of the left anterior and common cardinal veins regress. Although a large portion of the posterior cardinal veins regresses, the right and left subcardinal veins sprout from the base of the posterior cardinal veins and grow caudally [150]. The left subcardinal vein regresses, but the right subcardinal vein

AL Grawany

loses its connection with the posterior cardinal vein and joins with the right vitelline vein to form the portion of the IVC between the liver and kidneys (prerenal segment). The right and left supracardinal veins also sprout from the base of the posterior cardinal veins and receive drainage from the intercostal veins. Together with a portion of the posterior cardinal veins, the right and left supracardinal veins form the azygos vein on the right and the hemiazygos vein on the left. The right supracardinal vein also anastomoses with the right subcardinal vein to form the portion of the IVC below the kidneys (renal segment). The sacral segment of the IVC is derived from the right and left posterior cardinal veins and the sacral segment connecting them. Thus, the IVC is made up of elements from four separate venous systems: the right vitelline vein between the liver and heart; the right subcardinal vein between the liver and kidneys; the right supracardinal vein below the kidneys; and the right and left posterior cardinal veins with the sacral segment connecting them.

Abnormalities of systemic vein development

The complex development of the venous system results in a wide spectrum of systemic venous anomalies. Heterotaxy syndromes result from disorders of left-right axis determination during early embryonic development and are frequently associated with systemic venous abnormalities [151]. Failure of the left anterior and left common cardinal veins to regress results in a *persistent left SVC* (LSVC), the prevalence of which is higher in patients with CHD. An LSVC may be found in association with a right SVC (*bilateral SVCs*) or may be the only SVC if the right anterior and right common cardinal veins have regressed. An LSVC will drain normally into the right atrium via the coronary sinus in the majority of cases, but it will drain into the left atrium if the coronary sinus is partially or completely unroofed. Bilateral SVCs with an unroofed coronary sinus usually occur in association with other congenital heart defects.

Failure of the hepatic segment of the IVC to form results in an *interrupted IVC* with azygos continuation into the right or left SVC; the hepatic veins in this setting drain directly into the right atrium. Multiple variations of *bilateral IVCs* can occur.

KEY POINTS: DEVELOPMENT OF THE SYSTEMIC VEINS

- The primitive systemic venous system consists of three bilaterally symmetric systems: the vitelline veins, the umbilical veins, and the cardinal veins.
- The shift of the systemic venous return to the right atrium is associated with regression and remodeling, resulting in the adult asymmetrical venous pattern.
- Alterations in the complex development of the venous system lead to a wide spectrum of systemic venous anomalies.

Development of cardiac innervation

The development and anatomy of cardiac innervation are complex and have been reviewed in detail previously [152, 153]. Neural crest cells give rise to the parasympathetic preganglionic neurons (cranial neural crest), the sympathetic chain, and sympathetic postganglionic neurons (truncal neural crest), and the ganglia and neurons of the intrinsic cardiac plexuses [154].

The heart has both sensory (afferent) and motor (efferent) innervation (148). Sensory information is relayed from the heart to the brain via both parasympathetic and sympathetic nerve pathways (Figure 6.25). One set of afferent nerves travels with the vagus nerve via the nodose ganglion (inferior ganglion of the vagus nerve) to the nucleus of the solitary tract in the brainstem. The second set of sensory nerves travels with the sympathetic nerves to the dorsal root ganglion and spinal cord. The parasympathetic afferents play a role in controlling both sympathetic and parasympathetic output, whereas the sympathetic afferents do not have any tonic influence over autonomic activity but are mostly nociceptive, as they are activated by coronary occlusion and register cardiac pain.

The motor (efferent) pathways are part of the autonomic nervous system, and both the parasympathetic and sympathetic pathways use preganglionic to postganglionic relays. Parasympathetic preganglionic neurons originate from the nucleus ambiguus and dorsal motor nucleus of the vagus in the medulla oblongata and use the vagus tracts to connect with postganglionic relays in the cardiac ganglia. Sympathetic preganglionic neurons originate in the intermediolateral column in the thoracic spinal cord and synapse with postganglionic neurons in the ganglia of the lower cervical and upper thoracic sympathetic chain [153].

The cardiac plexuses are an accumulation of mixed neurons, both efferent and afferent, on the epicardial surface near the arterial and venous poles. These plexuses comprise ganglia that are interconnected by local neuronal circuits and regulate control of regional cardiac function [153]. The ganglia have an intrinsic activity that is modulated by sympathetic and parasympathetic (vagal) inputs. Postganglionic parasympathetic nerves extend to the SA and AV nodes to innervate the cardiac conduction system [152]. Innervation of myocardial cells in the right atrium is predominantly cholinergic and that of the left atrium and left and right ventricles is predominantly adrenergic [155].

The cardiac nervous system develops and matures slowly and is not fully functional until well after birth [154]. Parasympathetic innervation precedes sympathetic innervation, so the parasympathetic–cholinergic system becomes functional before the sympathetic–adrenergic system. Autonomic receptor-mediated effector mechanisms are present before functional innervation (pre-innervation phase), thereby allowing a cardiac response to circulating catecholamines to mitigate the effects of hypoxia and bradycardia [152].

Abnormalities of cardiac innervation

Development of cardiac innervation during the fetal period can be associated with innervation abnormalities in adult life [152].

Dysautonomias result from impaired autonomic interactions due to inadequate development, migration, survival, and function of sensory and autonomic neurons; the sympathetic

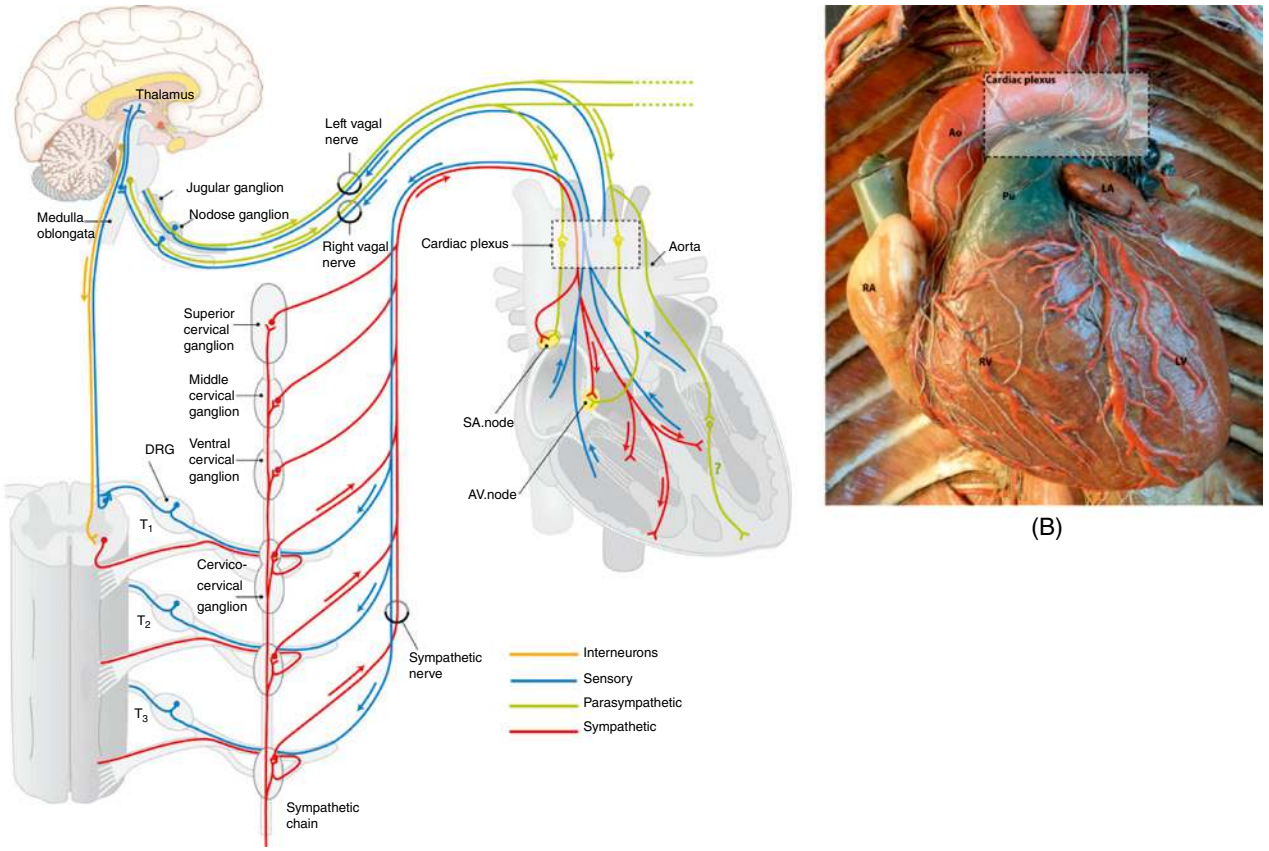

Figure 6.25 Overview of cardiac innervation. (A) Schematic drawing of the cardiac visceral innervation system. Cardiac innervation starts with a signal from the heart or baroreceptors (e.g., on the aorta), relayed by sensory nerves (blue) giving feedback on, for instance, the levels of oxygen, carbon dioxide and blood pressure. The brain will give a signal to parasympathetic or sympathetic nerves to either relax or stimulate the heart. Parasympathetic innervation is achieved mainly via the vagal nerve (green) that will synapse in cardiac ganglia from where postganglionic nerves innervate the SA node and AV node, and potentially ventricular myocytes. Sympathetic neurons (red) start in the grey matter of the spinal cord, where interneurons (orange) from the brain project to the sympathetic neurons. Via the ventral root of the spinal cord, sympathetic nerves synapse in the sympathetic chain, from where postganglionic nerves will enter the heart. (B) This wax mold shows how cardiac nerves enter via the cardiac plexus and follow cardiac vessels over the heart. neurons are affected more often than the parasympathetic neurons [156]. *Familial dysautonomia* (Riley–Day syndrome) is the best known of the hereditary sensory and autonomic neuropathies and is associated with orthostatic hypotension and an increased risk of sudden death. It is caused by mutations of the IKAP gene on chromosome 9q31 which affects the development of neurons and is associated with catecholamine hypersensitivity [157, 158].

Sudden infant death syndrome has been linked to abnormal development of the autonomic nervous system, with the final pathway thought to involve immature cardiorespiratory autonomic control with failure of the arousal responsiveness from sleep [159]. Multiple underlying candidate genes have been identified [160].

Autonomic dysfunction is present in individuals with Down syndrome as shown by chronotropic incompetence, reduced heart rate and blood pressure responses to autonomic tasks, and low work capacity [161–163]. This dysfunction may or may not be present at rest [164]. The risk of bradycardia is increased during induction of anesthesia in children with Down syndrome [165].

KEY POINTS: INNERVATION OF THE DEVELOPING HEART

- The heart has both sensory (afferent) and motor (efferent) innervation.
- The cardiac nervous system develops and matures slowly and is not fully functional until well after birth.

- Parasympathetic innervation precedes sympathetic innervation.
- Abnormalities in cardiac innervation may result from impaired autonomic interactions and abnormal development of the autonomic nervous system.

Development of the cardiac lymphatics

The heart has an extensive evolutionarily conserved lymphatic network. As reviewed by Gancz and colleagues, myocardial contractions force lymph in a unidirectional fashion from lymphatic capillaries in the endocardium and myocardium through extensive collecting vessels to the epicardium [166]. The lymph is then drained from the apex to the base and ultimately to the mediastinal lymph nodes. A reduction in lymph flow rate or an increased microvascular permeability leads to interstitial edema and myocardial dysfunction [167].

Lymphatic capillaries sprout from the mediastinal lymphatics around the eighth embryonic week [166]. By the beginning of the fourth month, these capillaries have extended from the base of the heart along the coronary arteries to cover most of the epicardial surface. Inward lymphatic growth then takes place in the myocardium and epicardium. Although the development of the cardiac lymphatic system ends prenatally, myocardial infarction is associated with a strong lymphangiogenic response in the infarcted zone [168]. Therapeutic strategies to boost this lymphangiogenesis are being evaluated to promote heart regeneration.

Summary

Table 6.2 shows the stages of human development and provides a timeline of the corresponding events in the development of the cardiovascular system, summarizing the information discussed in this chapter [26]. Four cell lines (cardiomyocytes, endocardium, epicardium, and endothelium) are derived from the mesoderm to form the building blocks of the heart and vascular system (Figure 6.26) [30]. Cardiac neural crest cells are critical to the formation and remodeling of the aortic arch arteries, outflow tract septation, semilunar valvulogenesis, cardiac neuronal tissue, and the insulation of the conduction system [169]. Reactivation of cardiac stem cells has opened the door for using regenerative medicine and novel therapies for treating congenital and acquired heart disease [11].

Table 6.2 Stages of human development with corresponding events in cardiac development

Carnegie stage	Human DPC	Mouse DPC	
CS8	17–19	7	The cardiac crescent forms
CS9	19–21	7.5	The embryo folds, the pericardiac cavity is placed in its final position, the gully of myocardium forms, the endocardial plexus forms, cardiac jelly forms
CS10	22–23	8	The heart beats, the endocardial tubes fuse, the **mesocardium** perforates, looping starts, the ventricle starts ballooning
CS11	23–26	8.5	The atria balloon, the pro-epicardium forms
CS12	26–30	9.5	The septum primum appears, the right venous valve appears, the muscular part of the ventricular septum forms, cells appear in the cardiac jelly, the epicardial growth starts
CS13	28–32	10.5	The atrioventricular cushions form, the pulmonary vein attaches to the atrium, the left venous valve appears, epicardial mesenchyme appears first in the atrioventricular sulcus
CS14	31–35	11.5	The atrioventricular cushions form, the pulmonary vein attaches to the atrium, the left venous valve appears, epicardial mesenchyme appears first in the atrioventricular sulcus
CS15	35–38	12	The atrioventricular cushions approach one another, the outflow ridges become apparent, capillaries form in the epicardial mesenchyme
CS16	37–42	12.5	The primary atrial septum closes, the outflow tract ridges approach the interventricular septum. The entire heart is covered in epicardium
CS17	42–44	13.5	Secondary atrial septum appears, the sinus node becomes discernible, the left and right atrioventricular connections become separate, the proximal outflow tract becomes septated, the semilunar valves develop
CS18	44–48	14.5	Papillary muscles appear, the atrioventricular valves start to form
CS19	48–51	15	The left venous valve fuses with the secondary septum, the mural leaflets of the mitral and tricuspid valve are released
CS21	53–54	16	The main branches of the coronary artery become apparent
CS22	54–56	16.5	The chordae tendinae form
CS23	56–60	17.5	The septal leaflet of the tricuspid valve delaminates

Introduction

It is well recognized that the large number, wide spectrum, and complex nature of congenital malformations of the cardiovascular system can make it quite challenging to understand the corresponding structural abnormalities and their associated functional and hemodynamic consequences. This issue can be further complicated by the seemingly bewildering nomenclature and classification systems used in congenital and pediatric cardiology. In addition, the diverse terminology (at times, different terms can even be used to refer to the same anatomic structure, pathologic finding, or lesion) and the numerous classification schemes for categorizing individual anomalies can pose obvious difficulties [1, 2]. This variable taxonomy can be confusing for many, but it is even more perplexing for individuals with limited knowledge or familiarity with the subject, further adding to the intimidating aspects of congenital heart disease (CHD).

Many clinicians have acknowledged the critical need for a consistent nomenclature and classification system for CHD that can be widely accepted by all disciplines involved in the care of these patients. As far back as the late 1970s, Shinebourne et al. indicated that "for a nomenclature system to be of value, it needed to be capable of describing any combination of cardiac malformations which may be encountered" [3]. It was also noted that the scheme "should allow for precise classification of such malformations during a patient's life." The lack of a consistent nomenclature for describing the various defects or uniform classification scheme for CHD continues to be a source of frustration and confusion in everyday practice. Work in this area is still ongoing but over the last several years significant progress has been made in the development of comprehensive standardized nomenclature and a classification code with the goal of unifying the terminology for pediatric and congenital cardiac care as will be highlighted in this chapter.

An understanding of the approaches developed to describe CHD and the elements considered in the morphologic assessment of the heart are important aspects of the practice of pediatric/congenital cardiac anesthesiology. This chapter provides a brief overview of the essential steps involved in anatomic evaluation in CHD. It addresses the segmental analysis of the heart and other relevant components of the diagnostic assessment of the congenitally malformed heart, but it does not dwell on the specifics of one

AL Grawany

language or taxonomy over the other for describing CHD. Thus, the discussion is not meant to be comprehensive but, instead, it aims to emphasize important points related to the structural evaluation of a patient with CHD. A discussion of the various classification systems for congenital cardiac lesions is beyond the scope of this chapter but is addressed in various chapters throughout this textbook.

Congenital heart surgery nomenclature and database project

In the late 1990s, the Society of Thoracic Surgeons, in collaboration with The European Association for Cardiothoracic Surgery, launched the International Congenital Heart Surgery Nomenclature and Database Project with the hope of standardizing the nomenclature used for CHD. One of the goals was to establish a foundation to facilitate multi-institutional analysis of patient outcomes. This effort led to the adoption of a common nomenclature and classification system of pediatric and CHD by these professional organizations [4]. Concurrently, another international nomenclature system, the European Paediatric Cardiac Code, was developed for congenital cardiac disease [5, 6]. In 2000, The International Nomenclature Committee for Pediatric and Congenital Heart Disease was created, which evolved into a society with various components, including a Nomenclature Working Group. As a result, the *International Pediatric and Congenital Cardiac Code* (IPCCC) was eventually developed, which allowed for cross-mapping of the two nomenclature systems for CHD [7]. The aim of the project was to provide an all-inclusive, internationally accepted, cohesive, and comprehensive system for describing pediatric cardiovascular diseases and CHD using a common nomenclature. This undertaking would ultimately enhance communication among healthcare providers; facilitate education, research, and patient care; and allow for multicenter assessment of clinical outcomes, quality assurance, risk stratification, and many other important benefits. In fact, the IPCCC nomenclature and classification code, in conjunction with the database created by the International Congenital Heart Surgery Nomenclature and Database Project can be freely downloaded from the internet (www.ipccc.net) and is currently being used worldwide. It has served as a resource in extensive surgical outcome analyses involving large numbers of patients. The reader is referred to various publications related to these projects, which address the nomenclature for specific defects, consensus definitions for several complex cardiac anomalies, classification schemes, and applications [8–24]. Ongoing collaborations with the World Health Organization, other international groups addressing standard medical terminology, and the health care industry, are likely to further advance this effort. In fact, this classification system has been accepted for incorporation into the 11th iteration of the International Classification of Diseases (ICD-11], representing a major step for further standardization of nomenclature across the globe [23, 25]. Despite the remarkable efforts to establish a comprehensive standardized nomenclature and hierarchical classification system, it is well recognized that ongoing debate and discussion will continue to take place in clinical practice while these schemes continue to be refined [24].

KEY POINTS: THE INTERNATIONAL PEDIATRIC AND CONGENITAL CARDIAC CODE (IPCCC)

- When initially developed, the IPCCC allowed for cross-mapping of two different nomenclature systems for CHD.
- The goal of this effort was to overcome the limitations of various nomenclature systems by creating a comprehensive and consistent common language.
- The IPCCC is used widely today and represents a standardized international nomenclature and classification system for pediatric and congenital heart disease.
- This classification system has been accepted by the WHO for incorporation into the 11th iteration of the ICD coding system (ICD-11 code).

Approaches for describing congenital heart disease

Several publications have addressed, in detail, the applications of an organized anatomic analysis in the diagnosis of CHD and the steps involved in a comprehensive structural assessment [3, 26–33]. The *segmental approach*, as initially described by Richard Van Praagh and colleagues in the 1960s, relies upon an examination of cardiac anatomy in a series of segments or "building blocks" [34, 35]. These major units are considered the essential components of the heart, whether normal or diseased [26]. The anatomy of the various cardiac segments and their relationships to each other represent the foundation of the segmental analysis. Robert Anderson and colleagues expanded upon this concept but reduced the emphasis on relationships by proposing a scheme based on blood flow through the heart, which focused on characterizing the connections between the segments [28, 32]. Based on this approach, the *sequential segmental approach* was developed.

The detailed methodology used in the sequential segment-by-segment approach allows for a stepwise examination of all cardiac segments by navigating through the heart in the direction of blood flow from the atria to the ventricles to the great arteries. The three main segments are the veins and atria, ventricles, and great arteries. The units are joined to each other by two connecting cardiac segments (or junctions): the atrioventricular (AV) junction (AV canal region), which connects the atria to the ventricles, and the ventriculoarterial (VA) junction (infundibulum/conus arteriosus), which connects the ventricles to the great arteries (Figure 7.1). This systematic examination offers an organized and rigorous method that facilitates the defining of congenital cardiovascular defects. The benefit of this analysis is that it can be applied to all congenital cardiac malformations, although it is particularly useful for characterizing complex defects. The merits of this approach are reflected in the fact that this system has been incorporated into clinical use within various disciplines related to CHD and applied in the evaluation of fetuses to adults [36–42].

The "Van Praaghian" and "Andersonian" nomenclature systems

Historically, and based on the development of the nomenclature as previously described, there have been two major

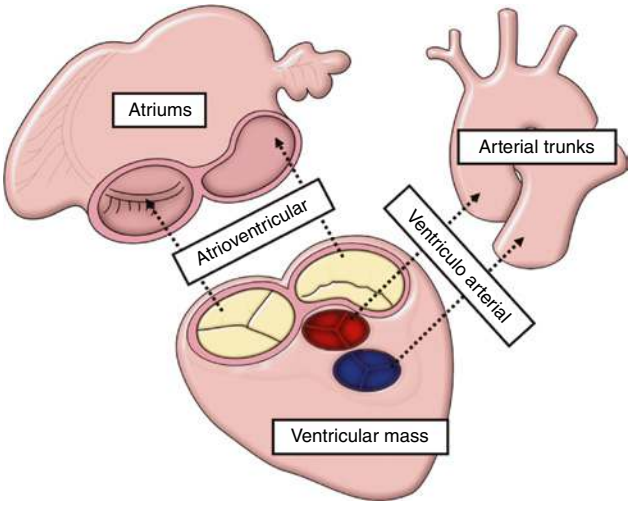

Figure 7.1 Sequential segmental analysis. Figure depicts the key components of the sequential segmental analysis: the three major building blocks (atria, ventricles, arterial trunks) and their joining segments (atrioventricular and ventriculoarterial junctions). (Source: Ms. Gemma Price. Reproduced with permission.)

philosophies regarding the segmental assessment of the congenitally malformed heart. These schools of thought have been led by two world-renowned leaders in the field: Drs. Richard Van Praagh and Robert H. Anderson. Colloquially, these have been referred to as the "Van Praaghian" and "Andersonian" nomenclature systems. The Van Praagh classification system was pioneered and evolved in Boston, Massachusetts and is widely used in North America, whereas that by Anderson was developed and is conventional throughout Europe.

Although these approaches to describe cardiac anatomy share common elements, there are many important differences. A significant one relates to the shorthand notation used in the Van Praagh system to facilitate communication among providers involved in the diagnosis and management of patients with CHD as described to follow. Other divergent viewpoints include terminology and the methods used to describe morphology and cardiac pathology. The disparities between the two major schools of nomenclature have created disagreements among advocates and specialists in the field, sometimes resulting in heated arguments and controversies between the different camps. Efforts have been made to reconcile these two approaches in recognition of the fact that both of these systems have virtues and that, in many ways, they may complement each other [43, 44]. The reader is referred to the excellent resource entitled *Atlas of Congenital Heart Disease Nomenclature: An Illustrated Guide to the Van Praagh and Anderson Approaches to Describing Congenital Cardiac Pathology* for an in-depth discussion on these two nomenclature systems [45].

Although clinicians have generally been divided as followers of the teachings of one school or the other, many practitioners have opted for a stance somewhere in the middle recognizing that the likelihood of implementing a single, universally accepted system is remote, and they continue to see merits in the various schemes currently used [46]. It should also be recognized that even these systems have evolved in their thinking over time [47]. In some cases, an alternate approach has been to simply describe the anatomy without regard for either system. Despite personal preferences, the expectation in most cases is for providers of CHD patients to be fluent in these nomenclature systems. It should be emphasized that regardless of the nomenclature or scheme favored, it is more important that each institution has a uniform and consistent approach for describing and referring to the various defects or structural abnormalities to optimize communication among all practitioners involved in patient care.

The Van Praagh notation

A unique feature of the Van Praagh style is the use of a three-letter notation, or code, enclosed in braces or curly brackets {X,X,X}. The letters in the set are abbreviations separated by commas that represent the sidedness or anatomical organization (referred to as "situs") of the three main cardiac segments of the heart in venoarterial sequence (atria, ventricles, great arteries) [2, 30]. In essence, the segments are to be considered in terms of the following:

- the atrial situs or sidedness of atrial chambers
- ventricular loop (ventricular topology)
- spatial relationship of the arterial trunks

The possibilities for each segment are denoted by different letters as shown in Box 7.1 (also refer to the discussion later in the chapter).

The normal anatomic configuration would be indicated by the notation coding of {S,D,S}. This notation corresponds to visceroatrial situs solitus or {S,-,-} with the vena cavae and the morphologic right atrium on the right side, and the morphologic left atrium on the left side; D-loop ventricles {-,D,-} where the right ventricle is right-handed, rightward and anterior to the morphologic left ventricle, whereas the left ventricle is left-handed, leftward and posterior as a result of a cardiac tube curved rightward (dextro or D-loop); and normal situs solitus of the great arteries {-,-,S} where the pulmonary artery is located anterior and leftward to the aorta. This shorthand system does not specify the "alignments" (AV or VA) between the cardiac segments, a term preferred by Van Praagh

Box 7.1: Van Praagh notation

In the Van Praagh notation the letters are abbreviations that represent the sidedness or anatomical organization (referred to as situs) of the three main cardiac segments of the heart in venoarterial sequence (atria, ventricles, and great arteries).

- *For the atrial situs (first letter)*:
  - "S" for "situs solitus" (normal arrangement)
  - "I" for "situs inversus" (mirror image arrangement)
  - "A" for "situs ambiguus"
- *For the ventricular loop (second letter)*:
  - "D" for "D-loop" (rightward orientation)
  - "L" for "L-loop" (leftward orientation)
  - "X" for cases where looping cannot be defined
- *For the position and relationship of the great arteries (third letter):*
  - "S" for normally related
  - "I" for inverted or mirror image relationship
  - "D" for D-transposed or malposed great arteries, with aorta to the right of the main pulmonary artery
  - "L" for L-transposed or malposed great arteries, with the aorta to the left of the main pulmonary artery
  - "A" for the aorta directly anterior to the main pulmonary artery

AL Grawany

over "connections," nomenclature favored by Anderson, to describe the segments between the atrial and ventricular chambers, and the ventricles and great arteries. In this system, the segmental alignments are noted separately [30, 31, 48]. As per Van Praagh, "significant abnormal VA alignments such as transposition of the great arteries (TGA) are indicated *before* the braces: TGA {-,-,-}," while "important abnormal segmental connections and other associated cardiovascular anomalies are listed *after* the braces: {-,-,-} with straddling tricuspid valve and ventricular septal defect of the AV canal type" [2].

At first glance, this nomenclature system may appear relatively straightforward and easy to understand, in fact, it has been widely utilized in many aspects of diagnostic imaging including echocardiography and radiology [41, 42]. However, the combination of letters can be somewhat complex to decode or interpret, particularly for individuals who are not familiar with the shorthand nomenclature. In addition, although the segmental classification scheme can be used to describe most congenital heart defects, some anomalies, such as heterotaxy syndromes, can be difficult to define precisely using this scheme. Therefore, even though it is well recognized and widely applied, this system has not been universally embraced. Some consider a more descriptive approach less likely to cause confusion, particularly, in the case of complex CHD [49].

KEY POINTS: APPROACHES FOR DESCRIBING CHD

- The sequential segmental approach is the essence of diagnostic assessment for CHD.
- This approach allows for a stepwise examination of all cardiac segments by navigating through the heart in the direction of blood flow.
- There are two major philosophies regarding the segmental assessment of the congenitally malformed heart: one led by Dr. Richard Van Praagh and the other by Professor Robert H. Anderson.
- An alternate approach consists of describing the anatomy without regard for either system, particularly in the case of complex CHD.
- It is more relevant for each institution to have a uniform and consistent system for describing and referring to the various congenital cardiac anomalies.

Segmental approach to diagnosis of congenital heart disease

For many decades, and with both the Van Praagh or Anderson systems, the *segmental approach* has been used to characterize congenital anomalies that affect the heart and related vascular structures [3, 26]. The steps taken in this segmental analysis are described in the sections that follow.

Cardiac position and apex orientation

The aspect of CHD evaluation related to cardiac position can be confusing because it is described differently by various sources and the terminology used (Figure 7.2). One approach describes the cardiac position as the spatial location of the majority of the cardiac mass within the thoracic cavity, using the sternum as the midline reference. The term *levocardia* indicates that the heart occupies most of the left hemithorax (i.e., a left-sided heart), *dextrocardia* indicates that the heart is in the right hemithorax (i.e., right-sided heart), and *mesocardia* indicates that the heart is in the midline position. In addition, a distinction is made between primary and secondary dextrocardia; the former is due to a structural cardiac defect, whereas the latter results from the heart being displaced by extracardiac conditions.

A second approach specifies both the cardiac position and orientation, as these are not to be considered synonymous when describing cardiac location. In this scheme, as in the previously mentioned approach, cardiac position refers to the overall location of the cardiac mass relative to the midline; however, the terminology is used differently. In this algorithm, the terms *levoposition*, *dextroposition*, and *mesoposition* are used to indicate that the cardiac mass is predominantly in the left hemithorax, right hemithorax, or middle, respectively. Furthermore, the terms levocardia, mesocardia, and dextrocardia are used to describe cardiac orientation, or alignment from the base (great arteries) to the apex (ventricular apex), instead of cardiac position. Levocardia indicates that the heart's cardiac apex points to the left side of the chest, mesocardia indicates that the heart's cardiac apex points straight inferiorly, and dextrocardia indicates that the heart's apex points to the right. Displacement of the heart into the right or left thoracic cavity is described as *dextropositioning* or *levopositioning*, respectively. Other terminology used related to the orientation of the cardiac apex is "levoversion" if it points to the left and "dextroversion" if it points to the right.

In most cases, the cardiac position and base-to-apex orientation are in agreement, meaning that both are aligned in the same direction. For example, in the case of the normal heart, the cardiac mass is in the left hemithorax and the ventricular apex is directed towards the left. Consequently, the distinction between these two parameters is irrelevant in most cases. However, when the heart is displaced, for example by the presence of abdominal contents in an infant with a congenital left diaphragmatic hernia, the cardiac mass may be pushed to the right hemithorax (dextroposition), while the cardiac apex still points to the left (levocardia). In such cases, the two descriptors should be noted. At times, these features are critically important for surgical planning.

It should be recognized that cardiac position and apex orientation cannot be utilized to establish cardiovascular anatomy, nor do these have a predictable relationship to cardiac pathology. A good example of this issue is the patient with dextrocardia in which complex CHD may be found or in some instances, a structurally normal heart.

KEY POINTS: CARDIAC POSITION AND APEX ORIENTATION

- Cardiac position refers to the spatial location of the majority of the cardiac mass within the thoracic cavity.
- Cardiac orientation refers to the alignment from the base (great arteries) to the apex (ventricular apex).
- In most cases, the cardiac position and base-to-apex orientation are in agreement.

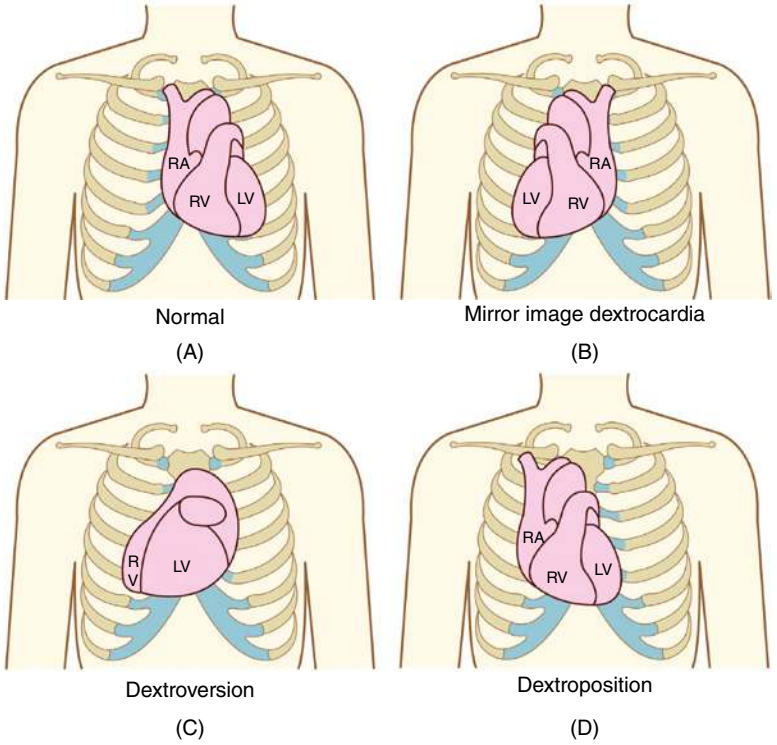

Figure 7.2 Pictorial representation of an anteroposterior view of the thorax showing (A) the normal position of the heart, (B) mirror image dextrocardia, (C) dextroversion, and (D) dextroposition. (Source: Ahmad et al. [50]. Reproduced with permission of Elsevier.)

Visceral and atrial situs

The first step of the sequential analysis, before defining the cardiac structures, is evaluating the anatomic relationships of the viscera (i.e., the abdominal and thoracic organs). This is referred to as determining the *visceral situs*, or pattern of anatomic organization (meaning sidedness). In clinical practice, to determine the visceral situs, the abdominal viscera are examined, focusing on the position of the liver, stomach, spleen, and abdominal great vessels (i.e., the aorta and inferior vena cava [IVC]). This examination is primarily performed using ultrasonography. The situs of the thorax can be evaluated by assessing bronchial morphology, as determined, for example, by chest radiography.

In the human body, there are distinct left-sided and right-sided structures [51]. In the normal arrangement, the liver is on the right side of the body, whereas the stomach and spleen are on the left. There is also a distinctive pattern to each lung in terms of lobes, anatomy of the bronchi, and course of the bronchi with respect to the associated pulmonary artery. The normal anatomic layout is characterized as follows: the right lung comprises three lobes, a short main bronchus, and a course of the bronchus above the right pulmonary artery (eparterial), whereas the left lung comprises two lobes and a longer left main bronchus (as compared with the right bronchus) that courses below the left pulmonary artery (hyparterial).

The normal (usual) arrangement of the thoracoabdominal organs is referred to as *visceral situs solitus*. In contrast, the mirror image arrangement, in which the left–right position and orientation of the organs is reversed, is referred to as *visceral situs inversus*. A third type of arrangement is referred to as *situs ambiguus* (Latin spelling; the term "situs ambiguous" commonly used, as in this chapter), which is defined in Van Praagh's school as "an abnormality in which there are components of situs solitus and situs inversus in the same person" [17]. In both situs solitus and situs inversus, an asymmetric pattern of the abdominal/thoracic organs is present. In contrast, in situs ambiguous there is symmetry of the abdominal/thoracic organs, but their position/orientation is variable. It has been proposed that "situs ambiguous can be considered to be present when the thoracic and abdominal organs are positioned in such a way with respect to each other as to be not clearly lateralized and thus have neither the usual, or normal, nor the mirror-imaged arrangements" [17]. When this arrangement occurs, there is a tendency towards duplication of either right-sided or left-sided structures. This abnormal anatomic organization is frequently found within the context of *heterotaxy*, which is defined as "an abnormality where the internal thoraco-abdominal organs demonstrate abnormal arrangement across the left-right axis of the body" [17]. In heterotaxy syndromes, a spectrum of cardiac and extracardiac anomalies can be present, including absence of lateralization of the abdominal viscera, lack of a spleen or presence of multiple spleens (*asplenia* and *polysplenia syndromes*), and rotation defects of the gastrointestinal system, among other defects.

Atrial situs is a term used to describe the arrangement of the atria as determined by the position of the morphologic

AL Grawany

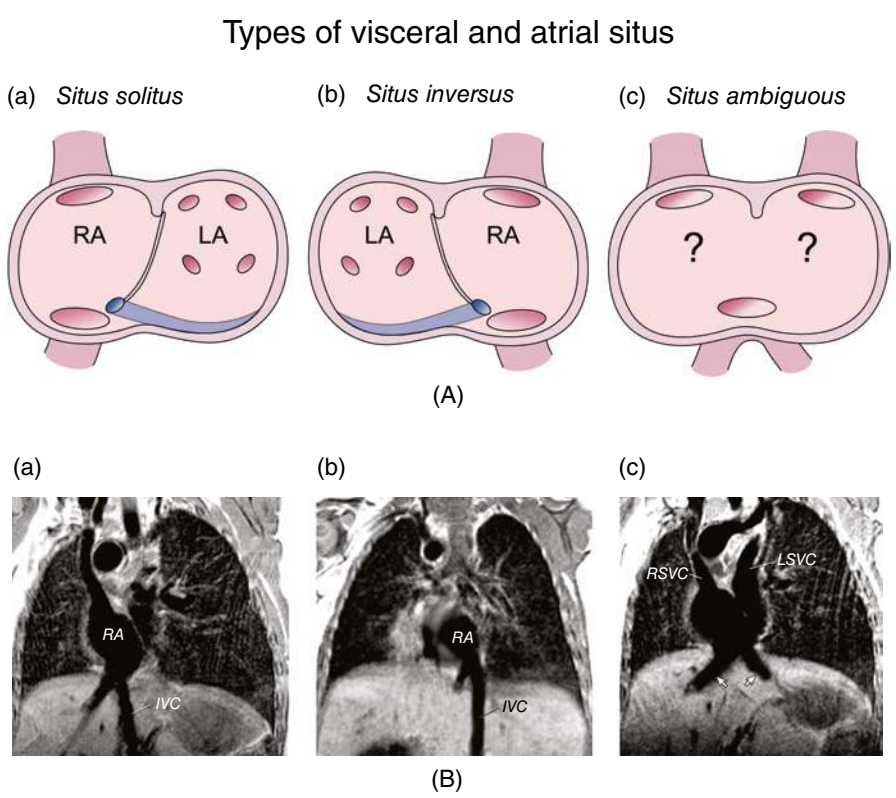

Figure 7.3 Atrial situs. (A): Graphic depiction of the various types of atrial situs (solitus, inversus, and ambiguous). In atrial situs solitus (a), the right-sided right atrium (RA) receives the caval veins and the orifice of the coronary sinus. The left-sided left atrium (LA) receives the pulmonary veins. In atrial situs inversus (b), the RA is left-sided and the LA is right-sided. In atrial situs ambiguous (c), the situs cannot be determined, as is frequently the case in heterotaxy syndrome. (B) Coronal plane spin echo magnetic resonance imaging in patients with heterotaxy syndrome and atrial situs solitus (a), atrial situs inversus (b), and atrial situs ambiguous (c). IVC, inferior vena cava; LSVC, left superior vena cava; RA, right atrium; RSVC, right superior vena cava. (Source: Geva [52]. Reproduced with permission of John Wiley & Sons.)

right and left atria. To evaluate the atrial situs, one must first morphologically identify the atrial chambers as described in the following section. The visceral anatomy may be used as an aid when defining atrial morphology because the atrial situs usually follows that of the viscera. Once the atrial chambers are identified, their arrangement (atrial situs) is defined (Figure 7.3). In *atrial situs solitus* (the normal arrangement), the morphologic right atrium is to the right of and anterior to the morphologic left atrium. In *atrial situs inversus*, the morphologic right atrium is to the left of and anterior to the morphologic left atrium. In *atrial situs ambiguous*, it is not feasible to clearly define the atrial sidedness.

The approach by Anderson classifies the atrial arrangements into four different types based on the morphology of the atrial appendages. Two of these variants fall within the category of *isomerism*, a term used to describe symmetry of a body structure or a mirror-image arrangement, in this case the atrial appendages. The four possible arrangements of the atrial chambers are *usual* (normally arranged or situs solitus), *mirror-imaged* (situs inversus), and – when both appendages have either right or left morphologic characteristics – the pathologic variants are referred to as either *right* or *left atrial isomerism*, respectively (Figure 7.4) [53–55]. Although the concept of isomerism as it relates to cardiac structures has been debated, the term is ubiquitous in day-to-day CHD parlance [56]. These atrial arrangements are associated with isomerism of the thoracic organs; *right isomerism* is usually found with asplenia, and *left isomerism* is found with polysplenia (Figure 7.5) [58].

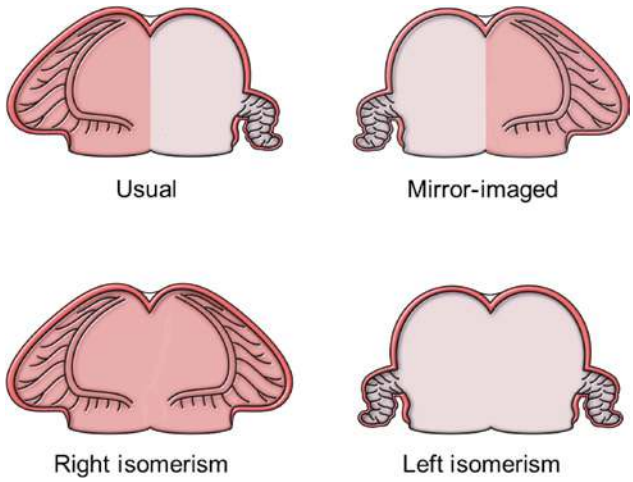

Figure 7.4 Atrial arrangements. The figure shows the four possible patterns of the atria (usual, mirror-imaged, right isomerism, and left isomerism) based on the morphology of the atrial appendages. (Source: Ms. Gemma Price. Reproduced with permission.)

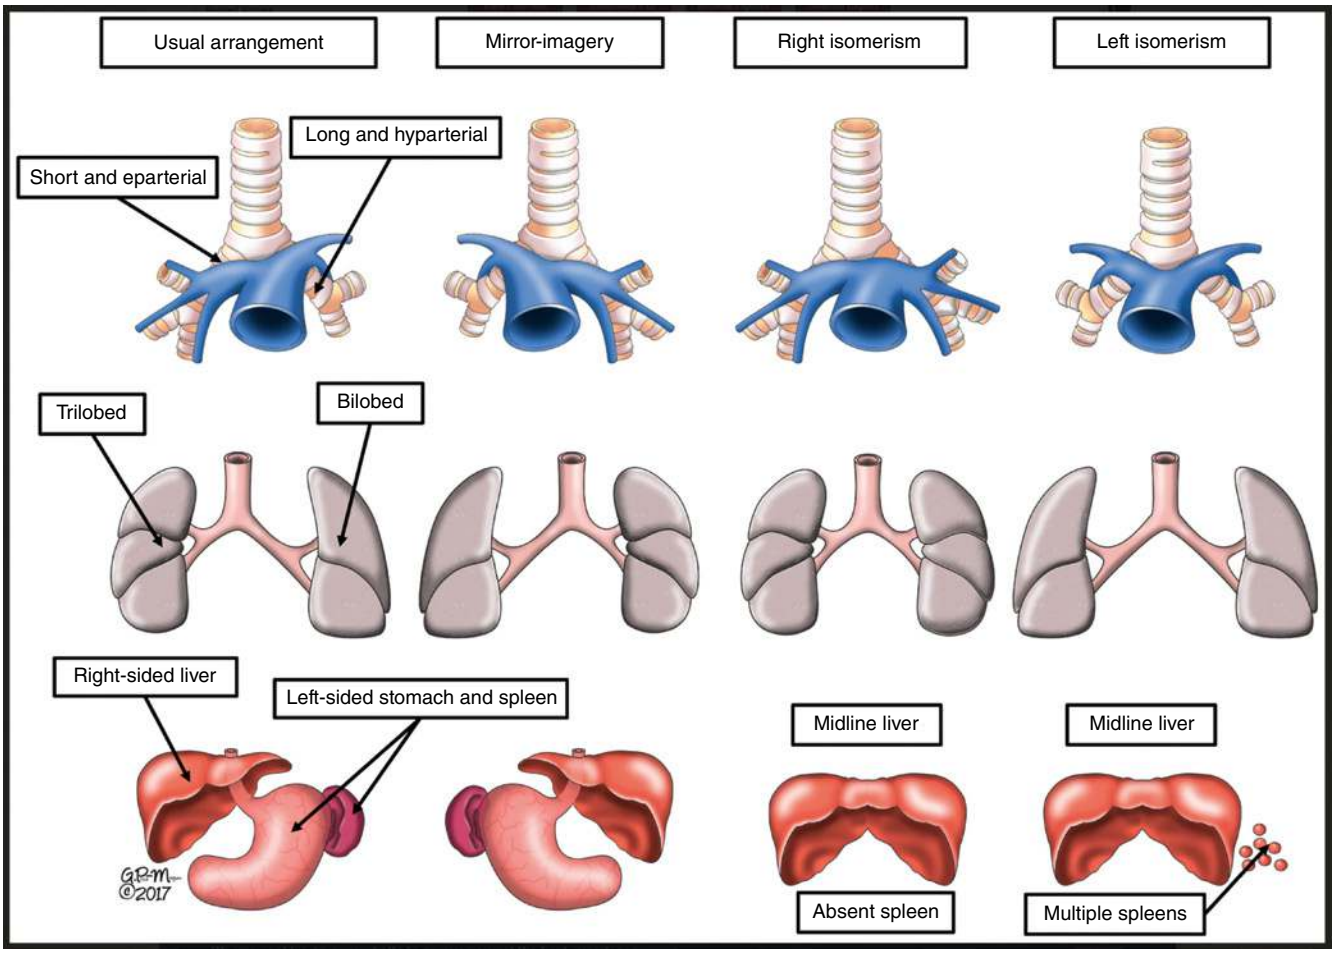

Figure 7.5 Variations of the bodily organs. The graphic displays the lateralized (left two columns) and isomeric (right two columns) arrangements of the bodily organs in the clinical settings. The *upper panels* show the bronchial morphology, and the relations of the bronchi to the pulmonary arteries. The *middle panels* show the pulmonary (lobar) morphology. The *lower panels* show the arrangement of the abdominal organs. (Source Anderson [57] / MDPI / CC BY 4.0.)

Because the atrial situs rarely differs from the visceral situs, as previously indicated, one may refer to this as the *visceroatrial situs*. In the Van Praagh shorthand notation [59], the types of visceroatrial situs are denoted as "S" for *situs solitus*, "I" for *situs inversus*, and "A" for *situs ambiguous*. Van Praagh has emphasized that the term situs ambiguous denotes that the visceroatrial situs is anatomically uncertain or indeterminate – as such, it is not a distinct or third type of situs, but rather a term used to indicate that the type of visceroatrial situs cannot be defined. As discussed under visceral situs ambiguous, this situs is usually seen in children with heterotaxy syndrome. In bilateral right-sidedness, or *right visceroatrial isomerism*, the atria, lungs, and bronchi are morphologically right-sided (Figure 7.5). Conversely, in bilateral left-sidedness, or *left visceroatrial isomerism*, the atria, lungs, and bronchi are morphologically left-sided. It must be emphasized that organ location, or situs, can differ, and discordance of the situs of different organs can exist (Figure 7.5).

KEY POINTS: VISCERAL AND ATRIAL SITUS

- The initial step of the sequential analysis involves assessing the visceral situs or anatomic relationships of the thoracoabdominal organs.
- The atrial situs rarely differs from the visceral situs.
- The three types of visceroatrial situs are situs soltitus (normal arrangement), situs inversus (mirror image arrangement), and situs ambiguous.
- In both situs solitus and situs inversus, there is asymmetry in the pattern of the abdominal/thoracic organs; by contrast, in situs ambiguous, a symmetric pattern is present with a tendency towards duplication of either right-sided or left-sided structures.
- Visceral situs ambiguous is usually associated with heterotaxy syndrome.

Great veins and atria

The structures most frequently considered under the subject heading of great veins are the vena cavae, pulmonary veins, and coronary sinus. *Systemic venous drainage* in the normal heart is via the superior vena cava (SVC) and IVC. These right-sided structures drain into the right atrium. The coronary sinus receives blood from the cardiac veins and empties into the floor of the right atrium, near the inferior aspect of the atrial septum and the orifice of the IVC. *Pulmonary venous drainage* is via the upper and lower right- and left-sided pulmonary veins. Venous variants (e.g., left SVC to the coronary sinus) or anomalies (e.g., interrupted IVC with azygous continuation or anomalous pulmonary venous connections) may co-exist with other defects in CHD; therefore, a complete anatomic examination includes an assessment of these structures to determine primarily their presence, patency, and sites of drainage.

Anatomic landmarks are the primary criteria used to identify and distinguish between the atrial chambers (Box 7.2). In a *morphologic right atrium*, the trabecular portion (pectinate muscles) extends from the crista terminalis to the base of the atrial appendage. A smooth sinusal portion is present between the crista terminalis and atrial septum. The septal aspect of the right atrium displays the superior and inferior limbic bands of the fossa ovale. The limbus is a thick muscular structure that can be used to identify the right atrium. The right atrial appendage has a broad base and a blunt tip (i.e. triangular shaped). In contrast, the *morphologic left atrium* has a smooth wall, and the left atrial appendage is narrow and elongated, or "finger-like." The septal aspect displays the thin valve of the foramen ovale. In the sequential segmental approach proposed by Anderson, the morphology of the atrial appendages is used as the foundation for identifying the atrial chambers.

The right atrium normally receives blood from the vena cavae and coronary sinus, and the left atrium receives blood from the pulmonary veins. However, as the systemic and pulmonary venous drainage may be variable and/or anomalous, as previously indicated, these criteria cannot be relied upon to definitively determine atrial morphology. Although the morphology of the atrial appendages is frequently used to define the atria and, therefore, the atrial situs, as noted, because the shape of the appendages may be subject to changes under various conditions, concern has been raised as to whether atrial appendage morphology is a reliable marker for identifying atrial structures and distinguishing between them [60].

The anatomic evaluation of the atria includes assessment of the interatrial septum and related areas for communications that may allow for atrial level shunting and the evaluation of pathology/variants that may be associated with structures such as the appendages and atrial cavities.

Box 7.2: Characteristics of the atrial chambers

Morphologic right atrium
- Broad-based (triangular-shaped) appendage
- Internal free wall has crista terminalis (also known as terminal crest), which is the boundary between the smooth-walled posterior aspect and the muscular anterior aspect of the chamber
- Extension of pectinate muscles toward the atrioventricular valve
- Septum secundum (limbus of the fossa ovalis)
- Normally receives the superior and inferior vena cavae and the coronary sinus

Morphologic left atrium
- Long and narrow (finger-like) appendage
- Smooth posterior surface receiving pulmonary veins, no crista terminalis
- Pectinate muscles contained within the appendage
- Septum primum (flap valve of the foramen ovale)
- Normally receives the pulmonary veins

KEY POINTS: GREAT VEINS AND ATRIA

- In the normal heart, systemic venous drainage is via the superior and inferior vena cavae into the right atrium and pulmonary venous drainage is via the right- and left-sided pulmonary veins into the left atrium.
- Anatomic landmarks are the primary criteria used to identify and distinguish between the morphologic right and left atria.
- Because systemic and pulmonary venous drainage can be variable and/or anomalous, these criteria cannot be relied upon to definitively determine atrial morphology.
- The anatomic evaluation of the atria includes assessment of the interatrial septum and the cavities to evaluate for pathology.

Ventricles and ventricular septum

An analysis of the ventricular segment includes determining the type of ventricular loop (topology or handedness of the ventricular mass; also referred to as describing the chirality) and the relative spatial relationship between the ventricles and the atria. *Ventricular looping*, as discussed in Chapter 6, can result in either D-loop (right-handed topology) or L-loop (left-handed topology) ventricles. In the normal D-loop heart, the morphologic right ventricle is right-handed (Figure 7.6A) and the morphologic left ventricle is left-handed, whereas in the L-loop heart, the morphologic right ventricle is left-handed (Figure 7.6B) and the morphologic left ventricle is right-handed. L-looping of the ventricles may also be referred to as ventricular inversion. The types of *ventricular situs* (loop or topology) have been described in the Van Praagh system [59] as follows: *solitus* or D-loop ventricles (D); *inverted* or L-loop ventricles (L); and *ambiguous* or X-loop ventricles, where X indicates unknown situs (looping cannot be determined).

The ventricles are defined by their anatomy and not by where they are spatially located. Ventricular morphology is used to identify the ventricles and, therefore, their location (Box 7.3). The morphologic *right ventricle* is triangular-shaped in nature and characterized by a trileaflet AV valve (tricuspid valve), consisting of septal, anterior, and posterior leaflets. The tricuspid valve inserts inferiorly onto the interventricular septum relative to the mitral valve and is termed septophilic because of its septal leaflet attachments to the interventricular septum. The densely trabeculated right ventricle consists of several papillary muscles. The pulmonary valve rests on a muscular infundibulum above the tricuspid valve. In contrast, the morphologic *left ventricle* is shaped similarly to a cone or bullet ellipse and is characterized by a bileaflet AV valve (mitral valve), consisting of anterior and posterior leaflets. There are no mitral valve attachments to the interventricular

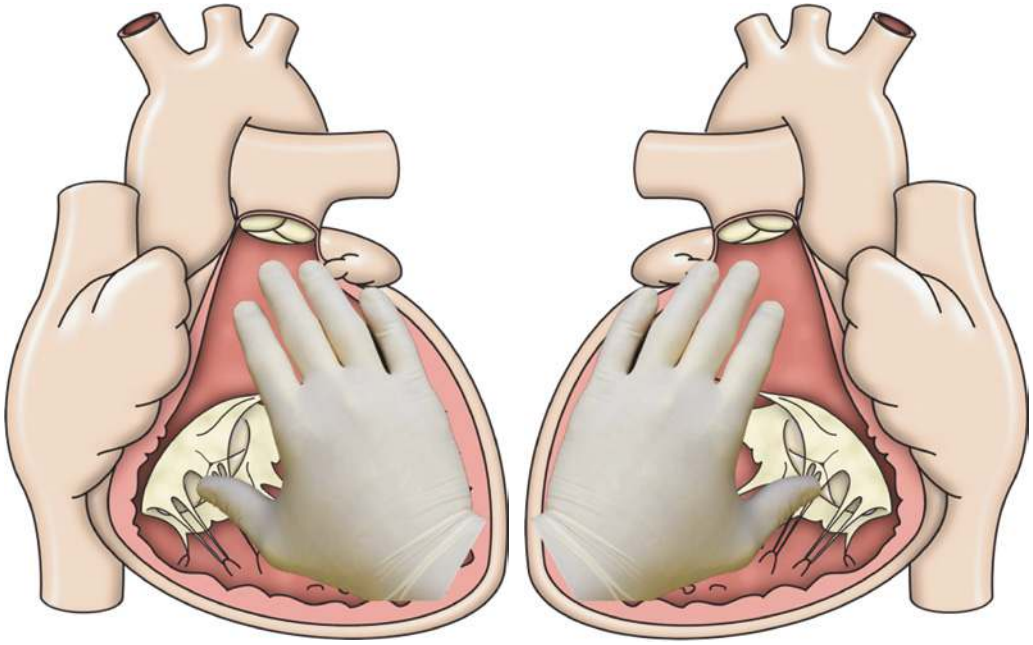

Figure 7.6 Ventricular topology. The figure shows how the position of the palmar surface of either the right hand (A) or the left hand (B) can be oriented over the septal aspect of the morphologic right ventricle (thumb over the ventricular inlet and fingers over the ventricular outlet), corresponding to D-loop (right-hand topology) or L-loop (left-hand topology). (Source: Ms. Gemma Price. Reproduced with permission.)

Box 7.3: Characteristics of the ventricular chambers

Morphologic right ventricle
- Trileaflet atrioventricular (tricuspid) valve with septal leaflet attachments to the interventricular septum (septophilic)
- Atrioventricular (tricuspid) valve more apically positioned on the interventricular septum when compared with the mitral valve
- Coarse muscular trabeculations at the apical portion
- Presence of moderator band and septomarginal trabeculation (characteristic muscle band on the septal aspect)
- Tricuspid valve is separated from the pulmonary valve by the crista supraventricularis (supraventricular crest) or infundibulum
- Chamber shaped like a triangle

Morphologic left ventricle
- Bileaflet atrioventricular (mitral) valve without septal attachments (septophobic)
- Atrioventricular (mitral) valve with superior position on the interventricular septum, as compared with the tricuspid valve
- Smooth muscular trabeculations at the apical portion
- Absence of moderator band, presence of paired papillary muscles
- Mitral valve in fibrous continuity to aortic valve (infundibulum absent)
- Chamber shaped like a cone

septum; therefore, the valve is referred to as septophobic. The left ventricle has a smooth wall (fine trabeculations) and contains two prominent papillary muscles. The anterolateral and posteromedial papillary muscles have chordal attachments supporting the anterior and posterior mitral valve leaflets. The aortic and mitral valves share fibrous continuity in the normal heart.

The *ventricular septum* separates the right and left ventricles. A ventricular septal defect represents an opening or gap in the ventricular septum. This is one of the most common intracardiac defects and also the most common type of CHD requiring surgery. These defects vary in size, shape, and location and can occur anywhere in the ventricular septum as single or multiple entities. They are classified into various types depending on their location (Figure 7.7), also refer to Chapter 6 [24]. The evaluation of the ventricular septum is complicated by the fact that it is not a straight wall that divides the ventricles but rather a three-dimensional structure that includes the membranous, muscular (also known as trabecular), infundibular, inlet, and AV segments. Characterizing defects in the ventricular septum thus requires a detailed, systematic examination as they can be circumscribed to a specific area or span various regions.

KEY POINTS: VENTRICLES AND VENTRICULAR SEPTUM

- Analysis of the ventricular segment involves determining the type of ventricular loop and the relative spatial relationship between the ventricles and the atria.
- Ventricular looping can result in D-loop (right-handed) or L-loop (left-handed) ventricular topology.
- The ventricles are defined by their anatomy and not by where they are spatially located; ventricular morphology is used to identify the ventricles and, therefore, their location.
- The ventricular septum is a three-dimensional structure comprising various segments, implying complexity in its evaluation and in examining interventricular communications.

AL Grawany

Diagrammatic illustration of the various segments of the ventricular septum as viewed from the left ventricle (A) and along the length of interventricular septum (B): membranous (MS), infundibular (IS), trabecular (TS), inlet (IS), and atrioventricular (AVS) septum. AV, aortic valve; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Source: Ammash [61]. Reproduced with permission of John Wiley & Sons.)

Atrioventricular junction

The AV junction, or AV canal, consists of the AV valves and AV septum.

Atrioventricular valves

An important aspect of the evaluation for CHD is an assessment of the AV valves (tricuspid and mitral valves). This analysis includes determining valvular patency, leaflet morphology (size, number, and commissures), annular dimensions and orifice shape, in addition to evaluating chordal structures and papillary muscles that comprise the support apparatus. Other features of the AV valves that are of interest include the point of septal insertion at the annulus and the presence/absence of chordal attachments to the ventricular septum. As indicated previously, these features facilitate the morphologic identification of the ventricles because the AV valves are *almost always* associated with their respective ventricles (i.e., the tricuspid valve with the right ventricle and the mitral valve with the left ventricle).

Atrioventricular connections

To ascertain the connection between the atria and ventricles, or the sequence of these structures, it is necessary to first fully analyze each of these segments and identify the chambers. Several AV connections/alignments may be possible, as depicted in Figure 7.8. The AV connection can either be biventricular or univentricular. Biventricular connections can be classified into either concordant or discordant. A *concordant AV connection* implies that the normal anatomic relationship exists, meaning the morphologic right atrium connects to the morphologic right ventricle and the morphologic left atrium connects to the morphologic left ventricle. In the case of a *discordant* AV *connection*, the morphologic right atrium opens into the morphologic left ventricle and the morphologic left atrium opens into the morphologic right ventricle [48]. Examples of cardiac defects in which the AV relationship is discordant include corrected transposition (characterized by both AV and VA discordance) and isolated ventricular inversion (AV discordance and VA concordance). The term univentricular AV connection is used when only one ventricle is connected to the atrial chamber. In children with a single ventricle, the AV relationship may differ.

The presence of concordant or discordant AV connections is independent of ventricular position, meaning that either connection can be seen in situs solitus or situs inversus. In the sequential analysis, the AV connection/alignment can also be described as *common* (e.g., common AV valve), *double inlet* (double-inlet left ventricle), *absent* (AV valve atresia), *overriding* (when the annulus of the valve sits above portions of both ventricles (or ventricle and outlet chamber; e.g. double outlet right atrium), or *straddling* (where parts of the tensor apparatus of the valve attach on both sides of the septum; e.g., straddling mitral valve) (Figure 7.8).

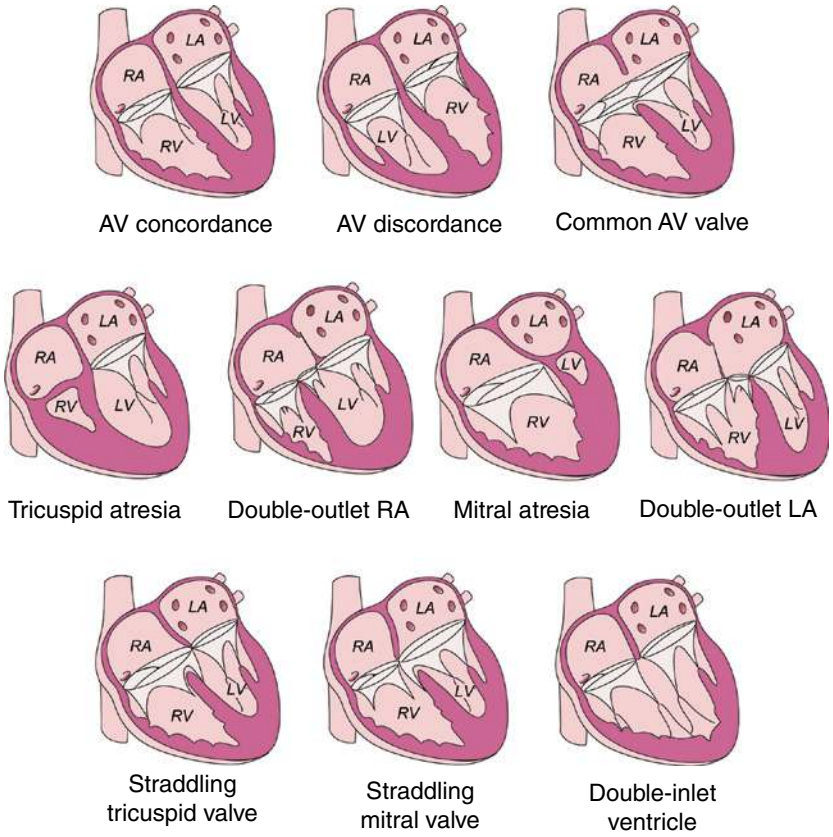

Figure 7.8 Atrioventricular alignments and connections. Diagrammatic representation of potential atrioventricular (AV) alignments and connections. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Source: Geva [52]. Reproduced with permission of John Wiley & Sons.)

KEY POINTS: ATRIOVENTRICULAR JUNCTION

- An important aspect of morphologic evaluation in CHD is the assessment of the AV valves.
- The AV valves are almost always associated with their respective ventricles.
- To determine the AV connections or sequence of anatomic structures, each of the chambers should be identified first.
- The AV connection can be either biventricular or univentricular; biventricular connections can be classified into either concordant or discordant.
- The presence of concordant or discordant AV connections is independent of ventricular position.

Ventriculoarterial junction

The VA junction (infundibulum/conus arteriosus) is the cardiac segment that connects the ventricles to the great arteries. Various aspects of this connection should be considered during a morphologic evaluation, as explained in the following sections.

Conal or infundibular anatomy

The distal region of the conus arteriosus, identified by the muscular infundibulum, is normally found immediately underneath the pulmonary valve, separating the tricuspid valve from the pulmonary valve. In contrast, there is fibrous continuity between the mitral and aortic valves (mitro-aortic continuity), and no intervening muscular tissue is present in the normal heart. An important element to include when describing cardiac anatomy is the morphology of the infundibulum, or outlet portion of the ventricles, which occurs essentially in four different anatomic types. These are depicted in Figure 7.9. In the normal heart, as previously noted, the infundibulum is in the subpulmonary location. Alternatively, the muscular infundibulum can be in the subaortic location (e.g. in D-transposition of the great arteries), bilateral (e.g. in a double-outlet right ventricle), or deficient/absent (e.g. in the rare case of a double-outlet left ventricle).

Semilunar valves

The semilunar or arterial valves are the connecting structures between the ventricular masses and great arteries. The valvular components usually described during an anatomic evaluation include the annulus, cusps, commissures, sinuses, sinotubular junction, and supporting ventricular musculature. Other important elements to assess as part of the anatomic examination include

AL Grawany

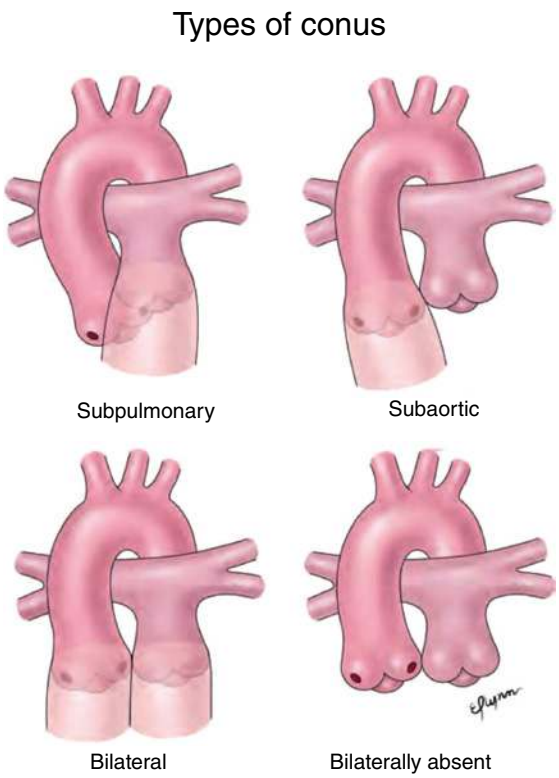

Figure 7.9 Types of conus (infundibulum). The location of the muscular infundibulum categorizes the conal anatomy into four basic types: subpulmonary conus, as found in the normal heart; subaortic conus, as often found in transposition of the great arteries; bilateral conus (in subpulmonary and aortic locations), as usually identified in patients with double-outlet right ventricle; and bilaterally absent (rare), as may be found in some patients with double-outlet left ventricle. (Source: Geva [52]. Reproduced with permission of John Wiley & Sons.)

valvular patency, degree of hypoplasia (when present), and potentially related abnormalities.

Ventriculoarterial connections

To determine the type of VA connection, one must examine the outflow tracts to define the ventricular origin of the great arteries and the relationship between the semilunar valves and the ventricles. There are no intrinsic features that distinguish between the great arteries, and therefore the branching pattern of the arterial trunks is used to establish their identity (see the sections that follow) [33]. Four basic VA connections are recognized: concordant, discordant, double-outlet, and single-outlet.

In *VA concordance* (connection to an appropriate ventricle), the pulmonary artery arises from the right ventricle and the aorta arises from the left ventricle. This connection has been considered normal in solitus normal or inverted normal. This relationship is in contrast to a *discordant VA connection* (connection to an inappropriate ventricle), in which the pulmonary artery arises from the left ventricle and the aorta arises from the right ventricle, as is most commonly seen in transposition of the great arteries (e.g. D-transposition, L-transposition, or A-transposition). Other connection types include double outlet and single outlet, as shown in Figure 7.10. The term *double outlet* is used when both great arteries originate from one ventricle or when one vessel arises from the ventricle and the second one overrides the septum by over 50% (e.g. double-outlet right ventricle). Another criterion used to identify this type of connection is a lack of fibrous continuity between the mitral valve and adjacent semilunar valve. A *single-outlet connection* refers to a solitary great artery arising from the ventricle, the other being atretic (e.g. pulmonary atresia and aortic atresia) or a common arterial trunk (e.g. truncus arteriosus).

KEY POINTS: VENTRICULOARTERIAL JUNCTION

- A muscular infundibulum (conus) normally separates the tricuspid and pulmonary valves, in contrast to the presence of fibrous continuity between the mitral and aortic valves.
- Examination of the semilunar valves is an important aspect of CHD evaluation.
- Determination of the type of VA connection requires definition of the ventricular origin of the great arteries and the relationship between the semilunar valves and the ventricles.
- No intrinsic feature distinguishes between the great arteries, and therefore the branching pattern of the arterial trunks is used to establish their identity.
- The four basic VA connections are concordant, discordant, double outlet, and single outlet.

Great arteries and their relationships

As described in detail in Chapter 6, the developmental changes that occur in the conotruncal region during embryonic life result in a spiral or criss–cross relationship between the great arteries in the normal heart. In individuals with normally related great arteries, the main pulmonary artery is anterior to the aorta and courses leftwards before bifurcating into the left and right branches, whereas the aorta is posterior with respect to the main pulmonary artery and courses rightwards, giving rise to the coronary arteries, the vessels of the head and neck, and most systemic arteries. In addition, the pulmonary valve sits anterior to and leftwards of the aortic valve. This great artery/semilunar valve relationship may be altered, resulting in a parallel (i.e. side-by-side) relationship and other abnormal spatial orientations. As part of a complete examination, the spatial relations between the great arteries and the semilunar valves (anterior-posterior and right–left position) are usually described. The Van Praagh system [59] defines the types of great arterial situs (i.e., spatial relations of the great arteries) as follows:

- *Solitus* (aortic valve right-sided relative to pulmonary valve) – normally related great arteries (S), or D-transposition/malposition (D)
- *Inversus* (aortic valve left-sided relative to the pulmonary valve) – inverted (mirror image), normally related great arteries (I), or L-transposition/malposition (L)
- *Ambiguous* (right-left location of the aortic valve, directly anterior to the pulmonary valve, is equivocal, meaning neither right or left) – A-transposition/malposition (A).

KEY POINTS: GREAT ARTERIES AND THEIR RELATIONSHIPS

- An important component of the morphologic examination in CHD is the description of the spatial relationships between the great arteries and the semilunar valves.
- In the normal heart, there is a spiral or criss–cross relationship between the great arteries; this relationship may be altered, resulting in a parallel relationship and other abnormal spatial orientations.
- The great arterial situs in the Van Praagh system is defined as solitus, inversus, or ambiguous.

Branch pulmonary arteries and ductus arteriosus

In the normal heart, the main pulmonary artery emerges from the morphologic right ventricle and courses to the left of the ascending aorta. The main pulmonary artery bifurcates into right and left branches. The course of each branch is distinct: the right pulmonary artery originates almost in perpendicular fashion from the main pulmonary artery and travels beneath the aortic arch and posterior to the SVC, whereas the left pulmonary artery continues in a smooth arch-like fashion from the pulmonary confluence over the left mainstem bronchus. As indicated previously, the thoracic organs are asymmetrical, which accounts for the different branching patterns of the right and left pulmonary arteries and their relationships to the tracheobronchial tree. These differences facilitate the determination of lung morphology and sidedness.

AL Grawany

The ductus arteriosus is a vascular channel that serves as an essential communication between the pulmonary artery and the descending aorta during fetal life. In most cases, the ductus arteriosus originates from the postero-superior aspect of the junction between the main and left pulmonary arteries and inserts into the anterolateral or ventral aspect of the descending thoracic aorta, just distal to the takeoff of the left subclavian artery. However, the site of origin and the course of the ductus arteriosus can be variable, which is most likely to be the case in complex cardiac pathology. This vascular channel should spontaneously close soon after birth. If it fails to close, a persistent connection between the great arteries is present, which allows for shunting (i.e. patent ductus arteriosus). In certain types of congenital malformations, patency of this communication is essential for either pulmonary or systemic blood flow and, therefore, for survival.

Aortic arch

The aortic arch can be divided into three components: the ascending, transverse, and descending portions. The origin of the three arch vessels (brachiocephalic, carotid, and subclavian arteries) are routinely determined as part of the aortic arch evaluation. An examination of these structures should focus on assessing vessel patency and size, aortic arch position, arch sidedness, and branching pattern (i.e. origin of the head and neck vessels). Vascular anomalies or variants should also be identified. Aortic arch sidedness (left or right) is defined by which mainstem bronchus is crossed by the aortic arch or, likewise, by the position of the aortic arch relative to the trachea. The aortic arch is normally left-sided, and the aortic arch vessels branch in sequence into the right innominate or brachiocephalic (which divides into the right subclavian and right common carotid arteries), left common carotid, and left subclavian arteries. Of note is that arch sidedness is not incorporated into the sequential segmental approach but nevertheless represents an important aspect of anatomic evaluation of the cardiovascular system.

KEY POINTS: BRANCH PULMONARY ARTERIES, DUCTUS ARTERIOSUS, AND AORTIC ARCH

- The main pulmonary artery arises anteriorly from the morphologic right ventricle and courses to the left of the ascending aorta bifurcating into its right and left branches.
- The ductus arteriosus is an essential communication between the great arteries during fetal life. It usually originates at the junction between the main and left pulmonary arteries and inserts into the ventral aspect of the descending thoracic aorta, just distal to the origin of the left subclavian artery.
- Important aspects of the aortic arch examination include determination of sidedness (normally left-sided) and branching pattern.
- Vascular anomalies or variants are also usually characterized.

Coronary arteries

An examination of the major epicardial coronary arteries, including their origin, proximal course, and branching pattern, is an essential component of the anatomic evaluation for CHD. Normally, two major coronary arteries (the right and left main) arise from the aortic root from their respective sinuses of Valsalva facing the main pulmonary artery. The left main coronary artery bifurcates into the left anterior descending and circumflex coronary arteries. In the clinical setting, advanced imaging modalities are required to assess the more distal branches of the main vessels (e.g., diagonals, marginals, and septal perforators) and the dominant coronary system (determined by the origin of the posterior descending branch). The right and circumflex coronary arteries normally course along the AV groove and near the AV valves. The left anterior descending coronary artery travels along the interventricular septum. Variations from these patterns or abnormalities in the origin, course, or branching of the coronary arteries may be recognized clinically as incidental findings, and they can be found in isolation or in association with other cardiac defects. In some instances, variable coronary artery patterns can influence the type of surgical repair (e.g. in tetralogy of Fallot the left anterior descending can arise from the right coronary artery and cross the right ventricular outflow tract, thereby precluding placement of a patch).

Description of associated malformations

In addition to the detailed examination described in previous sections, any morphologic approach for evaluating the cardiovascular system and major cardiac defects requires an accurate and detailed assessment of any co-existing malformations as part of a comprehensive anatomic analysis for CHD.

Summary

Caring for patients with structural malformations of the cardiovascular system is an important aspect of anesthesia practice and the main focus for those who specialize in pediatric cardiac anesthesiology. The variable spectrum of CHD ranging widely from relatively simple defects to complex ones, along with the different terminology, nomenclature and classification systems utilized in clinical practice, has created confusion and added to the already significant challenges. However, it is important for the practicing anesthesiologist who cares for these patients to understand the various nomenclature systems used to describe congenital cardiac pathology and not only be comfortable but well versed in these. Efforts in the medical community to establish a uniform naming system for pediatric and CHD have made significant strides in the last two decades. These will continue to incorporate the perspectives of many different disciplines and specialties to further refine this work while attempting to overcome many of the ongoing challenges.

To provide optimal care for patients with congenital cardiovascular malformations, one must have a solid understanding of the anatomic abnormalities, the altered pathophysiology, and the associated hemodynamic consequences

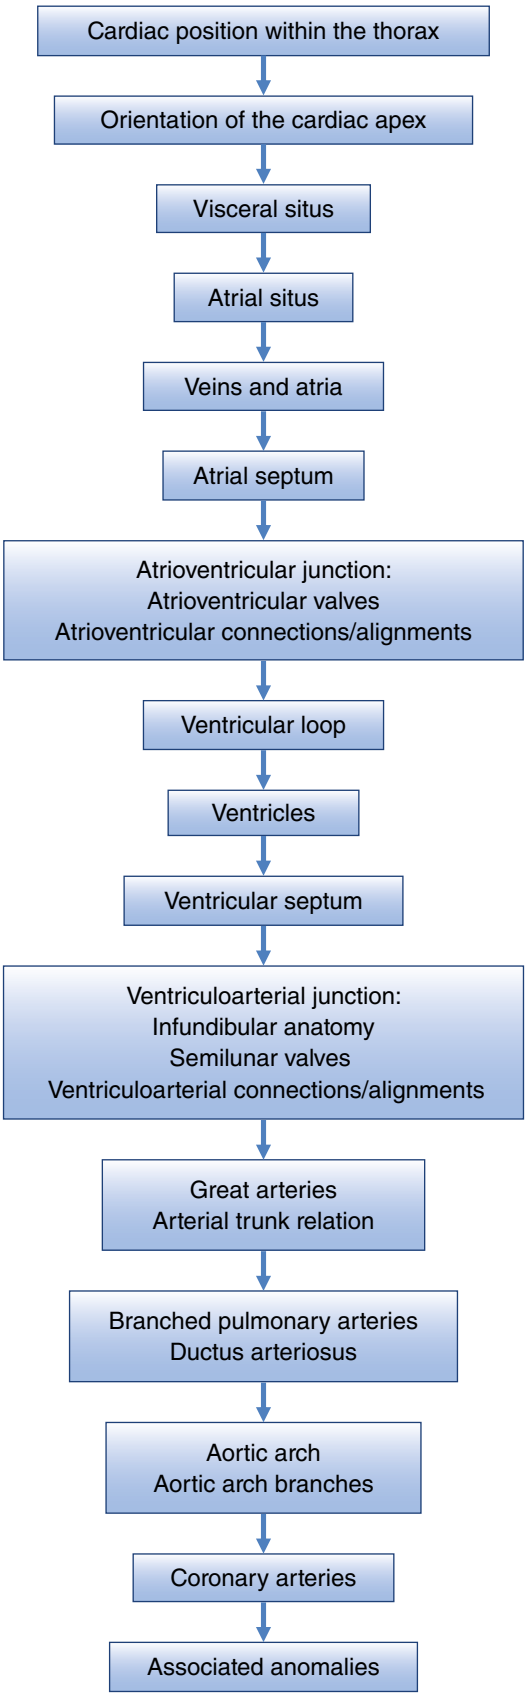

Figure 7.11 Segmental evaluation of congenital heart disease. Illustration of the steps involved in the segmental approach to diagnosis of congenital heart disease. (Source: Geva [52]. Reproduced with permission of John Wiley & Sons.)

of the disease. Important requirements in this regard include having a solid framework concerning the steps involved in the segmental anatomic evaluation of the heart as described in this chapter and summarized in Figure 7.11.

Introduction

Approximately 20–30% of patients with congenital heart disease (CHD) also have a genetic syndrome or association comprised of cardiac and extracardiac features [1]. Therefore, patients with genetic syndromes or associations are seen disproportionately in locations where care is provided to patients with CHD. The presence of a syndrome or genetic abnormality is a risk factor for perioperative morbidity/mortality for congenital heart surgery [2], and noncardiac and genetic abnormalities can be associated with additional risk factors such as prematurity and weight <2.5 kg [1]. Patel et al. analyzed the Society of Thoracic Surgeons Congenital Heart Surgery Database and reported on the overall prevalence of noncardiac congenital anatomic abnormalities, genetic abnormalities, and syndromes in neonates undergoing congenital heart surgery of 18.8%. The congenital heart lesions with the highest incidence of a noncardiac anomaly, genetic abnormality, or syndrome were an atrioventricular septal defect, interrupted aortic arch, truncus arteriosus, and tetralogy of Fallot. The most common genetic abnormalities were heterotaxy syndrome, 22q11 deletion, trisomy 21, and Turner syndrome [3]. The presence of a genetic syndrome or abnormality clearly makes a difference in in-hospital mortality in hypoplastic left heart syndrome (HLHS) and in conotruncal anomalies. The reported in-hospital mortality for HLHS in patients with a genetic abnormality is 26.7% compared with 19.8% in patients without a genetic abnormality [4]. Michielon et al. report that 22q11 deletion and Trisomy 21 are not risk factors for mortality after repair of conotruncal anomalies, but VACTERL association was associated with a higher risk of mortality [5]. In addition to the well-known chromosomal disorders and genetic syndromic associations in CHD, newer genetic analysis tools such as whole-exome sequencing (see below under Genetic Testing) are discovering many new, complex gene variants that are associated with CHD, and so the knowledge of the genetic basis of CHD is expanding and it is likely that an even higher percentage of CHD patients have variants that can explain both the cardiac disease and extracardiac manifestations [6]. Certain genetic syndromes are known to carry an increased anesthetic risk. An understanding of the genetic basis, manifestations, and impact of perioperative management in patients with these syndromes and associations is important for risk stratification, counseling, decision-making, and mitigation of anesthetic and perioperative risk [1].

Historically, cardiac repair was not offered for patients with some genetic syndromes, including Trisomy 21. In the present day, cardiac repair is often expected, and cardiac transplantation has been performed in patients with Trisomy 21. This change in the pattern of care has increased the life expectancy of patients with Trisomy 21, and patients with Eisenmenger syndrome and other sequelae of long-standing unrepaired cardiac disease rarely present for anesthetic care in the modern era in developed countries. This same evolution is now being seen with other syndromes with Trisomy 21 being the model for nonbiased treatment of CHD [7]. As operative management becomes more common, it is important to tailor perioperative management to optimize outcomes. Genetic-specific treatment and management protocols have been suggested to reduce perioperative morbidity and mortality [7].

In this chapter, common genetic syndromes and associations in patients with CHD are explored including the genetic defect and inheritance, cardiac and noncardiac manifestations, along with some anesthetic considerations and risk mitigation, and the effect of the syndrome on surgical morbidity and mortality. Detailed approaches to anesthetic and surgical management of the specific cardiac lesions are contained in the corresponding chapters in this textbook. Patients with congenital heart disease and genetic and dysmorphic associations present complex diagnostic and management decisions because of multiorgan disease, and many of these patients have neurodevelopmental disabilities, and some have limited life expectancy. Because of these issues, approaches to genetic testing, ethical considerations, and palliative care are also discussed.

Chromosome 22q11 deletion syndrome

Velocardiofacial syndrome (VCFS), which is also termed DiGeorge syndrome or sequence, 22Q11 deletion syndrome, CATCH 22, and conotruncal anomalies face syndrome, has a broad spectrum of phenotypic variation with more than 180 clinical features. VCFS is one of the most common multiple anomaly syndromes, estimated to occur in approximately 1 : 2,000 live births. VCFS is inherited as an autosomal dominant disorder caused by a microdeletion at chromosome 22q11.2 [8]. The phenotype is extremely heterogeneous, and there is no single clinical feature present in all cases, therefore the diagnosis is established by the chromosome defect itself. Congenital heart disease is present in 70% of cases and comprises a high proportion of all conotruncal anomalies, including more than 50% of cases of interrupted aortic arch, over 15% of patients with tetralogy of Fallot, about 50% of truncus arteriosus patients, and about one third of posteriorly malaligned ventricular septal defects. Hemizygosity of the gene TBX1 is responsible for cardiac defects. Other defects commonly present are cleft palate, usually submucous clefts. Facial anomalies are often associated and include high arched palate, low set ears, and occasionally, varying degrees of micrognathia (Figure 8.1) [8]. Other important features present in a variable percentage of patients are partial hypoparathyroidism causing neonatal hypocalcemia, and relative immunodeficiency from abnormal lymphocyte function. Neurodevelopmental disability is common in VCFS, although in some patients intelligence is normal. The average mean full-scale IQ is 70–75, with about 55% having an IQ range of 70–100; 45% having an IQ range of 55–70, and a few patients have moderate to severe disability [9]. Individuals with VCFS are at an increased risk for developing a number of neuropsychiatric disorders which include attention deficit with hyperactivity disorder, anxiety and mood disorders, autism spectrum disorder, psychotic disorders, and schizophrenia. Patients with the cardiac diseases noted above should be tested for the 22q11.2 deletion syndrome using fluorescence-in-situ hybridization (FISH) or chromosomal microarray (CMA), and other multisystem involvement should be assessed as well, especially hypocalcemia and immune dysfunction leading to increased infection risk, as these may affect anesthetic management. In patients with simpler forms of CHD and VCFS, i.e. tetralogy of Fallot, VSD, and simple truncus arteriosus, surgical outcomes are the same as patients without a chromosome defect. However, in the interrupted aortic arch, surgical outcomes are poorer with the 22q11.2 deletion. Finally, the later neurodevelopmental outcomes at one year or more after cardiac surgery are worse overall with 22q11.2 deletion [10]. In spite of the known mild craniofacial anomalies in this syndrome, airway management and tracheal intubation is most often not problematic.

Figure 8.1 Facial features of the velocardiofacial syndrome. Note the small low-set posteriorly rotated ears and slight retrognathia; the patient also has a high arched palate with submucous cleft. (Source: Shprintzen [53]. Reproduced with permission from John Wiley & Sons.)

AL Grawany

Trisomy 21

The most common genetic syndrome, Down syndrome (DS) affects about 1/700 live births [11]. Resulting from an additional 21st chromosome, diagnosis often occurs *in utero* with abnormal levels of maternal serum markers (alpha-fetoprotein, human chorionic gonadotropin, pregnancy-associated plasma protein-A, and inhibin A), as well as increased nuchal translucency and a shortened nasal bone on ultrasound in the first trimester [12, 13]. Postnatal diagnosis is based on a physical exam and FISH to confirm the presence of an extra chromosome 21 (3). Children with DS are typically hypotonic with highly mobile joints and distinctive physical features, including a small head with a short neck, macroglossia, palpebral fissures, broad short hands with a single palmar crease, and Brushfield's spots on the iris (3) (Figure 8.2) [14, 15]. They typically have short stature and obesity is prevalent with increasing age. Prematurity and low birth weight (<2,500 g) occur more frequently compared to the general population [11, 14]. The presence of a flat nasal bridge, macroglossia, and a smaller hypopharynx with decreased muscle tone, and increased tonsillar and adenoid hypertrophy lead to airway obstruction and obstructive sleep apnea (OSA). In addition, children with DS may have smaller airways with an increased incidence of subglottic stenosis, as well as lower airway disease from reduced airway branching units due to a reduced number of alveolar acini [14]. As many as 8% of children with DS have hypothyroidism which should be screened for annually. Hematologic disturbances including neutrophilia, polycythemia, and thrombocytopenia are common in the newborn period and, in addition, 10% of neonates with DS will have a transient myeloproliferative disorder, also known as transient megakaryoblastic leukemia. Cervical spine abnormalities such as atlantoaxial instability are estimated to occur in 15% of children with DS.

Figure 8.2 Typical facial features of Down syndrome. Note the epicanthal folds, upslanting palpebral fissures, flat facial profile, and relatively large tongue. (Source: Davidson [12]. Reproduced with permission from Elsevier.)

Greater than 40% of children with DS are born with congenital heart disease with atrioventricular septal defect (AVSD), ventricular septal defect (particularly a canal type VSD), tetralogy of Fallot, and patent ductus arteriosus being most common. Racial differences exist in which black children with DS have a much higher incidence of AVSD. Despite a higher prevalence of prematurity and comorbidities than children without DS, no significant difference has been found in survival after congenital cardiac surgery in children with DS [16–18]. Children with DS who undergo mask induction with sevoflurane are known to have an increased risk of bradycardia. In a study of 209 children with DS, 57% experienced significant bradycardia unrelated to the presence of congenital heart disease [11, 19]. While the bradycardia is typically self-limited, cases of cardiovascular collapse have been documented [20].

Down syndrome patients are known to be at higher risk of developing pulmonary hypertension (PH), especially in the neonatal period. While the lifetime incidence of PH in children with DS remains unknown, one large, retrospective study of children with DS reported an incidence of PH as high as 28% [21]. Prematurity and LBW increase the risk of the development of bronchopulmonary dysplasia-related PH. Chronic airway obstruction and hypoxia result in increased arteriolar hypertrophy of the pulmonary vasculature which can develop into pulmonary hypertension. Cardiac defects such as AVSD and VSD with a large left to right shunt lead to increased pulmonary blood flow which can further increase the pulmonary vascular resistance. These factors in addition to pulmonary hypoplasia and intrinsic endothelial dysfunction lead to an increased risk of developing pulmonary hypertension.

All patients with DS who require anesthesia should have a preoperative evaluation to screen for the presence of multisystem disease. Patients should be examined for the presence of atlantoaxial instability with radiographic images such as MRI reserved for those with worsening muscle tone or increasing weakness. While the likelihood of a spinal injury under anesthesia in a child with DS is very low, efforts to limit extreme motions of the cervical spine are warranted in all patients with DS [11]. Patients with DS who require anesthesia should at some point have an ECG and echocardiogram to rule out the presence of congenital heart disease and pulmonary hypertension. Thyroid tests to detect hypothyroidism should be performed. Screening for snoring and obstructive sleep apnea should also be performed in all patients with DS who require anesthesia. Blood tests to evaluate for thrombocytopenia are warranted before procedures at high risk for blood loss.

Even with adequate preparation, patients with DS can be challenging for anesthesiologists. Difficult vascular access due to xeroderma and obesity is common. Patients may have

increased procedural anxiety which can be worsened by hearing difficulty and language delays. DS patients may have difficulty expressing pain, yet they may be more sensitive to the effects of opioids due to OSA. While it has long been rumored that patients with DS require higher doses of anesthesia, there is no evidence supporting this, and recent studies have all but disproven this hypothesis [22]. Anesthetic risk in patients with DS is dependent on the severity and presence of comorbidities with younger, lower-weight children with cardiac disease and pulmonary hypertension at the highest risk of complications. In a review of 930 non-cardiac anesthetics in patients with DS, the cohort of patients with trisomy 21 had an increased incidence of perioperative respiratory adverse events mostly due to an increased incidence of obstructed ventilation [23].

Trisomy 18 and 13

Trisomy 13 (Patau syndrome) and Trisomy 18 (Edwards syndrome), result from having three copies of chromosomes 13 and 18, respectively. Trisomy 18 is the second most common autosomal trisomy occurring in about 1/6,000 live births, while Trisomy 13 occurs in 1/10,000 live births [24, 25]. Antenatal diagnosis occurs in most cases due to maternal age, maternal serum markers (significantly lower human chorionic gonadotropin, unconjugated estriol, and alpha-fetoprotein), and sonographic changes of the nasal bone and nuchal translucency [23]. Later sonographic findings identify up to 90% of cases. While preterm loss, stillbirth, and elective termination occur in a large majority of cases, survival to term increases with increasing gestational age. Among those who survive to term, the risk of early death is very high, with recent studies showing a survival to 1 year in only 5–10% of children with both Trisomy 13 and 18 [24–26].

Multiple congenital anomalies are often present in children with Trisomy 13 and 18, and invasive procedures are likely needed for survival in most children with the syndrome. Low birthweight occurs in most children with each syndrome. Central nervous system abnormalities are likely to present leading to central apnea, severe developmental delay, and seizures. Feeding difficulties, gastroesophageal reflux, and growth retardation occur in most patients, and a permanent feeding tube is required in many patients. Respiratory insufficiency is multifactorial. Central apnea is common, and hypotonia, micrognathia, laryngotracheomalacia, and a high frequency of cleft lip and palate can lead to obstructive apnea. Because of this, many patients with Trisomy 18 and 13 require lifelong invasive ventilatory support.

Cardiac disease occurs in up to 80% of patients with Trisomy 18 and Trisomy 13, with ASD, VSD, patent ductus arteriosus (PDA), and valvular abnormalities being most common. Until recently, few centers chose to operate on patients with Trisomy 18. Today, most centers offer cardiac surgery for patients with Trisomy 18. A 2019 study of the Society of Thoracic Surgeons Congenital Heart Surgery Database of children with T13 and T18 who underwent cardiac surgery (2010–2017) demonstrated that while 70% of centers offered surgery on these patients, mortality remained high at 15% with a high rate of complications [27].

Figure 8.3 A 3 month old infant with trisomy 18 (Edwards syndrome). Note the microphthalmia, micrognathia, short neck, and failure to thrive. The infant was also hypotonic with club foot, and had ventricular and atrial septal defects. (Source: Bali et al. [25]. Reproduced with permission from Turkish Society of Anaesthesiology and Reanimation.)

Those who required preoperative mechanical ventilation had an 8-fold increased risk of mortality.

Preoperative evaluation of the airway, severity of cardiac disease, and consequences of prematurity is necessary for all children with Trisomy 18 and 13. Difficult intubation and ventilation should be anticipated in patients with Trisomy 18 and 13 because of micrognathia, high prevalence of cleft lip and palate, and a narrow palate [28] (Figure 8.3). Most patients with these chromosomal disorders will require prolonged postoperative mechanical ventilation due to prematurity, central apnea and airway obstruction.

Williams-Beuren syndrome and Elastin arteriopathies

Williams syndrome (WS) is caused by a deletion on the long arm of chromosome 7q11.22 which most notably codes for the protein elastin, important in the elasticity of blood vessels. Nonsyndromic elastin arteriopathies have similar cardiovascular presentations of WS without the extravascular abnormalities. Diagnosis of WS is typically by FISH (see below under Genetic Testing), demonstrating a segment loss on chromosome 7. Patients with WS are known for their characteristic elfin facies, with a broad forehead, wide mouth, a short-upturned nose, and epicanthal folds [29] (Figure 8.4). Many have a gregarious, friendly personality; however, periprocedural anxiety is common (14). Feeding difficulties and reflux are common and up to 50% of WS patients have hypercalcemia, especially in infancy. Up to 70% of patients with WS have cardiovascular diseases, most notably supravalvular aortic stenosis (SVAS), supravalvular pulmonary stenosis and ostial

AL Grawany

stenosis of coronary arteries. Patients with severe outflow tract obstructions and/or coronary disease are at high risk for myocardial ischemia with induction of anesthesia [30, 31]. In addition to a 25% lifetime risk of sudden death in patients with WS, there were several cases of cardiac arrest under anesthesia documented in the literature with an estimated incidence of 5%. Several methods of risk stratification have been proposed in the literature, though prospective studies evaluating their accuracy have not been performed. All patients with WS who present for anesthesia should undergo risk stratification and perioperative planning, and it has been demonstrated that with such planning, the incidence of cardiac arrest may be minimized. Echocardiograms to evaluate the severity of supravalvar aortic and pulmonary stenosis, ECGs screening for latent ischemia should be performed on all patients with WS before anesthetic care. Evaluation of the coronaries should be performed in those with stenosis of the thoracic aorta, moderate to severe SVAS and those with signs of symptoms of ischemia. Both cardiac CT angiography and cardiac catheterization can be used to image the patency of the coronary arteries, with CT angiography having the advantage of being done without general anesthesia and avoiding the temporary interruption of coronary blood flow during catheter-based angiography which has been the cause of cardiac arrest in several patients with WS [32]. Younger patients (<3 years) with moderate to severe outflow tract gradients or those with biventricular outflow tract obstruction should be considered at high risk for myocardial ischemia during anesthesia (16). Such patients may benefit from preoperative hydration, the use of anesthesia drugs that maintain SVR and minimize myocardial oxygen consumption, and judicious use of vasopressors such as phenylephrine to maintain coronary perfusion pressure. All patients considered high risk should be cared for in centers with the capability for full resuscitation and the availability of extracorporeal membrane oxygenation (ECMO), as standard resuscitation measures may fail in patients with severe coronary stenosis or severe outflow tract obstruction. ECMO standby is used at several centers when caring for moderate to high-risk WS patients. Chapter 35 presents an extensive discussion of anesthetic risk stratification and approach in WS.

Noonan syndrome

Noonan syndrome (NS), occurring in 1/2,500 live births is the second most common genetic cause of congenital heart disease. Noonan syndrome typically occurs via autosomal dominant inheritance and is a heterogenous disease with a wide range of clinical characteristics. NS is considered a RASopathy, which results from germline mutations in the intracellular RAS/mitogen-activated protein kinase (MAPK) pathway [33, 34]. Diagnosis is suspected from fetal ultrasound and fetal echocardiography and can be confirmed by DNA sequencing. Distinctive facial features in patients with NS include a tall forehead, hypertelorism with prominent eyes and downslanting palpebral fissures, a small jaw and short, webbed neck, and low-set and posteriorly rotated ears and widespaced nipples with pectus excavatum [35] (Figure 8.5). Hearing and intellectual difficulties are common. Children with NS have short stature, feeding difficulties, and cryptorchidism in up to 80% of males (17, 18). Congenital heart disease occurs in over 80% of children with NS. Pulmonary valve stenosis is the most common congenital heart defect, occurring

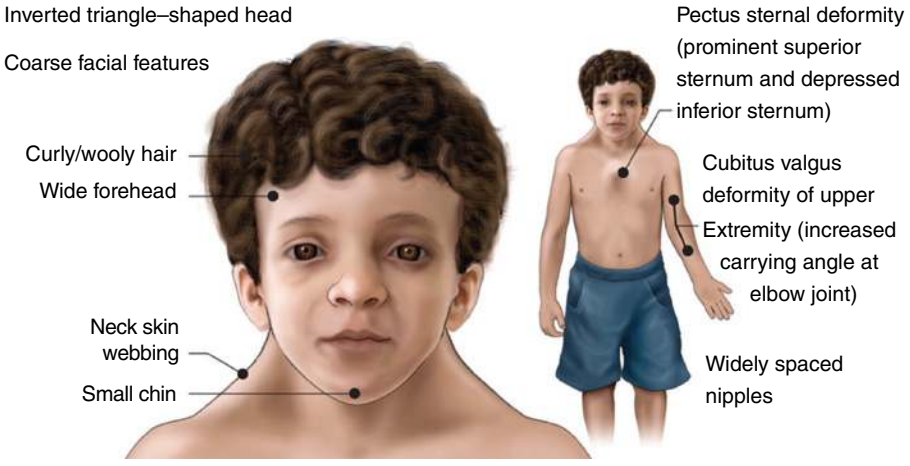

Figure 8.5 Noonan syndrome phenotypic features in a child. (Source: Bhambhani and Muenke [35] / American Academy of Family Physicians / Public Domain.)

in over 50% of patients. These dysplastic thickened pulmonary valve leaflets are often resistant to valvuloplasty. Atrial septal defect (ASD) is the second most common cardiac defect. Twenty percent of children with NS have hypertrophic cardiomyopathy often presenting as early as 6 months of age, far earlier than other forms of hypertrophic obstructive cardiomyopathy (HOCM) [33, 34, 36]. Among those NS patients with HOCM, obstruction of the left ventricular outflow tract and congestive heart failure are more common than typical HOCM patients. Earlier diagnosis and the presence of congestive heart failure symptoms are associated with worse long-term survival in patients with NS-associated HOCM [36].

Patients with NS who require anesthesia should have recent echocardiograms to screen for cardiac defects and to assess the severity of outflow tract obstruction. Patients with HOCM with moderate to severe left ventricular outflow tract (LVOT) obstruction should have preoperative IV placed for prehydration. Careful titration of induction agents with preservation of systematic vascular resistance while avoiding hypovolemia and tachycardia should be performed to minimize myocardial ischemia during anesthesia. Older patients with NS can have limited mouth opening and more severe micrognathia than infants due to joint immobility with advancing age, and difficult laryngoscopy should be anticipated.

Turner syndrome

Turner syndrome (TS), an X-linked chromosomal syndrome occurs due to loss of one sex chromosome (45XO). Prenatal diagnosis is often from chorionic villous sampling or amniocentesis. Affected females typically have short stature, a webbed neck, a broad chest with wide-spaced nipples, and gonadal dysgenesis [37, 38] (Figure 8.6). Airway anomalies include micrognathia, a narrow maxilla, and a high arched palate [39]. Swelling of the hands and feet due to lymphedema can occur and scoliosis is prevalent in up to 10% of children with Turner syndrome. Renal defects such as horseshoe kidney and renal agenesis can occur, and autoimmune diseases such as hypothyroidism and celiac disease occur with high prevalence [37].

Figure 8.6 A 14-year-old female with Turner syndrome. (Source: Acarturk [38]. Reproduced with permission from Springer Nature.)

The most common congenital heart defects in TS include a bicuspid aortic valve and coarctation of the aorta (CoA). Hypertension is common even in patients without CoA. These patients are at risk of aortic dissection and require lifelong evaluation of blood pressure and aortic dimensions [37].

A careful preoperative workup evaluating the presence and severity of cardiac disease, renal and thyroid function, and the airway is necessary before anesthetic care in patients with Turner syndrome. Difficult laryngoscopy and intubation should be anticipated due to limited neck mobility and retrognathia. Blood pressure lability as well as difficult vascular access may be encountered during anesthetic care [39].

Goldenhar syndrome

Interruption of the blood supply to the first and second brachial arches during the first trimester leads to oculo-auriculovertebral syndrome, also known as Goldenhar syndrome. Diagnosis typically occurs after birth after noting unilateral facial hypoplasia. Facial asymmetry, mandibular hypoplasia, eye abnormalities, microtia or absent ear on the affected side, and dental abnormalities of varying degrees are typically present [40]. Vertebral abnormalities including cervical vertebral fusion and vertebral hypoplasia are present in up to 60% of patients [40, 41] (Figure 8.7). Various degrees of hearing loss and intellectual disability can occur. Congenital heart defects, commonly ventricular septal defects as well as conotruncal defects have been noted in anywhere from 5 to 58% of patients with Goldenhar syndrome, but the actual prevalence of CHD in Goldenhar syndrome is likely closer to 20% [42].

Anesthetic concerns typically focus on airway management, noting that these patients are among some of the most difficult patients to intubate due to severe micrognathia, a hypoplastic, arched palate, airway deviation towards the affected side, limited neck mobility, and mouth opening. Preparation for difficult mask ventilation and laryngoscopy is mandatory when anesthetizing all patients with Goldenhar syndrome. While various techniques such as intubation through a laryngeal mask airway and video laryngoscopy have been employed successfully, preservation of spontaneous ventilation and having a plan should intubation attempts fail is necessary to avoid harm [43]. These patients often undergo several airway reconstructive surgeries to advance the mandible, though the success of these procedures in patients with Goldenhar syndrome is reported to be less than with other syndromes [44].

Mucopolysaccharidoses and glycogen storage diseases

Mucopolysaccharidoses (MPSs) are a collection of lysosomal storage diseases, caused by the functional deficiency of lysosomal enzymes from a genetic mutation in the pathways of the breakdown of glycosaminoglycans (GAG), which were previously termed mucopolysaccharides. These are rare metabolic disorders characterized by the accumulation of incompletely

AL Grawany

Figure 8.7 Goldenhar syndrome in a 7-year-old male. Note the facial asymmetry with hypoplastic mandible and ear deformity on the left side. (Source: Vendramini-Pittoli and Kokitsu-Nakata [42]. Reproduced with permission from Wolters Kluwer.)

degraded GAGs in virtually all tissues of the body. Classic phenotypes result, including dwarfism, bone and joint deformities, dysmorphic facial characteristics, developmental delay in some patients, ocular and hearing abnormalities, hepatosplenomegaly, and inguinal or umbilical hernias. Cardiac findings are frequent, but much more common in MPS I (Hurler, Hurler-Scheie Syndrome), MPS II (Hunter Syndrome), and MPS VI (Maroteaux-Lamy Syndrome) [45]. Table 8.1 presents the genetic inheritance, involved chromosomes, frequency, and cardiac and non-cardiac manifestations of these diseases [46–48]. In addition to the six major categories, each has several subtypes with a variable clinical phenotype that depends on the precise enzyme defect; thus presentation, including cardiac disease, is variable. The overall prevalence of these rare diseases together is 1 : 20,000 live births.

Cardiac valvular pathology is the most common manifestation, and leaflet thickening with dysfunction has been reported in more than 80% of patients with MPS I, 50–60% of patients with MPS II, and in essentially all patients with MPS VI [45]. Valvular regurgitation, not stenosis, is more common, and the mitral valve is most commonly affected rather than the aortic. Right-sided valvular disease is less severe. Markedly thickened mitral valve leaflets, and shortened cordae tendinae result in dysmorphic and poorly mobile leaflets. Coronary artery narrowing and occlusion by GAG deposition in proximal coronary arteries is most common in MPS I and II and can occur early, especially in rapidly progressing forms of the disease. Conduction abnormalities, consisting of bundle branch block or complete heart block are seen up to 40% of these patients, presumably from infiltration of the conduction system with GAGs. Valve repair or replacement is the most common cardiac surgery in patients with mucopolysaccharidoses.

In addition to the cardiac pathology, difficult intubation is the most common anesthetic challenge, and MPS I, II, and, VI have in common mucopolysaccharide deposits in the lips, tongue, epiglottis, tonsils, adenoids, and lower airway making them at high risk for airway obstruction and difficult laryngoscopy. In addition, many have a short, stiff neck, and cervical spine abnormalities including atlantoaxial instability and foraminal stenosis[49] (Figure 8.8). A complete preanesthetic evaluation including these and other involved organ systems and a plan to manage them is crucially important for these diseases [46]. Of particular concern if regional anesthesia is contemplated are case reports of paralysis after combined general/epidural anesthesia in Hurler and Morquio Syndromes (MPS IV); avoiding neuraxial anesthesia is recommended in these patients [50].

Pompe Disease is a glycogen storage disease, which is a group of diseases that share defects in the enzymes that break down glycogen. Pompe Disease has an infantile, juvenile, and adult form, depending on the degree of alpha-glucosidase deficiency [51]. Glycogen deposits within the cardiac myocytes result in hypertrophic cardiomyopathy, which varies with the enzyme deficiency and can be severe, resulting in biventricular outflow tract obstruction. Alternately, some patients demonstrate dilated cardiomyopathy. Danon Disease is an even more rare X-linked disorder that can also result in hypertrophic or dilated cardiomyopathy. Imaging studies, non-cardiac surgery, and cardiac surgery for resection of hypertrophied myocardium to relieve outflow tract obstruction are common anesthetics in this population.

Enzyme replacement therapy (ERT) has been available for the last decade or more for MPS I, II, IV, VI, and VII; which consists of weekly intravenous infusions of the defective enzyme, produced using recombinant DNA

Table 8.1 Cardiac genetic syndromes

Syndrome: Name, Eponyms, Inheritance,Incidence,Gene Locus, Gene Product	HEENT/Airway	Central nervous system	Cardiovascular	Pulmonary/Thoracic	Other	Additional anesthetic considerations
Alagille syndrome		Intracranial hemorrage/stroke; Developmental delay	90% with cardiovascular anomalies; most commonly branch pulmonary artery stenosis		Spontaneous bleeding of unknown etiology	Airway: unusual facies, possible cervical spine abnormalities with no reports of difficult intubation
Alagille-Watson syndrome, cholestasis with peripheral pulmonary stenosis, arteriohepatic dysplasia, syndromatic hepatic ductular hypoplasia			Other cardiac lesions: tetralogy of Fallot, tricuspid atesia, patent ductus arteriosus, ventricular septal defect		Biliary excretion abnormalities more than synthetic/metabolic hepatic abnormalities,	Abdominal distension may predispose to gastroesophageal reflux
Autosomal dominant					Butterfly Vertebrae; Possible shortened interpedicular distance,	Neurologic assessment, avoid succinylcholine with myopathies
1 : 70,000					exocrine pancreatic insufficiency	Cardiac work-up
Chromosome 20p12 microdeletion					Renal disease	Assess coagulation profile – caution with neuraxial analgesia/anesthesia
JAG 1 signaling gene, encodes a ligand for the NOTCH1 receptor, critical for the determination of cell fates in early development					Vitamin K malabsorption – coagulopathies	Caution with positioning – rickets/hepatic osteodystrophy
					Vitamin D malabsorption – rickets/pathologic fractures	
					Vitamin E malabsorption – peripheral myopathy/neuropathy	
					Liver transplant frequent in severe Alagille's	
CHARGE association	Swallowing/sucking difficulties	Colobomata: typical iris coloboma to anophthalmos	Right-sided congenital heart disease: tetralogy of Fallot, pulmonic stenosis, double outlet right ventricle	Atresia Choanae	Hypogenitalism	Possible difficult/impossible endotracheal intubation with micrognathia
Parental gonadal mosaicism in some cases; spontaneous mutation	Cleft palate associated with congenital heart disease, mostly tetralogy of Fallot	Cranial nerve dysfunction: CNI – anosmia, CN-VII – facial palsy, CN-VIII – hearing loss, CN-IX/CN-X – velopharyngeal incordination	atrioventricular septal congenital heart disease: ventricular/ atrial septal defect associated with tetralogy of Fallot	tracheoesophageal fistula associated with congenital heart disease, mostly tetralogy of Fallot	Renal anomalies (malrotation, hydronephrosis, reflux) associated with congenital heart disease, mostly atrioventricular septal defect	May require continuous positive airway pressure to maintain airway patency with laryngomalacia/velopalatal insufficiency
1 : 10,000	Hypoplastic mandible (micrognathia) associated with congenital heart disease, mostly tetralogy of Fallot	Delayed motor development, may involve truncal hypotonia	Aberrant subclavian artery and/or right aortic arch		Vertebral anomalies (hemivertebrae, scoliosis) associated with congenital heart disease	May require smaller than expected endotracheal tube for subglottic stenosis

AL Grawany

Heterozygous mutation in the CHD7 on chromosome 8q12.	Semicircular canal agenesis, sensorineural or conductive hearing loss	Developmental delay			
Chromodomain helicase DNA binding protein 7 (CHD7) gene–neural crest epigenetic chromatin remodeling	Three major issues: micrognathia, laryngomalacia, subglottic stenosis				Aspiration risk with swallowing dysfunction, cardiac work-up for congenital heart defects, Thyroid/Parathyroid functional studies for similarities between CHARGE and DiGeorge syndromes High incidence of post-operative airway events Successful airway management with laryngeal mask airway has been reported
DiGeorge (22q11-) syndrome	Craniofacial anomalies: Cleft palate, micrognathia, small mouth	Learning difficulties, other pyschiatric disorders	Cardiac defects: tetralogy of Fallot, interrupted aortic arch, ventricular septal defect, pulmonic stenosis, tricuspid atresia	Hypo- or aplasia of parathyroid gland resulting in hypocalcemia	Reports of vasomotor instability
(Velocardiofacial Syndrome, CATCH-22, conotruncal anomalies face syndrome)	Small thyroid cartiledge with increased anterior angle			Hypo- or aplasia of thymus gland resulting in immune deficiencies	Cardiac work-up for congenital heart disease
sporadic or autosomal dominant					
One in two thousand	Short trachea with a reduced number of cartilage rings			Renal & Skeletal anomalies	Possible difficult airway with dysmorphic faces
1.5- to 3.0-Mb hemizygous deletion of chromosome 22q11.2	Laryngobronchialmalacia			DiGeorge anomaly is likely a feature of Velocardiofacial Syndrome	Possible difficult extubation with velopharyngeal insufficiency
TXB1 deletion causes most cardiac defects and other phenotypic features; T-box genes are transcription factors involved in the regulation of developmental processes	Tracheal bronchi				Recurrent infection risk with thymic dysfunction, Persistent hypocalcemia with parathyroid dysfunction leading to seizures, report of tachycardia from epinephrine injected with local anesthetics

(*Continued*)

Table 8.1 (Continued)

Syndrome: Name, Eponyms, Inheritance,Incidence,Gene Locus, Gene Product	HEENT/Airway	Central nervous system	Cardiovascular	Pulmonary/Thoracic	Other	Additional anesthetic considerations
Down syndrome	High arched narrow palate, macroglossia, subglottic stenosis	Variable intellectual disablity	50% with congenital heart disease: Endocardial cushion defects (50%), ventricular septal defect, patent ductus arteriosus,tetralogy of Fallot	Upper airway obstruction/sleep apnea	Dental abnormalities	Radiologic cervical spine abnormalities do not correlate to neurologic symptoms
Trisomy 21	Obstructive sleep apnea				Higher risk for leukemia	
Errors in meiosis that lead to trisomy 21 are overwhelmingly of maternal origin; only about 5% occur during spermatogenesis.	Atlanto-axial subluxation	Possible altered response to opioids	Predisposed to pulmonary hypertension		Duodenal atresia, Hirschsprung's disease with gastroesophageal reflux	Atlantoaxial instabilitity may increase with loss of muscle tone under anesthesia
1 in 650–1,000	Smaller tracheal lumen diameter	Hypotonia	Predisposed to bradycardia with inhaled induction; halothane, sevoflurane		Immunosuppression and hypothyroidism	Smaller enotracheal tube (0.5–1 mm)) to avert tracheal trauma
Transient myeloproliferative disorder and megakaryoblastic leukemia of Down syndrome are associated with mutations in the GATA1 gene. Somatic mutations in the JAK2 gene are associated with acute lymphoblastic leukemia			Possible difficult arterial/venous access		Hypotonia, hyperextensibility, dysplastic pelvis	Possible difficult vascular access, Possible bradycardic response to high concentration volatile anesthetic agents
Ehler-Danlos Syndrome (EDS)	Dysphonia - hemi-laryngeal weakness	Mild/mod weakness, myalgia, and easy fatigability in the majority of patients	Bleeding symptoms for all EDS types			Bleeding symptoms are responsive to desmopressin
EDS – Classical type			Mitral valve prolapse, aortic root/sinus of Valsalva dilatation, septal defects		Classic: I and II – Skin hyperextensibility, widened atrophic scars, joint hypermobility	Report of scoliosis correction using spinal fusion complicated by bleeding and wound dehiscence (D-29.11)
autosomal dominant disorder type V collagen; chromosome 9q34.3; 1 : 20–50,000						
EDS – Hypermobility type		Decreased/absent analgesic effect from lidocaine given subcutaneously, or local anesthetic cream	Mitral valve prolapse, aortic root/sinus of Valsalva dilatation, septal defects		Hypermobility: III – Hyperextensibility ± smooth, velvety skin, generalized joint hypermobility	
autosmal dominant or recessive mutation in tenascin X gene						
EDS – Vascular type			Medium and large-size vessel fragility leading to rupture		Vascular: IV – Translucent skin, arterial/intestinal/ uterine fragility, extensive brusing, characteristic faces	Premature death from organ rupture (arterial, bowel, uterus)

AL Grawany

Autosmal dominant mutation in type III collagen gene: 1 : 100–250,000						Report of success using Recombinant Factor VIIa
EDS – Kyphoscoliosis type	Atlantoaxial subluxation may occur in Type IV				Kyphoscoliosis: VI – Joint laxity, muscle hypotonia, progressive scoliosis, scleral fragility	Report of scoliosis correction using spinal fusion complicated by arterial avulsion/rupture
autosomal recessive mutation in gene for lysyl hydroxylase: fewer than 60 cases						
EDS – Arthrochalasia type					Arthrochalasia: VIIA/B – Joint laxity with recurrent subluxations, congenital B/L hip dislocation	
Mutation in type I collagen gene; fewer than 30 cases						Careful positioning and skin protection
EDS – Dermatosparaxis type					Dermatosparaxis: VIIC – Severe skin fragility, sagging, redundant skin	Gentle intubation with minimal inspiratory pressures to avoid airway hematomas
10 cases reported						Consider possible cervical instability
13 subtypes recognized in 2017 reclassification						Cardiac work-up to assess valves and great vessels Avoid central vascular access or place under U/S visualization Prepare for significant blood loss Caution with neuraxial anesthesia/analgesia
Pompe disease: glycogen storage disease type II	Infantile onset: macroglossia	Infantile onset: rapidly progressive muscle weakness – axial hypotonia, areflexia	Infantile onset: cardiomegaly/ cardiomyopathy leading to cardiac failure	Infantile onset: respiratory insufficiency with frequent infections	Infantile onset: hepatomegly, elevated creatine kinase	Respiratory insufficiency & hypertrophic cardiomyopathy pose a significant anesthetic risk
Acid maltase deficiency						Maintain intravascular volume and diastolic blood pressure for coronary perfusion
1 : 60–140,000						Reports of arrhythmias due to decreased coronary perfusion with propofol Reports of successful regional anesthetic techniques
	Late-onset: macroglossia is infrequent	Late onset: progressive proximal muscle weakness – lower > upper extremity, Gower sign, decreased deep tendon reflexes	Late-onset: cardiomegaly/ cardiomyopathy is uncommon	Late onset: respiratory insufficiency/failure with infections, dyspnea on exertion,obstructive sleep apnea, Orthopnea	Late onset: moderate hepatomegaly, scoliosis/ kyphosis/lordosis	Respiratory insufficiency poses anesthetic risk

(*Continued*)

Table 8.1 (Continued)

Syndrome: Name, Eponyms, Inheritance,Incidence,Gene Locus, Gene Product	HEENT/Airway	Central nervous system	Cardiovascular	Pulmonary/Thoracic	Other	Additional anesthetic considerations
						Hypotonia/wheelchair-bound – avoid neuromuscular blocking drugs and succinylcholine for prolonged weakness and hyperkalemia Reports of prolonged respiratory depression with volatile agents
Goldenhar syndrome	Unilateral facial hypoplasia: prominent forehead, zygomatic hypoplasia, maxillar/mandibular hypoplasia	Epibulbar dermoid/ ipodermoid, eye anomalies; microphthalmia, anophthalmia, etc	30–60% CHD: 40% conotruncal, 30% septal, 15% targeted growth, 7% situs/looping, 4% left-sided obstruction		Vertebral anomalies: hemivertebrae, fused vertebrae, scoliosis	Difficult airway – reports of failed intubation
Hemifacial microsomia, oculo-auriculo-vertebral syndrome, facio-auriculo-vertebral syndrome	Unilateral macrostomia – lateral facial cleft	Preauricular skin tag/blind fistulas, microtia or other external ear malformations			Often with rib/extremity anomalies	Reports of successful intubation with multiple techniques
Most cases are sporadic mutations; autosomal recessive or autosomal dominant reported	Vertebral anomalies: atlas occipitalization, synostosis	Vertebral anomalies; bifid spine			genitourinary anomalies: ectopic kidney, renal agenesis, vesicuolureteral reflux, ureteropelvic junction obstruction	Evaluate cervical spine for instability
1 in 5,600	Laryngotracheal anomalies: Cartilaginous tracheal sleeve	Often with occipital encephalocoele				Cardiac work-up
Mutation in hemifacial microsomia gene on chromosome 14p32 in some patients	Significant incidence of C1–C2 instability	Often with complex retardation of development				
	Often with Cleft lip/palate/tongue, unilateral tongue hypoplasia, parotid gland aplasia					
	Often with tracheoesophageal fistula/esophageal atresia					
Heterotaxy syndrome	Infrequent: cleft lip/palate, micrognathia, choanal atresia, laryngeal cleft	Rare: Neural tube defects, encephalocoele, cerebellar or corpus callosum agenesis	High prevalence of CHD	Abnormal ciliary function in up to 40%; frequent respiratory infections	Intestinal malrotation; polysplenia, asplenia, transverse liver,	
X-linked; chromosome Xq26.3; Autosomal dominant: heterozygous mutation in CFC1 gene on chromosome 2q21.			Single ventricle; DORV, TAPVR, right or left atrial isomerism,dual or absent SA nodes, bilateral SVC, interrupted IVC, unbalanced AVSD,	Bilateral right or left lungs and bronchi	Rare: hemivertebra, sacral agenesis, hypoplastic kidneys, hypospadias	

AL Grawany

Multiple additional genes in phenotypic series: on chromosomes 3p22.2, 6q21, 7p12.3,10q22.1, 10q26.2,15q21.3,18q21.1			Cardiac arrhythmias: bradycardia in left atrial isomerism, atrial tachycardias in right atrial isomerism		
1 : 5,000–10,000 live births					
Hunter syndrome	Dural hyperplasia/thickening ligamentum flavum lead to cervical myelopathy with UMN signs	Normal intelligence with progressive neurodegeneration leading to vegetative state as teenagers	Cardiac disease: cardiomyopathy, asymmetric ventricle septal thicking, mitral/aortic valve thickening	GI dysfunction: idiopathic diarrhea, spontaneous gastric perforation, bowel pseduo-obstruction	Difficult airway: short neck, high larynx, large tongue, cervical instability
Mucopolysaccharidosis Type II	Coarse facies	Narrowing of the bony neural canal predisposing to cervical cord compression	Sudden death - likely arrhythmia from coronary insufficiency	Treatment with enzyme replacement therapy or stem cell transplantation with limited success	Reports of post-obstructive pulmonary edema at induction/extubation,
X-linked recessive	temperomandibular joint stiffness and short, stiff neck	Compressive myelopathy from meningeal thickening causing communicating hydrocephalus			Reports of successful intubation using multiple techniques: blind nasal, fiber optic, LMA
1 : 110–320,000 males	Adenotonsillar hypertrophy contributing to obstructive sleep apnea, progressive upper airway obstruction, infections				Reports of intubation failure using laryngeal mask airway
Mutation in the gene encoding iduronate 2-sulfatase (IDS) on chromosome Xq28	Glycosaminoglycan deposition in pharynx/larynx wall – laryngeal inlet prolapse/stridor/airway compromise				Report of delayed awakening following a single dose of opioid
Deficient enzyme, iduronate-2-sulfatase: is involved in the lysosomal degradation of the glycosaminoglycans heparan sulfate and dermatan sulfate	Progressive tracheal deformation; cricoid to lower bronchi				
	Trauma (airway instrumentation) may induce mucopolysaccharide deposition				
	C1 and C2 subluxation with odontoid dysplasia				
Hurler syndrome	Facial dysmorphism, obstructive sleep apnea is nearly universal	Developmental disability	Cardiac disease: cardiomyopathy, asymmetric ventricle septal thicking, mitral/aortic valve thickening	Progressive joint stiffness with decreased mobility, severe back pain, lumbar spondylolisthesis with cord compression	Difficult airway: short neck, high larynx, large tongue, cervical instability
Mucopolysaccharidosis type I	Coarse facies/gum hypertrophy, macroglossia	Possible hydrocephalus	Sudden death – likely arrhythmia from coronary insufficiency	Poor hand function likely from carpal tunnel syndrome	Epiglottis tip behind soft palate – oral airway exacerbates not relieves the obstruction
Autosomal recessive	TMJ stiffness and short stiff neck		mitral/aortic valve dysplasia, left ventricular hypertrophy, normal function – same or better following bone marrow transplant	Hepatosplenomegaly – likely leading to a high incidence of umbilical hernia	Reports of postobstructive pulmonary edema at induction/extubation

(*Continued*)

Table 8.1 (Continued)

Syndrome: Name, Eponyms, Inheritance,Incidence,Gene Locus, Gene Product	HEENT/Airway	Central nervous system	Cardiovascular	Pulmonary/Thoracic	Other	Additional anesthetic considerations
1 : 100,000	Adenotonsillar hypertrophy contributing to obstructive sleep apnea, progressive upper airway obstruction, infections				Treatment with enzyme replacement therapy, stem cell, or cord blood transplantation has had some good long term results	Reports of successful intubation using multiple techniques
homozygous or compound heterozygous mutation in the gene encoding alpha-L-iduronidase (IDUA) on chromosome 4p16.3	Glycosaminoglycan deposition in pharynx/larynx wall – laryngeal inlet prolapse/stridor/airway compromise					Report of failed epidural anesthesia – likely from mucopolysaccharide deposits on meninges
Iduronidase deficiency: hydrolyzes the terminal alpha-L-iduronic acid residues of the glycosaminoglycans dermatan sulfate and heparan sulfate	Ocular findings: corneal clouding, glaucoma					
Hurler-Scheie, and Scheie are milder forms of disease						
Loeys-Dietz syndrome	Widely spaced eyes, bifid uvula/cleft palate	Cerebral aneurysms	Aortic, thoracic, and abdominal arterial aneurysms and/or dissections	Pectus excavatum or carinatum	Unstable vertebral subluxations. Arachnodactyly, camptodactyly, clubfoot deformity, scoliosis, joint laxity.	Similar to Marfan Syndrome but earlier/worse aortic aneurysms.
Furlong syndrome		Craniosynostosis				Possible micrognathia
Autosomal dominant		Normal intelligence				Possible cervical spine abnormalities
Transforming growth factor-beta receptor 1 and 2 genes: 4 of the 5 types						Beta blocker and ACE receptor blocker/inhibitor therapy common
						Control hypertension/tachycardia
Marfan syndrome	High-arched palate	The widened lumbosacral canal may lead to increased cerebrospinal fluid volume: may need larger than normal doses of spinal or epidural anesthetics	Aortic dissection: avoid hypertension	Pectus excavatum	Characteristic facies:	Widened lumbosacral canal may lead to increased cerebrospinal fluid volume: may need larger than normal doses of spinal or epidural anesthetics
	Crowded teeth	Spinal arachnoid cysts	Mitral valve prolapse	Pulmonary blebs with spontaneous pneumothoraces	Dolichocephaly, long and narrow facies	avoid hypertension

AL Grawany

Variable inheritance; often autosomal dominant			Aortic or pulmonary artery dilatation: consider pre-operative echocardiography to confirm the absence	Obstructive sleep apnea	Lens dislocation, elongated globe, myopia	
1 : 3–10,000			Aortic insufficiency	Possible tracheomalacia	Increased risk of glaucoma, retinal detachment	
Heterozygous mutation in the fibrillin-1 gene (FBN1; 134797) on chromosome 15q21.1			Possible progressive narrowing of coronary arteries	Possible emphysema and bronchogenic cysts	Orthopedic abnormalities:	
Mutation fibrillin-1 gene: connective tissue protein					Tall with arm span greater than height Winged scapula Joint laxity leading to recurrent dislocations Ulnar deviation, arachnodactyly Scoliosis, kyphosis Congenital contractures, flat feet Gastrointestinal/genitourinary abnormalities: Inguinal, umbilical, and femoral hernias	
Maroteaux-Lamy syndrome	Possible difficult to impossible direct laryngoscopy and intubation:	Normal intelligence	Heart failure is the most common cause of death	At risk for airway obstruction: possible post-operative respiratory distress, post-obstructive pulmonary edema	Characteristic facies:	Cervical spinal cord compression
Mucopolysaccharidosis VI	Frontal bossing	Spinal compression from dural thickening, usually cervical: avoid neck extension	Aortic valve calcifications	Pectus carinatum	Coarse face, "tight" skin	Possible difficult intubation
Arylsulfatase B deficiency	Depressed nasal bridge	Communicating hydrocephalus from lumbar stenosis	Possible mitral valve involvement	Recurrent upper respiratory infections	Hirsutism	
Autosomal recessive	Enlarged tongue, gingival hypertrophy	Hearing loss: conductive and sensorineural	Hypertension	Sleep apnea	Corneal clouding	
1 : 238–433,000	Thick mucous secretions	Atlanto-axial instability from odontoid dysplasia		Restrictive lung disease	Orthopedic abnormalities:	
Homozygous or compound heterozygous mutation in the ARSB gene on chromosome 5q14.1	Short, stiff neck				Normal growth for the first few years, then stops	

(*Continued*)

Table 8.1 (Continued)

Syndrome: Name, Eponyms, Inheritance,Incidence,Gene Locus, Gene Product	HEENT/Airway	Central nervous system	Cardiovascular	Pulmonary/Thoracic	Other	Additional anesthetic considerations
Deficient arylsulfatase B; the lysosomal enzyme that removes the C4 sulfate ester group from the ***N***-acetylgalactosamine sugar residue at the nonreducing terminus of the glycosaminoglycans dermatan sulfate and chondroitin sulfate	Anterior larynx				Hypoplasia of hip acetabulae with small flared iliac wings	
	Possible atlanto-axial instability Intubation difficulty worsens with age At risk for airway obstruction due to mucopolysaccharide deposits in the lips, tongue, epiglottis, tonsils, adenoids, lower airway Loss of tonicity in the supraglottic region due to neuromuscular blockade might cause airway obstruction during manual ventilation; as such, consider not using neuromuscular blocking agents until the airway is secured.				Hypoplasia of L1–L2 vertebrae with lumbar kyphosis Proximal femoral dysplasia Contractures of joints due to deposits of polysaccharide in ligaments Restricted mobility of hips, knees, elbows Carpal tunnel syndrome, claw hand Hepatosplenomegaly with hypersplenism: Results in anemia, thrombocytopenia, genitourinary abnormalities: umbilical and inguinal hernias	
Morquio syndrome	Possible difficult mask ventilation, direct laryngoscopy, and intubation:	Cervical spine instability, odontoid hypoplasia with atlantoaxial subluxation: evaluate cervical spine pre-operatively	Mitral and aortic valve disease, especially aortic insufficiency late in the disease	Restrictive lung disease from kyphoscoliosis	Type A: severe form	Difficult airway tools that displace a significant amount of soft tissue in a rigid manner are preferable such as a video laryngoscope
Mucopolysaccharidosis IV	Short neck with limited movement	Sensorineural or mixed hearing loss	Possible pulmonary hypertension, cor pulmonale due to lung disease	Pectus carinatum, rib flaring	Type B: milder form	

AL Grawany

Mucopolysaccharidosis IVA	Neck flexion may occlude the airway	Normal intelligence		Obstructive or central sleep apnea	Characteristic facies:	
Galactosamine-6-sulfatase deficiency	Cervical spine instability			Recurrent lower airway infections	Dense calvarium	
Autosomal recessive	Possible limited mouth opening			Susceptible to pulmonary hemorrhage after bone marrow transplant	Coarse facial features	
1 : 216–640,000 (A and B)	Prominent mandible or maxilla				Short, antevered nose	
Mutation chromosome 16q24.3	Redundant pharyngeal mucosa				Short neck with limited movement	
Deficiency in galactosamin-6-sulfatase; lysosomal enzyme involved in the catabolism of keratan and chondroitin sulfate	Macroglossia				Broad mouth with redundant pharyngeal mucosa	
	Tonsillar and adenoid hypertrophy				Macroglossia	
Mucopolysaccharidosis IVB	Widely spaced maxillary anterior teeth				Widely spaced maxillary anterior teeth	
Autosomal recessive	May require smaller than predicted endotracheal tube				Corneal clouding, glaucoma	
1 : 216–640,000 (A and B)	Enamel hypoplasia with pitting (type A)				Orthopedic abnormalities:	
Mutation chromosome 3p22.3	Possible copious tracheobronchial secretions: consider antisialogogue				Short stature due to shortened trunk and neck	
Deficiency in beta-galactosidase; lysosomal hydrolase that cleaves the terminal beta-galactose from ganglioside substrates and other glycoconjugates					Shortened long bones, short hands, Odontoid hypoplasia with atlanto-axial subluxation, Flattened vertebral bodies (platyspondyly) Kyphoscoliosis, lumbar lordosis Joint laxity and instability: needs careful intraoperative positioning, Genu valgum GI abnormality: hepatosplenomegaly	
Noonan syndrome	Possible difficult intubation:	Arnold-Chiari malformation	Pulmonic stenosis	Pectus excavatum	Characteristic facies:	May be difficult to place epidural due to relatively narrow spinal canal with normal-sized spinal cord

(*Continued*)

Table 8.1 (Continued)

Syndrome: Name, Eponyms, Inheritance,Incidence,Gene Locus, Gene Product	HEENT/Airway	Central nervous system	Cardiovascular	Pulmonary/Thoracic	Other	Additional anesthetic considerations
Male Turner syndrome; Female Pseudo-Turner Syndrome; Turner Phenotype with Normal Karyotype	Webbed, short neck	Cerebral arteriovenous malformation	Hypertrophic obstructive cardiomyopathy	Kyphoscoliosis, thoracic lordosis	Triangular face	Possible difficult peripheral intravenous access due to subcutaneous edema
Autosomal dominant	Micrognathia		Bleeding diathesis – coagulation factor deficiency, platelet dysfunction, thrombocytopenia	Restrictive lung disease	High- arched eyebrows,	
1 : 1,000–2,500	Dental malocclusion	Possible hearing loss	Left ventricle hypertrophy		Downward slanting palpebral fissures	
Heterozygous mutation in the PTPN11 gene on chromosome 12q24.13(about 50% of patients; wide genotypic and phenotypic variability	Flat midface with depressed nasal bridge	Mild mental retardation	Patent ductus arteriosus		Epicanthal folds	
PTPN11 gene: protein tyrosine phosphatase SHP-2: modulates intercellular signaling including epidermal growth factor receptor	High arched palate		Aortic stenosis		Ptosis	
	Possible cervical cystic hygroma		Coarctation of the aorta		Myopia Strabismus Nystagmus Low set ears with thickened helix Orthopedic abnormality: short stature gastrointestinal abnormalities: Hepatosplenomegaly Poor feeding in infancy genitourinary abnormalities: Renal dysfunction, cryptorchidism genitourinary abnormalities: Lymphatic dysplasia	
Trisomy 13	Possible difficult direct laryngoscopy and intubation:	Hypotonia	Congenital heart defects:	Possible apnea: monitor post-operatively	Characteristic facies:	Spinal dysraphism: confirm absence prior to neuraxial technique

AL Grawany

Patau syndrome	Microcephaly: may require smaller than predicted endotracheal tube size	Myelomeningocele	Ventricular septal defect, Tetralogy of Fallot	Pectus carinatum	Microcephaly with occipital scalp defect
Sporadic: meotic non-dysjunction	Wide sagittal suture and fontanelles		Double-outlet right ventricle	Kyphoscoliosis	Low-set ears, abnormal helices
1 : 10,000	May require smaller than predicted endotracheal tube size	Developmental delay			Broad, flat nose
Chromosome 13 trisomy	Cleft lip or cleft palate	Febrile seizures			Microphthalmia, anophthalmia, cataracts
	Short neck	Holoprosencephaly with agenesis of the corpus callosum			Optic nerve hypoplasia, limited vision
	Micrognathia	Cerebellar hypoplasia			Short neck Capillary hemangioma on forehead, GI abnormalities: Microscopic pancreatic dysplasia Malrotation, omphalocele, Meckel's diverticulum, GU abnormalities: Unilateral renal agenesis, renal and urogenital duplication Hydronephrosis, polycystic kidneys Renal insufficiency Cryptorchidism, hypospadias Hypoplastic ovaries, abnormal insertion of fallopian tubes Orthopedic abnormalities: Polydactyly of hands, possibly feet Flexion deformities of hands, simian crease Radial aplasia Prominent heel, rocker-bottom foot deformity, clubfoot deformity Joint subluxation
Trisomy 18	Possible difficult direct laryngoscopy and intubation:	Sensorineural hearing loss	Greater than 95% incidence of cardiac defects:	Short sternum	Characteristic facies:

Syndrome: Name, Eponyms, Inheritance,Incidence,Gene Locus, Gene Product	HEENT/Airway	Central nervous system	Cardiovascular	Pulmonary/Thoracic	Other	Additional anesthetic considerations
Edwards syndrome	Microcephaly, prominent occiput, narrow bifrontal diameter	Severe mental retardation	Ventricular septal defect, atrial septal defect, patent ductus arteriosus, bicuspid aortic valve	Possible diaphragmatic muscle hypoplasia,	Microcephaly, prominent occiput	
Sporadic: meotic non-dysjunction	Micrognathia	Hypotonia in the neonatal period	Pulmonic stenosis, coarctation of the aorta	the absent or malformed right lung	Short palpebral fissures	
1 : 6–8,000	Cleft lip or cleft palate	Hypertonia after the neonatal period	Aberrant subclavian artery: confirm absence prior to placement of subclavian central venous line	Recurrent apnea in the neonatal period	Epicanthal folds, ptosis, corneal opacity	
Chromosome 18 trisomy		Possible holoprosencephaly			Low-set, malformed ears gastrointestinal abnormalities: Omphalocele, Meckel's diverticulum, malrotation Anal anomalies, ectopic pancreatic or splenic tissue Failure to thrive genitourinary abnormalities: Cryptorchidism Ectopic kidneys, horseshoe kidney, polycystic kidney Hydronephrosis, duplication of the collecting system Renal insufficiency Orthopedic abnormalities: Clenched hands at birth, index finger overlaps third finger, fifth finger overlaps the fourth Short, hypoplastic, or absent thumb Small, narrow pelvis with limited hip abduction Clubfoot deformity, rocker-bottom feet, syndactyly of second and third toes, short stature	

AL Grawany

Turner syndrome	Possible difficult intubation:	Sensorineural hearing loss	Congenital heart anomalies:	Broad, "shield-like" chest	Occurs in females
XO syndrome	Short, webbed neck: possible endobronchial intubation		Coarctation of the aorta	Mild pectus excavatum	Characteristic facies:
gonadal dysgenesis	High-arched palate		Bicuspid aortic valve		Webbed neck
meiotic nondisjunction, mosaicism	Micrognathia		Aortic dissection		Ptosis, inner canthal folds
1 : 2,500 females			Partial anomalous venous return		Protruding external ear
monosomy chromosome X			Possible prolonged QT		Strabismus, amblyopia
Half of the patients are mosaic (45 XO/46 XX) with milder manifestations			Hypertension		Orthopedic abnormalities:
			Hypercholesterolism		Short stature
					Increased carrying angle of elbows
					Short fourth metacarpal and metatarsal
					Narrow, deeply set nails
					Dislocated hips, puffy hands and feet
					Scoliosis, kyphosis
					Dislocation of patella
					gastrointestinal abnormalities:
					Crohn's disease, ulcerative colitis
					genitourinary abnormalities:
					Gonadal dysgenesis or agenesis with streak ovaries
					Fertility is rare
					Horseshoe kidney
					Possible duplicated collecting system
					Endocrine abnormalities:
					Absent thelarche and menarche: may be on hormone therapy
					Sometimes receive growth hormone replacement therapy
					Insulin resistance with type II diabetes
					Hypothyroidism

Syndrome: Name, Eponyms, Inheritance,Incidence,Gene Locus, Gene Product	HEENT/Airway	Central nervous system	Cardiovascular	Pulmonary/Thoracic	Other	Additional anesthetic considerations
VACTERL/VATER Sporadic inheritance 1 : 17,000 Possible defects at chromosome 2,7,16 (animal models) Candidate genes: SHH, FOX gli	Laryngeal stenosis Tracheal atresia Possible choanal atresia: cannot place nasal airway, perform nasal intubation, or place nasogastric tube	Vertebral anomalies: hemivertebrae, dysplastic vertebrae, vertebral fusion, tethered cord	Cardiac malformations	Tracheoesophageal fistula Ectopic bronchus	Obesity GI abnormalities: Anal atresia Trachoesophageal fistula Esophageal atresia Duodenal atresia Orthopedic abnormalities: Radial dysplasia Vertebral anomalies: hemivertebrae, dysplastic vertebrae, vertebral fusion Dysplastic thumb Preaxial polydactyly, syndactyly Hip dysplasia GU abnormalities: Renal dysplasia Defects of external genitalia	
Williams syndrome	Possible difficult intubation:	Cerebral artery stenosis	Congenital heart defects:		Characteristic facies:	High incidence of coronary artery abnormalities and obstruction even if the supravalvar aortic stenosis is not severe. Avoid hypotension and hypovolemia, tachycardia. Avoid prolonged fasting and anesthetic drugs that excessively veno- and vasodilate. Have volume infusion, and bolus vasoconstrictor agents available (phenylephrine).

AL Grawany

Williams-Beuren syndrome	Flat mid-face, wide mouth	Infantile hypotonia with hypertonia later	Aortic stenosis, usually supravalvular,can lead to sudden death,	"Elfin" facies
Autosomal dominant or spontaneous inheritance	Dental malocclusion, poor dentition	Visuospacial deficits	Bicuspid aortic valve, mitral valve prolapse, mitral insufficiency	Puffy eyes, lacy iris pattern
1 : 10,000		Attention deficit disorder	Left coronary artery stenosis, myocardial ischemia	Hyperacusis
Deletion chromosome 7q11.23		Hyperacusis	Peripheral pulmonary artery stenosis	Depressed nasal bridge with anteverted nares
Gene: elastin		Seizures	Abdominal aortic coarctation	Enamel hypoplasia with small teeth
			Tetralogy of Fallot, ventricular septal defect	Harsh voice
			Possible narrowing of celiac, mesenteric, or renal arteries	Orthopedic abnormalities:
			Hypertension	Short stature
			Sudden cardiovascular collapse and death	Hypoplastic nails
				Hallux valgus, progressive joint limitation
				gastrointestinal abnormalities:
				Chronic constipation, diverticulosis genitourinary abnormalities:
				Renal structural anomalies
				Nephrocalcinosis, recurrent UTIs
				Renal artery stenosis
				Endocrine abnormalities:
				Neonatal hypercalcemia
				Early menarche
				Possible hypothyroidism
				Musical ability
				Friendly, "cocktail party" personalities

methods [52] (Table 8.2). The uniform drawback of the current formulations is that they do not cross the blood-brain barrier or effectively penetrate many tissues, and thus do not affect central nervous system pathology and have variable effects on other organ systems. Improvements in organ systems pathology are mixed; for the cardiac pathologies, it is generally acknowledged that long-term ERT reduces or at least stabilizes LV mass index, septal hypertrophy, and ejection fraction in MPS I, II, IV, and VI in most studies. The valvular abnormalities are not improved [53]. Coronary artery pathology improvement has not been specifically addressed, but there are case reports of sudden unexpected death from coronary artery stenosis in ERT-treated patients. For other pertinent systems, although there have been a few reports of improved obstructive sleep apnea, coarseness of facial features, and respiratory infections with ERT, studies have not yet demonstrated a reduction in adenoidal or tonsillar hypertrophy. Another therapy for MPS disorders has been hematopoietic stem cell transplant, which has shown promise in MPS I, but with mixed results in MPS II, III, IV, and VI. The overall message for the anesthesiologist caring for MPS patients is that each patient requires very careful multisystem evaluation, and because of variable outcomes, patients receiving ERT or who have had stem cell transplants should not be assumed to have significant improvement because these therapies do not appear to be consistently effective in reversing already established pathology even though they may prevent progression of the disease.

ERT is available for Pompe disease, but not for Danon disease; a review of ERT for infantile-onset Pompe disease showed that ERT markedly extended overall survival and ventilation-free survival, and also improved cardiomyopathy [54]. ERT can also stabilize late-onset Pompe disease but is not a cure for this condition. Gene therapy for this disease is being proposed as a better alternative given these mixed results of ERT after more than 10 years of use [55].

Aortopathy syndromes

Hereditary aortopathy syndromes are a group of disorders resulting in thoracic aortic aneurysms, and are generally divided into syndromic (Marfan Syndrome, Loeys-Dietz Syndrome, Ehlers-Danlos Syndrome) and familial non-syndromic thoracic aortic aneurysms [56]. The section will discuss the syndromic conditions, which are most commonly encountered by congenital cardiovascular anesthesiologist.

Marfan syndrome

Marfan syndrome is an autosomal dominant disorder with a mutation in the fibrillin 1 (FBN-1) gene on chromosome 15 (15q21.1) responsible for most cases, although more than 1,000 individual mutations in this gene have been associated with the syndrome[57]. Transforming growth

Table 8.2 Classification of mucopolysaccharidoses with enzyme replacement therapies

Type	Syndrome	Phenotype MIM number (#)	Deficient Enzyme (EC Classification)	Gene symbol	Affected GAGs	Inheritance	Recombinant enzyme	Brand name

factor-beta (TGF-beta) receptors 1 and 2 are also involved. Approximately 75% of patients with Marfan Syndrome have an affected parent and 25% are *de novo* mutations, and the prevalence is estimated to be between 1 : 5,000 and 1 : 10,000 with both genders equally represented. Fibrillin-1 is a glycoprotein that makes up the main constituent of the microfibrils of the extracellular matrix in multiple organs. The cardinal clinical features of this syndrome are aortic root aneurysms and ectopia lentis, with mitral valve prolapse another common clinical feature. Aortic dissection and rupture is the major cause of early morbidity and mortality in Marfan Syndrome, with the risk increasing significantly during adolescence, with death in up to 50% of undiagnosed patients by age 40 [58]. Skeletal features include kyphoscoliosis, pectus carinatum, tall stature, foot abnormalities, long fingers, and facial features such as malar hypoplasia and retrognathia. Dural ectasia is also frequently seen in Marfan Syndrome. Diagnosis is made by applying a scoring system known as the revised Ghent criteria (Table 8.3), and genetic testing for the fibrillin 1 gene.

Medical management of Marfan Syndrome consists of medications to control blood pressure, heart rate, and myocardial contractility to prevent aneurysm progression and usually include a beta blocker such as atenolol, and an angiotensin receptor blocker such as losartan. In addition to cardiac surgery for aortic root aneurysm and mitral valve prolapse, Marfan syndrome patients may need anesthetic care for eye surgery, spine surgery, and other orthopedic surgeries, as well as repeated imaging studies for assessment of the aortic root. In rare cases, Marfan Syndrome can present in infancy as Infantile Marfan Syndrome, with aortic root dilation as the major feature [59].

Table 8.3 Revised Ghent criteria for the diagnosis of Marfan syndrome

Criteria for diagnosis of MFS
In the absence of a family history of MFS:
1. Aortic root Z score ≥2 AND ectopia lentis
2. Aortic root Z score ≥2 AND an *FBNI* mutation
3. Aortic root Z score ≥2 AND a systemic score[a] ≥7
4. Ectopia lends AND an *FBNI* mutation with a known aortic pathological abnormality
In the presence of a family history of MFS (as defined above):
1. Ectopia lends
2. Systemic score[a] ≥7
3. Aortic root Z score ≥2

Source: Castellano et al. [58]. Reproduced with permission from SAGE Publications.

MFS, Marfan syndrome; FBNI, fibrillin-I.

[a] Points for systemic score: wrist AND thumb sign = 3 (wrist OR thumb sign = I); pectus carinatum deformity = 2 (pectus excavatum or chest asymmetry = I); hindfoot deformity = 2 (plain pes planus = I); dural ectasia = 2; protrusio acetabuli = 2; reduced upper segment/lower segment ratio AND increased arm/height AND no severe scoliosis = I; scoliosis or thoracolumbar kyphosis = I; reduced elbow extension = I; facial features (3/5) = I (dolichocephaly, enophthalmos, downslanting palpebral fissures, malar hypoplasia, retrognathia); skin striae = I; myopia > 3 diopters = I; mitral valve prolapse = I.

Loeys-Dietz syndrome

Loeys-Dietz syndrome (LDS) is also an autosomal dominant connective tissue disorder characterized by aortic aneurysms, arterial tortuosity, hypertelorism, and bifid uvula or cleft palate that was described in 2005 [60]. Other clinical features include joint laxity, pectus deformity, dural ectasia, cervical spine abnormalities, and scoliosis. Four genetic mutations are associated with this disease, including TGF-beta receptors I and II, TGF-beta ligand gene and the SMAD3 gene. The most important feature of this disorder is widespread arterial involvement, with vascular tortuosity, a high risk of aneurysms and dissections throughout the arterial tree, and an aggressive vascular course. Aortic root aneurysms are even more common and severe than in Marfan Syndrome. There are no specific clinical criteria; the diagnosis is confirmed by molecular test, with arterial aneurysm or dissection, and a family history of the disorder being sufficient features. Medical therapy for prevention/slowing of aortic aneurysm growth is similar to Marfan Syndrome. In a case series of 79 patients with LDS and 256 with Marfan syndrome, 16% of LDS patients' initial presentation was acute aortic dissection, compared with 10% in the Marfan Syndrome group. The need for subsequent aortic surgery in LDS was 10–20 times greater with LDS than in Marfan Syndrome, ranging from 5 to 12%, and late mortality after aortic arch surgery in LDS was 33% [61]. Pregnancy in LDS has been associated with significant morbidity and mortality from an aortic dissection, but successful pregnancies and even cardiac surgery during pregnancy have been described with careful management plans [62].

Ehlers-Danlos syndrome

Ehlers-Danlos syndrome (EDS) is a heterogeneous group of connective tissue disorders, with all subtypes exhibiting joint hypermobility, skin hyperextensibility, and tissue fragility. Up to 25% of EDS patients have aortic aneurysms. There are many forms of EDS, and recently they have been categorized by six different groups, each with several subtypes. The classic and hypermobile forms account for over 90% of the cases. Mutations in multiple genes have been implicated in this disorder, encoding collagen fibrils or proteins involved in the processing of these collagens [63] (Table 8.1).

See Chapter 31 for additional discussion of aortopathy syndromes and cardiac surgical and anesthetic approaches.

VACTERL association

VATER association was first described in the early 1970s. The term "association" was used because it was a co-occurrence of a group of congenital anomalies that was more than random. The original VATER malformations included **V**ertebral defects, **A**nal atresia, **T**racheoesophageal fistula with esophageal atresia, and **R**adial and **R**enal dysplasia. Later, the association became known as VACTERL; **V**ascular anomalies including single umbilical artery, **C**ardiac defects, and **L**imb abnormalities beyond radial were the added congenital malformations [64] (Figure 8.9). The incidence of the VACTERL association is between 1/10,000 and 1/40,000. This large range is due to the difficulty in "diagnosing"

AL Grawany

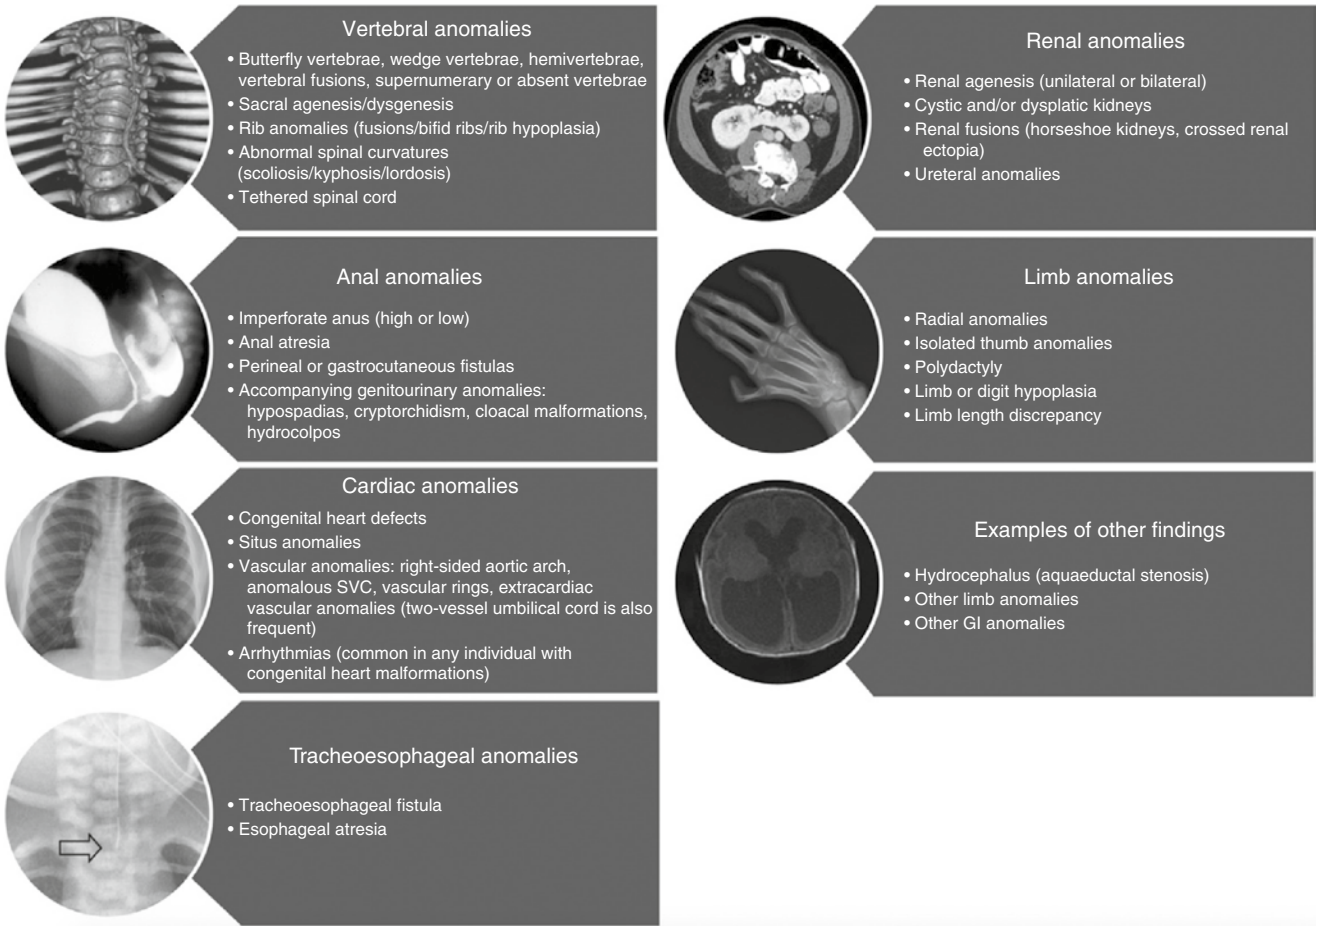

Figure 8.9 Examples of findings in the VACTERL association. The images in the circles represent radiological examples. Vertebral anomalies: 3D CT reconstruction showing thoracic segmentation anomalies; anal anomalies: contrast imaging showing rectoprostatic urethral fistula in a patient with ano-rectal malformations (ARMs); cardiac anomalies: chest radiograph showing midline heart in a patient with situs anomalies as part of the VACTERL association; tracheo-esophageal anomalies: radiograph showing the position of feeding tube placement (arrow) due to a tracheal pouch; renal anomalies: axial view from an abdominal CT showing horseshoe kidney; limb anomalies: skeletal anomalies affecting the radius, wrist, and thumb; examples of other findings: axial view from brain MRI showing hydrocephalus (due to aqueductal stenosis). GI, gastrointestinal; SVC, superior vena cava. (Source: Solomon et al. [31]. Reproduced with permission from Elsevier.)

patients with the association. Most agree that the presence of ≥3 malformations is required, but there is no genetic or diagnostic test for VACTERL. In fact, there is no one unifying cause for VACTERL. There are some cases or clusters in which there appears to be a genetic basis, although signaling pathways including Hedgehog, FGF, and NOTCH have been implicated, as well as environmental contributions [65, 66].

VACTERL may be suspected prenatally due to ultrasound findings including polyhydramnios or an absent gastric bubble suggestive of tracheoesophageal fistula/esophageal atresia (TEF/EA), colonic distension is suggestive of anal atresia, a single umbilical artery, renal and bony (vertebral, radial) abnormalities. After birth, inability to pass an oro- or nasogastric tube suggests TEF/EA, examination may suggest anal atresia, a single umbilical artery, cardiac and limb abnormalities. Patients with TEF/EA, anal atresia, single umbilical artery, or limb abnormalities should be considered at risk for VACTERL, and an echocardiogram should be performed. Of note, many other syndromes are associated with these malformations. For this reason, genetic testing should be undertaken. In addition, if patients have malformations that are not typical of VACTERL, this suggests that the patient may have a syndrome with overlapping features [65].

Vertebral abnormalities are present in 60–80% of patients with VACTERL and may include segmentation defects such as hemi-, butterfly, and wedge vertebrae. Other vertebral abnormalities include fusions and extra or missing vertebrae. These vertebral findings may be asymptomatic and picked up on radiological studies or they may cause symptoms that need to be addressed medically or surgically.

Imperforate anus, anal atresia, or anorectal malformations are present in 55–90% of patients with VACTERL. These may be detected during the newborn examination while trying to measure rectal temperature, or later with obstruction. In the first few days of life, a colostomy may be necessary with definitive surgical management occurring 1–2 months later [67].

Cardiac defects are often found in patients with VACTERL. Cunningham et al. reported that congenital heart defects were found in 67% of the patients in the study with ventricular septal defect being present in 58% of the patients with a

cardiac lesion. The congenital heart lesions ranged from the presence of persistent left superior vena cava or bicuspid aortic valve to lesions requiring repair or palliation in the neonatal period [68].

Tracheoesophageal fistula (TEF) with/without esophageal atresia is present in 50–80% of patients with VACTERL. Polyhydramnios or the absence of a gastric bubble on prenatal ultrasound may suggest the possibility of TEF. Postnatally, the inability to pass an oro- or nasogastric tube or choking with feeds may lead to the diagnosis. Surgery is generally necessary for the first days of life.

Renal anomalies may include unilateral agenesis, horseshoe kidney, and cystic or dysplastic kidneys. These may lead to decreased renal function. Limb malformations were originally confined to radial abnormalities, and these were found in approximately 50% of patients. Further characterization has led to the inclusion of lower limb anomalies and polydactyly [65].

Patients with VACTERL association may need surgical procedures in the first few days of life, most commonly a colostomy for anal atresia or a tracheoesophageal atresia repair. As the patient may not carry the diagnosis of VACTERL, one must consider the possibility of a coexisting cardiac lesion, and an echocardiogram should be performed. In addition, when a newborn patient presents to the neonatal or cardiovascular intensive care unit after birth, one must consider the possibility that other malformations including TEF/EA may exist [2]. A careful examination should be done. Patients presenting for cardiac surgery may have had a TEF/EA repair previously. Intraoperative transesophageal echocardiography may be contraindicated in these patients; epicardial echocardiography may be considered. Limb malformations, especially radial anomalies, may be associated with the difference in vascular anatomy. An ultrasound examination prior to line placement may be helpful. Renal anomalies should alert the perioperative team to the potential for preoperative or postoperative renal insufficiency. Markers of renal function should be analyzed pre-and postoperatively.

CHARGE syndrome

CHARGE syndrome was first described as an association of congenital anomalies in 1979, and the CHARGE acronym was coined in 1981: **C**oloboma, **H**eart defect, choanal **A**tresia, growth and developmental **R**etardation, **G**enital hypoplasia, and **E**ar anomalies/deafness. In 2004, Vissers et al. identified that a loss of function in the CHD7 gene (Chromodomain Helicase DNA-binding protein 7) located on chromosome 8q12 was associated with the syndrome. The mutation in the CHD7 gene was found to almost always be de novo, with rare occurrences of autosomal dominant inheritance [69]. However, CHARGE syndrome is still usually a clinical diagnosis based on the presence of major and minor phenotypic criteria. Some clinical features of the CHARGE syndrome are illustrated in Figure 8.10 [70].

The majority of patients have ocular abnormalities, most often coloboma. Coloboma can be associated with a variable reduction in visual acuity depending on the type of coloboma (iris, retina, choroid, etc.), with the chorioretinal coloboma being most common. Other ocular abnormalities may include microphthalmia, microcornea, cataracts, strabismus, ptosis, and refractive errors [70] (Table 8.4).

Congenital heart disease is reported in 75–80% of patients with CHARGE syndrome [71]. The type of defect varies, but there is a relative overrepresentation of conotruncal anomalies, atrioventricular septal defects, and septal defects [72]. Tetralogy of Fallot is the most common cyanotic defect associated with the syndrome [71].

Choanal atresia and other upper respiratory tract abnormalities are very common in patients with CHARGE syndrome. In 65% of patients, choanal atresia is noted after birth. Other causes of airway obstruction in these patients include subglottic stenosis and laryngotracheomalacia. Of note, 15–20% of these patients have cleft lip or palate, and 15–20% have tracheoesophageal fistula [70, 73] Obstructive sleep apnea is also very common. Abnormalities in growth and development may also be present, and patients may exhibit varying degrees of intellectual ability. Genital hypoplasia, especially in males, is a feature of the syndrome, and renal anomalies may also be present.

Outer ear abnormalities are very common in patients with CHARGE syndrome and can alert the care team to the possibility of the syndrome. The most common inner ear abnormality is the absence of the lateral semicircular canals, although other abnormalities are common. Most result in some sensorineural hearing loss or poor balance [70]. Cranial nerve dysfunction is also common in patients with CHARGE syndrome. Anosmia is almost always present. Cranial nerve dysfunction can lead to poor oromotor function, difficulty in swallowing, reflux, and aspiration. Endocrine issues may include hypothyroidism and hypocortisolism. Immunodeficiency can also be encountered. Some patients are athymic, and atypical severe combined immunodeficiency syndrome (SCID) may be present. This may result in increased susceptibility to infection [70].

Patients with CHARGE syndrome have congenital abnormalities spanning multiple organ systems. They are often medically complex, requiring multiple procedures and surgeries, including tracheoesophageal fistula repair, choanal atresia repair, congenital heart surgery, gastrostomy tube placement, fundoplication, tracheostomy, myringotomy tube placement, cochlear implants, direct laryngoscopy and bronchoscopy, diagnostic imaging procedures, and others. Anesthetic care may be challenging due to multiple congenital anomalies. Difficult intubation may be encountered due to respiratory tract abnormalities. Patients with feeding tubes may be susceptible to hypoglycemia while fasting. Patients with CHARGE syndrome have been reported to have a significant risk of postoperative airway events. These events were noted in 35% of general anesthetics, most commonly cardiac, gastrointestinal tract, and airway scope procedures. These events were most likely to occur in patients with feeding difficulties who had a gastrostomy tube or a fundoplication, implicating cranial nerve issues and difficulties managing secretions [74]. Postoperative obstruction due to adenotonsillar hypertrophy, secretions, and other airway abnormalities is also common. There are multiple reports of increased postoperative mortality, especially in the neonatal period [2, 75, 76]. Potential risk mitigation strategies include multidisciplinary planning, combining multiple procedures under one anesthetic, and having a healthy respect for cranial

AL Grawany

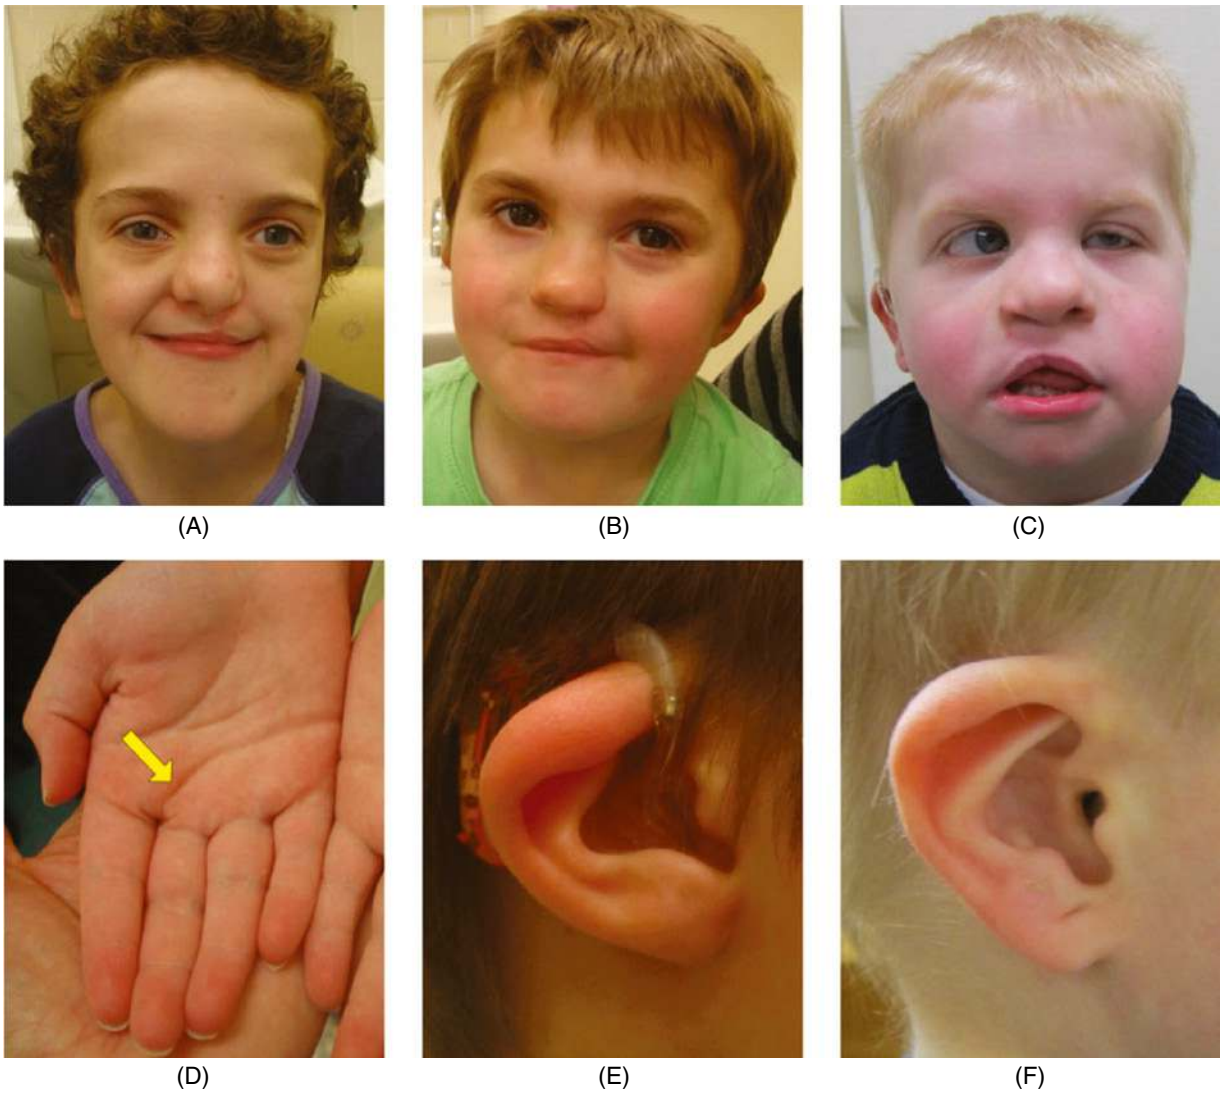

Figure 8.10 Clinical features of the CHARGE syndrome. (A) Cleft lip/palate repair, mild left facial palsy, and broad forehead in a 10-year-old girl. (B) Cleft lip/palate and square face with mild right facial palsy in a 6-year-old boy. (C) Left-sided microphthalmia, with prosthesis in situ, and a square face with broad forehead and broad nasal root in a 2.5-year-old boy. (D) "J"-shaped hockeystick palmar crease (yellow arrow). (E) Typical CHARGE ear with hypoplastic, overfolded helix and lobe, and a triangular concha. (F) Less typical appearing ear with a squared superior helix and crease on the lobe. (Source: Hsu et al. [35]. Reproduced with permission from John Wiley & Sons.)

nerve dysfunction, potential aspiration, and postoperative airway obstruction [2, 75, 76]. Due to these factors, early extubation after cardiac surgery may not be wise in patients with CHARGE syndrome. Refractory hypotension or failure to wean from cardiopulmonary bypass could be due to hypothyroidism or hypocortisolism in these patients. Treatment with liothyronine infusion or administration of a stress dose of hydrocortisone may be indicated.

Heterotaxy syndrome

Heterotaxy syndrome is a fascinating collection of disorders of left-right sidedness of multiple visceral organs; because the heart is the first organ to express laterality early in gestation, abnormalities of cardiac situs are very frequent in this syndrome, occurring in 75% or more of these patients [77]. Other findings are intestinal malrotation in about 70%, abnormalities of pulmonary situs in a similar percentage, and abnormal situs of the stomach, spleen, and liver in a high percentage, including asplenia and polysplenia. Heterotaxy syndrome may be seen in up to 3–7% of CHD patients and is estimated to occur in 1 : 5,000 to 10,000 live births. Many heterotaxy patients have single ventricle lesions, and heterotaxy syndrome can be broadly separated into asplenia and polysplenia patients. The asplenic patients have more than 50% incidence of single ventricle lesions, with total anomalous pulmonary venous return common as well. Abnormalities of systemic venous return are very common, including bilateral superior vena cavae, or interrupted inferior vena cavae. Patients with right atrial isomerism have bilateral right atria and often have bilateral sinoatrial nodes; conversely, those with left atrial isomerism often have no sinoatrial node. A classification scheme dividing heterotaxy syndrome into

Table 8.4 Phenotypic features of the CHARGE syndrome

Features	Details	Frequency
Coloboma	Iris, retina, choroid, disk, or microphthalmia	75–90%
Choanal atresia/stenosis	Unilateral or bilateral, bony or membranous	65%
Cranial nerve anomalies	Facial nerve palsy, auditory, vestibular, or vagal (swallowing problems)	Facial: 50–90%
	CNS abnormalities can also involve arhinencephaly, holoprosencephaly spectrum, or forebrain and hindbrain abnormalities	CNS abnormalities 55–85%
Characteristic ear anomalies	Outer ear tends to be symmetrically misshapen, low set, anteverted, cup-shaped, and wide with reduced vertical height	Outer ear 95–100%
	Triangular concha is a common finding	Inner ear: 90%
	Microtia, hypoplasia of the auditory canal, and preauricular tags can also be seen	
	Middle: ossicular malformation	
	Cochlear: Mondini defect	
	Temporal: absent/hypoplastic semicircular canals; highly predictive of the presence of a *CHD7* mutation	
Genital hypoplasia	Males: micropenis/cryptorchidism	50–70%
	Females: hypoplastic labia	
	Delayed puberty	
Developmental delay	IQ <70 is present in over 70%	70%
Cardiovascular malformation	Usually conotruncal, AV canal, and aortic arch abnormalities	50–85%
Growth deficiency	Hypothalamo-hypophyseal dysfunction leading to short stature and pubertal delay	70–80%
	Often birth centiles are low normal, around the 10th centile	
Orofacial cleft	Cleft lip/palate	15–20%
Distinctive facial features	Square face, prominent forehead, prominent nasal bridge and columella, and flat midface	NA
Additional features	Omphalocele/umbilical hernia	NA
	Bony scoliosis/hemivertebrae	
	Renal anomalies: dysgenesis or horseshoe/ectopic kidney	
	Hand and limb anomalies in 37%: polydactyly, J-shaped 'hockey stick' palmar flexion crease	
	Short neck, sloping shoulders, and nipple anomalies	
	Immune deficiency	

AV, atrioventricular; CNS, central nervous system; IQ, intelligence quotient; NA, not applicable.

isomerism of the left vs. right atrium is displayed in Table 8.5. indicating the major differences between these groups [78]. Because of these anatomic abnormalities of the conduction system, arrhythmias are very frequent in heterotaxy syndrome, including bradycardia syndromes in left atrial isomerism and atrial tachycardia syndromes with right atrial isomerism. Many of these patients undergo staged single ventricle palliation; and require procedures to correct TAPVR, provide pulmonary blood flow, or limit pulmonary blood flow in the neonatal period. The systemic venous abnormalities make these procedures particularly challenging, and survival for cardiac surgery in patients with heterotaxy syndrome is consistently lower than for the same cardiac operation in patients without heterotaxy, particularly for total anomalous pulmonary venous connection (TAPVC) and univentricular pathway [79]. In a large single-institution series of 264 heterotaxy patients with CHD, the mortality rate was 40.2%, with a median follow-up of 10.2 years (range 1–31 years), with no significant improvement in recent birth eras vs. patients born 1985–1991. Additional detail about surgical and anesthetic management of the cardiac lesions in heterotaxy syndrome is presented in Chapter 30. These patients also may require abdominal surgery for complications of intestinal malrotation.

The genetics of heterotaxy syndrome are complex and heterogeneous in both phenotype and genotype, with most cases appearing sporadically, and without disease history, and so suggesting de novo gene variants contribute [47, 80]. Abnormalities in the genes that determine cilia motility are involved in some heterotaxy cases. Cilia are microtubule-based organelles protruding from the cell surface that if motile, result in extracellular fluid flow. If immotile, these cilia can act as important signaling nodes; signaling between these forms of cilia are instrumental in breaking left-right symmetry during organogenesis; abnormal cilia genotypes have been associated with heterotaxy, and up to 40% of patients with heterotaxy have an abnormal respiratory ciliary function, leading to frequent respiratory complications. Patients with asplenia often have an abnormal immunologic function, but it is not always possible to assume even patients with polysplenia have normal immune systems, and so most of these patients are treated

AL Grawany

Table 8.5 Synopsis of cardiac and noncardiac anomalies in heterotaxy syndrome

Morphological features	Isomerism of left atrial appendage	Isomerism of right atrial appendage
Heart position	Any position (Dextrocardia, Mesocardia, Levocardia) Abnormal cardiac positions are common in 40–50% of patients.	Abnormal cardiac positions are more common in IRAA patients than the normal population.
Systemic veins	Interrupted IVC with azygos venous system continuation to SVC. Hepatic veins, isolated or in confluence drain into either of the atria. Bilateral SVC: Found in 40 % of cases and absent coronary sinus in 30–55% cases.	IVC drains into one of the atria. Hepatic veins may drain separately in the contralateral atrium (morphological representation of duplication of IVC). Bilateral SVC: Found in 50–60% cases and absent coronary sinus in 78% cases.
Pulmonary veins	PAPVC in >50% patients due to bilateral atrial connection of ipsilateral PVs or due to mal-aligned septum. Less frequently. TAPVC or TAPVD can be seen (10–12%). Scimitar syndrome in 1%.	Obstructed TAPVC is a common finding in >50% cases. Unobstructed TAPVC can also be present.
Atrial appendage	Both atrial appendages are of left atrial morphology (See text)	Both atrial appendages are of right atrial morphology (see text)
Atrial septum/Atrio-ventricular junction/valve	Partial AVSD, ostium primum ASD with two distinct AV orifices and cleft in left component of AV valve is common.	Common AV valve associated with complete AVSD or common atrium is frequently seen.
Univentricular AV connection	Less common (10–40%)	More common (more than 70%)
Outflow obstruction	Right outflow obstruction: less than 40%; Left ventricular outflow obstructions are seen more frequently (<50%) than IRA A.	Pulmonary stenosis/Atresia are common (>80%)
VA connection	The VA connection can be abnormal (TGA, DORV or single outlet) in around 50% of cases.	Abnormal ventriculo-arterial connection (single outlet, TGA, DORV) are more common (90–96%)
Significant CHD	Less frequent	>98%
Conduction system	Bilateral absence of sinus node may lead to bradyarrhythmias.	Two sinus nodes. The atrial tachyarrhythmias are common.
Lungs and bronchi	Bilateral morphological left bronchus and left lung rally (90%). Congenital lobar pneumonia and Scimital syndrome can be seen in few cases.	Bilateral morphological right bronchus and right lung (trilobed) (90%).
Spleen	Multiple spleens are commonly seen. In 5–10% cases, it may be absent or present singularly. Functional abnormalities are common.	The absence of a spleen is expected in this group. But in 10–15% of cases it may be present as a single or multiple masses. The spleen may be functionally abnormal.
Liver and stomach	Central liver is common in >70% cases. It may be asymmetrical, right or left-sided in few cases. The stomach may be central, right or left sided.	The majority patients have central liver. The stomach can be central, right or left.
Bowel malrotation and other abnormalities	Common in ILAA group.	Less frequent in this group
Pancreas	Not rare	Rare
Gall bladder	Common	Not reported in the literature

ASD, Atrial septal defect; AV, Atrio-ventricular; AVSD, Atrio-ventricular septal defect; CHD: Congenital heart disease; DORV: Double outlet right ventricle; ILA A, isomerism of left atrial appendage; IRA A, isomerism of right atrial appendage; IVC: Inferior vena cava; LVOTO: Left ventricular outflow tract obstruction; PAPVC: Partial anomalous pulmonary venous connection; PS/PA: Pulmonary stenosis or atresia; PV: Pulmonary valve; SVC: Superior vena cava; TAPVC/D: Total anomalous pulmonary venous connection/Drainage; TGA: Transposition of the great arteries; V-A (Concordance/Discordance), Ventriculo-Arterial (concordance or discordance).

with daily amoxicillin prophylaxis as well as targeted vaccination programs to prevent bacterial infections and sepsis [77].

Table of genetic syndromes and associations

Table 8.1. Displays the major cardiac genetic syndromes, with their major features, prevalence, gene defect, and cardiac and multisystem involvement including anesthetic considerations.

Genetic testing in CHD

Advances in both prenatal and postnatal genetic testing have prompted an earlier diagnosis of genetic syndromes in patients with congenital heart disease, which can inform prognosis, and assist the family and caregivers with therapeutic decision making. In addition, the genetic basis for CHD has seen an explosion of knowledge with advanced genetic testing. This section will review the most common genetic tests used in association with a CHD diagnosis. Prenatally, chorionic villus sampling between 10 and 13 weeks

gestation, or amniocentesis after 15 weeks can be offered; and blood testing postnatally can be sent [81]. With increasing utilization of genetic testing, these studies are now sent at any time in the life of a CHD patient, not just the neonatal period, i.e. children and adults often undergo testing, and parents may undergo testing to add data to help determine inheritance and risk of recurrence in future children. Because of the complexity of CHD genetics, an expert in cardiac genetics should guide the choice of testing modalities and their interpretations. Chapter 6 presents additional information about the genetics of cardiovascular development.

Chromosomal microarray (CMA)

Chromosomal microarray (CMA) compares patient deoxyribonucleic acid (DNA) to normal reference DNA to detect copy number variations (CNVs), which are DNA deletions and duplications on chromosomes. There are four different types of CMA studies with unique advantages and disadvantages, but for most indications in CHD patients, a comprehensive CMA is ordered, which includes both array comparative genomic hybridization and single nucleotide polymorphism techniques to assess the whole genome [82]. This test is considered the first-line evaluation for CHD patients with multiple congenital anomalies, developmental delay, or autism, and for all patients with major cardiovascular anomalies because of its high yield [83]. The main drawback for postnatal testing is a relatively long turnaround time of about 2 weeks; more rapid tests (see below) may be required for urgent clinical decision-making.

Fluorescence in-situ hybridization (FISH)

FISH and a similar test called multiplex ligation probe-dependent analysis are tests to detect copy number variations at specific regions, especially Trisomy 13, 18, 21, and sex chromosomes. The advantage of this approach is a more rapid turnaround time of 2–3 days, which can affect urgent management decisions in a neonate or unstable patient.

Chromosomal karyotype

A chromosomal karyotype is a visual inspection of all chromosomes to detect the number, i.e. trisomy and aneuploidy, and large structural anomalies like duplications or deletions, and banding patterns. This is an older test that is no longer recommended for multiple congenital anomalies in CHD patients.

Single gene sequencing

In diseases with known single-gene causes, this test determines the nucleotide sequence of the specified gene when one of these disorders is suspected. Turnaround time is 3–4 weeks.

Whole exome sequencing

Whole exome sequencing (WES) is a newer, large-scale sequencing technology that determines the nucleotide sequences of all of the protein-encoding regions of the entire genome, the exons. Analysis of this data is complex and depends significantly on the clinical information provided to focus the report on the relevant findings. This testing can also report incidental findings, and variants of unknown significance, i.e. not associated with a known disorder, which require family counseling about these results. This test is best for the assessment of multiple possible single-gene disorders simultaneously in a patient with a complex phenotype. Turnaround time is 3–4 months.

Panels of tests have been developed for specific diseases and related entities; Tables 8.6 and 8.7 display the approach utilized at Texas Children's Hospital.

Table 8.6 Recommended genetic testing by the lesion

Left-sided lesions	
HLHS	Male: CMA Female: CMA and rapid FISH for sex chromosomes to screen for Turner syndrome (if outside the newborn period or non-urgent, do only CMA) If CMA negative, with any of the following: renal anomalies, hypotonia, ear anomalies: consider Kabuki panel (may also do WES)
Coarctation of the aorta, moderate-to-severe aortic stenosis	CMA If CMA negative, with any of the following: renal anomalies, hypotonia, ear anomalies: consider Kabuki panel (may also do WES)
BAV in a female with any of the following: coarctation, PAPVR, LSVC, absent ductus arteriosus, cystic hygroma, lymphedema, shield chest, short stature, webbed neck	Karyotype
Supravalvar aortic stenosis	CMA If CMA negative, elastin gene (*ELN*) sequencing with deletion/duplication testing
Right-sided lesions	
Pulmonary stenosis with any of the following: hypertrophic cardiomyopathy, conduction abnormalities, fetal chylous effusions, short stature, webbed neck, shield chest, developmental delay, cryptorchidism, dysmorphic features	Noonan panel
Conotruncal defects	
TOF (PS or PA-VSD)	CMA If seen with bile duct paucity, cholestasis, butterfly vertebrae, ocular anomalies, growth delay, hearing loss, horseshoe kidney: also do *JAG1* and *NOTCH2* gene sequencing (or CHD panel that includes these)
Truncus arteriosus, DORV, IAA with VSD	CMA
Right aortic arch (even if isolated)	CMA

AL Grawany

Table 8.6 (Continued)

Aortic disease	
Aortic root dilation without CHD and features concerning for Marfan-like disorder	Aortopathy panel
Ascending aortic dilation with lung disease and/or pulmonary hypertension	Aortopathy panel
Others	
AVSD	Features suggestive of T21: karyotype (unless diagnosis critical, then rapid FISH for chromosome 21) No concerning facial features, or features not consistent with T21: CMA (will also detect T21) With short stature, conduction abnormalities, hypertrophic cardiomyopathy, webbed neck, shield chest, developmental delay, cryptorchidism, abnormal facies: consider Noonan panel
Heterotaxy	CMA and heterotaxy panel
All other CHD with the exception of isolated muscular VSDs, nonsyndromic isolated ASDs, isolated BAV, isolated LSVC	CMA

ASD, atrial septal defect; AVSD, atrioventricular septal defect; BAV, bicuspid aortic valve; CHD, congenital heart disease; CMA, chromosomal microarray; DORV, double-outlet right ventricle; FISH, fluorescent in-situ hybridization; HLHS, hypoplastic left heart syndrome; IAA, interrupted aortic arch; LSVC, left superior vena cava; PA, pulmonary atresia; PAPVR, partial anomalous pulmonary venous return; PS, pulmonary stenosis; T21, trisomy 21; TOF, tetralogy of Fallot; VSD, ventricular septal defect; WES: whole-exome sequencing.

Table 8.7 Recommended genetic testing by suspected diagnosis

Suspected diagnosis	**Testing**
Down syndrome	Karyotype If the diagnosis is critical in the newborn period, rapid FISH for chromosome 21 Will also be detected by CMA, but won't identify rearrangement, low-level mosaicism
Trisomy 13,18	Newborn rapid FISH for chromosome 13,18 *and* karyotype Will also be detected by CMA, but won't identify rearrangement, low-level mosaicism
Turner syndrome	With HLHS: rapid FISH for sex chromosomes If strongly suspect or to confirm the diagnosis: karyotype with FISH for Y centromere Will also be detected by CMA, but won't identify rearrangement, low-level mosaicism
Williams syndrome	Best: CMA Will also be detected with FISH for the Williams region If CMA negative or if family history of SVAS, strongly consider elastin gene (*ELN*) sequencing with deletion/duplication testing
22q11.2 deletion syndrome (DiGeorge syndrome, velocardiofacial syndrome)	Best: CMA Will also be detected with FISH for DiGeorge (usually includes chromosomes 22 and 10)
Noonan syndrome	Best: Noonan syndrome panel (adding deletion/duplication will diagnose an additional 5%) Will also be detected on WES
Marfan syndrome	Best: Aortopathy panel Will also be detected on WES
Loeys-Dietz syndrome	Best: Aortopathy panel Will also be detected on WES
Holt-Oram syndrome	TBX5 gene sequencing Will also be detected on WES and most CHD gene panels
Ehlers-Danlos syndrome	
• Hypermobile type (type 5)	There is no current diagnostic test (but there are clinical diagnostic criteria). If a personal history of easy bruising/bleeding, or abnormal skin (atrophic scars, poor wound healing, highly elastic), or family history of vascular/organ rupture, must exclude other types of EDS with EDS or aortopathy panel
• Vascular EDS (type 4)	Best: EDS panel (unless there is root dilation, then do aortopathy panel) Will also be detected on aortopathy panel or WES
• Classical EDS/ Classical-like EDS/ Cardiac-valvular EDS (types 1–3)	Best: EDS panel (unless there is root dilation, then do aortopathy panel) Will also be detected on aortopathy panel or WES
CHARGE syndrome	Best: CHD7 sequencing with deletion/duplication Will also be detected on WES

CHD, congenital heart disease; CMA, chromosomal microarray; EDS, Ehlers-Danlos syndrome; FISH, fluorescent in-situ hybridization; HLHS, hypoplastic left heart syndrome; SVAS, supravalvar aortic stenosis; WES, whole-exome sequencing.

Ethics in congenital heart disease

Ethical considerations for treatment

CHD patients with genetic syndromes often present with complex multisystem disease, in addition to congenital heart defects which may also be very complicated and may require multiple procedures for diagnosis and treatment in the catheterization laboratory and operating room. Long duration

ICU stays are necessary for some of these patients, and neurodevelopmental disabilities, either associated with the genetic syndrome, or because of neurological morbidity associated with the CHD itself or the treatment, occur in a significant proportion of these patients, with up to 25% syndromic patients with severe impairment, and 65% with mild or combined disability [84]. Knowledge about the genetics of CHD, and the prognosis for these patients, has expanded significantly as well. At the same time, surgical mortality for complex CHD continues to decrease, and the ability to treat complex lesions successfully with comprehensive multidisciplinary approaches to surgery, catheter intervention, and ICU care has increased so that patients who a decade ago would not be offered treatment, are now being offered these interventions. Cardiac surgery for Trisomy 13 and 18 patients (see above) is one example of this change [85]. Finally, the use of mechanical support, both as an acute intervention such as for ECMO-CPR (see Chapters 25 and 37) and failing to wean from bypass, and as a long-term bridge to transplant or even as destination therapy, has expanded greatly [86]. The ethical implications of this progress are profound, and the expectations and ethical perspectives of both providers and parents have great variability, and so it is crucially important that each institution have a clinical ethics program in place and a committee or team that can bring all the stakeholders together and provide consultation and advice in a multidisciplinary manner. Parents' understanding and perception of cardiac surgical risk vary greatly, and the relationships with the physicians involved in their child's care are crucial to establishing trust in times of critical decision-making [87]. In addition to the ICU team, interventional cardiologists and surgeons, the patient's primary cardiologist, and support for the family by social workers, clergy, or patient advocates are important. Trained, experienced ethicists who are objective parties not directly involved in the treatment of the patient are very important team members. Palliative care specialists are often involved in the care of these patients as well. The ethics consultation service should be utilized whenever there are significant questions or disagreements about a treatment course [88]. The parents and family need to be integrally involved in the process. Discussions about prognosis, outcome, the benefit of further treatment vs. risk of death, severe morbidity, or ongoing pain are very important for this group of patients. Although anesthesiologists are not always included in such discussions, as part of comprehensive multidisciplinary care, they should be involved as much as possible, particularly to add perspective about anesthetic risk and outcome, and ongoing pain from the procedures planned.

Palliative care in CHD

Palliative care is sometimes confused with hospice care, that provided at end of life to a patient with a terminal illness and limited life span, even by medical providers. Palliative care actually has a goal of improving the quality of life for patients and their families facing a life-threatening or life-limiting illness at any stage, not just the end of life, and the World Health Organization adds that for children, palliative care should begin with the diagnosis of a serious illness. An interdisciplinary team of physicians, nurses, chaplains, social workers, therapists, child life specialists, and others, is often involved. Palliative care objectives include defining goals of care, advance care planning, pain and symptom management, care coordination, and end of life assessment and management [89]. Palliative care in CHD can often start very early, even potentially in the prenatal period for some cardiac lesions. Involvement early in the neonatal period for genetic syndrome patients with critical heart disease can allow palliative care providers to establish a relationship with the parents and provide continuity between the obstetrical and pediatric environments and support short and long-term decision-making, in conjunction with treating physicians and other consultants [90]. For very high-risk patients, including some with multiple extracardiac anomalies, early discussion of goals of treatment can help avoid burdensome or futile interventions, start possible end-of-life discussions, and allow parallel planning depending on outcomes of procedures. Involving palliative care specialists can also promote better communication and acquisition of primary palliative care skills among intensivists, cardiologists, and surgeons, with the goal of a multidisciplinary team of experts unifying goals of comforting and curing.

The anesthesiologist can be involved in discussions about goals of care and contribute to discussions about providing pain relief and comfort. It is also important to understand goals for resuscitation and other invasive procedures during anesthetic care, and plan, with the parents, ICU team, and the patient when appropriate, what the treatment course will be in case of arrest or clinical deterioration. A question that often arises is whether a patient is a candidate for ECMO after a cardiac arrest. These issues should be clarified before providing the anesthetic, and the anesthesiologist should not assume that all orders that limit resuscitative efforts are automatically suspended during anesthetic care [91].

The increasing population of adult congenital heart disease patients is providing additional opportunities to engage palliative care specialists in planning, with the patient if intellectually able to understand and participate, their goals of care, advanced directives, and end of life planning. In a survey of 150 ACHD patients in the outpatient setting, 69% were willing to discuss advance care planning, 79% were willing to have a meeting to discuss their goals and care preferences, and 91% to speak to a clinician who specializes in palliative care [92].

Conclusions

With the high frequency of genetic syndromes with multisystem involvement in CHD, it is important for the anesthesiologist to have an understanding of the most common diagnoses to assist in planning for anesthetic care and in anticipating outcomes. This chapter has reviewed the genetic basis and clinical findings in the most common cardiac genetic syndromes. There are many additional, less common syndromes with cardiac involvement, and the reader is directed to comprehensive reference sources which can provide information about these rare patients [46–48, 93]. Finally, the anesthesiologist is a member of the multidisciplinary team providing expert, compassionate care to patients and families with these complex syndromes who often undergo multiple procedures, and should seek to be involved in clinical decision- making whenever possible.

Introduction

The circulatory system in congenital heart disease (CHD) continually changes and develops in response to both normal and pathologic stimuli. The response to anesthetic and surgical interventions must be understood in this framework and is often radically different from the usual, expected pediatric and adult situations with a "normal" cardiovascular system. This chapter will review developmental changes of the cardiovascular system from fetal life through to adulthood, in both the normal and pathophysiologic states associated with CHD. Not much is known about the development of the normal and diseased human heart. Much of the information discussed in this chapter was derived from animal models, and new information will undoubtedly be discovered as human myocardial tissue is studied.

Development from fetus to neonate

Circulatory pathways

The fetus receives oxygenated and nutrient-rich blood from the placenta via the umbilical vein and ejects desaturated blood through the umbilical arteries to the placenta, thus, the placenta, not the lung, serves as the organ of respiration. Blood flow largely bypasses the lungs *in utero*, accounting for only about 7% of the fetal combined ventricular output [1]. Pulmonary vascular resistance (PVR) is high, and the lungs are collapsed and filled with amniotic fluid. This forms the basis for fetal circulation, which is a parallel circulation, rather than the series circulation seen postnatally. Three fetal circulatory shunts exist to carry better-oxygenated blood from the umbilical vein to the systemic circulation: the ductus venosus, ductus arteriosus, and foramen ovale (Figure 9.1A) [2]. Approximately 50% of the umbilical venous blood, with an oxygen tension of about 30–35 mmHg, passes through the ductus venosus, and then goes into the right atrium. There it streams preferentially across the foramen ovale, guided by the valves of the sinus venosus and Chiari network into the left atrium. Thus, the brain and upper body preferentially receive this relatively well-oxygenated blood, which accounts for 20–30% of the combined ventricular output. Blood returning in the inferior vena cava represents about 70% of the total venous return to the heart, and two thirds of this deoxygenated blood passes into the right atrium and ventricle. About 90% of the blood flows through the ductus arteriosus to supply the lower fetal body.

After birth, there is a dramatic fall in PVR and an increase in pulmonary blood flow, with inflation and oxygenation of

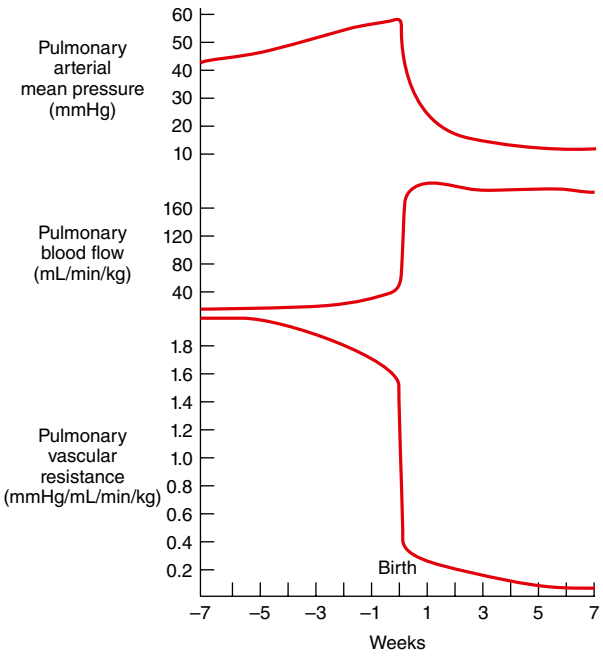

Figure 9.2 Changes in pulmonary artery pressure, pulmonary blood flow, and pulmonary vascular resistance in the lamb after birth. (Source: Rudolph [3]. Reproduced with permission of John Wiley & Sons.)

the lungs (Figure 9.2) [3]. The placental circulation is removed, and all of these changes lead to the closure of the ductus venosus, constriction of the ductus arteriosus, and reversal of pressure gradients in the left and right atria, leading to the closure of the foramen ovale. This leads to a state called the transitional circulation (Figure 9.1B), which is characterized by high pulmonary artery pressures and resistance (much lower than *in utero*, however), and a small amount of left-to-right flow through the ductus arteriosus. This is a labile state, and failure to maintain lower PVR can rapidly lead to reversion to fetal circulatory pathways, and right-to-left shunting at the ductus arteriosus and foramen ovale. This maintenance of fetal circulatory pathways is necessary for survival in many CHDs, particularly those dependent on a patent ductus arteriosus (PDA) for all or a significant portion of systemic or pulmonary blood flow, or atresia of atrioventricular valves. Maintenance of ductal patency with prostaglandin E1 (PGE_1) is crucial in these lesions. In a two-ventricle heart with large intracardiac shunts, maintenance of the fetal circulation leads to right-to-left shunting at the foramen and ductal levels, and thus hypoxia results. Conversion to the mature circulation (Figure 9.1C) in the normal heart occurs over a period of several weeks, as the PVR falls further, and the ductus arteriosus closes permanently by thrombosis, intimal proliferation, and fibrosis. Factors favoring the transition from fetal to mature circulation include normal oxygen tensions and physical expansion of the lungs, normal pH, nitric oxide, and prostacyclin. Factors favoring reversion to fetal circulation include low oxygen tension, acidotic pH, lung collapse, and inflammatory mediators (leukotrienes, thromboxane A2, platelet-activating factor) as seen in sepsis and other related conditions, and endothelin A receptor activators [4].

Myocardial contractility

The fetal myocardium is characterized by poorly organized cellular arrangements, and fewer myofibrils with a random orientation, in contrast to the parallel, well-organized myofibrillar arrangement of the adult myocardium [5] (see later in this chapter). Fetal hearts develop less tension per gram than adult hearts, because of increased water content and fewer contractile elements. Calcium cycling and

excitation-contraction coupling are also very different, with poorly organized T-tubules and immature sarcoplasmic reticulum, leading to more dependence on free cytosolic ionized calcium for normal contractility. Despite this immature state, the fetal heart can increase its stroke volume in a limited fashion up to left atrial pressures of 10–12 mmHg according to the Frank-Starling relationship, as long as afterload (i.e., arterial pressure) is kept low [6]. These features continue throughout the neonatal and early infancy periods.

KEY POINTS: DEVELOPMENT FROM FETUS TO NEONATE

- The transition from fetus to neonate involves a decrease in PVR, elevation of left heart pressures, and closure of shunts at the ductus arteriosus, foramen ovale, and ductus venosus.
- The transitional circulation is an intermediate state between fetal and adult circulation and may revert to fetal circulation with the persistence of hypoxemia, acidosis, CHD, or other conditions with elevated pulmonary artery pressures.
- The fetal heart develops less tension per gram of resistance than the mature heart and has limited ability to increase stroke volume up to left atrial pressure of only 10–12 mmHg.

Development from neonate to older infant and child

At birth, the neonatal heart must suddenly change from a parallel circulation to a series circulation, and the left ventricle, in particular, must adapt immediately to dramatically increased preload from blood returning from the lungs, and increased afterload as the placental circulation is removed. The very high oxygen consumption by the newborn necessitates a high cardiac output for the first few months of life. However, animal models have demonstrated that both the fetal and newborn myocardia develop less tension in response to increasing preload (sarcomere length), and that cardiac output increases less for the same degree of volume loading [7, 8] (Figure 9.3). Resting tension, however, is greater in the newborn than in the mature heart. This information suggests that the newborn heart is operating near the top of its Frank-Starling curve and that there is less reserve in response to both increased afterload and preload. This observation is borne out clinically in newborns (after complex heart surgery) who are often intolerant of even small increases in left atrial pressure or mean arterial pressure. The newborn myocardium also has only a limited ability to increase its inotropic state in response to exogenous catecholamines and is much more dependent on heart rate to maintain cardiac output than is the mature heart. One reason for this is the high levels of circulating endogenous catecholamines that appear after birth, which are necessary to make the transition to extrauterine life [9]. As these levels decrease in the weeks after birth, contractile reserve increases.

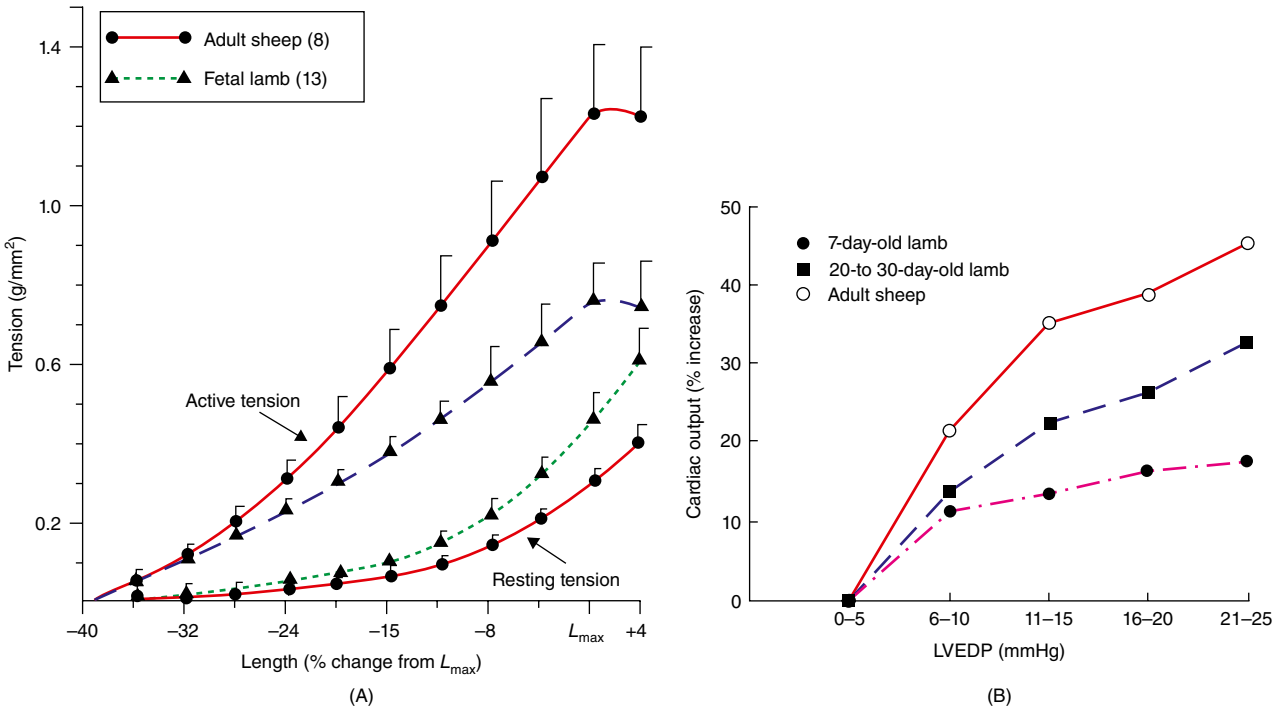

Figure 9.3 (A) Isometric resting and active length-tension relationships in fetal and adult lamb cardiac muscle strips. (Source: Friedman [7]. Reproduced with permission of Elsevier.) (B) Response to volume load of normal saline at 5 mL/kg/min, at constant heart rate. LVEDP, left ventricular end-diastolic pressure, Lmax, maximum muscle strip length. (Source: Friedman and George [8]. Reproduced with permission of Elsevier.)

The neonatal myocardium is less compliant than the mature myocardium, with increased resting tension as noted earlier, and a significantly greater increase in ventricular pressure with volume loading [10]. This implies that the diastolic function of the neonatal heart is also impaired compared with the mature heart [11]. The myofibrils of the newborn heart also appear to have a greater sensitivity to calcium, developing a greater tension than adult myofibrils when exposed to the same free Ca^{2+} concentration *in vitro* [12].

It must again be emphasized that nearly all of this data was obtained from animal models, and although the information appears to agree with what is observed clinically, there is a need for more non-invasive studies of normal human hearts from the neonatal period through adulthood to confirm these impressions of cardiac development.

Gene expression in cardiac development

Progress has been made recently in understanding the genetic aspects of human cardiac development, and in contrast to the physiologic studies which are almost exclusively performed in animal models, small amounts of human cardiac tissue obtained from biopsy or autopsy specimens can be used for these studies. Some aspects of these developmental changes will be reviewed.

Cardiomyocyte maturation begins after birth and is crucial for efficient contractility and metabolism. A hallmark of cardiomyocyte maturation is isoform switching of contractile genes from the fetal to the adult state [13]. Myosin is the major protein component of the thick filaments of the cardiac myofibril, and differences in the expression of this protein may play a significant role in myocardial contractility. Chromosome 14 has the genetic material responsible for producing the myosin heavy chain (MHC) which makes up the backbone of the thick filaments, and two major isoforms, namely α and ß, exist. The ß isoform predominates at birth but the α isoform becomes predominates through maturation [14]. The myosin light chain has multiple isoforms, and the relative proportions of these isoforms change with development, and also in response to pressure loading of the heart. The isoforms that predominate in the newborn myocardium appear to confer a greater sensitivity to Ca^{2+} than those seen in the mature heart [15] and may contribute to the increased sensitivity of the neonatal myocardium to Ca^{2+}.

Troponin I, C, and T are critical proteins that bind Ca^{2+} and regulate the interaction between myosin and actin, directly affecting the force of contraction. Troponin C, the Ca^{2+}-binding portion of the troponin moiety, does not change with development. Troponin I, however, has two major isoforms, a slow skeletal muscle type that predominates in the heart in fetal and neonatal life, and the cardiac isoform, which is the only isoform expressed in the mature heart [16]. Only the cardiac (mature) isoform responds to ß-adrenergic stimulation, producing a faster twitch development and greater twitch tension. However, contractility in the neonatal myofibrils containing the immature myosin light chain (MLC) isoform is more resistant to acidosis. Four isoforms of troponin T are expressed in the fetal and neonatal heart, but only one in the mature heart. These isoforms exhibit different levels of ATPase activity and Ca^{2+} sensitivity (see later), with greater ATPase activity and Ca^{2+} sensitivity seen in the immature forms [12]. Tropomyosin [17] has two isoforms and actin [18] has three isoforms, which are expressed in different proportions as developmental changes occur, but the functional significance of these changes has yet to be elucidated.

Some enzymes are affected by the loading conditions of the heart. Protein kinase C (PKC) is an enzyme with a major role in transmembrane signal transduction through phosphorylation of a number of downstream intracellular components (see the section on "Calcium cycling in the normal heart") [19]. There are six isoforms of this enzyme, and it is not affected during development. However, in aortic stenosis producing left ventricular hypertrophy, all isoforms except PKC-β are dramatically upregulated, and in dilated cardiomyopathy, there is a dramatic upregulation of PKC-β. Phosphodiesterase (PDE) is an enzyme involved in the termination of the action of cyclic adenosine monophosphate (cAMP), which regulates the contractile state of the myocardium (see later). Expression of the isoform PDE-5 is dramatically increased in the hypertrophied human right ventricle in patients with pulmonary hypertension, and inhibition of this enzyme improves ventricular contractility [20].

New information is available on the molecular and cellular basis for normal cardiac development and the causes of CHD [21]. A missense mutation in the myocardial protein actin has been discovered to be the cause of isolated secundum atrial septal defect in some patients [22]. Pluripotent cardiac progenitor cells reside in the human neonatal myocardium in relatively high numbers during the first month of life [23]. This knowledge has given rise to the exciting notion that these stem cells could potentially be used to facilitate recovery from cardiac morbidity or to enhance surgical repair.

Recent advances in genomics, such as RNA sequencing (RNA-Seq) have significantly contributed to the further understanding of cardiac development in humans. RNA-Seq has provided a comprehensive transcriptomic analysis of human heart development during early gestation [24]. Nebulin-related anchoring protein (NRAP) was among the genes that showed the largest fold change between 9- and 16-week gestational age. This protein is expressed at intercalated discs in cardiac muscle and is an actin-binding cytoskeletal protein [25, 26]. NRAP is involved during development in the myofibrillar assembly in the embryonic murine heart [27]. A patient with dilated cardiomyopathy with biventricular failure was found to have a homozygous truncating mutation (rs201084642) which introduced a stop codon to all NRAP isoforms [28]. Another study utilizing microarray RNA Seq analysis found that 316 genes were specifically associated with the human fetal heart, and 20 of those genes are the known candidates for congenital heart failure [29]. Specifically, the genes identified from the study associated with CHD include *PLN, NPPA, ANKRD1, MYH6, MYH7, ACTC1, CACNA1C, TBX20, HEY2, SLC8A1, RYR2, MYOCD, GJA1, ATP2A2, FBN2, SRPX, SCN5A, TBX5, HAND2,* and *KCNJ2*. This network of specific genes in the human fetal heart could represent a candidate common pathway close related to the development of CHD. An example of the

network is Notch-signaling cascade-related genes [30, 31]. Notch-signaling cascade plays a crucial role in cardiac cell fate regulation and orchestrates the morphogenesis of cardiac chambers and valves [32–34]. A recent study has suggested that *NOTCH1* haploinsufficiency alters specific gene networks affecting valve development and osteogenic factors, which in turn result in aortic valve disease [35]. *NOTCH1* ligands *JAG1* and *DLL4* have been shown to cause Alagille syndrome and aortic valve disease in human and animal models [36–38]. In addition, Genome-wide Copy Number Variant (CNV) analysis for congenital ventricular septal defects in the Chinese Han population revealed that VSD-related candidate genes are enriched in chromatin binding and transcription regulation, which are the biological processes underlying heart development. Specifically, this study suggested that *PAX3* and *LBX1* (in duplications) and *CRKL, GP1BB, PDLIM3, TBX1, TXNRD2* (in deletions) are associated with CHD. Enriched gene ontology (GO) revealed that these genes are involved in heart development, cardiovascular system development, and circulatory system development [39].

The extracellular matrix

The extracellular matrix (ECM) of the heart is important in translating the force generated from the shortening of sarcomere length to the cardiac chambers, resulting in stroke volume. The major components of the ECM are collagen types I and II, glycoproteins, and proteoglycans and the expression of these elements changes with development. The neonatal heart has a higher content of both total and type I collagen (which is stiffer and less compliant than type III collagen) when compared with the total protein content of the heart [40]. The collagen to total protein ratio reaches mature levels by about 5 months of life. This change, along with the greater water content of the immature myocardium, may partially explain the diminished diastolic function. Also, this relative lack of contractile elements reduces the ability of the neonatal myocardium to increase its inotropic state. A network of collagen-based connections, called the weave network, develops rapidly after birth, connecting myocytes and capillaries and allowing greater functional integrity to develop in response to the greater afterload stress on the heart [41]. This development of the ECM appears to be complete by approximately 6 months of age and results in a much more efficient transfer of force generated by sarcomere shortening to the cardiac chambers (Figure 9.4) [12].

The connection of the cardiac myocyte to the ECM is maintained by two specialized complexes that together comprise over 20 proteins. The costamere represents a major muscle multiprotein complex and produces a physical connection between the sarcomeres at the Z disk and the ECM. The integrin complex and the dystrophin-associated glycoprotein complexes are two major components of the costamere [42, 43] (Figure 9.5). The integrins are transmembrane glycoproteins consisting of two subunits, α and ß, which express several isoforms. Integrins such as integrin α5β1and α7β1 bind to collagen and fibronectin, which causes the attachment of the ECM to the myocytes, allowing force transduction to occur [44]. These integrins' expression is very dynamic; For example, the α5 subunit is prevalent in fetal and neonatal cardiomyocytes, while α7 replaces α5 at the onset of postnatal development [45]. However, subunit expression can switch and return to the fetal form under stress-producing myocyte hypertrophy and ischemia. Dystrophin-associated glycoprotein complexes also contribute to a substantial mechanical linkage from the ECM to the cardiac cytoskeleton, and contribute to force transduction [42, 43]. The proteins dystrophin, sarcoglycans, dystroglycan, and dystrobrevins are included in these complexes. These complexes play an integral role in cardiac function, and mutations in these proteins can be associated with cardiomyopathies, especially muscular dystrophy-associated cardiomyopathies. Reduction of dystrophin activity results in dilatation of all four cardiac chambers and reduced ventricular function. Mutations in dystrobrevins have been associated with left ventricular non-compaction.

Cell-to-cell connectivity

The intercalated discs mediate the cell-to-cell interactions that coordinate cardiac myocyte activity resulting in synchronous contraction, and maintaining the structural

AL Grawany

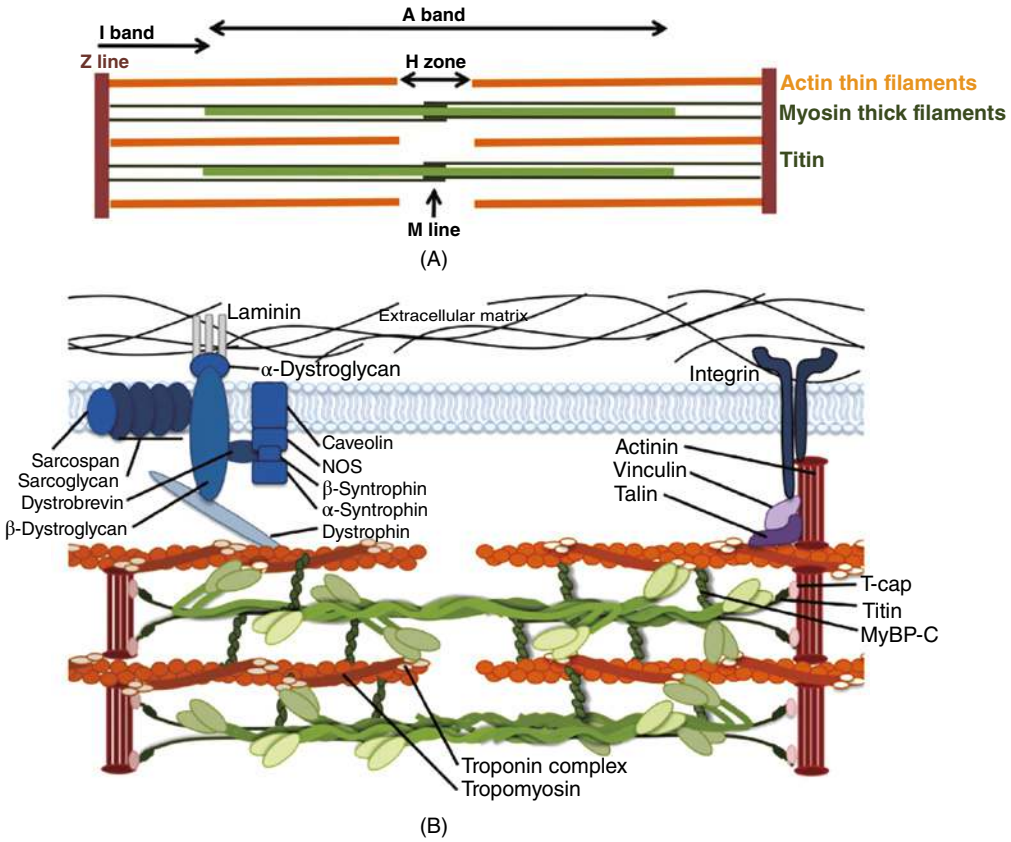

Figure 9.5 Anatomy of the cardiac sarcomere. (A) The basic organization of the sarcomere. The sarcomere forms the basic contractile unit. Thin filaments composed of actin are anchored at the Z line and form transient sliding interactions with thick filaments composed of myosin molecules. The M line, I band, and A band are anatomical features defined by their components (actin, myosin, and cytoskeletal proteins) and appearance in polarized light. Titin connects the Z line with the M line and contributes to the elastic properties and force production of the sarcomere through its extensible region in the I band. Coordinated shortening of the sarcomere creates contraction of the cardiomyocyte. (B) Major proteins of the sarcomere. Attachment to the extracellular matrix is mediated by costameres composed of the dystroglycan–glycoprotein complex and the integrin complex. Force transduction and intracellular signaling are coordinated through the costamere. The unique roles of each of these proteins are critical to the appropriate function of the heart. integrity of cardiac tissue [46] (Figure 9.6). These discs are situated in between cardiac myocytes at the longitudinal ends of the cells and consist of three types of connections: desmosomes, fascia adherens junctions, and gap junctions. The desmosomes have both intracellular and intercellular components. These structures serve to integrate signals from both cell-to-matrix and cell-to-cell interactions, ensuring force transmission, cell membrane integrity, and biochemical signaling. The fascia adherens junctions are responsible for holding the cardiac myocytes tightly together, and they anchor myofibrils and ensure transmission of contractile forces from cell to cell. Finally, the gap junctions form the electrical coupling apparatus between individual myocytes, ensuring rapid propagation of the electrical impulse, forming an electrical syncytium, and thus triggering the coordinated contraction of cardiac myocytes. Mutations in intercalated disc proteins have recently been found to be associated with cardiac disorders. These include adherens junctions mutations associated with heart failure and dilated cardiomyopathy, and desmosome complex mutations associated with some forms of arrhythmogenic right ventricular cardiomyopathy.

The preceding short review is meant to give the reader an idea of some of the aspects of the cellular biology of the developing circulation. The explosion of new information in this area, especially new data from human tissue, will lead to a more thorough understanding of the pathophysiology of disease states and will suggest avenues for future treatment. For a more complete treatment of this area, the reader is referred to several excellent reviews [47–49].

Innervation of the heart

Clinical observations in newborn infants have led to the hypothesis that the sympathetic innervation and control of the cardiovascular system are incomplete in the newborn infant compared with older children and adults and that the parasympathetic innervation is intact [5]. Examples of this include the frequency of bradycardia in the newborn in response to a number of stimuli, including vagal and vagotonic agents, and the relative lack of sensitivity in the newborn to sympathomimetic agents. Histologic studies in animal models have demonstrated incomplete sympathetic innervation in the neonatal heart when compared with the adult, but

no differences in the number or density of parasympathetic nerves [50, 51].

Autonomic cardiovascular control of cardiac activity can be evaluated by measuring heart rate variability in response to both respiration and beat-to-beat variability in systolic blood pressure [52]. The sympathetic and parasympathetic inputs into sinoatrial node activity contribute to heart rate variability changes, with greater heart rate variability resulting from greater parasympathetic input into sinoatrial node activity [53]. Studies using these methodologies for normal infants during sleep suggest that the parasympathetic predominance gradually diminishes until approximately 6 months of age, coinciding with greater sympathetic innervation of the heart similar to adult levels [54].

KEY POINTS: DEVELOPMENT FROM NEONATE TO OLDER INFANT AND CHILD

- The neonatal heart exhibits heart rate dependence, limited ability to increase contractile state, and limited tolerance for excessive afterload and preload.
- The costameres and dystrophin-associated glycoprotein complexes play central roles in connection of the cardiac myocyte to the ECM, thus forcing transduction in the heart.
- The intercalated discs maintain cell-to-cell connectivity between cardiac myocytes, allowing tight adhesion and electrical impulse transition to facilitate coordinated cardiac contraction.

Development from child to adult

Beyond the transition period from fetal to newborn life and into the first few months of postnatal life, there is not much human or animal information concerning the exact nature and extent of cardiac development at the cellular level. Most studies compare newborn or fetal animals with adult animals [55]. Cardiac chamber development is assumed to be influenced by blood flow [56]. Large flow or volume load in a ventricle result in ventricular enlargement. Small competent atrioventricular valves, as in tricuspid stenosis, result in lower blood flow and a small ventricle. Increases in myocardial mass with normal growth, as well as in ventricular outflow obstruction, are mainly due to hypertrophy of myocytes. Late gestational increases in blood cortisol are responsible for this growth pattern, and there is concern that antenatal glucocorticoids to induce lung maturity may inhibit cardiac myocyte proliferation. In the human infant, it is assumed that the cellular elements of the cardiac myocyte (i.e. adrenergic receptors, intracellular receptors and signaling, calcium cycling and regulation, and interaction of the contractile proteins) are similar to those in the adult by approximately 6 months of age. Similarly, cardiac depression by volatile anesthetic agents is greater in the newborn, changing to adult levels by approximately 6 months of age [57].

Normal values for physiologic variables by age

It is useful for the anesthesiologist to be aware of normal ranges for physiologic variables in premature and full-term newborns of all sizes and in infants and children of all ages (Table 9.1, Figure 9.7) [58]. Obviously, acceptable ranges for

Table 9.1 Normal heart rates and systolic blood pressure as a function of age

Age	Range of normal heart rates (beats/minute)	Range of normal systolic blood pressures, measured by oscillometric blood pressure device (mmHg)
Neonate (<30 days)	120–160	60–75
1–6 months	110–140	65–85
6–12 months	100–140	70–90
1–2 years	90–130	75–95
3–5 years	80–120	80–100
6–8 years	75–115	85–105
9–12 years	70–110	90–115
13–16 years	60–110	95–120
>16 years	60–100	100–125

these variables are highly dependent on the individual patient's pathophysiology, but the wide range of "normal" values may reassure the practitioner to accept "low" blood pressure; for example, if other indices of cardiac function and tissue oxygen delivery are acceptable. Values for awake, healthy infants and children are often significantly different than in anesthetized patients and those with significant cardiac disease undergoing invasive procedures, especially with regard to the higher resting blood pressure values [59–61].

De Graaff and colleagues published an important study of over 116,000 ASA I and II patients from 10 centers undergoing non-cardiac procedures with mostly sevoflurane anesthesia and reported the range of blood pressure values in the preparation (pre-surgical) phase, and the surgical phase in patients from 0 to 18 years of age, measured by non-invasive oscillometric method (NIBP) [62] (Figure 9.8). The data were reported from electronic anesthesia medical records and were carefully refined to remove any artifacts. Age- and gender-specific reference curves were calculated which specified the systolic, diastolic, and mean blood pressures. The range at each age from +2 to −2 standard deviations (SD), representing 95% of all blood pressure values and thus constituting the range of "normal" blood pressures were included. For example, during the preparation phase before incision, the 50th percentile (0 SD) of mean arterial pressure ranged from 33 mmHg at birth to 66 mmHg at age 18 years in boys. The −2 SD (2.5th percentile) values for mean blood pressure ranged from 17 mmHg at birth to 47 mmHg at 18 years. The lowest reference ranges for anesthetized children are much lower (approximately 20 mmHg) than those for awake children; the 2.5th percentiles (−2 SD) of the systolic and mean non-invasive blood pressure (NIBP) of a 4-years-old boy are 85 and 60 mmHg, respectively, when non-anesthetized, and 68 and 38 mmHg, respectively, when anesthetized. The blood pressure values during the surgical phase were slightly higher in the youngest age groups less than 6 months, but very little different at older ages. This population of patients without CHD undergoing non-cardiac procedures with non-invasive blood pressure monitoring is clearly very different from cardiac surgery patients with invasive blood pressure monitoring but still can serve as an important reference point for the cardiovascular anesthesiologist.

Myocardial sequelae of longstanding CHD

Hypertrophy of the cardiac chambers is a common response to a number of different chronic pathophysiologic states. Wall thickness increases through hypertrophy of the cardiac myocytes and non-contractile elements. Hypertrophy reduces

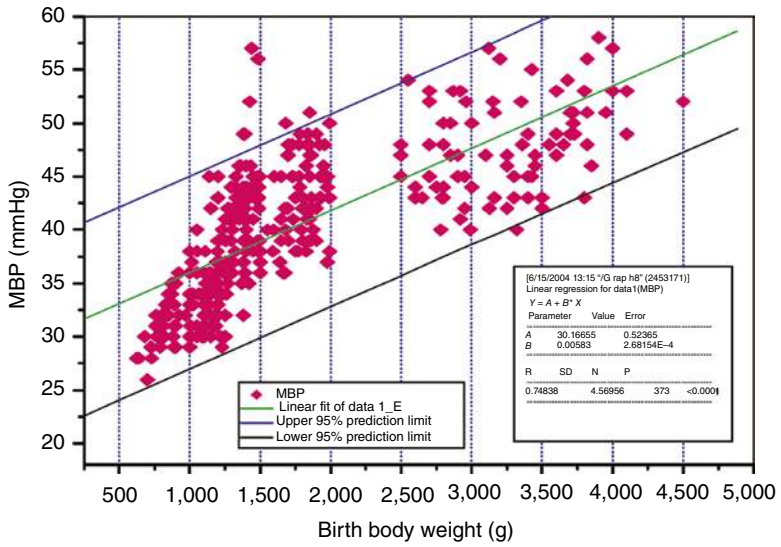

Figure 9.7 Linear regression of mean arterial pressure in 1-day-old neonates free of cardiopulmonary disease, measured by oscillometric methods in the awake state – 292 were premature and 81 full-term neonates. The middle green line is the 50th percentile, the upper blue line is the 95th percentile, and the lower black line is the 5th percentile. Note that in the 3.0 kg full-term neonate, normal mean arterial pressure can range from 37 to 56 mmHg. (Source: Pejovic et al. [58]. Reproduced with permission of Springer Nature.).

AL Grawany

wall stress in the dilated heart but also serves to reduce ventricular function, particularly diastolic function. This reduction in function serves to reduce myocardial oxygen consumption in response to a wide variety of chronic stresses, in both pressure and volume overloaded ventricles [63].

Pressure overload hypertrophy results in altered gene expression in the cardiomyocyte. Myosin isoform expression (see later) changes from the faster-reacting α-myosin to the slower ß-myosin, reducing myocardial function [64]. Integrin-linked kinase expression is increased in patients with hypertrophic cardiomyopathy and induces hypertrophy in an animal model [65]. Altered expression or mutations of other genes that regulate the production of cardiac cytoskeletal proteins, such as dystrophin, occur in patients with end-stage cardiomyopathy [66, 67].

Cardiomyocyte receptor function in normal and diseased hearts

The adrenergic receptor

The adrenergic receptors (ARs) are a part of a large superfamily of receptors that mediate their biological responses through the coupling of a specific guanine nucleotide regulatory protein, or G protein [68]. This superfamily of receptors shares a common structural motif, characterized by seven hydrophobic domains spanning the lipid bilayer. The seven domains are attached by three internal loops and three external loops between the amine terminus and the cytoplasmic carboxy terminus. The function of this receptor family is dependent on a specific agonist (or ligand) binding to the receptor, which causes a conformational change in the receptor. This structural change permits the interaction between the intracellular portion of the receptor and the G protein. This interaction, also referred to as "coupling," inevitably links the activated receptor to a specific biological response. The regulation of the biological response is initiated by the specificity of the receptor for a particular extracellular agonist and the coupling of a specific G protein to that activated receptor.

Once an extracellular ligand (or agonist) is specifically recognized by a cell surface receptor, the receptor goes through a conformational change that exposes a specific region of the receptor complex to the intracellular side of the plasma membrane [69] (Figure 9.9). This conformation change triggers the interaction of the G protein with the amino acids of the third intracellular loop of the receptor and hence leads to G protein activation. There are three different G proteins: stimulatory G protein (G_s), inhibitory G protein (G_i), and the G_q protein. Under normal conditions, all of the ß receptors interact with the G_s, the α1 interacts with G_q, and the α2 interacts with G_i. Each G protein is a heterotrimer made up of three subunits: α, ß, and γ. The activation of the G-protein-coupled receptor causes an exchange of bound guanosine diphosphate (GDP) for guanosine triphosphate (GTP) within the α subunit and initiates the disassociation of the ßγ subunit from the α subunit. The GTP-activated α subunit modulates the activity of a specific effector enzyme within a specific signaling pathway by catalyzing the hydrolysis of GTP to GDP and inorganic phosphate. This causes the transference of a high-energy phosphate group to an enzyme

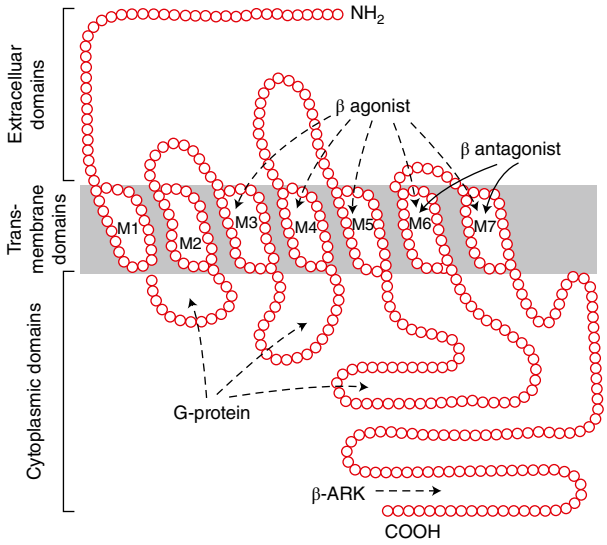

Figure 9.9 Molecular structure of the β-adrenergic receptor, demonstrating its three domains. The transmembrane domains serve as ligand-binding pockets for agonists (dashed arrows) and antagonists (solid arrows). The cytoplasmic domains interact with G proteins and β-adrenergic receptor kinases. (Source: Moss and Renz [68]. Reproduced with permission of Elsevier.)

and, in turn, causes the deactivation of the α subunit. This process will eventually lead to the reassociation of the α subunit with the ßγ complex. This cycle is continuously repeated until the agonist becomes unbound from the receptor. Downstream of enzyme activation, the production of a second messenger regulates the biological response.

Adrenergic receptors have been subdivided into two groups of receptors based on the results of binding studies using a series of selective agonists and antagonists. In 1948 Ahlquist used the difference in rank orders of the potency of a series of agonists to separate the ARs into two principal receptor groups, the α and ß receptor groups [70]. These findings have been confirmed repeatedly with the development of drugs that function to selectively antagonize the α receptor with no effect on the ß receptor. Soon after the distinction between the α and ß receptor types was known, it became more evident that the separation of α and ß receptors was not sufficient to explain pharmacological studies using rank order of potency for an antagonist, differing from an agonist because it blocks the biological response. With the advent of radioligand-labeled antagonists and new molecular cloning techniques examining receptor gene expression, it became clear that the two principal receptor groups could be further subdivided into additional subtypes.

To date, within the ß-adrenergic group, four different subtypes have been identified: $ß_1$, $ß_2$, $ß_3$, and $ß_4$. Pharmacologically, $ß_1$ and $ß_2$ are differentiated by their affinities to different catecholamines: epinephrine, norepinephrine, and isoproterenol. $ß_1$ has a similar affinity to epinephrine and norepinephrine, while $ß_2$ has a higher affinity to epinephrine than to norepinephrine. Both $ß_1$ and $ß_2$ have the same affinity to isoproterenol. The $ß_3$ and $ß_4$ receptors have minor roles in cardiovascular function and will not be discussed further.

The expression and distribution of each subtype are highly dependent on the organ, which adds another level of

specificity. The distribution of a particular receptor in two different tissue types may result in two different functions. When examining the cardiovascular response to adrenergic stimulation, the ß$_1$ receptor is predominantly expressed in heart tissue. The stimulation of the receptor subtype leads to both inotropic and chronotropic effects on cardiac function, resulting in an increase in the myocardial contractile force and a shortening of contractile timing, respectively. While ß$_2$ can also be found in the heart, it is mostly expressed in vascular smooth muscle tissue. The distribution and function relevance of this receptor subtype in the heart are controversial and may change with alterations in cardiac function. The percentage of ß$_2$ receptors in the non-failing heart averages about 20% in the ventricle [71] and 30% in the atrium. The ratio of ß$_1$ to ß$_2$ receptors is approximately 75 : 25% in the ventricles of younger hearts [72, 73].

Each signaling pathway is specific to each adrenergic receptor. Once the agonist binds to the ß$_1$ receptor causing the coupling of the G protein, the G-protein α subunit becomes activated followed by an increase in adenylate cyclase activity, which induces the conversion of ATP to cAMP. The second messenger, cAMP, phosphorylates protein kinase A (PKA). The function of a kinase is to phosphorylate other target proteins, which initiates a biological response. PKA phosphorylates many intracellular targets, including calcium channels, troponin I, and ryanodine receptors. PKA also plays a central role in regulating calcium sensitivity [74].

The ß$_2$ receptor has also been shown to function through the cAMP signaling pathway, causing the activation of PKA, but not nearly to the extent of ß$_1$ in cardiomyocytes [74]. The response of this stimulation appears to have a larger effect on smooth muscle; for example, the vascular smooth muscle. In this tissue type, the stimulation of ß$_2$ and the subsequent increase in cAMP promote the vasodilation of vascular smooth muscle and may lead to alterations in blood pressure. In these tissues, the effect of ß$_1$ stimulation appears to be minimal, due to the lack of ß$_1$ receptors in the smooth muscle.

Similar to the ß receptors, the α receptors can be pharmacologically subdivided into α_1 and α_2. The α receptor is distributed in most vascular smooth muscle and, to a lesser extent, in the heart. The α_2 receptor has been found in some vascular smooth muscle; however, its major functional importance is as a presynaptic receptor in the central and peripheral nervous systems. The use of molecular techniques has identified three additional subtypes of the α_1 receptor (α_{1A}, α_{1B}, and α_{1D}) and three additional subtypes of the α_2 receptor [68]. Binding of an agonist to an α_1 receptor in the heart or vascular smooth muscle results in activation of the G_q subunit of the G protein, which activates phospholipase C (see later), producing diacylglycerol and inositol-1,4,5-triphosphate, which releases Ca^{2+} from the sarcoplasmic reticulum and increases vascular smooth muscle tone or cardiac contractility. A schematic classification of adrenergic receptors incorporating recent knowledge of molecular pharmacology and signal transduction is presented in Figure 9.10 [68].

The adrenergic receptor concentration in cardiac tissue is very small and measured as fentomoles/mg protein. However, the response to stimulation of the receptor is significantly amplified by the signal that occurs downstream of the receptor. In rat ventricular myocytes, the ratio between the ß receptors and the next two downstream signaling components (ß receptor : G protein : adenylate cyclase) is 1 : 200 : 3 [76]. This demonstrates how a large response can be initiated by the activation of a small number of receptors. In addition, it also shows that the rate-limiting component that ultimately regulates intracellular production of cAMP is receptor density and the enzyme concentration of adenylate cyclase.

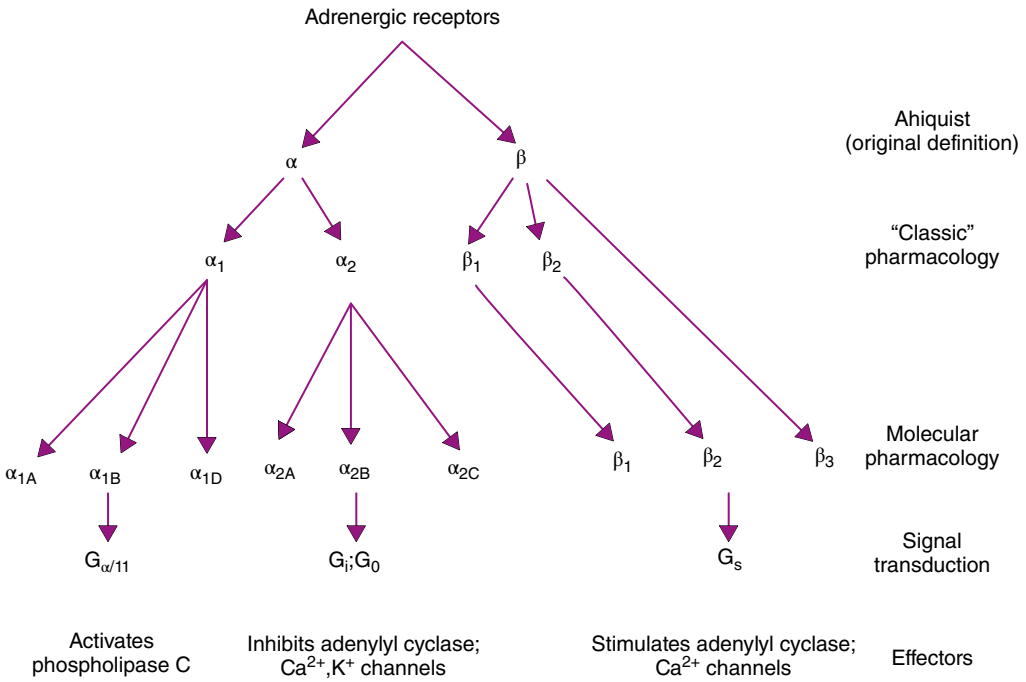

Figure 9.10 A schematic classification of adrenergic receptors. (Source: Moss and Renz [68]. Reproduced with permission of Elsevier.)

Developmental changes in adrenergic receptor signaling

Information concerning changes in adrenergic receptor function during the transition from neonatal to more mature myocardial development is limited to a few animal studies. As noted above, the neonatal heart has a limited inotropic response to catecholamine administration.

ß-Adrenergic receptor density is higher in the ventricular myocardium of neonatal versus adult rabbits, but the inotropic response to the same concentration of isoproterenol is significantly greater in adult tissue [77]. In the neonatal rat, the mechanism of the ß-adrenergic-mediated increase in contractility is entirely due to $ß_2$ stimulation, whereas in the adult rat it is due solely to $ß_1$ receptor activation. Coupling of the $ß_2$ receptor to G_i protein action is apparently defective in the neonatal rat because the ratio of G_i to G_s subunits is much higher in the neonate. The relative proportion of $ß_1$ and $ß_2$ receptors is the same in neonatal and adult hearts (83% $ß_1$, 17% $ß_2$) and approximates the ratio measured in children with simple acyanotic CHD, which is about 78% $ß_1$: 22% $ß_2$ [72].

There is animal and human evidence that α-adrenergic receptor-mediated chronotropic and inotropic effects on the cardiac myocyte change with development. In the neonatal animal model, α-stimulation produces positive inotropic and chronotropic effects, whereas in the adult it produces negative effects [78, 79]. The chronotropic response to α_1 stimulation diminished with increasing age in children being evaluated for autonomic dysfunction after vagal and sympathetic blockade [80].

Calcium cycling in the normal heart

Calcium assumes a central role in the process of myocardial contraction and relaxation, serving as the second messenger between depolarization of the cardiac myocyte and its contraction mediated by the actin-myosin system. Calcium's role in this excitation-contraction coupling in the normal mature heart will be reviewed briefly before discussion of developmental changes and changes with heart failure [81].

Cardiac muscle cell contraction depends on an increase in intracellular Ca^{2+} above a certain threshold, and relaxation ensues when intracellular Ca^{2+} falls below this threshold. Two major regions of Ca^{2+} flux occur: across the sarcolemmal membrane (slow response) and release from internal stores, the sarcoplasmic reticulum (rapid release and reuptake) [82, 83] (Figure 9.11). The primary site of entry of Ca^{2+}

through the sarcolemmal membrane is through the L-type, or low-voltage-dependent Ca^{2+} channels, which occurs in two types, a low-threshold, rapidly inactivating channel, and a higher threshold, more slowly inactivating channel [84]. Depolarization of the sarcolemmal membrane triggers the opening of these channels, resulting in the release of a large amount of Ca^{2+} from the sarcoplasmic reticulum (SR), the major internal Ca^{2+} storage organelle. Ca^{2+} entry through the slowly inactivating channels serves to fill the SR with adequate Ca^{2+} stores. Removal of Ca^{2+} from the cytoplasm to the exterior of the cell occurs via two major mechanisms: the sodium-calcium (Na^{+}—Ca^{2+}) exchanger, and the calcium ATPase pump. The Na^{+}—Ca^{2+} exchanger usually serves to exchange three sodium ions (moving into the cell) for one Ca^{2+} (moving out of the cell), although the reverse action, as well as a 1:1 exchange, are possible [85]. The Ca^{2+}-ATPase pump actively transports Ca^{2+} (in a 1:1 Ca^{2+}/ATP ratio) out of the cell in an energy-dependent, high-affinity but low-capacity manner [86]. The affinity of the sarcolemmal Ca^{2+}-ATPase pump is enhanced by calmodulin, a binder of free cytoplasmic Ca^{2+}. Although the calcium movement through the sarcolemma plays an important role in balancing internal and external Ca^{2+} concentrations and in supplying Ca^{2+} to replenish SR Ca^{2+} stores, and in initiating the Ca^{2+}-induced release of Ca^{2+} from the SR, it is important to recognize that the amount of Ca^{2+} flux is far less than across the SR, the far more important mechanism for excitation-contraction coupling in the mature heart [87]. The sarcolemmal Ca^{2+} flux mechanisms play a much more important role in the excitation-contraction coupling of the neonatal (immature) heart.

The massive release and reuptake of Ca^{2+} responsible for activation and deactivation of the actin-myosin complex and cardiomyocyte contraction and relaxation occur at the level of the SR. The SR is a closed, intracellular membranous network that is intimately related to the myofilaments responsible for contraction [88, 89] (Figure 9.12). The SR is connected to the sarcolemmal membrane via the transverse tubule (T-tubule) system. Depolarization of the sarcolemmal membrane results in the transfer of charge down the T-tubules to the SR, resulting in the opening of SR Ca^{2+} channels and the release of large amounts of Ca^{2+} into the cytoplasm, where

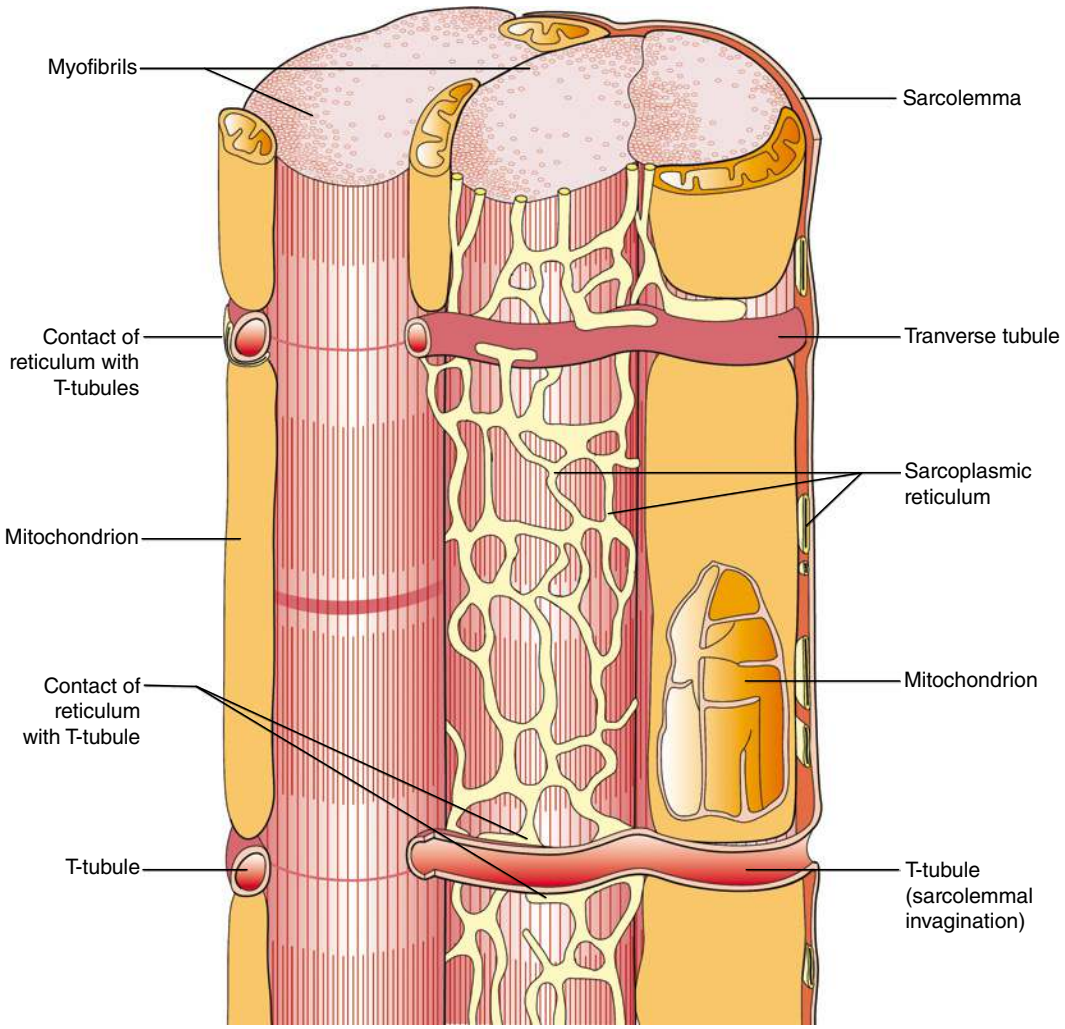

Figure 9.12 Normal, mature cardiac myocyte structure. (Source: Bloom and Fawcett [89]. Reproduced with permission of Elsevier.)

AL Grawany

it can then bind to troponin and initiate the actin-myosin interaction. The SR is divided into longitudinal SR and terminal cisternae; the latter connects to the T-tubules. The terminal cisternae are primarily involved in the release of Ca^{2+}, and the longitudinal SR in its reuptake [90].

The primary Ca^{2+} release mechanism of the SR is the ligand-gated Ca^{2+}-release channels (also known as the ryanodine receptors) that bind to the drug ryanodine. The channels are activated by two primary mechanisms: depolarization via the T-tubules, and binding of intracellular Ca^{2+} itself. The predominance of one mechanism over the other differs in cardiac vs. skeletal muscle. The proximity of the L-type sarcolemmal Ca^{2+} channels in the T-tubules to the ligand-gated Ca^{2+}-release channels allows the depolarization to rapidly allow Ca^{2+} into the cell and open the SR Ca^{2+} channels. These ligand-gated Ca^{2+} release channels close when the cytosolic Ca^{2+} concentration increases; normally it opens at 0.6 µM Ca^{2+} and closes at 3.0 µM Ca^{2+}.

The reuptake and sequestration of Ca^{2+} lead to the relaxation of the cardiac myocyte and is an active transport mechanism, primarily involving hydrolysis of ATP by the SR Ca^{2+}-ATPase (SERCA), located in the longitudinal SR [91]. It binds two Ca^{2+} ions with high affinity and rapidly transports them to the inside of the SR. This transport system differs from the sarcolemmal membrane: it has a higher affinity, allows for more rapid transport, and is not sensitive to calmodulin. Ca^{2+} is stored in the SR by calsequestrin, a high-capacity, low-affinity protein that acts as a Ca^{2+} sink.

There are two other proteins with essential roles in the regulation of Ca^{2+} flux: phospholamban and calmodulin [92, 93]. Phospholamban is associated with the sarco/endoplasmic reticulum Ca^{2+}-ATPase (SERCA) and can be phosphorylated by at least four different protein kinases (see earlier): cAMP-dependent, Ca^{2+}/calmodulin-dependent, cyclic guanosine monophosphate (cGMP)-dependent, or PKC. When phosphorylated, phospholamban increases the affinity of the SERCA for Ca^{2+}, facilitating Ca^{2+} flux back into the SR, thus affecting the inotropic and lusitropic state of the heart. Phospholamban plays an important role in the ß-adrenergic-mediated increase in the inotropic state of the heart. Calmodulin is a Ca^{2+} storage protein with four binding sites, found in the cytoplasm, which interacts with the sarcolemmal Ca^{2+}-ATPase (increasing its affinity for Ca^{2+}), the SR ligand-gated Ca^{2+}-release channel (inhibits its activity at optimal cytoplasmic Ca^{2+}), and binds to the Ca^{2+}/calmodulin-dependent protein kinase [93]. Mutations in the phospholamban gene have been described and may be a rare cause of dilated cardiomyopathy [94].

The increase in intracellular cytoplasmic Ca^{2+} initiates the contractile process. Myosin is the major component of the thick filaments, which make up the microscopic structure of the myofibril, and its interaction with actin (the major component of the thin filaments) provides the mechanical basis of cardiac muscle cell contraction [95]. Actin and myosin make up approximately 80% of the contractile apparatus and are arranged in a parallel, longitudinal fashion, projecting from a Z-line or band (Figure 9.13) to form the basic contractile unit called the sarcomere [96]. A three-dimensional lattice consisting of interdigitated thick and thin filaments in a hexagonal array, with three thin filaments in close proximity to each thick filament, is formed. The actin and myosin are linked by projections on the myosin protein called S1 cross-bridges, which bind to actin, and, via an energy-dependent hinge-like mechanism, produce the sliding filament cross-bridge action that is thought to produce sarcomere shortening and lengthening. The lattice is held together by connecting proteins such as titin, nebulin, and α-actinin [97]. The actin-myosin interaction is initiated when Ca^{2+} binds to troponin, a protein closely connected to actin, which consists of three subunits: a Ca^{2+}-

Table 9.2 Summary of major differences between neonatal and mature hearts

	Neonatal	Mature
Physiology		
Contractility	Limited	Normal
Heart rate dependence	High	Low
Contractile reserve	Low	High
Afterload tolerance	Low	Higher
Preload tolerance	Limited	Better
Ventricular interdependence	Significant	Less
Ca^{2+} cycling		
Predominant site of Ca^{2+} flux	Sarcolemma	SR
Dependence on normal Ca^{2+}	High	Lower
Circulating catecholamines	High	Lower
Adrenergic receptors	Down-regulated, insensitive	Normal
	β_2, α_1 predominant	β_1 predominant
Innervation	Parasympathetic predominates; sympathetic incomplete	Complete
Cytoskeleton	High collagen and water content	Lower collagen and water content
Cellular elements	Incomplete SR, disorganized myofibrils	Mature SR, organized myofibrils

SR, sarcoplasmic reticulum.

binding subunit (TNC), a tropomyosin-binding unit (TNT), and an inhibitory subunit (TNI). TNC can bind up to four Ca^{2+} ions, and this produces a conformational change on the thin filament, which allows the S1 myosin head cross-bridges to attach [98]. This also changes the TNI subunit's conformation and allows tropomyosin, another protein integral in filament interaction, to move aside and expose the binding sites on actin, allowing the strong binding to the S1 cross-bridges. With Ca^{2+} present, actin causes myosin ATPase to hydrolyze one ATP molecule, providing energy that results in the S1 myosin head pulling on the thin filament, resulting in sarcomere shortening. Troponin C is the most important aspect of the regulation of cardiocyte contraction and has a steep response curve to local levels of Ca^{2+}. The reuptake of Ca^{2+} into the SR causes Ca^{2+} levels to rapidly decline, and the inhibitory form of the troponin, tropomyosin, actin complex returns, resulting in the reversal of the cross-bridge binding and thus sarcomere relaxation.

Besides calcium, many other regulatory mechanisms exist to influence the interaction and sensitivity of Ca^{2+} binding to troponin. These mechanisms include ß-adrenergic stimulation, thyroid hormone, and phosphorylation by cAMP-dependent protein kinases.

Developmental changes in calcium cycling

Several aspects of the excitation-contraction system are different in the immature heart. The T-tubule is not fully formed [99], and the SR has less storage capacity and less structural organization [100], less mRNA expression [101, 102], and less responsiveness to chemical blockade [103, 104]. The TNI changes from a predominately cAMP-insensitive form to a cAMP-responsive form by 9 months of age, an additional factor contributing to the increased responsiveness seen with ß-adrenergic stimulation after the neonatal period [104]. All of this information has led to the theory that the neonatal cardiac myocyte is more dependent than the mature heart on free cytosolic Ca^{2+} fluxes, and more susceptible to blockade of the L-type Ca^{2+} sarcolemmal channels as a mechanism of myocardial depression. The latter is thought to be the mechanism producing greater myocardial depression observed with halothane in neonatal rat models compared with sevoflurane, and the same phenomenon is seen clinically [105]. A summary of the major differences in cardiac development and function between the neonatal and mature heart is presented in Table 9.2.

Thyroid hormone

Tri-iodothyronine (T3) has a critical role both in the development of the cardiovascular system and in acute regulation and performance. Normal T3 levels are essential for normal maturation and development of the heart through the expression of genes responsible for the production of the cardiac contractile proteins, elements of the calcium cycling apparatus, and development and density of ß-adrenergic receptors [106]. There are cell nucleus-mediated effects from exogenous T3 that occur from an increase in protein synthesis and require at least 8 hours to develop. These include upregulation of ß-adrenergic receptors, an increase in cardiac contractile protein synthesis, an increase in mitochondrial density, volume, and respiration, an increase in SERCA mRNA, and changes in MHC isoforms. However, there are acute effects of T3 on cardiac myocytes that occur in minutes from interactions with specific sarcolemmal receptors and include stimulation of L-type Ca^{2+}-pump activity, stimulation of SR Ca^{2+}-ATPase activity, increased protein kinase activity, and decrease in phospholamban [107]. Cardiac surgery and cardiopulmonary bypass interfere with the conversion of thyroxine (T4) to T3, and serum levels decrease significantly after cardiac surgery in infants and children [108]. T3 infusions improve myocardial function in children after cardiac surgery and reduce intensive care unit stay [109].

KEY POINTS: CARDIOMYOCYTE RECEPTOR FUNCTION IN NORMAL AND DISEASED HEARTS

- The adrenergic receptor system, particularly the β-receptor system, plays a central role in regulating cardiac contractility through G protein and adenylate cyclase coupling.
- Calcium cycling in the neonatal heart is characterized as immature, with underdeveloped T-tubules and sarcoplasmic reticulum, not reaching a mature state until an estimated 6–12 months of age.
- Thyroid hormone is essential for normal gene expression for production of cardiac contractile proteins, calcium cycling apparatus, and adrenergic receptor density, as well as acute effects to increase the sensitivity of adrenergic receptors and efficiency of calcium cycling.

Regulation of vascular tone in systemic and pulmonary circulations

The regulation of vascular tone is an important consideration in the understanding and treatment of CHD. Both the systemic and pulmonary circulations have complex systems to maintain a delicate balance between vasodilating and vasoconstricting mediators in normal patients. Abnormal responses may develop that lead to pulmonary or systemic hypertension, or conversely vasodilation. A schematic representation of some of these mediators is shown in Figure 9.14 [110]. To some extent, the control mechanisms reviewed are present in both the systemic and pulmonary circulations; however, certain mechanisms are more important in one circulation. For example, the endothelial-mediated systems (nitric oxide–cGMP pathways and others) predominate in the pulmonary circulation (low-resistance circulation), whereas the phospholipase systems predominate in the systemic circulation (high-resistance circulation). The endothelium-dependent control of vascular tone plays a significant role in the transition from fetal to postnatal circulation, with pathologic persistence of fetal endothelial milieu contributing to the transitional circulation and pulmonary hypertension, both of which may influence the pathophysiology of CHD [111].

Pulmonary circulation

Metabolites of arachidonic acid, called eicosanoids, are produced from cells and a group of eicosanoids acts as vasoactive agents. Eicosanoids metabolized via the lipoxygenase pathway will form leukotrienes, and those metabolized via the cyclooxygenase pathway form the prostaglandins. Important

vasodilating prostaglandins include PGE_1, which also promotes and maintains patency of the ductus arteriosus. Prostacyclin, PGI_2, is a potent pulmonary vasodilator [112]. Prostaglandins act on the vascular smooth muscle of the systemic and pulmonary circulations by binding to receptors in the smooth muscle cell membrane, activating adenylate cyclase, and increasing cAMP concentrations, which lead to lower Ca^{2+} levels and a reduction of vascular tone. Thromboxane A_2 is a potent leukotriene that has the opposite effects of the prostaglandins, producing vasoconstriction and platelet aggregation. Imbalance in this system caused by chronic hypoxia can lead to chronic pulmonary hypertension [113, 114].

Nitric oxide (NO) is an endothelium-derived relaxant factor that causes relaxation of vascular smooth muscle cells after diffusing into the cell and activating guanylate cyclase, increasing the concentration of cGMP, leading to a reduction in the local concentration of Ca^{2+} and thus reducing vascular tone [115]. Calcium-sensitive potassium channels contribute to the vasodilatation caused by NO via a cGMP-dependent protein kinase [116]. NO is formed from L-arginine by NO synthase and is almost immediately inactivated by binding to hemoglobin. Phosphodiesterase V breaks down cGMP; hence, the phosphodiesterase-inhibiting drugs, such as sildenafil, potentiate NO-mediated vasodilation [117].

Endothelins are powerful endothelium-derived vasoactive peptides, and endothelin-1 (ET-1) is the best characterized one. ET-1 is produced from proendothelin-1 by endothelin-converting enzymes in the endothelial cells of the systemic and pulmonary vasculature. Increased pressure, shear stress, and hypoxia can lead to increased production of ET-1 in the pulmonary circulation. Two ET-1 receptors, ETA and ETB, mediate effects on smooth muscle vascular tone [118]. The ETA receptor is found on the smooth muscle cell membrane and mediates vasoconstriction, while the ETB receptor is located on the endothelial cell itself, and results in increased NO synthase activity, producing vasodilation. The primary activity of ET-1 appears to be to stimulate the ETA receptor and indeed increased levels of ET-1 are found in many pulmonary hypertensive states such as Eisenmenger syndrome and primary pulmonary hypertension [119]. ET-1 increases in response to shear stress, hypoxia, or ischemia, and results in elevated intracellular Ca^{2+} and increased sensitivity to Ca^{2+}, increasing pulmonary vascular tone and pressure [114].

Systemic circulation

There are multiple levels of control over the peripheral circulation. Neural control by the sympathetic and parasympathetic nervous systems is produced from the stimulation of receptors on the afferent limb such as stretch receptors within the walls of the heart, and baroreceptors in the walls of arteries, such as the aortic arch and carotid sinuses. Stretch in the arterial wall stimulates the baroreceptors, producing vasodilation and heart rate slowing mediated by the vasomotor centers of the medulla [120]. Atrial stretch receptors inhibit the secretion of vasopressin from the hypothalamus. The efferent limb of the autonomic nervous system consists of sympathetic and parasympathetic nerve fibers. The sympathetic nerves can be divided into vasoconstrictor and vasodilator fibers. When stimulated, the vasoconstrictor fibers release norepinephrine, activating α-adrenergic receptors and producing vasoconstriction. The vasodilator fibers release acetylcholine or epinephrine and are mainly present in skeletal muscle. Parasympathetic fibers are vital in the control of heart rate and function but have only a minor role in controlling peripheral circulation [121].

Hormonal control and receptor-mediated intracellular signaling are other important mechanisms. Norepinephrine primarily stimulates peripheral α receptors and causes vasoconstriction. It is secreted by the adrenal medulla and by sympathetic nerves in proximity to the systemic blood vessels. Epinephrine is also secreted by the adrenal medulla, but its primary action is to stimulate the $ß_2$ receptors in the peripheral circulation, causing vasodilation through cAMP-mediated reductions in intracellular Ca^{2+} concentrations.

Angiotensin II is produced by activation of the renin-angiotensin-aldosterone axis in response to reduced flow and pressure sensed by the juxtaglomerular apparatus in the kidney. Renin produces angiotensin I by cleaving angiotensinogen, and angiotensin II is produced when angiotensin I passes through the lung by angiotensin-converting enzyme (ACE). Angiotensin II is a potent vasoconstrictor, and also induces the hypothalamus to secrete vasopressin (antidiuretic hormone), which also has vasoconstrictor properties.

Atrial natriuretic factor (ANF) is released from atrial myocytes in response to stretch (elevation of right or left atrial pressure) on the atrium. ANF has vasodilatory and cardioinhibitory effects and causes sodium retention from decreased tubular reabsorption of sodium in the kidney [122]. B-type natriuretic peptide (BNP) is released by the ventricular myocardium, also in response to stretch, and causes an increase in cGMP, leading to vasodilatation in both arterial and venous systems. In addition, it increases urinary sodium and water excretion [123].

Second messenger systems affect the activation of receptors on systemic vascular cell membranes, leading to changes in vascular tone. The phosphoinositide signaling system is the common pathway for many of these agonists [120] (Figure 9.15). Membrane kinases phosphorylate phosphatidylinositol, which is an inositol lipid located mainly in the inner lamella of the plasma membrane, producing phosphatidylinositol 4,5 biphosphate. The second messenger, inositol 1,4,5-triphosphate, is produced from this compound by the action of the enzyme phospholipase C (PLC) [124]. The sequence begins with the binding of an agonist, such as angiotensin II, vasopressin, norepinephrine, or endothelin, to a receptor with seven membrane-spanning domains. This receptor is linked to the activated G_q-protein subunit, which stimulates phosphatidylinositol-specific PLC (PI-PLC) to produce inositol 1,4,5,-triphosphate, which acts to cause release of Ca^{2+} from the SR, activating the actin-myosin system in the smooth muscle cells, producing vasoconstriction. Another second messenger, 1,2-diacylglycerol, is also produced, which goes on to activate protein kinase C, which in turn has a role in mitogenesis and thus the proliferation of smooth muscle cells. There are many isozymes of PLC; the form implicated in this series of events is the $PLC_ß$ form. The PLCγ isoform is

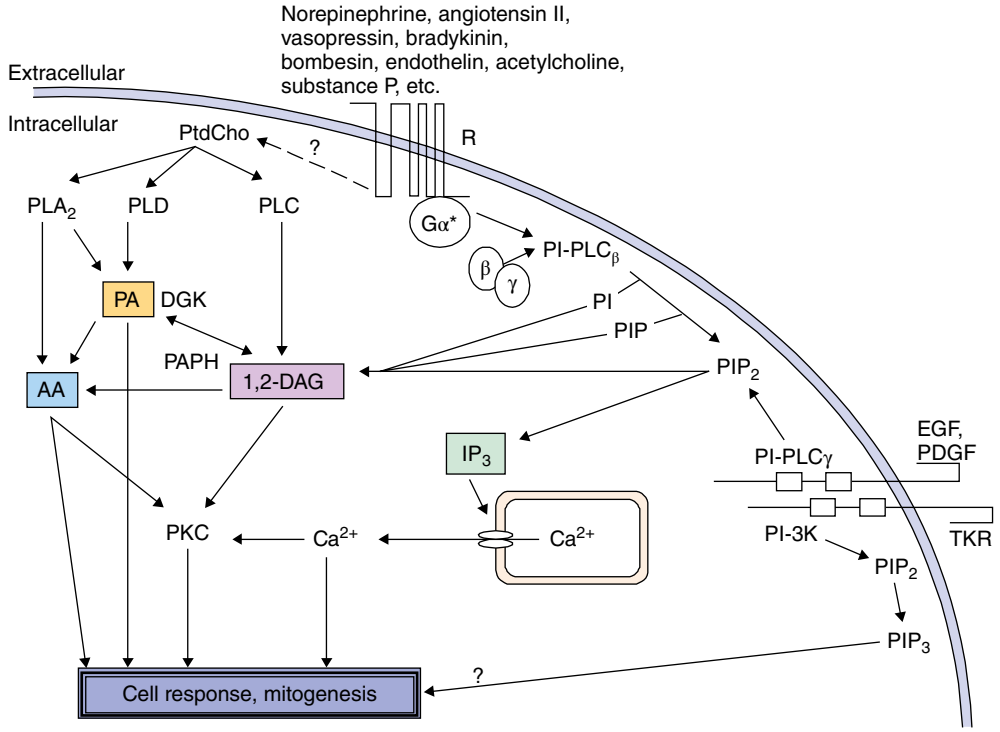

Figure 9.15 Phospholipase C system. Diagram summarizing the major receptor-activated pathways for the production of inositol 1,4,5-triphosphate (IP3) and 1,2-diacylglycerol (1,2-DAG). The binding of an agonist to a receptor R with seven membrane-spanning domains results in the activation of the phosphatidylinositol-specific phospholipase Cß (PI-PLCß), whereas the stimulation of tyrosine kinase receptors (TKRs) by polypeptide growth factors will activate phosphatidylinositol-specific phospholipase Cγ (PI-PLCγ). Both pathways will result in the hydrolysis of phosphatidylinositol 4,5-biphosphate (PIP2) and the formation of IP3 and 1,2-DAG. In addition, agonists that act on the heterotrimeric receptors may stimulate phosphatidylcholine (PtdCho) hydrolysis, and activation of tyrosine kinase receptors will stimulate the production of phosphatidylinositol 3,4,5-triphosphate (PIP3). AA, arachidonic acid; β, β subunits; DGK, diacylglycerol kinase; EGF, epidermal growth factor; G*, activated G-protein subunit; PAPH, phosphatidic acid phosphohydrolase; PDGF, platelet-derived growth factor; PI, phosphatidylinositol; PIP, phosphatidylinositol 4-phosphate; PI-3K, phosphatidylinositol 3-kinase; PKC, protein kinase C; PLA_2, phospholipase A_2; PLD, phospholipase D. activated when cell growth factors such as platelet-derived growth factors bind to their receptors on the cell surface and active tyrosine kinases. This results in the production of phosphatidylinositol 3,4,5-triphosphate, which is also implicated in mitogenesis.

Vasodilatation of the systemic circulation results from the formation of nitric oxide by nitrovasodilators, or by activation of ß$_2$-adrenergic receptors in the peripheral vasculature, both of which result in the activation of guanylate cyclase and the production of cGMP, which reduces intracellular Ca^{2+} concentrations, producing vasodilation [125].

The vascular beds in various peripheral tissues differ in the amount of local metabolic control of vascular tone. For example, pH has much more influence on the pulmonary circuit, with low pH leading to vasoconstriction and higher pH leading to vasodilatation, than in the vascular tone of other tissues. Local CO_2 concentration is much more important to central nervous system vasculature, with high levels leading to vasodilatation. A decrease in oxygen tension will often lead to vasodilatation, as adenosine is released in response to the decreased oxygen delivery; however, decreased oxygen tension increases tone in the pulmonary circulation. Autoregulation, or maintaining relatively constant blood flow over a wide range of arterial pressures, predominates in the cerebral circulation but is not as critical in other tissue beds. Autoregulation and CO_2 responsiveness are both blunted in the fetal and immature brain [126].

KEY POINTS: REGULATION OF VASCULAR TONE IN SYSTEMIC AND PULMONARY CIRCULATIONS

- The pulmonary vascular endothelium exerts major control of vascular tone and resistance, maintaining low resistance through complex pathways, including nitric oxide, prostaglandins, and cGMP.
- Systemic vascular tone and resistance are maintained in a higher resistance state than the pulmonary vascular circulation with more neurohormonal activation that includes the sympathoadrenal, renin-angiotensin-aldosterone, and phospholipase-C systems.
- Pathophysiologic derangements in vascular tone of pulmonary and systemic circulations have led to therapeutic approaches such as inhaled nitric oxide and endothelin receptor antagonists.

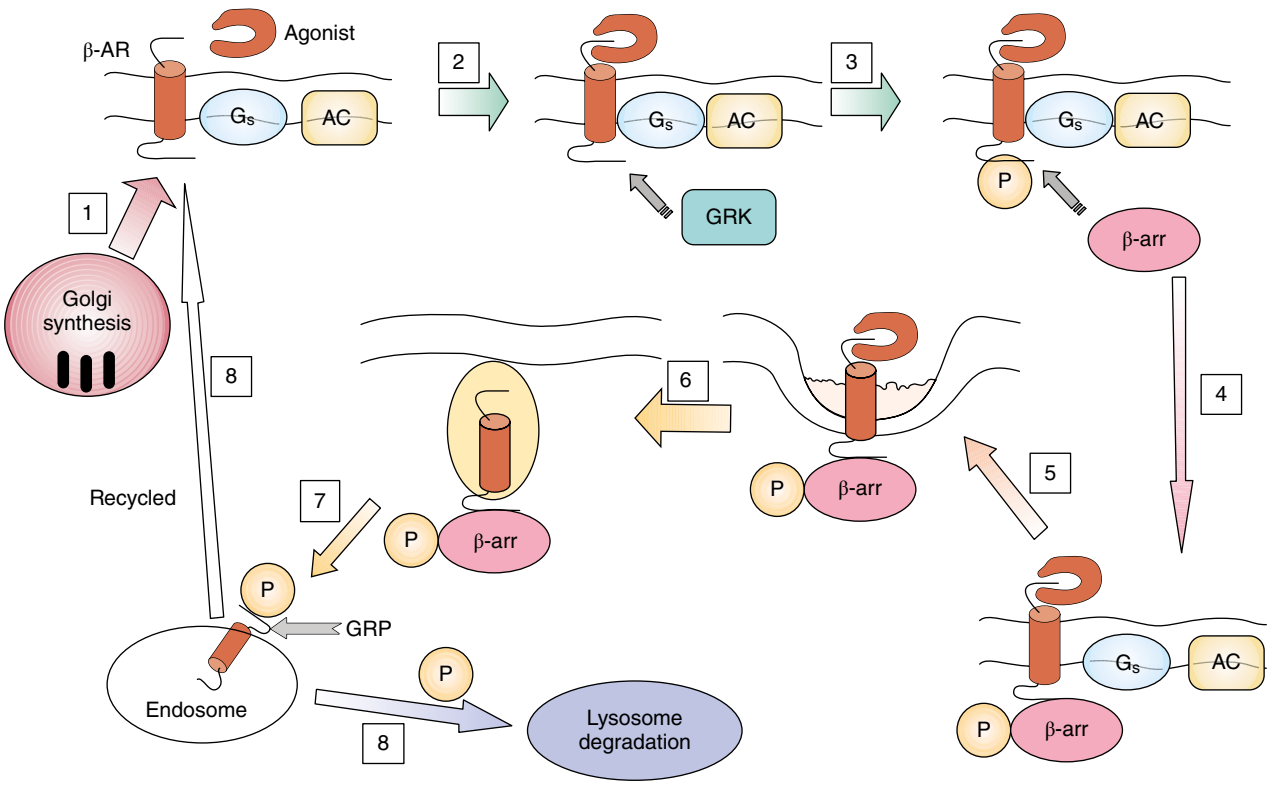

Figure 9.16 Desensitization and downregulation of the ß adrenoreceptor (ß-AR). 1, agonist binding; 2, phosphorylation of the ß-AR by G-protein-coupled receptor kinases (GRK); 3, ß-arrestin binds to the GRK-phosphorylated ß-AR, which is bound to the G_s protein. The receptor is then sequestrated to the endosomal compartment (4–7), to be dephosphorylated, and then either recycled back to the sarcolemma (8) or translocated to lysosomes for further degradation (8). Receptor signaling in myocardial dysfunction, CHD, and heart failure

A discussion of receptor signaling and calcium cycling in myocardial dysfunction is useful to serve as the basis for understanding many of the therapies discussed later in this text, and this section will focus on receptor physiology and calcium flux in three settings: acute myocardial dysfunction as seen after cardiac surgery and cardiopulmonary bypass, changes seen as responses to chronic cyanotic heart disease, and those seen with chronic congestive heart failure and cardiomyopathy.

Receptor signaling in acute myocardial dysfunction

Acute myocardial dysfunction, such as that sometimes seen after cardiopulmonary bypass, is often treated with catecholamines. These drugs are sometimes ineffective, especially when used in escalating doses. In children, the number and subtype distribution of ß-adrenergic receptors in atrial tissue is not affected by cardiac surgery with bypass; however, the activation of adenylate cyclase by isoproterenol is significantly reduced after bypass [127]. There is an uncoupling of ß receptors from the G_s – protein–adenylate cyclase complex. Desensitization to moderate or high doses of catecholamines may occur after only a few minutes of administration because increased cAMP concentrations result in uncoupling from the G_s protein [128].

Only a few minutes of high-dose catecholamine administration may result in the inactivation of the phosphorylated adrenergic receptors from sequestration. These receptors can be sequestered by endocytosis, in a process involving a protein called ß-arrestin, which binds to the receptor and clathrin, a sarcolemmal protein (Figure 9.16) [69]. These sequestered receptors may be either recycled back to the cell membrane surface or destroyed by lysosomes [129]. This permanent destruction and degradation of receptors occur after hours of exposure to catecholamines and is accompanied by decreased mRNA and receptor protein synthesis, resulting in a prolonged decrease in adrenergic receptor concentrations, which is reversed by decreasing exogenous catecholamines, but only as fast as new receptors can be synthesized.

Neonatal hearts may exhibit a different response to the acute or prolonged administration of catecholamines. Instead of desensitization, neonatal animal models demonstrate an enhanced ß-adrenergic receptor response, accompanied by an increase in adenylate cyclase activity [130]. Desensitization as described earlier occurs later in development. The exact translation of these data to humans is not clear.

Treatment with catecholamines may also increase the concentration of G_i protein subunits, decreasing the sensitivity of the ß-adrenergic receptor. This relative decrease in the ratio of G_s to G_i protein subunits has been demonstrated in

rat and dog models [131, 132]. Another possible mechanism of catecholamine-induced desensitization of the neonatal myocyte was demonstrated in a rat model, where prolonged exposure to norepinephrine caused an initial increase in functional L-type Ca^{2+} channels on the sarcolemmal membrane. Continued exposure caused a decrease in L-type Ca^{2+} channel mRNA to 50% of control values [133]. SERCA concentrations are reduced with chronic norepinephrine administration in the dog [134]. Finally, exposing adult or neonatal rat myocytes to high concentrations of catecholamines for 24 hours leads to increased apoptosis of myocardial cells, a genetically programmed energy-dependent mechanism for cell death and removal [135, 136]. This effect was mediated through ß-adrenergic receptors in the adult model and α receptors in the neonatal model.

All of these studies provide the theoretical basis for the argument that the administration of catecholamines to patients with acute myocardial dysfunction should be limited in dose and duration. Obviously, this is difficult to accomplish in the setting of weaning a hemodynamically unstable patient from cardiopulmonary bypass. Strategies that may limit catecholamine dose include administering low doses of catecholamines together with phosphodiesterase inhibitors, as well as adding corticosteroids, tri-iodothyronine, and vasopressin [137].

Receptor signaling in CHD

In the past decade, new information concerning adrenergic receptor signaling in patients with CHD has come to light. A study of 71 infants and children undergoing cardiac surgery used tissue from the right atrial appendage to study ß-adrenergic receptor density, distribution of $ß_1$ and $ß_2$ receptor subtypes, and coupling to adenylate cyclase [138]. This study found that patients with severe, or poorly compensated acyanotic (e.g. congestive heart failure) or cyanotic (e.g. severe cyanosis) disease had significantly reduced ß-adrenergic receptor densities. Outside of the newborn period, this down-regulation was $ß_1$-selective, but in newborns with critical aortic stenosis or transposition of the great arteries, there was additional significant downregulation of the $ß_2$ subtype. In patients with the tetralogy of Fallot, those treated with propranolol had a significant increase in the number and density of ß-adrenergic receptors, when compared with untreated patients. Beta-adrenergic receptor downregulation was correlated with increased circulating norepinephrine levels. Finally, in severely affected patients, adenylate cyclase activity was reduced, demonstrating a partial decoupling, as noted earlier. Other studies have determined that symptomatic tetralogy of Fallot patients (i.e. those with cyanotic spells) have a significantly greater number of ß-adrenergic receptors in their right ventricular outflow tract muscle, and their adenylate cyclase activity was greater than that in patients without cyanotic spells [73]. Alpha-1-adrenergic receptors are also affected by CHD. A study of atrial tissue excised at the surgery in 17 children evaluated α- vs. ß-adrenergic receptor stimulation with pharmacologic agents. The α component was responsible for 0–44% of the inotropic response, and ß stimulation for 56–100% of the response, with the degree of right ventricular hypertrophy and pressure load correlating with the amount of stimulation found [139].

Receptor signaling in congestive heart failure and cardiomyopathy

Like adults with heart failure, children with congestive heart failure due to chronic left-to-right shunting and volume overload of the heart have elevated levels of circulating norepinephrine. This leads to a downregulation in ß-adrenergic receptor density [140]. The degree of elevation of pulmonary artery pressure and amount of left-to-right shunting correlates with the plasma catecholamine levels and is inversely correlated with ß-adrenergic receptor density. All of these abnormalities return to normal levels after corrective surgery. The degree of receptor downregulation in congestive heart failure is correlated with postoperative morbidity in infants and children. Children with an intensive care unit stay of greater than 7 days or those who died during the early postoperative period (nine of 26) had significantly less $ß_1$ and $ß_2$ mRNA gene expression than those who had better outcomes [141]. In addition, the children receiving propranolol for treatment of their congestive heart failure had higher ß-adrenergic receptor mRNA levels and tended to have improved outcomes. Finally, children with dilated cardiomyopathy also have a reduced response to catecholamines, with one study showing no significant increase in ejection fraction during the dobutamine stress test, with an infusion of dobutamine at 5 and then 10 µg/kg/min [142]. Generally, studies in excised right atrial tissue in infants and children with CHD or cardiomyopathy demonstrate decreased density of $ß_1$ and $ß_2$ receptors, and decreased downstream adenylate cyclase function, with larger decreases associated with worse ventricular function [143].

This has been a brief discussion of receptor signaling in pediatric heart disease. This emerging field has many implications for treatment strategies, and the reader is referred to excellent reviews for more detailed information on this subject [144].

KEY POINTS: RECEPTOR SIGNALING IN MYOCARDIAL DYSFUNCTION, CHD, AND HEART FAILURE

- High catecholamine doses in acute myocardial dysfunction can desensitize the myocardium through uncoupling of G-protein adenylate cyclase complex, and sequestration of β-adrenergic receptors.
- Significant cyanotic or acyanotic CHD with heart failure can result in down-regulation of β-adrenergic receptors in neonatal or infant myocardium.
- Longstanding decreased ventricular function is often associated with the decreased density of β-adrenergic receptors and decreased adenylate cyclase function.

Myocardial preconditioning

Myocardial preconditioning refers to the finding that repeated, brief exposures of the myocardium to ischemia, volatile anesthetics, or other stresses induces a protective

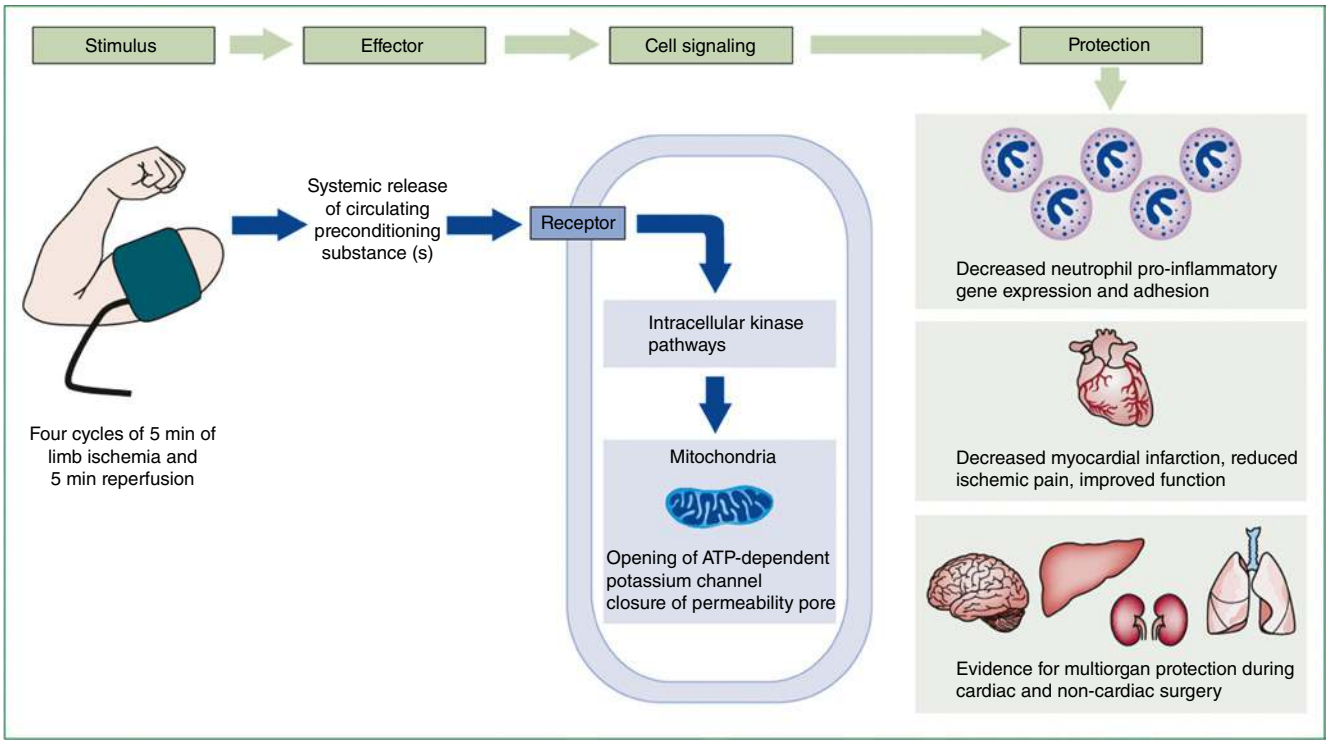

Figure 9.17 Biological effects of remote ischemic preconditioning. Transient ischemia of the arm liberates a circulating effector that induces remote cellular adaptation to a subsequent, extended and potentially lethal period of ischemia in remote tissues. (Source: Kharbanda et al. [146]. Reproduced with permission of Elsevier.)

effect to a later (i.e. 12–24 hours), more prolonged, ischemic insult, resulting in decreased myocardial infarction size and improved myocardial function after the insult [145]. Chronic cyanosis also induces a similar protective effect in the myocardium, although the effect size is smaller and more long-lasting (i.e. beyond 24 hours). Another mechanism is remote ischemic preconditioning (RIPC), in which ischemia is produced in a tissue bed remote to the myocardium, for example, skeletal muscle of the arm or leg by repeated inflation of a blood pressure cuff which is thought to liberate as yet uncharacterized neurohumoral or hormonal substances that can protect the myocardium (Figure 9.17) [146]. The mechanisms of myocardial preconditioning are complex but are thought to involve the release of various neurohormonal agents and peptides such as adenosine, bradykinin, and nitric oxide via a cGMP-dependent mechanism, which then triggers a series of signal transduction events within the cardiomyocyte that confer a "memory" effect that protects the myocardium from future ischemic insults. The signal transduction effects include PKC, tyrosine kinases, mitogen-activated protein kinases, glycogen synthase kinase 3β, and other enzymes [147]. This series of events allows activation of mitochondrial and sacrolemmal K_{ATP} channels, which leads to the preconditioning by elusive mechanisms. One recently discovered candidate for this end effector is the mitochondrial permeability transition pore (MPTP) [147]. This is a non-specific channel that spans both mitochondrial membranes, and when opened for a prolonged period results in a dissipation of mitochondrial electrical potential, inhibition of ATP synthesis, and ultimately mitochondrial swelling, rupture, failure of cellular energy metabolism, and cell death. Agents and stimuli that confer myocardial preconditioning have been found to keep the MPTP closed, thus possibly elucidating further the subcellular mechanisms involved.

Several recent pediatric cardiac surgery studies have been published elucidating the potential effects of myocardial preconditioning, which could have the beneficial effect of ameliorating the myocardial stunning effect seen in operations on infants with long aortic cross-clamp times [148]. In a study of 90 infants randomized to sevoflurane, propofol, or midazolam anesthesia for maintenance, plus a sufentanil infusion for analgesia, patients receiving sevoflurane had a very strong trend toward lower troponin T concentrations in the first 24 hours after surgery, potentially signifying less myocardial injury due to the pre-bypass exposure to sevoflurane [150]. Remote ischemic preconditioning produced by inflating a blood pressure cuff on a lower extremity to produce a 5-minute period of limb ischemia, for four cycles before cardiopulmonary bypass, was studied in 37 children undergoing cardiac surgery. Patients who underwent RIPC had lower peak troponin I levels (17 vs. 22 μg/L, $P = 0.04$), and lower inotrope score in the RIPC group at 3 and 6 hours post-bypass [149]. This interesting phenomenon of RIPC may work via modulation of the inflammatory response through some as yet unknown humoral mechanism. Some recent small controlled trials of RIPC in children measured inflammatory and myocardial injury markers such as tumor necrosis

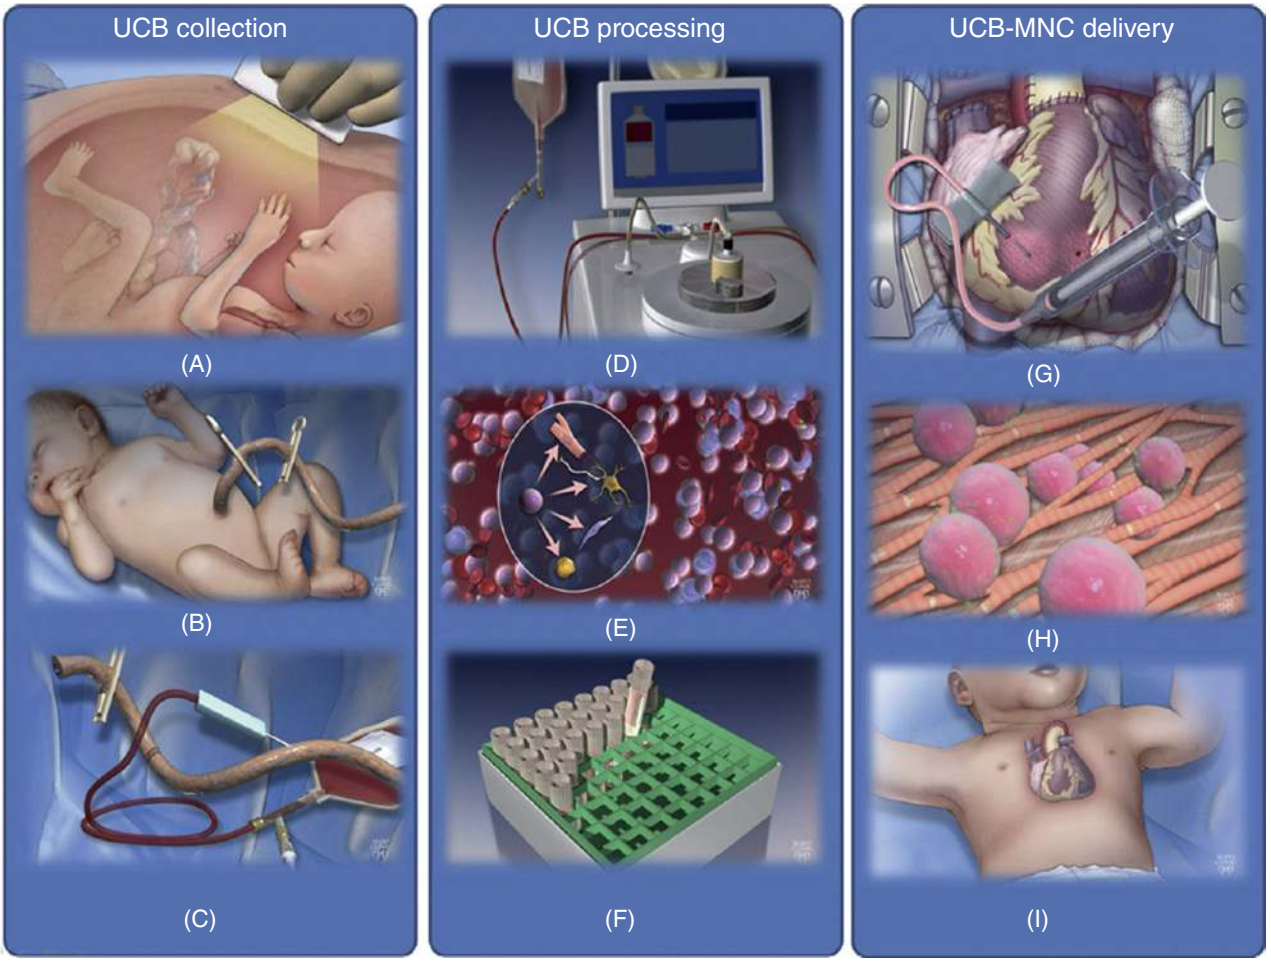

Figure 9.18 Diagnosis of hypoplastic left heart syndrome is established by a fetal echocardiogram (A). Umbilical cord blood (*UCB*) collection kit is sent to the family before birth and used to maximize collection volume (B and C). UCB is collected by local hospital staff, packaged, and transported by a dedicated courier to a specialized laboratory where the sample is processed to isolate the mononuclear cell product via Ficoll density gradient separation (D and E). The final cell-based product is cryopreserved in sterile 2 mL cryovials with 10% dimethyl sulfoxide at a predetermined concentration and stored in the vapor phase of liquid nitrogen (F). After the completion of superior cavopulmonary anastomosis, the UCB-derived mononuclear cells (*UCB-MNC*) are directly injected into the subepicardial myocardium (G). These autologous cells are transiently residing and contributing only to the paracrine influence within the myocardial microenvironment (H) establishing the safety and feasibility of this novel experimental therapy (I). (Source: Burkhart et al. [158]. Reproduced with permission of Elsevier.)

factor-alpha and interleukins (ILs). Several of these studies demonstrated decreases in creatine kinase, inflammatory mediators IL-8 and -10, heat shock protein, and cardiac enzymes creatine kinase and troponin I with RIPC. However, none of these studies demonstrated a clinical difference in ventilation time, intensive care unit stay, end-organ dysfunction, or death [151–154]. Thus, it would appear that despite the initial enthusiasm for this relatively simple clinical intervention, the studies to date demonstrate no clinical benefit. The exact mechanisms of RIPC are still not completely elucidated, and the small muscle mass of infants and children compared with adults, the different clinical approaches to anesthetic agent and corticosteroid use, and the small numbers of patients studied to date may prevent conclusive data. A large single-center, blinded, randomized controlled trial published in 2014 by McCrindle and colleagues studied 299 children aged neonate to 17 years.

[155] The RIPC group received four 5-minute cuff inflations on the thigh of 15 mmHg above systolic pressure before bypass. There were no differences in the primary outcome of the duration of hospital stay, nor in secondary outcomes of the duration of mechanical ventilation or hospital stay. There were also no differences in physiologic or laboratory outcomes, including markers of cardiac, hepatic, renal, or hemotologic dysfunction; inflammatory markers, or physiologic measures of hemodynamic instability. An international multicenter controlled trial of RIPC in the study of 5,401 adult patients with suspected ST-elevation myocardial infarction (STEMI) also did not show any difference in cardiac death or hospitalization for heart failure [156]. RIPC thus would appear to be an example of a promising therapy in the preclinical setting and small clinical studies, but when subjected to rigorous study design with an adequate sample size, does not change clinically important outcomes.

KEY POINTS: MYOCARDIAL PRECONDITIONING

- Myocardial preconditioning is a complex phenomenon by which repeated brief exposure of the myocardium to ischemia or other stresses induces a protective effect to later ischemic insults.
- The mitochondrial permeability transition pore is a common pathway for the various forms of ischemic preconditioning, staying closed and preventing mitochondrial failure.
- Remote ischemic preconditioning produced by inflation of a blood pressure cuff on a limb before CPB may reduce some inflammatory and ischemic cell death markers, but does not improve clinical outcomes.

Stem cell and other cell-based therapy for congenital heart disease

A very interesting and promising approach to regeneration and repair of cardiac myocytes damaged by chronic heart failure due to congenital heart disease, or cardiomyopathy is the administration of autologous or allogeneic stem cells, or other pre-differentiated cells types, into the myocardium [157]. Hypoplastic left heart syndrome (HLHS) patients remain a challenging group because the systemic right ventricle often fails even with technically perfect surgery and a stable postoperative course after the Norwood stage I palliation. Autologous cells derived from a mononuclear population of umbilical cord blood (UCB-MNC) at birth can assimilate into the myocardium. After processing to ensure sterility and a uniform population of mononuclear cells, umbilical cord blood-derived mononuclear cell (**UCB-MNC**) has been tested in an ongoing trial by injecting them directly into the right ventricular myocardium during the Stage II (bidirectional cavopulmonary anastomosis) operation for HLHS. A dose of 1–3 million umbilical cord-derived mononuclear cells per kilogram is injected [158] (Figure 9.18). Vicenti and colleagues published results of a phase II study of seven HLHS patients injected with these cells, compared retrospectively to 17 controls [159]. By 6 months postoperatively, treated patients had a 3% increase in right ventricular contractility vs. a 5% decrease for controls ($p = 0.03$). Somatic growth was also improved in the treated patients, up to 63rd percentile vs. decrease to the 8th percentile in the control group ($p = 0.02$). Sano and colleagues reported intracoronary infusion of cardiosphere-derived cells (CDC), a type of cardiac progenitor cells, harvested from the patient at the time of a previous Norwood stage I/II surgery, after stage II or stage III repair in 41 HLHS patients compared to 60 controls [160]. Two years after infusion, survival between groups was not different, but CDC treated patients had lower incidence of late heart failure ($p = 0.022$), adverse events ($p = 0.013$), and catheter interventions ($p = 0.005$). In patients with heart failure with reduced ejection fraction, mortality and late complications were improved in CDC treated patients vs. controls. Interestingly, the paracrine hypothesis is thought to be the predominant mechanism of action of the UCB-MNC and CDC. These cells reside only transiently in the myocardium, but can secrete factors that stimulate endogenous cellular proliferation, while shifting tissue remodeling pathways away from a fibrotic/inflammatory response, to one that can activate endogenous repair mechanisms. Several trials are ongoing and could provide a relatively simple method to improve cardiac function in single ventricle infants. Safety profile is reported to be excellent in the follow-up to date.

Introduction

A wide variety of anesthetic regimens are used for patients with congenital heart disease (CHD) undergoing cardiac or non-cardiac surgery, procedures in the cardiac catheterization laboratory, or other diagnostic or therapeutic procedures such as magnetic resonance imaging (MRI). The goal of all of these regimens is to produce general anesthesia or adequate sedation while preserving systemic cardiac output (CO) and oxygen delivery. Many of these patients have a limited cardiac reserve, and if a cardiac arrest or other adverse cardiac event occurs, successful resuscitation is less frequent than in patients with normal hearts [1]. Thus, intelligent selection of regimen and dosage, with the patient's unique pathophysiology in mind, along with anesthetic requirements for the particular procedure they are undergoing, is essential. This chapter reviews the effects on hemodynamics and myocardial contractility of anesthetic agents and muscle relaxants commonly used for patients with CHD.

Volatile agents

Although halothane is no longer available in the US, it is still used in some parts of the world, and it serves as the basis for comparison with newer agents because of the number of studies of its hemodynamic effects in children with and without heart disease. Therefore, data concerning halothane will be presented in this section. *In vitro* studies of effects on contractility in isolated adult human atrial fibers indicate that direct myocardial contractility depression is at its greatest with halothane and that sevoflurane is equal to isoflurane and desflurane [2] (Figure 10.1). These studies of myocardium reveal that the differences among these agents occur primarily from differing effects on calcium flux through L-type Ca^{2+} channels, both transsarcolemmal and in the sarcoplasmic reticulum (SR). Halothane reduces Ca^{2+} flux through the sarcolemma more than isoflurane, with the net result of less intracellular Ca^{2+} available to bind to the troponin–actin–myosin complex, which produces myocyte contraction. Another mechanism of myocardial depression is that halothane, but not isoflurane, directly activates ryanodine-sensitive SR Ca^{2+} channels, thereby reducing Ca^{2+} storage in the SR and making it less available for release during contraction. The effects of sevoflurane and desflurane on Ca^{2+} flux are similar to those of isoflurane [2].

It is important to note that infants from the newborn period up to an age of approximately 6 months exhibit an exaggerated degree of depression of myocardial contractility and blood pressure in response to all volatile agents, but especially halothane [3, 4] (Figure 10.2). This is probably due to the immaturity of the Ca^{2+} release and reuptake system, necessitating higher levels of free cytosolic Ca^{2+} to be available to bind to the troponin–actin–myosin complex to produce myocyte contraction [5]. Sevoflurane, and to a greater extent halothane, interferes with both L-type Ca^{2+} channel and Na^+/Ca^{2+}

Reproduced with permission of Wolters Kluwer Health, Inc.)

exchanger Ca^{2+} flux at the plasmalemmal membrane more in neonatal than in adult rat myocytes [6]. The volatile anesthetics interfered with Ca^{2+} release from the SR more in adult rat myocytes. Ca^{2+} release from the SR is thought to be less contributory to cytosolic Ca^{2+} levels in neonatal rat myocytes [7]. This information provides a mechanism for what is commonly observed clinically.

The effects of volatile agents on systemic vascular resistance (SVR), as measured by arterial blood pressure, differ between agents. Ca^{2+} flux in the smooth muscles of arterioles is reduced by all of these agents, resulting in less resting tone, and thus lower blood pressure and vascular resistance. Halothane exhibits the most pronounced reduction of blood pressure, due to the combination of reduction in arterial tone, as well as the more pronounced depression of myocardial contractility. Isoflurane and sevoflurane lower blood pressure primarily through a reduction in SVR [8].

Sevoflurane has largely replaced halothane throughout most of the world for induction and maintenance of anesthesia. The Pediatric Perioperative Cardiac Arrest Registry data demonstrated a decrease in anesthetic medication-related cardiac arrests, from 37% of the total in 1994–1997 to 18% in 1998–2004; the authors primarily attributed this decrease to the less frequent use of halothane, leading to fewer arrests, particularly in young infants [9].

In patients with CHD, several studies have been performed comparing newer agents with halothane. A study using transthoracic echocardiography comparing halothane, isoflurane, and sevoflurane [8] in 54 children with two-ventricle CHD (Table 10.1, Figure 10.3) reported that 1 and 1.5 MAC (minimum alveolar concentration) halothane caused significant myocardial depression, resulting in a decrease in mean arterial pressure (MAP, decline of 22 and 35%, respectively), ejection fraction (EF, decrease of 15 and 20%, respectively) and CO (decrease of 17 and 21%, respectively) in patients aged 1 month to 13 years undergoing cardiac surgery. Sevoflurane maintained both CO and heart rate (HR) and had less profound hypotensive (MAP decrease of

13 and 20% at 1 and 1.5 MAC, respectively) and negative inotropic (EF preserved at 1 MAC, 11% decrease at 1.5 MAC) effects than halothane. Isoflurane, at concentrations as high as 1.5 MAC, preserved CO and EF, caused less suppression of MAP (22 and 25%) than halothane, increased HR (17 and 20%), and decreased SVR (20 and 22%).

Russell and colleagues [10] compared sevoflurane to halothane in the pre-bypass period in 180 children with a variety of cardiac diagnoses, including 14 with single-ventricle physiology and 40 with tetralogy of Fallot (TOF). The incidence of significant hypotension, bradycardia, and arrhythmia requiring drug treatment with atropine, phenylephrine, epinephrine, or ephedrine was higher with halothane (two events per patient vs. one with sevoflurane). Serum lactate also increased slightly with halothane.

In a randomized crossover comparison study of 1 MAC isoflurane vs. sevoflurane, Dalal and colleagues studied 10 children with a variety of CHD, including both single- and two-ventricle diseases [11]. Stroke volume, EF, and cardiac index were determined for the systemic ventricle using cardiac MRI techniques. There were no differences between agents for these parameters, or differences in MAP or HR in this small study.

The effects of these agents on pulmonary (Qp) and systemic blood flow (Qs) in 30 biventricular patients with left-to-right shunts (secundum ASD, VSD) have also been assessed. Halothane, isoflurane, and sevoflurane did not change Qp:Qs as measured by echocardiography [12].

Wang and colleagues assessed differences in HR, cardiac rhythm, and blood pressure in 55 infants aged 2–12 months during 8% sevoflurane induction [13]. Twenty-nine had increased pulmonary blood flow (PBF) (atrial septal defect [ASD], ventricular septal defect [VSD], patent ductus arteriosus [PDA]), and 26 had decreased PBF (TOF, pulmonic stenosis). The first 10 minutes of the anesthetic were assessed, and differences between groups compared. HR decreased from baseline in both groups, with a greater decrease in patients with decreased PBF. Blood pressure decreased significantly in the increased PBF group but was unchanged in the patients with decreased PBF. Junctional rhythm was observed in one patient in the increased PBF group.

Patients with a single functional ventricle comprise an increasing proportion of patients undergoing anesthetics for both cardiac and non-cardiac surgery, and studies of the hemodynamic effects of anesthetic agents are limited. Ikemba and colleagues [14] studied 30 infants with a single functional ventricle immediately before their bidirectional cavopulmonary connection, randomized to receive sevoflurane at 1 and 1.5 MAC or fentanyl/midazolam at equivalent doses. Myocardial performance index (MPI), a transthoracic echocardiographic measurement of combined systolic and diastolic ventricular function that can be applied to single-ventricle

patients, was not changed with any of these regimens when compared with baseline, indicating that either sevoflurane or fentanyl/midazolam can be used in this population to maintain hemodynamic stability.

The effect of sevoflurane on systolic ventricular function has been studied in specific populations of CHD patients. Muyskens and colleagues [15] performed a retrospective review of patients with repaired Tetralogy of Fallot (rTOF) undergoing cardiac magnetic resonance imaging (CMR). After propensity score matching, the rTOF patients who required general anesthesia with maintenance sevoflurane (range 0.83–2.83%) were found to have a significant decrease in the CMR-derived left ventricular ejection fraction (49 vs. 56%) and CMR-derived right ventricular ejection fraction (41 vs. 48%). Elhoff and colleagues [16] assessed changes in ventricular function during 17 instances of sevoflurane-based general anesthesia for pediatric heart transplant recipients undergoing cardiac catheterization with endomyocardial biopsies. A baseline, pre-anesthetic echocardiogram was obtained. A significant decrease in ventricular function from baseline, as measured by repeat echocardiography was noted after attainment of a stable maintenance phase of general anesthesia with sevoflurane (MAC 0.7–1.0). There was, however, no consistent evidence of alteration of diastolic function under general anesthesia.

In normal children, desflurane commonly produces tachycardia and hypertension during the induction phase, followed by a slight reduction in HR and systolic blood pressure during steady state at 1 MAC anesthetic level [17, 18]. There are no reports of its hemodynamic profile in patients with CHD. In a study of 47 children (mean age 12.8 years) undergoing electrophysiological study for supraventricular tachycardia (SVT), desflurane allowed for induction of the SVT in all patients and demonstrated no clinically important differences in any electrophysiologic measurement, as compared with a fentanyl-based anesthetic [19]. The very low arrhythmogenic potential of desflurane has been demonstrated to be similar to that of isoflurane [20].

Some patients (6–12%) exposed to sevoflurane develop arrhythmias, mostly atrial or junctional [21, 22]. A study performed in infants (mean age 7.5 months) found that sevoflurane induction caused a 20% incidence of junctional bradycardia (less than 80 beats/min). Isoflurane, when utilized in children for electrophysiologic studies and radiofrequency ablation for SVT, does not affect sinoatrial or atrioventricular (AV) node conduction, and all arrhythmias were easily induced [23]. There are case reports of sevoflurane causing torsade de pointes in children with congenital long QT syndrome; this effect may be due to the increase in HR often seen with induction of anesthesia with this agent [24].

In a study of sevoflurane inhalation induction using electronic anesthesia data, Kraemer and colleagues [25] compared 209 children with Down syndrome with or without CHD with 268 healthy controls without Down syndrome or CHD. Fifty-seven percent of the Down syndrome patients experienced age-defined hypotension and bradycardia during the first 6 minutes of anesthesia, as compared with 12% of patients without Down syndrome or CHD (odds ratio, 9.56; 95% confidence interval 6.06–15.09). Bradycardia was not further characterized, i.e., sinus vs. junctional. Nogami and colleagues [26] describe a case of transient cardiac arrest in a 14-year-old Down syndrome patient with repaired ASD, VSD, and PDA during inhalational induction with 5% sevoflurane for a dental procedure. Severe bradycardia (HR <30 bpm) developed 1 minute after induction, followed by asystole. The mechanism for cardiac arrest was postulated to be secondary to autonomic cardiac dysfunction commonly seen in the Down syndrome population.

Few studies to date have addressed the effects of the different anesthetics on an important group of pediatric patients with heart disease: patients with cardiomyopathy or significantly decreased systolic ventricular function. Volatile agents were commonly employed in two retrospective series of anesthesia in children with cardiomyopathy. Lynch and colleagues administered volatile agents in 26% of 236 inductions, and only four patients (1.7%) had cardiac arrest on induction; none of the four received volatile agents [27]. Kipps and colleagues reported a series of 33 children; 12% received volatile agents for induction and 64% received them for maintenance [28]. Although there were 15 patients with severe complications, defined as significant hypotension, arrhythmia, cardiac arrest, extracorporeal membrane oxygenation cannulation, or death, no conclusions could be drawn about any association with use of volatile agents. Rather, severe ventricular dysfunction (shortening fraction <16%) was the most important predictor of complications.

Diastolic function with halothane and isoflurane has been studied in animal models of cardiomyopathy [29, 30]. The two agents differ, with halothane producing negative lusitropic effects, while isoflurane conserves or may even improve diastolic function. There are no reports measuring diastolic function in response to anesthetic agents in patients with CHD.

KEY POINTS: VOLATILE AGENTS

- Depression of myocardial contractility and CO is greatest with halothane, minimal with sevoflurane, and least with isoflurane and desflurane at end-tidal concentrations up to 1.5 MAC.
- All volatile agents may depress myocardial contractility and CO at high doses; infants less than 6 months of age are at the greatest risk.
- Patients with significantly decreased ventricular systolic function are presumed to be at greatest risk for further myocardial depression from any volatile agent.

Nitrous oxide (N_2O)

Despite its ubiquitous use as an adjunct to anesthetic induction and maintenance in patients with CHD, information regarding the effect of N_2O on hemodynamics in patients with CHD is very limited. Its use may be relatively contraindicated where increased FiO_2 is employed, or where enlargement of enclosed air collections is possible, such as in any intracardiac or intrathoracic surgery. Reports of increased pulmonary vascular resistance (PVR), sympathetic stimulation, or significantly decreased CO in response to N_2O in adult patients have not been substantiated in children with or without the cardiac disease [31, 32].

In infants and small children with normal hearts, Murray and colleagues found that addition of 30 and 60% N_2O to 1 MAC halothane or isoflurane resulted in a decreased HR and cardiac index, without changing EF and stroke volume measured echocardiographically [33]. These authors also demonstrated that when 0.6 MAC halothane or isoflurane was substituted for 60% N_2O during 0.9 MAC isoflurane or halothane anesthesia, HR, MAP, and cardiac index were unchanged [34].

In 14 patients with CHD recovering from surgery, Hickey and colleagues [35] administered 50% N_2O and observed a decrease of 9% in HR, 12% in MAP, and 13% in systemic cardiac index. However, mean pulmonary artery pressure and PVR were not significantly changed in these well-ventilated patients with a $PaCO_2$ of 34–35, and pH of 7.47–7.49, even in patients with elevated PVR at baseline. This single report represents the total number of patients with CHD in which N_2O administration has been carefully studied. Despite this paucity of information, extensive clinical experience has demonstrated N_2O to be safe and effective, particularly as an adjunct to inhaled induction of anesthesia for congenital heart surgery.

Opioids and benzodiazepines

Fentanyl and sufentanil have been studied as a sole anesthetic in patients with CHD. Hickey, Hansen, and colleagues [36–38] provided the basis for this technique with a series of studies in neonates and infants less than 1 year of age undergoing complex repairs, ranging from the Norwood operation to complete repair of biventricular lesions. Fentanyl doses of 50–75 μg/kg, and sufentanil doses of 5–40 μg/kg, administered with pancuronium 0.1–0.15 mg/kg, provided excellent hemodynamic stability with minimal changes in HR and blood pressure throughout the surgery. The increase in pulmonary artery pressure and resistance in response to suctioning in infants recovering from cardiac surgery was eliminated with 25 μg/kg fentanyl. Moore and colleagues [39] demonstrated that 5, 10, or 20 μg/kg sufentanil in children aged 4–12 years had no effect on EF as measured by echocardiography in patients undergoing repair of biventricular lesions. Increases in HR, blood pressure, and stress hormones were more effectively blunted by the higher doses. Glenski and colleagues [40] reported M-mode echocardiographic measures of contractility, blood pressure, and HR response using fentanyl (100 μg/kg) or sufentanil (20 μg/kg) in children aged 6 months to 9 years. Measurements were made at three different times: after a premedication with morphine and scopolamine, after induction, and after tracheal intubation. These opioids decreased both EF and shortening fraction after induction, but they returned to or above baseline after intubation.

Midazolam is often added to fentanyl anesthesia to provide sedation and amnesia, as a substitute for low-dose volatile anesthetic agent, particularly in hemodynamically unstable patients and young infants, where the myocardial depressant effects of volatile agents are more pronounced. Fentanyl and midazolam combinations have been studied in two different clinically utilized dose regimens to simulate 1 and 1.5 MAC of volatile agents (fentanyl 8–18 μg bolus followed by 1.7–4.3 μg/kg/h infusion, then repeat bolus at 50% of the original doses followed by increase of infusion by 50%, depending on age; midazolam 0.29 mg/kg bolus followed by 139 μg/kg/h infusion, then repeat bolus 50% of the original dose, followed by increase in infusion of 50% for all ages) for induction and the pre-bypass period in congenital heart surgery in biventricular patients [8] (Figure 10.3). Vecuronium was used for muscle relaxation in order to isolate the effects of the other two agents on hemodynamics. Measurements of CO and contractility were made by echocardiography. Fentanyl/midazolam caused a significant decrease (22%) in CO despite preservation of contractility. This was predominantly due to a decrease in HR. Co-administration of a vagolytic agent such as atropine [41] or pancuronium would probably preserve CO. The added effect of midazolam on echocardiographic indices of contractility has

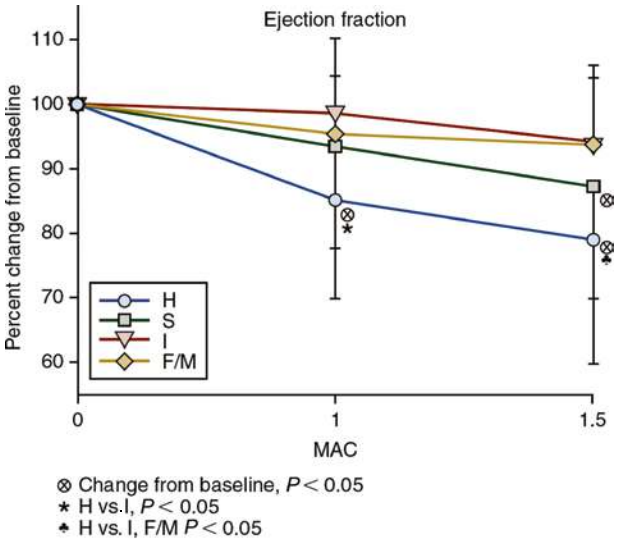

Figure 10.3 Hemodynamic changes assessed by echocardiography in 54 patients with two-ventricle congenital heart disease. (A) Ejection fraction. (B) Cardiac output. not been previously reported, however, increased inotropic support requirements have been documented in infants receiving sedation after cardiac surgery with the addition of midazolam bolus totaling 0.3 mg/kg, and infusion of 0.1–0.2 mg/kg/h in the early postoperative period [42].

The stress response to major cardiac surgery in infants and children has been the subject of considerable interest. Anand and Hickey reported the use of high dose sufentanil at a total mean dose of 37 μg/kg as the sole anesthetic for complex neonatal surgery [43]. The sufentanil was continued by infusion for 24 hours postoperatively. This regimen was compared with halothane plus morphine (mean dose of 0.35 mg/kg) intraoperatively, followed by intermittent morphine and diazepam postoperatively. Stress response, as measured by changes in adrenal hormones, cortisol, glucose, and lactate, was significantly reduced in the sufentanil group, and mortality and major complications such as sepsis and necrotizing enterocolitis were also significantly reduced. A later study from the same institution of 45 infants averaging 3 months of age undergoing biventricular repair with deep hypothermic cardiopulmonary bypass has been reported [44]. A total fentanyl dose of 100 μg/kg was administered, given either as intermittent boluses of 25 μg/kg, or as boluses plus infusion, with or without midazolam, and all regimens resulted in a significant endocrine stress response to cardiac surgery. Despite this, the outcome was excellent in all groups, with no adverse outcomes related to the anesthetic technique or the surgical stress response. The sole hemodynamic difference between the regimens was a lower MAP during cooling on bypass in the group who received midazolam. Finally, Duncan and colleagues [45] reported a dose–response study of 2, 25, 50, 100, and 150 μg/kg fentanyl before bypass in 40 children averaging 13 months and 8.5 kg. The 2 μg/kg group had significant increases in pre-bypass norepinephrine, glucose, and cortisol, and significantly higher HR and blood pressure than all other groups. A dose of 25 μg/kg or higher eliminated changes in these parameters for the duration of the surgery. It is difficult to interpret the significance of these stress response studies because they were evaluated by different age groups and lesions. Also, there was more than one decade between reports, during which time there were significant improvements in surgical, bypass, and postoperative management. If any group of patients had benefited from attenuation of the stress response, it would appear to be neonatal patients undergoing complex surgery. Current approaches to early extubation favor lower intraoperative opioid doses, e.g., <10–20 μg/kg fentanyl and use of adjuvants such as dexmedetomidine or regional anesthesia, rather than completely ablating the stress response [46]. Chapter 24 presents an extensive discussion of early extubation approaches for congenital cardiac surgery.

Remifentanil is a synthetic ultra-short-acting narcotic agent metabolized by plasma esterases with a half-life of 3–5 minutes that is independent of the duration of infusion [47]. It is particularly useful for short non-cardiac procedures with intense stimulation where opioid-based anesthesia and its hemodynamic stability would be desirable, yet where rapid emergence is also important. Donmez and colleagues [48] reported a series of 55 children undergoing cardiac catheterization with a remifentanil infusion of 0.1 μg/kg/min. This regimen maintained excellent cardiovascular stability, with minimal changes in HR, blood pressure, or oxygen saturation. Fifty-eight percent of patients required additional sedation with midazolam or ketamine. Apnea was infrequent, and a time to recovery score of 5 (10-point scale) was only 2–4 minutes. Patients undergoing long cardiac catheterization procedures could potentially benefit from this agent.

Remifentanil infusion at 0.3 μg/kg/min increased sinus cycle and Wenckebach cycle length from baseline but did not affect atrial-His or His-ventricular interval, or AV node, atrial, ventricular, or accessory pathway effective refractory period in 14 patients undergoing electrophysiology study and ablation for SVT [49]. In a similar study of 29 patients receiving 0.2 or 0.4 μg/kg/min remifentanil, the larger dose prolonged sinoatrial conduction time and sinus node recovery time, but not atrial-His interval [50]. These electrophysiological effects should be taken into account if the drug is used for electrophysiological studies.

Remifentanil administration has been reported for ASD repair, where patients are extubated in the operating room (OR) [51]. It apparently does not bind to the cardiopulmonary bypass (CPB) circuit [52] and its clearance in children before and after CPB appears to be predictable within a narrow range, making it a potentially useful agent for "fast-track" anesthesia and early extubation for simple surgical procedures. Friesen and colleagues compared remifentanil 0.3–0.7 μg/kg/min with fentanyl 15 μg/kg, both with isoflurane and pancuronium, in fast-track pediatric cardiac operations (ASD and VSD repairs) and found that HR was significantly slower in the OR in the remifentanil group, but there was no difference in time to extubation, analgesic requirements in ICU, nausea/vomiting or hypertension in ICU, or in ICU length of stay [53]. Akpek and colleagues compared higher-dose remifentanil (2 μg/kg load and 2 μg/kg/min maintenance infusion) with fentanyl (20 μg/kg load and 20 μg/kg/h infusion) in 33 infants with pulmonary hypertension undergoing surgery for repair of left-to-right shunting defects. Both groups had a midazolam infusion. There were no clinically important differences in hemodynamic, respiratory, or oxygen saturation parameters between groups, and no difference in clinical outcomes [54]. Thus, despite some theoretical advantages due to its pharmacokinetic profile, there are few clinically significant differences between remifentanil and fentanyl.

KEY POINTS: OPIOIDS AND BENZODIAZEPINES

- Fentanyl, sufentanil, and remifentanil have minimal effect on myocardial function, even at large doses.
- Synthetic opioids decrease catecholamine release and other measures of stress response, including pulmonary hypertension, at moderate and large doses.
- Complete ablation of the stress response with large opioid doses is employed less often in recent years without decrement in outcomes.
- Midazolam (and other benzodiazepines) in large doses may increase inotropic support needs in infants.

Propofol

Propofol has become a popular agent for sedation for cardiac catheterization procedures and induction of general anesthesia for cardiac surgery. In plasma concentrations found in routine clinical use, propofol has minimal negative inotropic effects in isolated animal cardiac preparations [55] or in human adult atrial muscle strips [56].

In children with normal hearts, propofol at induction doses consistently decreases systolic and mean arterial pressure by 5–25% without changing HR [57]. In a case series of 13 preterm neonates of 29–32 weeks gestational age, a propofol bolus of 1 mg/kg decreased MAP from 38 to 24 mmHg, and 5 of 13 patients had a severe decrease to <25 mmHg [58]. There has been one published study using echocardiography to assess myocardial contractility and CO in infants with normal hearts induced with propofol [57]. The shortening fraction or cardiac index was not changed, and SVR decreased by 14 and 27% at 1 and 5 minutes after induction, respectively. Load independent measures of contractility (stress velocity index and stress shortening index) decreased significantly from baseline at 5 minutes after induction with propofol.

Williams and colleagues [59] measured the hemodynamic effects of propofol in 31 patients aged 3 months to 12 years at a dose of 50–200 µg/kg/min undergoing cardiac catheterization (Figure 10.4). They found that propofol significantly decreased MAP and SVR; however, there was no change in systemic CO, HR, mean pulmonary artery pressure, or PVR. In patients with cardiac shunts, the net result was a significant increase in the right-to-left shunt, a decrease in the left-to-right shunt, and decreased Qp : Qs, resulting in a statistically significant decrease in PaO_2 and SaO_2, as well as reversal of the shunt from left-to-right to right-to-left in two patients. In another study of patients undergoing cardiac catheterization, Lebovic and colleagues [60] demonstrated that patients could experience a 20% decrease in HR or MAP. Combining propofol infusion with ketamine infusion for cardiac catheterization procedures demonstrated less change in MAP, preservation of baseline HR, and little effect on recovery time [61].

Propofol has no significant effect on sinoatrial or AV node conduction, or on the ability to induce SVT, and therefore is desirable as a primary agent during electrophysiologic studies and radiofrequency ablation [23, 62]. However, ectopic atrial tachycardia may be suppressed by propofol [63].

Although propofol is very useful for cardiac catheterization, short, stimulating procedures, and possibly for short-term sedation after cardiac surgery, its long-term use as an ICU sedative is contraindicated, with several reports of otherwise unexplained metabolic acidosis and myocardial failure after long-term (>48 hours), high dose use in pediatric patients [64, 65]. The mechanism of this cardiovascular collapse is postulated to be due to disruption of fatty acid oxidation caused by impaired entry of long-chain acylcarnitine esters into the mitochondria and failure of the mitochondrial respiratory chain [66]. Although a recent case series of short-term, low- to medium-dose post-anesthetic propofol infusion (median 7 hours) has been described without complication in 12 high-risk CHD patients with pulmonary hypertension, airway malacia, or underlying chromosomal abnormality, this practice should be limited to those centers with substantial expertise and experience with this technique [67]. Propofol infusions of duration greater than 6 hours, as might be observed for long cardiac catheterization procedures, are not recommended because of the potential for the propofol infusion syndrome.

In summary, propofol can be utilized in patients with adequate cardiovascular reserve who can tolerate a mild decrease in contractility and HR, and a decrease in SVR. Propofol may cause an increased intracardiac right-to-left shunt, and reversal of shunt in some patients, (i.e. acyanotic TOF), and thus hemodynamic data obtained in the cardiac catheterization laboratory should be interpreted accordingly. Although propofol use for induction of anesthesia has been described for patients with cardiomyopathies in several case series [27, 28], many authorities recommend against its use, particularly in hypertrophic or dilated cardiomyopathy, where even a small reduction in afterload and preload from propofol's venodilatory properties can result in cardiovascular collapse [68].

KEY POINTS: PROPOFOL

- Propofol at induction doses causes a mild decrease in myocardial contractility, but a significant decrease in MAP and HR, as well as some preload reduction from venodilation.

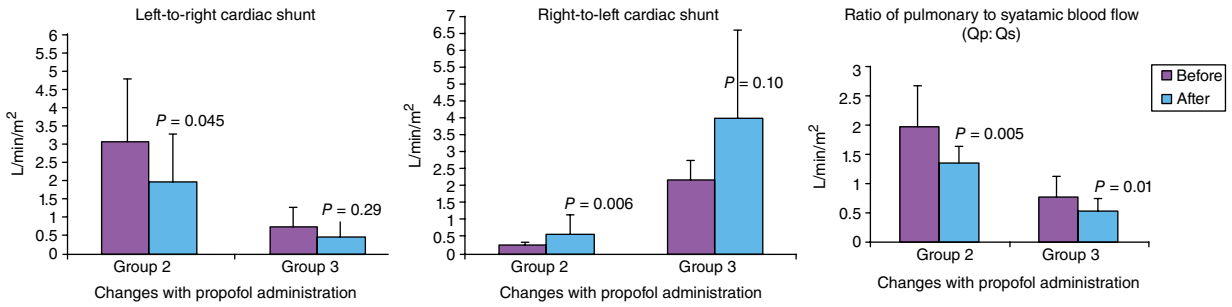

Figure 10.4 Changes in intracardiac shunting in response to propofol induction and infusion in children undergoing cardiac catheterization. Group 2, patients with net left-to-right cardiac shunting; group 3, patients with net right-to-left cardiac shunting. Qp : Qs decreased significantly in both groups. (Source: Williams et al. [59]. AL Grawany

- Propofol infusion has little effect on pulmonary vascular pressure and resistance, but decreases SVR, resulting in an increase in right-to-left shunting.
- Because of its effects to decrease preload, afterload, and myocardial contractility, propofol should be used with great caution, if at all, in patients with significantly decreased ventricular function, and those with left ventricular outflow obstruction.

Ketamine

The general anesthetic and analgesic effects of ketamine are mediated by its interaction with *N*-methyl-D-aspartate receptors in the brain [69]. It increases HR, blood pressure, and CO through central nervous system-mediated sympathomimetic stimulation and inhibition of the reuptake of catecholamines. Ketamine is a direct myocardial depressant when studied in isolated myocyte preparations [70] and in adult human failing atrial and ventricular muscle trabeculae [71] (Figure 10.5). The direct myocardial depression caused by ketamine may be unmasked when administered to patients whose sympathomimetic responses are already maximally stimulated from cardiomyopathy, or another condition leading to poor myocardial reserve, because a further increase in catecholamine release is limited. Similarly, if the patient is chronically receiving ß-adrenergic agonists, catecholamine receptors may be downregulated, resulting in a diminished response to endogenously generated catecholamines, allowing the myocardial depressant effects of ketamine to predominate.

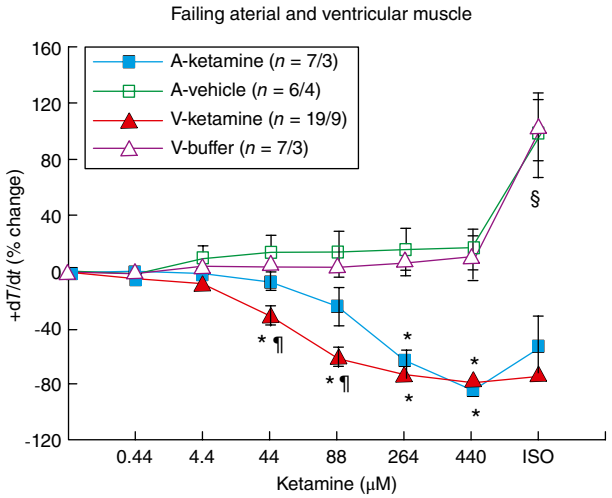

Figure 10.5 Developed tension over time (d*T*/d*t*) in cardiac muscle trabeculae in explanted hearts from adults undergoing cardiac transplantation in response to increasing ketamine concentrations. The upper limit of clinical concentration is 44 μM after a 2 mg/kg induction dose. A, atrial muscle; V, ventricular muscle; vehicle, control solution without ketamine; buffer, Krebs–Henseleit buffer control. $^{*}P < 0.05$ *versus* vehicle control; $P < 0.05$ *versus* A-Ketamine; $^{§}P < 0.05$ *versus* preceding dose. Numbers in parentheses represent numbers of muscle strips/number of patients. ISO, change with addition of 1 μM isoproterenol. (Source: Sprung et al. [71]. Reproduced with permission of Wolters Kluwer Health, Inc.)

The mechanism of myocardial depression is by inhibition of L-type voltage-dependent Ca^{2+} channels in the sarcolemmal membrane. An increased extracellular Ca^{2+} concentration may enhance this effect [70]. This direct myocardial depression effect is greater than that produced by etomidate [56]. In a patient with end-stage cardiomyopathy awaiting heart transplant, hemodynamic collapse occurred after the induction of anesthesia with ketamine [72]. In a study comparing ketamine (1.5 mg/kg) and sufentanil (mean total dose 3.42 μg/kg) for induction of anesthesia in 20 patients with end-stage cardiomyopathy undergoing cardiac transplantation, ketamine was found to increase MAP, SVR, central venous pressure, and pulmonary artery pressure, and decrease stroke volume index significantly [73]. Cardiac index decreased slightly, but not to a statistically significant degree. The sum total of the hemodynamic effects of ketamine induction in these patients was less myocardial work at the expense of a higher myocardial wall tension. Sufentanil induction did not change any of these parameters from baseline.

Other well-recognized untoward effects associated with ketamine use do not differ among patients with CHD. These include emergence reactions, excessive salivation, and an increase in cerebral metabolism, intracranial pressure, cerebral blood flow, and cerebral oxygen consumption [69].

Despite the adverse effects of ketamine, this drug has been a mainstay of induction of general anesthesia in patients with CHD [74, 75]. Administration can be intravenous (IV) or intramuscular (IM), and it will reliably maintain HR, blood pressure, and systemic CO at an induction dose of 1–2 mg/kg IV or 5–10 mg/kg IM, and a maintenance dose of 1–5 mg/kg/hour in patients with a variety of congenital heart diseases, including TOF [76, 77] (Figure 10.6).

Ketamine's effect on pulmonary vascular resistance has been investigated. Morray and colleagues [78] demonstrated that in patients undergoing cardiac catheterization, 2 mg/kg ketamine caused a minimal (<10%) increase in mean pulmonary artery pressure and in the ratio of PVR to SVR (Rp : Rs), with no change in direction of shunting or Qp : Qs. Hickey

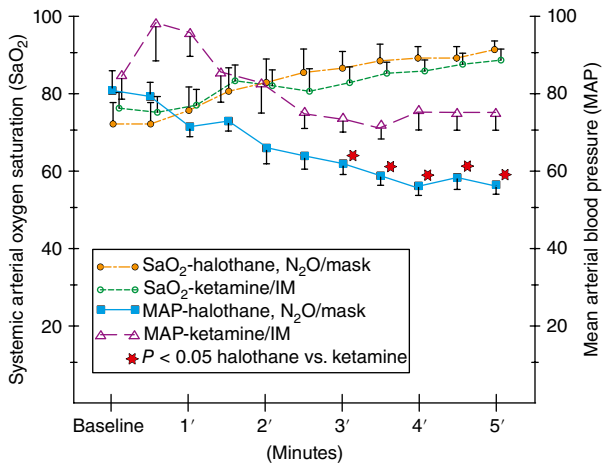

Figure 10.6 Oxygen saturation and mean arterial pressure in response to induction with intramuscular (IM) ketamine vs. halothane in patients with right-to-left cardiac shunting, most of whom had tetralogy of Fallot. (Source: Greeley et al. [76]. Reproduced with permission of Wolters Kluwer Health, Inc.)

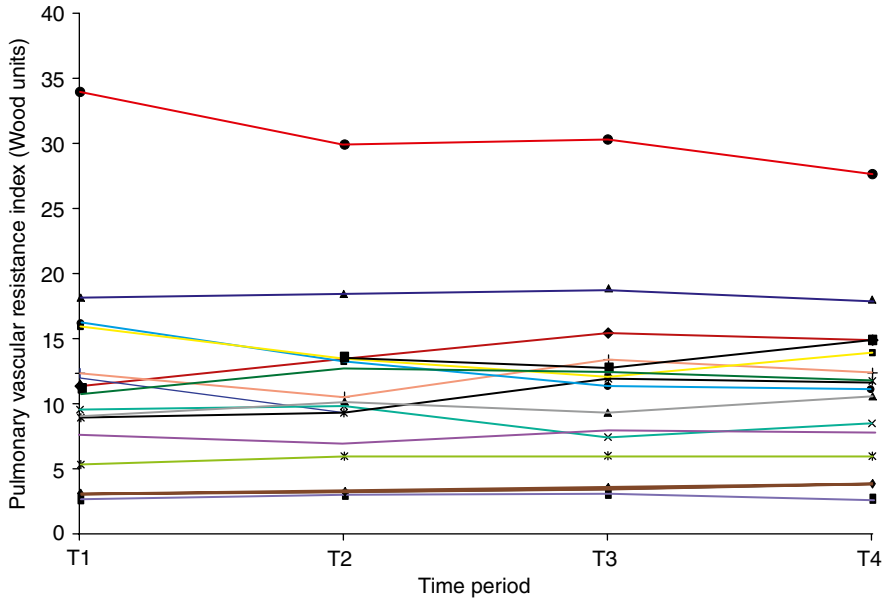

Figure 10.7 Pulmonary vascular resistance changes in 15 children with pulmonary hypertension undergoing cardiac catheterization, in response to ketamine 2 mg/kg intravenously, followed by an infusion of 10 μg/kg/min while breathing spontaneously with a baseline of 0.5 MAC sevoflurane. T1, baseline before ketamine; T2, 5 minutes after ketamine load; T3, 10 minutes after ketamine load; and T4, 15 minutes after ketamine load. (Source: Williams et al. [80]. Reproduced with permission of Wolters Kluwer Health, Inc.)

and colleagues [79] studied 14 postoperative infant cardiac surgery patients who had normal $PaCO_2$, breathing spontaneously through nasotracheal tubes. Ketamine 2 mg/kg had no effect on pulmonary artery pressure or calculated PVR in patients with either normal or elevated baseline PVR. Williams and colleagues reported that ketamine (2 mg/kg load, followed by an infusion of 10 μg/kg/min) did not change PVR at all in 15 children with severe pulmonary hypertension, when breathing spontaneously with a baseline of 0.5 MAC sevoflurane [80] (Figure 10.7). Williams and colleagues also performed a retrospective review of anesthetic technique and outcomes of 92 patients with pulmonary hypertension undergoing 192 anesthetics for noncardiac surgery, catheterization, and other diagnostic procedures, with ketamine administered for either induction or maintenance in 149 procedures (78%) [81]. Pulmonary hypertension was mild in 23%, moderate in 37%, and severe in 40%. There were nine major complications, including three cardiac arrests (1.7% incidence), and 20 minor complications; the majority of minor complications were self-limiting arrhythmias and hypotension. Ketamine administration was not associated with any of these complications, whether administered as the sole anesthetic agent or combined with volatile agents or propofol. Friesen and colleagues [82] administered ketamine (2 mg/kg) to 34 children with known pulmonary hypertension undergoing elective pulmonary hypertension studies with a controlled airway and ventilation. No pulmonary vasodilating medications were used simultaneously. Mean pulmonary artery pressures and PVR were clinically unchanged in this patient cohort. Ketamine appears to be a safe anesthetic option in children with mild to severe pulmonary hypertension.

Ketamine, supplemented with small doses of midazolam and/or morphine, has been used for interventional cardiac catheterization procedures [83] and for postoperative analgesia after cardiac surgery in children. Hemodynamic stability has been excellent, with few complications. The most notable adverse effect was transient apnea in 10% of spontaneously breathing newborns undergoing balloon atrial septostomy in the catheterization laboratory.

There is limited information regarding the effect of ketamine on electrophysiologic study parameters. Char and colleagues reported on 22 children aged 5–17 years undergoing electrophysiologic study and ablation for SVT who had a baseline propofol infusion for sedation [84]. Dexmedetomidine loading dose 1 μg/kg followed by infusion of 0.7 μg/kg/h was initiated, and electrophysiologic parameters measured. Then, with dexmedetomidine still infusing, a ketamine load of 1 mg/kg followed by infusion of 1 mg/kg/h was given, and parameters again measured. Dexmedetomidine depressed sinus node function (sinus node recovery time), prolonged QT interval, and increased AV node refractory period. All of the abnormal parameters were returned completely or partially to baseline values after ketamine. Atiyeh and colleagues reported on a 21-year-old female undergoing electrophysiologic study for refractory paroxysmal idiopathic ventricular tachycardia (VT) [85]. Maintenance anesthesia consisted of low dose propofol, alfentanil, and sevoflurane, and VT could not be induced despite isoproterenol infusion being increased to 5 μg/kg/min. After initiation of ketamine 15 μg/kg/min, VT could be easily and reproducibly induced, allowing successful mapping and ablation of VT focus.

Intramuscular induction of anesthesia may be achieved with ketamine 5 mg/kg, succinylcholine 4 mg/kg, and atropine 20 μg/kg mixed in the same syringe. This regimen is useful for small patients who present to the operating room without IV access in whom the inhalational

induction of anesthesia may produce undesirable hemodynamic effects. Endotracheal intubation can usually be achieved in 3–5 minutes, and attention can be turned to establishing IV access with the airway secure and a stable hemodynamic state. Ketamine may also be employed as a premedication, with an oral dose of 5–6 mg/kg most commonly administered.

In summary, ketamine is an attractive choice for IV or IM induction of anesthesia in patients with CHD with good or moderately limited hemodynamic reserve, including those with pulmonary hypertension or cyanosis. However, care must be taken in patients with severely limited cardiac reserve and depressed myocardial contractility. Such patients may be chronically receiving ß-adrenergic or similar agents, or their own endogenous sympathomimetic system might be maximally stimulated because of a low CO state. The myocardial depressant properties of ketamine may be unmasked, leading to hemodynamic compromise.

KEY POINTS: KETAMINE

- Ketamine will increase HR and blood pressure and preserve or increase myocardial contractility in patients with good hemodynamic reserve.
- Ketamine may act as a direct myocardial depressant in patients with poor ventricular function in whom myocardial β-adrenergic receptors are downregulated from endogenous or exogenous catecholamines.
- Ketamine is a safe anesthetic in pulmonary hypertension if oxygenation and ventilation are maintained.

Etomidate

Etomidate is an imidazole derivative introduced into clinical practice in 1972. It is thought to produce its hypnotic effects (without analgesia) by interaction with gamma-aminobutyric acid receptors [69]. Besides having a desirable lack of effect on hemodynamics, etomidate reduces cerebral blood flow and cerebral metabolic rate of oxygen consumption (30–50%), and intracranial pressure. It has little effect on ventilation, does not release histamine, and does not change airway smooth muscle tone. Of all of the available IV induction agents, etomidate consistently demonstrates the least direct myocardial depression in several *in vitro* models. Two well-designed studies using adult human atrial and ventricular tissue demonstrated no effect of etomidate on myocardial contractility in concentrations seen in clinical use (Figure 10.8). In the same model, ketamine showed slight, and thiopental strong, negative inotropic effects in clinical concentration ranges. This was true even in abnormal myocardial samples of ventricular tissue taken from hearts removed for cardiac transplantation [56, 86]. In a study of right ventricular tissue excised from infants and children during TOF repair, etomidate did not change contractility in the clinical concentration range in an *in vitro* tissue bath study, but did blunt responsiveness to isoproterenol at high concentrations, raising the possibility that the pediatric myocardium may respond differently after etomidate [87].

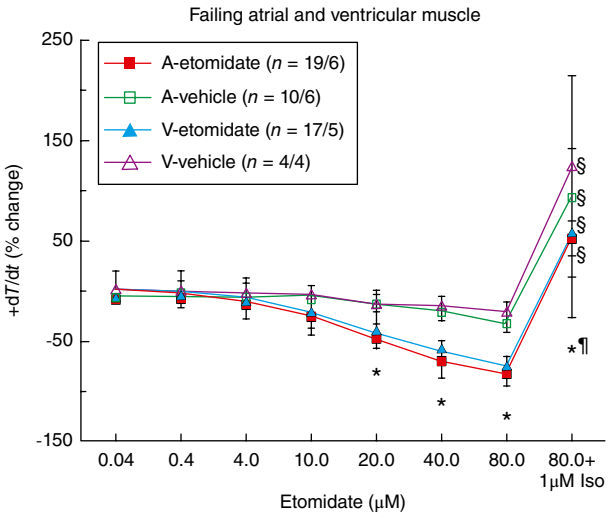

Figure 10.8 Developed tension over time (d*T*/d*t*) in cardiac muscle trabeculae in explanted hearts from adults undergoing cardiac transplantation in response to increasing etomidate concentrations. The upper limit of clinical concentration is 4 μM. A, atrial muscle, V, ventricular muscle; vehicle, 35% propylene glycol, in which etomidate is solubilized. $^{*}P < 0.05$ *versus* A-vehicle control; $^{¶}P < 0.05$ *versus* V-vehicle control, and $^{§}P < 0.05$ *versus* preceding dose. Numbers in parentheses represent numbers of muscle strips/number of patients. Iso, change with addition of 1 μM isoproterenol. (Source: Sprung et al. [86]. Reproduced with permission of Wolters Kluwer Health, Inc.)

These beneficial effects of etomidate are offset by a number of undesirable effects. Etomidate is water-insoluble and is thus formulated in propylene glycol, commonly producing pain on injection, which may be ameliorated by pretreatment with lidocaine and 1 : 1 dilution with sterile water. A new etomidate formulation dissolving the drug in a fat emulsion of medium and long-chain triglycerides virtually eliminates pain on injection in children [88]. Myoclonic movement, hiccoughs, and nausea and vomiting are frequent [69]. It should be noted that, as in adults, a single dose of etomidate used for induction in pediatric patients undergoing cardiac surgery with CPB suppresses the usual increase in plasma cortisol levels by inhibiting 11-ß-hydroxylase, the enzyme that converts 11-deoxycortisol to cortisol [89]. Cortisol levels returned to normal 24 hours later. Two adult studies have reported effects of etomidate induction on 30-day outcomes. Komatsu and colleagues reported on 2,144 ASA III and IV patients given etomidate for induction for non-cardiac surgery, propensity-matched with 5,233 given propofol [90]. Seventy-four percent of patients had cardiovascular disease, and those receiving etomidate had an odds ratio of 2.5 for death and 1.5 for cardiovascular morbidity and a longer hospital stay, but no difference in infectious morbidity or intraoperative vasopressor use. The authors speculate that adrenal suppression could have a bearing on this association. Wagner and colleagues reported a cohort of 3,127 adults undergoing cardiac surgery, 62% of whom received etomidate for induction [91]. No difference in severe hypotension, in-hospital mortality, mechanical ventilation time, or hospital length of stay was demonstrated either before or after propensity score analysis. They conclude that etomidate should remain an acceptable option in these patients.

There are a few published reports of the hemodynamic effects of etomidate in children with CHD. Twenty patients with a variety of congenital defects were studied in the cardiac catheterization laboratory. These authors found that etomidate at 0.3 mg/kg bolus followed by an infusion of 26 μg/kg/min had similar effects as ketamine 4 mg/kg followed by an infusion of 83 μg/kg/min, namely a slight increase in HR but no change in MAP during induction or the 60-minute infusion [92]. Sarkar and colleagues [93] studied etomidate bolus 0.3 mg/kg in 12 children undergoing cardiac catheterization for device closure of ASD, or radiofrequency ablation of atrial arrhythmias. There were no significant changes in any hemodynamic parameter, including HR, MAP, filling pressures, vascular resistances, Qp : Qs, or mixed venous oxygen saturation. Dhawan and colleagues studied 30 children under 12 years old undergoing cardiac catheterization with FiO_2 0.21 and basal sedation with morphine and midazolam, who had direct hemodynamic measurements before and after a 0.3 mg/kg bolus of etomidate [94]. In 15 patients with right-to-left shunt (TOF, VSD/PS, VSD/PA), there was no change in HR, right atrial pressure, MAP, Qp : Qs, or arterial blood gas values. In 15 patients with left-to-right shunts (VSD, ASD, PDA, aortopulmonary window), all of whom had significant baseline pulmonary hypertension, there was also no change in HR, right atrial pressure, mean pulmonary artery pressure (69 mmHg before, 71 mmHg after), Qp : Qs, PVR index (PVRI), or SVR index (SVRI). Dennhardt and colleagues [95] studied 50 neonates and infants (mean age 3.4 months) with congenital heart disease undergoing cardiac surgery, in whom general anesthesia was induced with etomidate. Effects on mean arterial blood pressure, regional cerebral oxygen saturation, and cardiac index were evaluated (Figure 10.9). This patient population exhibited stable systemic and regional cerebral perfusion after a single bolus of 0.4 mg/kg etomidate, leading the authors to conclude that etomidate is a beneficial induction agent in infants with congenital heart disease, or those with expected limited hemodynamic reserve.

A case report of stable hemodynamics in a pediatric patient with end-stage cardiomyopathy receiving a second anesthetic 4 weeks after cardiovascular collapse with ketamine induction (see earlier) demonstrates the utility of etomidate in this population [72]. Etomidate has also been utilized for induction of anesthesia in adults with congenital cardiac conditions such as ruptured aneurysm of the sinus of Valsalva, and cesarean section in a patient with uncorrected coronary artery to pulmonary artery fistula and was demonstrated to be devoid of cardiovascular effects in these patients [96, 97].

It would appear that etomidate is best utilized in patients with the most limited cardiac reserve. It seems to be particularly useful in teenagers or adults with poorly compensated palliated CHD presenting for cardiac transplantation, or revision of previous surgeries. Adrenal suppression occurs with even a single dose of etomidate, and consideration should be given to administer additional supplemental corticosteroids in patients receiving corticosteroids, or at risk of prolonged adrenal suppression. Many patients receiving etomidate for induction will already be receiving corticosteroids as part of their regimen for transplant or cardiac surgery. Repeated or prolonged administration of etomidate is not recommended for this reason.

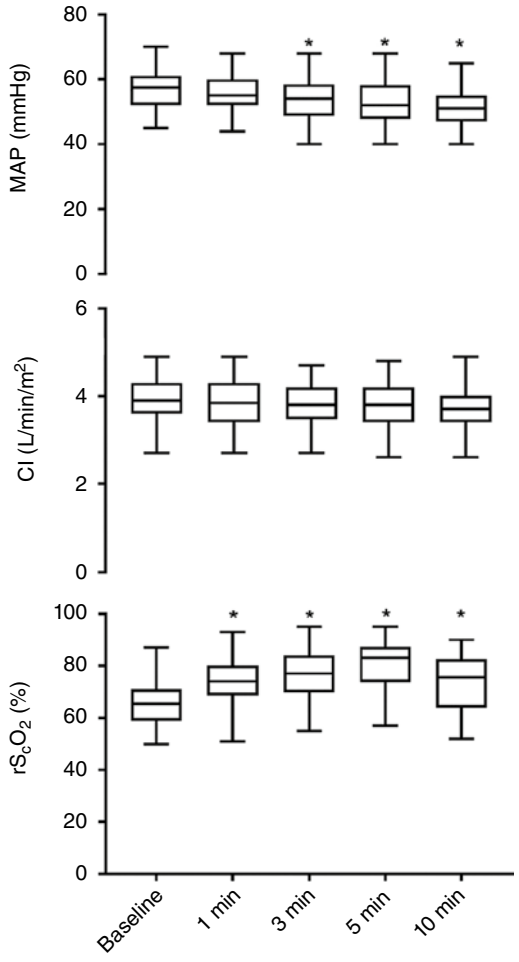

Figure 10.9 Mean arterial blood pressure, cardiac index and regional cerebral oxygen saturation at baseline and 1, 3, 5, and 10 minutes after induction with 0.4 mg/kg etomidate in neonates and infants undergoing cardiac surgery. (Source: Dennhardt et al. [95] / John Wiley & Sons / CC BY 4.0.)

KEY POINTS: ETOMIDATE

- Etomidate has no direct myocardial depressant effect at clinically administered doses, and as such is a preferred induction agent for patients with poor ventricular function.
- Etomidate has no effect on systemic or pulmonary hemodynamics when administered to patients with intracardiac shunting, including those with pulmonary hypertension.
- Etomidate will suppress adrenal function with a single induction dose.

Dexmedetomidine

Dexmedetomidine was introduced in the US in 1999 as a sedative agent for mechanically ventilated adults in intensive care settings. It is an IV agent that is an imidazole

derivative, and a highly selective α_2-adrenergic receptor agonist (1620 : 1 α_2–α_1 activity, vs. 220 : 1 for clonidine). Dexmedetomidine is a centrally acting agent with α_2-receptor binding sites in the locus ceruleus in the brain, producing sedation, and α_2 receptors in the spinal cord, producing some analgesic effect. Dexmedetomidine loading doses, particularly large doses of 0.75–1 µg/kg administered rapidly over <10 minutes, may cause systemic hypertension with binding to peripheral arterial α_2 receptors [98]. With a continuous infusion, dexmedetomidine causes a dose-dependent decrease in HR and MAP by decreasing CNS sympathetic nervous system activity. It also potentiates opioid effects and is thus potentially suitable for use both during and after pediatric cardiac surgery, as a component of a general anesthetic and as a sedative/analgesic agent in the intensive care unit (ICU). The usual dose for sedation is 0.2–0.7 µg/kg/hour; a loading dose of 0.5–1 µg/kg given over 10 minutes can be utilized if desired. It has minimal effect on respiration, and its clearance of 13 mL/kg/min, volume of distribution of 1.0 L/kg, and terminal half-life of 1.8 hours in children without heart disease are similar to adult values [99]. In infants aged 1–24 months receiving dexmedetomidine sedation after congenital heart surgery with bypass, clearance using allometric scaling was 28 mL/kg/min$^{0.75}$, and central volume of distribution was 1.2 L/kg [100]. In both premature infants and full-term neonates <30 days of age undergoing congenital heart surgery, dexmedetomidine clearance is substantially reduced and elimination half-life is substantially increased to as high as 7.6 hours for preterms. Both values assume near-adult levels after about 44 weeks postconceptional age [101, 102].

Because it is an imidazole derivative structurally similar to etomidate, dexmedetomidine theoretically has the potential for adrenal suppression with prolonged use. In 99 pediatric patients undergoing VSD repair, ASD/VSD repair, or Tetralogy of Fallot repair, plasma cortisol concentrations were compared after administration of dexmedetomidine (loading dose of 0.5 µg/kg, followed by infusion of 0.5 µg/kg/hour), etomidate (bolus dose of 0.3 mg/kg), or a control anesthetic. The cortisol level was found to decrease in all patients after induction of anesthesia, and return to baseline within 24 hours, but the degree of decrease at three hours post-induction was more significant in the group that received etomidate, compared to the control, or the group that received dexmedetomidine (Figure 10.10). Any inhibitory function of dexmedetomidine on the adrenal cortex was of weaker efficacy than that of etomidate [103]. Venn and colleagues reported no difference in cortisol, adrenocorticotropic hormone (ACTH), growth hormone, prolactin, insulin, glucose, and interleukin-6 in 20 adult ICU patients randomized to receive propofol or dexmedetomidine [104]. There were also no differences between the groups in response to ACTH stimulation test. However, Tucker and colleagues described a 1-year-old 10 kg burn patient who received high-dose dexmedetomidine infusion for 7 days and developed hypotension with low baseline cortisol levels and inadequate response to ACTH stimulation test, indicating adrenal insufficiency, which they believed was possibly related to dexmedetomidine [105]. No additional published reports exist implicating dexmedetomidine in adrenal suppression.

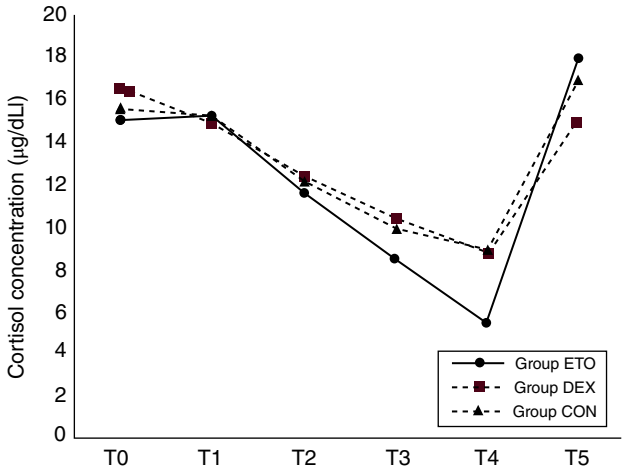

Figure 10.10 Comparison of plasma cortisol concentrations in children with CHD who received etomidate (ETO), dexmedetomidine (DEX) or a control anesthetic (CON). T0, time of intravenous access; T1, immediately after induction; T2, 30 minutes after intubation; T3, after superior and inferior vena cava catheterization; T4, 3 hours after induction; and T5, 24 hours after induction. (Source: Gu et al. [103].)

Dexmedetomidine has been studied as an adjunct agent in general anesthesia for pediatric cardiac surgery. In a study by Muktar and colleagues, dexmedetomidine 0.5 µg/kg load followed by 0.5 µg/kg/h infusion, with an isoflurane–fentanyl–midazolam anesthetic, significantly reduced HR, MAP, cortisol, blood glucose, and serum catecholamine response in children aged 1–6 years undergoing cardiac surgery with CPB, when compared with the baseline anesthetic [106].

Dexmedetomidine has been studied for postoperative sedation after pediatric cardiac surgery. Chrysostomou and colleagues studied 38 pediatric patients of median age 8 years after two-ventricle repair with CPB. Thirty-three of 38 patients had tracheal extubation in the OR. Dexmedetomidine infusion rate varied from 0.1 to 0.75 µg/kg/h (mean 0.3), and the desired sedation was achieved in 93% of patients, and analgesia in 83% of patients. There was no respiratory depression, but hypotension was observed in 15% of patients [107]. Dexmedetomidine has also been described as useful in weaning opioid-tolerant cardiac surgery patients relatively quickly with no hemodynamic side effects [108].

Dexmedetomidine as a sole sedative agent for pediatric cardiac catheterization was studied by Munro and colleagues in 20 children [109]. A loading dose of 1 µg/kg was followed by an infusion of 1 µg/kg/h, and propofol boluses were given for movement or increasing bispectral index value. Sixty percent of patients required propofol boluses. There was a slight decrease in MAP but not in HR, and no patient experienced airway obstruction or respiratory depression. Dexmedetomidine plus ketamine has been compared with dexmedetomidine plus propofol for pediatric cardiac catheterization in 44 patients [110]. There was no difference in sedation scores or respiratory parameters: HR was slower in the dexmedetomidine group, while MAP was not different. Recovery time was significantly longer in the dexmedetomidine group than in the propofol group.

Table 10.2 Electrophysiologic variables at baseline and after a 20-minute infusion of dexmedetomidine

	Baseline	DEX	*P*
Surface ECG intervals			
SCL	606 ± 140 ms	788 ± 165 ms	<0.01
PR	144 ± 19 ms	162 ± 17 ms	<0.01
QRS	76 ± 11 ms	79 ± 13 ms	NS
QTc	394 ± 9 ms	424 ± 9 ms	<0.01
Sinus automaticity			
CSNRT	212 ± 179 ms	293 ± 180 ms	<0.01
Atrial muscle properties			
AERP	207 ± 31 ms	208 ± 17 ms	NS
AV nodal properties			
AH interval	73 ± 14 ms	82 ± 12 ms	<0.01
AVNBCL	352 ± 87 ms	436 ± 105 ms	<0.01

ECG, electrocardiogram; SCL, sinus cycle length; PR, PR interval; QRS, QRS duration; QTC, corrected QT interval; CSNRT, corrected sinus node recovery time; AERP, atrial effective refractory period; AH interval, atrial–His interval; AVNBCL, AV node block cycle length; AVNERP, AV node effective refractory period; VABCL, ventriculoatrial block cycle length; HV interval, His–ventricular interval; VERP, ventricular effective refractory period.

It is important to note that dexmedetomidine frequently causes bradycardia and thus may not be suitable as a sedative for electrophysiologic studies. In 12 children undergoing electrophysiologic studies, Hammer and colleagues found that dexmedetomidine 1 μg/kg load followed by 0.7 μg/kg/h infusion for 20 minutes decreased HR by 15–20%, but more importantly depressed sinus node recovery times, sinus node automaticity, and increased AV nodal block cycle lengths and PR interval [111] (Table 10.2).

In more recent studies, case series reporting dexmedetomidine administration for intraoperative and postoperative use have been described in a variety of congenital and acquired heart diseases, including those with critical heart disease and decreased ventricular function. Klamt and colleagues prospectively randomized 32 children undergoing two-ventricle cardiac repairs to a midazolam–fentanyl anesthetic or a dexmedetomidine–fentanyl anesthetic [112]. Dexmedetomidine was infused at 1.0 μg/kg/h without loading dose for the first hour, and then decreased to 0.5 μg/kg/h, and HR and BP were recorded. Isoflurane was used to supplement the anesthetic and to control hemodynamic variables. HR and BP decreased from baseline in both groups but increased after skin incision only in the midazolam–fentanyl group. Eighty-six percent of the midazolam–fentanyl group required supplemental isoflurane, as compared with 31% of the dexmedetomidine–fentanyl group. In the dexmedetomidine group, two patients required phenylephrine before bypass for hypotension and one required atropine for bradycardia.

In a retrospective review, Lam and colleagues described 50 neonates and infants ≤12 months receiving dexmedetomidine sedation for a median of 78 hours, at doses ranging from 0.1 to 1.5 μg/kg/hour after congenital heart surgery or cardiac transplantation [113]. Despite a significant decrease in HR and MAP as well as central venous pressure after initiation of the dexmedetomidine infusion, inotrope score progressively decreased, and no critical hemodynamic events or bradyarrhythmias were observed that required boluses of IV fluids, adrenergic agents or atropine, or escalation of inotropic support. The authors concluded that dexmedetomidine is safe from a hemodynamic standpoint and can reduce opioid and benzodiazepine dosing. Lam and colleagues also described dexmedetomidine use in 21 infants (median age 3–4.2 months and weight 4.7–6.6 kg) with congestive heart failure as part of a sedation regimen for intensive care and compared safety and efficacy with 23 patients with congestive heart failure who were sedated without dexmedetomidine [114]. All patients were awaiting orthotopic heart transplantation and were studied in the 18 days before transplant; 75% had dilated cardiomyopathy and all but one was receiving mechanical ventilation. Mean arterial pressures were lower in the first 24 hours in the dexmedetomidine group, and HR was lower in the dexmedetomidine group in the first 6 hours. Three patients in the dexmedetomidine group (14%) had greater than a 50% decrease in MAP in the first 3 hours after initiation of dexmedetomidine infusion at 0.5–0.6 μg/kg/hour; one of the three also had bradycardia to 48 beats/min. Opioid and benzodiazepine doses were significantly lower in children receiving dexmedetomidine. The authors concluded that dexmedetomidine administration in infants with heart failure appears to be generally safe, but should be used cautiously.

Su and colleagues studied dose–response of dexmedetomidine as a primary sedative in a dose-escalation study of 36 infants aged 1–24 months after cardiac surgery, with loading dose and infusion rates spanning the range of doses used clinically [115]. Heart rates for the entire group decreased from a mean of 161 beats/min at baseline to a mean of 132 beats/min during dexmedetomidine infusion ($P < 0.0001$). The decrease in HR was dose- and plasma level-dependent with larger decreases in higher-dose groups. MAP and inotrope infusion scores did not change significantly during infusion. A single patient in the intermediate dosing cohort experienced intermittent complete heart block 5 hours after dexmedetomidine infusion initiation, resulting in bradycardia, which did not recur following discontinuation. A more recent study by this same group extended the study population to include 23 neonates with CHD after cardiac surgery [116]. Three neonatal patients developed bradyarrhythmias, one developed junctional rhythm, and one developed atrial ectopy. All patients required discontinuation of the dexmedetomidine infusion. One neonatal patient developed hemodynamically significant atrial ectopy, requiring CPR and extracorporeal membrane oxygenation. Their data suggests the need for dexmedetomidine dose reduction in neonates due to decreased clearance, with the greatest reduction required in the first 2 weeks of life.

Dexmedetomidine is often cited as facilitating early tracheal extubation because of its minimal effects on respiration and ability to reduce opioid doses. Le and colleagues

AL Grawany

reported a retrospective review of 269 patients undergoing cardiac surgery, 89 of whom received dexmedetomidine for postoperative sedation, and 180 matched controls from the year before introduction of dexmedetomidine to their institution [117]. There were no differences in any ventilation parameter: 42% of both groups had tracheal extubation in the OR; 75% of controls and 76% of dexmedetomidine patients were extubated in the first 24 hours, and the mean ventilator time was 29 hours in the control group and 35 hours in the dexmedetomidine group ($P = 0.17$), with no differences in patients <12 months. The authors concluded that dexmedetomidine did not have a significant impact on early extubation.

The effect of dexmedetomidine on pulmonary artery pressure and resistance has been reported in several studies. Lazol and colleagues studied 22 patients (median age 11 months) after reparative two-ventricle cardiac surgery, who received a dexmedetomidine loading dose (median 0.62 μg/kg) and infusion (median 0.5–0.65 μg/kg/h) and had echocardiographic estimation of pulmonary artery pressure using tricuspid regurgitation jet velocity [118]. Median pulmonary artery systolic pressure decreased from 30 mmHg before dexmedetomidine to 24 mmHg at 6 minutes after the loading dose, and 26 mmHg at 1 hour ($P < 0.001$). The ratio of pulmonary to systemic systolic pressure decreased from 33 to 25% ($P = 0.002$). There were no changes in inotropic infusions or left ventricular contractility. Friesen and colleagues studied 42 patients undergoing cardiac catheterization: 21 for routine post-transplant surveillance, and 21 for pulmonary hypertension studies [119]. After sevoflurane induction, endotracheal anesthesia was maintained with midazolam and remifentanil, and the response to dexmedetomidine loading doses of 0.5, 0.75, or 1.0 μg/kg over 10 minutes was measured. Most hemodynamic responses were similar in both groups, with a significant decrease in HR and an increase in SVRI. Cardiac index did not change. There was a small, statistically significant increase in pulmonary artery pressure in transplant patients, but not in those with pulmonary hypertension. Changes in PVRI and PVRI/SVRI were not significant in either group. Kanchi and colleagues [120] studied 25 children with known pulmonary hypertension undergoing elective cardiac catheterization/intervention with monitored anesthesia care. After sedation with midazolam and ketamine boluses, a bolus dose of 1 μg/kg dexmedetomidine was given over 10 minutes, followed by an infusion at 0.3 μg/kg/h until the end of the procedure. No significant change in mean pulmonary artery pressures was measured throughout the catheterizations. The authors concluded that dexmedetomidine can be used safely in patients with PAH undergoing cardiac catheterizations with the use of spontaneous ventilation.

Dexmedetomidine has been demonstrated in several case series to decrease the incidence of postoperative ventricular and supraventricular tachydysrhythmias in infants and children after congenital heart surgery with bypass [121]. The use of prophylactic dexmedetomidine to prevent postoperative junctional ectopic tachycardia in children after repair of congenital heart diseases has been described. In a prospective randomized study, El Amrousy and colleagues [122] studied 90 children with CHD undergoing cardiac surgery. 60 patients received dexmedetomidine (0.5 μg/kg loading dose completed 10 minutes prior to induction, with 0.5 μg/kg/h infusion continued for 48 hours postoperatively), and 30 patients received saline placebo. The incidence of JET was significantly reduced in the dexmedetomidine group (16.7% in placebo group vs. 3.3% in dexmedetomidine group; $P = 0.02$). Gautam and colleagues [123] studied 134 pediatric patients undergoing surgeries involving closure of a VSD (TOF repair, VSD patch closure, AVSD repair). 99 patients were exposed to dexmedetomidine either intraoperatively prior to incision, intraoperatively after weaning from bypass, or on arrival to the ICU. After multivariate analysis, the intraoperative pre-CPB initiation of dexmedetomidine was significantly associated with a greater reduction in JET (odds ratio 0.04; $P = 0.006$), compared to intraoperative post-CPB initiation (odds ratio 0.16; $P = 0.024$) and postoperative initiation (odds ratio 0.50; $P = 0.365$).

Dexmedetomidine is a potentially useful agent as an adjunct to general anesthesia, a postoperative sedative, and an adjunct sedative for cardiac catheterization (non-electrophysiologic studies) in pediatric patients with CHD. The patient must be able to tolerate the predictable decrease in HR, and frequent decrease in MAP associated with dexmedetomidine infusion. Clearance of dexmedetomidine is reduced in neonates, necessitating lower doses in this age group and heightened monitoring for side-effects.

KEY POINTS: DEXMEDETOMIDINE

- Dexmedetomidine allows for reduction of doses of opioids and benzodiazepines and may be a useful adjunct to intraoperative general anesthesia, and as a component of postoperative sedation regimens.
- Dexmedetomidine boluses in larger doses result in hypertension; side-effects of infusions include hypotension and bradycardia.
- Dexmedetomidine affects cardiac conduction and may suppress supraventricular and ventricular arrhythmias, but sinus and junctional bradycardia and sinus arrest are unusual but potentially serious side-effects.

The major hemodynamic and cardiac rhythm effects of the anesthetics, sedatives, and analgesics discussed in preceding sections are presented in Table 10.3.

Neuromuscular blocking agents and antagonists

Succinylcholine

Succinylcholine is rarely indicated for anesthesia for CHD because of its association with the development of malignant hyperthermia, hyperkalemic cardiac arrest, and bradycardia after IV bolus administration. Succinylcholine will produce a more rapid onset of muscle relaxation than non-depolarizing muscle relaxants [124] and generally its use is limited to full-stomach emergency indications, i.e., cardiac transplant, treatment of laryngospasm, and as a component of an intramuscular induction.

Table 10.3 Major hemodynamic and cardiac conduction effects of anesthetic, analgesic, and sedative agents

Drug class	Drug	Cardiovascular effects						Comments
		Heart rate	Cardiac rhythm	MAP/SVR	PAP/PVR	Myocardial contractility	Cardiac output	
Volatile anesthetics	Halothane	– – –	Ventricular extrasystoles, sinus/junctional bradycardia	– – –	– –	– – –	– – –	Contraindicated with decreased ventricular function
	Sevoflurane	–/+	Junctional bradycardia	–/NC	–	–	–/NC	
	Isoflurane	++	NC	– –	–	–/NC	NC	Preserves myocardial contractility to 1.5 MAC in CHD
	Desflurane	+++	NC/sinus tachycardia	–	–	–/NC	NC	
Nitrous oxide	Nitrous oxide	–	NC	–	NC	NC	–	
Benzodiazepines	Midazolam	–/NC	NC	–	NC	–/NC	–/NC	
Synthetic opioids	Fentanyl, sufentanil, remifentanil	– –	Sinus bradycardia	–/NC	– –	NC	–/NC	Preferred for prevention/treatment of pulmonary hypertension
Alkylphenol derivative	Propofol	–	Sinus bradycardia	– – –	NC	–	– –	Decreases preload; avoid in preload/afterload dependent patients
Imidazole derivative	Etomidate	NC	NC	NC	NC	NC	NC	Adrenal suppression
Arylcyclohexylamine	Ketamine	+++	NC/sinus tachycardia	++	NC	NC/–	+/–	Direct myocardial depressant in heart failure
α_2 agonist, imidazole derivative	Dexmedetomidine	– – –	Sinus/junctional bradycardia, heart block, asystole	++ with bolus; – – – with infusion	++ with bolus; – – – with infusion	NC	NC/–	Delayed clearance and longer half-life in neonates; bradyarrhythmias are a major adverse effect

α_2, alpha-2-adrenergic receptor; CHD, congenital heart disease; MAC, minimum alveolar concentration; MAP, mean arterial pressure; NC, no change; PAP, pulmonary artery pressure; SVR, systemic vascular resistance; +, small increase; ++, moderate increase; +++, large increase; –, small decrease; – –, moderate decrease; – – –, large decrease.

AL Grawany

Infants and children frequently exhibit bradycardia, junctional rhythm, ventricular premature beats and, rarely, asystole, after IV dosing of succinylcholine 1–2 mg/kg without atropine pretreatment. The frequency of these arrhythmias increases with a second dose. A dose of 4 mg/kg given IM, either alone, or with atropine 20 μg/kg and ketamine 5–10 mg/kg in the same syringe rarely causes bradycardia [125].

Pancuronium

Pancuronium is used in doses of 0.1–0.3 mg/kg for initial relaxation [126] and is particularly desirable in many small infants and young children with CHD because of the vagolytic and mild sympathomimetic effects, which preserve or increase HR, especially in the face of concomitant bradycardia from high-dose opioid anesthesia. In recent years, this drug has become unavailable in many parts of the world.

Vecuronium

Vecuronium is devoid of cardiovascular effects in children [127]. It is a useful agent when increases in HR are undesirable (e.g. in hypertrophic cardiomyopathy). When no uncertainties about the ability to manage the airway are evident, it is a useful alternative to succinylcholine in a dose of 0.3–0.4 mg/kg for modified rapid sequence induction.

Rocuronium

Rocuronium is a moderately rapid-onset, intermediate-duration, non-depolarizing neuromuscular blocker that is useful at a dose of 0.6–1.2 mg/kg IV. At the upper dose ranges it is an acceptable substitute for succinylcholine for modified rapid sequence induction. Cardiovascular effects are minimal, but because it causes pain on injection, or because it is a weak vagolytic medication, an increase in HR is often observed after injection. This agent may be utilized for IM administration in doses of 1.8–2 mg/kg, and when injected into the deltoid muscle will produce suitable intubating conditions in 3–4 minutes [128].

Atracurium and cisatracurium

Atracurium and cisatracurium are non-organ-dependent for elimination and are attractive choices in the face of significant hepatic and renal dysfunction. Atracurium at high dosages frequently causes histamine release, resulting in hypotension when injected rapidly [124], making it undesirable for many patients with CHD. Cisatracurium is a stereoisomer of atracurium, also degraded by Hoffmann elimination, does not release histamine, and like vecuronium is devoid of cardiovascular effects, even when administered rapidly [129].

Antagonists

The muscarinic effects of neostigmine must be blocked by atropine or glycopyrrolate to prevent potentially serious decreases in HR. Because the onset of cardiovascular effects of neostigmine and glycopyrrolate are similar, a useful regimen is to utilize neostigmine and glycopyrrolate in the same syringe in a 5 : 1 ratio of neostigmine: glycopyrrolate (i.e., 75 : 15 μg/kg) injected slowly to minimize the small risk of arrhythmia with neostigmine. Despite longstanding use of neostigmine for reversal of neuromuscular blockade, it may cause bradycardia or cardiac arrest, even if administered with appropriate anticholinergic agents. Sawasdiwipachai and colleagues reported on a case of a 1–year-old who suffered a cardiac arrest 2 weeks after a heart transplant, after a myocardial biopsy, and reversal of cisatracurium neuromuscular blockade with 70 μg/kg neostigmine and glycopyrrolate 14 μg/kg [130]. Acute cardiac rejection and an abnormal conduction system were postulated as causes in this infant, with direct effect on the muscarinic receptors playing a role. Two additional cases of cardiac arrest in children with transplanted hearts have also been reported [131]. The authors suggest preadministration of glycopyrrolate to avoid effects related to the muscarinic receptor, and consideration of sugammadex as an alternative with no effect on acetylcholine receptors, as reversal strategies in patients with transplanted hearts.

Sugammadex is a synthetic modified γ-cyclodextrin used for reversal of steroidal neuromuscular blockade. It forms tight 1 : 1 water-soluble complexes with free steroidal neuromuscular blocking drug, leading to rapid removal of the drug from the plasma. The effect of the neuromuscular blockade is terminated by rapid diffusion of the drug away from the neuromuscular junction, rather than competitive inhibition at the acetylcholine receptor. Thus, sugammadex is devoid of muscarinic effects [132]. It was approved for use in adults in 2015, and its use is steadily increasing in the pediatric population.

Sugammadex has been reported to prolong QTc interval in some adult patients [133]. De Kam and colleagues administered sugammadex to 80 healthy adult volunteers in a randomized, double-blind, placebo-controlled study designed to assess its effect on QTc intervals [134]. Sugammadex doses up to 32 mg/kg were studied, with either rocuronium 1.2 mg/kg or vecuronium 0.1 mg/kg, and an active control drug known to prolong QTc intervals. No effect was detected on the QTc intervals up to 24 hours after administration of sugammadex. Cammu and colleagues studied 12 adult patients with heart failure and EF < 25% undergoing general anesthesia with rocuronium neuromuscular blockade, and reversal with sugammadex 2 mg/kg [135]. Blood pressure and HR did not change for the first 10 minutes after administration, and both had increased by 30 minutes. Reversal of neuromuscular blockade was effective in all patients but, at 2.8 minutes, the mean time to reversal was longer than observed in healthy patients. No sugammadex-related adverse events were reported.

Recent studies have investigated the hemodynamic effects of sugammadex in pediatric patients. In a prospective randomized clinical study, Li and colleagues [136] compared the use of sugammadex (4 mg/kg) and neostigmine (30 μg/kg) with atropine (15 μg/kg) for reversal of neuromuscular blockade in 60 children aged 1–6 years old undergoing ASD or VSD repairs. Patients administered sugammadex had a significantly higher heart rate after drug administration (103 vs. 97 bpm; $P = 0.03$). The mean arterial pressure after drug administration was found to be similar in both groups. The authors conclude that sugammadex demonstrates superiority in maintenance of heart rate in children undergoing cardiac surgery. Alsuhebani and colleagues [137] studied the incidence of bradycardia (HR below fifth percentile for age) after sugammadex administration in 221 children (median age 8 years; median weight 28 kg). The median sugammadex dose

was 2 mg/kg (range 2–15.7 mg/kg). Bradycardia was seen in 18 patients (8%) at a median of 2 minutes after sugammadex administration, with no association between the dose administered and the incidence of bradycardia. Notably, 38% of the patients who developed bradycardia had comorbid cardiac conditions, with multivariate logistic regression showing that bradycardia risk after sugammadex administration was increased for patients with cardiac comorbidities (odds ratio 3.8; $P = 0.015$). However, no instances of bradycardia in this patient cohort were hemodynamically significant, and no treatment or intervention was necessary. These authors conclude that the use of sugammadex is safe in pediatric patients. To date, no physiologic mechanism has been described for the development of bradycardia in association with the administration of sugammadex.

KEY POINTS: NEUROMUSCULAR BLOCKING AGENTS AND ANTAGONISTS

- Succinylcholine may cause bradycardia, junctional rhythm, ventricular premature beats, and asystole in patients with CHD.
- Vecuronium, rocuronium, and cisatracurium are generally devoid of cardiovascular effects.
- Neostigmine may cause bradycardia or sinus arrest; adequate doses of anticholinergic agents must be administered concomitantly.
- Sugammadex is a novel reversal agent for neuromuscular blockade with a mechanism of action that avoids muscarinic side effects.

Special conditions affecting anesthetic pharmacokinetics and pharmacodynamics in congenital cardiac anesthesia

Intracardiac shunts

The presence of a right-to-left intracardiac shunt decreases the rate of rise of the concentration of inhaled anesthetic in the arterial blood, as a portion of the systemic CO bypasses the lungs and then dilutes the anesthetic concentration in the systemic arterial blood [138]. The anesthetic concentration in the blood thus never equals the exhaled concentration. Huntington and colleagues [138] studied six children with right-to-left shunts from a fenestrated Fontan operation whose average pulmonary to systemic blood flow ratio was 0.58. These patients achieved an arterial anesthetic concentration (Fa) of only 55% of inspired halothane concentration (Fi) after 15 minutes during wash-in of 0.8% halothane. After closure of the right-to-left shunt (occlusion of Fontan fenestration in the cardiac catheterization laboratory), the arterial concentration of halothane was equal to the inspired concentration. This difference between Fa and Fi is greater during induction or washout, and greater with less soluble drugs, such as sevoflurane, desflurane, and N_2O, than with more soluble drugs, such as halothane. Conversely, if the blood concentration of a volatile agent is high, the rate of decrease during washout is slowed with right-to-left shunting. This is an important consideration if myocardial depression occurs. The usual approach to reduce or discontinue the volatile agent and increase minute ventilation is often ineffective in this situation.

Other studies have demonstrated a delay in inhalational induction time in patients with right-to-left intracardiac shunting. Zeyneloglu and colleagues [139] investigated the induction characteristics of sevoflurane in 62 children undergoing open-heart surgery. Thirty-two patients had acyanotic heart disease, and 30 patients had cyanotic heart disease with right-to-left intracardiac shunting on preoperative cardiac catheterization. The duration to loss of eyelash reflex was found to be longer in the cyanotic group, as compared to the acyanotic group (56 vs. 45 seconds, $P = 0.044$). Similarly, Hasija and colleagues [140] studied 93 pediatric patients undergoing elective cardiac or noncardiac surgery under general anesthesia induced with sevoflurane. The time to induction (determined by loss of eyelash reflex and BIS <60) was significantly longer in the cyanotic children with right-to-left shunt undergoing cardiac surgery, with an almost two times delay, compared to the time to induction for patients with acyanotic CHD, or without CHD.

In the face of significant right-to-left intracardiac shunting, IV agents given by bolus may pass directly into the left side of the heart with less dilution by systemic venous blood and passage through the pulmonary vascular system. This may result in transiently high arterial, brain, and cardiac concentrations of drugs such as lidocaine [141]. Intravenous induction agents and muscle relaxants may also achieve sufficient arterial and brain concentrations more rapidly with right-to-left intracardiac shunts [142].

Left-to-right intracardiac shunts have little effect on the speed of induction with inhaled anesthetic agents [143]. The recirculation of blood through the lungs results in increased uptake of anesthetic and in a higher blood anesthetic concentration in the pulmonary capillaries, which reduces the concentration gradient between the alveoli and the pulmonary capillary blood, reducing anesthetic uptake. The two effects cancel each other. Only in the case of severe congestive heart failure from left-to-right shunt, with significant interstitial and alveolar edema, would left-to-right intracardiac shunting be expected to slow inhalation induction from the combined effects of diffusion limitation and ventilation–perfusion mismatch, resulting in alveolar dead-space ventilation in which no new anesthetic agent is taken up.

Cardiopulmonary bypass

The onset of CPB affects plasma levels of IV drugs by a number of different mechanisms [144]. Hemodilution of the patient's blood volume by a factor of 50–300%, depending on the size of the patient and the priming volume of the circuit, causes an immediate reduction in plasma levels. Many drugs also bind to the membrane oxygenator and other components of the bypass circuit, resulting in a further decrease in plasma levels. This effect is variable and is dependent on the drug, its size and lipid solubility (octanol: water partition coefficient), the type of bypass circuit used (i.e. silicone vs. polypropylene), the age and size of the patient, and the

plasma and bypass prime albumin concentrations. Hypothermia slows the metabolism of all drugs by reducing the rate of reaction of all enzymes involved in drug metabolism, whether they are in the liver (cytochrome P450 system), kidney, or plasma. Rewarming significantly increases the rate of metabolism of IV agents.

A constant, stable plasma fentanyl level [145] can be achieved in most children through the administration of a loading dose of 30–50 μg/kg followed by an infusion of 0.15–0.3 μg/kg/min. Plasma fentanyl levels decrease by 70–75% immediately upon institution of CPB with a silicone membrane oxygenator, presumably due to binding of the drug to oxygenator and bypass tubing. After cooling to 18–25 °C, fentanyl metabolism decreases considerably and free drug concentrations change very little, even without added drug [146]. Metabolism then increases and drug levels decline in the plasma as rewarming proceeds. Data concerning common anesthetic adjuvants such as midazolam suggest similar changes in plasma concentrations [144]. Thus, without supplementation of IV agents such as fentanyl and midazolam, either just before or at the initiation of bypass, plasma levels of IV anesthetics will decline significantly and there is an increased risk of inadequate anesthesia. A similar risk would appear to be true during the final phases of the rewarming period. Indeed, this concept is borne out by studies using bispectral index as an indicator of depth of sedation in children undergoing bypass with mild hypothermia [147]. Modified ultrafiltration has been reported to double the plasma fentanyl concentrations in a study of five neonates and infants, from 12.4 to 27.5 ng/mL, presumably due to hemoconcentration [148].

Volatile agents may be used during bypass to supplement anesthetic depth, or as vasodilators. Isoflurane is most commonly utilized at a concentration of 0.5–2% inspired into the sweep gas of the bypass circuit. Multiple adult studies have demonstrated the effectiveness and relatively rapid wash-in of this agent [144]. The blood levels of isoflurane are highly dependent on the type of oxygenator used. Wiesenack and colleagues reported on isoflurane blood and oxygenator concentrations in 24 adults undergoing elective coronary bypass surgery [149] (Figure 10.11). Isoflurane (1%) was added to the CPB sweep gas, at 3 L/min flows for 15 minutes, and isoflurane concentrations were measured in the blood, and at the oxygenator gas outflow port. Microporous polypropylene (PPL) hollow-fiber membrane oxygenators were compared with plasma-tight poly-(4-methyl-1-pentene) (PMP) membrane oxygenators, and dramatic differences were found. The PPL oxygenator had an area under the curve of blood level of isoflurane 8.5- to 13-fold higher than PMP oxygenators, with almost no blood transfer of isoflurane with PMP models. Isoflurane concentration was also significantly lower at the oxygenator exhaust port with the PMP models, reaching only 60% of inspired levels at 15 minutes, whereas with the PPL models exhaled isoflurane was equal to inspired after less than 5 minutes.

Most CPB oxygenators in clinical pediatric use are PPL models. Pediatric *in vitro* or *in vivo* data have not been published, and because sweep gas flow rates are often less than 1 L/min in small infants, volatile anesthetic uptake is probably much slower. It cannot be assumed that the desired blood anesthetic level is rapidly reached when volatile anesthetic agents are administered through the bypass circuit to infants and small children. In this study, blood levels were continuing to increase after 15 minutes. Washout of volatile agents is also slower at low sweep gas rates, and volatile agents should be discontinued early during the rewarming period to avoid the potential myocardial depressant effects of these agents while attempting to wean the patient from bypass.

Dexmedetomidine use during CPB in pediatric cardiac surgery has been increasing. In a recent phase 1 multicenter study, Zuppa and colleagues [150] investigated the safety and pharmacokinetic properties of dexmedetomidine in 122 neonates and infants aged 0–180 days undergoing repair of ventricular septal defects, D-transposition of the great arteries, or tetralogy of Fallot. Dexmedetomidine clearance during CPB was reduced by 95%, and clearance in the immediate postoperative period was reduced by 50%. Neonates achieved 90% of maximum clearance by 18 days, consistent with other published studies. There were five safety events occurring in the infant cohort: two episodes of junctional rhythm, two episodes of second- or third-degree heart block, and one episode of hypotension. The arrhythmias required temporary atrial or atrioventricular pacing for 30 minutes up to 48 hours. These authors introduce an externally validated pharmacokinetic model in order to achieve low, medium and high steady-state plasma dexmedetomidine concentrations on CPB (Figure 10.12). Using this group's data, Hammer and Shafer [151] constructed an accessible simulation program with dexmedetomidine dosing guidelines during CPB (https://steveshafer.shinyapps.io/stanpumpR_HelpPage/, under "Dexmedetomidine BJA 2020"). With carefully designed dosing strategies, dexmedetomidine is a safe addition to the anesthetic regimen for neonates and infants undergoing cardiac surgery with CPB.

Neuromuscular blocking agents have an enhanced effect during hypothermic bypass, [144] both from decreased metabolism and clearance, and because of the effects of hypothermia to potentiate the pharmacodynamic effects of the drugs at the neuromuscular junction. These effects rapidly reverse themselves during rewarming. These drugs have a small volume of distribution and thus few tissue stores from which to re-equilibrate plasma levels. Thus, plasma levels would be expected to decline in proportion to the hemodilution factor of the pump prime, subject to changes in protein binding. This may be offset by reductions in the patient's plasma volume on bypass due to vasoconstriction. The action of these drugs in response to bypass is accordingly more variable than other commonly used IV anesthetic agents. There is limited pediatric information available. Monitoring of neuromuscular blockade with a twitch monitor is recommended if early reversal is desired.

Hypothermia

Studies performed on animal models reveal hypothermia reduces the MAC of volatile anesthetics [152]. Liu and colleagues [153] studied the MAC of isoflurane in 33 children with left-to-right intracardiac shunts at 37, 34, or 31 °C. They found that MAC was reduced by 28% at 31 °C when compared with normothermia, indicating a decrease in MAC of approximately 5%/°C cooling. The bispectral index value correlates strongly with temperature during mild hypothermic

bypass in children [154], offering supporting evidence that hypothermia alone provides general anesthesia.

KEY POINTS: SPECIAL CONDITIONS AFFECTING ANESTHETICS

- Right-to-left intracardiac shunting slows volatile anesthetic uptake and washout; the greatest effect is in less soluble agents such as sevoflurane and desflurane, while the effect is smaller with the more soluble agents, such as halothane.
- CPB has highly variable effects on anesthetic drug pharmacokinetics and pharmacodynamics, depending on the type of oxygenator, flows, temperatures, and ultrafiltration.
- Hypothermia significantly decreases anesthetic requirements by lowering MAC and slowing metabolism of IV drugs.

Selection of anesthetic regimen in CHD

Pediatric patients with congenital and acquired heart disease are known to be at significantly higher risk for cardiac arrest and death, and other major complications of anesthesia. The four highest risk groups appear to be patients with supra-systemic pulmonary hypertension, severe left ventricular outflow tract obstruction, severe ventricular dysfunction, and infants with single ventricle physiology prior to cavopulmonary anastomosis [9, 27, 28, 155–160]. The incidence of cardiac arrest related to anesthesia is reported to be 0.7–6% in these patient groups, and anesthetic agent selection plays a role in at least some of these adverse outcomes.

The ideal anesthetic regimen for CHD would be devoid of any undesirable hemodynamic effects, would produce analgesia, amnesia, and muscle relaxation, and would be rapidly titratable. Hemodynamic perturbations would be controlled with vasoactive and inotropic agents alone, also rapidly titratable, achieving a desirable separation of anesthetic and hemodynamic effects for the two classes of drugs. The ideal regimen does not exist, and the pediatric cardiac anesthesiologist is left with devising an individualized strategy for each patient, accounting for pathophysiology and desired hemodynamic goals in each patient. Hemodynamic effects are continuously monitored, doses of different drugs are often titrated independently and at frequent intervals, and the anesthesiologist must sometimes change strategies. Vasoactive and inotropic agents must sometimes be added to counteract the untoward effects of a chosen anesthetic regimen.

The ideal anesthetic plan would involve thorough review of all data, including echocardiography and other imaging, careful examination of the patient, and the construction of a set of hemodynamic goals, which also consider the duration and invasiveness of the planned surgery, intervention, or diagnostic study. The well-known difficulties in approaching infants and young children with stranger anxiety and without IV access must frequently be taken into account. Then, an intelligent anesthetic regimen is selected which is likely to achieve the desired goals based on the known cardiovascular effects of the drugs as presented in this chapter. For example, the patient with severe left ventricular outflow tract obstruction has a stroke volume that depends on maintaining adequate preload and afterload. Important hemodynamic goals include avoiding tachycardia and increases in myocardial contractility, and regimens that include large doses of propofol or volatile agents are contraindicated. Patients with dilated cardiomyopathy and decreased ventricular function similarly should not receive agents in doses that further depress myocardial contractility or significantly alter preload or afterload. Patients with significant pulmonary hypertension should have a regimen that avoids large increases in catecholamine secretion from noxious stimuli that could precipitate a pulmonary hypertensive crisis. Chapter 21 discusses hemodynamic management, and Chapters 26–32 present the pathophysiology and anesthetic considerations for each of the major congenital cardiac lesions in detail.

A single-center retrospective chart review of choice of induction techniques for general anesthesia in children with CHD undergoing non-cardiac procedures showed that children of American Society of Anesthesiologists (ASA) three physical status and above and those with CHD of greater severity (based on residual lesion burden and functional status) tend to be induced with etomidate, ketamine, and opioids [161]. However, to date, there have been few, if any, controlled studies of anesthetic regimens and cardiovascular outcomes in CHD. No agent or regimen is proscribed for any particular cardiac lesion, and there are many different approaches for each lesion among experienced pediatric cardiovascular anesthesiologists. Careful consideration of the cardiovascular effects of the drugs and the patient's pathophysiology and desired hemodynamic goals should allow the pediatric cardiac anesthesiologist to devise a safe and effective anesthetic plan for patients with CHD.

KEY POINTS: ANESTHETIC REGIMEN SELECTION

- Review all data carefully and construct a set of desired hemodynamic goals for each patient considering their unique pathophysiology.
- Design an anesthetic drug strategy that is likely to achieve the optimal hemodynamic state.
- Carefully monitor and titrate anesthetic drugs and prepare to change strategies if hemodynamic goals are not achieved.

Introduction

On May 6, 1953, John H. Gibbon, Jr. successfully performed, for the first time, open-heart surgery using cardiopulmonary bypass (CPB) for the closure of a large atrial septal defect. The heart-lung machine, consisting of a simple oxygenator in conjunction with roller pumps, took over the function of the heart and lungs for a duration of 26 minutes. The machine worked properly during the total bypass time of 45 minutes, apart from some fibrin formation on the oxygenator due to inadequate anticoagulation [1]. Gibbon's success stood at the end of approximately 20 years of developing a heart-lung machine. In a 1937 publication, Gibbon published his first results of an experimental CPB in cats. In 1939, the former president of the American Association of Thoracic Surgeons, Leo Eloesser, said during a discussion following a lecture by Gibbon that his presentation reminded him of the seemingly impossible, fantastic stories of the novel writer, Jules Verne, that later often became reality [2]. In a series of 19 consecutive bypass uses in dogs, 12 of the animals survived. But the idea of perfusion with artificially produced circulating arterial blood did not originate with Gibbon. The idea was first documented in 1812, inspired by the French physiologist, César Julien-Jean Le Gallois. In his monograph "Expériences sur le principe de la vie" he described experiments to define the relationship of the respiratory and nervous system, and blood circulation. On August 9, 1951, in Turin, Dogliotti and Constantini used a partial bypass on humans for the first time [3]. When a patient whose condition during the surgical removal of a large mediastinal tumor drastically deteriorated, a heart-lung machine was used to maintain perfusion for 20 minutes and the patient was stabilized. On March 16, 1943, Willem Johan Kolff observed, during the clinical use of an artificial dialyzer, that oxygen was quickly absorbed by a cellulose membrane. This observation was the basis for the development of membrane oxygenators. Later Kolff presented the design of the first membrane oxygenator at the first Congress of the American Society for Artificial Internal Organs on June 5, 1955 [4]. Also in the 1950s, Arthur Keats, Denton Cooley and colleagues at Texas Children's Hospital pioneered several important breakthroughs in congenital cardiac surgery with bypass, including, in 1959, the first description of heparin–protamine titration [5]. In a seminal 1958 article, they described anesthetic problems in their first 200 cases of congenital heart surgery with bypass, which included

bypass times; changes in blood gases, electrolytes, and lactate; cardiac rhythm disturbances; and blood transfusions [6]. The first commercial oxygenators became available in the 1960s and the number of open cardiac surgery procedures increased rapidly at that point. Subsequent attempts to use the heart-lung machine to help correct complex congenital heart defects in small infants were hindered by high morbidity and mortality rates until Barratt-Boyes and Castaneda started using deep hypothermic circulatory arrest in the late 1960s and early 1970s. Less than two decades later, pediatric cardiac surgery and anesthesia had progressed to providing multistage palliation for infants with single-ventricle physiology. Today CPB is a standard feature of daily pediatric cardiac anesthesia practice. Advances in neonatal CPB techniques over the last 60 years have been among the most important factors leading to improved outcomes in pediatric cardiac surgery. Extracorporeal perfusion in newborns, infants, and children is in many aspects different from the adult patient. This is caused by the underlying physiologic changes as well as the different pathophysiology secondary to shunt physiology.

In this chapter, we review the equipment and techniques used in CPB, with a primary focus on neonatal and pediatric bypass. We will also summarize the effects of CPB on different organ systems. Extensive reviews on the multiorgan effects of congenital cardiac surgery are presented in Chapter 12, and neurological monitoring and outcomes in Chapter 14. In this chapter, we emphasize specific management issues that occur in daily practice. Further details on specific technical issues can be found in excellent extensive textbooks on the topic [7].

Basic bypass circuit setup

A basic bypass circuit (Figure 11.1) consists of a venous reservoir, an oxygenator/heat exchanger unit, roller pumps for perfusion, suction, and cardioplegia and the connecting

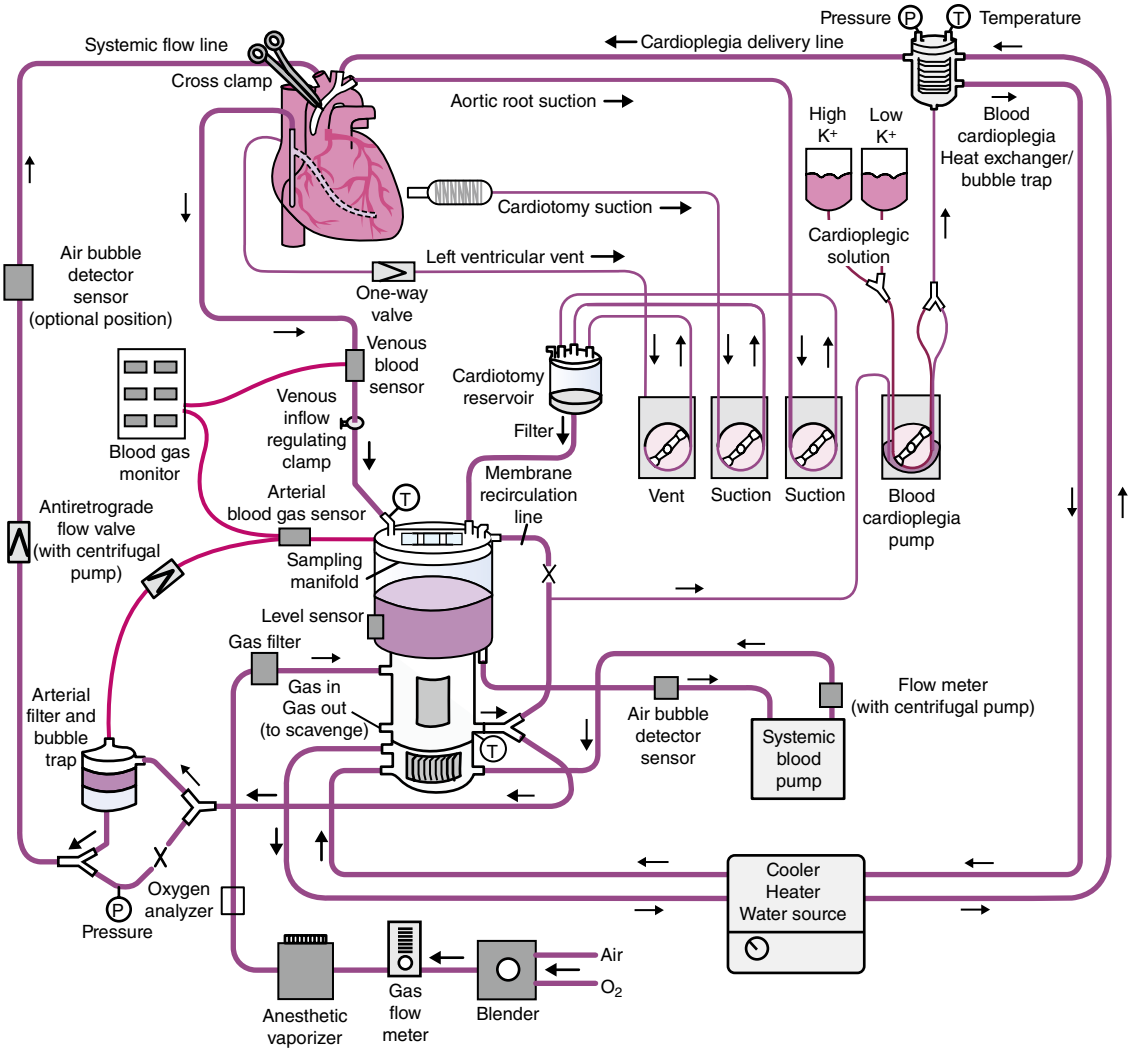

Figure 11.1 Schematic diagram of a cardiopulmonary bypass circuit. This scheme depicts a membrane oxygenator with an integral hard-shell venous reservoir and an external cardiotomy reservoir. Many circuits have the cardiotomy reservoir, venous reservoir, and oxygenator integrated into one single unit. The systemic blood pump may be either a roller or centrifugal pump. Most pediatric venous cannulations are bicaval with two separate venous cannulas instead of the single venous cannula depicted here. Carbon dioxide can also be added to the inspired gas to facilitate pH-stat blood gas management. Arrows indicate the direction of flow; P, pressure sensor; T, temperature sensors; X, placement of tubing clamps. (Source: Hessel et al. [7]. Reproduced with permission of Wolters Kluwer.)

AL Grawany

Table 11.1 Differences between adult and pediatric cardiopulmonary bypass

Parameter	Adult	Pediatrics
Temperature	Rarely below 32 °C	Commonly 18–20 °C
Deep hypothermic circulatory arrest (DHCA)	Rare	Common for arch repair (HLHS, IAA)
Pump prime	Crystalloids	Blood components and albumin
Dilution	25–33%	Up to 200%
Perfusion pressure	50–80 mmHg	30–50 mmHg
Flow rates	2.5 L/min/m^2 or 50–65 mL/kg/min	0–250 mL/kg/min
pH management	Alpha-stat	pH-stat
Hypoglycemia	Rare, only in hepatic injury	Common due to low hepatic glycogen stores
Hyperglycemia	Frequent increases mortality	Less common, may be protective
Cannulation techniques	Standardized, mostly ascending aorta and single-stage venous cannula	Variable, including ductus, aorta, main pulmonary artery; mostly bicaval venous cannulation
Ultrafiltration	Rare	Standard modified ultrafiltration or conventional ultrafiltration

HLHS, hypoplastic left heart syndrome; IAA, interrupted aortic arch.

tubing, cannulae, as well as monitoring and alarm devices. There are major differences between adult and pediatric CPB, stemming from anatomic, metabolic, and physiologic differences in these two groups of patients (Table 11.1). Much progress has been made in the miniaturization of circuits and components. Current technology allows a total priming volume as low as 95 mL for a neonatal circuit setup allowing transfusion-free repairs in smaller patients down to the 5–10 kg range in some institutions [8–10].

Cannulation and tubing

The selection of cannulas occurs on the basis of flow requirements and anatomic relations. Single-stage venous cannulation is rare and selective superior and inferior vena cava cannulation plus additional cannulation of a left persistent superior vena cava are routine. Thus, the infant patient routinely has an aortic cannula and two venous cannulas. A second aortic cannula may be used for cases of interrupted aortic arch to perfuse the descending aorta (Figure 11.2). Particular care must be observed during inferior vena cava (IVC) cannulation, as obstruction or malposition into a hepatic vein can occur. The addition of a small cannula for venting the systemic ventricle places significant demand on the surgeon to manage the position of the multiple cannulae in the small pericardial space of neonates and young infants. Venting the heart through an existing patent foramen ovale or atrial septal defect (ASD) or creating a small atrial communication is the preferred method for many congenital

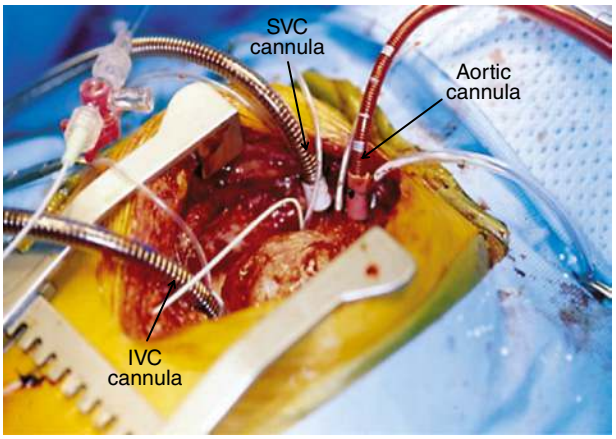

Figure 11.2 Aortobicaval cannulation in a neonate. IVC, inferior vena cava; SVC, superior vena cava.

cardiac surgeons, instead of a cannula in a superior pulmonary vein, to avoid damage to these delicate structures.

In daily clinical practice, the amount of systemic venous return on CPB is directly correlated with the amount of pump flow and vice versa. Venous drainage is often limited by the small size of the cannula and tubing as well as individual characteristics, the circuit used, and the use of accessory systems. Generally, venous drainage is obtained by gravity, placing the venous reservoir of the CPB circuit about 30 cm lower than the level of the heart; in this way, a negative pressure equivalent to about 20–25 mmHg is obtained. This is adequate for the vast majority of adult patients undergoing conventional procedures. In pediatric patients, however, where relatively small-size cannulas and tubing of the venous circuit are used to reduce the pump-priming volume, vacuum-assisted venous return is most often used. In this system, a constant vacuum (up to 80 mmHg) is created in the airtight venous reservoir, allowing more blood to be drained from the patient via the venous line. This system allows the performance of surgical procedures on CPB, even in small infants, without the need for large-size venous tubing and, therefore, without increasing the volume of the pump priming [11, 12]. The major potential limit in the clinical application of this system is the risk of generating gaseous microemboli in the venous circuit. If the arterial pump is stopped for various reasons and the vacuum source is left on the venous reservoir, microbubble transgression can occur from the gas compartment to the liquid compartment of the oxygenator, creating another source of gaseous microemboli as soon as the arterial pump is turned on again [9, 12].

Arterial cannulation is usually via the ascending aorta. Exceptions, however, are frequent in the newborn with malformation of the ascending aorta (e.g. interrupted aortic arch and hypoplastic left heart syndrome [HLHS]). In that scenario, the ductus arteriosus is primarily cannulated to maintain body perfusion on bypass and the pulmonary arteries are snared to prevent runoff until an anatomic correction takes place.

The clinician must also be aware that femoral cannulation is not feasible in small children <15 kg because of the small vessel size. Thus, on repeat sternotomy, this method of establishing CPB is usually not an option and careful retrosternal dissection must take place.

Table 11.2 Cardiopulmonary bypass tubing volumes

Tubing diameter (in.)	Volume per meter length (mL/m)
1/2	126
3/8	71
1/4	33
3/16	18

Table 11.3 Cardiopulmonary bypass tubing sizes

Arterial and venous tubing sizes	Patient weight
3/16 in. arterial line, 1/4 in. venous line	<10 kg
1/4 in. arterial line, 3/8 in. venous line	<20 kg
3/8 in. arterial line, 3/8 in. venous line	<50 kg

The aortic cannula represents the smallest diameter in the pediatric CPB circuit. The bypass tubing is responsible for the large foreign surface area and priming volume. The strategic selection of tubing dimensions can reduce the volume effectively (Tables 11.2 and 11.3). For example, in a 3.5 kg newborn with an approximate blood volume of 300 mL, the addition of a cardiotomy suction line of 6.3 mm (1/4 in.) diameter and with a total length of 250 cm would require approximately one third of the patient's blood volume (82.5 mL) before reaching the reservoir.

Malposition of cannulas is particularly problematic in pediatric perfusion. Systemic perfusion may be adversely impacted when placement of either venous or arterial cannulas is not ideal. If a venous obstruction occurs, the consequences are magnified because of low perfusion pressures. If the IVC cannula causes venous obstruction in the splanchnic bed, increased hydrostatic pressure causes ascites, and reduced perfusion pressure results in significant renal, hepatic, and gastrointestinal dysfunction. Obstruction of the superior vena cava (SVC) may produce an increase in intracranial pressure and result in decreased cerebral perfusion pressure and cerebral edema. It is possible to observe preferential flow to one side of the cerebral circulation or down the distal aorta (Figure 11.3). Transcranial Doppler monitoring of cerebral flow velocity or cerebral oximetry can provide an early warning of altered flow patterns caused by cannula misplacement [11]. Cooling patterns demonstrating rectal cooling preceding nasopharyngeal cooling may suggest a disproportionate amount of pump flow being directed away from the cerebral circulation [13].

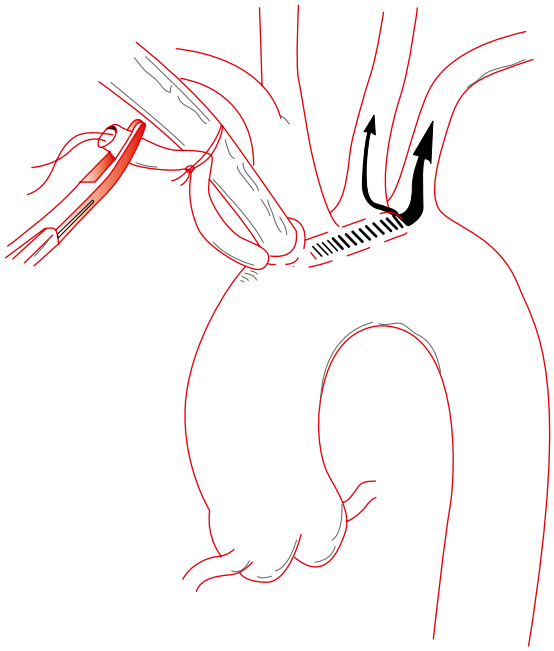

Figure 11.3 Malposition of the aortic cannula high in the ascending aorta. This cannulation technique is helpful for any surgery on the ascending aorta. Particular attention is needed to avoid preferential perfusion of the left cerebral hemisphere. Note the obstruction of flow to the innominate artery in this case. (Source: Gottlieb et al. [11]. Reproduced with permission of John Wiley & Sons.)

Pumps

The two pumps most commonly used for CPB are roller pumps and centrifugal pumps. Roller pumps have the advantages of simplicity, low cost, ease and reliability of flow calculation, and the ability to pump against high resistance without reducing flow. Disadvantages include the need to assess occlusiveness, spallation of the inner tubing surface, which potentially produces particulate arterial emboli, the capability of pumping large volumes of air, and the ability to create large positive and negative pressures. Centrifugal pumps offer the advantage of lesser air pumping capabilities, less ability to create large positive and negative pressures, less blood trauma, and virtually no spallation. Disadvantages include higher cost, the lack of occlusiveness (creating the possibility of accidental patient exsanguination), and afterload-dependent flow requiring constant flow measurement. In the setting of short-term CPB for cardiac surgery, it remains uncertain whether the selection of one pump over another is of clinical significance; most institutions employ roller pumps for congenital heart surgery.

Oxygenator

The efficiency of gas exchange in the natural lung is mainly attributable to the large surface area generated by the airway and circulatory networks and the low resistance to diffusion. These same features are essential to the design of an efficient artificial lung. Other necessary features of an ideal oxygenator include minimal trauma to blood, thromboresistance, minimal reaction with blood components, minimal generation of gaseous microemboli, the ability to maintain performance over long periods, low prime volume, consistent physical properties, reliability, ease of use, and low cost. The efficiency of a membrane oxygenator is two to three times less than that of the natural lung at rest, and about eight times less than the natural lung under conditions of maximal exercise. The primary limiting factor to efficient gas exchange in membrane oxygenators appears to be blood phase resistance to both O_2 and CO_2 diffusion. A second factor that has limited the use of microporous membranes in situations of long-term extracorporeal support is the progressive decrease in gas exchange function. The most common microporous

AL Grawany

membrane oxygenator design in clinical use is the hollow-fiber type in which the polypropylene membrane is formed into fibers that are bundled or woven together. The fibers are 200–250 µm in diameter and 10–15 cm long, and the membrane thickness is 25–50 µm. Although the existence of micropores in the membrane significantly increases the gas exchange of membrane oxygenators, long-term use results in the progressive wetting of the surface, plasma leakage through the pores, and subsequent deterioration of membrane performance, thus limiting its use to acute CPB procedures. The newest oxygenators incorporate an arterial line filter to reduce priming volumes.

Priming

Bypass prime composition and volume are adapted to the particular requirements of the patient. The composition, however, is often a matter of opinion and differences are as great as the number of pediatric heart centers. If there is a consensus, it is probably only with regard to reducing volumes to a minimum to reduce transfusion requirements and dilutional effects of the patient [8, 14].

Despite recent advances made in technology, the majority of neonates and infants still require perioperative transfusion of homologous blood components. The lower the body weight of the patient, the more banked blood products need to be added to the prime. To maintain colloid osmotic pressure and a minimal amount of coagulation factors, albumin and fresh frozen plasma (FFP) are added. The most suitable priming in neonates seems to be the combination of albumin or FFP and red blood cells in such proportions so as to maintain the hematocrit (Hct) at about 28–30% during normothermia. A few centers are still able to obtain fresh whole blood (<48 hours after donation) for neonates, but outcomes of studies using this technique vs. "reconstituted" whole blood (FFP plus packed red blood cells [PRBCs] from the same or different donors) are conflicting [10, 15, 16]. Albumin is reported to maintain colloid osmotic pressure (COP; normally around 20–25 mmHg) and to reduce fluid accumulation [8, 10, 17, 18] while adding FFP to the prime maintains COP increases the level of coagulation factors and reduces intraoperative transfusion requirements in complex neonatal and cyanotic cases [12, 19]. However, postoperative transfusion requirements are not affected despite higher fibrinogen concentrations and better thrombelastographic values at the end of CPB [9, 20]. The level of ionized calcium is adjusted, as all blood products contain significant amounts of citrate. This can lead to acute hypocalcemia and cardiac arrest with the initiation of bypass. In addition, added erythrocyte concentrates should be as fresh as possible (<3–5 days old) to avoid hyperkalemia and hyperlactatemia as side effects. The reasons for this suggestion are that the level of 2,3-diphosphoglycerate in stored red blood cells decreases, metabolic load increases (potassium and lactate levels by the end of the second day are up to 7–25 mmol/L [11, 21]), and the risk of complications with bypass is higher. The risk is particularly high in infants <5 kg if the prime contains irradiated blood [13, 22]. If the red blood cells (RBCs) in the prime are older than 5 days, a prime blood gas should be checked and corrected. Circulating and filtrating the prime for 20 minutes alleviates most of these problems. Alternatively, processing PRBCs via a cell saver is reasonable and may add additional benefits such as the avoidance of hyperglycemia, high citrate levels, and hyperkalemia [14–16, 23, 24]. In addition, lactate levels are reduced and microaggregates >20 µm are eliminated. Care must be taken to avoid using normal saline as a washing solution, as a hyperchloremic metabolic acidosis can be induced in newborns and infants. In addition, the use of cell-saving devices during pediatric cardiac surgery provides another means of reducing banked blood exposure [25]. A desirable practice is to adjust the prime composition in neonates and small infants to the patient's blood, with pH, Na^+, K^+, Ca^{2+} and temperature within narrow ranges.

PRBC requirements can be calculated on the basis of weight and starting Hct. The change in Hct, ΔHct, is calculated as follows:

$$\Delta\text{Hct} = \frac{(\text{Hct}_{\text{PAT}} \times \text{BV}_{\text{PAT}})}{\text{BV}_{\text{PAT}} + \text{PV}}$$

where HctPAT is patient hematocrit, BVPAT is the patient blood volume (see Table 11.4) and PV is the priming volume. The transfusion requirement is calculated as:

$$\text{PRBC (mL)} = \text{Hct}_{\text{DESIRED}} \times (\text{BV}_{\text{PAT}} + \text{PV}) - \frac{(\text{BV}_{\text{PAT}} \times \text{Hct}_{\text{PATIENT}})}{60\%}$$

where 60% is the average Hct of stored PRBCs. After initial prime composition, an Hct on the prime can be measured, and a further adjustment before CPB is made to achieve Hct in the goal range. In newborns, a goal Hct on the pump of 30–35% is maintained. Older patients or special circumstances (e.g., severe hypoxia) may require adjustments to a lower limit of around 25% or higher than 30% (severe hypoxia), even though both limits are controversial. Historically, many centers permitted marked hemodilution on CPB to avoid transfusion. Recent studies question this approach and provide evidence of improved neurological function when higher Hcts are maintained during CPB. A randomized controlled clinical study in infants undergoing CPB demonstrated adverse perioperative and developmental outcomes with extreme hemodilution [26]. This issue remains controversial, although the clinical data in support of higher Hcts of at least 25% are compelling [27, 28]. Also, hemostasis may be improved by higher Hct levels.

An interesting strategy described in recent years is utilizing a neonate's own umbilical cord blood (UCB) for prenatally diagnosed patients undergoing cardiac surgery with bypass [29]. UCB is collected in a sterile fashion in the delivery room, and with milking of the umbilical cord, 50–140 mL of UCB can be obtained. After sterile processing, the UCB can be utilized as whole blood, or separated into packed RBC and fresh frozen plasma components. UCB contains stem cells and other progenitor cells, growth factors, and cytokines, in addition to RBC. Theoretical advantages of UCB are lack of immunogenicity, high concentration of fetal hemoglobin to facilitate unloading of oxygen into the tissues, and potential benefits of the progenitor cells. Half of the collected blood can be used to prime the bypass machine, and half can be

Table 11.4 Estimated patient blood volumes by weight

Weight (kg)	Estimated blood volume (mL/kg)
<3 (neonate)	90
3–10	85
10–20	80
20–30	75
30–50	70
>50	65

used for post-bypass transfusion. Drawbacks to UCB include complexity of collection, bacterial contamination, and limited storage time. Small single-center studies from a few institutions are the only data available, but UCB appears to be safe. Larger studies with a more careful assessment of the fate of all of the cell types are needed before wider use of UCB for neonatal surgery.

KEY POINTS: BASIC BYPASS CIRCUIT SETUP

- The basic bypass circuit consists of the venous reservoir, the oxygenator/heat exchanger unit, roller pumps for perfusion, suction, and cardioplegia and the connecting tubing, cannulae, as well as monitoring and alarm devices.
- The oxygenator contains an integrated arterial filter.
- Priming for children <10 kg includes either fresh whole blood or reconstituted blood prime with PRBCs and/or FFP.
- Target hematocrits on bypass are >25% with a goal of >35% for neonates and complex cyanotic lesions or >28% for acyanotic lesions.

Differences between pediatric and adult CPB

Major differences need to be considered when dealing with the pediatric patient on CPB (Table 11.1). These include the degree of hemodilution, flow rates and perfusion pressure, temperature, cannulation, prime and blood gas management, ultrafiltration, hemodynamic management, and, in certain cases, the presence of aortopulmonary collaterals.

Hemodilution

Recent efforts to minimize circuit volumes have led to the development of smaller circuit elements. However, there continues to be a gross degree of hemodilution realized in the neonatal patient. This can be as much as three to 15 times the amount of hemodilution seen in an adult. For example, in a 3 kg child given 85 mL/kg, an estimated blood volume (EBV) of 255 mL contrasts with an average circuit prime volume of 300–400 mL. Thus, a prime : EBV ratio can exceed >2–3 : 1, or >100–150% of a neonate's blood volume.

In the average adult circuit, only a 25–33% dilution rate is realized. This degree of dilution necessitates the addition of donor blood up to a body weight of approximately 10 kg to maintain an adequate Hct for optimal oxygen delivery on bypass.

Perfusion pressures

Management of the pediatric patient undergoing CPB is made difficult by competing hemodynamic goals for the brain, heart, and viscera. The brain is protected from hypoperfusion by systemic vasoconstriction and pressure autoregulation. Optimal mean arterial pressure targets are not uniform. They depend on cerebral autoregulation and vasoreactivity. This varies by age and underlying conditions. Patients with prematurity, previous brain injury, underlying congenital heart disease, hypothermia, or patients on ECMO can have abnormal cerebral autoregulation which makes it difficult to optimize the brain perfusion pressures. Invasive measurements of cerebral blood flows are not feasible, but non-invasive continuous monitoring of pressure autoregulation may be performed using near-infrared spectroscopy (NIRS) as a surrogate of CBF by using the hemoglobin volume index (HVx). The HVx is a moving correlation between arterial blood pressure and blood volume measured by cerebral oximetry and is able to evaluate individual autoregulatory thresholds [30]. See Chapter 14 for additional detail.

Perfusion pressures in the neonate can be quite low, less than 30 mmHg. This is often due to the lack of reactivity of the neonatal vasculature or the presence of a shunt like a patent ductus arteriosus (PDA). With meticulous management of blood gases, Hct, temperature, and flow rates, the goal should be the minimal use of vasoconstricting agents (i.e. phenylephrine) to maintain ideal blood pressure. As a rule of thumb, perfusion pressure (MAP [mean arterial pressure] – CVP [central venous pressure]) goals in the neonate are 35–45 mmHg, and over the first 2 years of life, the target perfusion pressure increases to 45–50 mmHg. Although not yet validated by neurologic outcome studies, the lower limit of autoregulation as measured by the HVx in neonates averages about 30 mmHg in the first week of life and increases to about 40 mmHg by 30 days, with considerable variation [31]. At best, normal flow rates are combined with reasonable perfusion pressures to reach all tissue beds, including those that require a certain opening pressure for function (kidney, brain, splanchnic bed). One should also keep in mind that the lower limit of myocardial perfusion pressure is around 15 mmHg, calculated as MAP – CVP. This is relevant for diastolic pressures below 30 mmHg.

Flow rates

The flow rates for neonates are quite variable, ranging from 0 to 200 mL/kg/min. Deep hypothermic circulatory arrest (DHCA) is at one end of the spectrum, contrasted with high metabolic demands, vent return, circuit shunts, or patient collaterals, all of which contribute to the necessity of high flow rates at the other end. This can often exceed a cardiac index of 3 L/min/m^2. The flow rates are calculated on the basis of weight, but the perfusionist must adapt flows according to the individual case and to meet the demands. One strategy is to employ standard full flow rates in neonates and infants up to 10 kg of 150 mL/kg/min. With hypothermia and decreased metabolic demands, many centers will reduce flows to 80–100 mL/kg/min to reduce venous return to the field, lowering flows further to 25–50 mL/kg/min during deep hypothermia for intracardiac complex repairs.

AL Grawany

Recent data has demonstrated the feasibility of goal-directed, personalized CPB flow rates utilizing parameters such as mixed venous oxygen saturation (MVO_2) measured continuously in line from the CPB circuit, cerebral and somatic oxygen saturation measured by near-infrared spectroscopy, arterial blood gases, hemoglobin, and lactate concentration. Goals such as cerebral oxygen saturation (rSO_2) above 50%, maintaining somatic rSO_2 values higher than cerebral rSO_2, MVO_2 >70%, and lactate less than 2.5 mmol/L have been reported [32]. Bojan and colleagues retrospectively reviewed 180 neonatal surgeries and serum lactate values, and calculated oxygen delivery (DO_2, mL/min/m^2) utilizing CPB flow rates, hemoglobin concentrations, and PaO_2. [33] They determined a minimum DO_2 to maintain aerobic metabolism, indicated by a peak lactate concentration after aortic cross clamp removal <2.5 mmol/L, at normothermia and different levels of hypothermia. The average minimum DO_2 at 37 °C was 340 mL/min/m^2, a value significantly higher than older children and adults. Minimum DO_2 decreased linearly with temperature (Figure 11.4). The same group published a retrospective study of somatic to cerebral

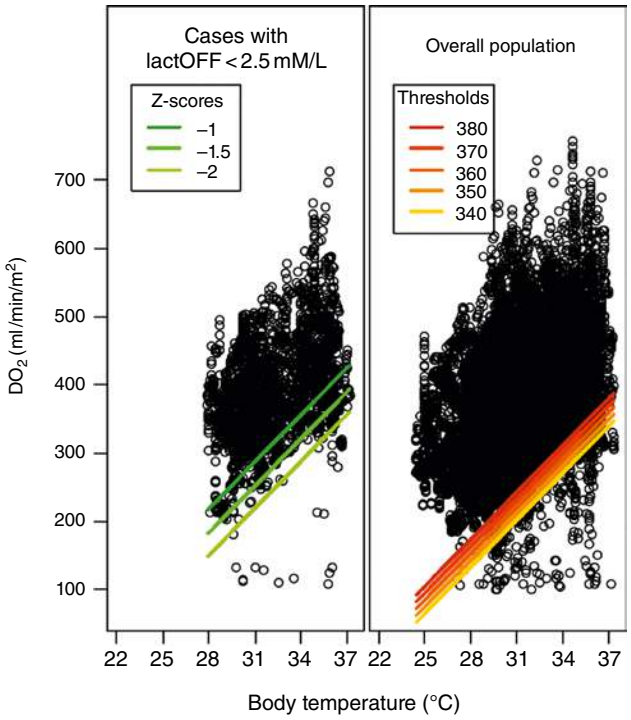

Figure 11.4 Oxygen delivery as a function of body temperature during aortic crossclamping. In the left panel are shown the observed oxygen deliveries (DO_2) in patients with first lactate after aortic crossclamp was removed (lactOFF) <2.5 mM, and the estimated −1, −1.5, and −2 DO2 Z scores, as a function of body temperature. In the right panel are the observed DO_2 values in the overall population, as a function of temperature, and several DO_2 thresholds tested for associations with lactate production. These were empirical thresholds chosen in an attempt to refine the −2 Z score. DO_2 threshold of 357 mL/min/m^2 was identified in the lactOFF <2.5 subgroup and found to be linked with lactate production. The final analysis revealed that the lowest threshold linked with lactate production and thought to represent the lowest suitable DO_2 during normothermic neonatal bypass was 340 mL/min/m^2. (Source: Bojan et al. [33]. Reproduced with permission of Elsevier.)

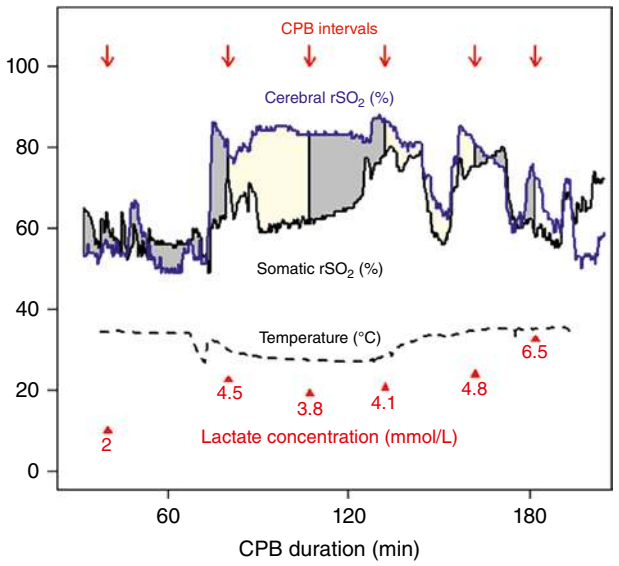

Figure 11.5 The somatic-cerebral NIRS gradient, lactate concentrations, and temperature during cardiopulmonary bypass in a neonate. For each time interval between two lactate measurements, the lactate concentration variation and the somatic-cerebral rSO_2 gradient were calculated. The somatic-cerebral rSO_2 gradient was the sum of all positive and negative areas resulting from excursions of the somatic rSO_2 above and below the cerebral rSO_2 and was calculated aby the trapezoidal method. rSO_2, regional oxygen saturation. (Source: Bojan et al. [34]. Reproduced with permission of Oxford University Press.)

rSO_2 difference during CPB in 24 neonates, and reported that there was a predictable increase in lactate concentration when the somatic to cerebral rSO_2 difference decreased or became negative [34] (Figure 11.5). Although potentially more complex than a standard flow rate specified according to weight or body surface area, combined with temperature, this approach of varying CPB flow according to oxygen demand may balance minimum oxygen delivery needs with the need to reduce flows to decrease blood return to the surgical field. More data, along with outcome studies, are needed to determine whether the goal-directed approach has any advantage over current methods.

Blood gas management

It is the current practice in some institutions to employ pH-stat management in all cases in which temperatures are taken to hypothermic levels. In this temperature-corrected strategy, the PCO_2 remains unchanged from 37 °C (40 mmHg). This strategy allows for cerebral vasodilation and more even cooling. The corrected PCO_2 ranges at 37 °C can be >80–100 mmHg.

Aortopulmonary collaterals

Uncommon in adults, but fairly common in patients with chronic cyanosis with decreased pulmonary blood flow, aortopulmonary collaterals can be a challenge. It can be difficult to empty the heart. Flow rates are frequently affected, and temperatures may need to be lowered substantially to

accommodate lower bypass flows to reduce blood return to the operative field. Flows may need to be decreased in conjunction with the use of vasodilating agents. Phentolamine 0.1 mg/kg and nitroglycerine are the drugs of choice during cooling and rewarming, titrated to effect. Phenylephrine is contraindicated and would only enhance collateral flow.

Temperature ranges

As a very basic comparison, there is a trend toward conducting adult cases at tepid or normothermic temperatures while many neonatal cases are still utilizing cold temperatures with or without DHCA. However, more and more neonatal cases are performed at mild hypothermia. The perfusion considerations are multiple, and this topic is discussed in a separate section on hypothermia and DHCA.

Glucose management

It is of utmost importance to maintain euglycemia in the neonate. Although there are increased glycogen stores in the neonatal myocardium, there are low hepatic glycogen stores. Exogenous glucose may be necessary in the early neonatal period to maintain normal glucose levels and should be continued into the pre-bypass period.

Perfusion considerations on CPB are directed at efforts to maintain normal glucose levels such as washing packed cells or minimizing glucose content in cardioplegia or intravenous (IV) fluids. When glucose levels are greater than 300 mg/dL, a saline hemodilutional washout with the hemoconcentrator is utilized. Frequent monitoring is recommended. Levels should be maintained at approximately 150 mg/dL just prior to DHCA.

Hyperglycemia worsens neurological injury, as elevated glucose levels result in the increased anaerobic metabolism of glucose and increased lactic acidosis. This leads to further depletion of ATP. Hypoglycemia alone can be treated but coupled with hypothermia, cerebral blood flow may be compromised by altering autoregulation. This can be further exacerbated with hyperventilation, as this may occur in weaning a patient with pulmonary hypertension from CPB. Overall, tight glycemic control (blood glucose level in the range of 80–110 mg/dL) is not indicated in children as the outcome was not any different from standard care in the intensive care unit (ICU) [35]. Hyperglycemia was not associated with lower neurodevelopmental outcomes at 8 years of age in the Boston Circulatory Arrest Study. However, lower glucose measurements below 90–100 mg/dL after CPB were associated with a higher risk of electroencephalogram (EEG) seizures. The authors speculate that limiting glucose as an important energy substrate for the neonatal brain, which may have increased requirements under conditions of low CPB flows or DHCA, may be a reason for this association [36]. In a more contemporary study of 93 neonates undergoing the arterial switch operation, patients with more than 50% of the intraoperative and early postoperative periods spent at glucose values between 80 and 110 mg/dL had more perioperative complications than those with >200 mg/dL more than 50% of the time [37]. The practice of many pediatric cardiac anesthesiologists is to maintain plasma glucose levels in the 100–200 mg/dL range for neonates and small infants.

Equipment

One circuit size for the adult patients at a given institution can adequately provide flows for patients from 50 kg and more. Most pediatric centers employ two or three circuits on the basis of the patient's weight, procedure, and flow requirements.

Ultrafiltration

Utilization of ultrafiltration in some form, whether it be conventional or modified, is seen in >90% of our neonatal and pediatric cases. Several system modifications may be necessary to allow for these options.

KEY POINTS: DIFFERENCES BETWEEN PEDIATRIC AND ADULT CPB

- The major differences between pediatric and adult CPB are the degree of hemodilution, flow rates, and perfusion pressures.
- Hemodilution is exaggerated and can reach more than 150% of the patient's blood volume.
- Flow rates are in the range of up to 200 mL/kg/min or an equivalent cardiac index of 3.0 L/min/m^2 and higher can be found in the neonate.
- Aortopulmonary collaterals can be a challenge during bypass and should be managed with vasodilators and increased flow rates.
- pH-stat is the preferred method of blood gas management during cooling in pediatric cases using deep hypothermic circulatory arrest.
- Glucose management with targets of 100–200 mg/dL is desirable.

Management of pediatric CPB

Stages of CPB

Cardiac cases using CPB can be divided into several basic phases: pre-bypass period and anticoagulation, bypass period with initial cooling, cross-clamping and myocardial protection, reperfusion of the heart, separation from CPB, modified ultrafiltration and hemostasis, and, lastly, sternal closure and transfer to the ICU.

Pre-bypass period

The pre-bypass period begins with surgical incision and lasts through to initial dissection and preparation for cannulation. During this period, transesophageal echocardiography (TEE) is performed to confirm the diagnosis and establish a basis for post-bypass comparison. Baseline activated clotting time values are obtained and metabolic abnormalities are corrected. Cannulation of the great vessels just prior to CPB can often precipitate arrhythmias, hypotension, and arterial desaturation, especially in small infants and children. Ventilation may need to be limited to minimize lung excursion to allow precise

cannulation in small infants. Coordination with the surgeon is particularly important. Hemodynamic stability is maintained by cautious fluid administration and small boluses of vasopressors, as deemed necessary. After placement of the aortic cannula, pressure in the aortic root is measured by the perfusionist through the cannula *in situ* and should be close to the MAP of the patient. A small volume infusion of 2–5 mL/kg is often used at that point to ensure unobstructed aortic cannula flow before bypass. If the aortic cannula is already in place, it is common practice to coordinate the administration of volume between the anesthesiologist and perfusionist while the surgeon completes cannulation.

Anticoagulation and hemostatic management

Development of the coagulation system is incomplete at birth and continues in the postnatal period until the age of about 6 months. This increases the risk of bleeding disproportionately in the neonatal and infant group up to 1 year or approximately 8 kg of weight [38–40]. Coagulation in cyanotic infants may be particularly impaired secondary to polycythemia, lower fibrinogen levels, low platelet count and abnormal platelet function [41], decreased concentrations of factors V, VII, and VIII, and increased fibrinolysis [42, 43].

Of particular importance is the role of antithrombin (AT) levels that do not reach adult values until 3–6 months. This low level of AT may reduce the ability of heparin to provide anticoagulation adequate to prevent thrombin generation during CPB in infants [38, 42, 44–46] and an exaggerated inflammatory response may occur [38, 42, 43, 47, 48]. Infants may require an initial heparin dose of 400 units/kg or higher. Manlhiot and colleagues reported AT levels and heparin consumption in 90 infants <1 year undergoing CPB surgery.[49] Baseline AT levels were strongly dependent on age, with lower levels in neonates (Figure 11.6). Lower AT levels were also associated with lower heparin response as measured by anti-factor Xa levels and higher heparin consumption (Figure 11.7A and B). It has also recently been shown that in infants with CHD, levels of other thrombin inhibitors are depressed compared with healthy infants. This may partially explain the high levels of thrombin generation during infant CPB. The coagulopathy induced by CPB affects children more profoundly than adults. There are many factors implicated, including hemodilution, contact activation, and initiation of a systemic inflammatory response. Despite large doses of heparin during CPB, heparin does not block thrombin generation completely but partially inhibits thrombin after it is produced. Thrombin is continuously generated, and a consumptive coagulopathy is initiated [44, 46]. The lower potential of newborn plasma to generate thrombin might, in part, downregulate thrombin markers during CPB. This, however, does not seem significant enough to completely prevent the subsequent reperfusion-induced thrombin peak [42, 43, 47–48, 50]. Thromboelastography (TEG) has actually shown that neonates and infants develop faster and stronger clots than adults [38–40, 51]. In addition, acquired coagulation defects in 58% of non-cyanotic and 71% of cyanotic infants have been reported [41, 52–54]. If thrombin formation could be completely inhibited during CPB, the consumption of coagulation proteins and platelets could largely be prevented. Initial heparin doses range from

[49] / Reproduced with permission of Elsevier.)

300–400 units/kg bolus before cannulation to 200–400 units/kg in the circuit, and to 50–100 units/kg ongoing administration every 30–120 minutes. Heparin's peak therapeutic effect occurs within 2 minutes. CPB may delay the peak effect by 10–20 minutes from hypothermia or hemodilution. Plasma binds 95% of heparin with some uptake by the extracellular fluid, alveolar macrophages, splenic/hepatic endothelial cells, and vascular smooth muscle. The plasma half-life is dose-dependent (i.e. 126 ± 24 minutes at a dose of 400 units/kg vs. 93 ± 6 minutes at a dose of 200 units/kg) [38–40, 55]. Heparin is metabolized by the reticuloendothelial system and is eliminated by the kidneys. Hypothermia and renal impairment, but not hepatic impairment, delay elimination. A roughly linear relationship exists between heparin dose and the activated clotting time (ACT) if certain criteria are maintained [41, 56], namely normal ATIII and factor XII activities, normothermia, near-normal platelet function, a platelet count >50,000/dL, and fibrinogen concentration >100 mg/dL. However, in children, the correlation is rather poor [42, 43, 57]. An ACT is measured before heparinization and repeated a minimum of 3 minutes after giving heparin. CPB is not initiated until an adequate ACT or heparin level is confirmed.

Given the variability in the ACT, heparin concentration can also be measured directly. A two-point (straight line) dose-response curve assists in judging how much additional heparin to administer. Acceptable levels during CPB are 2–4 units/mL, and in the newborn population up to 6 units/mL. This regimen increases required heparin doses on CPB but results in lower protamine doses and less blood loss [45, 58]. The optimum method of assessing adequate anticoagulation during CPB in children has thus not yet been defined and much work is required in this area. The use of heparin-coated biocompatible perfusion circuits is probably helpful in reducing the degree of activation of the coagulation system in children [47, 48, 59, 60], but it is rather expensive and has not gained wide acceptance.

The optimal ACT for CPB is controversial. Although the minimum recommended ACT is 400 seconds, other authors recommend 480 seconds [44, 46, 61], as heparin only partially inhibits thrombin formation. This is done to minimize the consumptive coagulopathy that may result from barely adequate anticoagulation. Failure to achieve a satisfactory ACT may be due to inadequate heparin or low concentrations of ATIII, or "heparin resistance." [49, 62]. Increases in acute-phase reactant proteins such as factor VIII and fibrinogen commonly shorten the APTT and may appear as heparin resistance. If 500 units/kg of heparin fail to achieve an adequate ACT, ATIII deficiency becomes more likely and FFP or recombinant ATIII (30 IU/kg) [50, 55] is necessary to increase antithrombin concentration.

Heparin dosing, ACT targets, and protamine reversal dosing were first established in the 1950s and published in a landmark paper by Keats, Cooley, and Telford from Texas Children's Hospital [63]. Today more than 60 years later, this approach is still used in most congenital heart surgery centers. The need for alternatives to heparin for bypass anticoagulation has been discussed for years, in part because of not only the problem of heparin-induced thrombocytopenia predominantly seen in the adult population but also the ongoing issue of bleeding and thrombosis with heparin in pediatric cardiac surgery despite many advances in monitoring and treatment of coagulopathy. Direct thrombin inhibitors such as bivalirudin can be utilized for pediatric cardiopulmonary bypass; the drawbacks with this drug are several and include that there is no reversal agent and it has a half-life of approximately 25 minutes, so a loading dose and infusion are necessary. In addition, bivalirudin lacks a widely available point-of-care test. The ecarin clotting time for bivalirudin is primarily a research tool. The ACT is used as a rough guide to anticoagulation, along with a viscoelastic method of coagulation assessment. Hasija and colleagues published a randomized, controlled safety and efficacy study of bivalirudin vs. heparin in 50 acyanotic patients aged 1–12 years who were undergoing corrective cardiac surgery with bypass[64]. Furthermore, 400 units/kg of heparin plus pump prime, vs. 1 mg/kg bilvalirudin bolus followed by 2.5 mg/kg/hour, and a pump prime dose, was studied. Using a 480 second ACT goal, 1 of 25 heparin patients required extra dosing as compared to 13 of 25 bivalirudin patients. ACT returned to baseline after protamine in the heparin group but remained elevated for an average of 2 hours in the bivalirudin group. With viscoelastic testing, heparin prolonged the onset of clotting, decreased the rate and strength of clot formation, and inhibited platelet function to a greater degree than bivalirudin. Duration of surgery was longer in the bivalirudin group, but chest tube drainage and transfusion were similar. No adverse events occurred.

More pediatric cardiac patients are arriving in the operating room (OR) because cardiac surgery is being anticoagulated with direct thrombin inhibitors. Patients on ventricular assist support achieve better and more accurate anticoagulation with these agents, namely bivalirudin, and this agent is now standard of care in many programs for a ventricular assist device (VAD), and even some ECMO patients [65, 66]. Bivalirudin infusion is usually discontinued prior to or on arrival to the OR. It is not thought to affect anticoagulation or hemostasis with heparin on bypass because of its relatively short half-life, but increased bleeding may occur with surgical dissection prior to bypass.

Initiation of CPB and flow requirements

After heparinization and cannulation, CPB is initiated by opening the venous outflow cannula to the reservoir. Slow decompression of the heart and maintaining a minimal output of the beating heart reduce the drop in blood pressure due to the hemodilution. Based on weight or body surface area, a flow requirement is calculated. The cardiac index is approximately 25–50% greater than that of an adult. For newborns, a flow of 2.6–3.2 L/min/m^2 is recommended, and for infants, a flow of 2.4–2.6 L/min/m^2 is sufficient. If normothermic CPB is chosen, flow rates in the range of 3.0–3.5 L/min/m^2 are required [51–53, 67]. This can be reduced during hypothermia (Figure 11.8) [68]. Infants have a much more compliant vasculature, which results in lower perfusion pressures on CPB. Causes of severe hypotension after initiation of bypass can be the presence of hemodynamically relevant shunts (e.g. major aortopulmonary collateral arteries) previously placed systemic to pulmonary artery (PA) shunt or a PDA, which both lead to a circulatory steal in the systemic circulation, requiring higher flows and possibly early

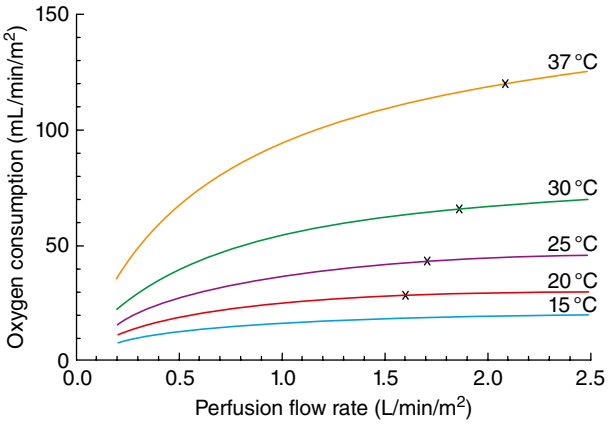

Figure 11.8 Nomogram relating oxygen consumption to perfusion flow rate and temperature. X indicates clinical flow rates used by Kirklin and Barrett-Boyes [68]. (Source: Kirklin and Barrett-Boyes [68]. Reproduced with permission of Elsevier.)

control by the surgeon. Increased bronchial and non-coronary collateral flow draining into the left atrium can be a particular problem, especially in cyanotic children, with a resultant significant negative impact on myocardial protection during periods of aortic cross-clamping. Because of the small and easily obstructed vena cavae in infants, careful assessment for venous obstruction is carried out immediately after initiation of bypass. The patient's head and face are assessed for signs of venous obstruction, including plethora and cyanosis of the scalp and face, distended fontanelle, and decrease in cerebral oxygen saturation to levels below the baseline. If a central venous catheter has been placed with its tip in the SVC, pressures should be low (i.e. <5 mmHg) and at times are negative if the placement is adjacent to the SVC cannula. Venous return judged by the volume in the venous reservoir is continually monitored by the perfusionist, with a sudden decrease prompting communication with the surgeon to investigate the cause.

The adequacy of perfusion is monitored by the usual parameters. These are MAP, the in-line measurement of mixed venous saturation, pH, base excess, and the regular testing of blood for heparin levels and lactate and other indices of end-organ perfusion (e.g., urine output, somatic and cerebral oxygenation values [NIRS for example]). (See above under flow)

Cooling and temperature management

Systemic cooling is often utilized for myocardial, cerebral, and other end-organ protection. Hypothermia is usually classified as mild (32–36 °C), moderate (24–32 °C), or deep (18–24 °C). In general, lower temperatures are used for more complex operations that carry a greater potential for requiring periods of low-flow bypass or circulatory arrest. Cooling is primarily achieved through the heat exchanger in the bypass circuit, although surface cooling with lower ambient air temperatures or forced-air warming systems set to lower temperatures is used in some institutions. Infants have a high ratio of surface area to body weight. Infants also have an immature thermal autoregulatory center. Because of these factors, wide fluctuations in body temperature occur easily. Warming and cooling on bypass occur much more readily. If the clinician is not careful, cooling can occur too rapidly, and deep brain structures may become dangerously cold. There is evidence to suggest that cooling too rapidly is deleterious to neurological function. Thus, it is important to cool slowly, evenly, and completely, and most investigators recommend at least 20 minutes of cooling if circulatory arrest is used (i.e., no faster than 1 °C/min) [69]. The opposite is also true. It is very easy to warm too rapidly and for hyperthermic overshoot to occur. Recent data suggest that hyperthermia can be very damaging, and temperature differences of even 1 or 2 °C are highly significant [70]. Monitoring should include nasopharyngeal, rectal, and arterial inflow temperatures. Rewarming the patient should occur at less than 8 °C temperature difference between the heat exchanger and patient blood temperature, with maximal inflow temperatures of 37.0 °C to avoid the formation of any micro air bubbles [71–73]. Special bypass techniques such as regional cerebral perfusion (see later) have been developed to avoid the necessity of using DHCA and may also be performed during this time.

In recent years, a number of centers have reported normothermic or mildly hypothermic bypass for a variety of congenital cardiac operations including some more complex neonatal surgeries such as the arterial switch operation [74]. Theoretical advantages include time saved by avoiding cooling and rewarming, improved coagulation and hemostasis, better oxygen and glucose transport in the neonatal brain, cellular membrane stability, better ATP production and utilization, and preservation of cerebral autoregulation. Despite the theoretical advantages, a meta-analysis of seven randomized controlled trials in pediatric patients revealed no differences in duration of CPB or aortic crossclamp, or in lactate or creatinine concentrations [75]. Corno and colleagues published a retrospective review of 99 patients <2 years of age undergoing normothermic (>35 °C) vs. hypothermic (28–34 °C) bypass, matched for cardiac lesion and surgical procedure [76]. They reported earlier extubation, shorter ICU stay, and lower transfusion requirement in the OR and ICU in the normothermic patients. Limitations of this study were its retrospective single-center nature, imperfect matching of patient groups, and small sample size. Neurodevelopmental follow-up of the cohort at 2–3 years after surgery revealed no differences between groups across multiple tested domains [77]. From the data reported so far about normothermic bypass for a variety of congenital operations, this approach would appear to be safe, but not to consistently lead to improved early clinical outcomes or shorter operating times.

Aortic cross-clamping, myocardial ischemia, and protection

Repair of most congenital heart lesions is becoming more feasible. Perioperative myocardial damage remains the most common cause of morbidity and mortality after successful surgical repair. Thus, effective myocardial protection assumes an even greater role than in the adult, as perioperative insults are less well tolerated and more difficult to treat. Neonatal hearts may be difficult to protect because of immaturity, cyanosis, hypertrophy of the right ventricle, complex coronary artery pattern, and duration of ischemia to achieve a good repair.

The neonatal heart is ultrastructurally immature. Myofibrils are arranged in a disorderly fashion and have a smaller percentage of contractile proteins than do those in adults (30 vs. 60%) [78]. The immature heart shows fewer mature mitochondria and a lower oxidative capacity [79]. Control of myocardial contractility in infants depends more on adrenal function and circulating catecholamines than on direct autonomic influences. There are also differences in myocardial calcium metabolism. In the mature myocardium, the sarcoplasmic reticulum is the predominant source of calcium ion for excitation-contraction coupling, but the sarcoplasmic reticulum is poorly developed in the immature heart (see Chapter 9). Because the neonatal myocardial cell is deficient in T-tubules, it is incapable of internal release and reuptake of calcium for contraction and instead depends heavily on transmembrane calcium transport for myocardial contraction. These differences in calcium handling by the cell provide some explanation for the clinical observation that newborns require greater serum ionized calcium levels for optimal myocardial contractility. Experimental evidence suggests that the newborn myocardium tolerates ischemia and reperfusion better than the adult heart. However, in practice, pediatric patients undergoing cardiac surgery have a greater incidence of low cardiac output postoperatively than adults. The discrepancy between the experimental evidence and the clinical experience may be related to the cardiac anomalies involved. Ventricular hypertrophy and cyanosis are common, and the hypertrophied heart has been found to have decreased subendocardial blood flow [80] and lower concentrations of high-energy phosphates before arrest. Chronic cyanosis has been associated with a decreased threshold for anaerobic metabolism during stress [81], diminished myocardial reserve [82], asynchronous left ventricular wall motion [83], and downregulation of β-adrenergic receptors [84]. Reoxygenation injury with the release of oxygen free radicals upon initiation of CPB can further exacerbate the pre-existing injury [85]. The abrupt increase in oxygen levels on bypass in chronically hypoxic infants leads to the loss of antioxidant reserve capacity and subsequent loss of myocardial function. Preventive measures include leukodepletion of blood prime, use of in-line arterial filters, and normoxic management (PaO_2 of 80–100 mmHg) initiating bypass. Over the course of 10–20 minutes, the fraction of inspired oxygen ratio (FiO_2) can be increased to obtain PaO_2 levels in the usual 100–150 mmHg range. As blood is fully oxygenated at such levels, further increases in oxygen levels only confer minimal increases in the oxygen content of the blood.

Finally, many congenital cardiac procedures require an incision of the ventricular muscle, which markedly changes the geometry of the chamber and induces focal edema.

The cornerstone of myocardial protection in pediatric cardiac surgery is hypothermia. Systemic hypothermia is, to some degree, used in nearly all congenital cardiac repairs. It is particularly important in cyanotic infants with increased non-coronary collateral flow to the heart.

Myocardial protection can be problematic in these cases because of cardioplegia washout and rewarming of the myocardium. Because systemic hypothermia allows reduced flow rates, it decreases myocardial collateral flow. Blood cardioplegia is often used in adults, but its advantages may be lost in infants undergoing deep hypothermia. However, if greater cardioplegic temperatures are used (warm cardioplegia), there is a clear advantage to the use of blood cardioplegia [86]. The optimal electrolyte composition of cardioplegia for pediatric patients is controversial. There is great institutional variation among solutions used. A certain amount of calcium is necessary in the solution to prevent the severe injury that may result from calcium paradox [87]. However, excessive amounts are deleterious. The addition of magnesium, a natural calcium antagonist, may solve this dilemma. Increasing the ionized magnesium level has been shown to improve postoperative rhythm stability and reduce calcium-induced mitochondrial dysfunction during reperfusion. Thus, in the absence of magnesium enrichment, hypocalcemic cardioplegia results in adequate myocardial protection in stressed hypoxic hearts. Magnesium was particularly beneficial during normocalcemic cardioplegia solution [88].

In addition to the specifics of cardioplegia administration reviewed in the following, a multifaceted approach to myocardial protection is taken by many institutions. For example, bypass prime composition is adjusted to closely match the patient's blood with regard to pH, serum Na^+, K^+, Ca^{2+}, and temperature. Initiation of bypass in a neonatal heart with cold, acidemic, hypocalcemic, hyperkalemic prime is a significant stress-increasing risk of inadequate myocardial protection. Gentle surgical handling of the heart by the primary surgeon and assistants is also felt to play a role, with excessive traction felt to disrupt the delicate fibrous skeleton of the heart, rendering less efficient the coupling of the myofibrils to mechanical force transduction of the heart. Gentle handling of the myocardium also lessens the risk of arrhythmia such as ventricular fibrillation, which on bypass represents an ischemic state of the heart. Monitoring carefully for the return of any cardiac electrical activity is important, giving consideration to more frequent cardioplegia dosing. Aggressively treating ventricular tachycardia, especially fibrillation, on bypass is very important. Meticulously maintaining venous drainage with proper cannula size selection and positioning, as well as venting of the left side of the heart prevents ventricular distension and subendocardial ischemia. Maintaining cold myocardial temperatures with ice slush application is also utilized to preserve a low-energy consumption state.

There is some evidence that volatile anesthetics can provide a degree of myocardial preconditioning when administered before CPB, in the setting of adults undergoing coronary bypass surgery. The cellular mechanisms are complex but are demonstrated to include mitochondrial and sarcolemmal potassium-ATP channel opening, transcription factors (NF-KB, HIF-1 alpha), new proteins (iNOS, COX-2), and mediators (NO, PGE, neutrophil inhibition). There is limited pediatric data, and no clinical studies have been published; hence, it is not clear whether this strategy is effective for neonatal and infant myocardial protection [89].

Induction and maintenance of cardioplegic cardiac arrest

Two basic methods of cardioplegic arrest are used: blood cardioplegia or crystalloid cardioplegia. The superiority of either method is still controversial [90].

Histidine-tryptophan-ketoglutarate (HTK), an intracellular crystalloid solution, has been widely used clinically for cardioplegic arrest during cardiac surgery. The HTK solution can offer sufficient cardiac protection to the neonatal heart for up to 2 hours of ischemia and provide equivalent myocardial protection to multidose cold blood cardioplegia with reduced transfusion requirements [91]. However, clinically significant hyponatremia can occur and severe fluctuations in sodium concentration should be corrected [92]. During induction, some institutions use warm blood cardioplegia with amino acid supplementation in stressed, hypoxic hearts to recover the intracellular energy stores before arrest [93]. This results in complete preservation of myocardial function, particularly in the chronic, hypoxic heart that might become ischemic under situations of stress.

Del Nido Cardioplegia solution has been increasingly used in congenital heart surgery in the past decade [94]. It is a 1 : 4 by volume blood: Crystalloid (Plasmalyte-A) solution containing potassium (~26 mEq/L), mannitol (~3.3 g/L), magnesium (~2 g/L), sodium bicarbonate (~13 mEq/L), and lidocaine (~130 mg/L). This solution is cooled and delivered at 8–12 °C, producing myocardial hypothermia to reduce oxygen consumption and promote myocardial preservation. The 20% by volume fully oxygenated patient blood supports aerobic metabolism for a finite period and also supports anaerobic glycolysis by providing buffering properties. Mannitol scavenges oxygen free radicals, reduces myocardial edema, and promotes osmotic diuresis. Magnesium acts as a calcium channel blocker, preventing the intracellular accumulation of calcium and diastolic dysfunction. Sodium bicarbonate and the Plasmalyte-A solution maintain neutral intracellular pH. The high potassium concentration produces a reliable depolarized diastolic arrest, and lidocaine acts as a sodium channel blocker and increases the refractory period of the cardiac myocyte.

Del Nido cardioplegia solution is administered antegrade as a single dose (20 mL/kg) during aortic clamping and has shown to provide safe myocardial protection with a longer period of arrest of up to 90 minutes. A dose of 10 mL/kg can be used for shorter crossclamp times of 30–45 minutes. Some centers re-dose at 60 minutes with a full or half dose, depending on the anticipated duration of crossclamping. This allows a bloodless operative field with less interruption compared to intermittent multidose cardioplegia. Single dose cardioplegia has been shown to have a higher rate of return to spontaneous rhythm, but no significant improvement in morbidity or lower requirement in inotropic support. Surgeon preference, anticipated aortic crossclamp duration, and case complexity should determine the selection of cardioplegia when planning procedures.

After aortic cross-clamping and sequestration of the coronary circulation, cardioplegia is generally administered in an antegrade fashion into the aortic root. As the neonatal heart lacks stenotic lesions, adequate distribution is not an issue. Perfusion pressures should be in the normal range of diastolic blood pressures and should not be higher than 30–50 mmHg. Higher pressures can lead to myocardial edema, particularly in the neonatal hypoxic heart [95]. The need for multidose cardioplegia in infants is controversial [96].

Myocardial collaterals are more important in neonatal hearts and can quickly lead to rewarming of the myocardium. Profound hypothermia or the reduction of flow can only provide limited additional protection, as other vital organs can be compromised (brain, kidney). Periodic reapplication of blood cardioplegia at intervals of 10–20 minutes counteracts non-coronary collateral washout.

Retrograde cardioplegia is utilized by some surgeons in selected situations, including cases that include an open aortic root and coronary artery translocations or transfers [97]. These include Ross procedures, arterial switch operations, and aortic root replacements. Retrograde cardioplegia is also used in some cases of severe aortic insufficiency where the ability to arrest the heart with standard aortic root cardioplegia is impaired. A small cannula, i.e. 6 Fr., is placed under direct vision into the coronary sinus, and cardioplegia is infused at pressures not exceeding about 50 mmHg. Because pediatric patients rarely have coronary stenosis, retrograde cardioplegia is used infrequently, and many surgeons prefer to avoid it altogether. Instead, the aortic root is opened immediately after cross-clamping, and cardioplegia solution is infused directly into each individual coronary artery ostia with special cannulae.

Reperfusion

Reperfusion is considered the phase when the coronaries are reperfused with regular systemic blood flow after cross-clamp removal and the patient is fully warmed. A few minutes before cross-clamp removal, lidocaine and magnesium sulfate may be administered to reduce the incidence of ventricular arrhythmias often seen after unclamping. Before aortic cross-clamp removal, TEE can be used to assist the surgeon in de-airing maneuvers, which may include manipulation of the heart and "milking" any intraventricular air through the aortic valve and out of the cardioplegia cannulation site. The patient may be positioned in Trendelenburg position before cross-clamp removal to avoid air bubbles being ejected into the cerebral circulation. This period is an important time in the course of cardioplegic arrest, as many mechanisms of cellular damage are completed during reperfusion. Optimally, normal sinus rhythm and myocardial contractility are restored during this time, while the patient is slowly rewarmed. In adults, reperfusion with warm blood before unclamping the aorta improved metabolic and functional recovery. Substrate-enriched reperfusion with the amino acids aspartate and glutamate, however, results in full recovery of function in infants [98]. Depending on the total ischemic time of the heart (aortic cross-clamp time), the heart requires time to restore the ATP stores in the myocardium. In general, 10–15 minutes are considered the minimum time requirement. For longer cross-clamp times, 25% of the time is considered appropriate as reperfusion time at our institution. Some centers administer calcium chloride 5–10 mg/kg into the CPB circuit 10–15 minutes after aortic unclamping to counteract the effect of higher magnesium concentrations from cardioplegia washout. The release of the cross-clamp often leads to a drop in blood pressure due to the higher release of anaerobic metabolites from the heart which causes vasodilation to a greater degree compared with the adult. This hypotension should not be treated by the administration of calcium at this point to reduce the risk of immediate reperfusion injury. In addition, at this time air can be ejected

into the right coronary artery, resulting in acute ischemia with ST-segment elevation and poor myocardial contractility; this is best treated with higher perfusion pressures and adequate time on CPB to allow passage of air through the coronary system and recovery of the myocardium. Calcium chloride 10–20 mg/kg can be administered to the CPB circuit or to the patient immediately before separating from bypass to correct the slight hypocalcemic state of CPB and improve myocardial contractility, but it should be avoided during the first 10–15 minutes of reperfusion of the heart. Additional doses of calcium are added to maintain normal levels of ionized calcium after bypass in neonates and infants, particularly as calcium and other electrolytes are lost quickly through the use of modified ultrafiltration and the infusion of citrate-rich blood products.

Separation from CPB and post-bypass phase

During rewarming, surgery is completed, and inotropic and vasoactive agents are started, but only after the ECG and myocardial contractility have improved to near normal. The rationale is that increasing myocardial oxygen demand too early in the post-ischemic heart may be detrimental. Ventilation commences after manual ventilation lung recruitment maneuvers, administration of nebulized β-agonist agents, if indicated, and thorough suctioning. The lungs are inspected visually if the pleura have been opened for complete inflation and deflation and any areas of atelectasis are addressed with inspiratory holding breaths near the patient's vital capacity. Severe ventilation problems may rarely need to be assessed with fiberoptic bronchoscopy for accurate assessment of endotracheal tube placement, and further suctioning of secretions. Hemofiltration and blood transfusion are used to achieve the desired Hct. Pressure transducers are re-zeroed and leveled. Left atrial and/or PA monitoring lines, if indicated, are placed at this time, as are temporary atrial and/or ventricular pacing wires. Forced air warming devices, circulating water mattresses, and ambient temperature are adjusted to desired levels. If the patient is incompletely rewarmed before separation from CPB, a significant temperature drop with the precipitous post-bypass reduction in core body temperature can occur ("afterdrop"). This may lead to vasoconstriction, shivering, increased oxygen consumption, and acidosis. However, post-ischemic hyperthermia can lead to delayed neuronal cell death and predispose to arrhythmias such as junctional ectopic tachycardia [99]. Mild degrees of hypothermia and certainly the avoidance of hyperthermia are essential in the perioperative period [100]. In the pediatric patient group, rectal temperature mostly reflects the peripheral temperature. Several endpoints have been proposed, such as nasopharyngeal temperatures greater than 35.0 °C, bladder temperature greater than 36.2 °C [101] or skin temperatures greater than 30 °C [102]. We use an endpoint of 35.5 °C rectal temperature, which is supported by the literature [103]. Cardiac rhythm is carefully assessed, and if the desired sinus rhythm at an adequate rate has not been achieved, atrial and/or ventricular pacing are instituted. If arrhythmias occur that have the potential to compromise hemodynamic status after CPB, they are treated before separation with pharmacologic approaches or internal cardioversion.

Finally, blood gas values are measured before weaning from CPB to optimize electrolytes and Hct. Once the patient is ventilated, warm and in a stable rhythm, in addition to all the post-CPB requirements being met, weaning is initiated by slowly decreasing the venous return. Arterial perfusion is continued until the appropriate filling is reached. If all parameters are stable, modified ultrafiltration is started. The heart is observed carefully during this process to avoid overfilling or to recognize right heart failure early on. Also, radial artery pressure may not be accurate following CPB and tends to underestimate both the systolic and mean central aortic pressures. A questionable pressure should be confirmed with central aortic pressure measured from the aortic cannula. A pulse oximeter waveform appearing immediately after termination of CPB is a sign of good peripheral perfusion and adequate rewarming. There may be a larger arterial–alveolar gradient between end-tidal carbon dioxide and arterial carbon dioxide tension at the end of bypass due to ventilation-perfusion mismatch. A rapidly increasing area under the curve of the capnograph and increasing end-tidal CO_2 are signs of good cardiac output and the pulmonary status during the termination of CPB. TEE and/or epicardiac echocardiography are essential to evaluate the cardiac repair. TEE is used prior to separation to assist in de-airing the heart. After separation from bypass, it has become standard of care for most institutions and operations to evaluate heart function, assess the repair and any residual lesions prior to removing the cannulas. The recently published Residual Lesion Score (RLS) Study evaluated 1,149 infants undergoing five common procedures: tetralogy of Fallot, complete atrioventricular canal (CAVC), arterial switch, coarctation or arch interruption with ventricular septal defect (VSD), and Norwood stage I palliation [104]. RLS was assessed on postoperative echo and graded as 1 (trivial or no residual lesions), 2 (minor residual lesions), or 3 (major residual lesions with/without reintervention before discharge). RLS 3 was present in 15–35% of patients depending on the operation. Patients with RLS 3 for any lesion were significantly more likely to suffer adverse outcomes than RLS 1 (fewer days alive and out of hospital), and other major outcomes were worse with RLS3 for all lesions except TOF. (Total ventilation time, total ICU stay, major medical events including cardiac arrest, ECMO cannulation, neurologic event, and others) (Figure 11.9A). This important study emphasizes the importance of the immediate post-bypass TEE/epicardial echo, and the contributions of the entire intraoperative team to decision making about immediate reinstitution of bypass and revision of the surgical repair. See Chapter 15 for further details about TEE and epicardial echocardiography.

Conventional ultrafiltration and modified ultrafiltration

The application of the CPB machine in children leads to a significant capillary leak more often than is the case in adults. This is caused by the relatively larger foreign surface area exposure and the resulting greater inflammatory response.

Hemofiltration has been defined as ultrafiltration with the return of intravascular replacement fluids to compensate for losses. In contrast, ultrafiltration simply removes fluid through a convective process involving filtration across membranes. Conventional ultrafiltration (CUF) during CPB or modified ultrafiltration (MUF) after the end of bypass both

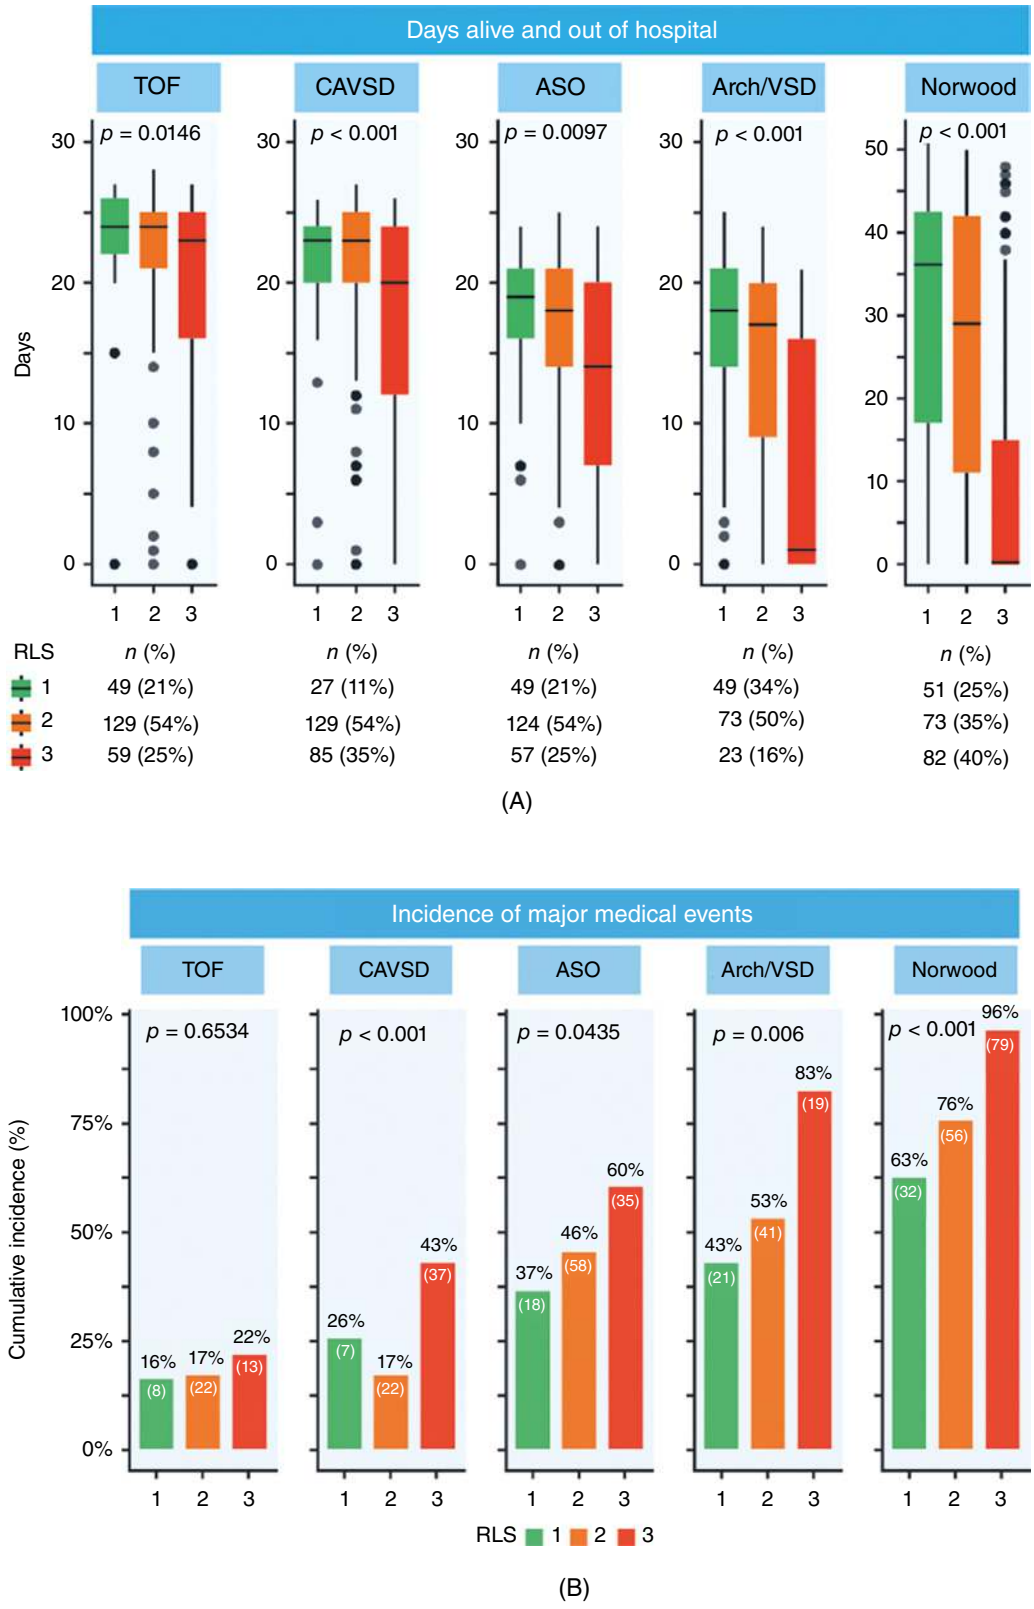

Figure 11.9 (A) Boxplot of days alive and out of hospital by RLS Score (higher number is better). The p values are from the Kruskal-Wallis Test. The number and percentage of patients in the 3 RLS classes are provided below the boxplot. TOF, tetralogy of Fallot; CAVSD, complete atrioventricular septal defect; ASO, arterial switch operation; Arch/VSD, aortic arch repair with ventricular septal defect; Norwood, Norwood stage I palliation. (B) Incidence of major medical events. P values are from Fisher's exact test. Includes mortality or heart transplant, cardiac arrest, ECMO cannulation, cardiac failure, mediastinitis, bleeding, neurologic event, renal failure, necrotizing enterocolitis, diaphragm or vocal cord paralysis, prolonged ventilation, sepsis, multisystem organ failure, noncardia operation, hemothorax, and readmission. (Source: Nathan et al. [104]. Reproduced with permission of Elsevier.)

reduce levels of proinflammatory cytokines and total interstitial body water after extracorporeal circulation. CUF and/or MUF are therefore standard procedures in all pediatric perfusion systems. The most commonly used procedure is MUF first described by Naik et al. [105, 106]. In this case, the bypass circuit is modified, and the flow is reversed at the end of CPB before protamine is given. Blood from the aortic cannula is directed through a hemofilter (blood flow rate of 100–300 mL/min) and infused back into the right atrium after warming and oxygenation. The ultrafilter pump is run at 10–30 mL/kg/min ultrafiltrate removal, with a vacuum on the ultrafilter. Replacement intravascular volume is infused from the venous reservoir as necessary. A steal phenomenon has been described whereby excessive flow rates divert blood from the aorta to the hemofilter, leading to cerebral and systemic deoxygenation. Several different methods of deciding when to terminate MUF are employed; some surgeons simply use a cutoff time of 15–20 minutes and others stop when the circuit volume has become diluted or when the desired Hct has been reached. Frequently, the surgeon's patience is the limiting factor. Filtering also will be stopped if the patient becomes hemodynamically unstable. Multiple beneficial effects can be observed (see Table 11.5); particularly important are the increase in Hct, the reduction of cytokines, improved myocardial perfusion, and a reduction in pulmonary vascular resistance (PVR) with the improvement of right heart function. Disadvantages of MUF are a delay in heparin reversal and decannulation of approximately 10–20 minutes, as well as the possibility of hemodynamic instability if preload is not adequately maintained by the perfusionist. However, surgical hemostasis can be carried out during this time period. The combination of MUF after CPB with zero balance conventional ultrafiltration (ZBUF) on bypass can eliminate additional unnecessary volume from cardioplegia or irrigation. The use of filtration during CPB (as conventional, dilutional, or zero balance ultrafiltration) also removes inflammatory mediators and vasoactive substances [107, 108]. Studies [109] have shown that compared with control patients, patients who have modified ultrafiltration after bypass have substantially less increase in total body water, have less interleukin-8 (IL-8) and complement in their bloodstream [110, 111], require less blood transfusion [112, 113], show improved coagulation factors [114, 115] and faster recovery of systolic blood pressure [105], pulmonary function [116], and cerebral metabolic activity [117] (Table 11.5). Modified ultrafiltration performed after CPB reverses hemodilution and decreases tissue edema and thereby accelerates postoperative recovery [118]. The combined use of ultrafiltration of prime solution, zero-balance ultrafiltration on bypass, and MUF strategy seems to be the most effective method, even though the principal clinical outcomes are similar between modalities [119]. A recent review of 90 clinical studies of the various forms of ultrafiltration concluded that MUF resulted in improved myocardial function, reduced fluid overload, and reduced bleeding and transfusion complications [120]. Zero-balance ultrafiltration (ZBUF) has been consistently associated with a reduction in inflammatory cytokines and improved pulmonary function and compliance. There is mixed evidence that any UF approach can reduce ventilation time and ICU stay. Because of the heterogeneity of the studies, no single approach was recommended.

Table 11.5 Effects of modified ultrafiltration

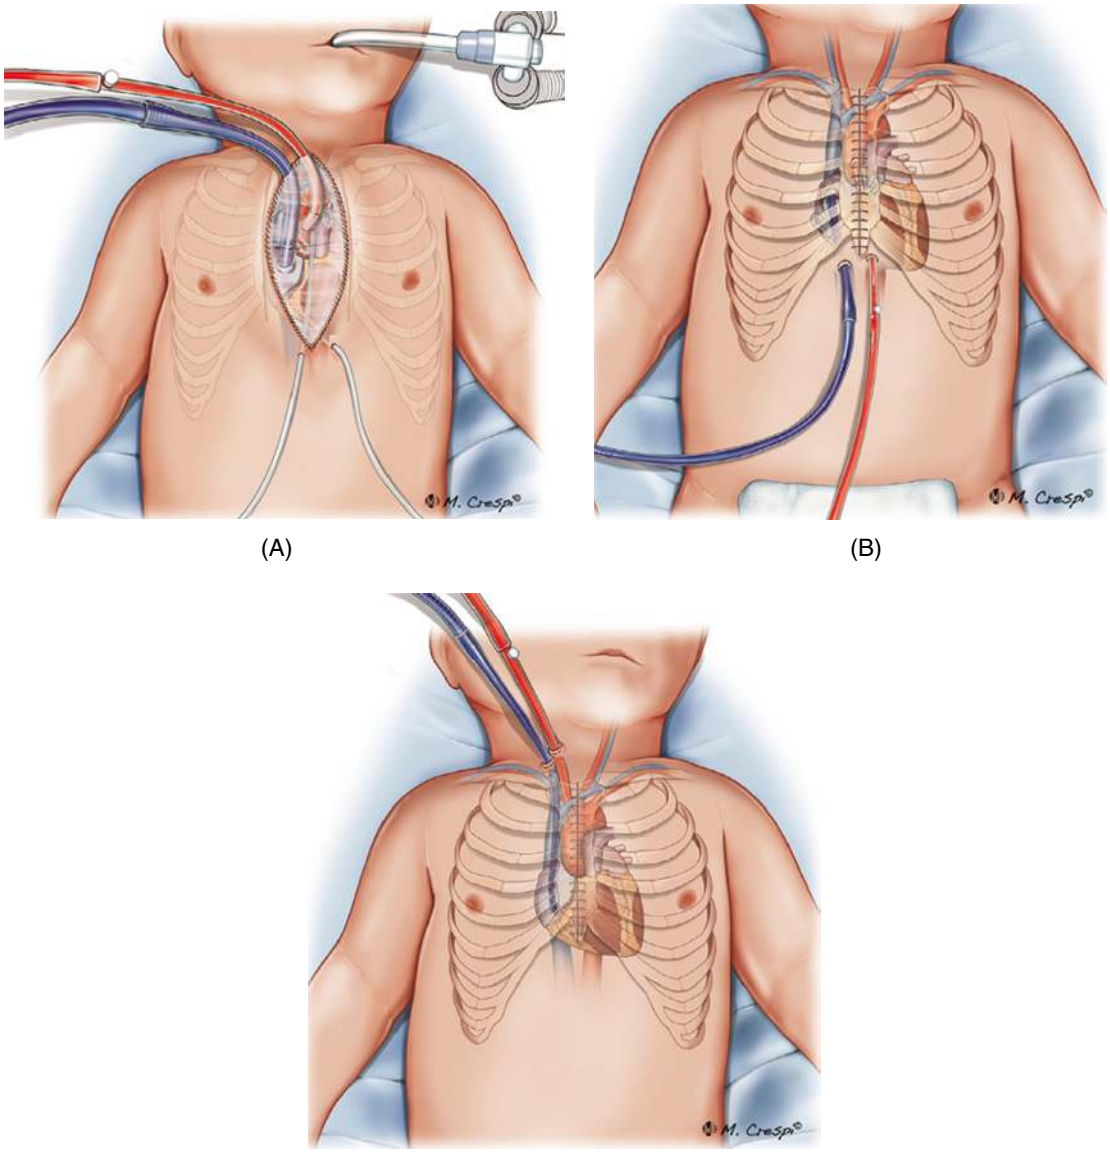
Parameter	Effect
PVR, PAP	Decreases due to oxygenation and warming
Stroke volume, CO	Left ventricular stroke volume increases secondary to improved pulmonary blood flow
SVR, blood pressure	Increases due to the reduction of vasoactive substances (interleukins, bradykinin, etc.)
Hemoglobin, hematocrit	Increases due to hemoconcentration
Interstitial body and lung water	Decreases secondary to water removal
Improved gas exchange [79]	Improved V/Q mismatch

Source: Elliott et al. [109]. Reproduced with permission of Elsevier.
CO, cardiac output; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance; SV, single ventricle; SVR, systemic vascular resistance; V/Q, ventilation-perfusion.

Failure to separate from CPB

Occasionally, despite escalating inotropic support, a child is unable to maintain adequate cardiac output and systemic oxygen delivery and therefore a return to CPB must be considered. An assessment of arterial blood gas and Ca^{2+} values, and whether intended inotropes are infusing correctly is important. Immediate TEE evaluation should be performed for the possibility of residual defects that require surgical attention. If no further surgical intervention is warranted, the source of the difficulty in weaning from CPB should be sought and other therapies must be considered. Is the Hct level adequate for this child? Too much hemodilution can lead to decreased systemic vascular resistance (SVR). The ideal Hct depends on the pathology and is probably in the range of 35–45% for complex repairs. Is the SVR too low? In children with low SVR who are either non-responsive to catecholamine infusions or who are experiencing adverse effects due to catecholamine therapy, arginine vasopressin has been shown to be a potent vasoconstrictor, with infusions resulting in increased MAPs and decreased catecholamine dependence. Its use in children appears promising when cardiac function is adequate [121, 122]. Fixed doses of 0.01–0.04 units/kg/hour of vasopressin are used. Exposure to endotoxin and cytokines as on CPB can trigger a *de novo* synthesis of the inducible, calcium-dependent isoform of nitric oxide synthase. Methylene blue inhibits this process by decreasing intracellular cyclic guanosine monophosphate concentrations through guanylate cyclase inhibition, thus blocking its vasodilator properties. It increases arterial pressure, SVR, and left ventricular stroke work, but does not increase cardiac output, oxygen delivery, or oxygen consumption. Methylene blue in a dose of 2 mg/kg followed by 1 mg/kg/hour has been used successfully in the setting of perioperative vasoplegia in adults [123], and neonatal sepsis [124], and in a case report of infective endocarditis in a 10-year-old girl [125]. Side-effects are rare in doses <2 mg/kg, but pulmonary hypertension and other side-effects can occur with repeat doses [126]. Is the right heart failing? Pulmonary hypertension

with resultant right heart failure may occur post-CPB, either as a result of long-standing increases in PA pressures or PVR, now exacerbated by the effects of CPB or as a result of acute increases in PA pressures or PVR secondary to protamine administration. Management has been challenging, as IV medications often affect both SVR and PVR. Selective pulmonary vasodilatation became possible with the introduction of inhaled nitric oxide (iNO), an endothelium-derived vasodilator that is rapidly deactivated by hemoglobin [127]. Several groups of patients have been shown to potentially benefit from iNO administration post-CPB [128, 129]. Patients with single-ventricle physiology undergoing total cavopulmonary anastomosis (Fontan procedure) with elevated PVR post-CPB, as well as children with elevated pulmonary venous pressures secondary to total anomalous pulmonary venous connection or congenital mitral stenosis, frequently show improvement with administration of iNO. For patients on iNO, caution should be exercised when transporting from the operating room to the ICU in order to avoid interruption of therapy, as rebound pulmonary hypertension and rapid clinical deterioration may occur. Other options to lower PVR include sildenafil 0.5 mg/kg through a nasogastric tube [130], IV sildenafil, or nebulized prostacyclin [131]. If severe left or right ventricular dysfunction persists in the absence of residual anatomic defects that can be surgically corrected, consideration may be given to continued mechanical support of the circulation. Currently, immediate pediatric options for mechanical circulatory support are extracorporeal membrane oxygenation or short-term left ventricular assist device in neonates, infants, and children. These techniques are most useful when recovery of ventricular function is expected within 24–72 hours, or when cardiopulmonary support is unavoidable. Cannulation configurations are shown in Figure 11.10 [132]. A recent review of postcardiotomy veno-arterial ECMO of more than 40 studies reporting more than 3,000 patients from 1990–2018 indicated a post-ECMO survival to hospital discharge of 40–60% in most studies [132]. Duration of ECMO support for survivors tended to be 3–5 days, and major complications included bleeding (13–69%), neurologic morbidity (11–51%), sepsis (10–50%), and renal failure (9–56%). Greater than 95% of reports of postcardiotomy mechanical support are ECMO. Veno-venous ECMO can be utilized for isolated respiratory failure. Another approach is short-term VAD support; Poh and colleagues reported 55 single ventricle patients supported with centrifugal VAD for postcardiotomy failure [133]. Median support was 3.5 days, and 53% were weaned off support, but only 33% survived hospital discharge. See Chapter 37 for further details about mechanical support.



Heparin reversal and transfusion management

During modified ultrafiltration, cardiac function and the quality of the surgical repair are assessed via TEE, and if found to be satisfactory, protamine is administered to neutralize residual heparin after completing MUF. In small infants and palliated anatomies, the goal Hct separating from bypass should be 40–45%. This improves hemodynamic stability and allows immediate correction of coagulation disorders by infusion of blood products.

Protamine 1–1.5 mg/kg is given for each 100 units of the initial heparin dose to reverse its effect. This assumes that any further doses are given to maintain a heparin level and prevent overdosing of protamine with its associated effects on platelet function (reduction of the interaction of the glycoprotein Ib receptor with von Willebrand factor) [134]. If the ACT is still elevated or CPB prime (heparinized) blood is reinfused into the patient, an additional 25% of the initial dose of protamine is added and the ACT rechecked. However, particularly in infants, the administration of protamine and the persistent treatment of a suspected incomplete heparin reversal should not distract and delay the treatment of other commonly associated post-bypass coagulopathies such as thrombocytopenia, platelet dysfunction, and other coagulation factor deficiencies [135–138]. Individualized management of anticoagulation and its reversal results in less activation of the coagulation cascade, less fibrinolysis, and reduced blood loss and need for transfusions [58], while improving the clot stability as assessed by thromboelastography. However, care should be taken not to overdose the total amount of protamine [139, 140]. After one-third to one-half of the planned protamine dose is administered, blood from the surgical field must not be returned to the cardiotomy reservoir to avoid circuit thrombosis in case it is necessary to reinstitute bypass. An ACT or heparin level confirms adequate heparin neutralization. More protamine (0.5–1 mg/kg) can be given if either test remains prolonged and bleeding is a problem. Hypotensive protamine reactions can occur when protamine complexes with heparin because complement is released. This is much less common in children than in adults. Hypotension can be attenuated by adding calcium chloride (2 mg/mg protamine). Pediatric protamine reactions are rare, occurring in 1.7–2.8% of patients undergoing CPB [141]. Life-threatening reactions to protamine represent true allergic or pulmonary hypertensive reactions. Protamine reactions should be treated with epinephrine as the first-line agent and careful volume resuscitation as required. For severe reactions, it may be necessary to readminister heparin and resume CPB. Hemostatic management can be guided by thrombelastography. Newer devices allow a full "point-of-care" functional assessment of the coagulation within 10–15 minutes [142]. A recent retrospective study of 100 infants assessed before and after a heparin–protamine titration system (Hepcon®, Medtronic Corp. Minneapolis, MN, USA) reported that more limited protamine dosing neutralized heparin but also prevented anticoagulation effects (prolonged R values on thromboelastography [TEG]) caused by excessive protamine [139]. Further details can be found in Chapter 16.

Antifibrinolytic therapy

Bleeding is more common in pediatric cardiac surgery patients than in adults. Both qualitative and quantitative abnormalities in coagulation proteins have significant functional sequelae, which influence the hematologic responses to CPB. Cyanotic CHD itself is associated with coagulation abnormalities, including platelet abnormalities and fibrinolysis. There is extensive published research on the use of aprotinin and lysine analog antifibrinolytics to modify the adverse effects of CPB in adults, but for pediatrics, their dose and effects are much less clear.

(A) (B)

(C)

Figure 11.10 (A) Central ECMO cannulation via aorta and right atrium with the open sternum. (B) central cannulation via the aorta and right atrium with closed sternum and subxiphoid cannulae exit. (C) Peripheral ECMO cannulation via carotid artery and internal jugular vein with the closed sternum. Left atrial decompression may also be required with direct left atrial cannulation, atrial septostomy, or other methods. Also, if systemic to pulmonary artery shunt is present, it is usually partially occluded with a clip to limit pulmonary blood flow as in (A) and (B). (Source: Lorusso et al. [132]. Reproduced with permission of Elsevier.)

Two agents are currently available to modify the hemostatic response to CPB: ε-aminocaproic acid (EACA) and tranexamic acid (TA). Aprotinin, a serine protease inhibitor with anti-inflammatory properties, was withdrawn from the market in 2007 due to safety concerns in adult patients and will not be discussed further.

Epsilon-aminocaproic acid (EACA) and tranexamic acid (TA)

Both EACA and TA appear effective in reducing bleeding and transfusion in cyanotic patients, provided an adequate dose is administered. Their efficacy in other high-risk and mixed populations is not as well established. These drugs seem to lack significant clinical anti-inflammatory efficiency beyond their effects on coagulation [143, 144]. Suppression of excessive plasmin activity may play an important role in the generation of proinflammatory cytokines during and after CPB [145]. For an excellent and detailed recent review, please refer to Eaton [146].

Tranexamic acid dosing

Chauhan et al. [147], in a dose-ranging study of TA published in 2004, found the most effective dosing scheme of the four studied to be a 10 mg/kg load, 10 mg/kg in the pump prime,

and 10 mg/kg after protamine. More recent pharmacokinetic studies have shown effective concentrations of 20 µg/mL [148] using a dosing schedule with 6.4 mg/kg followed by 2–3.1 mg/kg, depending on weight [149]. Another pharmacokinetic-based scheme specifies for neonates 0–2 mo.: 15 mg/kg bolus; 20 mcg/mL of CPB prime; 2.5 mg/kg/hour infusion; for infants 2–12 mo.: 9 mg/kg bolus; 20 mcg/mL of CPB prime; 2 mg/kg/hour infusion; and children >12 mo.: 4 mg/kg bolus; 20 mcg/mL of CPB prime; 2 mg/kg/hour infusion [150]. Continuous and discontinuous doses of TA effectively inhibit fibrinolysis [151]. A high-dose regimen leading to blood concentrations greater than that required for D-dimer inhibition may be more efficient than lower dosages [152]. Previous studies have described TA doses of up to 100 mg/kg as a loading dose in infants and children; reports of seizures associated with high dose TA in adults combined with the pharmacokinetic data cited above argue against these doses and they should not be used in children. [153]

EACA dosing

Based on a pharmacokinetic study [154], in neonates, an initial loading dose of 40 mg/kg, an infusion of 30 mg/kg/hour, and a pump prime dose of 0.1 mg/mL of prime will maintain plasma concentrations above 50 mg/L in 90% of neonates. In older patients, the initial loading dose is 75 mg/kg, a pump-priming dose of 75 mg/kg followed by an infusion of 75 mg/kg/hour to establish and maintain a therapeutic plasma concentration (130 µg/mL) in 95% of patients [155].

Rapid IV injection of TA or EACA may cause hypotension. We infuse loading doses over approximately 20 minutes before the surgical incision. Some institutions delay antifibrinolytic dosing until the institution of bypass in patients who have systemic to pulmonary artery shunts, citing the risk of thrombosis.

Comparison studies of antifibrinolytics

With the considerable variability among studies of the three drugs under consideration in terms of design, dose, and outcomes, it is difficult to draw any conclusions about relative efficacy from the literature. There are a few published comparison studies. Chauhan et al. [156] compared low-dose aprotinin, EACA, and the combination in 300 cyanotic patients undergoing cardiac surgery. There was no difference between EACA-treated and aprotinin-treated patients in any measured variable. The same group compared TA and EACA in a placebo-controlled study of 150 patients with cyanotic CHD [147]. Both drugs were superior to placebo, but there were no significant differences between the treated groups with respect to 24 hours blood loss, transfusion, or re-exploration rate. Finally, the effects of aprotinin and TA were compared in 100 children, evenly divided into four groups: placebo, TA, aprotinin, and a combination of the two drugs [157]. Again, all treatment groups fared better than placebo in 24 hours blood loss and transfusion, with no significant differences among the three treated groups. Thus, the limited comparative evidence would suggest that the three drugs are equivalent in efficacy for reduction of bleeding and transfusion, at least with the doses and patients studied, and there is little or no advantage to combination therapy.

In summary, evidence supports the efficacy of the lysine analog antifibrinolytics EACA and TA, and aprotinin to decrease bleeding and transfusion in pediatric patients undergoing cardiac surgery involving CPB. This benefit is likely to be more significant in high-risk groups, such as cyanotic patients, newborns, complex surgeries, and reoperations. Aprotinin seems to have the strongest anti-inflammatory capacity of the antifibrinolytics [158]. The safety profile of these drugs is not fully understood, but each may have significant side effects that require further research in the future [159–161]. Further discussion of antifibrinolytic therapy is presented in Chapter 16.

KEY POINTS: MANAGEMENT OF PEDIATRIC CPB

- Pre-bypass, 300–400 units/kg heparin are injected to reach a target ACT >400 seconds.
- Two methods of cardioplegic arrest are used: hyperkalemic blood cardioplegia or hyponatremic crystalloid cardioplegia.
- Reperfusion after unclamping should be at least 8–10 minutes or 25% of the total cross-clamp time.
- Separation from bypass is initiated after the resumption of ventilation and reduction of venous outflow to fill the heart.
- Conventional ultrafiltration during CPB and modified ultrafiltration after CPB are commonly employed.
- Afterwards, heparin reversal is achieved with protamine, and coagulation disturbances are corrected with platelets and other coagulation products, guided by ACT and/or laboratory diagnostics (e.g., TEG).
- The antifibrinolytics TA and EACA are effective and used in most surgeries with an increased risk of bleeding.

Effects of CPB on organ systems

Cardiopulmonary bypass-induced systemic inflammatory response syndrome (SIRS) is a host response to the exposure of blood components to the foreign surface of the CPB circuit and initiation of the complement cascade. The early inflammation phase is triggered as soon as blood comes into contact with the synthetic circuit by activation of F-XII (coagulation factor) and C3 (immune factor) [162–164], and the late phase, following the release of the aortic cross-clamping, is driven by ischemia-reperfusion and endotoxemia. As a consequence, pro- and anti-inflammatory mediators are released into the circulation and the balance between these two groups of mediators is probably more important than the absolute levels of any of them [163–169]. Hypothermia and transfusion, frequently associated with pediatric CPB, are also two non-specific factors activating the inflammatory response [163–165, 167, 169–172]. Hypothermia modifies the metabolism of inflammation biomarkers by delaying, rather than decreasing, inflammatory systemic response [162–165, 167, 168, 173, 174]. Furthermore, genetic factors are involved in the inflammatory response and may

account for inter-patient variability [163–174]. Although the lungs are often the primary organ targeted, SIRS after CPB may be severe enough to affect other end-organ function. One of the major challenges is how to modulate the systemic inflammatory response, not only to control the drawbacks of inflammation but also to preserve a level of inflammation needed for host defense and wound healing. This should be the goal of further research.

Currently, there are a number of strategies being employed targeting the prevention of SIRS and multisystem organ failure, including the use of corticosteroids, protease inhibitors, thromboxane inhibitors or antagonists, prostacyclins, complement inhibitors, and cytokine inhibitors, including monoclonal antibodies and IL-1 receptor antagonist. With the exception of corticosteroids, all of these other approaches are experimental and thus far have not shown a beneficial effect on clinical outcomes, even though some have shown the intended effect on their molecular targets.

Multiple studies in children on corticosteroids have consistently shown a reduction in the inflammatory response, with some demonstrating improvement in clinical outcome [164–175]. A limiting factor in some studies using corticosteroids has been the lack of effect on clinical outcome and the higher incidence of postoperative infections and renal dysfunction with increasing cumulative corticosteroid exposure [166, 157, 170, 176–180]. The routine prophylactic use of steroids therefore cannot be recommended and may only be indicated in high-risk patients (DHCA, arterial switch operation) [176, 177]. A 2020 Cochrane review performed a meta-analysis of pooled data from eight randomized controlled trials in 478 patients [181]. Conclusions were as follows: (i) Moderate certainty of evidence that corticosteroids do not change the risk of in-hospital mortality (RR 0.83, 95% CI 0.33–2.07); (ii) high certainty that they do reduce the duration of mechanical ventilation (mean 11.39 hours lower, 95% CI 20.29–2.45). In addition, there was high certainty that corticosteroids made no difference in ICU stay, and moderate certainty of no difference in the hospital stay. The STRESS study is underway and will randomize 1,200 infants less than 1 year in multiple centers to methylprednisolone 30 mg/kg in the CPB prime vs. placebo in a blinded fashion [182]. Primary outcome is a global rank score of death, major morbidities, and hospital length of stay.

There is also evidence that pulsatile CPB flow significantly decreases endotoxin levels. An explanation could be the improved microcirculation and end-organ perfusion during pulsatile perfusion [178, 179]. However, there is a paucity of clinical studies demonstrating an outcome difference with this technique, and therefore, it has not been widely adopted in pediatric perfusion practice. For further details on the mechanism of end-organ dysfunction and treatment, refer to Chapter 12.

Neurological injury and protection

Brain injury in children with CHD has been documented before and after surgery for CHD. Some complications are apparent soon after the operation, such as seizures, stroke, and coma, whereas others appear long after the operation, such as cognitive deficits and psychomotor delay. Radiological and pathological studies have described a spectrum of brain lesions after pediatric cardiac surgery, located mainly in the neocortex, periventricular white matter, and basal ganglia, corresponding to the neurological deficits seen clinically [180, 183]. These subtle defects manifest as a developmental signature that includes cognitive and intellectual impairment, attention and executive function deficits, visual-spatial and visual-motor skill deficiencies, speech and language delays, and behavioral difficulties. The spectrum of lesions is consistent with hypoxic–ischemic injury, contrary to mostly embolic events in the adult population. When this injury occurs – before, during, or after the operation – remains uncertain. Adverse neurological outcomes after neonatal cardiac surgery are multifactorial and related to both fixed and modifiable mechanisms. Fixed factors include known genetic syndromes, structural central nervous system malformations (an incidence of up to 29% in HLHS) [183], multiple surgeries (leading to multiple insults), blood flow patterns *in utero*, preoperative cerebral hypoxia, embolic events occurring during the balloon atrial septostomy procedure [184], socioeconomic status, and a poorly defined genetic predisposition. Potentially modifiable factors include preoperative hypoxia–ischemia, intraoperative use of DHCA, neuroinflammation of the brain [185–187], and postoperative cardiopulmonary derangements [188]. Some interventions that may limit brain injury from DHCA include preoperative steroids, hyperoxygenation before DHCA, allowing at least 20 minutes of cooling to ensure adequate cerebral protection, packing the head in ice, intermittent cerebral perfusion between 15 and 20 minute periods of DHCA (Figure 11.11), and modified ultrafiltration after CPB. Other modifiable factors of CPB management include optimal flow at all temperatures [189, 190], the avoidance of extreme hemodilution [27] and emboli [191], pH-stat management [192, 193], and modulation of the inflammatory response by the use of ultrafiltration and steroids [164]. According to a recent meta-analysis, the only intervention supported by a high degree of evidence is the avoidance of extreme hemodilution to Hct below 25% [194]. Whereas myocardial protection and systemic oxygen delivery are continuously monitored during neonatal CPB, adequate cerebral perfusion has traditionally been evaluated by surrogate markers such as perfusion pressure, mixed venous oxygen saturation, or base deficit and lactate levels. However, there are now real-time intraoperative cerebral monitoring devices available for clinical use, the potential benefits of which are becoming recognized [195]. The most widely used technologies include NIRS, transcranial Doppler, raw and processed electroencephalography, and serum measurement of S100B protein. Real-time technologies allow immediate interventions upon interruption of optimal cerebral flow and may improve outcome [196]. Improved strategies to prevent injury in these arenas are much needed [197]. For an extensive discussion of neurological monitoring and outcomes, see Chapter 14.

Pulmonary effects

Post-bypass lung injury may be a result of ischemia-reperfusion injury or may be associated with the systemic inflammatory response caused by extracorporeal circulation [198]. Alveolar injury is also associated with cyclic closing and opening of alveoli, with shear injury to the

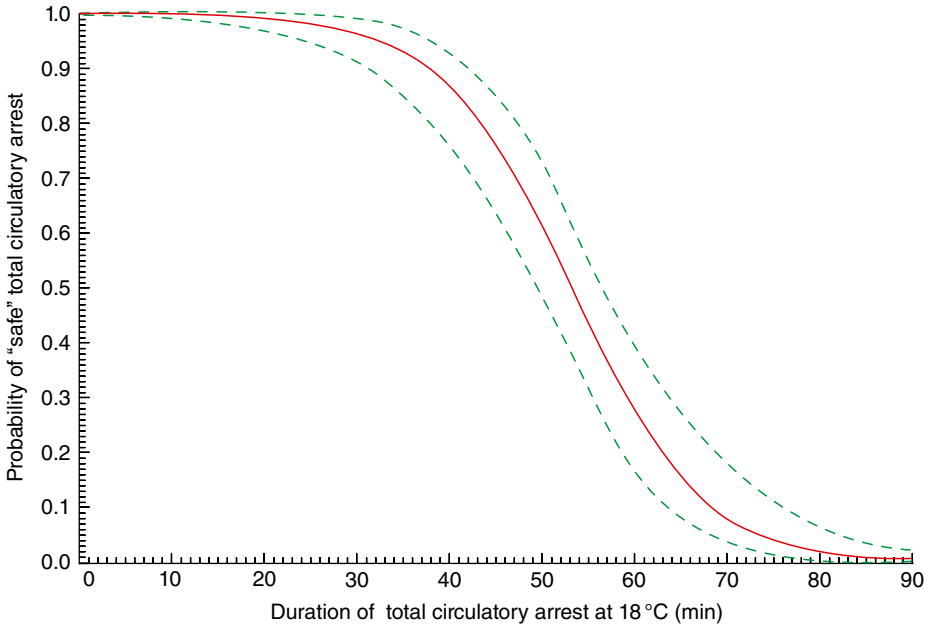


Figure 11.11 Probability of "safe" deep hypothermic circulatory arrest. At 18 °C, the likelihood of neurological injury becomes exponentially greater beyond 45 minutes of circulatory arrest. (Source: Kirklin and Barrett-Boyes [68]. Reproduced with permission of Elsevier.)

alveolar-capillary interface causing increased permeability and pulmonary edema with a significant pulmonary inflammatory reaction [199]. Etiologies of postoperative pulmonary dysfunction after CPB include a decrease in total lung capacity, functional residual capacity, atelectasis, pulmonary edema, increased inspiratory oxygen, and ventilation-perfusion mismatch [200]. Administration of a FiO_2 of 1.0 during CPB may lead to absorption atelectasis and oxygen toxicity. Lung injury could be prevented in a piglet model using continuous pulmonary perfusion on CPB [201]. In a study by Pizov et al. [202], lung function improved later postoperatively in patients ventilated with 100% oxygen during CPB. Several studies have assessed modes of ventilation on bypass and their effects. Continued ventilation throughout CPB is associated with superior postoperative respiratory function in certain clinical scenarios, possibly due to attenuation of the ischemia–reperfusion injury, but this technique has yet to gain wider acceptance. Maintaining ventilation and PA perfusion during CPB has shown some benefits in limiting pulmonary platelet and neutrophil sequestration, and attenuating thromboxane B_2 response after CPB [203, 204]. To date, the evidence favoring continuous ventilation alone during CPB on cardiopulmonary function is inconsistent, with most studies showing no benefit [205–207]. At our institution, we prefer continued ventilation at low tidal volumes, room air, and low positive end-expiratory pressure (PEEP) settings in patients undergoing simple procedures without cross-clamping like a right ventricle–conduit exchange, etc. if tolerated by the surgeon. Many surgeons will require total lung collapse to allow complete access to the heart, without movement, for neonatal and infant patients with limited intrapericardial space. In more complex cases, we start ventilation after thorough pulmonary toilet and suctioning with a recruitment maneuver. This is usually done in the context of de-airing and aortic clamp removal. Afterward, we continue ventilation at low settings with approximately 2 mL/kg and a PEEP setting of 5–8 cm H_2O with a FiO_2 of 0.21. Full ventilation is resumed just before weaning from bypass, usually in a pressure-regulated, volume-controlled mode to maintain minute ventilation with stable tidal volumes. The pressure limit is carefully monitored and set 5 cmH_2O above the upper inspiratory pressure.

Renal, hepatic, and gastrointestinal effects

Little is known about the epidemiology and risk factors for the development of acute renal failure in children post-CPB for cardiac surgery. The incidence of acute renal dysfunction complicating open-heart surgery in children is significant, at 11–17% [208, 209]. Low cardiac output was a significant predictor of developing a renal injury. Other risk factors include young age, the preoperative need for mechanical ventilation, use of milrinone, gentamicin and furosemide, the duration of CPB and anesthesia and multiple cross-clamp times as well as the transfusion of blood products [210]. This is often related to the complexity of the operation. Unexpectedly, DHCA was not a predictor of postoperative renal dysfunction. On the one hand, better and more sophisticated surgical and CPB techniques are available, while on the other, children with more complicated cardiac lesions requiring longer CPB time are operated on today. There is also evidence that the neonatal kidney is more vulnerable to conditions of hemodynamic stress [209] with loss of autoregulation leading to blood pressure-dependent renal blood flow and ischemia-induced renal injury. All of these conditions render the neonate more prone to complications of ischemia than the older infant or child. Renal replacement therapy is required in 1.6–7.7% of patients. In children, the mortality rate in those requiring dialysis following CPB is reported to

range from 46 to 67%. However, renal failure is often temporary. Among those who recover, 93–100% of survivors of renal replacement therapy after CPB surgery have normal renal function at discharge from the hospital [211, 212]. Peritoneal dialysis (PD) is a safe and effective treatment for children after CPB surgery and should be initiated early in the course of acute renal injury [213–217]. Peritoneal dialysis is also utilized in some centers routinely after complex neonatal and infant surgery, to counteract the frequent low urine production from antidiuretic hormone release and acute renal ischemic effects [215]. Peritoneal dialysis also effectively filters inflammatory mediators, and the overall result is to limit fluid accumulation and shorten the time of mechanical ventilation [218]. Kwiatkowski and colleagues randomized 73 patients <6 months who had oliguria after CPB surgery to PD vs. furosemide for prevention of fluid overload [219]. The furosemide group had a three-fold higher risk of 10% fluid overload and was more likely to have prolonged ventilator and inotrope use, and higher electrolyte abnormality scores. There were no differences in mortality, or ICU or hospital stay. There were no serious complications of PD. Plasma and urine neutrophil gelatinase-associated lipocalin thresholds are early predictive biomarkers for AKI [220]. A recent review of AKI after CPB in infants reinforces the conclusions noted above; despite some promising research on biomarkers of renal injury, none has become clinically available; the principles of supporting cardiac output and instituting renal replacement therapy early when AKI is recognized are emphasized [221].

Several investigations provide evidence that intestinal organ function is altered during CPB. Splanchnic, but not systemic, oxygen extraction increases during normothermic, non-pulsatile CPB. Splanchnic blood flow is not significantly affected by normothermic or hypothermic CPB at normal pump flows compared with the pre-bypass condition [222, 223]. The increase in splanchnic oxygen extraction during hypothermia, indicating a splanchnic oxygen supply/demand mismatch, was, therefore, most likely caused by a decrease in splanchnic oxygen delivery, in turn, caused by a decrease in hemoglobin concentration secondary to hemodilution. The splanchnic region might be more susceptible to a decrease in oxygen delivery by hemodilution, compared with other organs. Normothermic CPB leads to a loss of gastrointestinal (GI) barrier function independent of the duration of CPB. Current data indicate that intestinal mucosal autoregulation is maintained during CPB within the pressure range 50–75 mmHg [224]. Improving pump flow rather than infusing vasoconstrictive drugs to increase aortic pressure can improve both splanchnic and renal perfusion [225], and improve the postoperative course in children [226]. Although GI complications may have a low incidence (0.3–3%), they are associated with high mortality (13–63%) [227, 228]. Several risk factors (e.g., use of vasopressors, pre-existing comorbidities, perioperative hypotensive episodes, and valve surgery) have been evaluated for the development of alterations in GI organ function. Liver dysfunction rarely occurs after CPB.

Endocrine and metabolic response to CPB

In children, hypoalbuminemia and hyperchloremia are the predominant acid-base abnormalities after CPB, whereas lactic acidosis and wide ion gap acidosis are rare [229]. Hyperchloremia following CPB appears to be a benign phenomenon. By contrast, hypoalbuminemia, an alkalinizing force, was associated with a prolonged requirement for intensive care.

KEY POINTS: EFFECTS OF CPB ON ORGAN SYSTEMS

- A SIRS is the natural response of the body to contact with the circuit, surgery, and the disturbance of homeostasis.
- Multiple interventions have been attempted with minimal success except for the avoidance of blood transfusion and the minimization of the contact surface.
- All major organs are affected, from neuroinflammation to acute lung, GI tract, and kidney injury, as well as metabolic and endocrine disturbances.

Special CPB management issues

Warm CPB

Hypothermic CPB associated with cold myocardial protection is commonly used for neonatal cardiac surgery. The rationale is to protect the brain in case of failure of oxygen delivery (Figure 11.12). In addition, hypothermic bypass helps to complete cold myocardial protection by delaying myocardial rewarming and maintaining a low metabolic state. There is a growing body of evidence demonstrating that hypothermia also induces deleterious effects, which may culminate in end-organ dysfunction. The benefits of hypothermia are balanced by its drawbacks, including impaired hemostasis [230], microcirculatory dysfunction, capillary leakage, endotoxin release, disturbed glucose metabolism [231], and decreased myocardial contractility [232]. Hypothermia delays the recovery of the mechanical function of the myocardium and reduces basal metabolism.

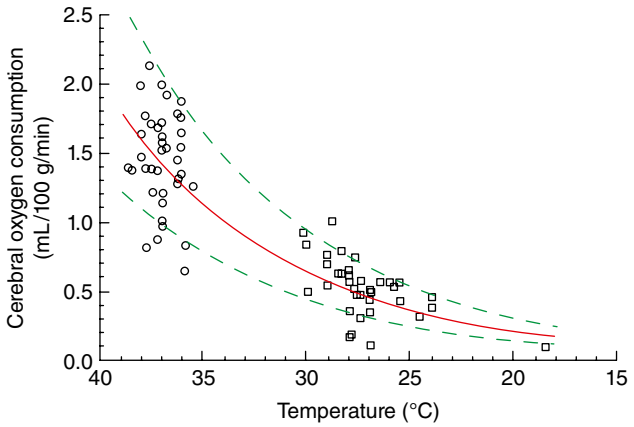

Figure 11.12 Relationship between cerebral oxygen consumption and nasopharyngeal temperature during bypass at a flow of 2 L/min/m². (Source: Kirklin and Barrett-Boyes [68]. Reproduced with permission of Elsevier.)

This reduction has only a minimal impact on oxygen needs. Less well understood is the deleterious effect of hypothermia on the myocardium. Reactivity of the microcirculation is impaired after deep hypothermia, as are many cellular functions. The lungs are very sensitive to CPB, and hypothermia may increase the capillary leakage more than normothermia by inducing microcirculatory dysfunction and impairing endothelial responses [233]. By reducing oxygen demand, hypothermia is effective in protecting the brain, but it impairs vasomotor and cerebral oxygen regulation [234], alters energy metabolism [235], and increases intracranial pressure, and overshoot during rewarming may induce neurological injury [236]. Furthermore, the protective effect of hypothermia on the inflammatory reaction and neurological recovery may have been previously overestimated [237]. The inflammatory reaction induced by CPB seems to be delayed rather than diminished by hypothermia [238]. Finally, with prolonged DHCA, long-term follow-up has shown impaired neurodevelopmental outcomes [239]. Therefore, normothermic CPB, already commonly used in adult cardiac surgery, has been promoted and progressively extended into pediatric practice [240]. Favorable surgical results have been achieved with normothermic bypass for even complex operations such as the arterial switch operation [241]. See the section above under Cooling and Temperature Management for more details.

Temperature is not the only characteristic of normothermic CPB. Other factors to be considered are flow and Hct. The flow generally used for mild hypothermic CPB is 2.0–2.4 L/min/m^2 (Figure 11.8). In normothermic CPB, pump flow is maintained throughout the procedure at 3.0–3.5 L/min/m^2. In terms of hemodilution on CPB, Hct is maintained above 30% during the procedure, with 40% by the end of CPB for normothermic CPB. Thus, normothermic CPB is better characterized by "normothermic, high-flow, high- hematocrit CPB" [57].

Deep hypothermic circulatory arrest

Hypothermia has been utilized since the early days of CPB to allow reduced flows in order to improve intracardiac surgical exposure. Bigelow et al. were the first to demonstrate in 1950 that hypothermia decreases the metabolic rate [242] (Figure 11.12). It decreases blood loss [240], provides myocardial protection [243], and, most importantly, is neuroprotective [244]. This mostly relates to the decrease in the metabolic rate by 64%, by cooling from 37 to 27 °C. Also, at a given temperature, the amount of gas in the solution increases proportionally to the decrease in temperature (ideal gas law). In CPB, this translates to cooling the patient not only to lower the metabolic rate but also to obtain a higher solubility of oxygen in blood and tissues. Pearl et al. [245] were able to show that the use of hyperoxia with a pH strategy led to the lowest production of acids during 60 minutes of DHCA. This is probably related to increased tissue oxygen loading pre-arrest.

The disadvantages of hypothermia include disruption of cerebral autoregulation (Figure 11.13) prolongation of CPB, and a greater tendency toward postoperative bleeding [246]. Postoperative recovery, however, is not prolonged by hypothermia [247]. Also, the wound infection rate does not seem

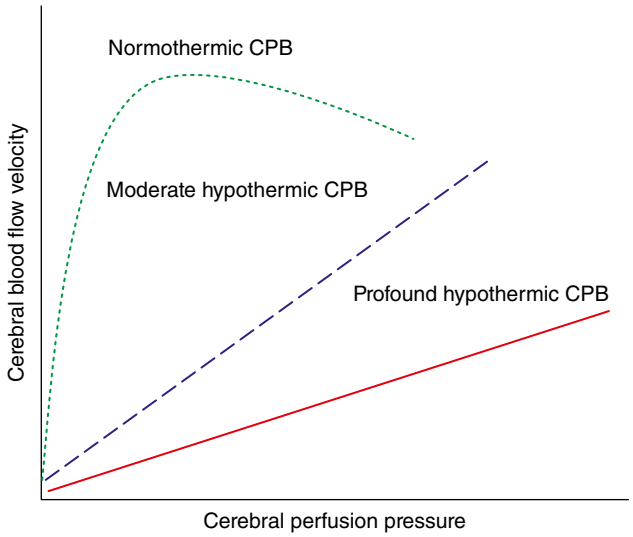

Figure 11.13 Cerebral blood flow velocity vs. cerebral perfusion pressure at different bypass temperatures. During normothermia, a normal pressure-flow velocity relationship is observed; during moderate or profound hypothermia, autoregulation is affected, and blood flow velocity is proportional to cerebral perfusion pressure in a linear relationship. (Source: Hillier et al. [234]. Reproduced with permission of Wolters Kluwer Health, Inc.)

to be influenced by hypothermic bypass [248]. Hypothermia during cardiac surgery only gained widespread use after the development of a heat exchanger that could be integrated into the CPB machine [249].

Deep hypothermic circulatory arrest involves cooling the patient's body temperature to 17–18 °C, stopping the bypass machine, draining the blood from the patient into the venous reservoir, and removing the cannulas from the heart. After the first reports of DHCA in the 1960s, this technique gained popularity in the 1970s and 1980s, because of the perfectly bloodless field it provided. This facilitated complex intracardiac and aortic repairs in newborns and small infants [250], as well as reducing edema. However, it soon became evident that DHCA was associated with neurological morbidity. Choreoathetosis, seizures, coma, and hemiparesis were all noted, especially with prolonged DHCA (>60 minutes) [251]. Clinical and experimental evidence suggests that DHCA preferentially damages the basal ganglia, which control tone and movement. The main input of the basal ganglia is the striatum, a highly dopaminergic region of the brain. Increases in free dopamine levels as an indicator of brain damage and cell disruption occur earlier in prolonged DHCA than in low-flow bypass strategies [252], and about 15 minutes earlier using alpha-stat versus pH-stat management [253]. It is interesting to note that the incidence of these acute morbidities seemed to increase when alpha-stat management became the accepted standard in many centers. Long-term adverse neurodevelopmental outcomes have also been associated with long periods of DHCA, including abnormalities in mental development [194], and in fine and gross motor skills. The Boston Circulatory Arrest Study is a remarkable achievement in which 180 newborns undergoing the arterial switch operation from 1988 to 1992 were studied, with follow-up now complete to the age of 16 years [254, 255]. The CPB

protocol in those years included alpha-stat management, routine hemodilution to a Hct of 20%, and the absence of an arterial filter on the CPB circuit. A DHCA time of greater than 41 minutes was associated with a significant increase in long-term neurodevelopmental problems. The effect of longer DHCA times was diminished, although still present at age 16 years with an association with lower visual-spatial scores and executive functioning. In the same patient cohort at age 16 years, shorter cooling time and higher nadir temperature were associated with impaired microstructural development of deep subcortical white matter when assessed with quantitative magnetic resonance imaging (MRI) [256]. In a recent study from a cohort of neonates undergoing surgery from 2004 to 2008, a longer duration of DHCA was also associated with a higher incidence of white matter injury on postoperative MRI [257].

Although the 41 minute cutoff is now a well-accepted limit in congenital heart surgery, multiple changes have subsequently been made to bypass protocols. Results from animal experiments utilizing a neonatal piglet model of DHCA, as well as data from the Boston Circulatory Arrest Study, led to the following recommendations for increasing the patient's safety margin when utilizing DHCA:

- Hematocrit of 25–30% should be the target [258].
- Systemic hypothermia should be achieved slowly, over no less than 20 minutes (Figure 11.14).
- pH-stat blood gas management should be used, at least for cooling, to improve tissue oxygen loading and more even cerebral cooling (Figure 11.15) [259, 260]. Core body temperatures of 17–18 °C should be utilized, and ice bags should be applied to the head [261]. Hyperoxia immediately before DHCA improves tissue oxygen loading [247].
- DHCA should be divided into periods of no longer than 20–30 minutes, allowing a reperfusion period of at least 2 minutes between each segment of DHCA, to improve neurological outcome [262].

- Low-flow CPB (at greater than 40–50 mL/kg/min) offers greater cerebral protection than DHCA [263]; regional cerebral perfusion may be better than low-flow CPB (see later).
- Cold normoxemic reperfusion of the brain after DHCA for 5–10 minutes may be beneficial to restore cerebral autoregulation and wash out accumulated metabolites before adding the metabolic burden of rewarming to the brain [264]. Controlled reoxygenation was also associated with reduced myocardial damage, oxidative stress, and cerebral and hepatic injury in cyanotic children despite similar inflammatory responses to hyperoxia [265].
- Normoxemia should be maintained to decrease exacerbation of brain injury after DHCA [266]. Neurological monitoring is useful in the individual patient to aid in determining the safe duration of DHCA [259, 267] (Figure 11.5).

Although there are situations where DHCA must be utilized, many surgeons are avoiding it whenever possible, by minimizing its duration and dividing the periods of its use, or using alternative methods, such as regional cerebral perfusion.

In the current era, DHCA is used by some surgeons for the following indications:

- Surgery for interrupted aortic arch
- Stage 1 palliation for hypoplastic left heart syndrome (HLHS)
- Obstructed total anomalous pulmonary venous drainage (TAPVD) (especially with a small pulmonary venous confluence)
- Repeat surgery for recurrent pulmonary vein obstruction in TAPVD
- Surgery on low-birth-weight neonates <2 kg

Regional cerebral perfusion

In order to avoid the use of DHCA, several novel CPB techniques have been developed over the past 15–20 years to allow perfusion of only the brain during critical periods of surgery, such as aortic reconstruction during the Norwood

operation, interrupted aortic arch repair with ventral septal defect (VSD), coarctation with VSD, or cases requiring the Damus–Kaye–Stansel procedure [268, 269]. These techniques are collectively referred to as regional cerebral perfusion (RCP). Other terms for this technique are regional low-flow cerebral perfusion, selective cerebral perfusion, antegrade cerebral perfusion, and selective regional cerebral perfusion. Several different techniques have been described on the basis of the primary description by Pigula et al. [268]. One variation of RCP utilizes a small Goretex graft of 3–4 mm sewn onto the innominate artery prior at the initiation of CPB, and this is then used as the aortic cannula during CPB. A pre-CPB test occlusion by the surgeon of the innominate artery with bilateral rSO_2 monitoring can serve as a functional test of an intact circle of Willis. If there is a significant and reproducible decline in rSO_2 on the side of the innominate occlusion, a non-intact circle of Willis (up to 5% of neonates) is assumed and a different CPB strategy (i.e., DHCA) can be planned. Other options for cannulation include a high cannulation technique of the innominate artery with a small 6 or 8 Fr. aortic cannula, which is advanced cephalad further distal into the innominate artery during RCP [270] (Figure 11.16). During aortic reconstruction, snares are placed around the brachiocephalic vessels and CPB flow is decreased, with only the brain receiving perfusion via the right carotid artery during this period. In this way, a bloodless operative field can be achieved, just as if DHCA was being performed, yet the brain

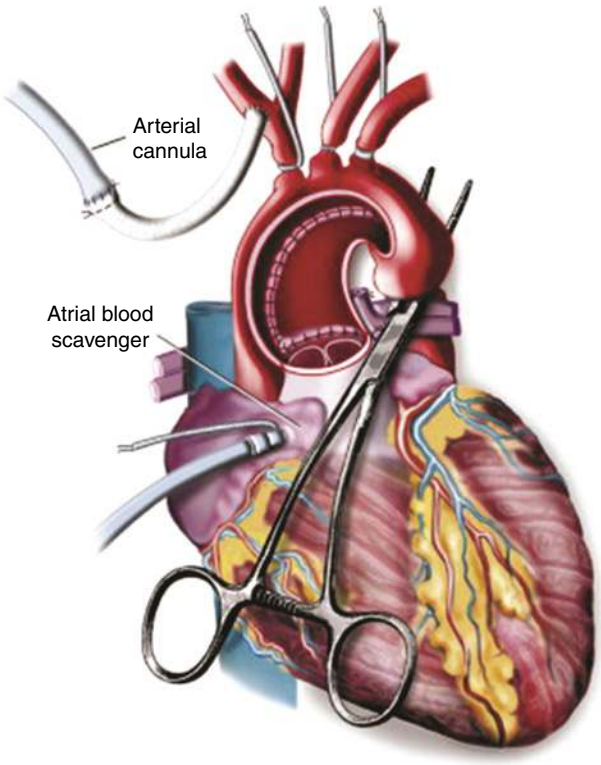

Figure 11.16 Regional cerebral perfusion during aortic arch reconstruction for hypoplastic left heart syndrome. A polytetrafluoroethylene graft is sewn to the right innominate artery as the aortic cannula inflow. Brachiocephalic vessels and descending aorta are snared, and perfusion to the brain occurs, leaving a bloodless operative field. (Source: Pigula et al. [268]. Reproduced with permission of Elsevier.)

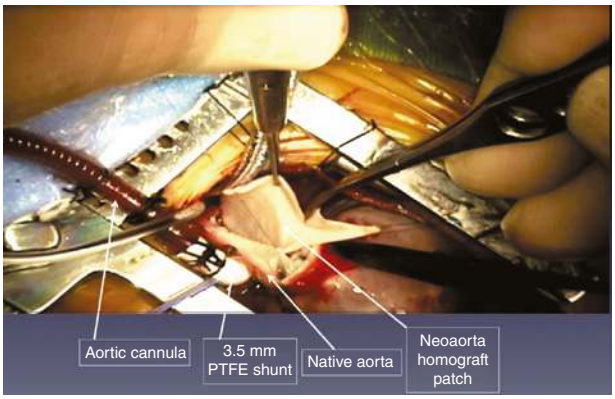

Figure 11.17 Regional cerebral perfusion. Note the bloodless operative field and the position of the graft and cannula.

is still receiving blood flow and oxygen, in theory increasing protection from hypoxic-ischemic brain injury (Figure 11.17). Another potential advantage of this technique is seen in newborns who have extensive arterial collaterals between the proximal branches of the aorta and the lower body via the internal mammary and long thoracic arteries. In this instance, the use of RCP also provides some blood flow to the lower body, potentially protecting renal, hepatic, and GI systems from ischemic damage as well [232, 271, 272]. Preliminary results are promising and support the notion of improved cerebral protection [270, 273], even at mild hypothermic temperatures [272, 274]. Neurological monitoring has been used to aid in determining how much flow is necessary during RCP [275]. Approximately 40–50% of full flow is used (starting at 40 mL/kg/min) and adjusted according to brain saturation and/or transcranial Doppler measurements, maintaining baseline saturation in the range before the onset of RCP (90–95% range). Average flows of 50–65 mL/kg/min during RCP are required to maintain baseline cerebral blood flow velocities, rSO_2, and pressures to overcome vessel resistances and capillary opening pressures [273, 276]. Flows <40 mL/kg/min over time are unable to maintain rSO_2 greater than 40% after DHCA [277]. If the left regional saturation rSO_2 falls to more than 10% below the right, flow is increased further, assuming that the circle of Willis could be variant or incomplete, as all flow to the left cerebral hemisphere needs to traverse the circle. If a left radial arterial line or a femoral arterial line/umbilical artery catheter is in place, abdominal perfusion pressures of >12 mmHg, correlating to radial artery pressures of 25–30 mmHg, are maintained [271].

Despite these theoretical advantages, and a study demonstrating that selective cerebral perfusion does provide oxygenated blood flow to both cerebral hemispheres [273], longer-term neurodevelopmental outcome studies to date have not demonstrated clear superiority of RCP vs. DHCA for aortic arch reconstruction in neonates. Andropoulos et al. reported 12 month neurodevelopmental outcomes of a cohort of 34 neonates after RCP using the Bayley Scales of Infant Development III and found the mean cognitive score equal to the reference population norm, while the language and motor scores were both 0.8 standard deviations below norms [278]. Later outcomes at 3 years of age after RCP in this cohort revealed Cognitive, Language, and Motor scores averaging

95 (0.33 standard deviation below norms). At 5 years, when more comprehensive testing is possible, IQ domains and language scores averaged 97–98; motor skills 90, and visual-motor integration 92 [31]. The study was not controlled and used the newest version of the Bayley test, preventing direct comparison with earlier studies by Goldberg (57 patients) [279] and Visconti (29 patients) [280], which demonstrated no neurodevelopmental outcome difference between RCP and DHCA, with both mental and motor scores significantly lower than population norms at 12 months. Algra et al. [281] randomized 36 HLHS patients undergoing Norwood stage I operation to DHCA vs. RCP and performed postoperative brain MRI. The overall incidence of new brain injury was significant at 76% and not different between groups, although the RCP patients were the only ones with new infarctions in deep brain structures. Significantly, RCP flow rates were higher in the Andropoulos et al. study [278] than in the other three, and theirs was also the only one to employ neurological monitoring to adjust RCP flows. Xie and colleagues reported a retrospective study of two ventricle infants undergoing aortic arch repair with DHCA at 18–20 °C ($n = 53$) compared to RCP at moderate hypothermia at 25 °C [282]. The RCP group had a lower rate of acute neurologic complications 3/61 vs. 10/53, $p < 0.05$), and a shorter duration of mechanical ventilation and ICU stay. Hoffman and colleagues reported long-term neurodevelopmental outcomes of 178 neonates followed out to 36 months of age [283]. Furthermore, 51 were single ventricle patients employing an RCP protocol with neuromonitoring and higher flows. Cognitive scores averaged 100, Language 95, and Motor 101 on the Bayley III, and were not different from the two-ventricle patients. Outcome studies of RCP must be interpreted with caution and the details of the technique must be assessed [273–283]. The differences in the various neurodevelopmental tests as new versions are developed also need to be taken into account [284]. The two studies employing neuromonitoring and higher RCP flows [31, 283] report neurodevelopmental outcome studies with most domains in the normal range at 3–5 years, in contrast to studies with lower flows and no neuromonitoring.

Alternative cannulation strategies for neonatal aortic arch reconstruction have been described to provide perfusion to the brain as in RCP, but utilize one or two additional cannulae to perfuse the descending aorta and subdiaphragmatic viscera, and aortic root to perfuse the myocardium while allowing a bloodless field [285–287]. In these studies, operating time was reduced, postoperative serum lactate concentrations were lower and fewer days were required for sternal closure. Kulyabin and colleagues randomized 15 infants undergoing aortic arch reconstruction to DHCA at 18–20 °C, RCP at 23–25 °C, and flows of 30–50 ml/kg/min, or RCP plus descending aorta cannulation at 28–30 °C [288]. Mortality was not different between groups, although 5 patients died early postoperatively. The risk of new postoperative MRI findings was higher in the DHCA group; 12/15 vs. 5/15 in both of the other groups ($p = 0.019$). The composite of all unfavorable events was lower in the RCP plus descending aorta cannulation group ($p = 0.041$).

In summary, there is no prospective, randomized controlled published evidence that demonstrates the superiority of any of these cannulation or bypass techniques in terms of quality of surgical reconstruction and hospital mortality. Since the Boston Circulatory Arrest Trial there has been a definite trend toward employing continuous CPB and minimizing DHCA for most pediatric cardiac procedures.

Blood gas management: pH-stat vs. alpha-stat

Some degree of hypothermia is utilized for nearly every cardiac operation in order to slow the metabolism and oxygen consumption of all organs, particularly the brain and heart [289]. During cooling, the carbon dioxide contained in blood becomes more soluble and its partial pressure decreases. The $PaCO_2$ sensed by the body therefore decreases as body temperature decreases, with the result that at a core temperature of 17–18 °C, if pH and $PaCO_2$ have not been corrected for temperature, the body is experiencing a pH of about 7.6 and $PaCO_2$ of 15–18 mmHg [290] (Figure 11.18). This very low $PaCO_2$ causes cerebral vasoconstriction, particularly during the cooling phase of bypass, which in turn leads to lower cerebral blood flow, less efficient brain cooling, and consequently less cerebral protection at a given temperature [259]. Since blood samples are heated to 37 °C prior to measurement of pH, $PaCO_2$, and PaO_2, the use of pH-stat management necessitates that blood gases are being corrected for the patient's actual body temperature by increasing the $PaCO_2$ on bypass as it is measured at 37 °C, so that the body experiences a $PaCO_2$ of approximately 40 and a pH of 7.4 at all temperatures. Conversely, alpha-stat management means not correcting the blood gases for temperature, as if the patient's blood was always at 37 °C, with the goal of a pH of 7.4 and $PaCO_2$ of 40 mmHg. In the early history of CPB, pH-stat was utilized to preserve cerebral blood flow [291]. Randomized controlled studies in the 1970s and 1980s on adults undergoing CPB confirmed that acute, post-CPB neurological problems were worsened with the use of pH-stat management [292]. Alpha-stat management was, therefore, adopted for both adult and pediatric CPB. However, recent animal studies in a neonatal piglet model have challenged this conclusion, proving that neurological outcome, both behavioral and neuropathological, is significantly worse when alpha-stat management is used [259, 260].

Advantages of pH-stat CPB have been shown to include:

- a decreased brain metabolic rate
- an increased rate of brain cooling and reperfusion [293], thereby providing better protection through more even and faster cooling and rewarming secondary to increased CBF [293, 294].
- molecular effects of altered arterial PO_2 and pH, including changes in cerebral oxygenation and brain enzyme activity as well as decreased brain electrical activity [295–296].
- improved oxygen delivery through decreased oxyhemoglobin affinity [297] by counteracting the pH and hypothermia-associated leftward shift in the oxyhemoglobin dissociation curve
- increased cortical oxygenation before arrest (through hypercapnic capillary vasodilation [298]) and decreased oxygen metabolic rate providing slower deoxygenation compared to alpha-stat management (10 vs. 7 minutes) [259] (Figure 11.15). Cortical anoxia occurs at 36 vs. 24 minutes for alpha-stat management, a safety margin of 50%.

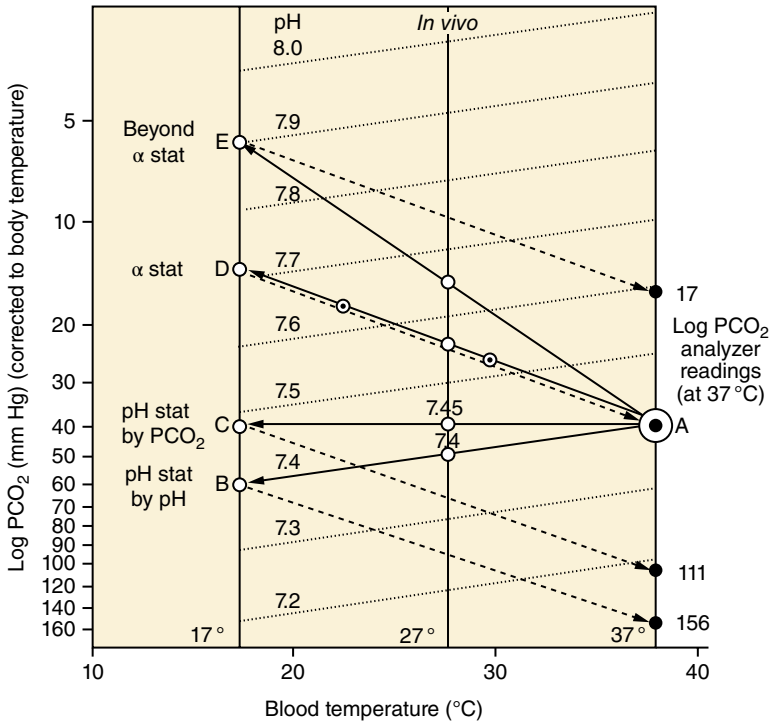

Figure 11.18 pH and PCO_2 change when blood temperature is varied between 17 and 37 °C. Point A is the starting point with pH 7.4 and PCO_2 of 40 at 37 °C. Points B, C, D, and E are the conditions the brain experiences at 17 °C with various blood gas management strategies. pH-stat management (correcting the pH and PCO_2 for temperature) results in an acid-base environment that is neutral, whereas α-stat management (not correcting for temperature) results in a very alkalotic environment at 17 °C. Warming the blood sample (as is done for blood gas measurement) results in very high PCO_2 values when pH-stat is used. The pH of blood becomes slightly more alkalotic with cooling owing to the decreased dissociation of hydrogen ions. (Source: Jonas [290]. Reproduced with permission of Taylor & Francis.)

In cyanotic infants with aortopulmonary collaterals, pH-stat management results in significantly improved brain oxygenation as measured by near-infrared cerebral oximetry [299]. A retrospective study of 16 patients revealed worse neurodevelopmental outcomes with alpha-stat management [257]. In a randomized prospective trial of pH vs. alpha-stat management in 182 infants <9 months of age, there was a strong trend toward improved outcomes with pH-stat management, including the earlier return of EEG activity, fewer seizures, and improved psychomotor development index [193]. Bellinger et al. [300], in their landmark study, examined the effects of alpha-stat and pH-stat on developmental and neurological outcomes after deep hypothermic CPB in infants. The Psychomotor Development Index scores of 110 patients did not differ significantly between the groups ($P = 0.97$). Bellinger et al. concluded that the use of alpha-stat or pH-stat strategy is not consistently associated with improved or impaired early neurodevelopmental outcomes in infants undergoing deep hypothermic CPB [300].

One reason for the differing results between pediatric and adult studies is that the increased cerebral blood flow produced by pH-stat management leads to a greater number of cerebral emboli in adults. Emboli occur much less frequently in children, and the primary etiology of neurological injury from CPB in pediatric patients is hypoxic-ischemic [301]. Thus, the increased cerebral blood flow observed on CPB with pH-stat management lessens this risk in children. Interestingly, this putative mechanism has been recently challenged by a study involving a controlled microembolic load and DHCA in pigs that revealed that pH-stat was still associated with improved outcomes when compared with alpha-stat [302]. Recent studies have also revealed a decrease in peak postoperative troponin levels, reduced ventilator dependence, and reduced ICU stays with pH-stat as compared with alpha-stat [303].

Currently, the preferred technique in adults is the alpha-stat method because it is believed that cell function and autoregulation are better preserved by maintaining neutral pH according to the temperature of the cell. In pediatric cardiac surgery, however, unlike adults, pH-stat enhances cerebral and systemic protection during DHCA. Most congenital heart surgery programs have reverted to pH-stat management. This necessitates careful attention to $PaCO_2$ during all phases of bypass, potentially reducing the sweep gas flow to decrease the efficiency of CO_2 removal, and often adding inspired CO_2 to the sweep gas of the bypass circuit, particularly in small infants.

Sickle cell disease

Sickle cell disease is an inherited hemoglobinopathy in which a mutation in the β-globin gene on chromosome 11 causes the sixth amino acid of the β-globin chain to be changed from valine to glutamic acid. The disease is inherited in an autosomal recessive pattern, with a homozygous form (Hgb SS) and a heterozygous form, or sickle cell trait (Hgb AS).

The sickle cell gene is most commonly observed in African populations, with 1 in 500 African Americans having Hgb SS, and 1 in 12 with sickle cell trait [304]. In the United States and most developed countries, there is now universal newborn screening for hemoglobinopathies, and sickle cell disease is, therefore, usually diagnosed at that time. After the normal postnatal decline in fetal hemoglobin (Hgb F) in the first 6 months, Hgb SS patients have Hgb S concentrations of 70–98%, and Hgb AS patients have Hgb S concentrations of 30–50%. Hgb S causes sickling of red cells, leading to chronic hemolytic anemia and impaired microvascular perfusion. This can result in end-organ dysfunction and permanent injury, including painful bony crises, splenic sequestration and autoinfarction, acute chest syndrome with hypoxemia, retinopathy, renal failure, pulmonary hypertension, and stroke. Hypoxemia, acidosis, cold temperature, hypovolemia, and microvascular stasis all promote sickling. Other less common forms of sickle cell disease are sickle cell-hemoglobin C disease (Hgb SC), and sickle cell-thalassemia variants. The reader is referred to excellent recent reviews for further detailed information about these disorders [304, 305]. Modern treatment for Hgb SS now includes chronic transfusion therapy to maintain the Hgb S at <30%, with Hgb levels of 9–10 g/dL. In addition, hydroxyurea is now commonly used in sickle cell disease because of its ability to increase the production of Hgb F, reduce Hgb S, and decrease the severity of disease manifestations. Hydroxyurea can substantially reduce the Hgb S percentage, and so this should be considered in the preoperative planning for these patients. The conditions commonly encountered for CPB – hypothermia, low flow, acidosis, and hypoxemia – all predispose to sickling, and a careful strategy is required to optimize outcomes in these patients [306, 307]. Although no universally accepted guidelines have been published, recent data and reviews provide important guidance. Careful consultation with the patient's hematologist and surgeon, and a clear strategy devised with the perfusionist, are essential when planning for CPB.

Exchange or straight transfusion has been used successfully for CPB surgery in homozygous sickle cell disease, either preoperatively, or in the operating room with the initiation of CPB [308, 309]. Preoperative exchange transfusion is cumbersome, expensive, and usually not necessary. If preoperative straight transfusion is utilized, the goals are to achieve an Hgb of 10 g/dL, with Hgb SS <30%. Other common approaches include a partial exchange transfusion performed at the time of initiation of CPB. CPB prime volume is increased to two to three times the patient's blood volume, with PRBCs and colloid or crystalloid calculated to achieve a Hct of 30% and Hgb S well below 30% on CPB. In addition, 25–33% of the patient's blood volume is diverted from the venous return upon initiation of CPB, and discarded instead of draining into the venous reservoir, further diluting Hgb S. Other recommendations for CPB are to perform the surgery at normothermia whenever possible and to limit hypothermia to mild (>32 °C) if it is needed. [307, 309]. If deeper levels of hypothermia are required, a more extensive exchange transfusion is necessary with Hgb S <10%. In addition, frequent arterial blood gases are measured on CPB with a goal of full arterial oxygen saturation (PaO_2 >100 mmHg), and mixed venous blood gases are also assessed with the goal of SvO_2 >75–80%. Maintaining full CPB flows at 2.4–3.2 L/min/m^2 or above, and perfusion pressures in the high normal range are also important. Finally, cardioplegia strategies may be altered, with some authors recommending only crystalloid cardioplegia, with an initial "warm" dose at 26–32 °C, to wash out any red cells from the coronary arteries before cold cardioplegia is given [307, 309]. As noted earlier, sickle cell trait (Hgb AS) patients may still have Hgb S concentrations of 30–50% at baseline, and, although asymptomatic under normal conditions, are at risk for sickling with CPB. Therefore, sickle trait patients should be approached in the same manner as homozygous sickle cell disease patients for CPB cases [309]. Using these CPB recommendations, Yousafi et al. reported outcomes for 21 pediatric and 26 adult patients with sickle cell disease or trait [309]. No patient had a perioperative sickling crisis; however, two patients had a stroke, and two had renal failure postoperatively. Chacon-Portillo and colleagues retrospectively reviewed 46 patients median age 1.3 years (range 3 days to 38 years) with sickle cell trait (80%), or sickle-beta thalassemia (20%-no homozygous Hgb SS patients) undergoing CPB surgery [310]. Exchange transfusion immediately before instituting CPB was accomplished in 65% of patients to achieve a targeted-on pump Hgb S of <30%. Four patients (9%) developed sickle cell complications, including two with acute chest syndrome, one with ischemic stroke, and one immune hemolysis. Three of four had exchange transfusion, and two of four had on bypass hematocrit slightly above 30%. Although numbers were small, the authors concluded that exchange transfusion did not alter the outcomes in this cohort. Regardless of the ultimate protocol for CPB management for the sickle cell patient, close vigilance in the postoperative period is critical, especially for acute chest syndrome with hypoxemia, the most common perioperative sickling complication [304]. Renal failure and stroke are also threats in the perioperative period after CPB surgery. Recommendations for sickle cell disease and CPB are summarized in Table 11.6. Published data about other hemoglobinopathies such as thalassemia are scant, and the anesthesiologist should consult with the patient's hematologist and surgeon when planning strategies for this rare situation [305]. The decision about whether to perform exchange transfusion should but subject to multidisciplinary discussion among the surgeon, anesthesiologist, hematologist, and perfusionist, and take into account the patient's baseline Hgb S%, and complexity of the planned operation, duration of bypass, and degree of hypothermia.

Cold agglutinins

Cold agglutinin disease in pediatric patients is most commonly observed after *Mycoplasma pneumoniae* infection, in as many as 55% of patients in the first 2 weeks of this disease [307]. Antibody levels peak in the third week and decrease significantly by 2–3 months after infection. Cold agglutinins are usually immunoglobulins of the IgM class and are characterized by reaction at cold temperatures with surface red blood cell antigens, causing activation of the complement pathway, with agglutination and hemolysis. Reported adverse effects during hypothermic CPB include massive hemagglutination, microvascular thrombosis and hemolysis, with coronary thrombosis, inability to deliver cardioplegia,

Table 11.6 Recommendations for homozygous (Hgb SS) or heterozygous (Hgb AS) sickle cell disease and cardiopulmonary bypass (CPB)

Preoperative	Intraoperative CPB	Postoperative
Maintain euvolemia with IV hydration Avoid hypoxemia, hypothermia, acidosis Consider straight transfusion to Hgb >10 g/dL and Hgb S <30% Exchange transfusion rarely indicated	Partial exchange transfusion with CPB: prime volume two to three times blood volume with PRBCs; target Hct on CPB >30%, Hgb S <30% Avoid hypothermic bypass, temperature >32 °C if needed Warm crystalloid cardioplegia for first dose Full flow CPB at all times >2.4 L/min/m^2 Avoid hypoxemia: PaO_2 >100 mmHg SvO_2 >75–80% Avoid hypotension Temperature corrected pH 7.35–7.45	Avoid hypoxemia; SpO_2 >95% at all times Maintain euvolemia Avoid hypothermia, maintain core temperature 36–37 °C Avoid acidosis: pH >7.35 Maintain Hgb >10 g/dL and Hgb S <30%

Hct, hematocrit; Hgb, hemoglobin; IV, intravenous; PRBCs, packed red blood cells; SpO_2, pulse oximeter saturation; SvO_2, mixed venous oxygen saturation.

and oxygenator failure. Typically, cold agglutinin disease is characterized by high antibody levels at 4 °C and low levels at normothermic temperature; however, the level of hypothermia at which agglutination occurs can vary, and when cold agglutinin disease is diagnosed preoperatively it is important to define the temperature range at risk. The true incidence of cold agglutinin disease in pediatric patients is not known, but it appears to be very low. Elective cases in the face of post-*Mycoplasma* cold agglutinin disease should be postponed. When the thermal threshold is defined, CPB temperatures are maintained well above that threshold. Patients with high titers and a warm temperature threshold are at the greatest risk, and consideration can be given to high-volume plasmapheresis preoperatively if surgery must proceed. Maintaining normothermia pre- and post-CPB is also important, as is a consideration for warm crystalloid cardioplegia. Occasionally cold agglutinins may only be suspected intraoperatively when agglutination occurs during hypothermic CPB. Rapid testing can be performed by most blood banks and clinical laboratories; increasing the temperature to the highest tolerable level should be done emergently in this situation. Recommendations for the management of cold agglutinins are summarized in Figure 11.19 [307].

Leukoreduction and irradiation of blood products

Leukoreduction of blood products (PRBCs, platelets, and whole blood) has been described in attempts to reduce the inflammatory response to CPB from leukocyte reduction, by employing leukocyte-reducing blood filters either before or during CPB. However, in the two controlled trials in pediatric patients, there were no clinical outcome differences in leukoreduced patients [311]. More commonly, leukoreduction is performed to provide "cytomegalovirus (CMV)-safe" blood products, as this virus is contained entirely in white blood cells [312]. Leukoreduction for all units of PRBCs, platelets, and whole blood has become standard practice in many hospitals because of the high prevalence (35–65%) of seropositivity for CMV in donated blood units. Despite this practice, 0.02–0.25% of blood units still test positive for CMV, and so transmission is still possible [312]. Patients who are or who may become transplant recipients may require CMV-negative blood confirmed by donor serology; local policies vary and need to be well understood by the anesthesiologist.

Irradiation of blood products (PRBCs, platelets, FFP, whole blood) prevents graft-versus-host disease from transfused leukocytes. This is a rare but serious complication and has resulted in uniform irradiation policies for high-risk groups, which include premature neonates and young infants in the first 3 months of life, immunosuppressed patients such as some transplant recipients, and those who have had blood donated by relatives [313, 314]. Irradiation causes several changes due to hemolysis of PRBCs, including potassium release, acidosis, increased lactate, increased free hemoglobin, and decreased glucose [315]. Hyperkalemia with K^+ levels over 20 mmol/L is common even with irradiated PRBC units less than 7 days after donation. Irradiated PRBC units should be checked for K^+ levels, and consideration should be given to washing the units before CPB, especially in neonates.

KEY POINTS: SPECIAL CPB MANAGEMENT ISSUES

- Warm or tepid temperatures are successfully used in pediatric cardiac surgery.
- DHCA remains a cornerstone of neuroprotection for complex cases involving aortic reconstructions, such as the Norwood procedures.
- Deep hypothermia involves complex management issues in respect of the maintenance of hematocrit, even cooling of the brain over 20 minutes using a pH-stat strategy, cold, normoxemic reperfusion, and the avoidance of hyperthermia postoperatively.
- RCP was developed in an attempt to provide continuous cerebral perfusion throughout the repair. A minimal flow of 40 mL/kg/min is required.
- To date, there is no proven superiority of one method over the other.

Monitoring anticoagulation during and after CPB

Since the landmark 1959 paper by Keats and colleagues from Texas Children's Hospital, heparin reversal by protamine, and its assessment using the ACT has been the standard approach for confirming anticoagulation with heparin, and reversal of the heparin by protamine [63]. The celite ACT test with a target time of 400–480 seconds has remained the standard for initiation and maintenance of anticoagulation on CPB in many institutions for over 50 years. Reversal of the heparin effect is achieved with protamine, and return to baseline ACT serves as a confirmation of neutralization of this heparin effect. ACT is a point-of-care test performed by the perfusionist on a device often mounted on the CPB machine, and its rapid turnaround is unmatched by other tests. However, the ACT is only a gross measure of the initiation of clotting, will be affected by many factors other than heparin (e.g., thrombocytopenia or platelet dysfunction), and does not measure fibrinolysis or other aspects of clot persistence (clot strength). Several other point-of-care heparin and coagulation monitors will be discussed here; the reader is referred to Chapter 13 for additional details.

Point-of-care heparin–protamine titration systems for the measurement of plasma heparin concentrations (Hepcon, HMS Plus®; Medtronic, Inc., Minneapolis, MN, USA) perform an *in vitro* bedside assay to determine plasma heparin concentrations. Plasma heparin levels of 3.0 units/mL are considered adequate anticoagulation for CPB, and the use of this system is effective to titrate additional heparin doses during bypass. In a study of 44 patients under the age of 6 months undergoing CPB, Guzzetta et al. compared ACT, Hepcon, and direct plasma heparin concentration using an antifactor Xa chromogenic substrate assay [316]. ACT showed no correlation with plasma heparin concentration after the initial heparin bolus or during CPB; there was a

AL Grawany

modest correlation with one of the ACT methods just before termination of CPB. Hepcon demonstrated a good correlation with direct plasma heparin level measurement, as well as an acceptable bias by Bland–Altman analysis, with Factor Xa heparin levels higher by 0.49–0.67 units/mL than Hepcon heparin levels. Gautam et al. reported on 100 patients aged 1 month–5 years who had two different methods of protamine dosing compared, the first based on estimated blood volume of the patient plus CPB prime volume and the second based on patient blood volume alone [317]. Hepcon, ACT, and TEG (see later) were measured in both groups, and although protamine neutralization of heparin was successful by both methods, the authors concluded that the protamine dose calculated by Hepcon resulted in lower plasma protamine concentrations; excess protamine prolonged the clotting time (R value; see later) as measured by TEG. Therefore, heparin–protamine titration may result in more accurate maintenance of desired heparin levels during bypass, as well as avoiding excessive protamine dosing after neutralization.

Thromboelastography (TEG®; Medtronic, Inc.) and thromboelastometry (ROTEM®; TEM International GmbH, Munich, Germany) are related methods that measure clot initiation and maintenance of clot integrity and therefore provide a more complete profile of the coagulation system. TEG uses the shear elasticity of a 0.36 mL blood sample, measured by the constraint of rotation of a cup and pin as fibrin strands and then a platelet-fibrin clot forms, attached to a torsion wire transduced to an electronic signal that displays a plot [318] (Figure 11.20). Time to initiation of the clot, maximum clot strength, and breakdown as a result of fibrinolysis are measured. Heparinase can be added to the sample to eliminate the heparin effect, and kaolin to speed the initiation of clot formation to make TEG more of a real-time point-of-care test. Despite this, a minimum of 10–15 minutes are required to acquire data about the time of initiation, and the speed of initiation of clot, and 45–60 minutes to acquire a full profile that includes fibrinolysis. Data in the adult population demonstrates that TEG can guide the anesthesiologist as to what blood product (platelets, FFP, cryoprecipitate) and what dose to administer. TEG studies have demonstrated that the method is sensitive to reduced platelet number and fibrinogen concentration and that these parameters, especially maximum amplitude, correlated well with post-bypass bleeding [319]. Platelet count <120,000 L^{-1} and fibrinogen concentration of <100 mg/dL were predictive of bleeding and abnormal TEG results. More recent studies in high-risk pediatric cardiac patients have also demonstrated that a low maximum amplitude (MA) on the TEG is associated with an increased risk for bleeding [319, 320].

Thromboelastometry (ROTEM) is similar to TEG in that a small blood sample in a cup is rotated around a pin, but instead of a torsion wire, the formation of a clot (constraint of rotation of cup) is detected by an optical light-emitting diode detection system. This feature, and better fixation of the rotating pin, may make ROTEM more resistant to vibration and small movements, to make it more suitable for point-of-care testing in the operating room. The ROTEM tracing and parameters are similar to TEG (Figure 11.21) [321]. In addition to heparinase, cytochalasin D can be added to the test to discern fibrin polymerization early, with clot strength at 10 minutes having a strong correlation to clot strength at 30 minutes ($r = 0.91–0.97$, $P < 0.001$) [322]. This allows the test to be done during CPB with results that can be interpreted after about 15 minutes. The post-bypass ROTEM maximum clot firmness parameter correlated with bleeding in one small study [323]. A comparison of TEG and ROTEM parameters is given in Table 11.7 [324].

Because platelet defects, both in number and function due to activation from the bypass components and procedure, are the most common and serious cause of post-bypass

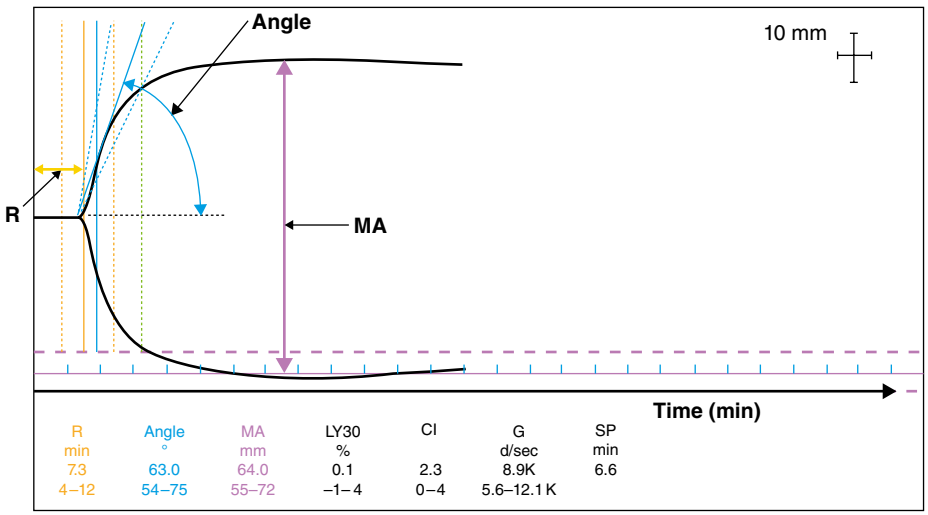

Figure 11.20 Normal thromboelastography tracing. R, reaction time (in minutes until first detectable levels of fibrin clot formation). Sensitive to heparin and coagulation factor levels. Angle – reflects fibrinogen activity, but it does not always correlate with direct measurements. MA, maximum amplitude – clot strength, the combination of platelet count and function plus fibrinogen activity. LY30, percent clot lysis after 30 minutes – measurement of fibrinolysis. G, clot firmness in dynes/second (d/sec): CI, coagulation index: complilation of R, K, angle, and A; SP (split point): time from sample placement (or activation with an exogenous procoagulant) until the earliest detectable resistance. coagulopathy in young infants [325], point-of-care platelet function tests have been proposed to guide the administration of platelets (Sonoclot®, Sienco, Inc., Boulder CO, USA; TEG PlateletMapping®, Medtronic, Inc.). Data are very limited in pediatric cardiac surgery, and to date these tests cannot be recommended as part of routine care [326, 327].

Each institution must develop an approach to monitoring coagulation for CPB cases to reduce unnecessary blood transfusion while achieving prompt hemostasis, and avoiding inappropriate protamine dosing, particularly for neonatal and other complex cases at high bleeding risk. The available evidence suggests that a heparin–protamine titration system to ensure accurate heparin dosing and reversal, combined with point-of-care clot formation and integrity tests such as TEG or ROTEM, may be best able to achieve this [328]. Irrespective of the testing regimen, recent data have confirmed the classical papers demonstrating that platelets are the primary defect, followed by hypofibrinogenemia, in complex cardiac surgery in infants [329]. See Chapter 16 for an extensive discussion of bleeding and hemostasis.

KEY POINTS: MONITORING ANTICOAGULATION DURING AND AFTER CPB

- For over 60 years the standard method has been heparin administration and protamine neutralization monitored by ACT.
- Heparin–protamine titration systems allow for more accurate heparin and protamine dosing.
- TEG and thromboelastometry allow more accurate blood product administration after bypass.

Complications and safety

The most frequent causes of death or injury related to CPB mishaps have been arterial embolism and consumptive coagulopathies. Other life-threatening events include thrombus in the extracorporeal circuit, inadequate pressures and flows, aortic dissections, separation of extracorporeal lines, drug administration errors, protamine administration during CPB, heparin overdose, transfusion reactions, negative pressure complications (principally air entrainment), electrical failure, and failure to provide gas exchange. The incidence of fatal accidents in recent surveys of adult and pediatric perfusion is in the range of 1 in 1,300 to 1 in 4,900 procedures. Serious or permanent injury is reported in 1 in 1,139 to 1 in 2,500 cases. Near misses or incidents occur in approximately 1 in 138 to 1 in 198 cases [330–332]. Pre-bypass checklists,

vigilance on the part of all members of the team, and the use of standard perfusion monitors and devices will minimize catastrophes.

The most common problems in pediatric practice are inadequate pressures or flow from either poor venous return (most often due to cannula placement) or problems at the arterial cannulation site (malposition of the aortic cannula, e.g., in the innominate artery with preferential perfusion of the right carotid; dissection or hematoma).

Most situations can be controlled by rapid recognition, correction, or – in rare cases – separation from bypass and restoration of normal circulation unless the aorta has been ruptured. A great deal of suspicion and good communication amongst the team are vital in this respect.

Emergency cardiopulmonary bypass

Patients at high risk for cardiopulmonary collapse during anesthesia induction or during surgical dissection should be prepared for emergent cannulation for cardiopulmonary bypass. Preoperative identification of these patients is critically important. Multidisciplinary planning among cardiac surgery, anesthesia, nursing and perfusion teams is important to resuscitate these patients. Other preoperative measures such as ultrasound or CT imaging of the femoral blood vessels to delineate their size and patency is important in case femoral cannulation is required. Cannulation strategy with appropriate femoral or other bypass cannulae available is essential. Early blood priming the bypass circuit before induction of anesthesia, presence of surgeon and perfusionist in the operating room, and having instruments and nursing and scrub personnel prepared are all essential preparations.

Conclusions and future perspectives

In summary, pediatric CPB is challenging as it extends the spectrum of extracorporeal circulation in many aspects. Familiarity with differences to adult bypass circuits and management is of the utmost importance and the team, consisting of cardiac surgeon, perfusionist, and anesthesiologist has to work very closely together to reach the goal of good perfusion practice. The results of this hard work are rewarding, however, and offer many children a better perspective and greater life expectancy. There are myriad variations in bypass technique, specific to each institution and often to each individual surgeon within an institution. No one technique has been conclusively proven to be superior to others with regard to myocardial and clinical outcomes; better neurological outcomes have been demonstrated with avoidance of extreme hemodilution and prolonged DHCA. Future directions lead towards a "goal-directed perfusion management" with special emphasis on organ protection and further technical advances in miniaturization of the CPB circuit size to reduce the use of blood transfusions and the inflammatory response. Together with the determination of a safe Hct limit, this may render the asanguineous neonatal CPB possible. A checklist approach is useful in developing the individual anesthesiologist's approach to CPB in children (see Table 11.6).

Introduction

The diagnosis and surgical management of congenital cardiac disease in the pediatric patient present a profound challenge to a developmentally immature physiology. Associated congenital syndromes, chronic abnormalities in hemodynamics, and immature developmental physiology of the young child all result in the potential for multisystem aberration. The exposure of a patient in this relatively tenuous state to the systemic challenges associated with cardiopulmonary bypass (CPB) results in both short- and long-term challenges in the management of these children.

The systemic response to congenital cardiac surgery

CPB triggers complex cellular and humoral inflammatory responses designed to respond to noxious stimuli (Figure 12.1). Children are particularly prone to the effects of this response, due to the large relative surface area of bypass circuit, increased metabolic demand requiring higher flows, and developing organ systems particularly prone to injury [1]. These consequences of CPB predispose the pediatric patient to end-organ injury and multisystem organ failure (MSOF). The management of this end-organ dysfunction, which includes coagulopathy, pulmonary and myocardial dysfunction, renal insufficiency, and diffuse capillary leak, represents a major challenge in postoperative management.

Activation of complement, the kinin–kallikrein–bradykinin system, and the coagulation system results in a systemic response that is both highly redundant and multisystemic (Figure 12.2). These events are triggered immediately upon contact of the patient's blood with the foreign surfaces of the CPB circuit. Further activation occurs as a result of mechanical stress on blood components, hypotension, nonpulsatile perfusion, hypothermia, intestinal hypoperfusion, and systemic reperfusion following the release of the aortic cross-clamp. Additionally, the administration of heparin and protamine

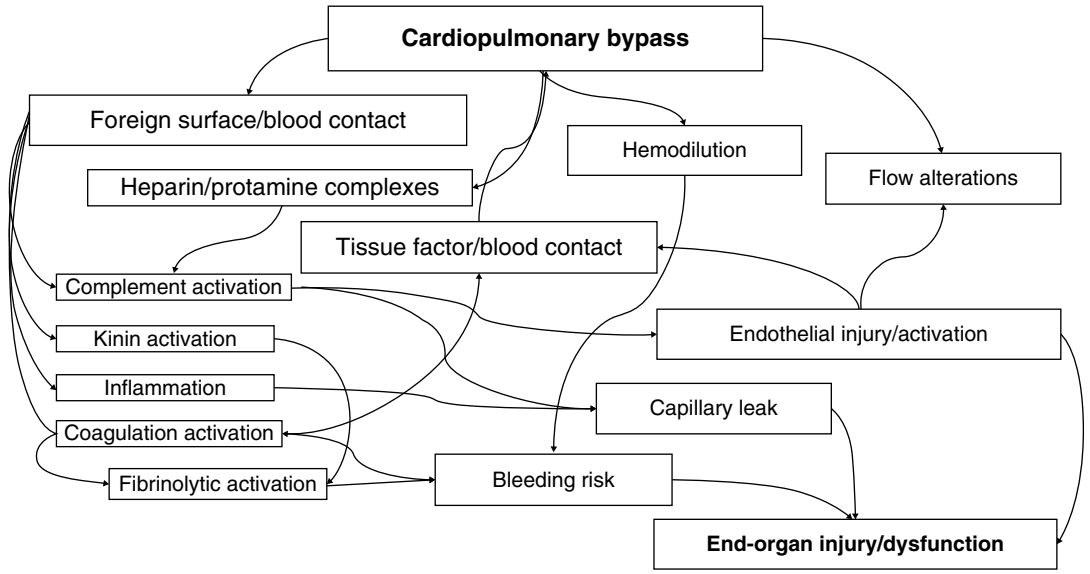

Figure 12.1 Summary of the multiple systemic pathways involved in the physiologic response to cardiopulmonary bypass (CPB). Activation of the contact system by elements of the CPB circuit produces an array of physiologic humoral activations. Dilution of coagulation elements by crystalloid solutions decreases coagulability of blood and contributes to bleeding risk. Alterations in flow, such as ischemia–reperfusion injury, and nonpulsatile flow produce changes in endothelial function, such as expression of tissue factor and disordered endothelial-dependent relaxation. Inflammatory cells, platelets, complement fragments, and cytokines mediate many of these pathways.

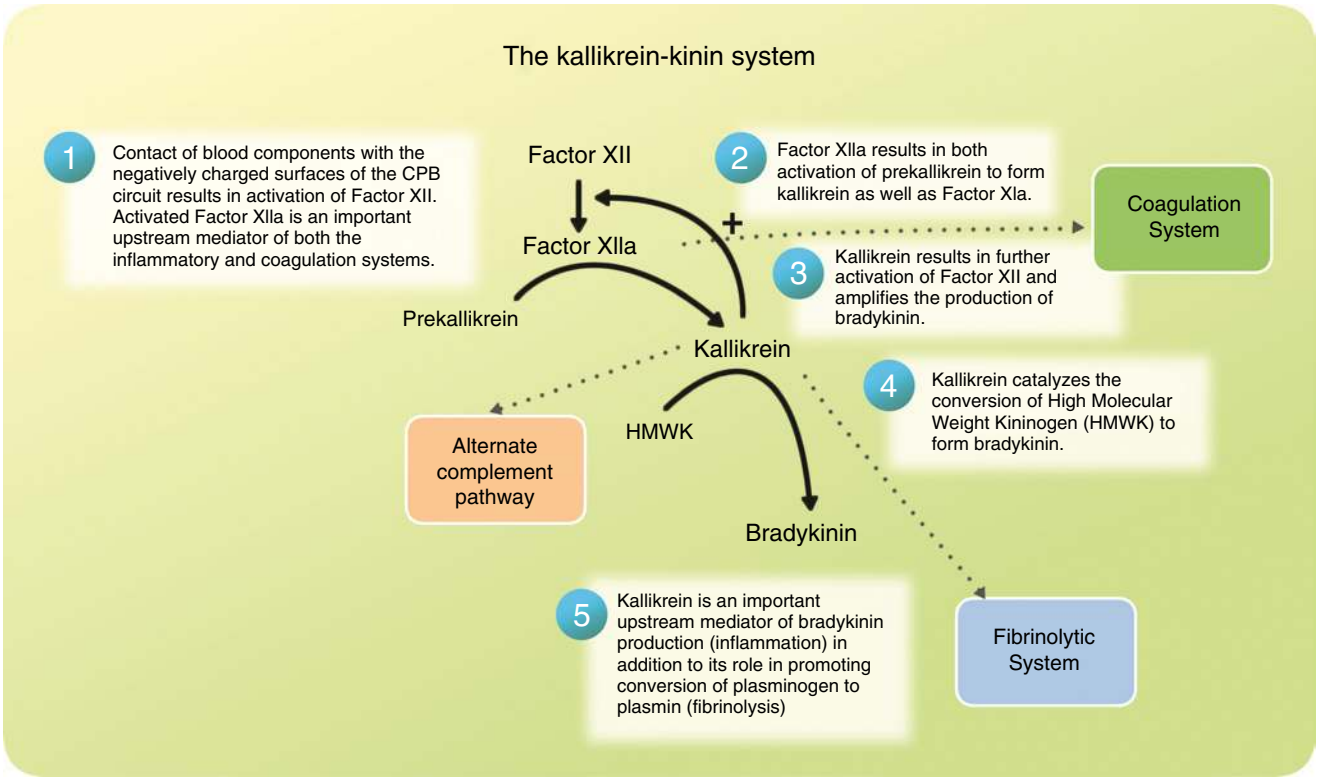

Figure 12.2 Diagram showing the initiation of the inflammatory cascades produced by contact of blood with nonbiologic elements of the CPB circuit. Note the central role of kallikrein.

during the course of cardiac surgery results in an increase in cellular and humoral processes that contributes to systemic inflammation and end-organ injury [1].

Systems mediating the systemic inflammatory response to CPB

Complement pathway activation

Exposure of blood to the components of the CPB circuit results in rapid activation of complement via the alternate pathway and initiates inflammation. While this component of the complement system is designed to respond to microbial cell-surface components and mediate the body's defense against microorganisms, it may also be activated by exposure of blood to foreign surfaces, endotoxin, and kallikrein [2]. This activation results in conversion of C5 and C3 to C5a and C3a, respectively. C3a and C5a are potent anaphylatoxins that activate and degranulate neutrophils and mast cells and initiate platelet aggregation. C5a and C3a also act directly on endothelium, producing increased vascular permeability and smooth muscle contraction. C5a primes monocytes and macrophages to greatly increase the production of tumor necrosis factor alpha (TNF-alpha) in the presence of endotoxin. This initial increase in TNF-alpha may represent an early central event in the upregulation of the systemic inflammatory response [3].

In addition to the activation of the alternate complement pathway by contact with foreign surfaces, the classical complement pathway further contributes to the systemic inflammatory response when activated by heparin–protamine complexes. Their presence results in generation of C4a and further increases in C3a production, resulting in increasing vascular permeability. These processes (C5a and C3a activation, TNF-alpha production) result in successive surges in humoral mediators of the inflammatory response: toxic oxygen metabolites, pro-inflammatory cytokines (interleukin-1 [IL-1], TNF-alpha, IL-6, IL-8, and lipopolysaccharide [LPS]), and anti-inflammatory cytokines, which limit systemic inflammation (IL-4, IL-10). The TNF-alpha levels increase dramatically following the initiation of CPB and peak at 2 hours and 18–24 hours postoperatively [4]. The levels of C5a and C3a are directly related to the duration of CPB, and infants exhibit a more dramatic increase than neonates [5]. Despite the known physiologic effects of these inflammatory mediators, attempts to correlate clinical outcomes with the degree of complement activation (using C3a and C5a plasma levels as markers) have led to inconsistent results [6, 7].

Activation of the kinin system

Kinins are polypeptides generated from kininogens following tissue injury or noxious stimulation. Their functions are incompletely understood, but are known to be involved in blood pressure regulation and mediation of inflammation through activation of G-protein–coupled B1 and B2 receptors. Kinins are potent vasodilators, which also increase vascular permeability, smooth muscle contraction, and neutrophil chemotaxis. While B2 receptors are constitutively expressed in most tissues, B1 receptors are induced and functionally expressed in the presence of inflammatory cytokines, endotoxin, and following tissue injury. The generation of kinins depends upon the contact of blood with the negatively charged surfaces of the CPB circuit and subsequent activation of factor XII (FXII) to FXIIa. FXIIa results in the production of kallikrein from prekallikrein, which then results in further activation of FXII and the production of bradykinin from high-molecular-weight kininogen (HMWK). This positive feedback loop amplifies the production of bradykinin, a potent mediator of both acute and chronic inflammation. Bradykinin, in turn, results in further generation of inflammatory cytokines and the endothelial release of nitric oxide and tissue-plasminogen activator.

Activation of inflammation

The response to CPB is also mediated by various cytokines, which facilitate communication between components of the immune and inflammatory systems. They are polypeptide hormones of low molecular weight (5–20 kDa) produced by macrophages, monocytes, lymphocytes, fibroblasts, and endothelium. They modulate humoral and cellular immunity in addition to the maturation and activation of immune cells. The plasma concentration of cytokines at baseline is in picomolar concentrations (10–12) and may increase up to 1,000-fold in the setting of injury or infection. Data regarding the degree of cytokine release following CPB and the ratio of pro-inflammatory versus anti-inflammatory cytokines are often conflicting owing to inconsistencies in the source, technique, and the timing of sampling. It is clear, however, that identifiable waves of cytokine release characterize the inflammatory response to CPB and that important clinical and laboratory consequences of this response are observable in the perioperative period. Additionally, the functions of individual cytokines are highly redundant and pleiotropic, which presents a significant challenge to those looking to mitigate their downstream effects for clinical benefit.

Endothelial injury

Normal endothelium is an important custodian of smooth muscle, producing vasoactive mediators such as nitric oxide and prostacyclin, which fine-tune microcirculatory function. Injury to this critical monolayer decreases the production of these vasodilatory mediators and increases the release of vasoconstrictors endothelin and thromboxane A2 [8]. Endothelin probably mediates increased pulmonary vascular resistance, as higher plasma levels are found in patients who develop pulmonary hypertension. In a swine model of renal injury following CPB, an endothelin-1 (ET-1) receptor antagonist reversed many changes associated with endothelial dysfunction and renal injury [9].

The pulmonary endothelium is responsible for breakdown of several potent vasoconstrictors: angiotensin, catecholamines, and eicosanoids. Its injury therefore results in sustained increases in pulmonary vascular resistance following CPB. Endothelial dysfunction results in increases in capillary permeability and interstitial edema in addition to microcirculatory dysfunction. Efforts to improve pulmonary flow during CPB [10, 11], or supplement the NO pathway with L-arginine [12, 13], may contribute to minimizing post-CPB pulmonary pathology.

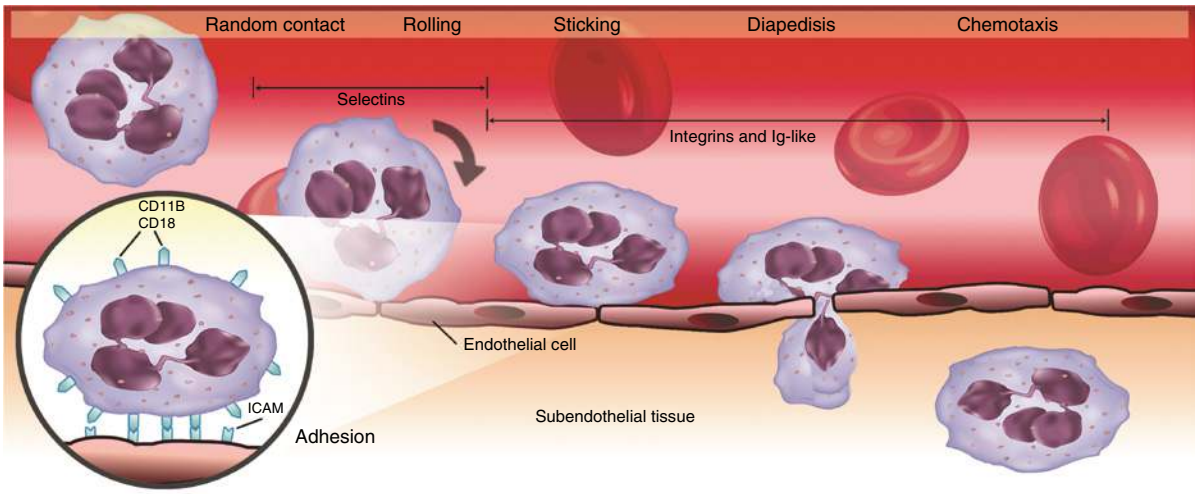

Figure 12.3 Neutrophil adhesion, diapedesis, transendothelial migration and chemotaxis. ICAM, intercellular adhesion molecule.

Neutrophil activation and sequestration

Neutrophil activation plays a pivotal role in ischemia–reperfusion injury and destruction of the extracellular endothelial cell matrix. CPB produces widespread activation of neutrophils and increased expression of adhesion molecules on neutrophils and endothelium. Activated neutrophils adhere to endothelium and migrate across interendothelial junctions to produce their effects in subendothelial tissues. Selectins, integrins, and immunoglobulins mediate neutrophil adhesion, migration, and chemotaxis (Figure 12.3). Notably, selectin expression increases substantially following CPB in pediatric patients and may be associated with clinical outcomes [14, 15]. Additionally, IL-1 and TNF-alpha result in increased ELAM-1 (endothelial leukocyte adhesion molecule-1) expression on endothelium, facilitating further the binding of neutrophils to the endothelium. Additionally, IL-8 promotes interaction of activated neutrophils with endothelial ICAM-1 receptors and results in further neutrophil migration to the extravascular space.

Endotoxemia

CPB decreases gastric mucosal pH and intestinal perfusion and increases intestinal permeability. Endothelial dysfunction decreases the release of nitric oxide and prostacyclin, thus increasing the vascular resistance in splanchnic beds. The resulting intestinal hypoperfusion allows translocation of predominantly Gram-negative bacteria. Endotoxin, the LPS component of the bacteria outer cell membrane, binds macrophages and monocytes and triggers further release of inflammatory mediators. Endotoxin is present in the circulation of 96% of children following CPB [16].

Endotoxin is a recognized prologue of inflammation in the setting of enteric pathology. Circulating endotoxin and inflammatory mediators (IL-1, IL-1beta, and IL-8) correlate with the severity of necrotizing enterocolitis (NEC) in newborns [17]. Children with greater endotoxin burden have higher serum levels of IL-6, more hemodynamic instability, and greater mortality [16]. Data suggest that milrinone may improve GI blood flow and thereby reduce endotoxemia and IL-6 levels in adults undergoing CPB [18]. Additionally, hypothermia during CPB has been associated with increased levels of endotoxin [19].

Activation of the coagulation system

Hemostasis is extensively altered during cardiac surgery. CPB produces widespread perturbations in platelet function, thrombin activation, endothelial function, and inflammatory cells.

Old and new models of coagulation

The familiar "coagulation cascade" (Figure 12.4) has served for years as an important educational paradigm in many respects. It has led to the development of our common coagulation tests, which have been useful in identifying deficiencies in the coagulation pathways. It has also been useful in identifying coagulation inhibitors. Yet, while abundantly referenced formally and discussed informally, the traditional cascade model does not explain some essential observations. For example, patients with FXII or prekallikrein deficiency typically do not have bleeding problems, a conclusion unlikely to be drawn by tracing the pathways of the cascade. Likewise, patients with FVIII or FIX deficiencies (hemophilias A and B) have severe coagulopathies, also unexplained directly by the cascade. The cascade model does not account for the roles of cells and tissues where the coagulation reactions occur.

Consequently, pedagogy in coagulation has shifted toward the *cell-based model of coagulation*, originally proposed by Hoffman and Monroe in 2001 [20] (Figure 12.5A and B). It is useful to carefully step through the cell-based model, because doing so will explain the abovementioned limitations in the traditional cascade model. In this revised model, coagulation proceeds by the processes of *initiation, amplification, and propagation* [20–22]. In the *initiation* phase, elements of the intrinsic pathway (FXII, FXI, prekallikrein, HMWK), which are important for the generation of kinins as mentioned above and for initiating coagulation in a laboratory glass vessel, are not essential for the initiation of coagulation *in vivo*. Rather, the *initiation phase* begins when FVIIa contacts tissue factor (TF) at the site of vascular

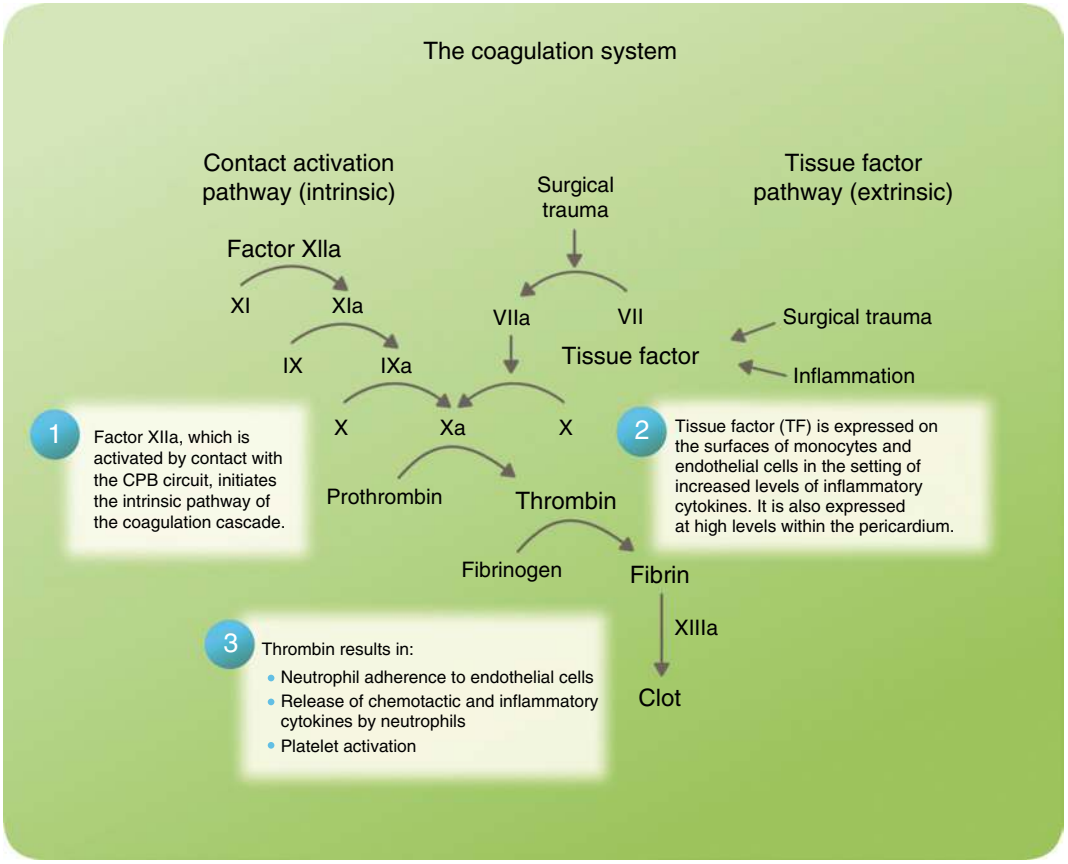

Figure 12.4 The familiar coagulation cascade model showing intrinsic and extrinsic pathways. Rectangles denote enzymes or their corresponding zymogens, and ovals represent cofactors. As mentioned in the text, this model has provided much utility in the past, but fails to account for some simple clinical observations. Examples include failure to fully explain why contact factor deficiencies are not associated with significant bleeding and why factor VIII and IX deficiencies are associated with severe bleeding.

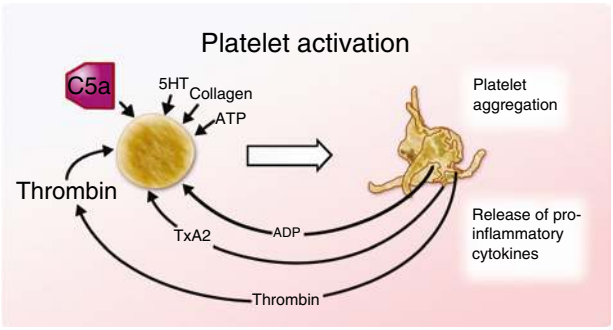
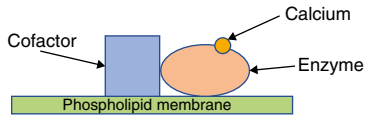
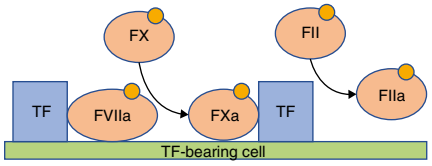
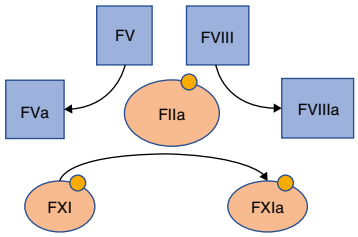


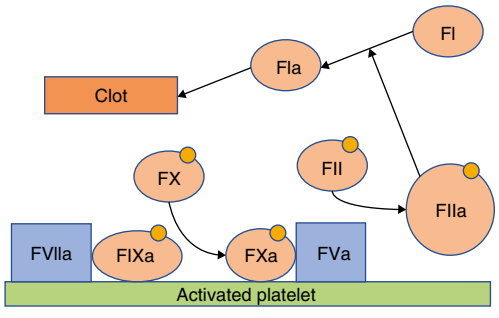
injury. The resulting TF–FVIIa complex activates FX and FIX. The resulting FXa is sufficient to generate a small amount of thrombin (FIIa), localized to the site of injury, since FIIa diffusing away from the site is significantly dampened by antithrombin (AT), and the FVIIa–TF–FX complex is rapidly inhibited by tissue factor pathway inhibitor (TFPI).

In the *amplification phase*, the thrombin that is present activates FV and FVIII, important cofactors for FXa and FIXa, which form complexes on platelet surfaces to increase further generation of thrombin. Platelet activation results in a proliferative increase in phospholipid surface rich in phosphatidylserine, essential for these enzymatic complexes to bind and function, and produces secretion of additional coagulation factors (FV, FVIII, von Willebrand factor [vWF]) from platelet granules [23]. Thrombin also provides an important positive feedback loop by activating FXI, which also generates additional FIXa.









Once these elements are in place (activated platelets, activated cofactors FVa and FVIIIa, thrombin, and FXa and FIXa), the *propagation phase* is marked by sustained thrombin generation provided by the prothrombinase complex (FXa–FVa). The success of this phase depends mostly on activity of the tenase complex (FVIIIa–FIXa), which generates continued amounts of FXa. The endpoint of coagulation is this local, sustained generation of thrombin, which catalyzes conversion of fibrinogen into fibrin monomer, spontaneously polymerizing into fibrin strands to form a stable clot. Thrombin also activates FXIII, which cross-links and stabilizes fibrin clot, increases neutrophil adherence to endothelium, and stimulates neutrophil release of chemotactic and inflammatory cytokines.

Coagulation is normally confined to the region of injury by several mechanisms. Inactivated platelets do not express significant levels of phosphatidylserine on the plasma surface of their membranes and, therefore, do not support coagulation factor activity very well. Upon activation, the platelet outer membrane expresses phosphatidylserine and serves as a platform for the formation of coagulation complexes. Normal endothelium does not express TF, nor does it contain appreciable amounts of exposed phosphatidylserine and, therefore, does not support coagulation. Therefore, any FVIIIa–FIXa or FVa–FXa that diffuse away from the site of injury will not generate thrombin. AT and heparin cofactor II rapidly attenuate any stray FIIa. Thrombin also forms a complex with thrombomodulin on endothelial surfaces, activating protein C, an important control element that cleaves FVa and FVIIIa into inactive fragments.

AL Grawany

(A)

Process	Description	Diagram
General scheme	Assembly of enzyme with cofactor, on phospholipid surface, with calcium ions	
Initiation	FVIIa/TF complex generates Fxa, which generates a small amount of thrombin at the site of injury	
Amplification	Activation of FV, FVIII, and FXI by thrombin (FIIa); activation of platelets with secretion of multiple factors	
Propagation	Sustained generation of FXa on activated platelet surface by FVIIIa/FIXa complex allows for continued production of the prothrombinase complex (FXa/FVa), which produces massive sustained thrombin generation. Thrombin in such quantities converts fibrinogen to fibrin, which polymerizes to form a clot.	

(B)

Figure 12.5 (A) Widespread platelet activation is triggered in the setting of cardiopulmonary bypass (CPB) by the activity of c5a, thrombin, and the secretion of platelet activating factor (PAF) by endothelium. Platelet activation results in a dramatic change in platelet morphology, exocytosis of dense granules and alpha granules, and aggregation. Aggregation is mediated by von Willebrand factor (vWF) and glycoprotein IIb/IIIa receptors that bind fibrinogen. The phospholipid surface of the platelet is the site of assembly of enzyme complexes essential to clot formation. (B) The revised model of coagulation, the cell-based model. Essential to understanding this pathway is the assembly of enzyme complexes on phospholipid surfaces with the requirement for calcium ions. The pathway consists of three overlapping phases: initiation, amplification, and propagation. In the *initiation* phase, exposure of blood to tissue factor (TF) produces a small amount of activated factor X (FXa). This, with FV results in the formation of a small amount of local thrombin (FIIa). In the *amplification* phase, this amount of thrombin is insufficient to produce significant fibrin clot, but it activates FV and FVIII, greatly increasing their activity, and activates FXI, which provides a positive feedback loop by activating FIX. Platelets are activated by contact with the site of injury and provide a massively greater phospholipid surface for the assembly of the complexes in the *propagation* phase. Here, sustained thrombin generation is maintained by continued generation of the FVIIIa/FIXa complex and the prothrombinase complex (FVa/FXa).

CPB and the coagulation system

CPB produces profound alterations in coagulation factor levels and activities, which are quantitatively different in children when compared to adults [24–27]. Because of the large relative pump-prime volume, hemodilution is a much greater cause of decreased factor levels after CPB in children [27]. Dilution and consumption of coagulation factors is the major cause of post-CPB coagulopathy in children [28].

Despite high levels of heparin during CPB, thrombin is generated [25, 29]. It is tempting to assign thrombin generation during CPB to activation of the contact pathway, since blood is exposed to the nonbiologic surfaces of the CPB system. However, patients with contact factor deficiencies (FXII, prekallikrein, FXI) still manifest thrombin generation during CPB [30, 31], indicating that the contact pathway is not driving coagulation during CPB. Rather, exposure of blood to TF is likely the cause. Inflammatory cytokines produce TF expression on endothelium and monocytes, and contact of blood with the nonendothelialized tissues in the mediastinal cavity and elsewhere produces thrombin activation [32]. Thrombin then perpetuates both inflammatory and thrombotic processes. This prothrombotic state may persist for several hours postoperatively, even in the setting of clinical bleeding. In infants, TF expression may extend into the postoperative period [32].

Platelets are activated during CPB and extrude their contents [1, 24]. Glycoprotein receptors become expressed on the platelet surface. Released factors include platelet factor-4, beta-thromboglobulin, and vWF from alpha granules, while the platelet surface expresses adhesion molecules such as P-selectin. Platelet activation and adhesion to endothelium results in additional expression of transmembrane receptors that mediate binding and transmigration of activated neutrophils. This results in additional recruitment of neutrophils to the extravascular space. Furthermore, platelets of young infants are generally less reactive than those of older children and adults, and decreased platelet activation, as measured by changes in adhesive receptor density, has been observed following CPB in infants [33].

Recent attention has been paid to acquired von Willebrand disease (aVWD), represented by loss of high-molecular-weight vWF multimers, in children with congenital heart defects. Reportedly, aVWD is common in this population, both before and after surgery [34–36], but interestingly did not seem to correlate with clinical evidence of bleeding, possibly since endothelial secretion of vWF occurs during surgery due to the stress response [35–37], thus attenuating the effect of a preexisting aVWD. The frequency of aVWD among pediatric patients on other means of extracorporeal circulation, such as *extracorporeal membrane oxygenation* (ECMO) or ventricular assist device (VAD), has been reported at 100% [38], potentially implicating the role of shear stress on blood components as a possible contributor to loss of the high-molecular-weight multimers of vWF. See Chapters 11 and 16 for further discussion of bleeding and coagulation.

Mitigating the deleterious effects of CPB

Practitioners have sought to develop effective means of mitigating the systemic response following CPB in children. Practices include perioperative corticosteroids, modified ultrafiltration (MUF), protease inhibitors, and biocoating of CPB circuitry. Although many such strategies achieve reduction in the levels of various inflammatory markers, studies demonstrating improvement in relevant clinical outcomes show more modest results. Two methods commonly in use include perioperative glucocorticoids and MUF. It is clear that effective modulation of the systemic inflammatory response to CPB in clinically meaningful ways remains elusive.

Corticosteroids

Perioperative corticosteroids are often intended to reduce the systemic inflammatory response and its deleterious effects. Corticosteroids act through nuclear transcription factors, whose binding to promoter regions decreases expression of pro-inflammatory mediators. While studies have demonstrated reductions in inflammatory mediator expression, there is little consensus on the clinical benefits of steroid administration in this setting. Furthermore, there is tremendous heterogeneity among the patient management regimens, and sample sizes are often small. These issues complicate the efforts of systemic reviews and limit their utility.

Thus, a comprehensive review of steroids to minimize the impact of CPB is beyond the scope of any one chapter. With this in mind, however, it is possible to summarize some common themes in our current understanding. In 2012, Pasquali et al. conducted an analysis of data from the Pediatric Health Information Systems (PHIS) and Society of Thoracic Surgeons Congenital Heart Surgery (STS-CHS) Databases [39]. They reported results from 30 pediatric cardiac centers across the United States from 2004 to 2008, comparing outcomes of neonates receiving methylprednisolone on the day prior to or on the day of surgery. The study population included 3,180 neonates from 25 centers. They found no difference in mortality or length of hospital or intensive care unit (ICU) stay between the methylprednisolone and control groups. More recently, Bronicki and colleagues [40] published their findings from a meta-analysis of randomized prospective trials involving steroid treatment to mitigate the impact of inflammation in pediatric CPB. Their findings showed a significant heterogeneity between trials, necessitating the use of a random-effect model. Nonetheless, the authors observe a significant improvement on short-term fluid balance associated with steroid treatment, but no measurable impact on infection or mortality. Likewise, a recent Cochrane review [41] reported findings from a meta-analysis of current pediatric steroid trials, showing that steroid therapy may decrease the duration of mechanical ventilation, but did not show a measurable impact on mortality. Such recent data regarding the lack of clinical effectiveness of perioperative steroids is leading many centers to reconsider their routine use.

Modified ultrafiltration

Hypothermia, hemodilution, and the profound inflammatory response to CPB result in widespread capillary leak and increase in total body water. Dilution of plasma proteins, particularly in the smallest patients, results in further increase in interstitial fluid. Management of total body fluid overload

can be especially challenging in the postoperative period due to concomitant myocardial dysfunction and renal immaturity often seen in the pediatric patient. MUF removes water, low-molecular-weight solutes, and inflammatory mediators via filtration immediately following CPB. It also allows return of the contents of the CPB circuit to the patient in a concentrated form [42]. MUF has been shown in an animal model to attenuate pulmonary-derived inflammatory markers (based on reductions in IL-6 and IL-8 concentrations obtained by bronchoalveolar lavage) seen following bypass. In this model, MUF reduced pulmonary vascular resistance [43]. MUF has been shown to be effective in reducing weight gain during CPB, decreasing levels of activated complement C3a and C5a, and reducing concentrations of pro-inflammatory cytokines [44]. While some studies have shown little appreciable difference in the levels of inflammatory mediators following MUF, others have shown increase in plasma concentrations of IL-6, IL-8, and neutrophil elastase [45].

Clinically, MUF reduces total body water, decreases transfusion requirement, reduces postoperative coagulopathy, and decreases inflammatory marker levels after CPB [46]. A 2011 survey of international pediatric perfusion practice found that 71% of centers reported using some form of MUF [47]. While the clinical outcome differences associated with MUF are not dramatic, the beneficial effects of MUF may be more easily demonstrated in neonatal patients requiring a longer duration of CPB [48].

Protease inhibitors

Protease inhibitors are a class of drugs whose primary role is inhibition of various signaling pathways. Aprotinin, originally marketed as a kallikrein and plasmin inhibitor, decreases transfusion requirements following CPB, but also has substantial anti-inflammatory effects [49, 50]. Two randomized trials have shown decreased hospital stay and cost associated with aprotinin [51, 52]. Another blinded, controlled, randomized, prospective trial in 60 children weighing under 10 kg reported decreased ventilator time [53]. Both aprotinin and tranexamic acid (not a protease inhibitor) reduce expression of pro-inflammatory genes and increase expression of anti-inflammatory proteins [54].

Since 2006, aprotinin use has severely declined, and aprotinin is now unavailable in many countries, including the United States. The departure of aprotinin has been driven mostly by epidemiologic evidence for renal failure in adults [55–58]. Whether the same risk transfers to the pediatric population is unclear: Three retrospective studies did not identify aprotinin as an independent risk factor for perioperative renal failure in children [59–61]. However, another retrospective pediatric study reported an association between aprotinin and perioperative renal failure when compared with aminocaproic acid, after controlling for confounding variables [62].

Biocompatible CPB circuits

Efforts to improve CPB circuit biocompatibility are often anticipated to decrease activation of cellular and humoral inflammation and attenuate end-organ injury associated with CPB. Although the initial rationale for heparin coating of CPB circuitry was related to the anti-thrombotic effects of heparin, the use of heparin-coated CPB circuit components has reduced complement activation, cytokine production, and improved pulmonary function [63–65]. Heparin-coated circuits also appear to adsorb lipoproteins, which may create a circuit surface that approximates that of cell membranes [66]. A recent small randomized study of perfusion circuits coated with a novel ternary polymer (SEC-1) showed significantly decreased inflammatory markers and improved preservation of multiple coagulation elements [67].

Though definitive data on clinical outcomes in children regarding heparin-bonded circuits are lacking, adult data suggest that biocompatible circuits are associated with reduction in RBC transfusion, re-sternotomy, duration of mechanical ventilation and ICU length of stay, and inflammatory response following CPB [68, 69]. The clinical impact of biocompatible perfusion circuitry in children warrants further study, particularly in high-risk patients.

KEY POINTS: THE SYSTEMIC INFLAMMATORY RESPONSE AND CONGENITAL CARDIAC SURGERY

- Cardiac surgery and bypass induce complex cellular and humoral inflammatory responses.
- Inflammatory events are initiated by contact of blood with foreign surfaces, heparin–protamine complexes, endotoxin, and transfusion.
- Endothelial damage induces diffuse capillary leakage and coagulation system activation.
- Platelet activation results in coagulation system activation and recruitment of additional inflammatory cells.
- Activated neutrophils cause proteolytic tissue injury, capillary leak, and increased pulmonary vasoconstrictor response.
- Cardiac beta-adrenergic receptors decrease in number and efficiency during bypass.
- Evidence for use of glucocorticoids is equivocal.
- MUF removes free water and inflammatory mediators after CPB.
- Heparin-bonded circuits improve laboratory markers of inflammation, with modest or equivocal improvements in clinical outcomes.

Clinical effects of congenital heart surgery on hemostasis and thrombosis

These major physiologic disturbances of the inflammatory and coagulation pathways produce significant morbidity in the form of hemorrhagic and thrombotic complications. Perioperative risk of bleeding and thrombosis increases in both severity and frequency with decreasing age of the child [26, 70–73]. Infants under 1 year of age experience average blood losses within the first 24 hours after surgery of about 40 cc/kg, which is about half of the patient's blood volume [73]. Perioperative thrombosis is also associated with significant morbidity, sometimes severe [74–78]. Venous thrombosis in children is a potentially devastating complication of congenital heart surgery and is reported to occur in as many as

16% of cases [79–81]. Central venous thrombosis and massive thrombotic disease in multiple organs occur with highest frequency in the youngest children and can yield catastrophic sequelae [33, 82, 83].

Unique aspects of pediatric coagulation

It is important to understand that, like many other organ systems, the hemostatic system of young infants differs significantly from that of older children and adults [21, 84, 85], giving rise to a concept known as "developmental hemostasis" (Figure 12.6). Healthy infants exhibit levels of the contact factors (FXII and FXI, HMWK, prekallikrein) that are 40–50% of adult levels at birth, and approach adult levels by 6 months of age. This profile is also followed by the vitamin K-dependent factors (FII, FVII, FIX, and FX) [84, 86–88]. FV, FVIII, and vWF reach adult levels more rapidly, and, as is the case for vWF, can exceed adult levels. Coagulation inhibitors (AT-III, C1 inhibitor, heparin cofactor II, protein C, and protein S) again follow the pattern of the contact and vitamin K-dependent factors [84]. Fibrinogen and plasminogen, although present at nearly adult levels in the term newborn, exist in forms that differ in their post-translational modification [89, 90]. Accordingly, laboratory reference ranges need to be based on age-matched samples from normal children.

Hemostasis in congenital heart disease

Congenital heart disease (CHD) imposes additional modifications on pediatric hemostasis (Table 12.1). In cyanotic children, polycythemia further dilutes coagulation factors. Decreased levels of FV, FVII, and FVIII and increased fibrinolysis, thrombocytopenia, and abnormal platelet function are frequently present and correlate with the degree of cyanosis [91]. Thrombocytopenia resulting from decreased platelet survival and fibrinogen dysfunction complicate the hemostatic picture and contribute to increased risk for bleeding [92, 93]. Children with CHD have increased incidence of heritable coagulopathies [94, 95] and combined deficiencies or partial deficiencies of FVIII, FXI, and FXII [96]. As mentioned above, loss of high-molecular-weight vWF multimers, representing a form of aVWD, is often observed in children with cardiac defects [97].

Table 12.1 Effects of cyanosis on coagulation physiology

Thrombocytopenia
Decreased platelet survival
Acquired von Willebrand disease
Fibrinogen dysfunction
Low-grade consumptive coagulopathy
Decreased coagulation factor levels
Accelerated fibrinolysis

Hemostatic anomalies of cyanosis are widespread and complex, and involve multiple elements of the coagulation and fibrinolytic systems [92, 93].

Risk factors for hemorrhagic complications in pediatric cardiac surgery

Numerous studies have identified clinical risk factors for hemostatic complications after pediatric cardiac surgery. In their classic study of over 500 pediatric patients, Williams et al. found that postoperative bleeding is associated with higher hematocrit, complex surgery, lower platelet count, and duration of circulatory arrest, but younger age was the most significant contributor [98]. Since then, other multivariate analyses have revealed that hypothermia, surgical complexity, high preoperative hematocrit, low platelet count, and decreased platelet function were highly correlated with

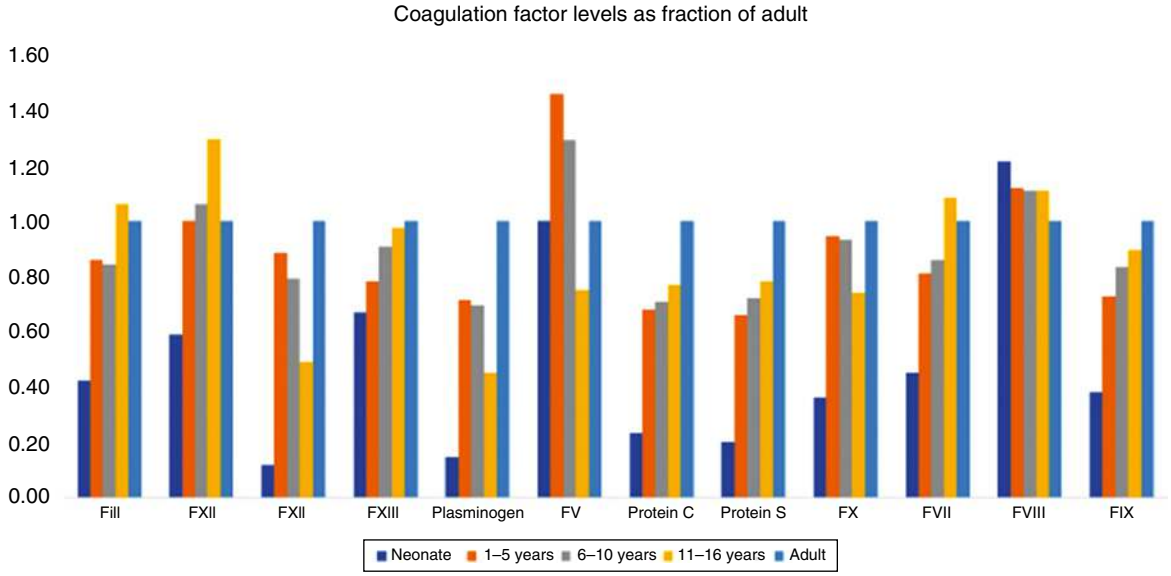


Figure 12.6 Developmental hemostasis. Factor levels in infants and younger children are generally lower than those of adults and evolve with age. Laboratory factor measurements and assays of coagulation need to be standardized for appropriate age groups. (Source: Data from Attard et al. [84].)

AL Grawany

Box 12.1: Coagulation system and cardiac surgery

- Coagulation system of infants and children is unique
  - Lower levels of many factors
  - Expression of differently processed forms of some factors
- Congenital heart disease imposes changes on coagulation system:
  - Frequent concurrent deficiencies of many factors
  - Cyanosis-induced decreases in factors V, VII, and VIII
  - Increased fibrinolysis
  - Low-grade disseminated intravascular coagulation (DIC)
  - Decreased platelet number and function
- Cardiac surgery imposes changes on the coagulation system of children:
  - Hemodilution
  - Fibrinolysis
  - Platelet dysfunction
  - Thrombin generation and factor consumption

blood loss and transfusion [70, 73, 98–101]. Some evidence suggests postoperative bleeding risk may vary among different ethnic groups [102]. Box 12.1 summarizes coagulation system changes in pediatric cardiac surgery.

Transfusion, inflammation, and outcomes

Transfusion alone appears to exacerbate the systemic inflammation of cardiac surgery. Transfusion following cardiac surgery is associated with various markers of inflammation [103], and with clinical outcomes such as longer ventilator times [104–106]. Univariate analyses show that red cell transfusion is associated with nearly every complication of congenital heart surgery, and transfusion is strongly associated with infectious complications, after controlling for confounding variables in a propensity analysis [107]. The authors have argued transfusion-related immunologic responses alone are good reasons to optimize transfusion management [105, 106, 108].

Transfusion in pediatric cardiac surgery

The rational approach to a bleeding pediatric cardiac surgery patient represents a significant clinical challenge for which the literature often provides limited prospective data. In a study with 75 children, platelet transfusion was most effective for post-CPB bleeding in patients under 8 kg. Continued bleeding was improved with cryoprecipitate but was made worse by plasma in this study [70]. Plasma is often ineffective in children probably because higher doses are required than the usual 10–15 mL/kg [109, 110]. Plasma added to the bypass prime may be beneficial, but the effect seems confined to the smallest patients [111, 112]. Fibrinogen concentrate has been proposed as an alternative for cryoprecipitate, but efficacy appears to be best for the adult cardiac surgery population [113–117], as data in children do not currently support its use [118].

While transfusion is frequently required in children in order to maintain adequate oxygen delivery, efforts should be made to reduce the volume of transfusion required. In a recent systematic review [119] of 299 studies of transfusion optimization from 22 countries, the authors concluded that the following efforts have merit in managing perioperative bleeding: antifibrinolytic drugs, objective transfusion guidelines, point-of-care testing, MUF, and circuit optimization. A large amount of heterogeneity regarding end point definition, patient population, and management schema and frequently small trial sizes made definitive conclusions difficult.

Still unclear is the issue of liberal versus restrictive transfusion thresholds. Although the literature on transfusion thresholds in adults is rapidly expanding, similar studies in children with CHD are fewer and less conclusive. Cholette [120] provides a recent summary of the pediatric cardiac surgery literature on restrictive versus liberal transfusion thresholds, summarizing the four existing studies [121–124] at the time. Despite concerns regarding exclusion criteria and small study size, the authors concluded that a more restrictive transfusion regimen (target hemoglobin 7 g/dL for biventricular repairs, 9 g/dL for cavopulmonary surgeries) may be well tolerated or even advantageous in these populations. They issue caution, however, that these results need to be validated and reproduced in larger trials and by other investigators before practice guidelines can be issued.

Objective, laboratory-guided transfusion algorithms have shown significant benefit in adult cardiac surgery [125], but it is difficult to extrapolate these conclusions to children, since adult and pediatric cardiac surgery are qualitatively different [126, 127]. Furthermore, not all reports of transfusion algorithms in children have shown positive results [128]. To be clinically useful, laboratory-guided protocols must rely on some reproducible, widely accessible metric. Routine coagulation tests, thromboelastography (TEG), and platelet count can predict postoperative bleeding in children after CPB [129, 130], which assists clinicians somewhat in identifying patients at risk. The use of TEG to specifically guide transfusion practice in pediatric cardiac surgery has been reported, with generally favorable results [28, 117, 131, 132]. A 2-year retrospective study of an objective transfusion algorithm in pediatric cardiac surgery has shown a significant savings of red cells, cryoprecipitate, and plasma and a 75% reduction in mortality following implementation of the algorithm [133]. In a recent review, the authors summarize a very broad literature, which includes the use of factor concentrates, but continue to emphasize the recurring observations that algorithms need to be institution-specific and that a transfusion-guided algorithm is superior to non-algorithm-guided transfusion [134].

Antifibrinolytics in pediatric cardiac surgery

Thrombin generation during CPB, and kinin activity from kallikrein activation, produce plasmin and thus activation of the fibrinolytic pathway. Accordingly, antifibrinolytic drugs (aprotinin, aminocaproic acid, and tranexamic acid) have long been useful adjuvants for limiting blood loss due to cardiac surgery. In general terms, their efficacy in children has been less consistent than in adults. Unlike adults, most children do not exhibit profound fibrinolytic activity after CPB [33, 72], and consequently, efforts to reduce bleeding by the

use of antifibrinolytic drugs are usually less effective in children than in adults [52, 135–139]. Some evidence in children suggests that fibrinolysis alone does not correlate with blood loss or transfusion in children [72]. The literature on antifibrinolytics for pediatric cardiac surgery is very broad, with much heterogeneity in end point definition and treatment protocols; therefore, the interested reader is referred to an excellent recent review [140].

When it was still available, aprotinin has been used in pediatric cardiac surgery, despite lack of the Food and Drug Administration (FDA) approval for pediatric use. Endpoints of blood losses and transfusion appear not as striking as those for adults, and a wide range of dosing schemes has been reported. Many prospective pediatric trials report hemostatic benefits with aprotinin [141–143], but most show equivocal results [52, 135–138, 144–146]. One of these studies [146] was terminated early by the FDA due to growing safety concerns in adults [55–58]. Nevertheless, beneficial effects of aprotinin in children extend beyond hemostasis. As mentioned previously, decreased hospital stay, shorter ventilator time, and decreased cost have been associated with aprotinin in children [51–53]. These improvements are likely a result of the anti-inflammatory effects of aprotinin, producing improved organ preservation and suppressed response to extracorporeal circulation.

The lysine analogs (aminocaproic acid and tranexamic acid) have been the only antifibrinolytics in clinical use since 2006. The lysine analogs probably do have efficacy in children, but less than that of aprotinin [147–149]. As with aprotinin, the efficacy of lysine analogs in children has been inconsistently reported, and differs between subgroups. Pediatric use of aminocaproic acid has been reported, but many of these studies were performed in the 1960s and 1970s, when surgical, anesthetic, and perfusion techniques were quite different than they are today [150, 151]. Williams et al. compared aminocaproic acid versus placebo control in a nonrandomized study involving 140 children and demonstrated nonsignificant decreases in blood losses and transfusion requirements [152]. Tranexamic acid has shown efficacy in children undergoing redo cardiac procedures [139], both in cyanotic and noncyanotic patients [153]. An earlier study of pediatric use of tranexamic acid was only able to demonstrate a reduction in postoperative blood loss in a subset of cyanotic children [154]. In a nonblinded trial, both aminocaproic acid and tranexamic acid were found to be equally beneficial in 150 cyanotic children [155]. The overall conclusion regarding the currently available antifibrinolytics (lysine analogs) is that these agents are safe and effective in the pediatric population [140].

MUF in pediatric cardiac surgery

As mentioned previously, MUF concentrates hemostatic factors and removes inflammatory mediators, thus reducing postoperative coagulopathy [156]. MUF appears to be most effective at improving hemostasis for the smallest infants [48, 157, 158]. Bando et al. compared MUF after CPB against conventional ultrafiltration and observed a 2.5-fold decreased risk of red cell transfusion and 6-fold decreased risk of coagulation factor transfusion with MUF [48]. Other investigators have shown similar improvements in post-CPB coagulopathy or transfusion requirements with MUF [159–163]. Additional benefits include improved hemodynamics and cardiac performance [159, 160, 163–165], decreased ventilatory support [48, 163], and shortened hospital stay [44, 162, 163] (Table 12.2). These effects have not been reported in all studies [157, 166]. A meta-analysis of eight MUF studies showed improved hematocrit and hemodynamics compared with standard ultrafiltration, but later end points were equivocal [167].

Table 12.2 Reported benefits of modified ultrafiltration

Concentration of red cells and coagulation factors
Decreased red cell and coagulation factors
Decreased need for inotropic support
Shorter ventilator times
Shorter ICU stay
Shorter hospital stay

Modified ultrafiltration after CPB improves not only hemostasis and transfusion, but has benefit in other organ systems, possibly due to decreased levels of inflammatory mediators, decreased capillary leak, and improved myocardial performance [156].

Other methods to minimize transfusion

Investigators have reported successful use of alterations in perfusion techniques, some of which avoid transfusion altogether, even in very small infants. Minimizing the volume of the pump prime [168–171], or use of a miniaturized bypass circuit [171, 172], has shown efficacy for reducing transfusion in small children. Alterations in pump composition such as a remote pump head resulted in no transfusion for 122 of 178 infants under 5 kg [173]. Use of washed red cells [174], fresh whole blood [71, 170, 175], heparin-coated circuits [176], use of an autologous blood prime [177], and anticoagulation management based on heparin concentration rather than ACT [178] have all reported efficacy in the pediatric population. However, practice guidelines have yet to be issued for most of these techniques often due to small study size, heterogeneity of end point definition and patient management protocol, possibility of publication bias, and lack of reproducibility of the results.

Other hemostatic agents

Recombinant activated factor VII (rFVIIa) has been used with increasing frequency as a rescue hemostatic agent in cardiac surgery for about the past two decades. Case reports of its use in pediatric cardiac surgery abound [179–183]. Serious concern exists regarding perioperative thrombosis, but the anecdotal nature of case reports and small case series makes it difficult to evaluate thrombotic risk associated with this agent, since it is typically administered to patients in dire need, who are likely to be at increased risk for thrombosis. To deal with this issue of confounding, a recent propensity analysis of 143 subjects receiving rFVIIa matched 1 : 2 with controls was reported by Downey and colleagues [184], who observed significant morbidity associated with the use of rFVIIa, including an independent risk for thrombosis. The rational use of rFVIIa in pediatric cardiac surgery has been

reviewed [185, 186]; the authors emphasize the need for randomized trials to clarify efficacy, subgroup analysis of population at risk, and the realistic assessment of thrombotic complications. Furthermore, a Task Force has been formed by the Congenital Cardiac Anesthesia Society, assigned to monitor the literature and issue recommendations as data become available [186].

Low antithrombin-3 (AT3) levels may place very young children at increased risk for bleeding, since such deficiency decreases the efficacy of heparin and therefore results in greater coagulation activation during CPB, with corresponding increase in coagulation factor consumption. Recent investigations have identified low AT3 as an independent risk factor for transfusion following cardiac surgery [29, 187], and a prospective trial of recombinant AT3 has reported efficacy specifically for small infants when this deficiency can be identified preoperatively [188]. Supplemental AT3 has also shown efficacy in the setting of ECMO [189].

Desmopressin has minimal hemostatic effects in adult cardiac surgery, and its specific impact in the pediatric population is probably also modest at best [190–193]. The use of other factor concentrates (fibrinogen concentrate, prothrombin complex concentrate) in pediatric cardiac surgery has been recently reviewed [118, 194]. These agents, initially proposed as rescue treatments for refractory hemorrhage, are now appearing in transfusion algorithms as standard treatments. The authors emphasize the need for high-quality studies of safety and efficacy, with standardized definitions of outcomes, prior to issuing any evidence-based recommendations.

Thrombosis in pediatric cardiac surgery

Thrombosis is frustratingly common in children with CHD since it is associated with significant morbidity [74–78]. In a series of single ventricle patients, systemic-to-pulmonary shunt occlusion accounted for 9% mortality during a 6-year follow-up [195]. Other authors report a 14% post-discharge mortality in a similar series, 81% of which was sudden and unexpected. Aspirin did not alter risk in this population [196]. In long-term studies, thrombosis has been identified as the first [197] or second [198] most common cause of late mortality in Fontan patients. Echocardiographic evidence of thrombus exists in as many as a third of asymptomatic children following the Fontan operation [74], with venous thromboembolism and stroke occurring in 19% of these patients [78]. The vascular access necessary for catheterization procedures is associated with a high rate of thrombosis [78], and post-thrombotic syndrome frequently complicates the clinical course [199]. Furthermore, reported incidence rates of thrombosis vary widely between institutions [74, 200–203], complicating comparisons between studies and interpretations of their results.

Risk factors for thrombosis in children with CHD

Thrombosis has some identifiable risk factors. Petaja et al. describe thrombotic events heralded by hypofibrinolysis in a small series of 10 neonates undergoing cardiac operations [33]. In this study, central venous thrombosis was associated with increased PAI-1, AT3, and protein C levels. In another case series of children with thrombosis and CHD, both acquired and inherited risk factors were found to be significant [200]. Some of these factors included multiple cardiac catheterization procedures, presence of a central venous line, pulmonary stenosis, aortic coarctation, and systemic infection. However, this study identified only 59 subjects with thrombosis and CHD, and an analysis of the interaction between environmental and genetic variables was not performed. Steen and colleagues recently confirmed the strong contribution of a central venous line to thrombosis risk in their cohort of 851 critically ill children [204]. Other risk factors identified in their cohort included longer ventilator times and ICU stay, low cardiac output syndrome, sepsis, catheter-associated blood stream infection, and cardiac catheterization. Interestingly, CPB was observed to have a protective role in thrombosis in this population.

Ali and colleagues recently reported thrombosis outcomes from their cohort of 369 pediatric subjects, 18% of whom experienced thrombosis [205]. Thrombosis in their population was associated with cyanosis, neonatal surgery, preoperative antiplatelet or anticoagulant therapy, and post-CPB transfusion. Transfusion was also identified as a thrombotic risk factor in a previous study of 138 children [206]. In other reports, markers of inflammation such as elevated free heme [207] or C-reactive protein levels [75] may also predict risk. Recent evidence is emerging that red cells probably contribute to coagulation activity [208], and some studies report that red cell transfusion increases thrombosis risk in pediatric surgery [208–212].

The role of genetic thrombophilias, such as FV Leiden (FVL), as a risk factor in this population has been evaluated, but the findings are difficult to interpret [81, 83]. Petaja's group reported central venous thrombosis in 20 of 1,591 pediatric patients undergoing CPB [83]. Of these, 12 were tested for activated protein C resistance, and 2 were positive. Ong et al. [81] screened a group of 200 consecutive pediatric cardiac surgery patients for FVL, but found the mutation not to be significantly associated with thrombotic risk. Protein C sensitivity, the laboratory coagulation phenotype which is reduced in the presence of the FVL mutation, has been associated with the degree of cyanosis in children with CHD, independent of FVIII levels and the presence of FVL [213], suggesting that cyanotic children are at decreased risk for thrombosis. Box 12.2 summarizes risk factors for thrombosis.

Box 12.2: Risk factors for thrombosis in children with congenital heart disease

- Presence of a central venous line
- Multiple intravascular interventions
- Pulmonary or aortic stenotic lesions
- Cyanosis
- Polycythemia
- Cavopulmonary anastomosis

KEY POINTS: EFFECTS OF CONGENITAL HEART SURGERY ON COAGULATION, HEMOSTASIS, AND THROMBOSIS

- Coagulation in cyanotic CHD is altered by cyanosis and surgery overlaid upon normal developmental coagulation.
- Bypass induces activation of the coagulation and fibrinolytic systems, placing cyanotic, thrombocytopenic infants at the greatest risk for postoperative hemorrhage.
- Lysine analogs have efficacy in bypass, especially cyanotic or resternotomy patients.
- Aprotinin improves hemostasis and hemodynamics and reduces inflammatory response and ICU stay.
- MUF improves hemostasis and other clinical outcomes.
- Thrombosis is a source of significant morbidity, and it is incompletely understood.
- Although treatment guidelines have been issued, primary prevention of thrombosis in children with CHD suffers from lack of strong supporting data.

Pulmonary effects of congenital heart surgery

Neonatal and pediatric pulmonary physiology: a compromised state

All physiologic systems carry an inherent amount of reserve, which is the capacity to increase their function to maintain homeostasis in the setting of a physiologic compromise. The pulmonary system is indeed able to compensate for injury by increasing ventilation and redistributing pulmonary flow. However, there are numerous features of the pediatric pulmonary system that place infants and children at increased risk of pulmonary failure in the setting of systemic injury (Table 12.3).

Metabolic compromise: The demands placed on the respiratory system of children are greater at baseline than those of adults, because of the increased metabolic rate of childhood [214]. Infants and young children, being in the active phases of growth and development, consume two to three times as much oxygen on a per kilogram basis, and generate correspondingly more carbon dioxide than do older children or adults [215]. Furthermore, hypoxic and hypercapnic drive of ventilation is attenuated in infants compared with older children or adults [216, 217]. Compromise of ventilation will therefore lead to respiratory failure sooner, and failure will accelerate faster in children, especially infants.

Table 12.3 Respiratory physiology in neonates and small infants

- Increased physiologic demands due to growth and development
- Mechanical compromise of chest bellows
- Metabolic compromise of diaphragm
- Decreased total lung capacity and functional residual capacity (FRC)
- Closure of smaller airways at FRC
- Atelectasis from surfactant deficiency
- Shunting due to retained lung fluid
- Decreased 2,3-diphosphoglycerate shift of fetal hemoglobin
- Pulmonary vascular disease from lesions with pulmonary overcirculation

Mechanical compromise: Air movement in and out of the lungs is driven by muscular actions on the bony structures of the chest. The diaphragm is the principal muscle of ventilation, but intercostals, scalenes, sternocleidomastoid, and even pectorals can be recruited in sequence as respiratory function demands. In children, the horizontal positioning of the ribs, and the increased compliance of nonossified bone, renders the intercostals and other accessory muscles at a distinct mechanical disadvantage [218]. Hence, the diaphragm must assume a greater share of respiratory work, and recruitment of accessory muscles offers less of an advantage.

The diaphragm of the infant, however, is less able to sustain increased aerobic work than that of the older child. Small children are also less able to increase their tidal volumes and therefore must increase minute ventilation by increasing in respiratory rate. The diaphragm and intercostal muscles of young infants have fewer of the type I, slow-twitch fibers than do the corresponding muscles of older children or adults [219]. These fibers are uniquely capable of higher oxidative capacity and offer a degree of insurance against fatigue when ventilatory demands are increased.

Ventilatory compromise: The resting ventilation of infants and young children differs markedly from that of older children in its classic spirometry. Because total lung capacity (TLC) is an effort-driven parameter, the TLC of an adult on a weight basis is much greater than that of a small child. Functional residual capacity (FRC) is defined as the lung capacity at which the elastic recoil forces of the lung and the passive recoil of the chest wall are equal and represents the volume in the lungs at the time of end expiration during quiet breathing. For infants and small children, FRC is significantly reduced; hence, a hypoventilating or apneic infant sequesters a disproportionally smaller reserve of intrapulmonary oxygen than an older child, leading to a more rapid development of hypoxemia [220, 221].

The closing volume of an infant's smaller airways is within the range of the infant's normal tidal volume [217, 220]. This means that during normal ventilation, some of the smaller airways close, resulting in air trapping. A specific lung volume is therefore not in communication with extrapulmonary air, possibly leading to atelectasis, ventilation–perfusion mismatching, and hypoxemia. Awake infants can re-establish their lung volumes by crying, deep vital capacity breathing, sighing, and movement, all of which are diminished or ablated by iatrogenic interventions such as anesthesia and sedation.

While small airway resistance contributes about 20% to the total airway resistance of the adult airway, these smaller airways contribute about half of the total airway resistance in infants [222–224]. Therefore, inflammatory injury to the lung, which results in small airway edema and lumen narrowing, makes a greater contribution to obstructive airway disease in smaller children. In the cardiac setting, this is highly relevant,

AL Grawany

as the inflammation associated with CPB and edema resulting from volume overload or increased pulmonary venous pressures are common.

The lungs of children have not finished growing. Although the major parts of the bronchial tree are formed during gestation, expansion of the alveolar population continues into the eighth year of life. Pulmonary vessel growth follows the development of alveoli. Smooth muscle development in pulmonary arteries of normal lungs is complete in adolescence.

Compromise of neonatal oxygen delivery: Very young infants can experience transpulmonary shunting, hypoxemia, and impaired oxygen delivery for other reasons. A newborn infant's lungs occasionally retain residual lung fluid, which contributes to transient tachypnea of the newborn [225]. This is often, but not always, self-limiting. Atelectasis in the first few days of life in term neonates or in preterm infants due to surfactant deficiency can also contribute to shunting [226]. Fetal hemoglobin has a significantly attenuated shift of its oxygen affinity in the presence of increased 2,3-diphosphoglycerate, which can compromise neonatal oxygen delivery in the setting of anemia or tissue hypoxia states [227].

Compromise arising from CHD: CHD further imposes another set of unique compromises to the pediatric pulmonary system. Pulmonary hypertension, most often arising from preexisting pulmonary vascular disease (PVD), is a frequent and often predictable sequela of pulmonary overcirculation, and portends significant perioperative morbidity [228–230]. PVD develops as increased pulmonary flow produces a recognized histologic pattern of pulmonary vascular remodeling. PVD increases in severity with both the duration and magnitude of excessive pulmonary blood flow.

In normal neonates, pulmonary vascular endothelium and vascular smooth muscle continue to develop into their mature phenotypes after birth and throughout the first years of childhood. When pulmonary flow is excessive, a different developmental trajectory is followed, with histologic evidence of medial hypertrophy, intimal hyperplasia, and decreased numbers of interacinar arteries being evident within months [231]. A histologic grading system, known as the Heath–Edwards classification, is used to assign a severity score to these changes (on a scale of 1–6). The Heath–Edwards grade predicts reversibility of PVD changes upon correction of excessive pulmonary flow. Pulmonary resistance is increased in PVD, and pulmonary vessels in PVD have increased sensitivity to vasoconstrictive stimuli of hypoxemia, hypercarbia, and acidosis, placing the patient with PVD at significant risk for perioperative cardiac failure [232]. Indeed, pulmonary hypertension, regardless of cause, continues to be a major risk factor for heart failure and other cardiac complications in patients with CHD. However, as hemodynamic data from the catheterization laboratory correlates with histologic grade, and lung biopsy carries significant risk, biopsy is not routinely used to assess prognosis in univentricular heart surgery [231, 233–236].

Cardiac performance significantly impacts pulmonary function. Increased pulmonary venous pressure, whether from arrhythmia, valve dysfunction, systolic dysfunction, or obstructive lesions, results in increased lung water and interstitial edema [237]. In the cardiac surgical setting, this can have disastrous effects on pulmonary compliance and gas exchange, elevating the work of breathing for what is often an already compromised patient. This is discussed in greater detail below. Cardiac surgeries which result in alterations of thoracic venous or lymphatic drainage (i.e. cavopulmonary connection or thoracic duct injury) may result in pleural effusion and/or chylothorax, which is exacerbated by the endothelial dysfunction associated with CPB. Postoperative prolonged pleural effusions are a significant source of prolonged mechanical ventilation and hospital stay [238–240].

Pediatric cardiac surgical patients often have impaired nutritional status, an often under-appreciated aspect of clinical care [241]. Approximately one in four children with CHD meets the criteria for failure to thrive within the first year of life, and half of those with single ventricle physiology require supplemental tube feeding [242]. The consequences of delayed growth and suboptimal nutrition for the cardiorespiratory system are not simply a matter of size [243]. Respiratory muscle drive and cardiac performance are measurably impaired in malnutrition [70, 244–246]. Both humoral and cell-mediated immune suppression render the malnourished child susceptible to perioperative infection [246–248]. Growth failure in the congenital heart surgery population has been associated with longer hospital length of stay, increased risk for infection, worse neurodevelopmental outcome, and mortality [242].

Children with congenital heart malformations often have other associated anomalies of the head, neck, mandible, teeth, and upper airway, both congenital and acquired. CHARGE, VACTERL, and Trisomy 21 frequently have associated malformations, which can make it difficult to secure the airway by the standard means of direct laryngoscopy [249–253]. With many children with CHD undergoing numerous cardiac surgeries, acquired respiratory tract disorders are increasingly common. Recent retrospective studies have shown a rate of acquired airway abnormality of 6.7%. The most common acquired airway abnormalities were vocal cord paralysis, bronchomalacia, and subglottic stenosis. All of these disorders can complicate airway management with many children having a combination of acquired and congenital airway abnormalities [254]. When these difficulties are appreciated, alternative approaches of airway management can be considered. If such difficulties are not appreciated, these associated anomalies may lead to prolonged apnea and failure to oxygenate or ventilate. When extubation is planned in the operating room, a greater degree of ventilatory performance is probably prudent to prevent the urgent need for reintubation under hurried circumstances.

It is therefore no surprise that children with CHD face a perioperative course fraught with potential pulmonary complications. Indeed, pulmonary complications represent significant sources of perioperative morbidity and mortality, increasing in severity and frequency with the decreasing age of the child [255–258]. In a study of nearly 700 children with CHD, preoperative respiratory insufficiency predicted the longest postoperative length of ICU stay [259].

Effects of CPB on pulmonary physiology in children

CPB and pulmonary vascular resistance

The obligatory mechanical support of the circulation during repair of congenital heart lesions is by no means a benign intervention. The coagulation system is severely attenuated while the entire blood volume of the patient is circulated in an elaborate system of plastic polymers and uncoated steel for an unspecified duration, during which time the entire patient is intentionally cooled to nonphysiologic temperatures. During much of this time, there is often no coronary flow, pulmonary flow is almost completely arrested, and perfusion to the remaining vital organs loses the pulsatile waveform under which these organs have thrived and evolved. Blood in contact with TF-bearing surfaces is often returned directly to circulation, and hemolysis is generated from suctioning and blood–air contact. Reperfusion and rewarming release the heralded cascade of ischemia–reperfusion responses, and post-bypass transfusion brings a flood of transplanted cells and proteins from a genetically distinct host. The lungs, now receiving 100% of the cardiac output (in a two-ventricle repair), bearing a massive area for gas exchange in a delicate capillary bed, and having an exquisitely sensitive arterial tree, respond profoundly to these perturbations, both local and remote.

Increased PVR, therefore, frequently complicates the postoperative care of pediatric cardiac surgery patients and represents a major risk factor for morbidity [260–262]. In various pediatric cardiac populations, increased PVR is associated with prolonged duration of ICU stay, prolonged duration of mechanical ventilation, and increased postoperative mortality [259, 260, 263–266]. It is a gross simplification to attribute the important postoperative increase in PVR to a single vasoactive mediator or process. Direct causes of increased PVR in the postoperative patient are quite numerous and include increased reactivity of the pulmonary vasculature, duration of CPB, hypothermia, acidosis, endothelial dysfunction, and preexisting PVD [260].

The endothelium is a pivotal tissue in the pathophysiology of elevated PVR following cardiac surgery. Through its secretion of vasorelaxant prostanoids and nitric oxide, the endothelium guards against unopposed vasoconstriction mediated by catecholamines, angiotensin, and endothelin [267]. This relaxant function is acutely disrupted by CPB [10, 268–270]. Although the cellular and subcellular mechanisms responsible for CPB-induced endothelial dysfunction have not been completely characterized, pulmonary ischemia–reperfusion injury is thought to be crucial in its etiology, despite early conjectures that the bronchial circulation provided adequate maintenance of pulmonary perfusion during CPB [10, 271]. Continuous perfusion of the lungs during CPB has been shown to improve oxygenation and decrease duration of postoperative mechanical ventilation in children [11, 272]. In fact, the perfusate need not even be blood; in a small prospective trial, lung perfusion with blood-free organ preservation solution during CPB resulted in improved oxygenation and decreased inflammatory response [272]. Laboratory studies have provided evidence for calpain and NF-κB as molecular mediators responsible for this ischemia-related increase in PVR [273, 274] (Table 12.4).

Table 12.4 Effects of cardiac surgery on lung physiology in children

- Ischemia–reperfusion injury
  - Impaired endothelial-dependent relaxation
  - Increased vasoreactivity of pulmonary vasculature
  - Increased lung water
- Impaired gas exchange
- Reduced lung compliance
- Decreased surfactant production and quality
  - Atelectasis of lung segments or lobes
  - Transpulmonary shunting
- Loss of lung volumes from deflation during cardiopulmonary bypass or presence of devices

Management of post-CPB pulmonary hypertension

Because CPB-induced increase in PVR is the result of a complex interplay of inflammation, reperfusion, and endothelial dysfunction, clinicians have successfully intervened with therapies directed toward a multitude of cellular and physiologic pathways. General measures include optimization of hematocrit, pH, ionized calcium and other electrolytes, temperature, adequate ventilation, high-dose narcotic, neuromuscular blockade, and treatment of arrhythmias. Pulmonary vasodilators (nitric oxide and its donors, phosphodiesterase inhibitors (PDEIs), and prostaglandin analogs) and inotropic support constitute the mainstay of specific therapy, as discussed below [275]. Additional adjunctive treatments involving anti-inflammatory agents [276], antioxidants, and protease inhibitors have shown some usefulness. In practice, pulmonary hypertension and right ventricular failure often involve multimodal management with a variety of agents and therapies [274, 277, 278].

Soon after the discovery of nitric oxide as the fundamental endothelial-derived vasodilator, inhaled nitric oxide (iNO) was employed as an agent to treat pulmonary hypertension [279, 280]. Nitric oxide is a small molecule that diffuses rapidly across membranes and has a biological half-life of only a few seconds owing to its rapid binding and inactivation by hemoglobin. It binds reversibly to and activates soluble guanylate cyclase, which catalyzes the conversion of guanosine 5′-triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). This subsequent messenger activates cGMP-dependent protein kinase, which phosphorylates various proteins and causes vasodilation in multiple vascular beds [281]. Because the duration of action of nitric oxide is so short, inhaled NO (iNO) has the advantage of selectively dilating pulmonary arteries.

Clinical use of iNO has expanded dramatically since its discovery, because of its relatively low toxicity at doses less than 20 ppm, selectivity of the pulmonary vascular bed, efficacy in numerous settings, and ease of administration in ventilated patients [282–284]. In pediatric cardiac surgery, iNO has shown efficacy in reducing pulmonary pressures and improving oxygenation and right ventricular function [285–287]. Patients most likely to respond to iNO appear to be those with elevated preoperative PVR, although some with the highest PVR may be unresponsive [288, 289]. However, despite the efficacy of iNO in improving pulmonary resistance and hemodynamics in the acute postoperative setting, there are limited data from prospective, randomized

AL Grawany

trials [290]. A Cochrane review was inconclusive, owing to heterogeneity of populations, inherent publication bias, and lack of quality data [291]. Because the cost of administration of iNO is high (approximately $3,000 USD/day), large-scale, multicenter studies are needed to better define the congenital heart population most likely to experience long-term benefit [292]. A recent review of children undergoing heart surgery who did and did not have pulmonary hypertension found that administration of iNO after pediatric cardiac surgery increases length of stay and billed charges, while not providing improved inpatient mortality in either group, and may be detrimental to those without pulmonary hypertension [293].

Toxicity of iNO is very low at clinically relevant concentrations. Methemoglobinemia is a potential problem if high doses (>80 ppm) are administered for an extended time, or for patients with genetic deficiency of methemoglobin reductase. Peroxynitrite results from the reaction of nitric oxide with superoxide and is a potent oxidant and pulmonary irritant. In high concentrations, peroxynitrite can damage DNA, induce apoptosis, and impair the vasorelaxant function of endothelium [294]. iNO also increases ET-1 secretion, which may account for some of the rebound pulmonary hypertension observed when iNO is discontinued [295].

Nitric oxide donors and precursors have been employed in the treatment of increased PVR in the postoperative setting. Nitric oxide is a product of arginine, an amino acid in the urea cycle. Since low levels of urea cycle intermediates have been observed in CHD patients following CPB, investigators have successfully prevented postoperative pulmonary hypertension in children by supplementation with both oral and intravenous citrulline, lending further evidence to the pivotal role of the pulmonary endothelium [296–298]. Nitroglycerin is a potent nitric oxide donor with a very short half-life and has been useful in pediatric cardiac surgery [299]. However, nitroglycerin is a nonspecific vasodilator and preferentially dilates the venous circulation, potentially leading to decreased preload and decreased cardiac output.

Inhaled epoprostenol (prostacyclin) is a prostaglandin analog with nonspecific vasodilating properties. It acts via specific membrane receptors to increase intracellular cAMP and, therefore, activate cAMP-dependent protein kinases. Long-term management of pulmonary hypertension, related or unrelated to CHD, often involves intravenous infusion of epoprostenol. Prostacyclin has shown efficacy for both adults and children with pulmonary hypertension related to CHD [284, 300, 301]. Inhaled prostacyclin shares the advantage of iNO, in that both treatments are very selective for the pulmonary vasculature and have little, if any, effect on systemic vascular resistance. In the post-transplant cardiac surgery population, a large randomized trial found no difference in efficacy between iNO and prostacyclin [302]. In an uncontrolled case series of post-CPB pediatric patients, inhaled prostacyclin was effective at decreasing pulmonary pressure, but one-third of the subjects required norepinephrine as a systemic vasoconstrictor agent, indicating that this agent is somewhat less selective for the pulmonary vasculature than iNO [303].

PDEIs represent another pharmacological approach to increased PVR. These agents increase the intracellular levels of cyclic nucleotides (cAMP and cGMP) by inhibiting enzymes responsible for their breakdown. PDEIs selective for PDE-5 inhibit breakdown of cGMP and are therefore vasodilatory, with sildenafil being the agent in most frequent clinical use. Sildenafil has been useful for managing both idiopathic pulmonary hypertension and pulmonary hypertension associated with CHD in children [304]. In laboratory models of pulmonary hypertension, PDEIs have shown efficacy both alone and in combination with other agents [305, 306]. Because of their favorable safety profile, PDEI use has expanded, especially in the pediatric population [307–311]. However, the quality of the evidence for many of these studies is suboptimal, relying on retrospective associations and prospective studies with small sample size or in limited populations, making it difficult to extrapolate their findings to other populations or practices.

ET-1 is a vasoconstrictive peptide released from endothelium. In the pulmonary circulation, ET-1 binds to specific ET(A) receptors on smooth muscle and initiates protein kinase C activation and increased intracellular calcium levels, producing vasoconstriction. Specific ET(A) receptor antagonists have been effective for the treatment of pulmonary hypertension, specifically in the post-CPB setting [312, 313]. As in the case for PDEIs, ET(A) receptor antagonists were first used in outpatients for the management of idiopathic pulmonary hypertension, and their clinical application expanded from there into the cardiac surgery, transplant, and ICU settings [300, 314–318]. Also, as in the case for PDEIs, extrapolation of the findings from many of these studies may be hampered by small sample sizes and lack of appropriate controls.

MUF is a nonpharmacologic technique that has multiple salutary effects on pediatric organ systems in the post-CPB period [319]. Most of the pulmonary benefits of MUF appear to result from improved hemodynamics (vascular tone, ventricular function) and decrease in lung edema. MUF in animal models decreases pulmonary resistance [320]. MUF in a study of infants with transposition of the great arteries and in a mixed population of CHD showed improved oxygenation and hemodynamics [321, 322]. Bando et al. identified neonates and patients with preoperative pulmonary hypertension as a specific subgroup that experiences greater benefit from MUF, albeit in a noncontrolled, retrospective analysis [48].

CPB and lung parenchyma

The compromised state of gas exchange for infants and small children is further impaired after CPB. Lung injury in this setting arises from several concurrent insults: the inflammatory response to CPB, oxidative pulmonary injury, loss of surfactant production, increased lung edema, atelectasis, and loss of lung volumes. As any pediatric intensive care practitioner can attest, the inability to separate from mechanical ventilation is a major contributor to prolonged ICU stay [259].

Pulmonary capillary leak following CPB produces accumulation of interstitial lung water, which is the central pathophysiologic process mostly responsible for impaired gas exchange and decreased pulmonary compliance. Although some pulmonary edema occurs in nearly all patients, a small fraction of patients experience respiratory distress syndrome following CPB, characterized by severe lung edema, and an associated high morbidity and mortality [323]. As mentioned

in detail in the previous section, CPB activates neutrophils, which then translocate across pulmonary capillaries. Once in tissues, activated neutrophils release free radicals and proteolytic enzymes, which further disrupt the integrity of the pulmonary capillaries [324, 325]. Pulmonary ischemia and reperfusion also contribute to impaired postoperative ventilatory function. Reduced ventilation and decreased total lung compliance correlate significantly with markers of oxidative injury in infants following cardiac surgery [326].

Deflation of the lungs during CPB produces large areas of atelectasis, and accumulation of secretions can prolong airway collapse and loss of lung volumes. These effects are magnified in small infants, where decreased pulmonary surfactant production may be further impaired by CPB [327, 328]. Accumulation of blood or fluid in the pleural spaces, or the presence of chest tubes or other devices, can contribute to lobar or segmental collapse.

Transfusion-related acute lung injury (TRALI) occasionally complicates the postoperative course of children with CHD. TRALI is often a diagnosis of exclusion, being an uncommon cause of pulmonary edema. Because TRALI is most likely caused by donor antibodies directed against recipient leukocytes, plasma is often the cause, although identity of the offending blood unit is not part of the case definition [329]. In pediatric cardiac surgery, transfusion of blood products is significantly associated with postoperative morbidity, including pulmonary complications, but it is unclear what role immunologically identified TRALI may have in this association, and to what extent blood transfusion is simply a marker for case complexity. TRALI appears to be less common in children than in adults, although part of this observation may be a result of under-reporting or under-recognition [330].

Techniques to improve respiratory function

Multiple strategies have been proposed for improving gas exchange and lung compliance; these largely focus on controlling two processes: reduction of lung water and prevention of atelectasis [331, 332].

As pulmonary edema is a result of inflammation, reperfusion, and oxidative injury, efforts to control or reduce pulmonary edema have focused on these pathophysiologic processes. Although activated neutrophils directly disrupt the pulmonary capillary barrier, leukocyte depletion of circulating blood has shown modest or inconsistent results and depends significantly on the population being studied [333–335]. Leukocyte depletion has been reported for the CPB pump prime, residual pump blood, or continuous leukofiltering during CPB [336–342]. Interestingly, improved respiratory function has been achieved in this setting with the use of neutrophil elastase inhibitors [343]. Many of these studies report data from experimental animal models or adult patients; therefore, extrapolation to children may not necessarily be valid, although one author has identified children as a population most likely to benefit [335].

Pulmonary perfusion during CPB avoids reperfusion injury, and therefore, lung edema, by omitting a period of lung ischemia. Apparently bronchial circulation is insufficient alone to meet metabolic demands of the lung for a sustained period of time. Lung water and markers of inflammation can be significantly attenuated by pulmonary perfusion during CPB, either with blood or with a protectant solution [10, 11, 272, 344, 345]. Improved oxygenation is also achieved by maintaining lung perfusion during CPB.

Pulmonary injury and dysfunction resulting from TRALI can be prevented by minimizing transfusion, especially of plasma and cryoprecipitate. Efforts to optimize blood transfusion are discussed earlier in this chapter. Supportive care is the mainstay of treatment, consisting of oxygen supplementation, noninvasive or invasive ventilation, positive end-expiratory pressure (PEEP), and diuresis [346]. Notification of the blood bank is prudent when TRALI is suspected, as donor identification may prevent future cases [347].

MUF, mentioned previously for its benefits in attenuating pulmonary vasoreactivity following pediatric CPB, has shown benefit for the removal of lung water, resulting in increased lung compliance and improved gas exchange, with the effect being most notable within the first 6 hours postoperatively [348–352]. MUF also decreases the duration of mechanical ventilation following congenital heart surgery, with the youngest infants most likely to benefit [353–355].

Atelectasis in small infants is often due to deficient or dysfunctional surfactant. Surfactant is a physiologic necessity for maintaining airway and alveolar patency during ventilation, and CPB has deleterious effects on measures of surfactant activity [301, 302, 331, 332]. A retrospective study of exogenous surfactant for infants with respiratory distress syndrome after cardiac surgery reported an improvement in oxygenation index and shorter duration of mechanical ventilation and hospital stay when compared with historical controls [356]. Other authors have reported benefits of pulmonary surfactant supplementation in children with CHD during ECMO or in respiratory distress outside the perioperative period [357–359].

Optimization of mechanical ventilation parameters in the post bypass period is critical in maintaining oxygenation and ventilation, but attention should also be given to the effects on cardiopulmonary interactions and pulmonary vascular resistance. Ventilation at or near FRC results in the lowest PVR. Volumes below FRC lead to atelectasis, while higher volumes lead to pulmonary vessel compression, thus increasing PVR. While most advocate for a lung-protective strategy of lower tidal volumes and optimal PEEP, this must be balanced with the specific cardiac physiology and how mean airway pressure will affect preload and afterload [360].

For surgeries at risk for postoperative pleural effusions, and the Fontan in particular, there is recent evidence that management protocols may reduce duration of pleural drainage and hospital stay [361, 362]. These protocols typically include a combination of pharmacologic therapies including anticoagulation, fluid and dietary management, and respiratory therapy, which may or may not be initiated in the operating room [363, 364].

The routine practice of suspending ventilation during CPB results in near-total atelectasis by the end of CPB. Recruitment of collapsed alveoli and maintenance of ventilation are necessary for separation from CPB. While a sustained inflation (recruitment maneuver) alone is probably ineffective for maintaining open alveoli, it can effectively prevent atelectasis well into the postoperative period when followed by maintenance of PEEP [365, 366]. But these findings are based on adult data and have not been duplicated in children.

However, a randomized study of dornase alpha (a mucolytic agent) after pediatric CPB reported significantly improved radiographic atelectasis scores and oxygenation as compared with controls receiving chest physiotherapy [367].

KEY POINTS: PULMONARY EFFECTS OF CONGENITAL HEART SURGERY

- Ventilation in infants is physiologically compromised, compared with older children.
- PVD results from increased pulmonary blood flow, causing increased vascular resistance, increased sensitivity to vasoconstrictor stimuli, and histologic changes.
- Multiple factors increase PVR following CPB: ischemia–reperfusion injury, endothelial dysfunction, and preexisting PVD.
- Management of post-CPB PVR is with vasodilators: iNO, prostanoids, and PDEIs.
- The direct effects of pulmonary capillary leak are decreased pulmonary compliance and decreased gas exchange.
- Avoidance of ischemia–reperfusion, use of MUF, and recruitment of atelectatic lung segments decrease clinical impact of pulmonary capillary leak.

Renal effects of congenital heart surgery

Introduction, incidence, and definition of the problem

Renal injury is a well-known complication of the surgical management of CHD. Depending on the outcome definition, and the population under study, acute kidney injury (AKI) affects up to 64% of children requiring CPB [368–370]. The incidence is difficult to quantify accurately due to the range of definitions of acute renal failure (ARF) and significant institutional variability in the institution of renal replacement therapy [371, 372]. The kidneys are exposed to a range of insults associated with the surgical management of CHD and renal injury is thought to be the result of hypotension, systemic inflammatory response, and perioperative use of nephrotoxic medications [368, 369, 373].

Several studies have identified perioperative factors that increase the risk to the kidney. Younger age, smaller size, duration of CPB and aortic cross-clamp, intraoperative transfusion, early postoperative hypotension, 24-hour postoperative lactate levels, duration of mechanical ventilation, and vasopressor use have all been associated with renal injury [368, 370, 372–375]. Genetic factors have also been identified [376]. Renal injury co-associates with many risk factors for postoperative low cardiac output syndrome (LCOS), so the association of renal injury with inotropic support may represent an epiphenomenon. The PRIMACOR study, in fact, found no independent association of reduced postoperative creatinine clearance with the use of milrinone [377]. In a retrospective study examining the risk of ARF after cardiac surgery preceded by cardiac catheterization, young age, amount of iodinated contrast received, and the presence of LCOS were identified as risk factors. Age less than 2 years was associated with a 20-fold increase in the risk of perioperative AKI in children who underwent preoperative cardiac catheterization [378].

Younger children are particularly prone to renal injury, as the kidney of an infant functions less effectively until approximately 2–3 years of age [379]. Infants have decreased glomerular filtration rate (GFR) due to increased renal vascular resistance in the setting of low mean arterial pressure. When decreased GFR is considered in the setting of immature tubular cell function, tubular reabsorption is substantially impaired when compared with adult patients. Given that many challenging cardiac operations occur in the newborn period, it is little surprise that an increased incidence of renal dysfunction is seen in the youngest patients, independent of immature renal function.

One operational cause of our inability to understand or predict the occurrence of AKI following congenital heart surgery has been the lack of a consistent definition of AKI across studies. In 2001, the Acute Dialysis Quality Initiative Group proposed the adult RIFLE (risk, injury, failure, loss, and end-stage renal disease), which aimed to standardize the definition of AKI and stratify kidney injury based on the degree of elevation of serum creatinine, decrease in estimated GFR, or prolonged oliguria. The pediatric modification of the RIFLE score (pRIFLE) detects acute renal injury in critically ill children and is a predictor of length of stay and mortality, independent of the Pediatric Risk of Mortality (PRISM) score [380, 381]. Pediatric RIFLE scoring stratifies renal dysfunction based on reduction in estimated creatinine clearance, elevation in serum creatinine above baseline, or reduction in urine output (Table 12.5). The Acute Kidney Injury Network (AKIN) has devised a similar score, the AKIN score, which appears to correlate well with pRIFLE [369, 380]. Late renal failure (pRIFLE categories L and E), however, remains difficult to define in the postoperative congenital cardiac population, due to wide variation in postoperative use of peritoneal dialysis (PD) [382]. Small increases in serum creatinine in the early postoperative period predict kidney injury using the pRIFLE criteria, and more severe renal injury predicts worse clinical outcomes. Recently, the Kidney Disease Improving Global Outcomes (KDIGO) classification systems integrated the pRIFLE and AKIN classification systems. Importantly, while progress has been made in the staging and characterization of renal dysfunction, many studies also vary in their postoperative observation window, accounting for some variability in reported incidence. In comparing the various scoring systems, pRIFLE is more sensitive for the detection of mild degrees of renal dysfunction, KDIGO is applicable to both adult and pediatric patients and does not limit the diagnostic time frame, and AKIN does not require knowledge of the patient's height or baseline creatinine clearance. KDIGO is thought to be the most inclusive classification of renal injury by those investigators who focus in this area [383] (Table 12.5).

Emerging biomarkers of renal dysfunction

Serum creatinine is most commonly used to estimate GFR, the volume of filtrate entering the renal tubules at the glomerulus per unit of time. Estimates of GFR using serum

Table 12.5 Staging of acute kidney injury in children

AKI staging	Criteria – eGFR or SCr	Criteria – urine output (UOP)
pRIFLE		
Stage 1 (Risk)	eGFR decreased by 25%	UOP < 0.5 mL/kg/hour for 8 h
Stage 2 (Injury)	eGFR decreased by 50% eGFR decreased by 75%	UOP < 0.5 mL/kg/hour for 16 h
Stage 3 (Failure)	Persistent failure >4 weeks	UOP < 0.3 mL/kg/hour for 24 h or anuria >12 h
Stage 4 (Loss)	ESRD, Persistent failure >3 months	
Stage 5 (End-stage)		
AKIN		
Stage 1	SCr increased by 50% or 0.3 mg/dL	UOP < 0.5 mL/kg/hour for 6 h
Stage 2	SCr increased by 100%	UOP < 0.5 mL/kg/hour for 12 h UOP < 0.3 mL/kg/hour for 24 h or anuria >12 h
Stage 3	SCr increased by 200%	
KDIGO		
Stage 1	SCr increased by 50% or 0.3 mg/dL	UOP < 0.5 mL/kg/hour for 6–12 h
Stage 2	SCr increased by 100%	UOP < 0.5 mL/kg/hour for > 12 h
Stage 3	SCr increased by 200% or eGFR <35 mL/min/1.73 m^2 (age <18 years)	UOP < 0.3 mL/kg/hour for 24 h or anuria >12 h

AKIN, Acute Kidney Injury Network; eGFR estimated glomerular filtration rate (estimated using the Schwartz method); ESRD, end-stage renal disease; KDIGO, Kidney Diseases Improving Global Outcomes; pRIFLE, pediatric RIFLE; SCr, serum creatinine; UOP, urine output.

creatinine measurements may be insensitive indicators; serum creatinine often does not rise until GFR falls below 80 mL/min/1.73 m^2. Because creatinine is also secreted by the proximal tubule, GFR may be reduced by up to 50% before elevations in serum creatinine are observed [384].

There is substantial interest in other potential indicators of renal dysfunction, which are more sensitive to declining GFR, and reflect renal function in real time. Biomarkers are often studied in children undergoing cardiac surgery as most pediatric patients lack significant renal comorbidities and the time of the renal insult is relatively well defined. These biomarkers offer the potential ability to detect tubular injury prior to a rise in serum creatinine or a reduction in urine output. Cystatin C and neutrophil gelatinase-associated lipocalin (NGAL) are the two markers in clinical use today.

Cystatin C is a cysteine protease inhibitor produced by nucleated cells throughout the body at a constant rate. It is filtered at the glomerulus and not secreted by tubules, and its levels are independent of gender, muscle mass, and fluid overload. Normal levels of cystatin C are somewhat higher in neonates and small infants (Figure 12.7) [385]. Serum cystatin C levels show stronger correlation with measured GFR than do serum creatinine levels in young children and adolescents [386]. Cystatin C has emerged as a highly sensitive indicator of renal dysfunction in children following cardiac surgery, and serum elevation of cystatin C occurs within hours of injury to the kidney (Figure 12.8) [386–388]. Cystatin C concentrations correlate with the severity of AKI (defined by pRIFLE criteria) beginning 2 hours after CPB. Interestingly, half of the patients included in this study were less than 2 years of age. The first postoperative cystatin C levels and the postoperative cystatin C changes from baseline value were independently associated with duration of mechanical ventilation in this study, whereas serum creatinine levels were not [387].

NGAL is a marker of tubular injury and its levels rise early following a given insult and levels correlate both with the degree and severity of AKI [389, 390]. The diagnostic utility of NGAL in AKI has been reviewed extensively [391]. Because NGAL is useful in risk prediction, NGAL levels have been used as a measure of renal injury in clinical trials. The ability to detect renal tubular injury that does not result in an increase in serum creatinine makes NGAL a useful measure of subclinical AKI. In studies of both adult and pediatric patients, NGAL elevation in the absence of increased creatinine was associated with a two- to three-fold increase in risk of death or dialysis [392].

Association of renal injury with clinical outcomes

In adult cardiac surgery, even mild renal dysfunction is associated with greater length of hospital stay, cost, and mortality. It is unclear to what degree these associations also exist for children. Many authors have studied this question using retrospective data and have reported associations between

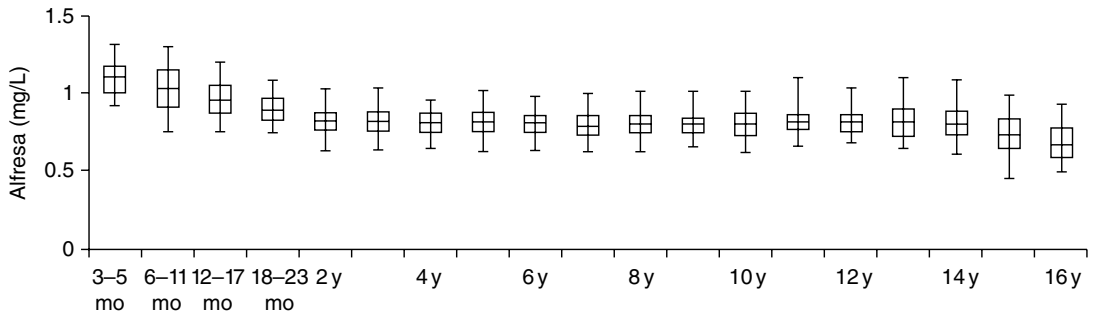

Figure 12.7 Serum cystatin C in children aged 3 months (mo) to 16 years (y). The box plot extends from the 25th percentile to the 75th percentile, with the horizontal line at the median, and the whiskers show the central 95% of the data for the Alfresa assay. [360]. Reproduced with permission of Wolters Kluwer Health, Inc.)

poor clinical outcomes and mild renal dysfunction. Some studies, however, are small or do not control for sufficient covariates.

Although some studies do suggest that subclinical AKI may portend significant clinical consequences for children, it is clear that the more severe forms of perioperative AKI are significant harbingers of poor outcome. Tóth et al., using propensity-matching, observed AKI in 32% of patients, with 11.5% meeting criteria for risk, 1.7% for injury, and 18.7% for failure by pRIFLE [393]. They further reported an association between AKI, increased length of ICU stay, and mechanical ventilation, but not in-hospital mortality in their 1,510 patient cohort. Morgan et al. studied the neonatal population for a follow-up of 2 years and found AKI in 64% of subjects, as defined by AKIN criteria. AKI was associated with duration of mechanical ventilation, length of ICU stay, and length of hospital stay after accounting for covariates by regression [370]. They observed an increase in 2-year mortality in patients with AKIN stage 2 or higher [370, 394]. In a retrospective cohort of 409 children undergoing congenital cardiac surgery, early AKI by pRIFLE criteria was observed in 20% of subjects and was associated with length of ICU stay, duration of mechanical ventilation, and mortality [395]. In another retrospective cohort of 693 postoperative cardiac patients, investigators observed a 15% incidence of AKI (11% mild, 3% moderate, 1% severe), by AKIN criteria. These investigators observed that only moderate and severe AKI were associated with prolonged postoperative recovery [375].

Renal failure and renal replacement therapy following cardiac surgery in children

The use of renal replacement therapy for postoperative renal failure is difficult to determine given the wide variability in practice patterns across institutions. In patients with severe hemodynamic instability, continuous veno-venous hemofiltration (CVVH) may provide the optimal means of renal replacement therapy. Most patients, however, will tolerate the initiation of PD as a means of augmenting the function of failing kidneys, as a method of avoiding volume overload, or as a means of modulating the inflammatory response seen post-CPB in these children. Duration of AKI prior to the initiation of renal replacement therapy was associated with increased mortality in children following cardiac surgery [396, 397].

Peritoneal dialysis

PD is frequently used in postoperative management of patients following cardiac surgery. Although initial application in this population was intended for the management of postoperative renal failure, its indications have expanded to include fluid overload, optimization of cardiac loading conditions, decompression of the abdominal cavity, and mitigation of the inflammatory sequelae of CPB. Peritoneal drainage catheters (PDCs) can be used as either a passive drain in the abdominal cavity or a means of initiating PD for active fluid and electrolyte management. An analysis of data from 2006 and 2009 in the Kids' Inpatient Database in this population found that young age, higher Risk Adjustment for Congenital Heart Surgery (RACHS-1) score, ARF, CPB, nonelective admission, and hospital region in the south or west were associated with increased rates of PD catheter placement. There is widespread variability in the indications and frequency for PD in pediatric cardiac surgical patients across institutions, although those patients undergoing PDC placement represent a relatively high-risk subset within the postoperative population [382].

PD carries some risk. In a review of 1,128 patients undergoing congenital cardiac surgery who underwent PDC placement, 130 developed complications. Most events were minor and included leakage and mechanical dysfunction, 6.2% developed severe complications (hydrothorax, hemoperitoneum, bowel perforation, and peritonitis). However, mortality in patients with PD complications was not significantly different than those without PD complications [398].

PD in the management of postoperative fluid overload

Fluid overload is often seen in young patients following CPB. As outlined extensively in this chapter, capillary leak associated with CPB, transfusion, administration of crystalloid, myocardial dysfunction, and activation of the renin–angiotensin–aldosterone system all contribute to postoperative fluid overload. Reduced GFR and medullary concentrating ability in young children also predispose to fluid overload. Fluid overload can delay sternal closure, prolong duration of mechanical ventilation, and limit the ability of the GI tract to process enteral nutrition properly. Fluid overload as measured by daily weight is associated with worse clinical outcome among infants undergoing cardiac surgery [399].

The use of PDCs allows for the safe and effective removal of fluid during the postoperative period. It improves early postoperative hemodynamics and ICU outcomes [400–402]. In two different observational studies of children undergoing congenital cardiac surgery, early PD was associated with a significantly negative fluid balance [402, 403]. In a 2017 study, infants who were oliguric in the early postoperative period were randomized to furosemide or PD. Those who underwent PD were three times less likely to develop fluid overload and less likely to require postoperative mechanical ventilation. They did not find, however, a reduction in time until delayed sternal closure, duration of mechanical ventilation, hospital length of stay, or mortality [404, 405].

PD for the mitigation of the systemic inflammatory response

PD can mitigate the inflammatory response to CPB. In congenital heart surgery, serum IL-6 levels have been associated with AKI and duration of mechanical ventilation, and PD removes pro-inflammatory cytokines IL-6 and IL-8 [406, 407]. In an observational study comparing passive peritoneal drainage and diuresis with PD, the latter was associated with earlier sternal closure (24 vs. 63 hours), lower mean inotropic scores, shorter duration of mechanical ventilation (71 vs. 125 hours), and greater net negative fluid balance [408]. A propensity-matched study compared early (within 6 hours of CPB) or late initiation of PD and found substantial reduction in adverse events in the early PD initiation group. The decision to initiate PD was at the discretion of the patient's care team [409]. This area would most certainly benefit from randomization of patients in more highly protocolized trials to further clarify the potential benefits of this intervention.

Continuous veno-venous hemofiltration

Hemodialysis allows for volume and solute management using ultrafiltration and diffusion across a semi-permeable membrane. When done intermittently, it results in rapid shifts of solute and solvent, and a large extracorporeal volume burden, which makes it an unpopular choice in the postoperative population. CVVH is thought to be a better-tolerated means of volume management used in postoperative cardiac surgery patients. Anticoagulation is necessary to maintain patency of CVVH systems, and complications can arise related to vascular access for CVVH. In the event that more aggressive solute clearance is required, continuous veno-venous hemodialysis may be required, in which case dialysis fluid is introduced into the hemofiltration cartridge, which increases electrolyte clearance. Hypokalemia is frequently seen during this procedure, and potassium may be added to the dialysis solution to avoid this complication.

KEY POINTS: RENAL EFFECTS OF CONGENITAL HEART SURGERY

- Impaired renal function is common after bypass and is most frequent and severe in infants undergoing complex operations.
- Studies of perioperative renal injury in children are contradictory because of differences in end point definition and monitoring windows.
- Perioperative renal injury is associated with poor clinical outcomes – duration of mechanical ventilation, length of ICU and hospital stay, and mortality – with worse injury associated with worse outcome.
- Use of PD can improve early postoperative hemodynamics, but not necessarily mortality or other long-term outcomes.
- Continuous veno-venous hemodialysis is a form of renal replacement therapy which can avoid rapid fluid and solute shifts associated with intermittent dialysis.

GI and hepatic consequences of cardiac surgery in children

Splanchnic circulation

Mesenteric Ischemia and NEC

Bowel ischemia has been reported in adults following CPB [410–413]. Reported risk factors include age, atherosclerosis, heart failure, renal failure, use of vasoconstrictors, prolonged mechanical ventilation, and use of intra-aortic balloon counterpulsation [412, 414–416]. Reports of mesenteric ischemia are very rare in the pediatric population. The single exception is gut ischemia seen after use of intra-aortic balloon pumps [417, 418].

NEC is a common and devastating disease in the neonate. The pathogenesis of NEC is not clearly defined and is likely multifactorial with a complex interplay of altered intestinal microbiota, genetic polymorphisms, an immature intestinal barrier, and an exaggerated inflammatory response [419]. Primarily a disease of the premature infant, especially those with very low birth weight (i.e. <1,500 g), 10% of infants affected are term or near-term neonates [420]. The incidence of NEC in the neonate with CHD ranges from 2.5 to 7.8%, and this population accounts for most of the term infants with the disease [420–425]. In a large, retrospective analysis of term infants with CHD, McElhinney et al. found that diagnosis of hypoplastic left heart syndrome, truncus arteriosus, and aortopulmonary window were independently associated with NEC, with hypoplastic left heart syndrome conveying the highest risk [425]. In the Single Ventricle Reconstruction trial examining 549 neonates with single ventricle physiology across 15 centers, the incidence of NEC was 2.5% as defined by pneumatosis intestinalis or free air on radiographs [426]. In a retrospective study of neonates who underwent a hybrid procedure (bilateral pulmonary artery banding, ductal stenting, possible atrial septal stent), the incidence of NEC was 11%, but neonates who developed NEC were significantly younger than hybrid neonates who did not develop NEC [423].

NEC in the neonate with CHD may be a distinct disease process from that in the neonate without CHD. Vascular insufficiency rather than gut immaturity could be the underlying cause of bowel ischemia in this population. Episodes of hypoperfusion, shock, and diastolic flow reversal in the aorta and superior mesenteric artery have been associated with NEC in the CHD population [427–431]. Mechanisms of intestinal ischemia may be related to physiologic steal that can occur in a parallel circulation. Clinical presentation tends to occur earlier in the neonate with CHD. In a retrospective look at 202 CHD patients with NEC, 48% were diagnosed before medical or surgical intervention on the cardiac lesion [432]. In the CHD population, NEC lesions are typically found in the colon, as opposed to lesions in children without CHD where the jejunum and ileum are most often affected [433]. Several studies have found that infants with CHD had decreased risk of perforation, strictures, need for a stoma, sepsis, and short gut syndrome compared with infants without CHD [425, 432, 434, 435]. While mortality in neonates with CHD and NEC does not appear to be higher than that of cardiac neonates without NEC, morbidity is adversely affected. The diagnosis of NEC extends critical care and hospital length of stay significantly and increases the financial burden of care by $95,600–$316,000 [436–438].

Although a great deal has been learned about the pathogenesis of NEC, progress with respect to prevention and early detection has been slow, with radiographic imaging still the current standard. Gastric tonometry, abdominal ultrasound/Doppler, and a variety of biomarkers have not been successful in the early detection or prevention of NEC. Near-infrared spectroscopy (NIRS), a noninvasive technology that measures regional oxygen saturation, has been investigated as an early warning device for evolving tissue hypoxia. In 2011, Gay et al. described how abdominal NIRS probes were able to rapidly detect changes in mesenteric blood flow in an animal model of NEC [439]. A number of case reports describe changes in abdominal NIRS values in neonates with NEC [440, 441]. In an interesting study by Fortune et al., the authors found that the cerebral–splanchnic oxygen ratio (CSOR) could be more predictive of abdominal pathology than splanchnic NIRS alone. The authors demonstrated that a CSOR value of less than 0.75% predicted splanchnic ischemia with a positive predictive value of 0.75 and a negative predictive value of 0.96 [442].

In summary, neonates with CHD are at increased risk for NEC. Mortality does not appear to increase with this diagnosis in the CHD population, although hospital and critical care unit length of stay is prolonged. NIRS shows promise as a tool for early prediction of mesenteric ischemia, but further investigation is needed.

Hepatic dysfunction

Acute hepatic failure has been described in the postoperative course of infants and children following cardiac surgery, but the relationship to the intraoperative course is uncertain. In a prospective observational study of 232 patients at a single institution, liver dysfunction was noted in 9.3% of patients, as defined by a scoring system calculated using alanine amino transferase, total bilirubin, and prothrombin time. Shock in the postoperative period was the most important predisposing factor for hepatic dysfunction [443]. Previous retrospective studies link low cardiac output and elevated right atrial pressures as risk factors for hepatic failure [444, 445].

Authors reviewed 16 cases of acute hepatic failure in the setting of MSOF in children after cardiac surgery at a single institution spanning a 4-year period. Over this time period, 3.5% of patients developed MSOF in the postoperative period. All patients underwent surgical correction using either deep hypothermic cardiac arrest (DHCA) or low-flow CPB (25% of initial flows). DHCA was always less than 60 minutes at 16 °C. Duration of low-flow CPB was not described. Hepatic failure occurred in all 16 patients as defined by a serum glutamic oxaloacetic transaminase (SGOT) >500 IU/L and a prothrombin time prolonged by at least 50%. SGOT values decreased after 48 hours in both survivors and nonsurvivors and normalized by 1 week in all survivors. Central venous pressures ranged, respectively, from 3 to 17 mmHg and 8 to 17 mmHg at 4 and 24 hours postoperatively. Hepatic perfusion pressures ranged, respectively, from 35 to 67 mmHg and from 21 to 66 mmHg at 4 and 24 hours postoperatively. The most striking aspect of the perioperative course was the dose of epinephrine used. Doses ranged from 0.05 to 1.19 μg/kg/min with a mean of 0.43 μg/kg/min and were administered for a poorly contracting myocardium [446] There are anecdotal reports of hepatic failure and MSOF following cannula malposition of the inferior caval cannula in bicaval cannulation for CPB.

Effects of chronically elevated systemic venous pressure

While the Fontan palliation results in a near-normal systemic arterial saturation, elevated systemic venous pressure results. Because portal venous blood comprises 75% of hepatic arterial blood flow, normal blood flow within the liver is dependent upon portal venous pressure exceeding that of the hepatic vein draining the liver parenchyma. The GI system in particular is vulnerable to the adverse consequences of chronic elevations in systemic venous pressure by virtue of its reliance on a pressure gradient between two low-pressure venous systems in series. In the setting of reduced cardiac output for any reason, blood flow is diverted away from the GI tract in favor of the cerebral and coronary systems. Chronic liver injury in these patients is the expected consequence, and care of these patients should include regular monitoring of hepatic function. Protein losing enteropathy (PLE) is another potentially devastating consequence of the Fontan circulation, though its consequences may be more severe. Although its etiology is not clearly understood, chronic elevations in systemic venous pressure resulting in increased lymphatic pressure is thought to result in protein loss in the GI tract [447].

Chronic elevations in systemic venous pressure and hypoxemia result in dilatation of hepatic sinusoids and hepatocyte necrosis and may progress to varying degrees of fibrosis of the tissues adjacent to the hepatic veins. This fibrosis may progress to cirrhosis. As the body begins to compensate for reductions in portal venous flow by increasing the arterial component of hepatic blood flow, focal nodules of hepatocyte regeneration may result [448, 449].

Feeding and nutrition

Feeding difficulties and weight gain are commonly seen in children with CHD. Poor oral feeding, intolerance of enteral feeds, and an increased risk of NEC all complicate the recovery of many neonates and infants following cardiac surgery. Vocal cord dysfunction, prolonged need for narcotic or sedative infusions, prolonged mechanical ventilation, oropharyngeal aspiration, and intestinal ischemia have all been postulated to be contributory. Need for prolonged mechanical ventilation was associated with an increased time to full enteral feeds and was also associated with the need for nonoral feeds at the time of discharge [450]. In a single-center study of patients undergoing surgical gastrostomy following cardiac surgery, the authors found a higher incidence of feeding intolerance in cardiac surgical patients (18.8 vs. 5.6% in noncardiac surgical patients) and a longer time to achieve full enteral nutrition targets. In this cohort, 58% of children were able to wean from gastrostomy tube feedings by 12 months following placement [451].

A retrospective analysis of data from the National Pediatric Cardiology Quality Improvement Collaborative data registry examined the data from patients who underwent Stage 1 palliation of hypoplastic left heart syndrome from 2008

to 2016 was examined to determine factors associated with feeding outcomes. Factors associated with increased time to full enteral feeding included earlier gestational age, need for arch reintervention, multiple repeat procedural interventions, and GI anomaly [452]. Some studies have shown that the use of institutional feeding protocols has been correlated with decreased time to full enteral feeds and with decreased rates of NEC, but other studies have been unable to demonstrate this [453, 454].

Endocrine response and pediatric cardiac surgery

Critical illness-related corticosteroid insufficiency

The acute stress response to critical illness and surgical stress is the result of activation of the hypothalamic–pituitary–adrenal (HPA) axis and sympathoadrenal system. During stress, the HPA axis typically responds by enhancing the release of cortisol (Figure 12.9). Approximately 85% of cortisol in the circulation is bound to corticosteroid-binding globulin (CBG) and 10% is bound to albumin. The remaining portion, free cortisol, is thought to be that which is biologically active [455]. Cortisol exerts its effects by binding to intracellular glucocorticoid receptors, which play an important role in glucose metabolism, adrenergic receptor function, maintenance of endothelial integrity, and the systemic inflammatory response. CBG serves as a reservoir for protein-bound cortisol and is increasingly thought to play a role in facilitation of the activities of cortisol [456]. In critical illness, the HPA response to stress may be inadequate and result in persistent and profound inflammatory processes and hemodynamic insufficiency. It may result from either inadequate adrenal steroid production or decreased peripheral sensitivity to glucocorticoids. This dysfunction of the HPA axis in critical illness is usually temporary, can occur without structural insult to the hypothalamus, pituitary, or adrenal glands, and is termed critical illness-related corticosteroid insufficiency (CIRCI).

Diagnosis of CIRCI

CIRCI, also known as relative adrenal insufficiency, has been defined as an inadequate level of serum cortisol relative to the severity of the patient's illness and has been hypothesized

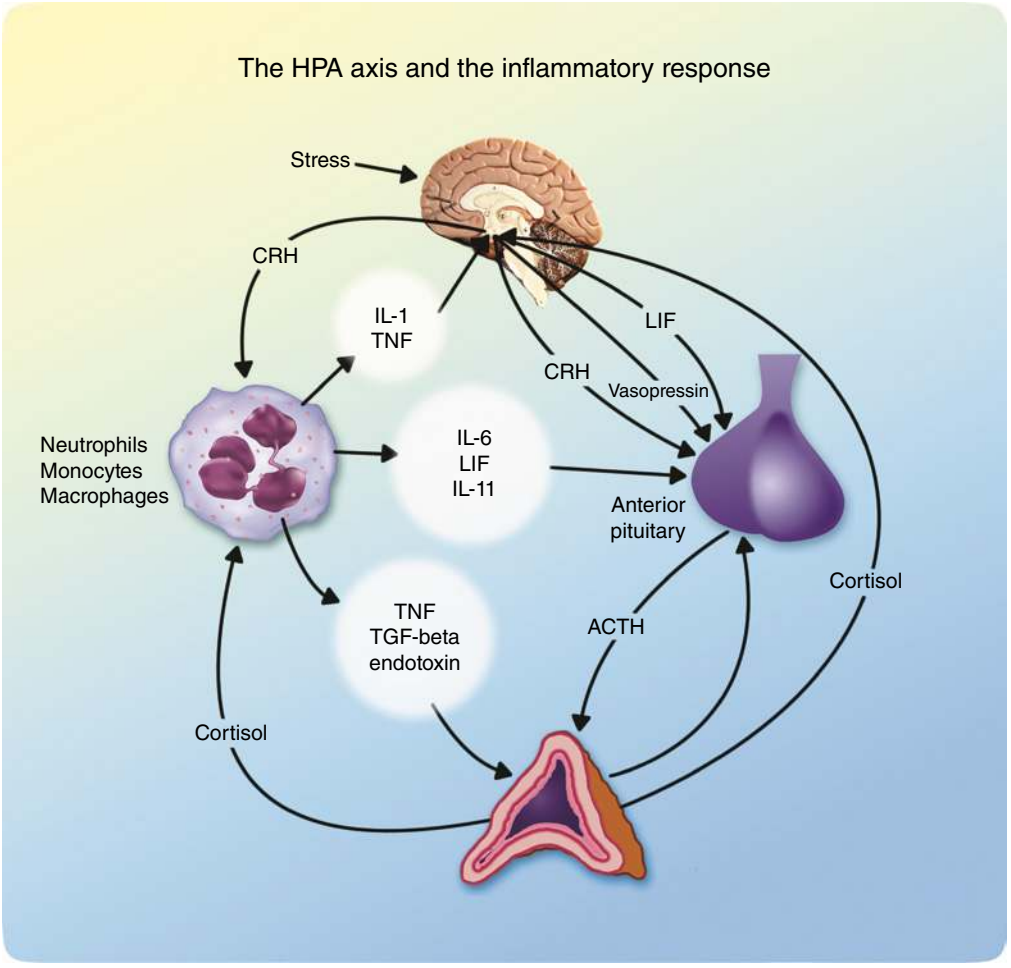

Figure 12.9 Activation of the hypothalamic–pituitary–adrenal (HPA) axis by a stressor and the interaction with the inflammatory response. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; IL-6, interleukin-6; IL-11, interleukin-11; LIF, leukemia inhibitory factor; TGF-beta, transforming growth factor-beta; TNF, tumor necrosis factor. (Source: Adapted from Marik et al. [487]).

to be associated with LCOS following cardiac surgery in children [457]. The diagnosis of CIRCI in children following congenital heart surgery remains difficult. Studies in this patient population report an incidence of 17–47%, but there is little agreement on the definition of CIRCI and the studies vary widely in the diagnostic criteria used [458–462]. In 2007, Menon et al. found no consensus among pediatric intensivists or endocrinologists as to the incidence or definition of adrenal insufficiency. Pediatric endocrinologists commonly use a cortisol level <18.1 μg/dL following a corticotropin stimulation test, whereas pediatric intensivists made the diagnosis most commonly when a baseline serum cortisol was less than 5 μg/dL. Similarly, there is wide practice variability as to the patients who receive steroids, dosing, and what type of corticosteroid is administered [463].

There is substantial debate as to whether total cortisol (bound and unbound fractions) is an adequate reflection of the activity of the HPA axis when only the unbound fraction is thought to be biologically active. In a study whose purpose was to examine the effect of CPB on the HPA axis in children undergoing cardiac surgery, Wald et al. looked at the correlation of postoperative free and total cortisol levels and CBG levels with clinical outcomes. Interestingly, in their cohort of 51 patients, CBG levels varied widely and decreased from 28.8 ± 9.8 to 22 ± 8.4 mg/L following separation from bypass. Postoperative CBG levels <19 mg/L correlated with increased length of stay and greater inotrope scores, even when adjusted for age and bypass duration. CBG levels were also independent predictors of inotrope score and fluid requirement in the first 24 hours postoperatively using multivariate analysis [464]. Building upon their previous study, Wald et al. measured several markers of endocrine function (total cortisol, free cortisol, ACTH, and CGB) in infants undergoing cardiac surgery who received dexamethasone and the hormonal response to cosyntropin at three different time points: immediately before CPB, at arrival in the ICU, and 24 hours after surgery. There was a significant decline in all aspects of the HPA axis; however, these low values did not correlate with clinical outcomes. However, patients with an inadequate response to cosyntropin (<9 mg/dL) during the postoperative period required increased fluid resuscitation and had longer lengths of stay [464]. In a prospective observational study of adrenal function in children undergoing Norwood palliation or interrupted arch with ventral septal defect (VSD) repair, Mackie et al. found that higher total cortisol levels correlated with lower cardiac index and higher atrial filling pressures at 48 hours postoperatively [459]. Although some postoperative patients have laboratory evidence of suspected CIRCI, there is conflicting evidence of a link to clinical outcomes in the first postoperative days [459–461, 465].

Management of CIRCI

Annane et al. published a trial in which corticosteroid supplementation was found to reduce mortality in adult patients with septic shock [466]. Subsequently, a larger prospective trial of corticosteroid administration in adult septic shock failed to demonstrate the same mortality benefit [467]. Several studies have recently been published examining the effect of steroid supplementation in children following congenital cardiac surgery. A Cochrane review published in 2020 reviewed the available studies to determine the usefulness of prophylactic administration of steroids for children undergoing cardiac surgery. Methylprednisolone, hydrocortisone, and dexamethasone were the steroids investigated. Based on analyses, it was found that corticosteroids do not change the risk of mortality for children undergoing heart surgery utilizing CPB. While corticosteroids were found to reduce the duration of mechanical ventilation, they did not result in shortened length of intensive care or hospital stay [41].

The administration of corticosteroids in the setting of suspected CIRCI in the postoperative period has been associated with improved hemodynamics [457, 468, 469]. Millar et al. reviewed the hemodynamic effects of corticosteroid administration. In those children who had undergone cardiac surgery, 41% demonstrated a greater than 20% increase in mean arterial pressure within 24 hours of steroid administration [470]. A positive hemodynamic response to steroids did not correlate with random total cortisol levels. A summary of the studies to date evaluating the effects of postoperative glucocorticoid administration is summarized in Table 12.6 [471].

Corticosteroid administration is associated with well-known risks. Infection, altered glucose metabolism, difficulty with wound healing, elevation in white blood cell count, and adrenal suppression are among these risks. Certainly, the short-term hemodynamic benefits may outweigh these risks in the most critically ill subset of patients following congenital cardiac surgery. Most of the studies examining the administration of corticosteroids in this patient population reported no increase in hyperglycemia or white blood cell count [457, 458]. There is some evidence to suggest that an increase in mediastinal infection may be seen in those receiving perioperative steroids in low-risk surgical patients or in those with the highest number of days of corticosteroid exposure [472]. In a retrospective review of children less than 5 years of age undergoing cardiac surgery at a single center, cumulative days of corticosteroid exposure were independently associated with risk of infection [429, 472]. Additionally, there is increasing concern regarding the negative long-term cognitive and neuromotor consequences of steroid exposure during the neonatal period [473]. Given the current data, it is important to carefully consider the routine treatment of low total cortisol with exogenous glucocorticoids.

There is no consensus on the use of corticosteroids in pediatric patients undergoing cardiac surgery, and there is a wide variability in practice. More recently, there are several collaborative efforts to perform randomized, double-blind, placebo-controlled multicenter trials. The DECISION trial was performed in four centers (Brazil, China, and Russia) and administer placebo or dexamethasone in children less than 1 year of age undergoing cardiac surgery utilizing CPB. Dexamethasone did not significantly reduce major complications or mortality at 30 days [474, 475]. Currently, the STeroids to REduce Systemic inflammation after infant heart Surgery (STRESS) trial is a multicenter study ongoing in the United States. The study will evaluate patients less than 1 year of age undergoing cardiac surgery with CPB and look at several end points, including operative mortality, death or major complication, hospital length of stay, LCOS, or need for additional steroid administration in the first 72 hours after surgery [476].

Table 12.6 Use of steroid therapy postoperatively in children with congenital heart disease

Study	Design	Patients	Intervention	Outcome	Notes
Shore et al. [468]	Retrospective review	<1 year old 38% patients not postoperative	Compared patients treated with high-dose epinephrine with those who received high-dose epinephrine and hydrocortisone	Significant decrease in epinephrine within 12 hours of hydrocortisone. Hydrocortisone-treated patients required longer duration of inotropic support	
Suominen et al. [457]	Retrospective review	Neonates with LCOS who received hydrocortisone	Hydrocortisone for 5 days	Hydrocortisone significantly increased mean and systemic blood pressure, significant weaning of epinephrine within 24 hours of hydrocortisone	
Ando et al. [458]	Prospective RCT	Neonates undergoing biventricular repair	Placebo vs. hydrocortisone for 72 hours followed by 4-day wean	Hydrocortisone group had improved hemodynamics, less positive fluid balance, less body edema, improved oxygenation, shorter duration of mechanical ventilation	
Millar et al. [470]	Retrospective review of patients who received steroids for hypotension	35% of patients not postoperative	28.4% hydrocortisone, 17.6% dexamethasone, 3.9% methylprednisolone	41% had improvement in blood pressure, all patients with response survived. 20% mortality in nonresponders	27.4% nosocomial infections, no GI bleeding
Robert et al. [469]	Double-blind randomized control trial	Neonates undergoing cardiac surgery with cardiopulmonary bypass	Placebo vs continuous hydrocortisone infusion tapered over 5 days	Prophylactic hydrocortisone infusion reduced low cardiac output syndrome, improved fluid balance and urine output

Stress hyperglycemia

Collectively, hyperglycemia, insulin resistance, and glucose intolerance in the setting of acute illness are referred to as stress hyperglycemia [477]. Studies have shown both a strong correlation between stress hyperglycemia and poor outcomes and a linear relationship between the degree of hyperglycemia and disease severity [478, 479]. Many clinicians and investigators have assumed this relationship is causal and critical care units have embarked upon protocols targeting various levels of glycemic control. However, studies examining strict glycemic control have not shown improved outcomes [480–482].

Several investigators have suggested that stress hyperglycemia is an adaptive response [483]. Stress hyperglycemia and insulin resistance are phylogenetically preserved responses that allow organisms to survive during stress [484, 485]. The HPA axis, sympathoadrenal system, and pro-inflammatory cytokines work collectively to induce hyperglycemia during stress by increasing gluconeogenesis. Glucose transport from the bloodstream to the cellular membrane depends on two mechanisms: a glucose concentration gradient across the interstitial space and a complex regulation among plasma membrane glucose transporters (GLUTs) that facilitate non-insulin-mediated glucose uptake across the lipid cell membrane [486]. In order for glucose to reach cells with reduced blood flow, stress hyperglycemia increases the glucose diffusion gradient and promotes glucose delivery to the cell. During infection, the regulation of GLUTs may play a role in redistributing glucose away from peripheral tissues and toward immune cells and the nervous system [483]. Hyperinsulinemia, severe acute hyperglycemia, and acute fluctuations in glucose concentrations have been implicated in endothelial cell dysfunction through an exaggerated oxidative stress response, which would support more moderate glucose levels versus tight glycemic control (TGC) [477].

Outcome studies in the pediatric population: Hyperglycemia has been associated with perioperative morbidity and mortality in adult patients undergoing cardiac surgery [487–489]. In the pediatric population, retrospective studies linking hyperglycemia and outcome have yielded mixed results [332, 490–494]. To date, three randomized controlled trials in the critically ill pediatric population have been published [495–497]. In 2009, a randomized controlled trial of 700 critically ill pediatric patients, three-quarters of whom were admitted after cardiac surgery, demonstrated that TGC led to a reduction in vasoactive support, infection rate, ICU length of stay, and mortality compared with usual care [450]. Subset analysis of cardiac patients was not done. In the TGC group, investigators targeted glucose levels of 50–80 mg/dL in infants and 70–100 mg/dL in children aged 1–16 years. The prevalence of hypoglycemia was 25% (70 infants, 17 children), with possible symptoms of hypoglycemia noted in only three patients [497].

AL Grawany

In 2012, the Safe Pediatric Euglycemia after Cardiac Surgery (SPECS) study published results of 980 patients younger than 36 months of age who underwent CPB. This was a two-center, randomized controlled trial with patients randomized into either a TGC (glucose levels of 80–110 mg/dL) or a standard care group. In order to minimize the risks of hypoglycemia, a subcutaneous sensor was inserted prior to sternal incision in the TGC group. This sensor was wirelessly paired with a continuous glucose monitor that displayed blood glucose levels every 5 minutes and alarmed if a glucose level dropped below manually set limits. Healthcare-associated infection, organ dysfunction, length of stay, and mortality were no different between the groups. The rate of hypoglycemia (<60 mg/dL) was 19% in the TGC group compared with 9% in the standard care group [495].

Macrae et al. conducted a randomized controlled trial involving children admitted to 13 pediatric critical care units in England [496]. Patients between 36 weeks corrected gestational age and 16 years of age were eligible if they had an arterial catheter in place and were on mechanical ventilation and vasoactive drugs with an anticipated duration of treatment of at least 12 hours. A total of 1,369 children were assigned to either the TGC group with targeted glucose levels of 72–126 mg/dL or the conventional treatment group in which glucose levels exceeding 216 mg/dL were treated until they fell below 180 mg/dL. Two-thirds of patients in this study were admitted to the critical care units following cardiac surgery, and these patients underwent subset analysis. The 30-day primary outcome was the number of children alive and free from mechanical ventilation. Secondary outcomes included ICU and hospital length of stay, duration of mechanical ventilation and receipt of vasoactive drugs, need for renal replacement therapy, incidence of bloodstream infection, use of antibiotics for more than 10 days, number of red cell transfusions, Paediatric Logistic Organ Dysfunction (PELOD) score, rate of readmission to the ICU, and costs. TGC was associated with a smaller proportion of patients receiving renal replacement therapy, yet authors did not report the significance of this in the cardiac population. No difference in other outcomes was found between the TGC and the conventional treatment groups in the cardiac population, yet hospital length of stay and costs were significantly lower in the noncardiac population. Hypoglycemia occurred more often in the TGC group, with an incidence of 15.9% in the TGC group vs. 3.7% in the conventional treatment group [496].

The risk of hypoglycemia

Support for TGC in the pediatric cardiac population remains elusive and is probably due to the feared impact of hypoglycemia on the developing brain. Both hyperglycemia and hypoglycemia have been associated with neurologic damage [498, 499]. Although the major oxidative fuel of the brain is glucose, fetal and neonatal brains also have the capacity to oxidize ketone bodies, lactate, and perhaps amino acids [500–503]. With regard to neurocognitive and developmental outcomes, Mesotten et al. performed extensive neurologic testing in the infants and children in the previously described study by Vlasselaers in which there was a prevalence of hypoglycemia of 25% [497]. At 3-year follow-up, these investigators found that TGC was associated with improved motor coordination and cognitive flexibility and that hypoglycemia was not associated with worse neurocognitive outcome [504]. Alternatively, a 1-year follow-up study by the SPECS group did not find a difference between TGC and standard care on neurodevelopmental outcomes. It did, however, raise concern that patients who had recorded moderate (40–49 mg/dL) to severe (<40 mg/dL) hypoglycemia at times during the study may have worse neurodevelopmental outcomes [505].

In conclusion, there are no clear guidelines for glycemic control following pediatric cardiac surgery and CPB. While hyperglycemia in the early postoperative period is universally seen, it is usually limited and can be attenuated by limiting glucose administration in the intraoperative and immediate postoperative periods [506–508]. Perhaps patients who have persistent hyperglycemia or who fail to convalesce as expected are the subset most likely to reveal the appropriate strategy of glycemic management in future studies [492].

Thyroid hormone

Thyroid hormone has a range of direct and indirect effects on the cardiovascular system that is mediated by genomic and nongenomic mechanisms [509–512]. Administration of triiodothyronine (T3) is associated with a decrease in systemic vascular resistance, an increase in the force of ventricular contraction, and more rapid diastolic relaxation [513–515].

Cardiac surgery, both with and without CPB, is associated with depression of thyroid hormone levels in adults and children. In 1978, Zucker et al. first measured low levels of thyroid hormone and low thyroid-stimulating hormone (TSH) in 19 children undergoing CPB, five of whom were on dopamine infusions that had previously been shown to depress TSH levels in healthy volunteers [516]. Bettendorf et al. measured plasma TSH, thyroxine (T4), T3, and thyroglobulin (Tg) in 132 children undergoing heart surgery before and up to 21 days postoperatively [517]. In addition to 85 patients placed on dopamine infusions, betadine solution was used for operative skin preparation and found to cause low thyroid levels in the neonate. Linder et al. found that postoperative levels of TSH were lowest at day 1, while T3 and T4 were at their lowest on day 2. TSH typically increased to levels above those obtained preoperatively at day 5. Patients on dopamine infusions had the most striking changes in thyroid hormone levels. There was also a significant correlation between postoperative urinary iodine excretion and lowest T3 levels. Investigators also noted longer periods of mechanical ventilation and oxygen supplementation as well as higher inotrope use in patients with T3 levels <0.6 nmol/L [518].

Of interest in these studies was the decrease in TSH levels suggesting changes at the hypothalamic–pituitary–thyroid axis. This pattern is also seen in nonthryoidal illness syndrome, once called "sick euthyroid syndrome," a condition often seen in the setting of critical illness. It is unclear whether nonthryoidal illness syndrome is an adaptive response to critical illness that lowers oxygen consumption and catabolic burden or is maladaptive, potentially resulting in LCOS and organ failure. If maladaptive, could T3 infusions improve cardiovascular performance and improve outcomes?

In adults undergoing coronary bypass surgery, parental T3 repletion improves postoperative cardiac index and lowers

the incidence of atrial fibrillation in select patients [519–522]. In pediatric patients undergoing cardiac surgery, three randomized, placebo-controlled trials of T3 supplementation demonstrated the safety of T3 infusions in the perioperative period but were underpowered to detect differences in clinical outcome. Chowdhury et al. found no difference in inotrope scores, day on mechanical ventilation, or postoperative length of stay, although there was a trend in clinical improvement in neonates [523]. Mackie et al. performed a randomized, double-blind, placebo-controlled pilot trial of T3 in neonates undergoing the Norwood procedure or arch repair with VSD closure [524]. Primary endpoints were a composite clinical score composed of time until negative fluid balance, time until sternal closure, and time until first extubation. No differences were seen in the composite score between the treatment and placebo groups. The authors pointed out that the single variable of time until first negative fluid balance was shorter by half a day in the treatment group ($P = 0.27$). Bettendorf et al. did observe an improvement in cardiac index as measured by echocardiography [525]. A 2004 Cochrane review concluded that there was insufficient evidence regarding risk or benefit from T3 supplementation in the pediatric cardiac surgery population [526].

In 2010, results from the Triiodothryonine Supplementation in Infants and Children Undergoing CPB (TRICC) trial were published [527]. This study was a prospective, multicenter, double-blind, randomized, placebo-controlled trial examining T3 repletion versus placebo in children less than 2 years of age undergoing cardiac surgery. No difference was found between the groups in the primary end point of time from aortic cross-clamp removal to extubation. However, subgroup analysis showed a significant interaction between age and treatment effects. In children less than 5 months of age, T3 repletion shortened time to extubation to a median of 55 hours, compared with 98 hours in the placebo group. In children greater than 5 months of age, there was a small but significant delay to extubation in the T3 group (20 hours in the T3 group, 16 hours in the placebo group). The risk of adverse events was similar between the two treatment groups [527].

In 2012, investigators published results of additional analysis from the TRICC trial examining the relationship between postoperative cytokine and T3 levels [528]. Studies in healthy adults had previously shown that infusion of recombinant IL-6 appeared to decrease T3 levels at 24 hours after the infusion [485]. In 1996, a study by Saatvedt and Lindberg demonstrated a significant inverse correlation between postoperative T3 and IL-6 levels in children following CPB [529]. In the TRICC subgroup, investigators found that postoperative cytokine levels were predictive of T3 levels at 6, 12, 24, and 72 hours. These authors suggested that preoperative screening of certain cytokines might help to risk-stratify patients at risk for prolonged intubation and determine which patients might benefit from postoperative T3 supplementation.

A meta-analysis completed by Flores et al. reviewed 9 studies and included 711 pediatric patients. Dosing and administration of T3 varied widely between 0.4 and 5 mg/kg and a single dose to continued hormone replacement during the ICU stay. The group receiving thyroid replacement required less inotropic support; however, there was no difference in duration of mechanical ventilation, ICU stay, hospital length of stay, and mortality between groups [530]. Ultimately, the effects of CPB on thyroid hormone are well known; however, the clinical significance of thyroid replacement remains equivocal.

KEY POINTS: GASTROINTESTINAL, HEPATIC, AND ENDOCRINE CONSEQUENCES OF CARDIAC SURGERY IN CHILDREN

- Hepatic dysfunction is noted in up to 9% of patients, with shock in the postoperative period being the most frequent risk factor.
- CIRCI can be observed after bypass; diagnosis is clinical and by ACTH stimulation test. It is managed using stress dose corticosteroids.
- Hyperglycemia is common after bypass surgery and does not appear to have a major effect on short- or long-term outcomes in the cardiac population.
- Bypass is associated with decreased conversion of T4 to T3, and supplementation of T3 in infants is associated with shorter time to extubation.

Introduction

Vascular access is an essential part of anesthetic management in children undergoing cardiac surgery. In children with congenital heart disease (CHD), particularly neonates, it may be extremely difficult to obtain secure vascular access, and thorough knowledge of pediatric vascular anatomy, as well as the skills to cannulate the vessels, is mandatory. Traditional techniques of catheter placement rely mainly on anatomic landmarks, can be time-consuming, and often involve serious risks. Higher rates of successful catheter insertion and lower rates of complications can be obtained with recently introduced ultrasound-guided techniques if properly applied during catheterization. Some complications can be life-threatening, and therefore, many institutions around the world recommend, and sometimes mandate, the use of ultrasound guidance to enhance patient safety, especially in cases of central venous catheter (CVC) placement. Positive outcomes and maximum benefits can only be gained if meticulous attention is paid to every aspect of catheter placement and maintenance. Hence, risk–benefit assessments should always be performed and indications considered. Large-bore peripheral venous catheters are required to administer fluids and blood products with minimal resistance to flow, arterial catheters are used for continuous blood pressure monitoring and blood sampling, and central catheters for direct infusion of vasoactive drugs and bolus administration of resuscitative drugs. Hemodynamic assessment via invasive monitoring is also crucial for understanding and responding in a timely manner to the pathophysiologic processes associated with patients' underlying cardiac conditions and associated surgical procedures. This chapter describes techniques of vascular access for children with CHD, emphasizing ultrasound guidance for successful placement of venous and arterial catheters, and reviews the interpretation of data obtained from invasive monitoring and strategies for avoiding complications.

Venous access

Peripheral venous access

Peripheral venous cannulation in pediatric cardiac patients can usually be accomplished with few complications. Ideally, a large cannula is inserted into a large vein of the arm or leg, but if this is anticipated as initially difficult, another practical approach can be adopted. A small superficial vein at any site is cannulated with a small catheter (24 or 22 gauge [ga]) before induction or during inhalation induction of anesthesia. Once the airway is secured and the patient immobile, larger-bore venous access can be attempted. Cannula sizes appropriate for intraoperative use are selected according to the patient's weight as follows: <3 kg, 24 ga; 3–10 kg, 22 ga; 11–20 kg, 20 ga; 21–30 kg, 18 ga; >30 kg, 16 ga. Typical locations for peripheral venous access include tributaries of the cephalic and basilic veins and dorsal metacarpal veins at the dorsum of the hands; basilic, cephalic, and median cubital veins of the forearm; the great saphenous vein at the ankle; the dorsal venous arch of the foot; and the lateral malleolus vein of the lower extremities.

Once the patient is cannulated and in the surgical position, it is important to make sure that each intravenous (IV) line is functioning without abnormal flow resistance before draping is commenced. If flow of the infused fluid in the line is in some way affected by body position (e.g. wrist flexion or extension), cautious monitoring of the catheter during surgery is necessary to avoid extravasation. Only a large-bore, short catheter in a large vein with flow unaffected by positional change should be used for rapid infusion of more viscous colloids or packed red blood cells [1]. Extravasation of these fluids can lead to compartment syndrome and the need for fasciotomy and permanent loss of limb function in severe cases.

Commonly selected locations for this purpose include the saphenous vein at the ankle, the cephalic or basilic vein of the forearm, and the external jugular vein (EJV). When the vein can be successfully punctured but advancement of the catheter to its full length is impossible, a spring-wire guidewire 0.018″ (for 22 ga) or 0.015″ in size may be used to facilitate cannulation [2].

Peripheral vein cannulation in pediatric patients is not always an easy task; therefore, sufficient planning and preparation often help to overcome anticipated difficulties. One of the useful tools for prediction is the difficult intravenous access (DIVA) score, which consists of four variables to which numbered scores are assigned: three points are given for prematurity; three for age less than 1 year and one point for age 1–2 years; two points for vein not palpable; and two for vein not visible. One study has shown that the first attempt at IV line placement is unsuccessful in more than 50% of children with a DIVA score of 4 or more [3]. The DIVA score has been refined and validated, and three predictors, including history of stay in the newborn intensive care unit (ICU), operator's inexperience, and skin color, have been incorporated [4]. Recognition of a child with a high DIVA score should warn anesthesiologists and prompt them to prepare a backup plan for anticipated difficult peripheral venous access. In the face of unanticipated DIVA, calling for the help of an experienced and skilled anesthesiologist, if available, is far more important than multiple attempts and hope for successful cannulation. Each consecutive puncture and failed cannulation increase difficulty of subsequent attempts and risk of complications.

New technologies have been developed in the past several years to facilitate venous access in children, with variable results [5–9]. Among them, ultrasound and illumination techniques are promising, particularly in children with anticipated cannulation difficulties. Ultrasound-guided methods for peripheral IV access will be discussed in detail later in this chapter. With respect to illumination techniques, a few commercially available vein locator devices can be used. The AccuVein® AV300 or AV400 (AccuVein Inc., Huntington, NY, USA) is a vein illumination device that operates by projecting infrared light, which is absorbed by hemoglobin, and making the veins visible through a viewfinder. The VeinViewer® (Luminetx Corp., Memphis, TN, USA) uses near-infrared light and projects a real-time image of the vein pattern directly onto the patient's skin. Neither obesity [5] nor skin color [6] interferes with vein visibility. Although the efficacy and use of these devices under routine and anticipated difficult IV access conditions have not been validated in large-scale studies of pediatric patients, further evaluation would be beneficial because they are easy to operate, non-invasive, and portable.

Technique. Venipuncture is simple and common for all peripheral veins. For veins of the dorsum of the hand, holding the hand in place with the wrist fully flexed while stretching the dorsum of the hand with one's thumb and index finger makes the dorsal metacarpal veins easier to cannulate (Figure 13.1A). If the vein is visible or palpated, the puncture is straightforward. If the vein is not visible or cannot be palpated, blind insertion attempts have traditionally been made based on typical anatomic locations. However, new devices, such as the VeinViewer, may visualize the vessel and facilitate successful cannulation (Figure 13.1B, C). Even if blood flow is not observed in the cannula, it may be advanced into the vessel and cannulation can be confirmed by an infusion trial with a small amount of infusate. Lack of signs of local extravasation indicates successful cannulation.

Central venous access

Central venous access is often necessary during surgery for congenital heart defects to measure central venous pressure (CVP), deliver vasoactive drugs or high-osmolarity solutions into the central circulation, and to repeatedly sample blood to monitor venous oxygen saturation and other metabolic parameters. To achieve these goals, multi-lumen catheters are recommended. The largest distal lumen should be used for pressure monitoring, whereas proximal lumen(s) should be used for other purposes including administration of vasoactive medications. Because large-size catheters in small vessels are associated with higher rates of thrombosis, the size of the catheter should be the smallest acceptable.

In patients with single-ventricle physiology who have undergone palliative cavopulmonary anastomosis surgery, a catheter inserted via the upper limb or neck veins [10] can be used to measure pulmonary artery pressure, which may be important to assess. If access is required only for inotrope infusion, it would be prudent to insert the line elsewhere because thrombosis or occlusion of the superior vena cava (SVC) would limit pulmonary blood flow [11, 12]. Catheters inserted from below the diaphragm should reach the inferior vena cava (IVC) for accurate assessment of atrial pressure [13]. In patients

Figure 13.1 Peripheral venous access with the VeinViewer. (A) The VeinViewer could not show the left dorsal metacarpal vein in a patient aged 9 months. (B, C) The VeinViewer clearly showed the left dorsal metacarpal vein in another patient aged 2 months.

with single-ventricle physiology and adequate atrial septectomy, monitored pressure reflects systemic ventricular diastolic pressure. If complete atrial or ventricular mixing is observed, line flushing or bolus administration of drugs should be performed with care, because clots or inadvertent air infusion can result in paradoxical systemic embolism.

Percutaneous central venous access

Among various available approaches to central venous access, the percutaneous approach has become standard practice at many institutions. This has been particularly true because of the development and widespread use of portable ultrasound devices for ultrasound-guided catheter insertion (see later). Common sites for percutaneous central venous access include the internal jugular, subclavian, and femoral veins. Various central catheters are commercially available. Recommended sizes and lengths for each insertion site are listed in Table 13.1.

Full barrier precautions are mandatory upon catheter placement. Sterile technique with gowns and wide draping should be applied during all percutaneous central cannulations to reduce the risk of catheter-associated infection. After sterile skin preparation with chlorhexidine-containing solution or iodine, wide draping is performed, preferably with a clear, fluid-impermeable, adhesive and aperture drape so that the underlying anatomy is clearly visible. The Seldinger technique is the standard approach. The basic principle is to place a guidewire into the target vessel and then thread a large-bore catheter over the guidewire. For guidewire placement, either an introducer needle or an angiocatheter (catheter-over-needle) may be used. The authors' preference is to use an angiocatheter in infants weighing less than 10 kg (see Figure 13.2). In these patients, a 4 Fr central catheter is routinely used. A 0.015″ or 0.018″ guidewire should be used for cannulation. The wire is first threaded into a 24 ga catheter to enter the vessel. Using this small, 24 ga angiocatheter to puncture the vessel may minimize hematoma formation should inadvertent artery puncture occur, and reduce damage of the vessel should the needle penetrate its posterior wall. Once the catheter is placed in the vein, a short extension tube can be attached and used as a manometer to verify venous access. This verification is extremely important in patients with cyanotic lesions, because the color of blood aspirated from the catheter is not a reliable indicator of correct venous placement. One advantage of an introducer needle is that threading the outer catheter over the inner needle is not necessary. Disadvantages include the necessity to use a large needle (20 ga for a 0.018″ or 0.021″ guidewire) and the possibility of damaging the guidewire if improperly inserted, which can lead to serious complications. Because the tip of the needle may damage the structure of the thin guidewire, attention should be paid not to retract the guidewire through the needle while it is still in the vessel if there is any resistance at all; they should be removed simultaneously to avoid breaking the guidewire and a fragment being retained intravascularly. Guidewires with straight, slightly curved (angled), or J-shaped tips are available. The shape of the tip may be one of the causes of unsuccessful threading [14], particularly in neonates or small infants. The radius of the curvature of the wire's J-shaped tip is often identical to or larger than the diameter of the infant's vessel (~5 mm) [15, 16]. Our preference is to use the straight end of the guidewire in this patient population (see Figure 13.2). After the desired vein is punctured, the guidewire is carefully advanced into

Table 13.1 Recommended central venous catheter sizes and lengths

Patient height (cm)	Internal jugular/ subclavian vein	Femoral vein
<60	20 ga, single lumen, 8 cm 3–4 Fr, double lumen, 8 cm	20 ga, single lumen, 12 cm 3–4 Fr, double lumen 12 cm
60–80	4 Fr, double lumen, 8 cm	4 Fr, double lumen, 12 cm
80–130	4 Fr, double lumen, 12 cm	4 Fr, double lumen, 12–15 cm
130–160	5 Fr, double lumen, 12–15 cm	5 Fr, double lumen, 15 cm
160–170	7 Fr, double lumen, 15 cm	7 Fr, double lumen, 20 cm
>170	8 Fr, double lumen, 16 cm	8 Fr, double lumen 20 cm

AL Grawany

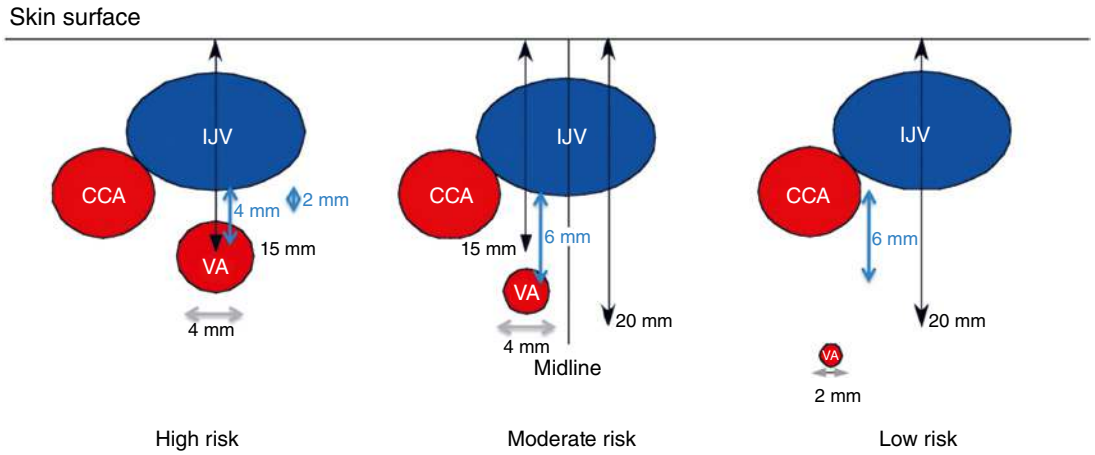

Figure 13.2 Schematic representation of risk classification for vertebral artery puncture. The width, depth from the skin, the distance from the IJV of the VA, and the overlapping between the IJV and VA are illustrated using out-of-plane Doppler color flow imaging. In high-risk cases, the vertebral artery (VA) is wide (>4 mm), locates shallow (<15 mm from the skin), near the internal jugular vein (IJV) (<2 mm), and overlaps with the IJV. In low-risk cases, the VA is small (<2 mm), locates deep (>20 mm from the skin), distant from the IJV (>6 mm), and does not overlap with the IJV. The common carotid artery (CCA) does not affect the classification.

the SVC. The resistance to the wire's passage should be minimal; if any resistance is encountered, the wire must be carefully withdrawn. Forcing a guidewire in the presence of resistance can lead to significant complications. The electrocardiogram (ECG) should be observed carefully as the guidewire is slowly advanced. Premature atrial contractions (PACs) are usually observed as the first guidewire-induced dysrhythmias, signifying atrial location. If no PACs occur, the guidewire is most likely not in the atrium. Premature ventricular contractions, especially if multifocal in nature and occurring as the first observed dysrhythmia, indicate that the guidewire is probably in the ventricle and should be immediately withdrawn. Insertion of a transesophageal echocardiography (TEE) probe before attempting central venous access may facilitate visualization of the guidewire and confirmation of its correct location [17].

After guidewire placement, a very small incision is made followed by careful dilation and catheter cannulation. Dilators included in prepackaged CVC kits are often one size larger than the catheters (e.g. a 5 Fr dilator for a 4 Fr catheter). This might not be optimal with small infants; passage of the catheter without dilation or use of a dilator of the same size as the catheter would be preferable. This allows for the smallest possible entry into the vein, to minimize bleeding and trauma to the vessel wall, both of which can lead to thrombosis or vascular insufficiency. In small infants, attention should be paid to blood loss during the catheterization procedure; direct compression of bleeding puncture sites with the heel of the non-dominant hand should be applied while threading dilators or catheters. Difficult catheterization often requires more hands, and assistance should be requested accordingly. Once the catheter is advanced to the desired depth, it should be secured with sutures and dressing.

Internal jugular vein

The internal jugular vein (IJV) originates from the jugular foramen at the base of the skull. The right IJV is large and lateral to the common carotid artery (CCA) along most of its length (termed the carotid sheath) and is the most common site for central venous access in pediatric patients undergoing cardiac surgery. The IJV provides a direct route to the right atrium (RA) and is an optimal site for catheterization. In patients with supracardiac-type total anomalous pulmonary venous return (TAPVR), the vertical vein draining blood from the common chamber to the brachiocephalic vein and the left IJV and left subclavian vein (SCV) usually contains oxygen-rich blood. Oxygen-rich blood can be drawn while puncturing the left IJV, and it is sometimes difficult to distinguish whether the blood is from an artery or a vein. We recommend use of a pressure transducer for confirmation. Some surgeons discourage the use of the left veins in TAPVR. The right IJV, right SCV, or femoral veins (FVs) can be used instead of the left IJV and/or SCV.

Some simulated models have shown that penetration of the posterior wall of the IJV is unavoidable [18, 19]. Inadvertent CCA puncture can occur unless its exact location is known. The CCA and IJV overlap area differs among studies from various countries and approaches [20–23]. Both the lower approach (at the junction of the two heads of the sternocleidomastoid muscle) and the higher approach (at the cricoid cartilage) provide a similar pattern of overlap (Table 13.2). The overlap between the IJV and the CCA increases with head rotation to either side [24]. In addition, the right IJV is preferred to the left because of a smaller overlap area with the CCA on the right side and its more lateral position [24]. Greater head rotation (more than 30°) to the left should be avoided, because this increases the right IJV and CCA overlap and risk of carotid puncture. Positive inspiratory pressure, but not the Trendelenburg position, can increase the cross-sectional area of the IJV [25]. Use of combination of the Trendelenburg position, liver compression, and simulated Valsalva maneuver can effectively increase the diameter of the IJV [26]. Gentle skin traction can also improve the success rate of catheterization [27]. An anchoring maneuver using a pilot needle facilitates IJV catheterization at its

Table 13.2 The overlapping of the right common carotid artery (CCA) and internal jugular vein (IJV) in pediatric patients

	CCA IJV	IJV CCA	IJV CCA
Higher approach (n = 130)	43.1%	43.8%	13.1%
Lower approach (n = 216)	35.2%	53.2%	11.6%

The CCA and IJV are at the cricoid cartilage in the higher approach and at the junction of the two heads of the sternocleidomastoid muscle in the lower approach. Schematic representation of CCA and IJV as imaged by ultrasound with operator standing at patient's head. Results are combined from studies [19–22].

entry in the majority of infants. If the pilot needle is left in the IJV, and the IV catheter (22 or 24 ga) is passed just posterior to the puncture point of the pilot needle to track the pilot needle path at a 10–20° angle to the skin, a natural tumbling movement of the pilot needle helps to anchor the anterior wall of the IJV and facilitate puncture with the catheter needle [28]. The bevel-down approach to the right IJV may decrease the incidence of posterior venous wall damage and hematoma formation compared with the bevel-up approach [29].

Technique. With a landmark approach, the location of the clavicle, sternocleidomastoid muscle, and cricoid cartilage should be confirmed by visually observing and palpating the neck. After disinfecting the insertion site, the skin is usually punctured midway between the mastoid process and the sternal notch in the "high" approach, at the junction of the two heads of the sternocleidomastoid muscle or at the level of the cricoid cartilage in the "middle" approach, or near the jugular notch in the "low" approach (Figure 13.3). After aspiration of dark-colored blood from the punctured vessel, the Seldinger technique should be used for guidewire and catheter placement (described earlier). If the artery is inadvertently punctured, compress the puncture site for several minutes to ensure hemostasis. Ultrasound-guided puncture will be discussed in detail later in the chapter.

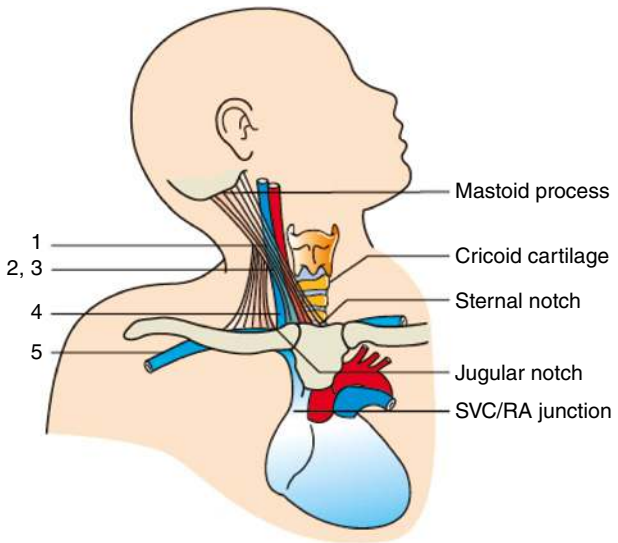

Figure 13.3 Sites for central venous cannulation of the superior vena cava (SVC). 1, high approach, midway between mastoid process and sternal notch; 2, 3, middle approach using apex of muscular triangle or cricoid cartilage; 4, low approach using jugular notch; 5, lateral approach to subclavian venipuncture. RA, right atrium. (Source: Andropoulos et al. [30]. Reproduced with permission from Wolters Kluwer Health, Inc.)

Subclavian vein

Subclavian central venous catheterization is a relatively safe procedure, with minimal complications in pediatric patients [31–35]. The SCV is an extension of the axillary vein at the outer border of the first rib, lies under the clavicle, and runs in the subclavian groove on the first rib. The SCV joins the IJV to form the brachiocephalic vein. It lies anterior to the anterior scalene muscle, and the subclavian artery lies posterior to the anterior scalene muscle. Catheterization of the SCV has several advantages, including its relatively constant position in reference to surface landmarks in patients of all ages, comfort for the awake patient, and less tip migration and greater stability with patient movement. Disadvantages include risk of pneumothorax and the potential inability to dilate the space between the clavicle and the first rib. There is also a possibility that a subclavian catheter will enter the contralateral brachiocephalic vein or ipsilateral IJV instead of the SVC.

Technique. For right-side subclavian venous puncture, positioning with the patient's right upper arm abducted 0° maximizes clavicle and SCV overlap. In the 5°–10° head-down tilt position, puncture the skin near the clavicle at the midpoint or just lateral to the clavicle. Advance the tip of the needle to contact the clavicle. The tip should then be advanced underneath the clavicle with the needle kept in the horizontal position to avoid puncturing the subclavian artery or the lung. When no blood return is obtained, withdraw the needle gently while pulling back the plug with the syringe attached to the angiocatheter. After obtaining dark-colored blood return without pulsation, cautiously advance the guidewire and then the dilator.

External jugular vein (EJV)

The course of the EJV can be readily seen on either side of the patient's neck. The EJV can also be used as a peripheral vein that provides rapid and easy vascular access. Inadvertent arte-

rial puncture is extremely rare with this approach. Although the EJV is a viable site for central venous access with a low complication rate, the EJV has positional concerns because of its angle relative to entry to the SCV, which may hinder the passage of a guidewire into the SVC. This is particularly true in younger patients. Success rates of percutaneous central catheterization via the EJV vary from 54 to 90% [36–40].

Technique. With the patient's head extended, the central portion of the EJV compressed, and the EJV stretched peripherally, puncture the skin with an angiocatheter (<10 kg, 22 ga; 10–20 kg, 20 ga; >20 kg, 18 ga) and insert a curve-tipped guidewire after obtaining dark-colored blood. A small incision with a 25–27 ga needle at the insertion point can aid angiocatheter insertion.

Femoral vein

Another major site of access to the central circulation is the FV. The FV is the most commonly accessed central route in pediatric patients outside the operating room (OR) because of the relatively high rate of success and low incidence of complications [41, 42]. Once thought to be associated with an increased risk of infection, studies have since concluded that cannulation of the FV is of no greater risk than other sites [43, 44]. Several studies [13] have reported that mean CVP measured in the IVC below the diaphragm is identical to that measured in the RA in patients with or without CHD (in the absence of increased intra-abdominal pressure or IVC obstruction). Agreement of IVC and RA pressures in patients with an interrupted IVC with azygos vein continuation into the SVC, commonly seen in heterotaxy syndrome, have not been evaluated; however, the catheter can be used for other purposes such as drug or fluid infusion.

Technique. The patient should be positioned with a rolled towel placed under the hips to obtain moderate extension. The puncture site should be 1–2 cm inferior to the inguinal ligament and 0.5–1 cm medial to the femoral artery impulse, with the needle pointed toward the umbilicus. Ultrasound guidance is useful for identifying important anatomic structures to aid in successful, uncomplicated placement (see later). It is important to puncture the vessel below the inguinal ligament to minimize the risk of retroperitoneal bleeding. Once cannulated, the Seldinger technique should be used as for IJV cannulation. The tip of the catheter should be located in the mid-IVC.

Umbilical vein

In neonates, a catheter can be placed in the umbilical vein for emergency access when peripheral venous access is not readily available [45, 46]. This vessel can be cannulated at the umbilical stump up to a week after birth. Therefore, umbilical line placement is often performed by physicians in the neonatal ICU.

At some institutions, umbilical catheters are routinely used in neonates with cardiac disease for whom surgery is planned in the first 2 weeks of life [47]. Catheters (5 Fr double- or triple-lumen umbilical venous catheters) are used to infuse volume and vasoactive drugs as well as to concomitantly monitor CVP. One benefit of using the umbilical vein is that it spares the femoral, jugular, and subclavian veins from the risk of thrombosis and permanent occlusion. This is particularly important in neonates with specific diseases in whom multiple interventions are inevitable as they grow older. One caveat is that if the ductus venosus closes after birth, the umbilical catheter does not pass into the IVC, often ending with the catheter tip in branches of the hepatic vein. If on radiography the tip of the catheter is located at sites other than the IVC, the catheter should not be used as a central line.

Technique. With the sterile technique and after placing a loose tie of vessel tape around the umbilical base, the two thick-walled umbilical arteries and the single thin-walled umbilical vein can be readily identified. While dilating with a hemostat, the catheter can be passed easily without a guidewire. If resistance is minimal, the catheter can be advanced to a premeasured distance (usually 7–12 cm). Catheter tip position should be determined radiographically as early as possible to confirm its passage through the ductus venosus and into the IVC.

Direct transthoracic intracardiac vascular access

Intracardiac catheters are generally inserted by the surgeon under direct visualization into the right or left atrium [48, 49] and secured by a purse-string suture [50]. Pulmonary artery (PA) catheters can be located high in the right ventricular outflow tract through the pulmonary valve, or in the main PA. Continuous monitoring of mixed venous saturation in the PA or SVC with an oximetric catheter can be performed with this procedure [48]. Monitoring of continuous SVC oxygen saturation has been shown to be very useful in the post-bypass management of neonates undergoing the Norwood procedure for hypoplastic left heart syndrome [51]. Intracardiac catheters are usually placed during the rewarming phase on cardiopulmonary bypass (CPB) and may be used for pressure monitoring or administration of vasoactive drugs. The benefits of this approach include less time spent on CVC placement, assurance of the location of the catheter tip, and no potential harm to the vessel. Disadvantages include unavailability of central access in the pre-bypass period and a higher risk of cardiac tamponade after catheter removal. Due to this potential risk of post-removal bleeding, mediastinal drainage tubes are usually left in place until all intracardiac lines are removed. This may also be considered a disadvantage, because removal of the lines may leave the patient without central venous access or may delay discharge from the ICU.

A left atrial catheter is often indicated if ventricular dysfunction, coronary artery perfusion abnormalities, or mitral valve dysfunction is anticipated postoperatively. Pulmonary artery catheters are particularly useful in the management of patients with preoperatively known or postoperatively anticipated pulmonary hypertension (e.g., obstructive TAPVR, complete atrioventricular canal, severe mitral valve disease). A PA catheter may be indicated for infants with pulmonary hypertension and patients with residual right ventricle outflow tract obstruction because pull-back of the catheter can provide a pressure gradient between the right ventricle (RV) and the PA.

Tunneled percutaneous or intracardiac lines

In patients with difficult venous access and an anticipated prolonged postoperative course, a tunneled silicone catheter may be used to ensure long-term central venous access. Hickman and Broviac are brands of single- and double-lumen catheters that provide external access. These catheters can be placed percutaneously in standard fashion as mentioned in the previous section, or placed transthoracically into the SVC or RA, as with a standard transthoracic catheter but with a subcutaneous tunnel separating the skin exit several centimeters from the chest wall entry site. Compared with standard polyurethane transthoracic catheters, these catheters preserve other access sites for possible future interventions and are less thrombogenic.

Ascertainment of correct position of upper body central catheters

Proper placement of CVCs is necessary to prevent complications and to provide accurate CVP measurements. Some experts recommend that the CVC tip should be in the SVC, above the pericardial reflection, to make sure that it is located outside the pericardium. This will minimize the risk of cardiac tamponade should perforation occur. If the CVC tip is located in the more proximal SVC, the risk of thrombosis increases, and the catheter could migrate into other vessels such as the azygos vein, where pressure monitoring will no longer represent CVP. Others recommend that the CVC tip be positioned in the SVC, just above the SVC–RA junction. This will reduce the risk of thrombosis, malposition, and tip perforation and increase the longevity of the catheter. Various methods have been proposed to determine proper placement and will be discussed below. In the OR setting, TEE-guided catheter tip positioning is a reliable and safe method and thus can be considered the gold standard [17].

Echocardiography

Transesophageal echocardiography is used for many congenital heart operations. Catheter tips and guidewires are easily imaged with TEE, and one study using TEE-guided CVC placement demonstrated a 100% success rate for correct placement in the SVC when TEE was used, as compared with 86% when surface anatomical landmarks were used in infants and children undergoing congenital heart surgery [17]. The TEE probe is placed before CVC attempts are made, and the SVC–RA junction in the 90° plane is imaged. When the vessel is punctured and the guidewire passed, it should be visualized passing from the SVC into the RA. Then the catheter is passed to its full length, the guidewire removed, and the tip of the CVC identified. Flushing the CVC with saline creates an easily visible stream of contrast which identifies the tip. The CVC is then pulled back until it is above the RA, in the distal SVC 1–2 cm above the crista terminalis. Using this technique, immediate, accurate confirmation of placement is obtained before final securing, and before the surgery. The proximal SVC, which is more than 2 cm above the RA, is difficult to image using TEE, so this method is most accurate in placing CVC in the distal SVC. Also, the commonly accepted radiographic SVC–RA junction is often higher than the SVC–RA junction noted by TEE [17].

Transthoracic echocardiography can also be utilized for SVC catheter placement. Park et al. reported 106 right IJV catheter placements in 2- to 12-month-old infants undergoing cardiac surgery [52]. TTE was 96.2% successful at identifying the crista terminalis and allowing placement of the CVC tip within 10 mm above this structure. A 4–10 MHz wide band linear echo probe with standard cardiac ultrasound machine was used in transverse plane at the right second, third or fourth intercostal space. Cross-sectional images of the ascending aorta, PA, and SVC were obtained, and then the probe was rotated 90° clockwise to obtain images of the SVC–RA junction. The catheter tip was advanced to the desired location, with saline flush aiding in identifying the tip. Two-thirds of the catheters could be visualized using the longitudinal view; the others could be visualized using the transverse short axis view with the catheter identified as a white dot in the SVC, and placed at the level of the PA bifurcation.

Radiography

The chest radiograph is still considered the gold standard to confirm proper placement of the catheter [53]; however, post-insertion chest radiography before surgical incision merely to confirm placement of the catheter tip may not be justified in the OR in terms of time, cost, and radiation exposure to the patient. A chest radiograph should be routinely obtained immediately after surgery to reconfirm catheter tip location; the catheter tip should be seen in the area from the level of the first rib to above the pericardial reflection. Based on studies on embalmed and fresh cadavers, the carina is an easily recognizable radiographic landmark in pediatric patients and can be used to confirm that the catheter tip is outside the cardiac chamber [54]. The caveat is that the commonly accepted radiographic SVC–RA junction is often higher than that noted by TEE [55]. Therefore, the catheter tip located within the atrial silhouette on the chest radiograph can be outside the atrium as documented by TEE. Furthermore, an SVC catheter directed posteriorly down the azygos vein may not be detected by anteroposterior chest radiography alone.

Electrocardiographically guided placement

Intravascular ECG may be used in children to guide correct CVC placement [56, 57]. A normal or hyperosmolar (3%) saline-filled lumen with a special ECG adaptor or a guidewire within the lumen attached to a sterile alligator clip serves as an exploratory electrocardiographic electrode. Prepackaged CVC sets are commercially available to allow intracardiac ECG monitoring [58]. A sudden increase in P-wave size (P atriale) occurs as the catheter enters the RA. The catheter tip can then be pulled back 1–2 cm to the desired position within the SVC. Because this method requires special equipment not always available in the OR, TEE can be used as a sufficient substitute.

Height- and weight-based formulae

In the absence of TEE guidance or intravascular ECG, CVC tip position may not be confirmed until postoperative chest radiography, allowing for any potential malpositioning to persist undetected. One study proposed formulae to predict

AL Grawany

the depth of CVC insertion, with the aim of preventing inadvertent catheter tip placement in the RA [30]. Using a large database of CVC placement data in children, the following formulas were developed for catheter insertion via the right IJV or SCV, with the targeted location of the catheter tip at the radiographically determined SVC–RA junction:

$$\left[(\text{Height in cm}/10)-1\right]\text{ cm for patients} \le 100\text{ cm in height}$$
$$\left[(\text{Height in cm}/10)-2\right]\text{ cm for patients} > 100\text{ cm in height}$$

The authors also provided a weight-based formula for length of CVC insertion via the right IJV or SCV. Use of these formulae should result in CVC placement in the mid-SVC in more than 95% of patients. Caveats of these simplified formulae are that for the IJV, the puncture site is high, precisely midway between the mastoid process and the sternal notch. For the SCV, the puncture site is 1–2 cm lateral to the clavicle midpoint. The formulae must be adjusted if different puncture sites are desired. In addition, the formulae were developed for targeting of the catheter tip to the radiographic SVC–RA junction. As mentioned earlier, the radiographic SVC–RA junction is usually higher than the TEE-confirmed SVC–RA junction. A more recent study [53] used a smaller number of pediatric patients to provide height-based formulae for determining the depth of the right internal jugular catheter (Table 13.3). They used TEE or intracardiac ECG to precisely guide the catheter tip to slightly above the SVC–RA junction and measured the depth of the CVC at the site of right internal jugular catheterization. The formulas listed here have not been validated for accuracy in a prospective fashion and therefore should be used with caution.

Table 13.3 Recommended lengths for central venous catheter insertion

	Andropoulos et al. [30]	Yoon et al. [53]
Formula	**(Ht/10 – 1) cm if Ht ≤ 100 (Ht/10 – 2) cm if Ht > 100**	**(0.07 × Ht) + 1.7**

120	10.0	10.1
130	11.0	10.8
140	12.0	11.5
150	13.0	–
160	14.0	–
170	15.0	–

Ht, height; IJV, internal jugular vein; SCV, subclavian vein.
In two-lumen catheters, the second orifice is usually at 1.5–2 cm from the tip of the catheter. Catheters should be placed more than 4.5–5 cm from the skin. Insertion points differ among patients, especially in the IJV; thus, it is necessary to adjust 0.5–1 cm from the standard lengths.

Peripherally (percutaneously) inserted central catheters

Given its safety and reliability as a method to efficiently obtain central access, the peripherally inserted central catheter (PICC) has emerged as a favorable percutaneously inserted central line in pediatric patients with acute or chronic illness. The PICC line is a thin, soft, and long catheter that can be used for long-term IV antibiotics, nutrition or medications, and blood draws. In use for more than a decade [59], PICCs are routinely used in newborns expected to require prolonged venous access. The complication rate for these catheters is very low [60, 61], and they are generally easy to insert into the central circulation via the antecubital, saphenous, hand, axillary, or wrist veins. Because of the increased popularity of PICCs for IV access in children, many institutions have adopted a team approach for pediatric PICC placement. Most important for successful placement is early access, before the large, visible, superficial veins are exposed to injury from attempts at peripheral IV placement. In critically ill newborns with CHD, it is best to insert a PICC line soon after hospital admission. Commercially available PICCs are 1–5 Fr, single or double lumen, 6–65 cm, and made from polyurethane or silicone. For a newborn, a 2 or 3 Fr PICC line is often used [62]. Centrally delivered medications or fluids are administered through a PICC line; however, these are often inadequate as the sole pre-bypass access for cardiac surgery. Despite the primary intention of PICCs to be placed centrally, only half are successful; however, non-centrally (mid-clavicle and more distal) placed PICCs can still be used safely and reliably for the administration of medications and isotonic fluids. Insertion of PICCs should follow the techniques described for peripheral venous access and central line insertions.

KEY POINTS: VENOUS ACCESS

- Obtaining venous access in infants and children undergoing surgery for CHD can be very challenging. A backup plan should be instituted in the case of anticipated or unanticipated difficult IV access.
- Selection of the catheter size and its insertion site should be tailored to patient characteristics/needs and the nature of the surgical procedure. A strategic approach is necessary to preserve access sites in small infants with single-ventricular physiology.
- For central venous access, the use of full barrier precautions and the Seldinger technique are standard practice.
- Correct position of the CVC tip is important to avoid serious complications. Various methods are available to ascertain proper placement, and understanding the advantages and disadvantages of each method is crucial.

Arterial access

Arterial catheters are necessary during congenital heart surgery to monitor beat-to-beat changes in arterial pressure and to draw intermittent blood samples. Common sites for arterial line

Table 13.4 Recommended catheter sizes and lengths for arterial access based on site and patient weight

Weight	Radial/dorsalis pedis/ posterior tibial arteries	Brachial artery
<2 kg	24 ga	Not recommended
2–5 kg	22 ga	24 ga
5–30 kg	22 ga	22 ga
>30 kg	20 ga	22 ga
Weight	**Femoral/axillary arteries**	
<10 kg	2.5 Fr, 5 cm	
10–50 kg	3 Fr, 8 cm	
>50 kg	4 Fr, 12 cm	

placement include the radial, femoral, brachial, axillary, dorsalis pedis, and posterior tibial arteries. Table 13.4 displays recommended catheter sizes for arterial access based on site and patient weight. Percutaneous entry is often possible, particularly with the aid of ultrasound, but on occasion a cutdown technique may be required to expedite artery access. Ultrasound-guided insertion techniques are discussed later in this chapter. In the study involving brachial, radial, ulnar, umbilical, femoral, and pedal arteries, vascular complications were highest in femoral arterial access in the perioperative setting [63].

Radial artery

This is the most commonly accessible location for initial arterial cannulation in most infants and children. Before cannulation, the Allen's test can be considered to verify sufficient collateral ulnar circulation [64]. Cannulation ipsilateral to an existing or planned systemic-to-PA shunt should be avoided.

Technique. Secure the patient's hand gently to an armboard, with the wrist slightly dorsiflexed and with a small roll underneath it (Figure 13.4). Prepare the skin with antiseptic solution. Use palpation to identify the artery. Alternatively, audio Doppler or ultrasound guidance can be helpful if the pulse is weak. Lighter anesthesia during catheterization may provide a stronger pulse and increase the success rate. Use a 24 or 22 ga angiocatheter flushed with heparinized saline to optimize the flow of blood into the needle hub. The first attempt offers the greatest chance of success; therefore, conditions, such as lighting, positioning, and vessel identification should be optimized. Puncture of the artery is indicated by brisk flashback. Advance the needle and catheter 1–2 mm into the artery to ensure intraluminal placement and attempt to thread the catheter over the needle its full length into the artery. Alternatively, the artery can be transfixed, the needle pulled back, and the cannula gently withdrawn until brisk flashback is observed (Figure 13.4D). The cannula can then be advanced into the artery (Figure 13.4F, G) or a small 0.015″ intravascular guidewire can be inserted into the artery and the cannula advanced over the wire. Either way, minimal resistance signifies successful threading. If the first attempt is unsuccessful, additional attempts can be made at the same site or slightly proximal to it, to avoid areas of arterial spasm, thrombosis, or dissection. Circulation distal to the catheter should be determined by inspection of the color and capillary refilling time of the fingertips and nailbeds and pulse quality as determined by pulse oximetry. We recommend that the catheter be secured with clear adhesive dressing and tape, to ensure that the insertion site and catheter hub are visible.

Femoral artery

The common or superficial femoral artery is large and easily accessible in most patients and is a logical choice when radial arterial access is not available. Our practice is to avoid the femoral artery for prolonged catheterization, when alternative sites are available, because of potential vascular damage of the involved leg. However, if the patient experiences extreme hypotension or peripheral vasoconstriction when no other major vessels are easily palpable, the femoral artery may represent the only viable choice for arterial catheterization. Left-sided femoral artery catheterization is preferred if future cardiac catheterization is anticipated.

Technique. Place a small towel under the patient's hips to extend the leg slightly to a neutral position. Positioning can be aided by slight external rotation with the knees restrained by taping to the bed. After sterile preparation and draping, palpate the course of the superficial femoral artery and puncture the vessel 1–2 cm inferior to the inguinal ligament to avoid puncturing the artery above the pelvic brim, where a retroperitoneal hematoma could form. Audio Doppler or ultrasound can be used to identify the course of the vessel if the pulse is weak. Various puncture techniques are available: direct puncture with an angiocatheter; an introducer needle supplied with a commercially prepackaged kit; or a 21 ga butterfly needle with the extension tube removed. The needles should be flushed with heparinized saline to increase flashback. Use a small, flexible, 0.015″ or 0.018″ guidewire. Threading a polyethylene catheter over the guidewire can often be done without making a skin incision. Importantly, a dilator should not be used because it could cause arterial spasm, dissection, or bleeding if the puncture site is large. Secure the catheter by suturing around the entry site and suturing wings around the hub. Distal perfusion should be assessed immediately, and a pulse oximetry probe should be placed on the foot for continuous monitoring and early warning of poor arterial perfusion.

Brachial artery

The brachial artery has been used successfully as an arterial access site in neonates and small children [65]. However, this site may have theoretical concerns because it has poor collateral circulation compared with the radial, femoral, and axillary arteries, though this has not been proved by any studies to date. The present consensus is that the brachial artery should be reserved for situations when other options are limited, for example, when a right upper-extremity arterial line is necessary to monitor pressure during cross-clamping for repair of coarctation of the aorta, CPB for aortic arch hypoplasia, or interruption.

Technique. A 24 ga catheter should be used in patients weighing less than 5 kg. Restrain the arm in a neutral position on an armboard, and identify the arterial pulse above the elbow crease, above the bifurcation into the radial and ulnar arteries. The method of cannulation is the same as for

AL Grawany

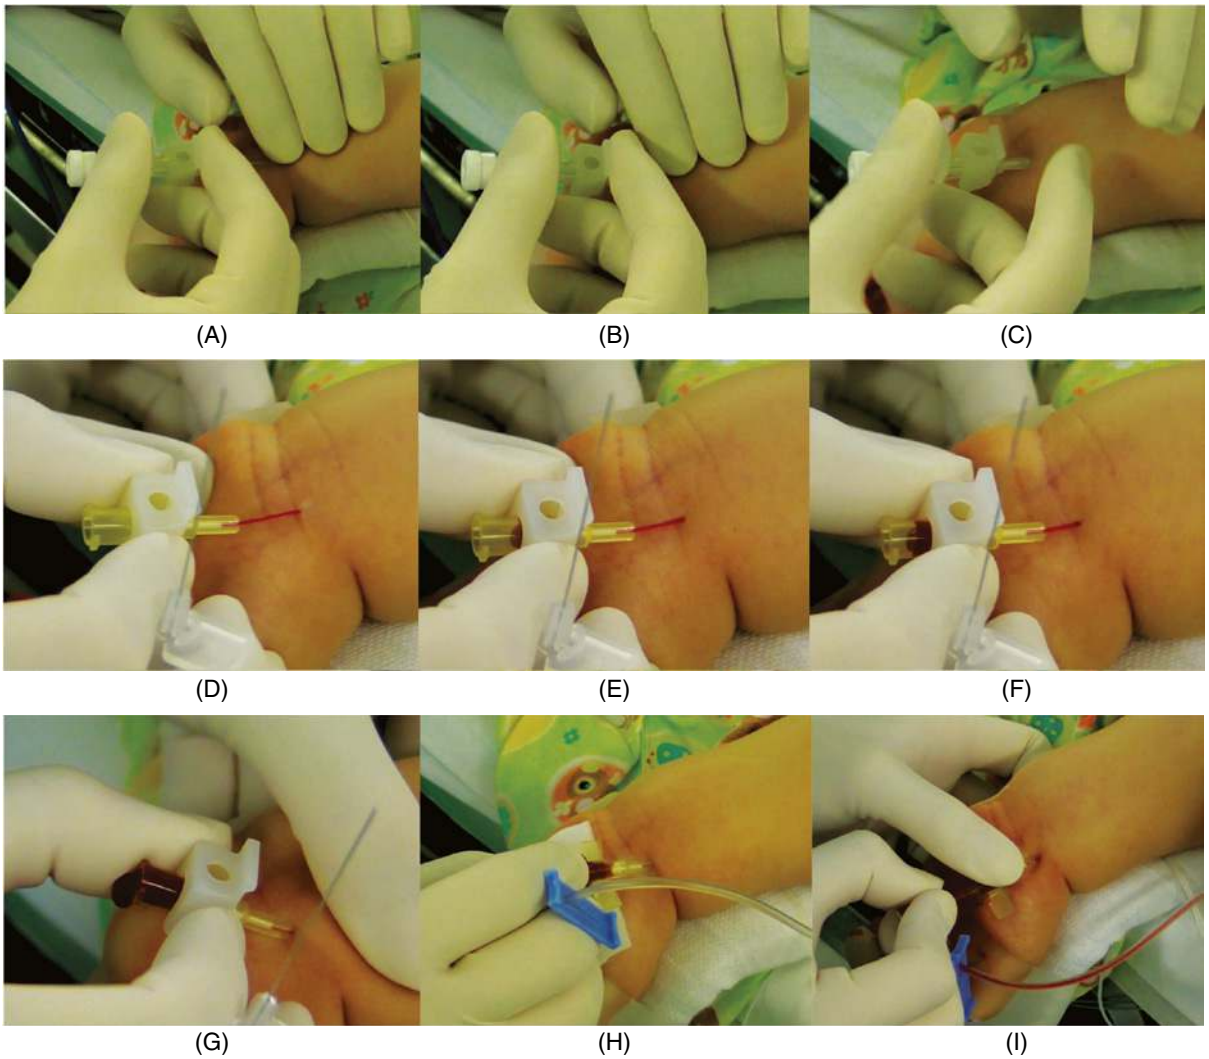

Figure 13.4 Radial artery puncture and catheterization with a 24 ga angiocatheter without ultrasound guidance in a child aged 27 months. The angiocatheter is placed at approximately 10° to the skin (A, B). Blood return cannot be obtained while puncturing (C). When bright-colored blood is obtained from the inner needle of the angiocatheter while withdrawing (D), advance the outer cannula beneath the skin to enter the cannula into the artery (E, F) and confirm continuous blood return (G). A connector is attached to the catheter (H), and arterial blood is aspirated (I).

radial arterial catheterization. Again, distal perfusion should be monitored continuously by pulse oximetry. The catheter should be replaced postoperatively with a catheter at a site that has better collateral circulation as soon as possible.

Axillary artery

The axillary artery is large and well collateralized. Several studies have shown this artery to be a viable option for critically ill children when other sites are not accessible [66–68]. In addition, the complication rate is low. However, given the potential for arm and hand ischemia and intrathoracic bleeding, the axillary artery should be a site of last resort when other options are not available.

Technique. Abduct the arm 90° and extend it slightly at the shoulder. Palpate the artery high in the axilla, puncture with an angiocatheter, and exchange over a guidewire for a longer catheter. A short catheter may be pulled out of the vessel with shoulder extension. Therefore, longer catheters (e.g., 5 cm) are recommended. As with the brachial artery, distal perfusion should be assessed and carefully monitored for potential upper-extremity ischemia. Catheter tip position located outside the first rib should also be confirmed by chest radiography. Because the axillary artery is close to the brachiocephalic artery, it is imperative to flush the catheter gently by hand after blood draws, thereby preventing air bubbles or clots from being introduced into the circulation and minimizing the risk of retrograde cerebral embolization.

Umbilical artery

The umbilical artery can be cannulated in a newborn during the first 72 hours of life and is the site of choice in newborns requiring surgery within a week after birth. Umbilical artery catheterization entails potential risks regardless of the

position of the catheter; placement of the catheter with its tip at the seventh to eighth thoracic segment may be associated with fewer complications than placement at lower positions [69, 70]. Umbilical arterial lines have an uncertain link with necrotizing enterocolitis. A neonate with ductus-dependent circulation, low diastolic pressure, and subsequent systemic steal can be at increased risk of this complication. Umbilical catheters are generally inserted in the delivery room or in the neonatal ICU shortly after birth. Lower-extremity emboli, vascular insufficiency, and renal artery thrombosis have been reported with this site; however, the overall risk is low, and the site is highly desirable because it is a large central artery, which allows for accurate pressure monitoring throughout surgery, while preserving other sites for potential future arterial access.

Technique. Prepare the umbilical stump in a sterile manner and transect. Two small muscular-walled arteries and a larger thin-walled vein are easily identified on the umbilical cord cutoff. Insert a 3.5 Fr catheter blindly into the artery after dilating the vessel. The catheter tip should be placed at the level of the diaphragm or low in the descending aorta, and its position should be confirmed radiographically as soon as possible.

Temporal artery

The superficial temporal artery was widely used, particularly in premature babies. However, it is now avoided because of potentially severe cerebral thromboembolic complications [71, 72]. The exception is when brachiocephalic pressure must be measured during surgery for an aberrant subclavian artery (e.g., corrections for coarctation of the aorta, aortic arch interruption or hypoplasia with an aberrant right subclavian artery arising distal to the obstruction); the only way to measure pressure during cross-clamping or bypass is via direct aortic pressure. This site should be used only during surgery, and the catheter must be removed immediately after operation.

Technique. Use a 24 ga catheter for newborns. Palpate the artery just anterosuperior to the tragus of the ear, just superior to the zygomatic arch. The artery should be approached with a very superficial approach angle (e.g., 10°–15°). Cannulation is performed in the same manner as with the radial artery.

Dorsalis pedis/posterior tibial arteries

Peripheral vasoconstriction and vasomotor instability during the early post-CPB period make the superficial arteries in the lower extremities less suitable as sites for arterial cannulation than the radial artery. An accurate arterial pressure waveform cannot be obtained during the early post-bypass period. These arteries may be indicated for non-bypass surgeries or for continuous pressure monitoring in the ICU.

Technique. For the dorsalis pedis artery, position the foot in slight plantar flexion to straighten the course of the artery, which can be palpated between the second and third metatarsals. For the posterior tibial artery, dorsiflex the foot to expose the artery between the medial malleolus and Achilles tendon. The artery is often deep to the puncture site and may require a steeper puncture angle. Fix the patient's ankle with the arterial line to a board (3) so that the line is not accidentally removed as it is covered by surgical drapes (Figure 13.5).

Ulnar artery

The ulnar artery is only considered when attempts with the radial artery have been unsuccessful or the vessel has thrombosed due to past interventions. It should be used as the last resort, when other options are not available. There is a high risk of ischemia of the hand if both radial and ulnar artery

(A) (B)

Figure 13.5 A posterior tibial arterial catheter. (A) The posterior tibial artery is catheterized with a 24 ga angiocatheter. (B) The patient's ankle with the artery line has been fixed to a board to prevent movement when the line is covered by surgical drapes.

AL Grawany

perfusions are severely compromised. However, one study of 18 ulnar artery catheters in a pediatric ICU reported an ischemia rate of 5.6%, no different from those associated with radial and femoral artery catheters [73].

Arterial cutdown

Cutdown of the radial artery is a reliable and efficient method for establishing arterial access during congenital heart surgery. This method is used as the first and primary method of securing arterial access in some institutions, whereas others only resort to it when all other attempts fail. Despite the speed and ease of access for cutdown, the existing literature indicates that a percutaneous approach is favorable to cutdown in terms of complications (e.g., bleeding, infection, failure, distal ischemia, long-term vessel occlusion).

Technique. Position the arm as for percutaneous radial catheterization. After preparation and draping for surgery, make an incision at the proximal wrist crease, between the styloid process and the flexor carpi radialis tendon. Isolate the exposed artery with a heavy silk suture, vessel loop, or right-angle forceps. It is no longer considered necessary to ligate the artery distally to prevent bleeding; the artery can remain patent after cutdown if not distally ligated. The simplest technique is to directly cannulate the exposed artery with an angiocatheter, in the same manner as for placement of a percutaneous radial artery catheter. Suture the catheter to the skin at its hub and close the incision with nylon sutures on either side of the catheter. To remove, cut the suture at the hub of the catheter, remove the catheter, and apply pressure for a few minutes until bleeding stops. The remaining skin sutures can be removed later.

KEY POINTS: ARTERIAL ACCESS

- In most cases of congenital heart surgery, the radial artery is the preferred site for arterial pressure monitoring, with the second choice being the femoral artery.
- Like venous access, a strategic approach is necessary for selecting the site of arterial access for univentricular patients.
- With a few exceptions, temporal artery cannulation should be avoided because of the risk of devastating cerebroembolic complications.
- Despite theoretical concerns, brachial artery cannulation has been successfully performed in neonates and infants and may be a candidate cannulation site after failure of radial artery catheterization.

Ultrasound guidance for vascular access in congenital heart surgery

Ultrasound-guided vascular access can increase the success rate of line insertion and decrease complication rates associated with catheterization. Ultrasound guidance has been used in many institutions to enhance patient safety, especially during central venous line placement. Understanding the anatomic relations of tissues on sonographically obtained images is essential for safe catheter placement. Fundamental knowledge of the physical principles of ultrasound waves and equipment is necessary for understanding the sonoanatomy of the visualized tissues. Various studies have reported increased success rates and safety of vascular access with the ultrasound guidance.

Sonoanatomy

The differentiation of veins from arteries or muscle can be accomplished with ultrasonography, and it also allows detection of peripheral veins in children. Muscles are moderately echogenic, and adipose tissue is relatively hyperechoic compared with the inner side of a vein filled with low blood echogenicity. Veins are easily compressed, and their lumens are not visible when under compression; thus, they are usually distinguished from muscle or adipose tissue by visual contrast of echogenicity. Another method is to use a low-velocity color Doppler signal (5–20 cm/s), which can be observed as intraluminal color flow. All three layers of a vein wall cannot be distinguished on ultrasonographic images. When the vein is in spasm, the inner layer of the smooth muscle becomes thicker and more visible.

For pediatric vascular access, a linear probe with 5–15 MHz frequency and 1–5 cm depth settings is ideal and adequate in most cases. Higher-frequency ultrasound with 50 MHz can visualize more superficial structures [74]. Various types of portable linear probes are commercially available. Portable ultrasound machines equipped with linear probes are more favorable for pediatric central vein access than larger multifunctional ultrasound imaging systems equipped with TEE probes due to limited space in the OR. A hockey stick-type, 30-mm-wide, small probe might be optimal for vessel imaging, especially in neonates and infants; however, it is sometimes difficult to hold such small probes stably on the tiny necks of neonates and infants. The beveled needle tip produces two echoes, which are obtained when the needle tip reaches the vessel lumen [75]. The distal echo is more intense than the proximal one. The echogenic polymer-coated needle is better visualized than Teflon-coated, etched-tip, echogenic polymer-coated, or untreated needles [76]. Ultrasound also facilitates venous puncture of the great saphenous vein. Direct visualization via ultrasound is a promising technique for the establishment of venous access of the great saphenous vein at the level of the medial malleolus in infants [77].

Ultrasound-guided peripheral vein access

Ultrasound guidance can improve the success rate of peripheral venous access in children with difficult venous access compared with the blind technique [78] and is a promising method. Ultrasound-assisted catheterization saves time spent in the OR when a difficult access scenario is encountered and can, in fact, circumvent this very scenario when chosen as a primary method after adequate patient evaluation. Common veins used include cephalic, basilic, saphenous and brachial veins. The basilic vein is suitable for ultrasound guided peripheral venous puncture because it runs on the convex portion of the foream, making it easy to visualize, especially in lean patients.

Figure 13.6 Positioning of the ultrasound probe for cannulation of the cephalic vein.

Technique. Once a vein has been chosen, search for a long straight portion. During an ultrasound guided approach, it is important to scan the length of the vessel to determine patency and trajectory. The most common technique used is the short axis or out-of-plane approach. The long axis or in-plane approach is preferred by more experienced practitioners, as it allows for dynamic visualization of the needle tip. For the short-axis, out-of-plane technique, place the ultrasound probe at an angle of 60°–80° angle to the skin (Figure 13.6). Sweep or swing the probe along the arm and place it perpendicular to the vein. The vein should be kept continuously in the middle of the visualized field without moving the probe to the side in the perpendicular position. Puncture the skin and visualize the tip of the needle at the center of the anterior wall of the vein. The probe can be moved along the vein while maintaining the probe position perpendicular to the vein. Penetrate the anterior wall with the inner needle of the angiocatheter at an angle of 5°–10° to the skin. Carefully advance the needle, paying attention not to penetrate the posterior wall of the vein. Two high-echoic enhancements from the needle tip placed inside the vessel are observed in the out-of-plane image (Figure 13.7). After obtaining venous blood return from the inner needle, an approximate 2 mm advancement of a 24 ga angiocatheter is required to penetrate the anterior wall by the outer catheter of the angiocatheter. Penetration of the inner needle and outer catheter beyond the anterior wall of the vein is more visible in plane than out of plane. Blood pressure cuff inflation can increase the lumen of the vein in adults and potentially in children.

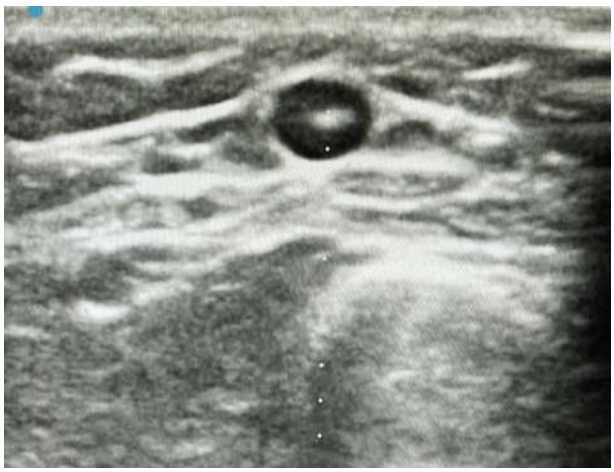

Figure 13.7 Out-of-plane ultrasound image of the cephalic vein with the needle tip as the high echoic signal within the vessel.

After placement of a peripheral venous catheter, if there is a question about whether the catheter is properly sited within the vein, blood return may be elicted with gentle aspiration with larger catheters, and rapid flush of 3–5 mL of saline should be performed. The ultrasound probe can be utilized, especially in small children and infants, to obtain a subxiphoid four chamber view of the heart while saline is rapidly injected into the peripheral catheter. The appearance of saline contrast in the right atrium is confirmation of intravascular placement.

Ultrasound-guided central vascular access

Ultrasound-guided central vascular access has become routine in many institutions, although superiority of either the real-time ultrasound-guided approach or the anatomic landmark approach for locating the IJV has been a matter of debate. The use of ultrasound guidance has been questioned for central catheterization in children; however, many researchers support its application [79–82]. Ultrasound is particularly useful for assisting access to the IJV and FVs in all age groups and the SCV in infants. Randomized studies [80, 83–88] have shown that arterial puncture rates during central catheterization are higher with landmark than with ultrasound guidance (Table 13.5). The use of real-time ultrasound increases insertion success, has higher overall success, reduces access time, and reduces arterial puncture; however, ultrasound-assisted central vein catheterization is not totally reliable. A video analysis reported accidental artery catheterization in five CCAs and one femoral artery despite the use of real-time ultrasonographic guidance, probably due to penetration of the posterior wall of the IJV [89]. Simulated models have indicated that penetration of the posterior wall of the IJV is unavoidable in certain cases [18, 19]. The available evidence tends to support the use of two-dimensional ultrasound to augment the landmark technique for pediatric catheter placement, but more studies are needed [81, 87, 88, 90]. The use of ultrasound during central catheter placement in adults and children remains limited, not universally adhered to, and is

The inadvertent arterial puncture rate is lower with ultrasound guidance than with the landmark method ($P = 0.0026$).

AL Grawany

most strongly associated with the availability of equipment. Trained anesthesiologists can insert IJV lines safely using the landmark technique [90], and ultrasound-guided insertion techniques require education, training, and practice even when working with the adult patient population. Despite the widespread use of ultrasound in children, formal training for this technique is typically lacking. Trainees may benefit more than experienced operators from the use of ultrasound for central catheterization [91, 92].

Ultrasound-guided IJV puncture

The IJV is frequently used for ultrasound-guided or ultrasound-assisted vascular access in children (Figure 13.8). Ultrasound can be used to place central catheters in the IJV even in neonates and infants. Ultrasonographic localization of the IJV is likely superior to the landmark technique in terms of overall success, speed, and decreased incidence of carotid artery puncture [83]. Both audio Doppler and ultrasound are useful for access to the IJV in children older than 1 year of age [84]. Ultrasound may be more useful than audio Doppler in infants and neonates. Location of the IJV with static ultrasonography and the anatomic landmark approach or combining pre-procedural ultrasonographic assessment with real-time ultrasound-guided venipuncture is recommended for central vein catheterization [79, 93, 94].

In pediatric patients, anatomic structures of the vertebral, thyrocervical trunk, suprascapular, transverse cervical, and inferior thyroid arteries, as well as the CCA, can be observed by ultrasonography including Doppler color flow imaging (Figure 13.8). The brachiocephalic artery divides into the right subclavian artery and the right CCA. The right vertebral artery branches from the subclavian artery. The thyrocervical trunk bifurcates from the subclavian artery next to the vertebral artery and into mainly three arteries, the suprascapular, transverse cervical, and inferior thyroid arteries. Numerous variations have been reported for the vessels arising from the aortic arch [95], with different origin variants of the right vertebral artery and some variants of the thyrocervical trunk and its branches [96]. The vertebral artery usually lies under the CCA and enters the vertebral column at the fifth or sixth vertebra; however, it sometimes lies under the IJV. The relationships between the IJV and the vertebral artery can be seen in out-of-plane images (Figure 13.9A) and in-plane images (Figure 13.9B) with Doppler color flow ultrasound, even in neonates and infants. The depth from the skin to the vertebral arteries, the width of the vertebral arteries, and the distance from the IJVs to the vertebral arteries (Figure 13.2), as well as the extent of overlap between the IJVs and vertebral arteries, with scores of zero to three for each measurement, should be checked [97]. The summed scores are categorized as low risk (0–3), moderate risk (4–7), or high risk (8–10). High risk is approximately 13% for accidental puncture of the vertebral arteries. From the thyrocervical trunk (Figure 13.10A), the suprascapular, transverse cervical (Figure 13.10B), and inferior thyroid arteries arise, in that order. Inexperienced practitioners can mistake these arteries for the vertebral artery with ultrasound imaging of this vessel [98]. In some cases, such as anomalous origin of the vertebral artery or IJV spasm, the relationship between the vertebral artery and the IJV may be more clearly understood with in-plane imaging [99].

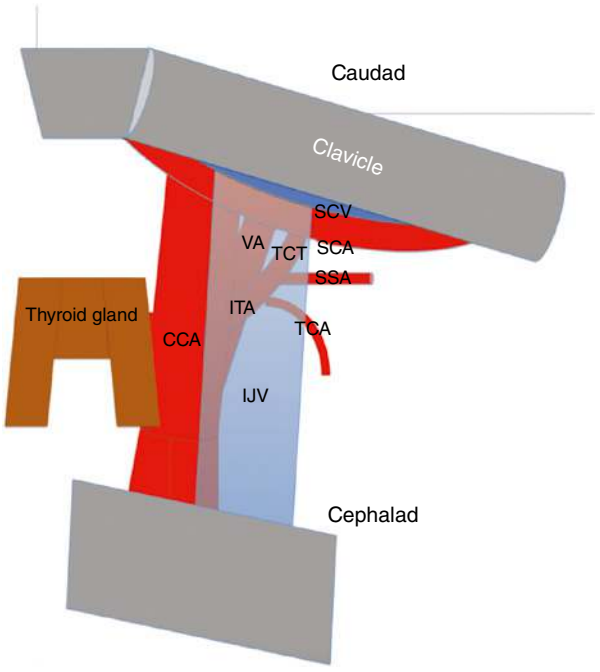

Figure 13.8 Schematic of the anatomic relations among the common carotid artery (CCA), internal jugular vein (IJV), vertebral artery (VA), thyrocervical trunk (TCT), subclavian artery (SCA), subclavian vein (SCV), suprascapular artery (SSA), transverse cervical artery (TCA), and inferior thyroid artery (ITA).

Technique. For right-side IJV puncture, the ultrasound instrument may be placed on the right side of the patient. Before catheterization of the IJV, the pulsation of the carotid artery should be confirmed by palpation at the middle of the patient's neck. (Figure 13.11A2). Under the IJV, the pulsatile vessel, possibly the vertebral artery, can sometimes be felt to be obviously different from the carotid artery. The relationship between the vertebral artery and the IJV, in addition to the relationship between the carotid artery and the IJV, should be assessed by ultrasound imaging out of plane (Figure 13.11B1) and in plane (Figure 13.11B2). Images of other arteries around the IJV, such as the subclavian artery, thyrocervical trunk (Figure 13.10A), transverse cervical artery (Figure 13.10B), and inferior thyroid artery, are sometimes obtained. After disinfecting the puncture site, place the probe with sterilized cover perpendicular to the IJV using the swing or sweep technique to keep the probe perpendicular to the vein in the ultrasound-guided, out-of-plane technique. Before puncturing the skin under real-time ultrasound guidance, depress the targeted skin surface puncture point above the IJV with the tip of a dull, metal, sterilized instrument, such as a hemostat, to simulate puncture without puncturing the skin surface. Obtain an ultrasound image of the intended needle on the screen to confirm the accurate point of puncture at the midpoint between the outer and inner wedges of the IJV. The IJV should be continuously kept in the middle of the monitor without moving the probe to the side and maintaining its perpendicular position. The tip of a 24 ga angiocatheter may be placed at a precalculated angle to the skin (Figure 13.12).

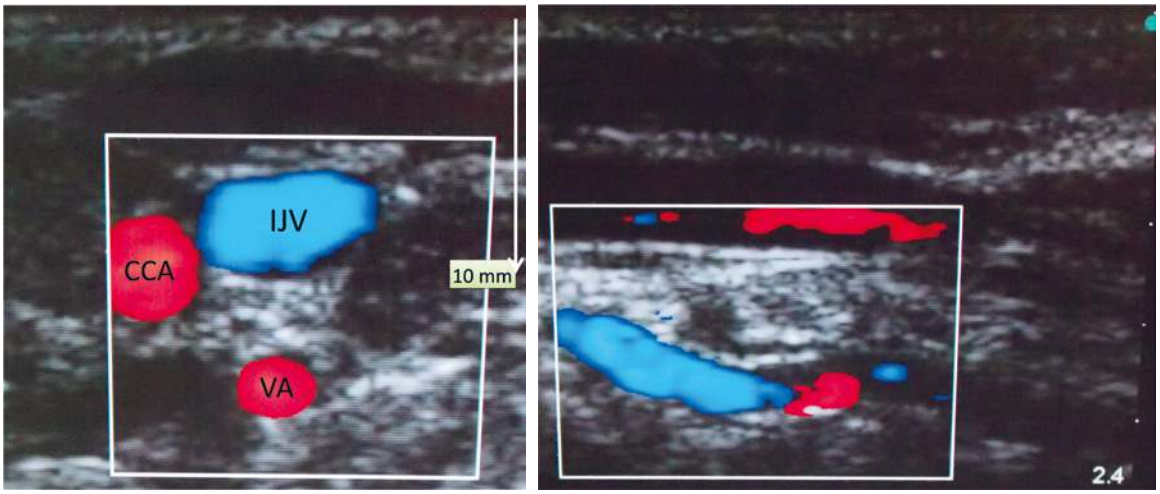

Figure 13.9 Out-of-plane (A) and in-plane (B) Doppler color flow imaging of the common carotid artery (CCA), internal jugular vein (IJV), and vertebral artery (VA) in a 5-month-old infant.

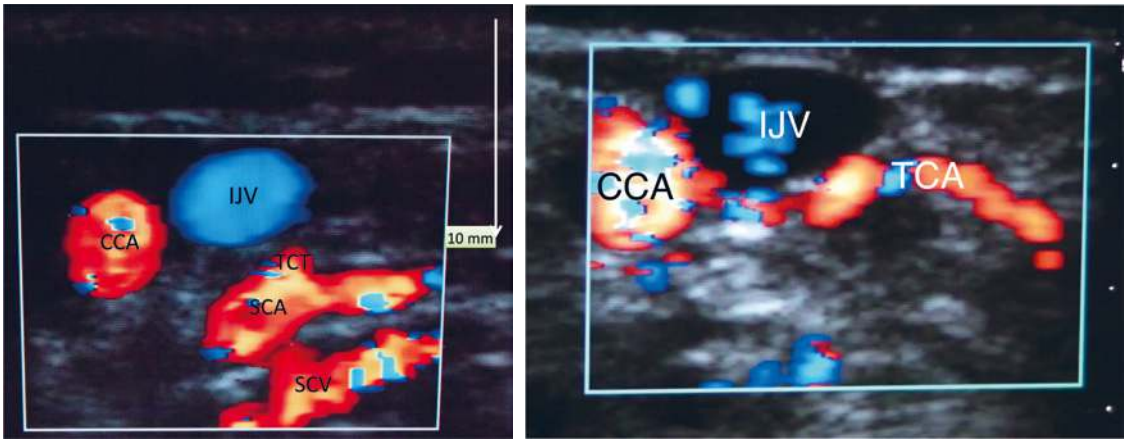

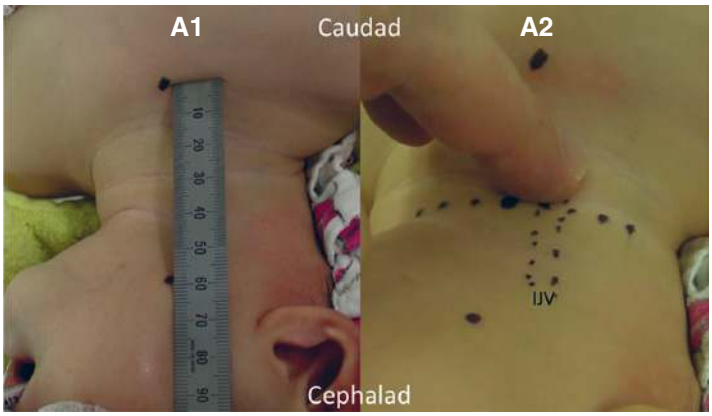

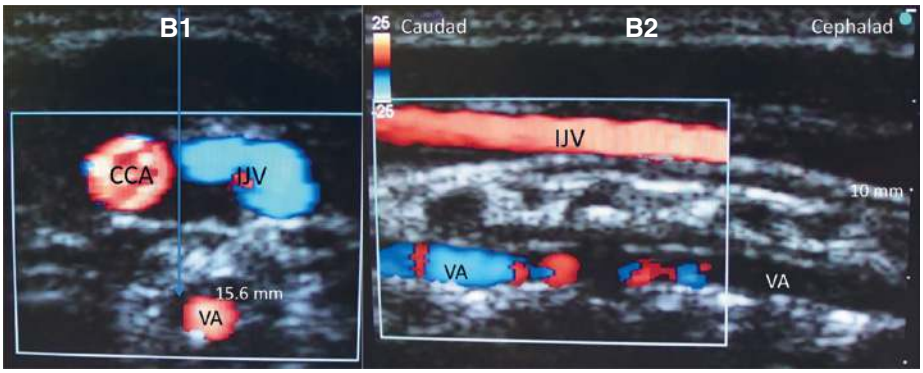

Figure 13.10 Out-of-plane Doppler color-flow imaging of the neck vessels. (A) Out-of-plane Doppler color-flow imaging of the common carotid artery (CCA), internal jugular vein (IJV), subclavian artery (SCA), thyrocervical trunk (TCT), and subclavian vein (SCV) in a 5 month-old infant. The image was obtained near the clavicle. (B) Imaging of the CCA, IJV, and transverse cervical artery (TCA) in an 11-month-old infant. The image was obtained at a site slightly caudal from the mid-portion of the neck, above the clavicle.

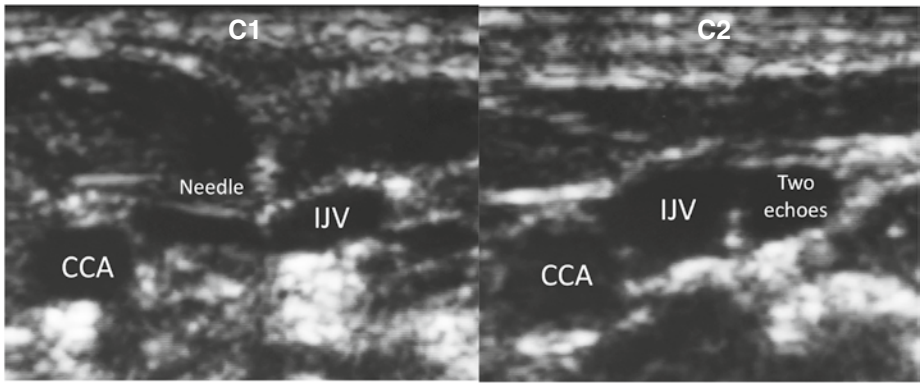
Puncture the skin and visualize the tip of the needle at the center of the anterior wall of the IJV. The probe can be moved along the IJV, maintaining it perpendicular to the vein. Bear in mind that the probe is 12–16 mm thick in its short axis, which hinders the proper advancement of the needle. By inserting the needle 3–5 mm below the skin and then placing the probe near the needle, one can avoid hindrance by the probe – considering the relationship between the depth from the skin and the angle of the probe. Continue observing the tip of the needle on ultrasound throughout the procedure. The tip can be observed at the anterior wall of the IJV (Figure 13.11C1). Two bright echo enhancements of the tip may be seen inside the IJV (Figure 13.11C2). Additional needle advancement is necessary to penetrate the anterior wall with the outer catheter. The distance from the tip of the inner needle and the tip of the outer catheter is approximately 2 mm for a 24 ga angiocatheter. After obtaining dark-colored non-pulsatile blood return (Figure 13.11D1), the slightly curved guidewire should be carefully inserted into the IJV (Figure 13.11D2). When any resistance is encountered during guidewire advancement, advancement must be stopped, and the blood return should be reconfirmed. The course of the guidewire should be confirmed by ultrasound (Figure 13.12) or fluoroscopic imaging before inserting dilators. If there is no blood return, the needle should be withdrawn, and re-puncture is required. If inadvertent artery puncture occurs, press on the puncture site for several minutes to aid in hemostasis. After smooth insertion of the guidewire, the outer catheter must be advanced carefully into the IJV (Figure 13.11D3), and dark-colored blood return should be reconfirmed (Figure 13.11D4) to avoid artery catheterization. As discussed earlier, once the catheter is placed in the vein, a short extension tube can be connected to



AL Grawany

Figure 13.11 Internal jugular vein (IJV) puncture under real-time ultrasound guidance. (A) The distance from the clavicle and the angle of the mandible is approximately 60 mm (A1). The common carotid artery (CCA) and the IJV are outlined and palpated (A2). (B) The CCA and the IJV are visualized by ultrasound Doppler color flow out-of-plane (B1) and in-plane (B2) (VA, vertebral artery). The tip of the angiocatheter is advanced into the IJV and positioned at the anterior wall of the IJV (C1). Two bright echo enhancements are seen at the tip of the needle (C2). Blood return is obtained through the 24 ga angiocatheter; dark-colored and non-pulsatile blood return is obtained (D1). Blood return has increased (D2). The guidewire is inserted and the needle is advanced (D3). We always suspect that the guidewire might possibly advance into arteries behind the IJV. Dark-colored blood return is obtained again; this blood is believed to be venous (D4).

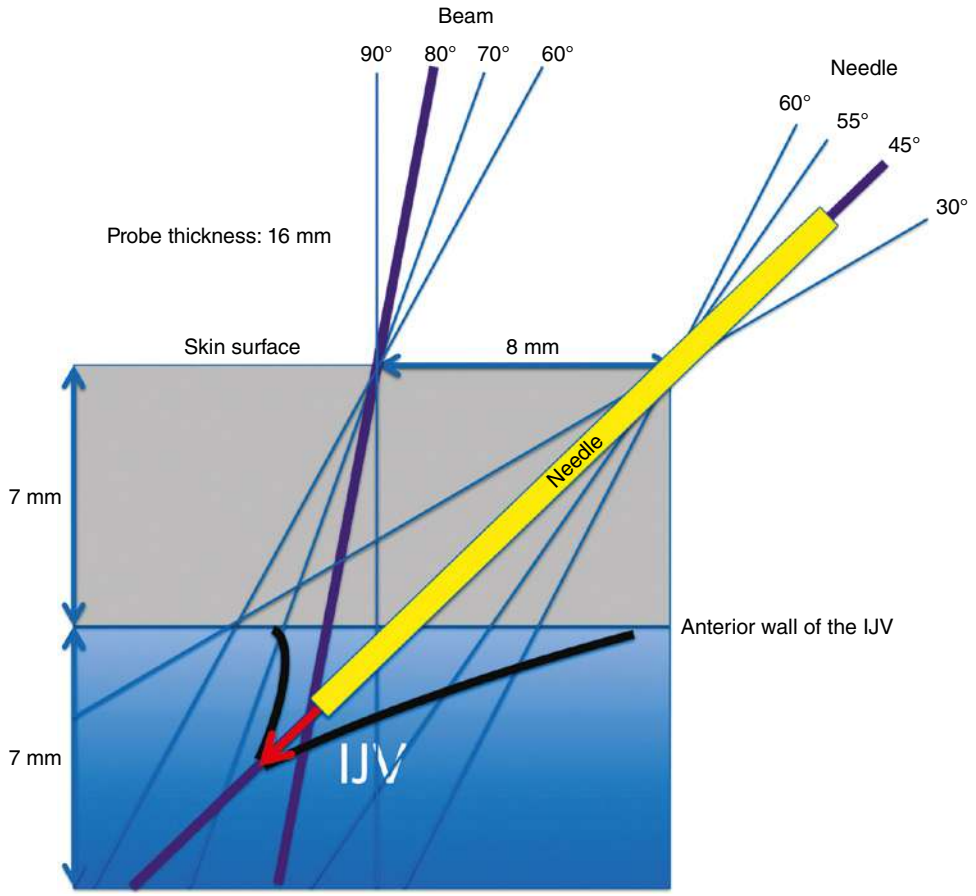

Figure 13.12 The relationship between ultrasound beam and needle angles. To effectively obtain an image of the needle tip on the monitor, the ultrasound beam and needle angles should be as parallel to each other as possible. More than an 8 mm distance between the center of the needle and the puncture site on the skin surface is required when a 16 mm-thick ultrasound probe is used. When the internal jugular vein (IJV) with a 7 mm anterior-posterior length is located 7 mm beneath the skin, the optimal beam angle is 70°–80° to obtain a good image of the needle tip in the IJV while advancing the needle at a 45° angle to the skin. When the beam angle is 60° to the skin, the optimal angle of the needle is approximately 30° angle to the skin. Adjust the angle according to the probe thickness and IJV depth.

the catheter, which can then be used to verify venous access. Carefully insert the dilator along the guidewire so as not to damage vessels or the guidewire while confirming the smooth movement of the guidewire. If any resistance is felt during dilator insertion, stop the advancement and confirm the smooth movement of the guidewire in the IJV. Use fluoroscopy if necessary. Guidewire deformation may suggest complications such as vein or artery perforation. Confirmation of an in-plane, long-axis image of the guidewire (Figure 13.13) is useful in most patients [100]. Careful insertion of dilators is mandatory to avoid serious complications.

Ultrasound-guided SCV puncture

Central catheters can be placed via the SCV under ultrasound guidance [82, 101–103]. The SCV, in addition to the IJV, carotid artery, clavicle, and its shadow can be identified by transectional scanning (Figure 13.14). An ultrasound-guided supraclavicular approach for SCV puncture is now possible for central venous catheterization in small infants, offering all of the advantages of SCV catheterization without the risk of "pinch-off" syndrome [100]. Supraclavicular ultrasound-guided catheterization of the SCV in the pediatric and neonatal ICU appears to be a promising technique in the emergency context [101]. It is safe and reliable, with few early complications. Furthermore, owing to the low level of sedation needed for its placement, it does not compromise the airway of the patient.

Technique. The principle of the ultrasound-guided approach for SCV catheterization is to place the ultrasound probe at the supraclavicular level to obtain a longitudinal view of the SCV and to gain access to the vein via the usual infraclavicular route for cannulation. Place the ultrasound probe on the mid-portion of the neck. Slide the probe caudally, and lean 45°–60° to the skin. Both the subclavian artery and vein are first visualized transversely under the IJV, and then a longitudinal view of the brachiocephalic vein, beginning at the junction of the IJV–SCV, can be obtained. After reaching the IJV–SCV junction, rotate the ultrasound probe laterally and caudally to obtain longitudinal images of the SCV and the brachiocephalic vein. With in-plane imaging, place the needle under the probe to simultaneously observe the SCV and the needle tip. Puncture the mid-portion of the venous anterior wall. After obtaining dark-colored venous

AL Grawany

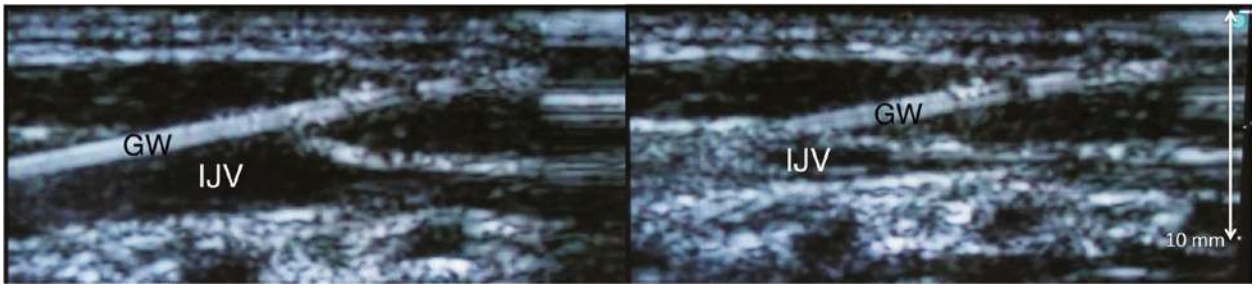

Figure 13.13 In-plane ultrasound images of the guidewire (GW) in a 6-month-old infant. (A) The GW is seen in the internal jugular vein (IJV). (B) The IJV is compressed, and the inner portion of the IJV cannot be seen.

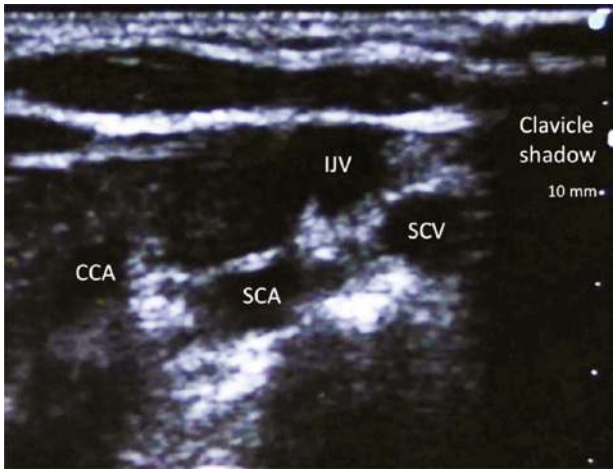

Figure 13.14 The subclavian vein (SCV), internal jugular vein (IJV), common carotid artery (CCA), and clavicle. In a 5-month-old infant, the SCV, IJV, CCA, and the clavicle and its shadow can be identified by transectional scanning. SCA, subclavian artery.

blood, insert the guidewire, and advance the procedure as for ultrasound-guided IJV catheterization.

Ultrasound-guided brachiocephalic vein puncture

Ultrasound-guided supraclavicular catheterization of the brachiocephalic vein is now possible for central venous line placement in small children. Place the broadband linear array ultrasound probe in the supraclavicular region to obtain a longitudinal view of the brachiocephalic vein, beginning at the junction of the IJV and SCV. Using the in-plane technique, direct the needle under ultrasound guidance into the brachiocephalic vein. This provides good needle guidance with no disturbing ultrasound shadow caused by bony structures. The success rate of central catheterization via the brachiocephalic vein in children appears to be very high [104].

Ultrasound-guided EJV puncture

The EJV can often be seen on the lateral side of the patient's neck. Ultrasound imaging facilitates confirmation of its course; however, safety and success rates of the conventional surface anatomic landmark technique and the ultrasound-guided technique are similar for inexperienced trainees [105].

Ultrasound-guided FV puncture

The FV is an optimal site for ultrasound guidance, and the infection rate does not appear to be high, as mentioned earlier.

Technique. As described earlier, the patient is positioned with a rolled towel under the hips for moderate extension. For right-side FV puncture, place the ultrasound monitor on the patient's left side. The practitioner may stand on the patient's right side in order to see the monitor over the patient. Check to ensure that the femoral artery and FV are 1–2 cm from the inguinal ligament by palpation, and then use the ultrasound. The femoral artery is located on the left, lateral side and runs toward the practitioner with a pulsatile, Doppler red-colored flow. The FV is located on the right medial side and runs away from the practitioner with a non-pulsatile, blue-colored flow. Before insertion, check the course of the vessels, and place the probe perpendicular to the FV using the swing or sweep technique. The FV in children is located 7–22 mm from the skin [106], which is usually deeper than the IJV and enables one to obtain an ultrasound image more easily than for the IJV. After sterilization, puncture the skin 1–2 cm from the inguinal ligament according to the probe thickness as described for ultrasound-guided IJV puncture.

Ultrasound-guided arterial catheterization

Ultrasound-guided radial artery catheterization can be useful even in neonates and infants. Radial artery insertion by ultrasound is often selected after the failure of radial artery catheterization by palpation. Ultrasound can visualize the course of the small radial artery even in difficult cases in neonates and infants. Highly successful catheterization can often be achieved when ultrasound images of the tip of the puncture needle and the radial artery are obtained in the same screen under the skin. Ultrasound guidance can improve the success rate of artery catheterization in infants. Fewer attempts with the ultrasound technique are required compared with the traditional technique [107, 108]. Ultrasound-guided radial artery catheterization in infants and small children can provide a greater chance of success at the first attempt compared with the Doppler-assisted technique [109].

Serious complications, such as permanent ischemic damage, are infrequently observed in with ultrasound-guided arterial catheterization for perioperative and intensive care monitoring. However, ultrasound guidance may not facilitate faster catheterization of the radial artery in children.

Technique. Prepare the patient's hand position as described for the palpation method (see earlier). Before catheterization of the radial artery, the course of the radial artery can be palpated and then confirmed with ultrasound Doppler color flow. Once the radial artery has been located by ultrasound, the pulsation of the radial artery becomes easier to capture visually on the monitor, even in neonates and infants. After disinfecting the skin, place the probe with sterilized cover directed perpendicular to the radial artery using the swing or sweep technique to keep the probe directed perpendicular to the artery using the ultrasound-guided, out-of-plane technique. Obtain the ultrasound image of the intended needle on the screen to confirm the accurate point for puncture (Figure 13.15). The radial artery image should be continuously maintained in the middle of the monitor. When bright-colored, brisk flashback is obtained from the inner needle while puncturing, advance the catheter 1–2 mm to enter the artery. When the artery is transfixed, withdraw the needle and gently withdraw the catheter until brisk flashback is observed. The catheter can then be advanced into the artery. Alternatively, when

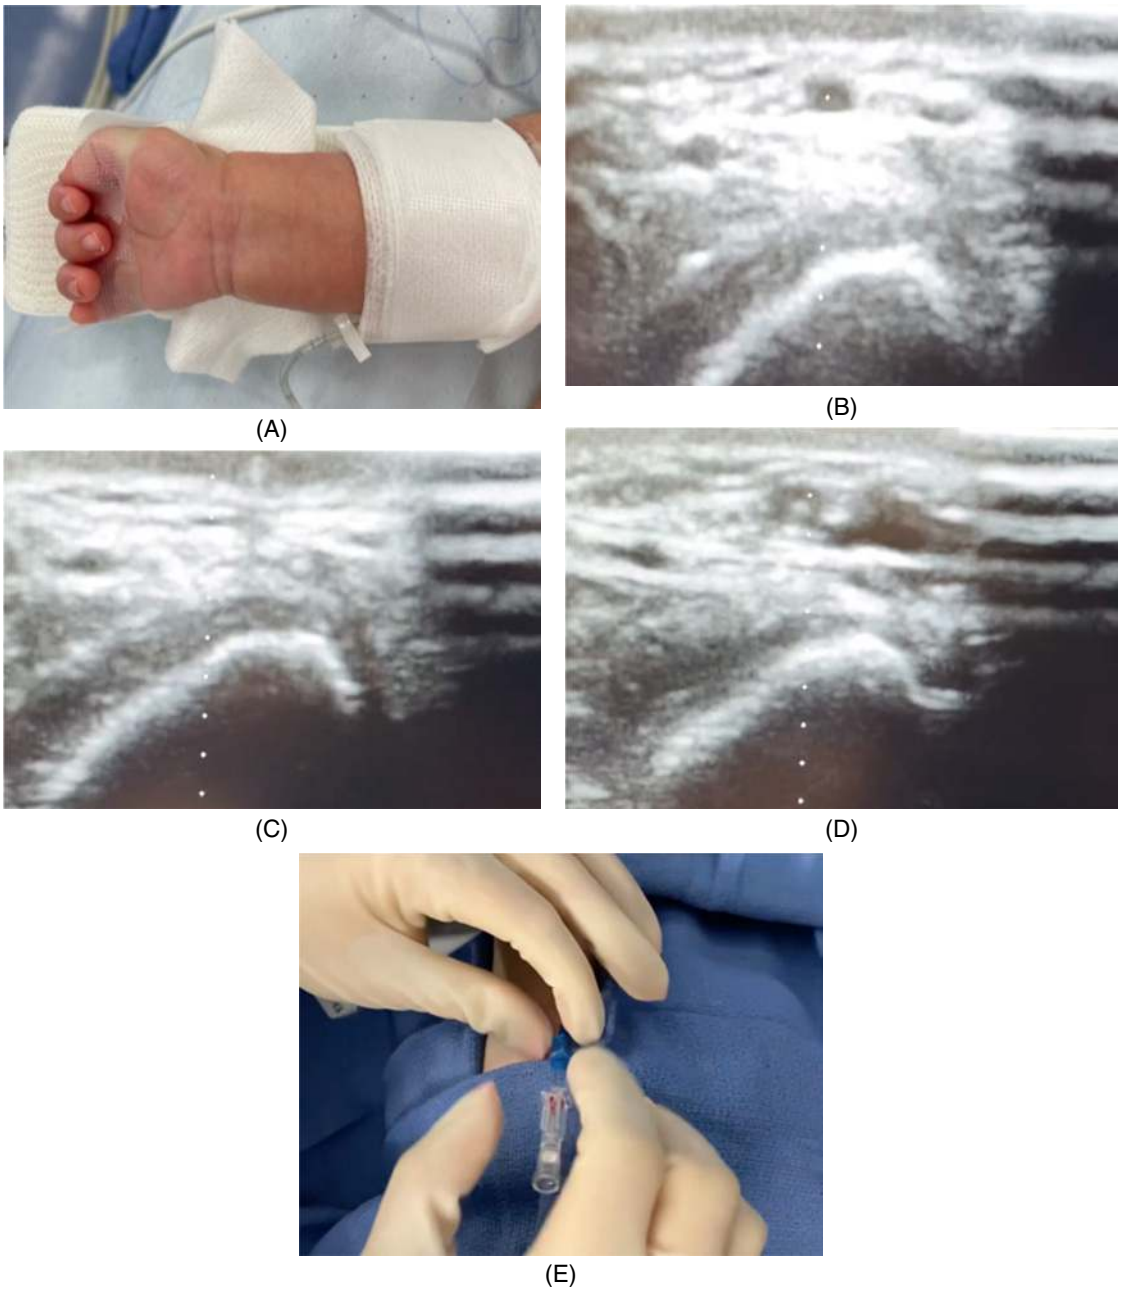

Figure 13.15 (A–E) Ultrasound-guilded radial arterial cannulation. See text for details.

AL Grawany

the tip of the needle is visualized inside the artery at the center, the needle and catheter together can be advanced fully into the artery, keeping the tip of the needle in ultrasound view in the center of the artery during advancement. There is no need to watch for a flashback in the hub of the needle with this method. This technique has the advantage of lessening risk of puncture or damage to the back wall of the artery. Remove the needle when the catheter is advanced to the hub. Connect the catheter to the pressure tubing, paying close attention to avoiding air in the line. Place a cushion between the skin and the catheter with the connector to avoid skin necrosis and cover the catheter with the connector with sterile tape. We often obtain non-pulsatile, bright-colored blood from a 24 ga angiocatheter just after catheterization. Pulsatile blood inside the connected needle can be obtained after connecting to the pressure monitor line. Because of the small radial arterial size in small children, subcutaneous nitroglycerin injection (0.5 μg/kg in 0.5 mL saline) prior to the ultrasound guided radial arterial access significantly increased the diameter of the radial artery. This led to an increase in the success rate of the first attempt, a decrease in the number of cannulation attempts, and cannulation related complications [110].

An alternative ultrasound technique is to image the radial artery in the longitudinal plane and visualize the entire length of the needle and catheter inserted into the vein [111] (Figure 13.16). A controlled study of short axis vs. long axis ultrasound imaging for radial artery catheterization in 97 infants and children revealed no difference in success rate (94% short axis vs. 98% long axis), time to cannualtion, or complications. The incidence of puncturing the posterial arterial wall was higher in the short axis group; (96 vs. 18%, $p < 0.001$).[112]

KEY POINTS: ULTRASOUND-GUIDED VASCULAR ACCESS

- Ultrasound-guided vascular access can increase the success rate of catheter insertion and decrease complication rates associated with catheterization.
- The use of real-time, ultrasound-guided IJV puncture increases first-insertion success, reduces access time, has greater overall success, and reduces inadvertent arterial puncture.
- An ultrasound-guided supraclavicular approach for SCV puncture is now possible for central venous catheterization in small infants.

Percutaneous PA catheterization

Although multi-lumen, flow-directed PA catheters have long been used widely in adult practice, great controversy has arisen during the past several decades [113–117], and their use has decreased significantly, especially in children, and become rare in infants [118]. The Pulmonary Artery Catheter Consensus Conference published a consensus statement regarding the use of PA catheters in pediatric patients [119]. It recommends that PA catheters should only be used in selected patients, such as those with pulmonary hypertension and shock refractory to standard fluid resuscitation and vasoactive agents [120]. In patients undergoing congenital heart surgery, PA pressure monitoring may be indicated for reasons related to the cardiac condition of the patient or the nature of surgery. Patients undergoing surgery on left-sided lesions and who do not have intracardiac shunting, those who are at risk of left ventricular dysfunction, and those with pulmonary hypertension may have indications for PA catheterization. Examples of surgical procedures include aortic surgery, aortic valve surgery or replacement, subaortic resection or myomectomy for hypertrophic cardiomyopathy, and mitral valve repair or replacement. However, PA catheterization has a limited role, if inserted percutaneously, for several reasons. First, adequately sized catheters and sheaths are not available in sizes small enough for the smallest pediatric patients. Secondly, most of these patients have intracardiac shunting, and standard thermodilution cardiac output (CO) measurements, and mixed venous oxygen saturation (SvO_2) measurements are unreliable. In addition, a PA catheter in the right side of the heart may interfere with the surgical field. Thus, when PA pressure or SvO_2 monitoring is indicated, transthoracic PA lines placed under direct visualization at the end of CPB surgery are the most commonly used approach.

Percutaneous PA catheterization is used less frequently in children than in adults, mainly due to greater difficulty in gaining access because of patient size and the unavailability of small-sized PA catheters; however, if the patient is large enough to insert a 5 or 6 Fr introducer sheath in the FV or IJV, percutaneous PA catheter insertion may be feasible.

Pulmonary artery catheters are available in various sizes (4–8 Fr) for different functions, such as pressure monitoring, thermodilution measurement of intermittent or continuous CO, continuous measurement of venous saturation, and cardiac pacing. Commonly used sizes for pediatric patients are 4 Fr (non-balloon-tipped, two-lumen, oximetry catheter), 5 Fr (balloon-tipped, four-lumen, thermodilution catheter), 5.5 Fr (balloon-tipped, four-lumen, oximetry and thermodilution catheter), and 7.5 and 8 Fr (balloon-tipped, three-lumen, oximetry and thermodilution catheter).

It must be stressed that a PA catheter should be used as a diagnostic and hemodynamic monitoring tool and not as a therapeutic intervention; interpretation of the data derived from a PA catheter and subsequent management decisions are crucial to benefit patients fully, requiring attending physician-level expertise. Efficacy studies supporting the use of PA catheterization in children undergoing congenital heart surgery are scarce in the existing literature. Therefore, risks incurred by PA catheter placement should be well taken into account.

Technique. The previously mentioned consensus statement, as well as the guidelines set by the American Society of Anesthesiologists task force, recommends that PA catheters should only be used by suitably experienced personnel to minimize complications, thus requiring adequate supervision throughout the procedure [121] The selection of PA catheter should be based on clinical need and patient size. To obtain maximal benefits, a PA catheter with oximetry and thermodilution CO measurement capabilities is desirable. Commercially available catheters equipped with these

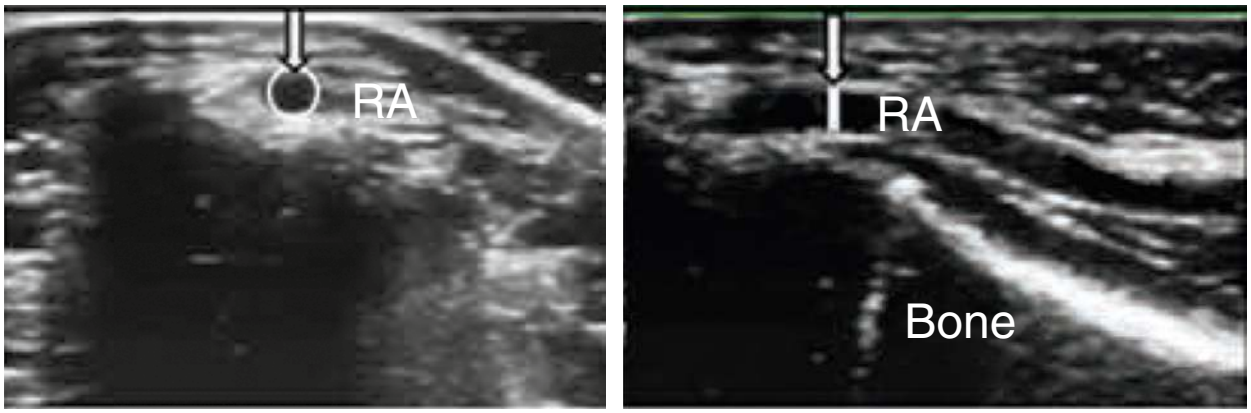

Figure 13.16 (A) Radial artery in short axis view. (B) radial artery in long-axis view. (Source: Kim et al [111]. Reproduced with permission from Wolters Kluwer Health, Inc.)

functions are 5.5 or 7.5 Fr in size and thus require a 6 or 8 Fr introducer sheath, respectively. A 5.5 Fr PA catheter should be used in patients up to approximately 40 kg in weight. Because of the direct path and curvature of the catheter, appropriate sites of insertion are the right IJV, left SCV, and FVs.

After full barrier precautions are taken and using the Seldinger technique following guidelines described earlier for percutaneous central catheter insertion, insert an introducer sheath into a central vein. The balloon integrity should be tested before insertion by inflating the recommended volume of air. Insert a flexible sterile sleeve before placement to protect the PA catheter outside the body and to allow for sterile repositioning later. Connect, flush, and calibrate the PA and CVP ports before insertion. Advance the catheter as far as the RA with the balloon deflated, then inflate the balloon and advance the catheter into the PA while observing the pressure tracing. The catheter's advancement toward the tricuspid valve is signified by enlarging V waves on the CVP tracing. The catheter passes through the tricuspid valve during diastole and the characteristic RV trace becomes visible on the PA tracing, with no dicrotic notch and moderate diastolic pressure. Hasten advancement of the catheter through the RV because of the propensity for dysrhythmias. The diastolic pressure increases and the dicrotic notch becomes apparent as the catheter tip passes through the pulmonary valve. Gently advance the catheter until a pulmonary capillary wedge pressure (PCWP) tracing is obtained, at which point the balloon should be deflated so that the PA tracing returns. It may be necessary to reduce or remove any redundant length or loop in the RA or RV by slowly withdrawing the catheter 1–2 cm. The balloon can then be reinflated to determine the minimum inflation volume necessary to obtain a wedge pressure tracing. The best position for the catheter tip is where the full or near-full inflation volume (0.5–1.5 mL) produces a wedge pressure tracing. Advancement of the catheter to the PA should be relatively rapid because prolonged manipulation may result in loss of catheter stiffness, thereby causing coiling in the RV or difficulties in catheter advancement. When difficulty advancing the catheter through the pulmonary valve is encountered, counter-clockwise rotation of the catheter, along with positioning the patient with the right side down, may result in successful placement. Alternatively, TEE may be used to visualize and guide the PA catheter. The PA pressure should always be monitored with the waveform displayed on the monitor so that migration of the catheter into the distal PA or RV can be detected immediately. Leaving the catheter in the wedged position undetected can lead to particularly serious complications such as PA rupture or pulmonary infarction. The catheter should be withdrawn several centimeters during the bypass period to reduce the risk of PA perforation.

Specific information that can be gathered with regular PA catheters includes PA pressure (systolic, diastolic, and mean), PCWP, RA pressure, mixed venous gases, and CO by thermodilution. Measurement of the PCWP is important because it is a reasonable estimate of left atrial pressure (LAP), which in turn is an estimate of left ventricular end-diastolic pressure (LVEDP). The assumption that PCWP reflects LAP is only valid if patency of vascular channels between the distal port of the PA catheter and the left atrium is ensured. This will occur only in dependent portions of the lung (West's zone 3), where pulmonary venous pressure exceeds alveolar pressure. Fortunately, with the patient in the supine position, a large portion of the lung is functioning in zone 3, and PA catheters will preferentially float into zone 3. To avoid erroneous readings, the PCWP should be measured at end expiration. The PCWP may not accurately reflect LVEDP in the presence of pulmonary venous or arterial hypertension, mitral valve disease, or positive end-expiratory pressure. The LVEDP is an index of left ventricular end-diastolic volume, the classic measure of left ventricular preload. The relation between left ventricular end-diastolic pressure and volume is best described by the left ventricular compliance curve, which is non-linear and is affected by many factors, such as ventricular compliance. Because TEE can provide more precise information regarding ventricular volume status, the usefulness of measuring PCWP becomes questionable.

Cardiac output can be measured with the standard thermodilution technique. In brief, a thermodilution PA catheter is connected to a CO monitor, a known amount of solution (injectate) of known temperature is rapidly injected into the proximal lumen of the catheter, this cooler-than-blood temperature solution mixes with the surrounding blood, the

AL Grawany

temperature is measured downstream in the thermistor on the PA catheter, and a decrease in temperature is recorded. The magnitude of the temperature change depends on the amount of blood that mixes with the injectate, and hence CO. The CO computer constructs a time–temperature curve to calculate CO from the area under the curve (AUC). When CO is low, more time is required for the temperature to return to baseline, producing a larger AUC. In contrast, with high CO, the injectate is carried more quickly through the heart, and the temperature returns to baseline faster, producing a smaller AUC. Thus, CO is inversely proportional to the AUC. Several factors may affect bolus CO determination: inaccurate temperature and volume of the injectate, rapid intravascular volume infusion during measurement, timing during the respiratory cycle, inaccurate computation constant, and thermal instability during the immediate post-bypass period. In addition, the presence of an intracardiac shunt can lead to erroneous CO values. For example, a left-to-right intracardiac shunt will cause recirculation of the injectate and create a larger AUC (decreased peak height and slower return to baseline), providing an erroneously low CO reading. A right-to-left shunt will have the opposite effect, providing an erroneously high CO reading. Therefore, the presence of an intracardiac shunt precludes the use of the thermodilution method to calculate CO. Technologic advances have produced PA catheters for continuous thermodilution CO monitoring using thermal indicators. Whereas the intermittent bolus technique uses cold injectate as the indicator, the new technology uses small energy impulses (warming of blood), which are emitted from a thermal filament directly into the bloodstream as the indicator; no fluid injection is required. These pulses of thermal energy emitted in a random on-off pattern change blood temperature, which is then detected by the thermistor at the tip of the PA catheter. Using a proprietary algorithm to analyze the thermal signal measured at the thermistor, a time–temperature curve is generated to calculate CO from the AUC. Typically, the displayed value for CO is updated every 30 seconds and represents the average CO over the previous 3–6 minutes. In this sense, this technology provides continual, frequently updated CO values.

Once CO is measured, systemic and pulmonary vascular resistances can be calculated. According to Ohm's law, vascular resistance equals the pressure drop (pressure difference between the upstream and downstream circulation) divided by blood flow (CO). This equation is based on the assumptions that blood flow is steady-state, continuous, and laminar, and blood vessels are rigid conduits. This may be unrealistic for the pulmonary circulation, because pulmonary blood flow may cease at end diastole and pulmonary vessels are distensible [122]. Therefore, pulmonary vascular resistance calculated by PA catheters may have limited value, although it is widely used; interpretation should be performed with caution. Other hemodynamic parameters [123–128] that can be calculated by PA catheter are listed in Table 13.6.

In addition to calculated hemodynamic variables, PA catheters can also provide important information regarding oxygen delivery and consumption, which may be used to guide therapy in critically ill children with low-CO syndrome. Because the arterial oxygen content is relatively constant under conditions of regular gas exchange, the major reflection of alterations in tissue oxygen extraction is SvO_2 [129]. If oxygen delivery is compromised to the periphery, tissues will increase their extraction of oxygen to compensate for reduced oxygen delivery. This will result in a decrease in SvO_2. Therefore, SvO_2 is an indirect indicator of the adequacy of tissue oxygenation, or a reflection of the balance between oxygen requirement and oxygen delivery. The relation between SvO_2 and CO can be shown by the modified Fick equation:

$$SvO_2 = \frac{SaO_2 - VO_2}{1.34 \times Hb \times CO}$$

where SaO_2 is the arterial oxygen saturation, VO_2 is the rate of oxygen consumption, and Hb is the hemoglobin concentration. From this equation, it is apparent that SvO_2 varies directly with CO, Hb, and SaO_2 and indirectly with metabolic rate (oxygen consumption).

A fiberoptic-equipped PA catheter allows for continuous monitoring of SvO_2 to guide timely therapeutic interventions during the perioperative period. Interpretation of SvO_2 may become difficult under conditions of intracardiac shunt, peripheral arterial venous shunt, sepsis, and cirrhosis.

KEY POINTS: PULMONARY ARTERY CATHETERIZATION

- A PA catheter should only be indicated in selected patients with CHD. Experienced physicians should directly supervise PA catheterization and its maintenance to avoid serious complications and erroneous interpretation of the data.
- Available sizes of PA catheter are a limiting factor for percutaneous insertion in children.
- In addition to hemodynamic parameters derived from the PA catheter, oxygen wellness should be calculated to direct therapy in ill children with low CO.

Interpretation of intravascular pressure waveforms

The information derived from intravascular catheters exceeds that of merely monitoring an absolute number; it is enhanced by observing the waveforms themselves. Accurate interpretation of the waveforms requires some understanding of the mechanical and electronic technical components of pressure monitoring. Pressure waves in the arterial and venous systems represent the transmission of forces generated in the ventricles. Measurement of these forces requires their transmission to a device that converts mechanical energy into electrical signals, which are processed and displayed. A system for intravascular pressure monitoring consists of intravascular catheters, fluid-filled tubing, connectors, transducers, amplifiers, and display devices. Understanding this system is a prerequisite for interpreting pressure waveforms. Although the use of commercially available, disposable transducer kits is common practice these days, the shortest possible, large-bore, stiff, plastic tubing should be tailored to the patient's size.

Table 13.6 Normal values of hemodynamic and oxygen parameters

	Formula	Neonate/infant	Children			Adolescent/Adult	Unit	Source
			Toddler	Preschool	School Aged			
HR		100–180	93–160	70–140	62–140	60–100	min^{-1}	[119–121]
LVCO	HR × SV	0.8–5.0	1.7–3.8	1.3–5.4	3.2–6.3	4.0–8.0	L/min	[120]
LVCI	LVCO/BSA	2.0–4.0	3.5–6.5	3.0–7.1	3.3–6.9	2.8–4.2	$L/min/m^2$	[120, 122]

LVSV	LVEDV – LVESV or CO/HR	5–13	18–32	13–60	47–65	60–130	mL/beat	[120, 121, 123]
LVSVI	LVSV/BSA	40–75	31–55	37–70	42–76	30–65	$mLbeat/m^2$	[121, 122]
LVEF	LVSV × 100/LVEDV	45–81		46–71	47–77	47–78	%	[120, 123, 124]
RVEF	RVSV × 100/RVEDV	59–73	39–63	55–73			%	[118, 121, 122]
LVSWI	(MAP – PCWP) × SVI × 0.0136	20–40		30–62		45–60	$g/beat/m^2$	[120]
SVR	(MAP – CVP) × 80/CO	2,800–4,000		1,200–2,800		800–1,200	$dyne\text{-}sec/cm^5$	[120, 122]
PVR	(PAP – PCWP) × 80/CO	<2,000–3,200		<40–320		<250	$dyne\text{-}sec/cm^5$	[122]
RVEDV		31–47		57–83		100–160	ml	[121]
Arterial O2 content (CaO2)	$1.34 \times Hb \times SaO_2 + 0.0031 \times PaO_2$	15–18		16–18		18–20	mL/dL	[122]
Mixed venous O2 content (CvO2)	$1.34 \times Hb \times SvO_2 + 0.0031 \times PvO_2$	11–14		12–14		13–16	mL/dL	[122]
Arterial-venous oxygen difference	$CaO_2 - CvO_2$	4–7		4–6		4–5.5	mL/dL	[122]
Pulmonary capillary O2 content (CcO2)	$1.34 \times Hb \times SCcO_2 + 0.0031 \times PcO_2$	16–19		17–19		19–21	mLdL	[122]
Pulmonary shunt fraction (Qs/Qt)	$100 \times (CcO_2 - CaO_2)/(CcO_2 - CvO_2)$			2–8			%	[122]
O2 delivery index (DO2I)	$CO \times CaO_2 \times 10/BSA$	450–750		450–700		450–640	$mL/min/m^2$	[122]
O2 consumption index (VO2I)	$(CaO_2 - CvO_2) \times CI \times 10$	150–200		120–200		85–170	$mL/min/m^2$	[122]

CI, cardiac index; CO, cardiac output; EDV, end-diastolic volume; HR, heart rate; LV, left ventricle; PVR, pulmonary vascular resistance; RV, right ventricle; SV, stroke volume; SVI, stroke volume index; SVR, systemic vascular resistance; SWI, stroke work index

AL Grawany

Minimization of the number of stopcocks and connections will improve the fidelity of the transmitted pressure wave [130]. It is imperative that the tubing system be thoroughly flushed before use to eliminate air bubbles or clots. In addition, it is important to recalibrate at the RA level (mid-axillary line) periodically to correct for transducer "drift." Ringing and damping are two common sources of erroneous data acquisition from pressure monitoring and are associated with problems of dynamic accuracy [131–133]. Because a pressure monitoring system has resistance, inertia, and compliance, it can oscillate or "ring," that is, overestimate the systolic pressure and underestimate the diastolic pressure. A system that is ringing (underdamped) results in higher systolic pressure and lower diastolic pressure. In contrast, a damped system provides lower systemic pressure and higher diastolic pressure. In the face of either ringing or damping, mean pressure is preserved and provides an accurate number. If the dynamic response of a system is in question, mechanical devices (e.g. a Resonance OverShoot Eliminator [ROSE™]; Argon Medical Devices, Inc., Plano TX, USA; Accudynamic®, Abbott Critical Care Systems, Abbott Park IL, USA) can be incorporated to alter the resonance frequency and/or damping factor of the transducer system [134, 135]. The resonance frequency can be tested by flushing the system with a pressurized bag of heparinized saline, stopping abruptly, and observing the number and amplitude of oscillations required to return to baseline waveform (dynamic response) [136]. Proper damping is indicated by one oscillation below and one oscillation above the mean before returning to normal.

Arterial pressure waveform

Regular cardiac rhythm and the presence of CO can be confirmed by observation of the waveform on the monitor display. This is useful when prolonged use of electrocautery disturbs the ECG trace. Steep upstroke of the waveform implies good ventricular function, whereas slow upstroke may indicate poor contractility, left ventricular outflow tract obstruction, or peripheral vasoconstriction. The area under the systolic portion of the pressure curve is proportional to the stroke volume [137]. The position of the dicrotic notch is associated with changes in peripheral vascular resistance. In infants, a normal dicrotic notch is found in the upper half of the pressure wave. A dicrotic notch located high on the downslope of the arterial waveform may indicate increased systemic vascular resistance, whereas one located lower on the downslope may indicate low resistance. A low-placed dicrotic notch with a steeper diastolic downslope is also observed in hypovolemic patients. A decrease in both peak systolic pressure and pulse pressure, which is accentuated by positive pressure ventilation, is an early indicator of hypovolemia or cardiac tamponade. Aortic stenosis will result in a pressure waveform with a slow-rising upstroke, delayed peak, and narrow pulse pressure, whereas aortic regurgitation will result in a steep upstroke, bifid peak, widened pulse pressure, and low diastolic pressure. Low diastolic blood pressure can also reflect excessive distal "run-off," as in patients with large patent ductus arteriosus. A sudden increase in diastolic pressure occurs on ligation of the ductus because diastolic run-off into the PA ceases.

The systolic pressure is higher in the more distal arteries due to the wave-reflection phenomenon [138]. As the pressure wave passes down the arterial tree, it is modified by arterial narrowing, loss of arterial elastic tissue, and the addition of reflected waves, until it reaches the distal catheter. With distal progression, pulse wave amplification will produce a higher peaked pressure wave with a slightly higher systolic pressure. This is most pronounced in the arteries of the foot, where the systolic pressure may be 5–15 Torr higher than in the ascending aorta (Figure 13.17) [139]. Diastolic and mean pressures change very little with progression. This concept is important for interpreting arterial pressure tracings. The post-bypass arterial tracing is frequently damped with catheters in small distal arteries (e.g., radial or foot arteries), probably due to vasoconstriction induced by CPB [140]. This usually does not last long after bypass; however, it can be troubling to observe, particularly during potentially critical periods of weaning from bypass. For long and difficult surgeries with long bypass or cross-clamp times, it may be prudent to place catheters in larger, more central arteries (e.g., femoral or umbilical) or to ask the surgeon to measure pressure directly in the aortic root from the aortic cannula immediately after bypass to obtain an accurate arterial pressure.

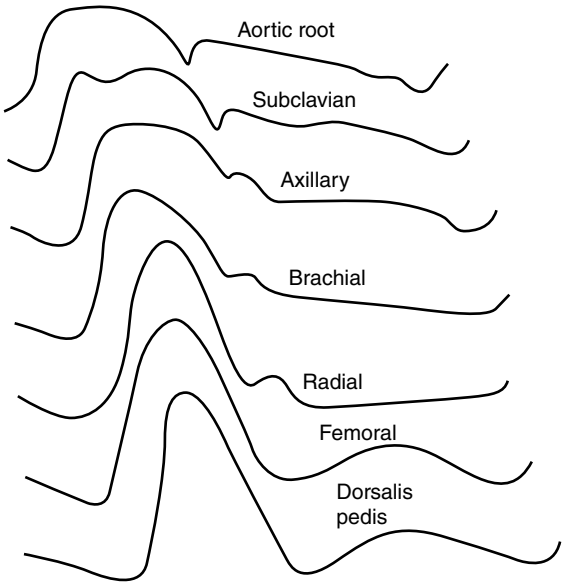

Figure 13.17 Progression of the arterial pressure tracing from the root of the aorta to more peripheral arteries. Pulse-wave amplification produces a higher systolic peak and slightly lower diastolic pressure in the smaller distal arteries, especially the dorsalis pedis. (Source: Reich et al. [139]. Reproduced with permission of Elsevier.)

Failure of arterial pressure monitoring during congenital heart surgery is possible. Reasons for failure can include arterial spasm, kinking or clotting of the catheter, compression of an aberrant right subclavian artery by a TEE probe, or compression of the axillary artery by a sternal retractor. A back-up manual blood pressure cuff should be always available. Alternatively, placement of a femoral artery catheter may be performed by the surgeon.

Central venous and left atrial waveforms

The usual sites of filling pressure measurement are the CVP (right atrial pressure) and LAP. In the presence of normal tricuspid and mitral valves, the CVP and LAP reflect their

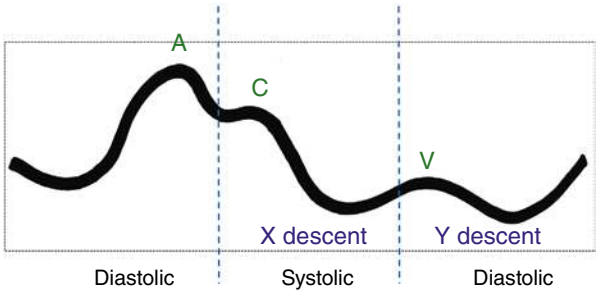

Figure 13.18 Central venous pressure waveform. The A wave represents increased atrial pressure. The C wave represents closure of the tricuspid valve. Downward movement of the ventricle during systolic contraction forms the X descent. The V wave arises from the pressure produced when the blood filling the right atrium comes up against a closed tricuspid valve. Opening of the tricuspid valve in diastole, with blood flowing into the right ventricle, produces the Y descent.

respective ventricular end-diastolic pressures. Normal atrial pressure traces have three positive waves, A, C, and V, corresponding to atrial contraction, closure of tricuspid or mitral valve, and ventricular contraction (Figure 13.18). The right atrial V wave is normally lower in amplitude than the A wave; however, in patients with atrial septal defect, the higher LAP may be transmitted to the RA during atrial filling, causing the right atrial A and V waves to be equal in amplitude. Changes in the components of atrial pressures may indicate pathologic ventricular function and cardiac rhythm. For example, a large V wave in the CVP may be caused by severe tricuspid regurgitation, which may reflect right heart failure, pulmonary hypertension, or right ventricular ischemia. Similarly, a large V wave in the LAP indicates mitral valve regurgitation. Disappearance of the A wave with appearance of an enlarged V wave indicates lack of atrial contraction because of loss of atrioventricular synchrony, as in junctional ectopic tachycardia, supraventricular tachycardia, atrial fibrillation, or atrial flutter (Figure 13.19). This is particularly important in discerning pathologic tachyarrhythmia from sinus tachycardia. In the face of rapid heart rate, the P wave of the ECG is often indiscernible, making cardiac rhythm from ECG difficult to determine. In contrast, the presence of an A wave in atrial pressure waveforms assures atrioventricular synchrony.

The transducer position is particularly important for accurate measurement of atrial pressure, and it is usually set at the level of the RA. Slight position changes can easily provide erroneously high or low numbers because both the CVP and LAP measure low pressures of several cmH_2O. Constant vigilance is necessary to keep the transducer level in the correct position and accurately calibrated.

KEY POINTS: INTERPRETATON OF INTRAVASCULAR PRESSURE WAVEFORMS

- Observation of the pressure waveform *per se* can provide additional diagnostic information and should be displayed continuously during pressure monitoring.
- Common errors made in data acquisition from arterial catheters include calibration error, improper calibration (gain), underdamping, and overdamping.
- In the presence of normal tricuspid and mitral valves, the CVP and LAP reflect their respective ventricular end-diastolic pressures.

Newer techniques in pediatric intravascular monitoring

Cardiac output monitoring

Because traditional percutaneous, balloon-tipped PA catheterization is limited in small children, and those with intracardiac shunting, several other recently derived methods invented for adults to measure CO and oxygen delivery in patients with CHD have been applied to infants and children [141]. Lithium dilution CO (LiDCO) uses a standard central line in the SVC or even a peripheral IV catheter, and a special femoral artery catheter equipped with a lithium-detecting electrode. A dilute solution of lithium chloride is injected into the vein, and arterial blood is withdrawn into

Figure 13.19 Electrocardiogram demonstrating normal sinus rhythm in the first third of the panel, with onset of supraventricular tachycardia. Note the arterial pressure tracing with a 12–15 Torr decrease in systolic pressure, and the loss of the A wave on the central venous pressure tracing, with the appearance of large V waves with a systolic pressure increase from 10 to 16 mmHg.

AL Grawany

the lithium electrode. The cardiac index is related to the AUC of the change of lithium concentration. This method has been demonstrated to have reasonable correlation with thermodilution CO in children after congenital heart surgery. In a study of 48 measurements in 17 patients weighing 2.6–34 kg, the correlation between LiDCO and thermodilution CO was good (r^2 = 0.96), and the mean bias was −0.1 ± 0.31 L/min [142].

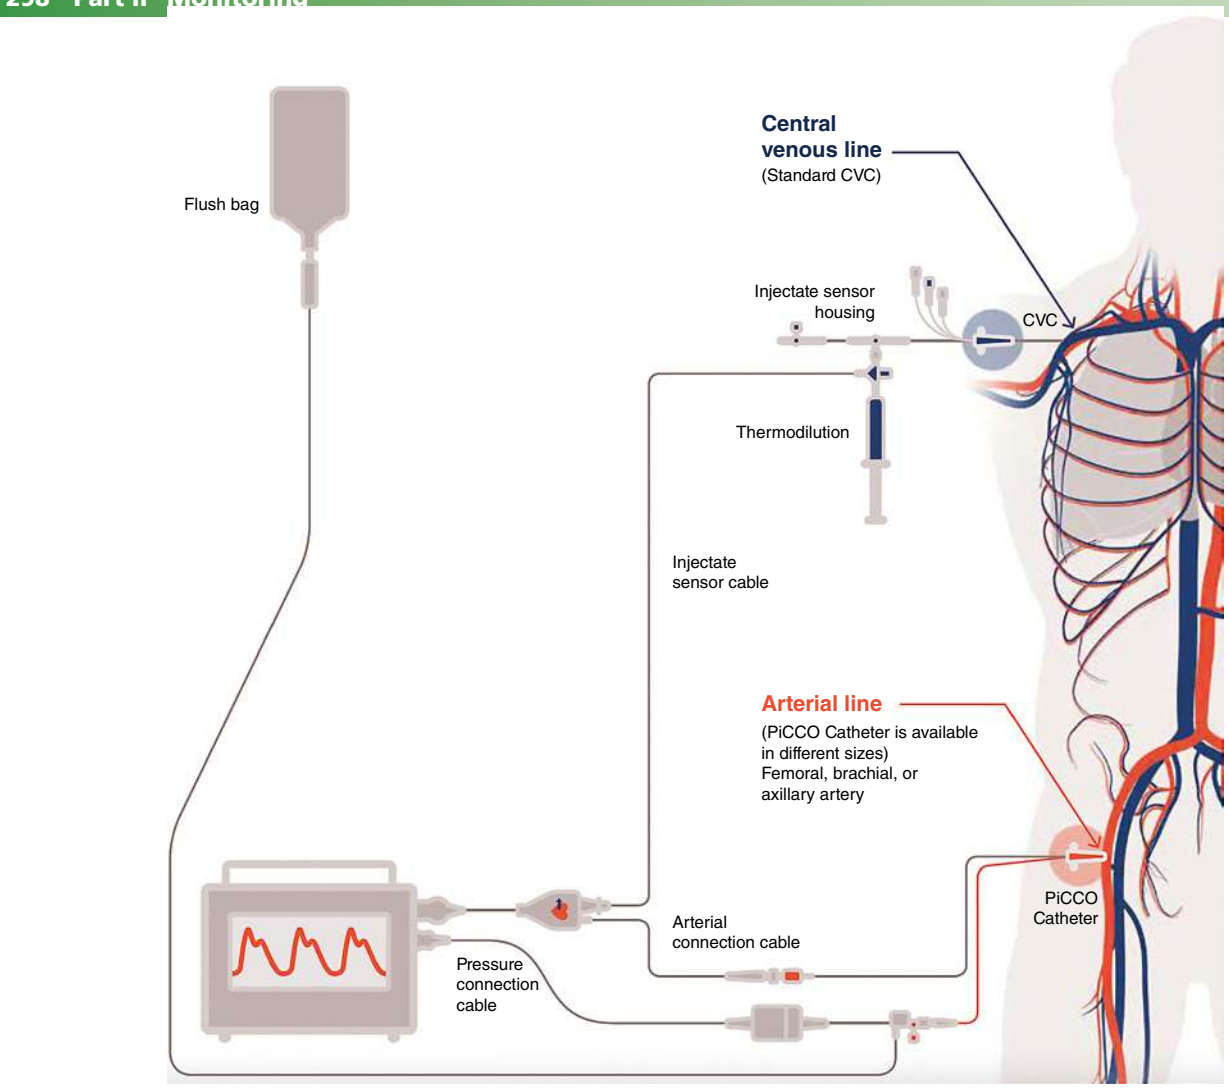
Transpulmonary thermodilution CO uses a similar principle as LiDCO, except with temperature as the indicator instead of lithium concentration. Cold saline is injected into a CVC, and via a thermistor placed in a femoral artery, a time–temperature curve is derived, which correlates reasonably well with standard thermodilution CO as measured by a standard PA catheter [143]. Both lithium and any thermodilution method are limited to patients without any intracardiac shunting, significantly restricting their use in CHD.

Yet another newer method is pulse contour analysis of the arterial waveform (PiCCO,Pulsion Medical Systems, Gettinge AB, Feldkirche, Germany), which relates the contour and AUC of the systolic portion of the arterial waveform to the stroke volume, and thus the CO. This continuous method is periodically calibrated using the transpulmonary thermodilution CO as described above (again making the method invalid with intracardiac shunting) and demonstrates a good correlation with standard thermodilution with a PA catheter in a study of 24 pediatric patients after cardiac surgery (r^2 = 0.86, mean bias 0.05 ± 0.4 L/min/m^2) [144]. A standard central venous catheter is used for injection; and a special femoral arterial catheter, minimum size 3 Fr, are utilized with the PiCCO system (Figure 13.20 A-D). Stroke volume variation (SVV) and pulse pressure variation (PPV) can be calculated using the arterial waveform (see above), and fluid responsiveness can be assessed. SVV/PPV of 10% or less can be an indicator of adequate intravascular volume status. The PiCCO system will also derive a systemic vascular resistance index, stroke volume index, global end-diastolic index (a measure of preload), and contractility parameters. None of these parameters has published data pertaining to congenital heart disease patients. In 15 pediatric patients averaging 22.9 kg, with septic or cardiogenic shock without CHD, 49 cardiac index measurements by PiCCO had close correlation with echocardiographically derived cardiac index by the volume-time integral method (r = 0.94, $R2$ = 0.89, p < 0.01) [145] In this same patient cohort, global end-diastolic index derived with PiCCO had significant correlations with CVP, and echocardiographically-derived inferior vena cava collapsibility index in spontaneously ventilating patients, and the IVC distensibility index in mechanically ventilated patients. [146] There are no published pediatric outcome studies, and although a comprehensive review concludes that both lithium dilution and transpulmonary thermodilution methods have good correlation with standard thermodilution CO, these methods have not yet found their place in pediatric cardiac surgical care [147]. A 2018 survey of 97 pediatric cardiac intensivists from 62 international centers revealed that only 4% used PiCCO for diagnosis and to guide therapy in low cardiac output syndrome after cardiac surgery. [148]

Central venous oxygen saturation monitoring

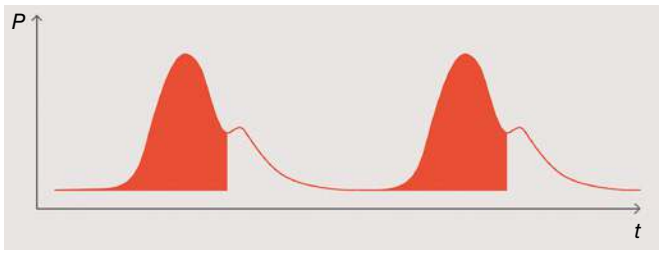
Monitoring of intravascular oxyhemoglobin saturation using reflectance catheters has been used in the umbilical artery, PA, and adult-sized CVCs for a number of years, but only recently have standard pediatric sized 4 and 5 Fr, double- and triple-lumen CVCs become available for routine use to measure central venous oxygen saturation ($ScvO_2$) in pediatric patients. The advantage of this method is that it is a measure of oxygen delivery that is independent of intracardiac shunting, and thus may have better utility in the CHD patient. In 16 pediatric patients undergoing cardiac surgery, Liakopoulos et al. demonstrated good correlation between $ScvO_2$ as measured with the catheter and with blood co-oximetry (r^2 = 0.88, bias −0.03 ± 4.72%, precision −8.02 to +8.09%) [149]. Three more recent studies in 75 critically ill infants and children undergoing cardiac or other major surgery report a wider range of correlation (r^2 = 0.28 to 0.93), bias (−1.1 to +2.6%), and precision (−18 to +23%) [150–152]. Outcome data are lacking for this technique, but it has been useful as an adjunct for continuous trend monitoring of oxygen delivery in major cases.

Complications of vascular access



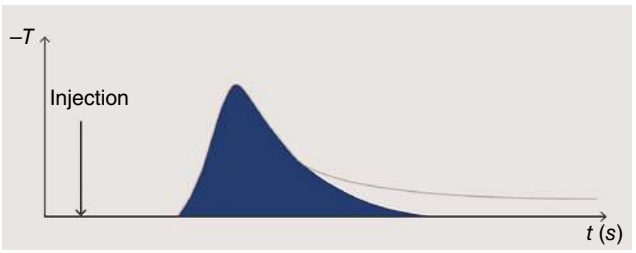
Incidence and risk factors

Central catheterization remains a mandatory procedure in many critically ill pediatric patients. Notwithstanding its certain advantages (e.g. large-bore catheters, monitoring, drug administration), central catheterization carries risks of serious complications. These can be categorized into mechanical or insertion-related complications (e.g. inadvertent arterial puncture, malposition, arterial catheterization, arrhythmia, hematoma, pneumothorax, hemothorax, cardiac tamponade) and maintenance-related complications (e.g. obstruction, occlusion, systemic venous air embolization, infection). If detected promptly, minor complications can be readily corrected; however, some (pneumothorax, hemothorax, cardiac tamponade) may be life-threatening. Sufficient knowledge and preparation, diligent technique, skill, and experience are obligatory.



The incidence of all vascular access-related complications is difficult to ascertain from published research, but numerous case reports and studies have addressed this issue. Among early mechanical complications, the most frequent are arterial puncture, malposition, artery catheterization, and hematoma. The most frequent life-threatening complications are pneumothorax, cardiac tamponade, and hemothorax. The most frequent catheter maintenance-related complications are obstruction, occlusion, and sepsis.

The relationship between insertion site and complications has been well studied [153–155]. The SCV approach is anatomically more prone to early insertion-related complications [156] than IJV or FV catheterizations; however, significantly more maintenance-related problems develop in children with indwelling femoral catheters [155].



Operator experience appears to influence the rate of complications. In one study, resident anesthesiologists caused significantly more complications, both common and rare, than their senior colleagues; however, when closely

AL Grawany

supervised, the rates of acute mechanical complications [90], deep vein thrombosis (DVT), and infection were lower. Lower complication rates and higher success rates were obtained after sufficient training in landmark and ultrasound-guided techniques [91].

In general, risk factors for central venous catheterization-related complications include previous unsuccessful insertion attempts, more than two punctures, inexperience, body mass index <20 and >30, previous catheterizations, previous catheterization attempts, previous operations, radiotherapy, severe dehydration or hypovolemia, and large catheter size [155]. In neonates, catheter insertion can be challenging due to anatomic difficulties [156]. In older children, insertion-related problems appear not to be associated with age; however, maintenance-related complications are more commonly observed in younger children [151]. Similar to the adult population, duration of catheterization is closely related to frequency of maintenance-related complications in pediatric patients [155].

Totally implantable central catheters (ports), PICCs, and tunneled external central catheters (e.g., Broviac catheters) have been used more often in critically or chronically ill pediatric patients. In a study summarizing implanted catheter-related issues, the overall rate of reported complications was 31%; leakage was a specific problem necessitating reinsertion or repair. Infections were observed in 6% of patients with implanted central catheters and developed more than 30 days after catheterization [157]. When Broviac and clampless valved catheters were compared, malfunction was more frequently observed in the former group, whereas catheter displacement was more commonly found in the latter [158].

Thrombosis

Catheter thrombotic occlusions and catheter-related thrombosis in pediatric patients have become increasingly prevalent. The incidence of central catheter-related DVT has been reported to be 0.13/1,000 catheter-days [159]. This is one of the most frequent complications, especially among infants. Central venous thrombosis is reported to occur in 5.8% of neonatal patients, 10 times that of older patients; 40–50% of central venous thrombosis in this group occurs after congenital heart surgery [160]. A recent study examining the incidence of asymptomatic CVC-related DVT in pediatric ICU patients revealed that age was independently associated with DVT; children aged more than 13 years were more likely to develop DVT than those aged less than 1 year [161].

Factors contributing to the risk of thrombosis include large-bore catheters in small vessels (i.e., larger than 4 Fr in small infants), duration of cannulation exceeding 7 days, venous stasis due to extreme fluid restriction or low CO, infusion of high-osmolarity fluids, and hypercoagulable states.

Indwelling central catheters act as additional foci for clot formation, and migrating clots can obstruct pulmonary, coronary, and cerebral vessels, leading to life-threatening events. Rare conditions, such as arteriovenous malformations, may serve as sources of emboli; the brain is at particular risk of paradoxical embolism, further facilitated by the presence of right-to-left intracardiac shunts and pulmonary vascular abnormalities [162].

Immediate consequences of SVC thrombosis include SVC syndrome [12] with increased intracranial pressure and chylothorax due to ineffective drainage of the thoracic duct. Thrombosis of the IVC results in renal and intestinal dysfunction, ascites, and edema of the lower abdomen and extremities [153]. Assess carefully for signs of thrombosis; suspicion of thrombosis should be evaluated by ultrasound examination [163].

A wide range of options is available for the management of catheter-related thromboembolism. These include removing the catheter, heparinization, administration of thrombolytic agents such as tissue plasminogen activator and urokinase, antithrombin III replacement, and surgical thrombectomy. In children, 5,000 IU of intraluminal urokinase was reported to be as effective as 25,000 IU in resolving withdrawal occlusion in partially implanted central catheters [164]. Systemic urokinase may rescue a significant proportion of central catheters refractory to intraluminal urokinase or those apparently completely occluded.

Prevention of SVC thrombosis is crucial and avoiding SVC catheterization in patients weighing less than 4 kg is often preferable. In children undergoing superior cavopulmonary anastomosis, EJV catheterization reliably predicts IJV and pulmonary arterial pressures and may obviate the risk of life-threatening cavopulmonary thrombosis [39]. Thrombosis is also associated with higher rates of infection [165, 166]. Heparin-bonded catheters can decrease the rate of thrombosis and do not increase the risk of bleeding [165, 167]. In patients with occlusion of central veins due to previous catheters, magnetic resonance venography can be useful in identifying patent veins for future interventions [168].

Thrombosis or dissection of an artery is a serious complication that must be treated immediately.[169, 170] It is important to inspect the distal extremity after catheter placement, comparing it with the contralateral extremity, assessing capillary refill, and to palpate distal pulses. Place a pulse oximetry probe distal to the catheter to serve as a continuous monitor for potential vascular insufficiency. Transient compromise of perfusion immediately after placement of a catheter, due to arterial spasm or during low output states, may be observed. If perfusion of an extremity is significantly compromised, ultrasound examination, removal of the catheter, use of vasodilators, warming the extremity, administration of heparin or thrombolytics, surgical consultation, thrombectomy, or surgical reconstruction is indicated. Microsurgical repair with a saphenous vein graft rather than simple thrombectomy is preferred by some groups for repair of small arteries with dissection or other significant injury. [171, 172]

Neonatal arterial thrombosis has become more common with the use of umbilical artery catheters [173]; however, catheter-induced aortic thrombosis is rare. In a study of approximately 4,000 infants with an inserted umbilical artery catheter, 44 developed major thromboembolic problems requiring varying degrees of surgical management [174]. The most common location of arterial thrombosis associated with umbilical artery catheterization in neonates is the abdominal aorta [173].

It is possible to use ultrasound to measure the diameter of arteries before cannulation; generally, the largest diameter artery is preferable. Previous cardiac catheterization is often

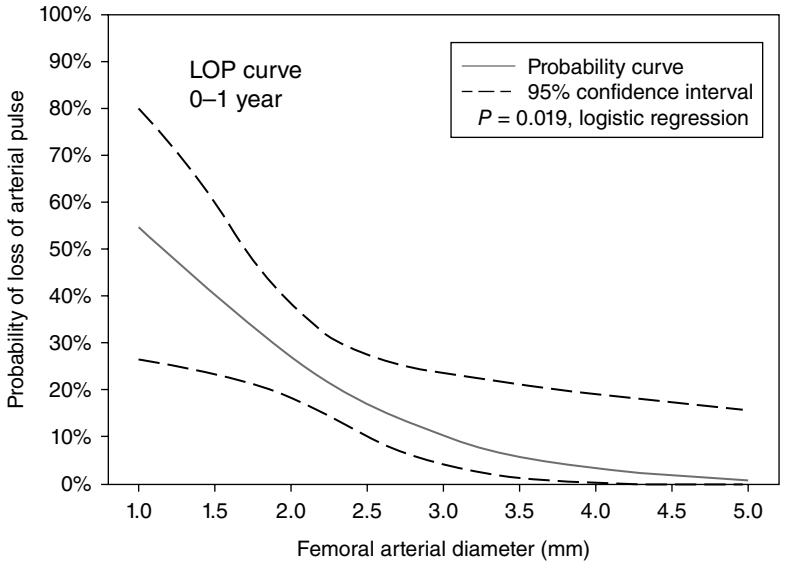

Figure 13.21 Probability curve for loss of palpable pedal pulse (LOP) at the end of the cardiac catherization procedure in which the femoral artery was accessed in children between the age of 0–1 year. A significant increase occurred with artery diameter less than 3 mm. (Source: Tadphale et al. [174]. Reproduced with permission from Springer Nature.)

via the right femoral artery, potentially reducing its diameter. In the case of the femoral artery, puncture of the common femoral artery above the bifurcation into superficial and profunda femoris arteries is preferable because of the larger diameter at that level. The smallest catheter size (see above) should be utilized to minimize the risk of thrombosis. In a prospective study of 400 cardiac catheterization patients aged 0–4 years, a femoral artery diameter of less than 3 mm was associated with a significantly increased risk of loss of pedal pulses after the procedure [174] (Figure 13.21). NEW Similarly, ultrasound examination of the diameter of femoral veins pre-cannulation can be effective at choosing the larger vessel and increasing cannulation success and decreasing risk of thrombosis.

In a report by Kamyscek and colleagues of institution of routine postcatheterization ultrasound within 4 hours, in the 349 patients less than 6 months of age, incidence of detection of femoral arterial thrombosis increased from 8.3 to 23.4% with routine ultrasound.($p = 0.006$) Risk factors included lower weight, larger arterial sheath size, and longer procedure duration. Treatment was with unfractionated, or low molecular weight heparin and was successful in all cases. This data suggests that clinical signs and symptoms of femoral artery thrombosis are less sensitive than ultrasound due to collateral flow; and that high index of suspicion for arterial thrombosis in small patients should trigger early formal ultrasound examination to facilitate successful non-invasive therapy. [175]

Infection

Catheter-related sepsis can result in significant morbidity, increased mortality, prolonged ICU stay, and increased expense. Numerous studies have described the incidence of, risk factors for, and management of catheter-related infections. Sepsis was reported in 5.8–7.6% of pediatric patients, and the rate of catheter-related bloodstream infections (CRBSIs) was 0.1–6.4 infections/1,000 catheter-days [44, 176, 177]. The incidence of arterial catheterization-related infections in the pediatric population is very low; the calculated rate is 6.2% [178]. The pathogen mainly responsible is *Staphylococcus epidermidis*, and its colonization is not dependent on the catheter insertion site [155].

Risk factors for CRBSIs include weight less than 8 kg, cardiac failure, cancer, silicone catheters, guidewire exchange catheterization, obstructed catheters, and more than 12 days of catheter placement [179]. A higher incidence of central line-associated bloodstream infections was found in children between 1 and 2 years of age [180]. The safe period for an indwelling CVC is 3 days in infants less than 12 months old and 6 days in older children; the infection rate increases if catheters are left in place for more than 10 days [180]. The number of catheter lumens does not appear to influence the rate of this complication [44].

Several strategies may be used to reduce catheter-related infections [181]. First is the use of full barrier precautions (e.g., sterile gown, mask, gloves, and careful aseptic technique during insertion). Second, a potent antiseptic solution should be used for skin scrubbing and during redressing of the insertion site every 3–7 days. In addition, systemic antibiotic administration or antibiotic bonding to the resin of the catheter may be advantageous (Box 13.1).

Chlorhexidine has been shown to be superior to other antiseptic solutions and is being used more frequently for catheter insertion-related antisepsis. Novel chlorhexidine-impregnated dressings or chlorhexidine-impregnated sponges are safe and effective in preventing CRBSIs and non-catheter-related bloodstream infections in neonates requiring prolonged central venous access, and their use significantly reduces the rates of central catheter colonization in infants and children after cardiac surgery [182–184]. Although it provides effective skin protection, chlorhexidine may cause contact dermatitis, particularly in low-weight infants, and some cases of

AL Grawany

Box 13.1: Central line catheter care bundles

Insertion bundle
- Use full sterile barrier precautions: gown, cap, mask, gloves, wide sterile draping
- Wash hands before the procedure
- For all children aged ≥2 months, use chlorhexidine gluconate to scrub the insertion site for 30 seconds for all areas except the groin, which should be scrubbed for 2 minutes. Scrubbing should be followed by 30–60 seconds of air drying
- No iodine skin prep or ointment is used at the insertion site
- Use a sterilized prepackaged tray with catheter that contains all necessary equipment and supplies including full sterile barriers
- Create an insertion checklist, which empowers staff to stop a non-emergent procedure if it does not follow sterile insertion practices
- Use only polyurethane or Teflon catheters[a]
- Conduct insertion training for all care providers, including sides and video

Maintenance bundle
- Assess daily whether catheter is needed
- Catheter-site care
  - No iodine ointment
  - Use a chlorhexidine gluconate scrub to sites for dressing changes (30 seconds scrub, 30 seconds air-dry)
  - Change gauze dressings every 2 days unless they are soiled, dampened, or loosened[a]
  - Change clear dressings every 7 days unless they are soiled, dampened, or loosened[a]
  - Use a prepackaged dressing-change kit or supply area
- Catheter hub, cap, and tubing care
  - Replace administration sets, including add-on devices, no more frequently than every 72 hours unless they are soiled or suspected to be infected
  - Replace tubing that is used to administer blood, blood products, or lipids within 24 hours of initiating infusion[a]
  - Change caps no more often then 72 hours (or according to manufacturer recommendations); however, caps should be replaced when the administration set is changed[a]
  - The prepackaged cap-change kit, or supply area elements to be designated by the local institution

[a] These procedures are according to the Centers for Disease Control and Prevention recommendations.

anaphylactic reaction to chlorhexidine-impregnated catheters have also been reported [185].

The use of antibiotics for prevention of central catheterization-related infections has not yet been supported by strong evidence. Although vancomycin added to the solution used for total parenteral nutrition effectively reduced catheter-related sepsis in a neonatal ICU and offered potential benefits (e.g. fewer catheters, earlier weight gain), its widespread implementation has not been recommended [186]. The addition of vancomycin to heparin flush solutions did not reduce bacteremia with vancomycin-susceptible organisms [187]. In a meta-analysis of 21 randomized controlled trials comparing the incidence of specific bacterial and fungal species colonization on minocycline/rifampicin-impregnated catheters, the proportion of all colonized antibiotic-impregnated catheters found to harbor *Candida* species was greater than the proportion of all colonized non-impregnated standard catheters [188]. Commercially available antimicrobial catheters may become colonized with distinct microbial flora, probably related their antimicrobial spectrum of activity [188].

Suspected CRBSI should be addressed by peripheral blood culture and blood culture from the central catheter. Remove the catheter when possible and send the tip for bacterial culture. Design antibiotic therapy empirically against the most common institution-specific pathogens and provide coverage for *S. epidermidis*. Proper education may also reduce infection frequency; in a quasi-experimental study designed to improve the quality of clinical practice in a neonatal ICU, the rate of CRBSIs decreased from 8.4 to 1.28 cases/1,000 central line-days [189].

Malposition/perforation

Perforation of a vein or the heart can occur during CVC placement or any time thereafter. The cause of perforation can be a needle, guidewire, dilator, or the catheter itself. Malpositioning of the CVC may not necessarily lead to complications *perse*, but a catheter tip in the RA [190, 191] or not parallel to the SVC clearly predisposes to subsequent complications. Other predisposing factors for CVC perforation include a left-sided approach, use of a guidewire end without a flexible tip, a stiffer catheter, and "long-arm" CVC inserted in the basilic or cephalic veins. With left-sided lines, the catheter tip is frequently at a 45°–90° angle to the SVC or atrium. Models have shown that this position is more likely to lead to great vessel perforation [192]. Up to 5–10% of patients with CHD have a left SVC [193], which drains most often into the coronary sinus or left atrium; both of these sites are undesirable for catheterization. An ideal position is in the mid-SVC, with the tip parallel to the vein wall. Long-arm CVCs tend to be more mobile than other CVCs, thus increasing the possibility of the catheter tip migrating into the RA with arm movement. The material of which catheters are made may also be associated with incidence of this complication; soft polyurethane or silicone catheters are much less likely to perforate than stiffer polyethylene catheters [194].

Inability to consistently aspirate blood, abnormal waveform, or signs or symptoms of pericardial tamponade or hemothorax indicate perforation. Treatment involves aspiration of as much blood as possible through the catheter and establishment of alternate access; intravascular volume replacement; and drainage of the pericardial or pleural blood by needle or surgical exploration. Confirmation of catheter tip location with an anteroposterior radiograph after insertion is obligatory.

The mid-SVC, above the pericardial reflection, is the recommended position for the catheter tip; however, positioning a multi-lumen catheter too cephalad in the SVC may result in a situation in which one of the proximal ports is not inside the jugular vein, leading to extravascular extravasation of important or caustic drugs or fluids. Many studies of catheter placement in children have shown that the internal jugular route results in tip placement in the SVC or RA 98–100% of the time, whereas the subclavian route results in a 5–15% rate of catheter malposition (i.e., across the midline in the contralateral brachiocephalic vein or up the ipsilateral IJV).

Accurate CVP measurements are generally obtained with IVC catheters, whether placed above or below the diaphragm. Umbilical venous catheters should be placed above the diaphragm at the IVC–RA junction, but not in the RA, to ensure passage through the ductus venosus and a parallel position to the IVC wall [195].

Some rare, inadvertent, CVC placement locations have been reported. Catheters may pass into the superior intercostal, thymic, azygos, or ascending lumbar veins or even into the liver parenchyma, depending on the insertion site [196–198]. Dural puncture, intrathecal catheterization, or extradural catheter insertion have also been reported [199–202]. In a case report, neurologic complications (paraplegia, urine retention, and milky cerebrospinal fluid) developed after abnormal placement of a catheter into the lumbar venous plexus via the left saphenous vein [198]. If malposition is strongly suspected, the catheter must be removed, and the patient assessed for other complications.

Pneumothorax/hemothorax

Pneumothorax occurs in 7% of central venous catheterization cases [203], being most frequent with the subclavian approach (2.6%) [204], but it may also occur with the IJV approach (0.38%) [87], especially with low puncture sites. In four reported cases of hemothorax [205–208], the complication resulted in a fatal outcome in all cases. Perforation of the punctured vein, leading to pneumo- or hemothorax, may be caused not only by the advancing needle (as in the Seldinger technique), but also by guidewires, dilators, or relatively rigid catheters.

Pneumothorax and hemothorax can be avoided by cautious advancement of needles, guidewires, dilators, and catheters. An ultrasound guidance system greatly facilitates catheter insertion when used properly. The following tips may also be helpful:

- In the subclavian approach, it is important to advance the needle only during expiration.
- A very shallow approach, with the needle directed just posterior to the clavicle and at the sternal notch, is recommended.
- For the IJV, a higher puncture site and limit of caudad advancement of the needle to stop above the clavicle are preferable.
- Continuous aspiration with a saline-filled syringe should be performed as the needle is advanced.
- If air is aspirated, stop puncture attempts immediately and monitor carefully for compromise of ventilation and hemodynamics. Chest radiography should be performed, and pleural drainage should be initiated if indicated. After sternotomy, the pleura can be opened on the side where the pneumothorax is suspected or diagnosed.

Cardiac tamponade

Cardiac tamponade is a severe complication of central venous catheterization and is closely related to catheter malposition and vessel perforation during puncture or placement. The incidence of cardiac tamponade after pediatric cardiac surgery ranges from 0.04 to 7% [209]. Catheter characteristics (rigid polyethylene catheters are more likely to cause tamponade than flexible silicone or polyurethane catheters [192]) and vessel wall tear caused by an abnormally placed catheter might be associated with increased risk of tamponade, but detailed studies have not been carried out. Age-associated difficulties with catheter insertion may also be related to a higher risk. In a study of 10 children with cardiac tamponade, 7 were infants, and most complications occurred during needle advancement, with symptoms developing within minutes to up to 12 hours after the procedure [210].

Inadvertent arterial puncture or catheter placement

Inadvertent puncture of the CCA during IJV catheterization is a well-recognized complication; however, other arteries, including the subclavian, vertebral, transverse cervical, and thyroid inferior arteries, are occasionally located behind the IJV and are at risk of perforation [208, 211, 212]. Some authors suggest identifying the presence of vertebral arteries to avoid accidental puncture during IJV catheterization in pediatric patients [96, 98].

Inadvertent arterial puncture can nearly always be prevented by the use of ultrasound guidance. The presence of potential anatomic variations should be confirmed with ultrasound Doppler color flow imaging, and real-time, ultrasound-guided venipuncture should follow a preprocedural ultrasonographic assessment [96, 98].

If this complication occurs, the following principles may be useful. After needle puncture, remove the needle immediately, elevate the area, and hold firm pressure for 5–10 minutes. A small-bore needle puncture of the carotid or femoral artery (e.g., 20 ga or smaller) is not usually an indication to cancel surgery. If a larger hole is created (i.e., a dilator and catheter have been placed), pressure transduction can be used to confirm the location. In this case, a discussion with the surgeon must ensue. Normally, the catheter can be removed, and pressure held without consequences, unless a very large catheter was used (e.g., introducer sheath or large-bore CVP catheter), in which cases surgical exploration and repair should be undertaken. In most cases of elective cardiac surgery, it is prudent to postpone the surgery if a large hole has been made in the artery. Surgery can usually be performed safely 24 hours later, if no bleeding has occurred. If surgery must proceed after an unintended arterial puncture with a large needle or catheter, sterile preparation of the site and inclusion in the surgical field are prudent to facilitate direct observation and access for repair during the surgery if indicated.

Arrhythmias

Central catheters and guidewires can cause arrhythmias. Too deep advancement of the catheter or guidewire has been associated with ectopic atrial tachycardia, especially with the catheter tip in the RA mechanically stimulating and potentially injuring the conduction system of the heart. Atrial fibrillation is also associated with CVC placement. Arrhythmias occur more commonly with passage of the guidewire. These include isolated PACs, supraventricular tachycardia, and, if the guidewire is advanced into the RV,

AL Grawany

premature ventricular contractions or even ventricular tachycardia or fibrillation.

For prevention, a marked guidewire should be used for IJV catheterization. Extreme care must be taken when passing a guidewire to stop advancement if significant arrhythmias are encountered, and when advancing the catheter over the wire. Guidewires must be advanced at as shallow an angle as possible, and in accordance with the body size of the patient. Pediatric patients at particular risk of arrhythmia are those with a known history of arrhythmia, cardiomyopathy, or RV hypertrophy [213]. Cardioversion is effective when atrial fibrillation or life-threatening supraventricular tachycardia develops [213, 214].

Systemic venous air embolus

Systemic air embolus is a constant threat for patients with central or peripheral venous catheters and intracardiac shunting, particularly those with two ventricles and right-to-left shunting and infants with a single ventricle and obligate mixing of systemic and pulmonary venous return in the systemic ventricle. Air may lodge in the coronary arteries, especially the right, the PA, or the brain, leading to potentially serious consequences. The incidence of venous air embolization caused by central or peripheral IV catheters has not been studied in detail, and it is possible that this complication is vastly underestimated or even neglected [215].

Large air emboli can be observed by TEE or transcranial Doppler ultrasound, but prevention is most important. Extreme attention must be paid to avoid the introduction of air into the systemic venous circulation. Careful preparation of venous infusions includes the following: thorough de-airing of all infusions before connection; de-airing of continuous-flush central venous lines; air filters on continuous infusions; and careful technique when injecting drugs and fluids, which involves holding the syringe upright, flushing fluid from the proximal IV tubing, and aspirating and tapping the syringe before injection [216]. Constant vigilance, the use of TEE to monitor for intracardiac air and transcranial Doppler for systemic arterial air, and meticulous technique of catheter removal may reduce the risk of air embolus.

Foreign bodies

Embolization of catheter or guidewire fragments sheared off during difficult insertion procedures, and disrupted catheter fragments in response to repeated mechanical compression between the clavicle and the ipsilateral first rib have been reported [217, 218]. The latter, known as "pinch-off" syndrome, develops occasionally after a long period of catheter indwelling (1 month to 3 years) and poses many treatment difficulties [218]. Prevention includes selection of alternative techniques (percutaneous supraclavicular or IJV approaches or ultrasound-guided catheterization of the axillary vein). If resistance is encountered when withdrawing the guidewire, the guidewire and the needle, or the catheter and the needle, must be withdrawn completely from the vessel together as a unit. Before insertion of long-term indwelling catheters (e.g., for home parenteral nutrition), information should be provided to patients and/or their caregivers regarding possible complications related to catheter shearing.

Complications related to intracardiac catheters

This category is unique to children undergoing congenital heart surgery because intracardiac catheters are rarely used in other situations. In a large retrospective study of 6,690 transthoracic intracardiac catheters in 5,666 pediatric cardiac patients over a 10 year period, there was an overall 0.6% incidence of serious complications, defined as significant bleeding or catheter retention [49]. The risk was greatest for PA catheters (1.1%, with three cases of severe cardiac tamponade and one death for 1,680 catheters) followed by left atrial catheters, then right atrial catheters. The authors concluded that the benefits of intracardiac catheters far outweigh associated risks if care is exercised in placing and removing them and if complications are recognized rapidly and managed aggressively. However, another study reported a relatively high complication rate (37%) of bleeding in 523 transthoracic intracardiac catheters (276 right atrial, 155 left atrial, 68 common atrial, and 24 RV or PA catheters), with the highest rate (47%) in left atrial catheters [219]. These bleeding events required intervention in 8.3% of the patients and caused hemodynamic compromise in 2.6%.

More recent single center studies report similar intracardiac catheter complication rates. Stein and colleagues reported 176 transthoracic catheters in 124 neonates, of which 37% were right atrium, 27% common atrium, and 34% left atrium, with only one PA catheter. 20% of patients received packed red blood cell transfusions after line removal, but there were no deaths, cardiac arrests, or ECMO cannulations [220]. Beham and colleagues reported 115 intracardiac catheters in 112 patients; 45 were RA, 68 LA, and 2 PA catheters [221].

Serious complications occurred in 5.1% of patients, with bleeding requiring transfusion in 3.5%, cardiac tamponade resulting in death in one patient, and tension pneumothorax in one patient. These outcome studies suggest that PA catheters are associated with the highest risk of adverse events; they are used less frequently in more recent reports. Although intracardiac lines are a common vascular access modality with low risk of serious adverse events, a well-established protocol for their removal, with corrected coagulation, mediastinal drainage tube in place, adequate patient sedation, packed red blood cells available, and emergency response surgical team available, is important to minimize adverse outcomes. To date, there have been no outcome studies available comparing transthoracic and percutaneous catheters.

Other complications

Chylothorax [222], phrenic nerve injury [223, 224], vertebral arteriovenous fistula [225], brachial arteriovenous fistula [226], Horner's syndrome [227–229], and tracheal puncture [230] have also been described. These complications can be prevented by skilled personnel and the use of ultrasound-guided techniques to accurately identify vessel location.

KEY POINTS: COMPLICATIONS OF VASCULAR ACCESS

- Complications associated with vascular access can be categorized into catheter insertion- and maintenance-related complications. The most common are arterial puncture and catheter obstruction, respectively.
- The most frequent life-threatening complication of central catheterization is pneumothorax.
- Insertion-related complications occur more frequently with the subclavian approach than with the IJV or femoral approach.
- Appropriate training in pediatric central catheterization, especially in ultrasound-guided techniques, can reduce complications.
- To avoid serious or life-threatening outcomes, risk factors for central catheterization-related complications in children and those for central catheterization-related bloodstream infections should be taken into consideration when planning the procedure.

Conclusions

Vascular access in children undergoing surgery for CHD can be challenging and presents a difficult task for pediatric anesthesiologists. Each needs to gain experience and proper technique to develop his or her own approach to vascular access. No one approach has been shown to be superior to another. However, there is accumulating data favoring ultrasound-guided catheter insertion and we believe this technique will become a standard practice for percutaneous central venous access because the importance of decreased complication rates, insertion time, and expense cannot be overemphasized. Attention to the details of vascular access is important for enhancing patient safety. This, along with a strategy to preserve access sites in small infants with single-ventricle physiology and who may need multiple cardiac surgeries, ultrasound-guided line placement and the use of antibiotic-impregnated catheters will improve the outcome of vascular access procedures.

Introduction

Operative management of the child with congenital heart disease (CHD) was largely refined to its current state in the decades prior to the year 2000, during which operative mortality improved substantially. Data from the metropolitan Atlanta congenital defects program showed a profound increase in 1-year survival of the most critical heart defects, including hypoplastic left heart syndrome (HLHS), truncus arteriosus, pulmonary atresia, tricuspid atresia, and Tetralogy of Fallot from 67% (1979–1993) to 83% (1994–2005) [1]. Predictably, the increased expectation of survival is accompanied by willingness to perform surgery on increasingly complex patients. A multi-institution comparison of survival rates by case complexity using the Risk Adjustment for Congenital Heart Surgery (RACHS) showed a shift of fewer RACHS category 1 cases (low complexity) and more RACHS category 3, 4, and 6 cases (higher complexity) between 1996 and 2004. Further, mortality of RACHS category 6 (predominantly Norwood stage I palliation for HLHS) cases decreased from 48% in 1996 to 17% in 2004 [2]. The most common neonatal operations in the Society of Thoracic Surgeons' Congenital Heart Surgery Database are Norwood stage 1 palliation at 10.2% and arterial switch operation without ventricular septal defect (VSD) at 6.9%, and the surgical mortality of these lesions has decreased to 13.8%, and 2.0%, respectively, as of 2019 [3].

Despite these remarkable gains, survivors of complex CHD are at risk of having a characteristic array of neurodevelopmental deficits. These include poor impulse control, attention deficit/hyperactivity, mild language and cognitive deficits, and limited executive functioning ability [4–8]. Often appearing outwardly normal, children with such deficits perform poorly in academics and lack employability; they suffer high rates of depression and poor quality of life [9–14]. In addition to potentially modifiable factors, the presence of genetic syndromes and increasing complexity of the cardiac lesion are associated with a higher incidence of neurodevelopmental disability (Figure 14.1) [15]. The relative role of modifiable (acute neurologic injuries) and nonmodifiable factors contributing to the neurologic abnormalities seen in patients with CHD is a subject of study and debate. This chapter, written for the anesthesiologist, has an understandable bias toward discussion of the potentially modifiable perioperative factors that have been associated with neurologic injury. The pediatric cardiac anesthesiologist should be familiar with acute, perioperatively acquired neurologic injuries in this population and proposed strategies to avoid them.

Acute neurologic injury in the perioperative period has been quantified using magnetic resonance imaging (MRI)

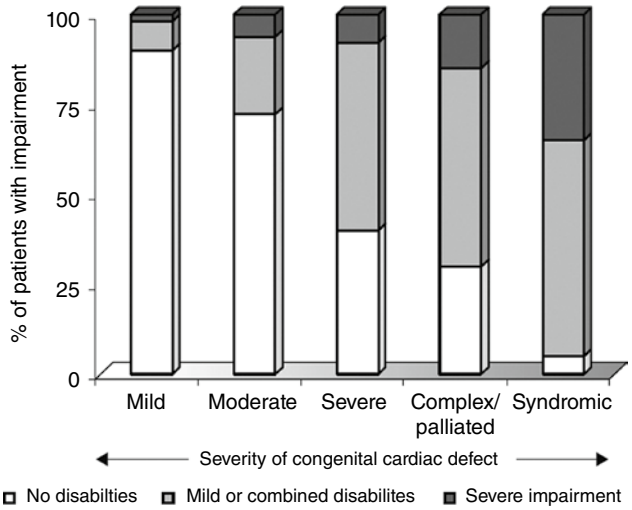

Figure 14.1 Schematic presentation of neurodevelopmental abnormalities in children with congenital heart disease (CHD). Children with milder forms of CHD (e.g., ventricular septal defect without an associated genetic syndrome) have a low incidence, and more than mild abnormalities are rare. Increasingly complex forms of CHD (e.g., transposition or total anomalous pulmonary venous connection) are associated with increasing risk of neurodevelopmental deficits. Only the minority of children with very complex CHD (e.g., functionally univentricular heart, hypoplastic left heart syndrome) are completely normal in all respects. CHD associated with chromosomal abnormalities (e.g., Down's and DiGeorge syndromes) or multiple congenital anomalies (VACTERL, CHARGE associations) are nearly always associated with neurodevelopmental abnormalities, in many cases severe. Figure 14.2 The incidence of preexisting and new postoperative neurologic injuries diagnosed by brain magnetic resonance imaging (MRI) observed in neonates subjected to cardiopulmonary bypass. The findings are compiled from six reports, seven centers, and 400 subjects. Median and range are shown with on outlier. WMI, white matter injury. Data are from references [16–23].

technology. Preoperative neurologic injuries visible by MRI occur with an incidence between 20 and 40% in newborns with critical heart defects [8, 16–18]. After surgery, 35–75% of patients will have a new lesion [19]. Despite differences in nomenclature of MRI findings, it is clear that the preponderance of *new* injuries seen after cardiac surgery in the infant occurs in the white matter (see Figure 14.2) [16, 17, 19–23]. Most studies further specified the preponderant white matter lesion as periventricular leukomalacia, an injury that has been extensively described in preterm infants exposed to extrauterine life (see Figure 14.3). In the preterm population, periventricular leukomalacia is associated with reduction in brain growth and neurodevelopmental impairments with deficits similar to those described in children with critical heart lesions [24, 25]. Current understanding of the pathogenesis of preterm periventricular leukomalacia posits that the preterm brain is susceptible to ischemia due to an incomplete redundancy of penetrating arterioles in the deep white matter, combined with a population of developing oligodendrocyte precursors with enhanced ischemic sensitivity [26–28]. This pattern of injury in the patient with CHD suggests that oxygen deprivation is the leading cause of intraoperative injury, not embolic or hemorrhagic injury as is more commonly seen in adults.

It has been assumed that improvements in hemodynamic management during cardiac surgery have the potential to mitigate neurologic injuries in children who require cardiopulmonary bypass (CPB). However, the management of CPB for infants and children has been challenging to study clinically due to wide practice variability and lack of intercenter consensus. Pump prime, flow rate, cardioplegia solutions and administration intervals, vasodilator therapy, steroid use, cooling and rewarming practices, blood gas management, hematocrit goals, electrolyte control, ultrafiltration techniques, and the use of deep hypothermic circulatory arrest (DHCA) are all integral aspects of a complex practice that forms the protocol at a given institution. Each of these can impact cerebral perfusion, but no standardization exists for any of these parameters. Therefore, understanding the consequence of altering a single aspect of bypass care is unclear, and demonstrating the optimal combination of bypass parameters is prohibitively difficult.

Due to the pressing need to improve neurocognitive outcome and poor guidance afforded by evidence-based approaches to bypass management, effort and expense have been directed toward developing perioperative neuromonitoring strategies for children who require cardiac surgery and CPB. The monitoring technologies described in this chapter have been in routine use for more than a decade, but there is no

universal consensus regarding their usefulness or validity, and there is no standard of care neuromonitoring practice for the patient with CHD. This chapter reviews cerebrovascular physiology and the impact of CPB on cerebral hemodynamics, available neuromonitoring modalities, and proposed strategies for improving neurodevelopmental outcomes after congenital heart surgery.

KEY POINTS: MRI-DIAGNOSED BRAIN INJURY IN NEONATAL CARDIAC SURGERY

- Preoperative neurologic injuries occur in 20–40% of newborns with critical heart defects.
- After surgery, 35–75% of these patients will have a new brain injury.
- The most common brain lesion visible in the MRI of infants after congenital heart surgery is white matter injury (WMI), similar to periventricular leukomalacia seen in preterm infants.

Cerebrovascular physiology during cardiac surgery

Understanding cerebral perfusion and how it is affected by CPB is necessary to understand normal and abnormal neuromonitoring results during cardiac surgery. In health, cerebral perfusion regulation is known to be a finely tuned, multilayered servo control of several homeostatic mechanisms, each acting independently with regard to stimulus and frequency, but in concert at the point of action: mediating cerebral vascular resistance. These mechanisms include neurovascular coupling (also known as metabolic autoregulation), CO_2 reactivity, pressure autoregulation, hypoxic vasodilatation, hypoglycemic vasodilatation, and the uneven action of systemic vasoconstrictors to cerebral relative to noncerebral vasculature. Physiologic changes of the cerebral vasculature during bypass were largely defined by a series of studies performed in the 1980s and 1990s. Cerebral blood flow (CBF) was measured using the Kety–Schmidt technique, and CBF velocity was measured with transcranial Doppler (TCD) in both human infant and animal model studies. These efforts have highlighted the effects of extreme

hypothermia and circulatory arrest on vascular tone, CBF, and oxygen delivery and utilization within the brain.

Cooling and rewarming

During the cooling phase of CPB, CBF is reduced, and cerebral metabolism is reduced, presumably due to neurovascular coupling, which matches CBF to metabolism. However, during deep hypothermia, cerebral metabolism is exponentially reduced, while CBF is reduced linearly with reduction in temperature [29] (see Figure 14.4). This results in a state of "luxury perfusion" during hypothermia [30–33]. As shown another way, at normothermic bypass between 35.5°C and 37°C, the ratio of CBF (in mL/100g/min) to cerebral metabolic rate for oxygen consumption ($CMRO_2$, in mL/100g/min) is normal (20 : 1). At 30°C, the ratio increases to 30 : 1, and at 18°C, it increases to 75 : 1, indicating uncoupling of brain metabolism and vascular tone (see Figure 14.5) [29]. Based on the measured decrease in $CMRO_2$ in children during deep hypothermic bypass, Greeley et al. famously estimated a duration of ischemia that could be safely tolerated between 39 and 65 minutes [31]. When rewarmed after hypothermia in the absence of circulatory arrest, there is a return to normal CBF and metabolism with normal flow/metabolism coupling.

It is generally stated that cooling ablates pressure autoregulation as well as metabolic autoregulation. The two mechanisms are distinct processes that occur at distinct frequencies. Neurovascular coupling (metabolic autoregulation) is mediated by a neurovascular unit comprising an astrocyte bridge between neuronal synapses and penetrating arterioles.

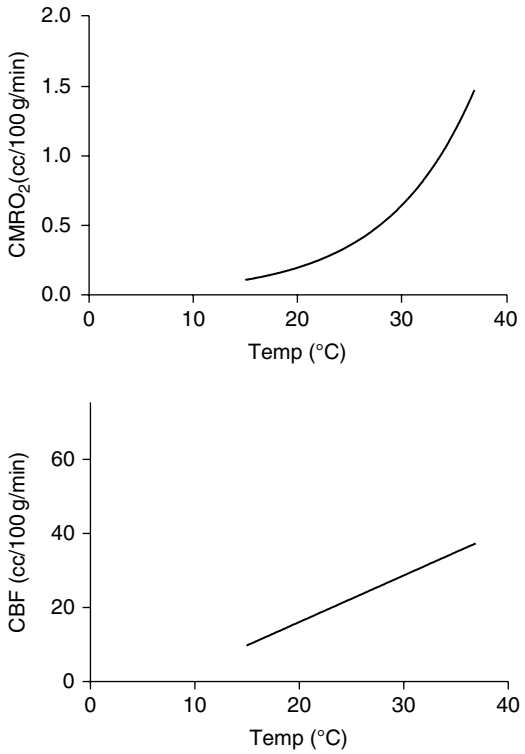

Figure 14.4 Cooling results in a linear decrease in cerebral blood flow and an exponential decrease in cerebral metabolic rate for oxygen consumption ($CMRO_2$). (Source: Adapted from Kern et al. [29].)

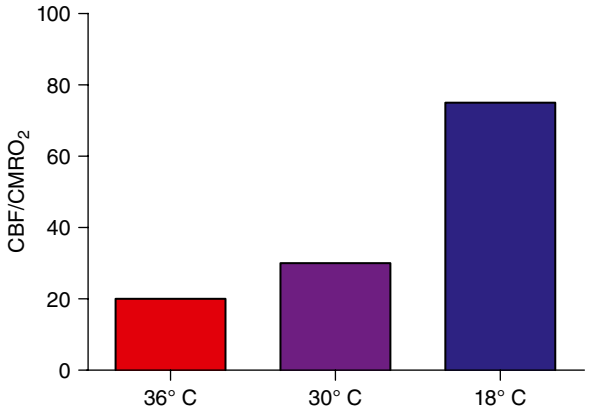

Figure 14.5 Metabolic autoregulation is attenuated with progressive hypothermia during cardiopulmonary bypass in infants. With decreasing temperature, the ratio of cerebral blood flow (CBF) to cerebral metabolic rate for oxygen consumption ($CMRO_2$) increases, yielding a luxury perfusion during hypothermia. (Source: Adapted from Kern et al. [29].)

Neurovascular coupling is spatially specific and rapidly active, effecting vascular changes within 1 second of local neuronal activation [34]. By contrast, pressure autoregulation responds to sustained changes in cerebral perfusion pressure lasting 30 seconds or longer and causes more global changes in CBF [35]. The conclusion that hypothermia also ablates pressure autoregulation comes from two independent investigations, one using TCD and the other using the Kety–Schmidt technique with xenon washout during infant bypass [31, 33, 36]. However, in both data sets, the measurements of flow or flow velocity are taken at lower cerebral perfusion pressures than those taken at normothermia, and most of the hypothermic measurements are taken below the apparent limit of autoregulation evident in the normothermic plots [37].

More recent preclinical and clinical data challenges the assumption that cooling ablates pressure autoregulation. A piglet model was used to more directly assess the relationship between deep hypothermia and pressure autoregulation. Piglets with normal arterial blood pressure demonstrated intact autoregulation, even during deep hypothermia. [38] When neonates were studied using dynamic autoregulation measurements during hypothermic bypass, the state of impaired autoregulation was accompanied, in all cases, by arterial blood pressure below the limit of autoregulation [39]. It is reasonable to conclude from this combined data that pressure autoregulation is not ablated by deep hypothermia, but rather it is impaired by the hypotensive state that frequently accompanies deep hypothermic bypass.

pH-stat vs. alpha-stat blood gas management

pH-stat management corrects blood gas values for temperature during CPB, which results in a higher arterial CO_2 tension during hypothermia than is achieved with alpha-stat blood gas management. Obviously, regardless of the measurement technique used for determining the amount of CO_2 in the blood, removing less CO_2 or adding CO_2 to the sweep gas with

AL Grawany

the oxygenator during bypass results in a higher arterial CO_2 tension. CO_2 diffuses freely across the blood–brain barrier, acidifying cerebrospinal fluid, which exerts a potent cerebral vasodilatory effect. The cerebrospinal fluid slowly returns to normal pH after exposure to high CO_2 levels by increased activity of carbonic anhydrase in the choroid plexus, replacing reabsorbed acidic spinal fluid with spinal fluid having a higher concentration of bicarbonate buffer. Driving CBF changes by manipulation of arterial CO_2 tension is, therefore, time limited by the rate of spinal fluid absorption and production. Spinal fluid production is slower in infants than in adults, but in adults, the entire spinal fluid volume is produced three to four times per day. Not surprisingly, then, animal models have shown that sustained changes in arterial CO_2 tension cause CBF changes that last approximately 1 day [40, 41]. In addition to increasing CBF, arterial hypercapnia shifts the oxyhemoglobin dissociation curve to the right, facilitating oxygen unloading [42]. Thus, in most pediatric centers, pH-stat (hypercapnia) strategy is favored for perceived neuroprotection.

In animal models of DHCA, neurologic outcome is improved when pH-stat is used. This has been more difficult to demonstrate in human infants, although a trend toward a lower death rate, fewer seizures, and greater hemodynamic stability has been observed [43]. Long-term neurologic follow-up at 4 years of age has not shown a difference between pH-stat or alpha-stat blood gas management, and this has only been studied retrospectively in a pediatric setting [42, 44].

Hemodilution and transfusion practices during CPB

Traditionally, profound anemia was used during deep hypothermic CPB to offset the effect of cooling on blood viscosity. This practice, rooted in theory, was challenged by demonstration of increased neurologic injury in a piglet model of hypothermic circulatory arrest using a target hematocrit of 30% when compared with a target of 20% [45]. More convincing was a randomized study of hematocrit goals at Boston Children's Hospital. The combined data from two trials at Boston included the neurodevelopmental outcomes of 271 infants at 1 year of age. The Psychomotor Development Index (PDI) increased linearly with hematocrit up to 23.5%. The Mental Development Index (MDI) did not exhibit an association with hematocrit. The overall conclusion of this analysis was that although a hematocrit higher than 24% improved outcome, the effects of hemodilution vary according to age and other parameters of perfusion, especially pH management, precluding delineation of a universally optimal hematocrit [46].

KEY POINT: HEMODILUTION DURING BYPASS

- The optimal hematocrit target for hemodilution during CPB is unknown, but hematocrit less than 24% during hypothermic bypass is associated with developmental abnormalities in the motor domain and should be avoided.

Temperature management

Hypothermia remains the cornerstone of brain protection for ischemic injury. Cerebral hyperthermia frequently develops after congenital heart surgery with CPB. The metabolic rate and oxygen consumption of the brain are raised during a period when oxygen delivery may be compromised due to hypotension. This places vulnerable watershed areas and partially injured brain tissue at risk for injury extension [47]. Bissonnette and colleagues measured temperatures in the jugular bulb, tympanic membrane, lower esophagus, and rectum during and after surgery in 15 infants and showed that the jugular bulb temperature continued to rise for at least 6 hours postoperatively [48]. The authors found that rectal temperature does not reflect cerebral temperature in the perioperative period. Other investigators further showed that nasopharyngeal and not tympanic temperature best reflects brain temperature [47]. However, Cottrell and colleagues were unable to show any association between neurocognitive performance and postoperative temperature in a cohort of 329 infants who underwent cardiac surgery [49].

In some patients, brain metabolism is not adequately suppressed during rapid cooling to deep hypothermic levels. In a study of infants undergoing cooling to 15 °C, 6 of 17 had low jugular venous bulb saturation when this temperature was achieved (87 ± 6% vs. 98 ± 1% in subjects with apparently normal cooling), suggesting ongoing oxygen consumption that outstripped delivery of oxygen to the brain [50]. There is general concern that uneven or inefficient cooling of the brain may lead to neurologic deficits. Rapid cooling times have been associated in pilot studies with developmental delay and the rare complication of choreoathetosis [51, 52]. There is little debate about the benefits of cooling during CPB, yet there is also insufficient data to suggest that any cooling strategy leads to better patient outcome [44].

Normothermic or mildly hypothermic CPB has gained popularity in recent years. Hannon and colleagues retrospectively studied 78 patients undergoing normothermic (35 °C or greater) vs. hypothermic bypass (28–34 °C) [53]. Patients were less than 2 years of age (median 7 months), and operations requiring deep hypothermia for DHCA or aortic arch reconstruction were excluded, and follow-up was 2–3 years after surgery. For both groups, the odds ratios for neurodevelopmental delay in one or more areas ranged from 2–8 times that of a normal population. After multivariable adjustment, including for genetic conditions (Trisomy 21, DiGeorge syndrome, 22q11.2 deletion syndromes), there was no difference in the incidence of neurodevelopmental delay between the groups.

Glucose management

In the Boston Circulatory Arrest Study (BCAS), hyperglycemia was not associated with worse neurologic outcome and does not appear to be a risk factor for infants and children [54]. Intraoperative glucose concentrations were not related to developmental scores up to 8 years of age, but low glucose concentrations were associated with subclinical seizure activity [55]. In a study of 188 neonates and infants younger than 6 months undergoing surgery with CPB, mean intensive care unit (ICU) admission glucose was 328 mg/dL, maximum was 340 mg/dL, and 89% of patients had at least one

value greater than 200 mg/dL. In that cohort, hyperglycemia was not associated with lower neurodevelopment scores at 1 year of age [56]. Krueger and colleagues assessed neurodevelopmental outcomes at age 4 years in 167 infants undergoing cardiac surgery with bypass as infants [57]. Fourteen percent had hyperglycemia (>145 mg/dL) in the postoperative period, and insulin was administered if the glucose value was above 216 mg/dL. Higher postoperative glucose levels were not associated with lower neurodevelopmental scores across multiple domains. Tight glucose control is not indicated by evidentiary review in children who require CPB and is likely to be harmful in this population [44].

Circulatory arrest

For infants who require reconstruction of the aortic arch, a bloodless field cannot be achieved with standard cannulation techniques. When DHCA is employed for this scenario, a profound cerebrovascular derangement occurs that persists into the rewarming and postoperative recovery periods. This cerebrovascular injury has been characterized by low $CMRO_2$ that fails to return to baseline values, low CBF (with a normal CBF:$CMRO_2$ ratio), and a distinctive TCD flow velocity pattern showing absent or reversed flow during diastole (see Figure 14.6) [58–61]. These derangements have been shown to be reduced in incidence by the use of low-flow CPB instead of circulatory arrest, delayed rewarming, the use of pH-stat blood gas management during cooling, modified ultrafiltration, thromboxane A_2 antagonism, and the administration of nitric oxide donors [59, 62–66]. Although these therapies mitigate the post-circulatory arrest physiologic derangement of the cerebral vasculature, there is no evidence that they change the incidence of periventricular leukomalacia, nor is it proven that these techniques improve the neurocognitive performance of patients with CHD.

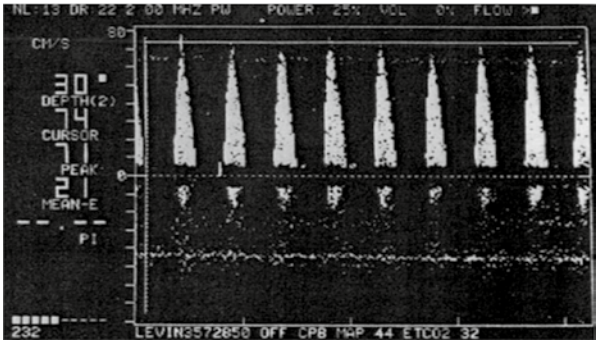

Figure 14.6 After cardiopulmonary bypass with deep hypothermia and a period of circulatory arrest, there is an absence of cerebral blood flow during diastole. This pattern of flow velocity measured with transcranial ultrasound is indicative of high cerebrovascular resistance. (Source: Jonassen et al. [58]. Reproduced with permission from Elsevier.)

KEY POINTS: DHCA

- DHCA in infants is associated with a profound cerebrovascular disturbance characterized by low $CMRO_2$ and low CBF that is absent or reversed in diastole.
- This condition persists into the postoperative period.

Selective cerebral perfusion

Selective cerebral perfusion (also termed regional low-flow cerebral perfusion, antegrade cerebral perfusion, or regional cerebral perfusion) is the surgical response to concerns that circulatory arrest causes neurologic injury. A variety of techniques achieve the same goal of delivering bypass flow to the cerebral vasculature while leaving a bloodless aortic arch for surgical repair. In one version of the technique, a polytetrafluoroethylene graft is sewn into the innominate artery and subsequently cannulated for bypass, in lieu of the traditional cannulation at the aortic root. When selective perfusion is desired, the great vessels are snared, and flow is continued at a reduced rate, now entirely directed to the circle of Willis (see Figure 14.7) [67]. It seems evident that circulatory arrest

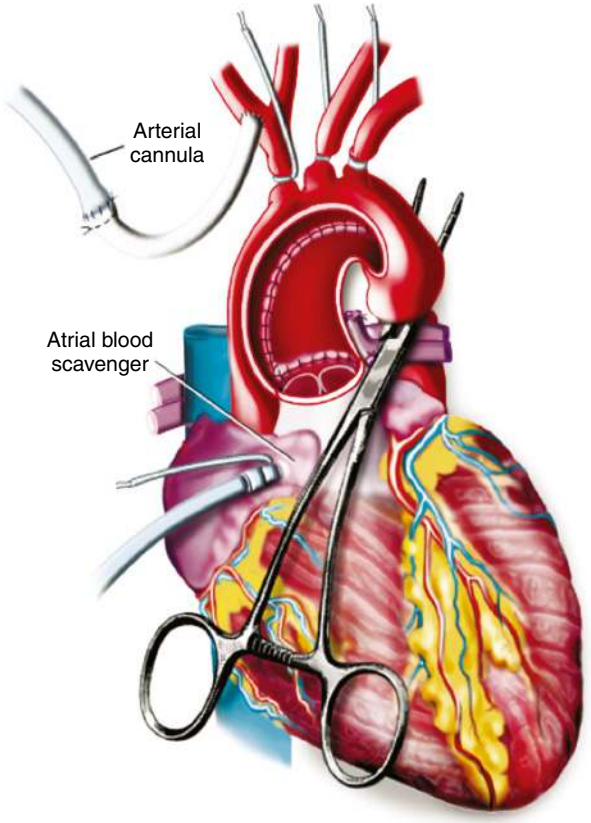

Figure 14.7 Selective cerebral perfusion performed by sewing a graft to the innominate artery and snaring the great vessels. (Source: Pigula et al. [67]. Reproduced with permission from Elsevier.)

and impaired neurovascular recovery after circulatory arrest would cause neurologic injury, but there is no agreement that circulatory arrest should be replaced with either low-flow bypass or newer techniques of selective antegrade cerebral perfusion.

For instance, neurocognitive testing of a 238-subject cohort at 4 years of age following surgery in infancy at the Children's Hospital of Philadelphia showed that the duration of hypothermic circulatory arrest was not associated with a poor

AL Grawany

performance in any category of the neurodevelopmental test [68]. Gaynor and colleagues argued with this result that nonmodifiable factors such as genetic anomaly, socioeconomic status, maternal education, and gestational age were overwhelmingly responsible for poor results on neurocognitive testing and that circulatory arrest is not a contributor to poor neurologic outcome. This result and interpretation contradict the most popular reading of studies related to the Boston circulatory arrest trial, which showed increased seizures and lower development scores in multiple functional domains at 1, 4, and 8 years of follow-up in subjects who underwent circulatory arrest as a randomized intervention [4, 6, 54, 69, 70]. With later testing in the teenage years of the same cohort, differences between arrest and nonarrest groups are less apparent [71]. Although the Boston circulatory arrest trial is one of the most widely studied and cited research efforts on the topic of neurologic injury and circulatory arrest, it is difficult to compare contemporary practice with the bypass strategy from 1990, which included deliberate hemodilution to a hematocrit of 20% [72].

More recently, the "Hearts and Minds" study performed in Auckland, New Zealand, and Melbourne, Australia, found that longer periods of circulatory arrest were associated with a significant increase in the severity of periventricular WMI [22] (see Figure 14.8). In the Hearts and Minds study, many nonmodifiable characteristics were more significantly associated with WMI than the use of circulatory arrest. These included the nature of the cardiac lesion and the brain maturity score. The presence of WMI was not associated with 2-year neurocognitive performance in that cohort.

Two trials comparing circulatory arrest with selective cerebral perfusion found no difference in neurocognitive outcomes at 1 year. Visconti and colleagues studied 29 subjects with HLHS who received either selective cerebral perfusion or circulatory arrest without randomization for the Norwood procedure [73]. Goldberg and colleagues studied 77 subjects with the same condition, randomized for the two bypass strategies [74]. Neither study showed significant improvements with the selective perfusion technique, but it has been argued that neurodevelopmental scores in both groups were lower than expected.

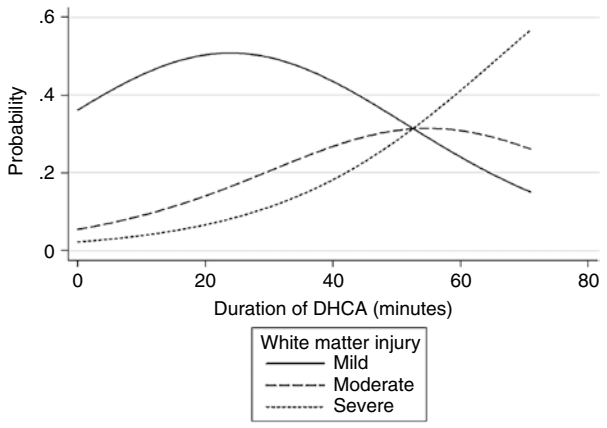

Figure 14.8 Data from the Hearts and Minds study showed that longer circulatory arrest times were associated with an increase in the severity of white matter injury. DHCA, deep hypothermic circulatory arrest. (Source: Beca et al. [22]. Reproduced with permission from Wolters Kluwer Health, Inc.)

Another randomized trial of selective cerebral perfusion vs. circulatory arrest was done with 37 neonates requiring arch reconstruction. More than 70% of subjects in both groups of that study had a new MRI injury. WMI was the most common new lesion in both groups, but 33% of the subjects in the selective perfusion group had a deep embolic stroke on the side used for selective perfusion [75]. This high rate of an unusual neurologic injury is contrasted with a cohort of 57 neonates with high-risk lesions, all undergoing selective cerebral perfusion from Texas Children's Hospital. In that observational cohort, a 40% incidence of new injury was seen, with WMI being the most common, and none had evidence of unilateral embolic load, despite a high flow rate during selective perfusion (56 ± 10 mL/kg/min). In the Texas cohort, the duration of selective perfusion was not associated with poor neurocognitive outcome, but the duration of circulatory arrest was associated with significant worsening in the cognitive domain at 1-year follow-up [8].

Selective cerebral perfusion and flow rates

Adding to the debate over whether to use hypothermic circulatory arrest or selective cerebral perfusion is the problem of choosing a flow rate when perfusing the circle of Willis directly. In the normal state of perfusion, the brain is protected from over- and under-perfusion, specifically by the mechanism of pressure autoregulation. There is evidence that pressure autoregulation is entirely pressure-driven and that cardiac output (or pump flow rates) is not relevant to cerebral perfusion as long as perfusion pressure is within the limits of autoregulation [76–78]. However, the ability of the cerebral vasculature to increase and decrease flow is at least conceptually dependent on a parallel vascular connection with the rest of the systemic circulation from which it can draw flow when vasodilating and to which it can push flow when vasoconstricting. With the great vessels snared and flow directed to the carotid artery, there is an unknown narrowing of the range of flow rates that yield pressures acceptable for cerebral perfusion. Inconceivably wide ranges of selective perfusion flow rates have been published, from 10 to 100 mL/kg/min [79, 80].

Experimental work in piglets has addressed this question. DeCampli, Myung and colleagues, and Sasaki and colleagues independently studied similarly aged infant piglets with selective perfusion techniques at different flow rates [81–83]. By recording arterial blood pressure at the limb ipsilateral to the cannulation site, it was possible to see the relationship between flow rates and resultant pressure directed to the cerebral vasculature (see Figure 14.9). Published reports of neonates studied during selective cerebral perfusion have recorded the right radial arterial blood pressure during right innominate cannulation, which allows for the same relationship to be described in humans (see Figure 14.9) [16, 80, 84–87]. Although the piglet data suggests a safe range of flow rates between 20 and 30 mL/kg/min, examination of the human data clearly shows that the piglet data cannot be translated in this manner. The human infant achieves a lower cerebral perfusion pressure for the same flow rates when compared with the piglet during selective perfusion. Further, the use of pH-stat blood gas management in the human infant increases the required flow rate, whereas pH-stat blood gas management in

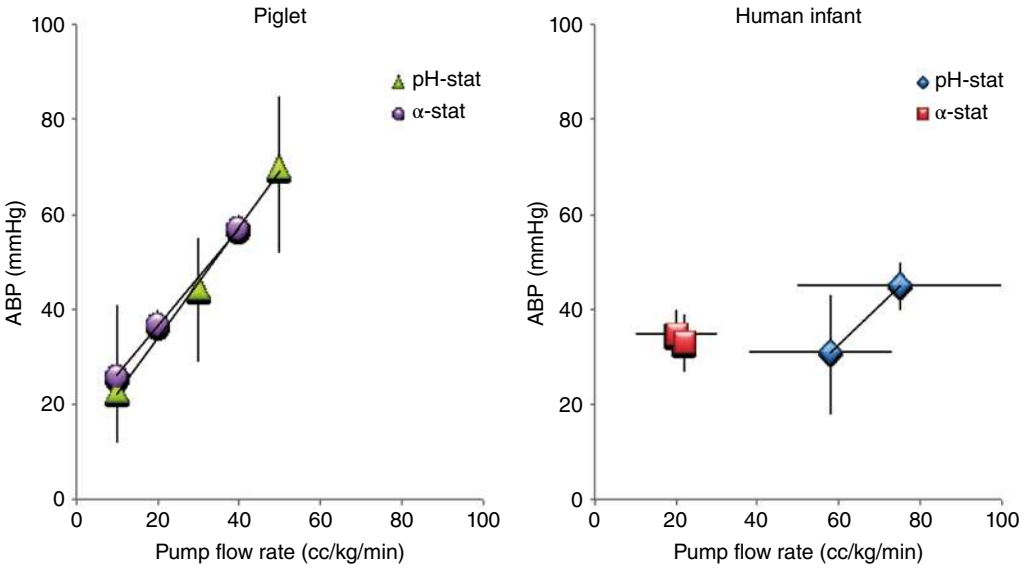

Figure 14.9 The relationships between arterial blood pressure (ABP) and pump flow rates are shown for the piglet model of selective cerebral perfusion and the human infant for two blood gas management strategies.

Table 14.1 Human vs. neonatal piglet models of selective cerebral perfusion

Study subject	Brain weight (g)	Body weight (kg)	P_aCO_2 Mgt	CBF/brain wt (mL/100 g/min)	CBF/body wt (mL/kg/min)
Piglet	60	3	α-stat	25	5
Piglet	60	3	pH-stat	60	12
Human infant	450	3	α-stat	12	18
Human infant,	450	3	pH-stat	20	30

The translation of piglet studies of cerebral perfusion is best understood after comparing the relative mass of the piglet and human brain, the relative body mass of the piglet and human infant, and cerebral blood flow expressed in standard units (mL/100 g/min), and in units relevant to perfusion (mL/kg/min). The effect of blood gas management is also shown. The human brain under pH-stat management is predicted to require six times the pump flow rate of a piglet under α-stat management. The effect of noncerebral tissue vasculature remains unknown.

the piglet does not seem to change flow rate requirements during selective perfusion.

The translation of selective perfusion data from piglet to human would require accounting for differences in brain size (60 g piglet brain, 450 g human infant brain), brain development (the piglet is born ambulating with myelinated white matter, with different metabolic requirements and CBF), as well as the ratio of cerebral to collateral systemic circulation that occurs due to anatomic differences. Given the observed response to blood gas management changes shown in Figure 14.9, one can argue that the ratio of cerebral to noncerebral perfusion in the human during selective perfusion is much higher than the piglet model of selective perfusion. The basis of this argument is that CO_2 tension changes in the blood affect cerebral vascular tone, but leave noncerebral vascular tone relatively unchanged. If the piglet had a large percentage of CBF to total blood flow during selective perfusion, the pressure would drop with pH-stat management, as it does in human infants.

CBFs during bypass have been measured in piglets and human infants under both alpha-stat and pH-stat blood gas management and are summarized in Table 14.1 to facilitate comparison of the human infant with the piglet model [33, 83, 88–92]. The piglet has a higher CBF/100 g of tissue, but pump flows are determined by body weight, not brain size. Therefore, the CBF rates/kg body weight are much smaller. These differences limit the applicability of piglet studies of selective perfusion to clinical practice.

An alternative approach has been to rely on neuromonitoring of individual patients to determine selective perfusion flow rates. The TCD is used to determine flow velocities in the middle cerebral artery after cooling, but before selective perfusion. With initiation of selective perfusion, flows are gradually increased from zero until the flow velocities are equal to the preselective perfusion values [80]. This technique results in a wide interpatient variability in flow rates, with a mean flow rate of 56 ± 10 mL/kg/min. Of 57 high-risk patients reported with this technique, 23 (40%) had a new MRI-detected brain lesion after surgery. Most lesions were WMI, and the lesions were evenly divided between ipsilateral and contralateral hemispheres with respect to the cannulation site. Nonrandomized neurodevelopmental outcomes using the Bayley Scales of Infant Development at 12 months yielded cognitive domains on a par with population norms, and language and motor domains 0.8 and 0.9 standard deviations (SDs) lower than population norms [8].

KEY POINTS: SELECTIVE CEREBRAL PERFUSION

- During selective perfusion, with the great vessels snared and flow directed to the carotid, there is an unknown narrowing of the range of flow rates that yield pressures acceptable for cerebral perfusion.
- Flow rates for selective perfusion have ranged from 10 to 100 mL/kg/min.
- A TCD and near-infrared spectroscopy (NIRS)-guided flow protocol with mean 56 mL/kg/min has been published, yielding a low rate of new MRI injury and good 12-month neurodevelopmental outcomes.

KEY POINTS: EVIDENCE-BASED MEDICINE AND PHYSIOLOGICAL MONITORING OUTCOME STUDIES

- The pulse oximeter is a mandatory intraoperative monitor despite failure of research to show any outcome benefit after randomization of nearly 23,000 subjects.
- The universal refusal of practitioners to disbelieve the apparent benefit provided by pulse oximetry casts doubt on the ability of the randomized trial to demonstrate benefit for any monitoring modality.

Neurological monitoring during congenital heart surgery

> If a man will begin with certainties, he shall end in doubts: but if he will be content to begin with doubts, he shall end in certainties.
>
> Francis Bacon, 1605 [93]

Empiricism, inductive reasoning, and the scientific method have converted medicine from mysticism to an evidence-based practice. The randomized controlled clinical trial is not new to medical science, but the modern ability to assimilate the vast catalog of medical data has been transformative [94]. The contemporary concept of evidence-based medicine by meta-analysis is a rigorous, methodical scoring of available evidence that provides a common platform for the standardization of practice [95]. Neuromonitoring has been reviewed with this matrix. In the case of all three neuromonitors presented in this chapter (electroencephalography, TCD ultrasonography, and reflectance NIRS), the final evidentiary scores were level III, i.e., no demonstrable benefit [44]. The antithesis of evidence-based practice includes two categories of offense: nonconformity to practices shown to be beneficial and adherence to practices not shown to be beneficial. While no monitoring device has been shown by this evidentiary standard to be beneficial, the American Society of Anesthesiologists continues to recommend a standard, minimum acceptable intraoperative monitoring platform to include pulse oximetry, blood pressure, and electrocardiography [96]. This breach of evidence-based practice is most pointed for the pulse oximeter, which is a mandatory intraoperative monitor despite failure of research to show any outcome benefit after randomization of nearly 23,000 subjects [97]. The universal refusal of practitioners to disbelieve the apparent benefit provided by pulse oximetry casts doubt on the ability of the randomized trial to demonstrate benefit for any monitoring modality [98]. For similar reasons, final conclusions in meta-analyses of intraoperative neuromonitoring, including those described hereafter in this chapter, are commonly upgraded in tone from "not indicated" to "may be considered," despite the inability to support this conclusion with data [44, 99].

Electroencephalographic technologies

The standard electroencephalogram (EEG) with 2–16 channels has been utilized in congenital heart surgery [100]. The EEG has a primary clinical purpose of detecting and diagnosing seizure activity. More recently, it has been used as a guide of anesthetic depth and to document electrocerebral silence before circulatory arrest [101]. EEG is affected by several factors, including anesthetic agents, temperature, and CPB. Impracticalities associated with intraoperative EEG include electrical signal interference, complexity of placement, and interpretation. Newer devices using processed EEG technology are more user-friendly and have been extensively reviewed [102, 103]. Although the value of perioperative EEG monitoring has better rationale in recent years (see below), there is conflicting outcome data. For example, neonates after stage I repair of HLHS had normal perioperative EEG findings when postoperative MRI scans showed ischemic injuries [20].

The Bispectral (BIS™) Index Monitor (Covidien, Inc., Mansfield, MA, USA) is currently promoted to guide the depth of anesthesia. BIS sensors are applied to the forehead and temple, producing a frontotemporal montage, which connects to a processing unit. The device is easy to use, and the monitor requires no calibration. The proprietary algorithm of Covidien (originally Aspect Medical Systems) renders the BIS index from one-channel processing of the EEG [104]. The BIS index ranges from 0 (isoelectric EEG) to 100 (awake), with mean awake values in the 90–100 range in adults, infants, and children [105]. While awareness is a concern with surgery requiring CPB in adults, there is a scarcity of data in the literature regarding this problem in children requiring heart surgery [106, 107]. The BIS monitor also reports a burst suppression ratio, which would, in theory, be useful to see the effect of cooling on suppression of electrical activity in the brain. However, the literature has only case reports describing this practice in pediatrics [108, 109].

In a cohort of children undergoing open heart surgery with an anesthetic tailored for "fast tracking," BIS scores increased during rewarming, a period considered at risk for awareness under anesthesia [110]. However, in that study and a similar study of infants younger than 1 year, BIS did not correlate with biochemical surrogates of light anesthesia, including stress hormones.

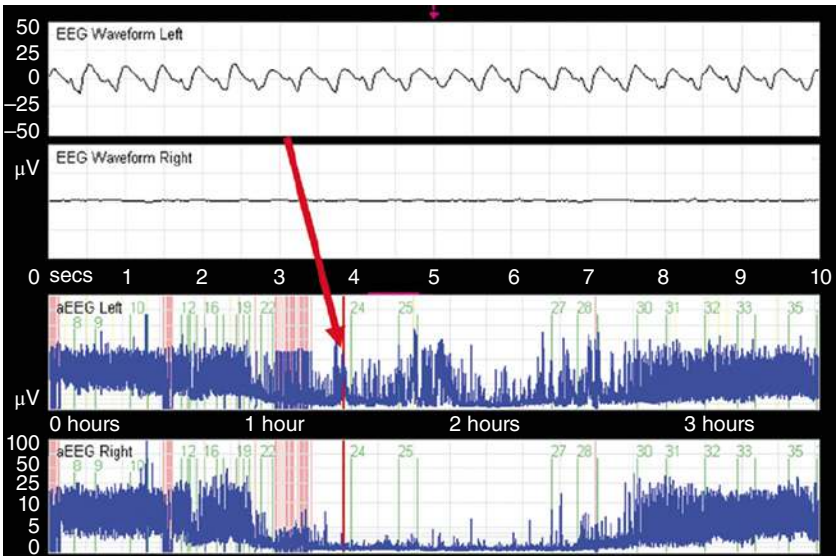

Figure 14.10 Intraoperative aEEG recording with repetitive ictal pattern indicating left-sided seizure on the raw EEG trace (top row) and corresponding to the left compressed trace (third row) highlighted by the red arrow. (Source: Gunn et al. [113]. Reproduced with permission from Elsevier.)

Andropoulos and colleagues reported a cohort of 68 neonates undergoing single ventricle (SV) and two-ventricle (2V) repairs who underwent full 11-lead neonatal EEG monitoring for 6 hours preoperatively and 72 hours postoperatively [111]. High-flow bypass with neuromonitoring including NIRS with a treatment protocol for rSO_2 <50% was utilized. Selective cerebral perfusion with transcranial Doppler-guided flow rates were also employed, and DHCA was minimized. There were no preoperative EEG seizures identified. In the 72-hour postoperative period, one patient experienced two brief EEG seizures for a total of 125 seconds; for an overall incidence of 1.5% (95% confidence interval 0.3–7.9%). This EEG seizure incidence is lower than most other cohorts (see below), and the discussion focused on targeted management of CBF and oxygenation and the fact that significant doses of benzodiazepines were administered intraoperatively and postoperatively in this population (median of about 2 mg/kg midazolam in the perioperative period), which could suppress seizures. This report emphasizes the importance of specifying anesthetic/sedative and bypass and neuromonitoring protocols when reporting EEG seizure incidence.

Amplitude-integrated EEG (aEEG) has been utilized in neonatal intensive care for two decades and has prognostic outcome value for term neonates with hypoxic–ischemic encephalopathy (HIE) and who undergo therapeutic hypothermia [112]. Four needle or adhesive electrodes plus a reference electrode are applied to yield a two-channel EEG, from two parietal and two frontal locations. The raw EEG signal is smoothed, rectified, amplitude integrated, and displayed at the bedside. The aEEG signal is evaluated for background pattern, ictal discharges, burst suppression, low voltage, or an isoelectric EEG, allowing real-time assessment and treatment. Reports of intraoperative use of aEEG for infant cardiac surgery are limited. Gunn and colleagues studied 39 neonates undergoing Norwood stage I palliation for HLHS with selective cerebral perfusion and reported intraoperative seizures in 9 (23%), predominately occurring at hypothermia of 20–24 °C [113] (Figure 14.10). Of note, NIRS was not utilized in this study nor was the CPB flow rate during selective cerebral perfusion specified (see above). Eighteen percent of this cohort experienced seizures in the early postoperative period. Seizures were not associated with later neurodevelopmental impairment at 2 years, but were associated with increased early mortality. Failure of the background aEEG pattern to return to normal by 48 hours was associated with increased early mortality and lower motor scores at 2 years. In other cohorts, postoperative abnormal aEEG patterns, consisting of seizures, abnormal background activity, and abnormal sleep–wake cycles, have been associated with new postoperative MRI brain injury after cardiac surgery in neonates and lower IQ but not motor scores at age 4 years [112, 114].

Pittet and colleagues reported 31 neonates with conventional 13- or 19-lead video EEG monitoring before cardiac surgery, and 5 (16%) experienced EEG seizures, with no clinical correlate [115]. All neonates with preoperative seizures had significant brain injury on MRI, including acute stroke, watershed injury, intracerebral hemorrhage, and WMI. Of the 157 recorded seizures, 62% were in the same area as MRI brain injury.

In a 2021 systematic review and meta-analysis of DHCA and EEG monitoring in the perioperative period for pediatric cardiac surgery, Alkhatip and colleagues reviewed 19 studies with 1,267 patients [116]. The event rate of EEG seizures was 14.9%, and seizures were associated with acute neurological findings, MRI abnormalities, and lower IQ and PDI scores on longer term follow-up. Longer DHCA times were associated with a higher incidence of EEG seizures.

While intraoperative utilization of either conventional or aEEG monitors remains limited due to complexity and space constraints, postoperative EEG monitoring for high-risk neonates and infants undergoing cardiac surgery is increasingly common, and the American Clinical Neurophysiological Society recommends continuous EEG monitoring in this patient group [117]. It seems intuitive to treat EEG seizures

AL Grawany

since they are clearly a manifestation of brain injury, and many centers are now doing this; whether seizure treatment and suppression will improve longer term neurodevelopmental outcomes needs to be further studied [118].

KEY POINTS: EEG TECHNOLOGIES

- EEG seizures occur in 10–25% of high-risk patients in the perioperative period in most studies.
- Most studies associate EEG seizures with adverse long-term neurodevelopmental outcomes.
- Postoperative EEG monitoring for high-risk patients is increasingly practiced.
- Outcome studies of seizure treatment are lacking.

Transcranial Doppler ultrasound

TCD ultrasonography is a sensitive, real-time monitor of CBF velocity and embolic events during congenital heart surgery. Currently available instruments utilize pulsed-wave ultrasound at 2 MHz frequency, which is range-gated, emits a power of 100 mW and has a sample volume length up to 15 mm. Typically, the middle cerebral artery is insonated during cardiac surgery, either across the fontanel or through the temporal bone window. Systolic, mean, and diastolic flow velocities are easily measured, as well as the pulsatility index, which is equal to the peak (systolic) velocity minus the end-diastolic velocity divided by the mean velocity [119].

The most challenging aspect of TCD use is setting the proper angle and depth to reliably interrogate flow velocity in the middle cerebral artery. This is facilitated by the presence of pulsatile blood flow and is therefore best done before initiation of bypass. Once located, small movements will require ongoing adjustments during the monitoring period to optimize the angle and depth of insonation. Cerebral vessels are not visualized by the ultrasound used, but are recognized by the patterns of flow velocity generated. When the temporal window is used, the bifurcation of the middle and anterior cerebral arteries is recognized in the Doppler signal by a maximal antegrade signal emanating from the middle cerebral artery and a similar magnitude retrograde signal emanating from the anterior cerebral artery. Insonation of the same vessel is necessary to effectively use the TCD during surgery, and the use of the middle and anterior cerebral arteries bifurcation allows the same region to be identified due to the simultaneous bidirectional flow signal (see Figure 14.11). The anterior fontanelle window can also be utilized in young infants, taking care to insonate the bifurcation of the anterior and middle cerebral arteries on the desired side, usually the right, and recognizing that the depth of insonation is significantly greater through this location.

TCD ultrasonography has been used extensively in pediatric cardiac surgical research to examine the cerebral physiologic responses to CPB, hypothermia, low-flow bypass, regional perfusion techniques, and circulatory arrest. These studies are discussed in the section on "cerebrovascular physiology during cardiac surgery." TCD monitoring can also be used to detect cerebral emboli, but the embolic load detected with this method has not been shown to correlate with acute postoperative neurologic deficits [120] or long-term neurodevelopmental outcomes [121]. The number of emboli detected by TCD is greatest after removal of the aortic cross-clamp, suggesting de-airing maneuvers guided by echocardiography, with Trendelenburg position; lung inflation to promote movement of air out of the pulmonary veins; and venting of the aortic root as strategies for mitigation [122]. In addition, TCD monitoring can be used to detect cannula malposition at either the superior vena cava or aortic sites, which is seen as an abrupt decrement in the middle cerebral artery flow velocity [123].

Monitors of cerebral oxygenation

Jugular venous bulb oximetry

Jugular bulb venous oximetry ($SjvO_2$) has been used in children with CHD since the late 1980s. It is considered the gold standard for the assessment of global cerebral oxygenation, against which reflectance NIRS monitors were validated. The catheter can be placed in the jugular bulb by retrograde cannulation of the right internal jugular vein, with or without fluoroscopic confirmation of catheter tip placement [91]. Alternatively, the superior vena cava can be cannulated in the surgical field after exposure [124]. $SjvO_2$ is conceptually a measure of the ratio of oxygen delivery to consumption in the brain. During bypass in adults, low $SjvO_2$ has been associated with low cerebral perfusion pressure and low $PaCO_2$, whereas high $SjvO_2$ is associated with low temperature [125]. The limited data available for $SjvO_2$ monitoring are not likely to be augmented in the future because the method is invasive and time-consuming when compared with reflectance NIRS, which renders a physiologically similar variable.

Near-infrared spectroscopy

In 1977, Frans Jobsis envisioned a neuromonitor for critically ill preterm neonates based on reflectance NIRS [126]. The "NIRO-SCOPE" he developed was first used in 1985, in the neonatal ICU at Duke University and led to the claim that [127]:

For effective measurement of cerebral oxygen sufficiency in a sick newborn, an instrument should be noninvasive, be adaptable at the bedside, not interfere with patient care, and give continuous rapid information. The signals should directly assess brain oxygen delivery and utilization and be sensitive to small changes. The NIRO-SCOPE appears to fulfill these basic requirements.

The technology developed by Jobsis and his colleagues has evolved into at least eight US Food and Drug Administration (FDA)-approved devices: INVOS™ 5100C and 7100 (Medtronic/Covidien, Mansfield, MA, USA), Fore-Sight® (CASMED®/Edwards, CAS Medical Systems, Inc., Branford, CT, USA), Equanox™ 3- and 4-wavelength versions (Nonin Medical Inc., Plymouth, MN, USA), CerOx™ (Ornim Inc., Dedham, MA, USA), NIRO®-200NX (Hamamatsu Photonics, Hamamatsu City, Japan), and O_3 Regional Oximetry (Massimo, Irvine, CA, USA), of which all except the CerOx are currently also approved for pediatric use. All devices utilize similar technology and are susceptible to similar artifacts and pitfalls [128].

Cerebral oximeters include a sensor placed on the forehead below the hairline. Near-infrared light penetrates human tissues, including bone, without ionization. Light in this spectrum is, however, absorbed by specific biologic chromophores

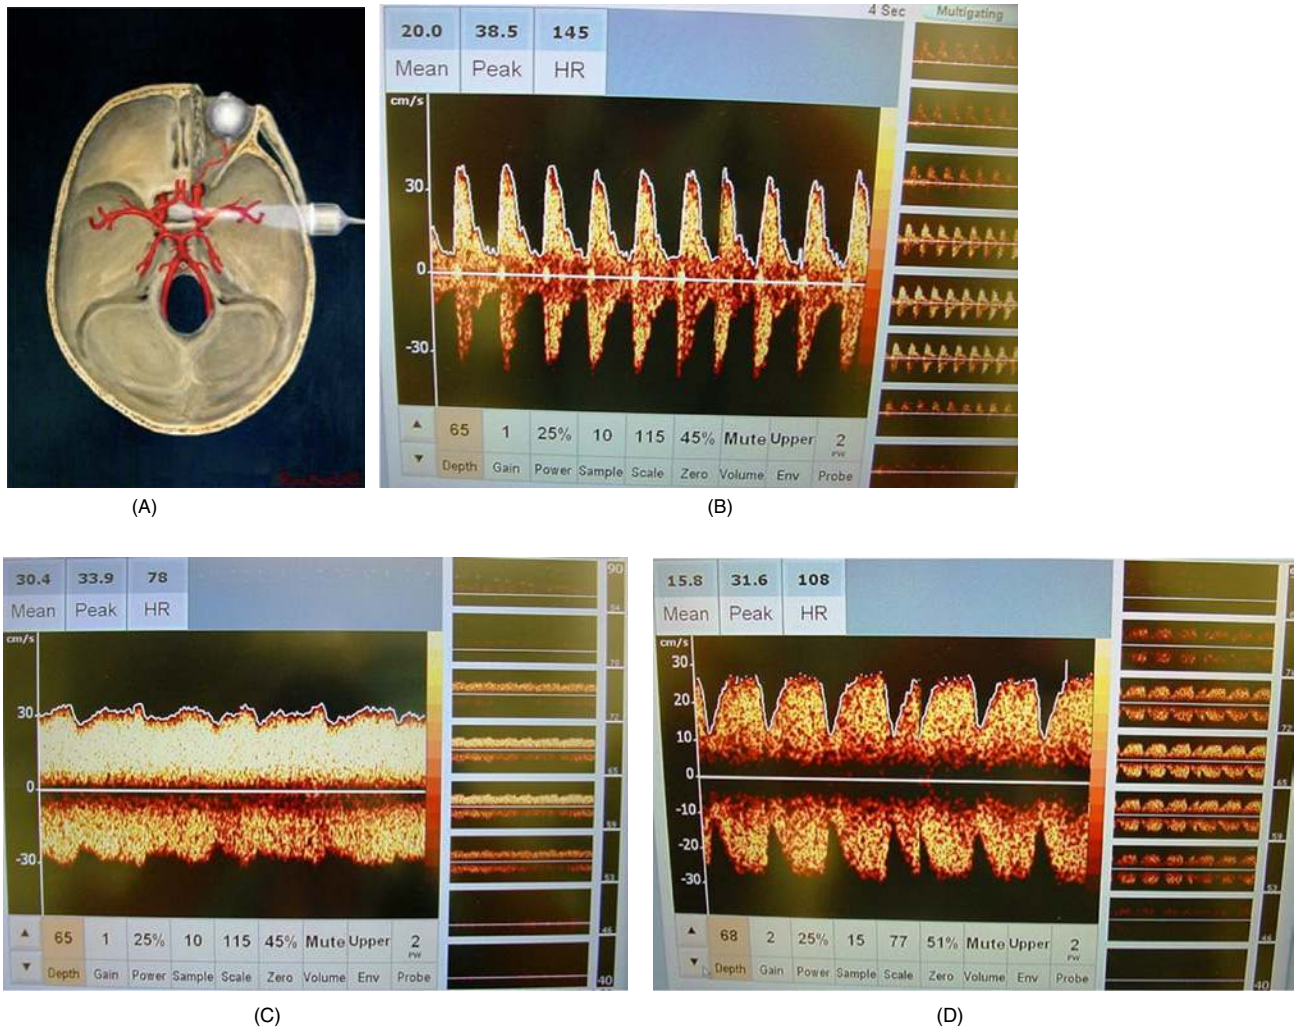

Figure 14.11 (A) The bifurcation of the middle and anterior cerebral arteries is insonated by transcranial Doppler through the temporal bone window. (Source: Runeaaslid / Wikipedia / CC BY 3.0, https://commons.wikimedia.org/wiki/File:Transcranial_doppler.jpg) (B) Transcranial Doppler waveform pre-bypass. Note in the biphasic pattern, the flow velocity above zero baseline is toward the transducer (middle cerebral artery) and the velocity below zero is away from the transducer (anterior cerebral artery). Mean and peak velocities in cm/s are displayed. The panels on the right of screen are multigating patterns at different depths of insonation. (C) Flow velocity on full flow bypass at 150 mL/kg/min. HR, heart rate.

(i.e., hemoglobin and cytochrome oxidase AA_3), with molar absorptivity that is dependent on the state of oxidation of the chromophore (see Figure 14.12).

When near-infrared light, whether originating from a laser or a light-emitting diode, is applied to the human forehead, it passes through tissue in all directions, refracting off various tissue interfaces such that a portion of the light returns to the surface where it can be detected. In the laboratory, using a cuvette and spectrophotometer, the Beer–Lambert equation is used to calculate the concentration of a single chromophore based on absorbance (A). Absorbance is calculated from the relative intensities of recovered (I) and incident (I_0) light passing through a cuvette in a spectrophotometer:

$$A = -\log\left(\frac{I}{I_0}\right) = \varepsilon_\lambda LC$$

where A is absorbance, ε_λ is the molar absorptivity of the chromophore at the specified wavelength of light, L is the path length of light, and C is the concentration of the chromophore in the cuvette. Naturally, hemoglobin does not occur within cuvettes in the brain, and the path length of reflected light encountering the cerebral cortex from the forehead can only be estimated. However, when multiple wavelengths of light are used, the ratio of oxygenated hemoglobin concentration to total hemoglobin concentration can be calculated, effectively cancelling unknown and estimated factors. Proprietary variations on these principles exist to account for scattering of light outside the interoptode arc, absorption by nonhemoglobin species, and extracranial (noncerebral) absorption for each of the marketed devices.

Regional cerebral oximetry is thought to describe the oxygen saturation of frontal cortical blood that is 70% venous, 5% capillary, and 25% arterial. Thus, cerebral oximetry is venous

AL Grawany

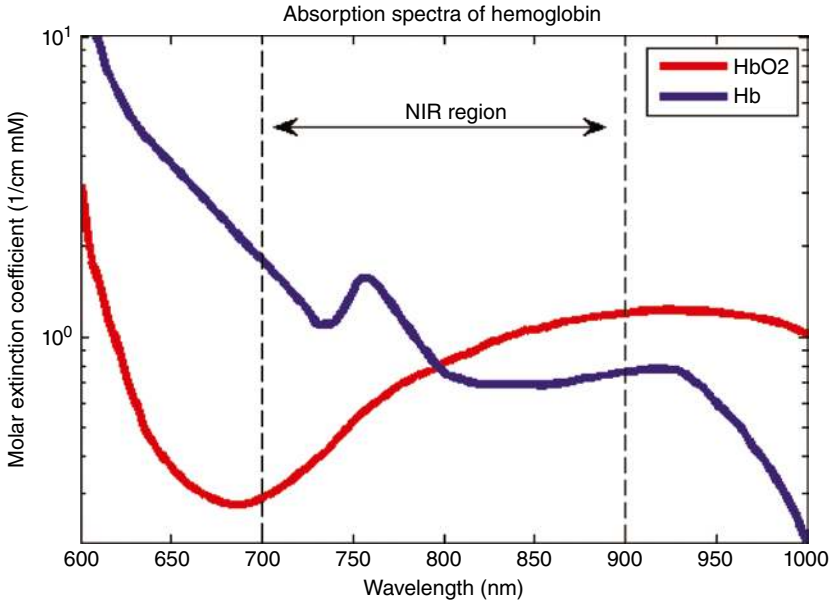

Figure 14.12 The absorption spectra of hemoglobin and oxyhemoglobin in the near-infrared (NIR) range. At the isosbestic wavelength of 805–810 nm, hemoglobin and oxyhemoglobin have similar absorption. Above this wavelength, oxygenated hemoglobin has greater absorption, and below this wavelength, hemoglobin has greater absorption. (Adrian Curtin / Wikimedia Commons / CC BY-SA 3.0, https://commons.wikimedia.org/wiki/File:Oxy_and_Deoxy_Hemoglobin_Near-Infrared_absorption_spectra.png.)

weighted, but with some arterial contribution making it consistently higher than, but trending with, jugular venous oximetry [129–131]. In piglets during CPB including hypothermic circulatory arrest, the correlation between jugular venous oximetry and cerebral oximetry was strong ($r = 0.91$) [132]. Clinical replication of this data was significant, albeit less robust [131, 133, 134]. Critics of cerebral oximetry have not challenged the evidence that cortical oxygenation can be measured with reflectance NIRS. Rather, the relevance to outcome, potential to misguide management, and justification of cost have been the questions raised by evidentiary review [44]. Some highlights of the numerous observational studies showing an association between low cerebral oximetry and neurologic injury or neurocognitive outcome are discussed below. Figure 14.13 displays bilateral regional cerebral oxygen saturation (rSO_2) intraoperatively in a neonate undergoing stage I palliation for HLHS.

A prospective study of 250 children with EEG, TCD, and cerebral oximetry monitoring during cardiac surgery showed that cortical desaturation (cerebral oximetry reductions of 20% from baseline) was the most common monitoring event. Postoperative neurologic abnormalities, including seizures, speech, movement, and visual disturbances, occurred in 26% of subjects with neuromonitoring abnormalities that were not treated. By comparison, neurologic sequelae were observed in only 6% of subjects with monitoring events that were treated and in 7% of subjects with no monitoring abnormalities [98]. Pre- and post-Norwood procedure brain MRI data from 22 subjects showed an association between new lesions and prolonged cortical desaturation [20]. Another cohort of 53 neonates with diverse congenital heart lesions showed an association between cortical desaturation and new brain lesions detected by MRI [135]. Using a mixed outcome metric combining length of ICU stay, need for extracorporeal membrane oxygenation (ECMO), and death, an association was found between 48-hour mean cerebral oximetry measurements and poor outcome in 50 neonates after Norwood for HLHS [136].

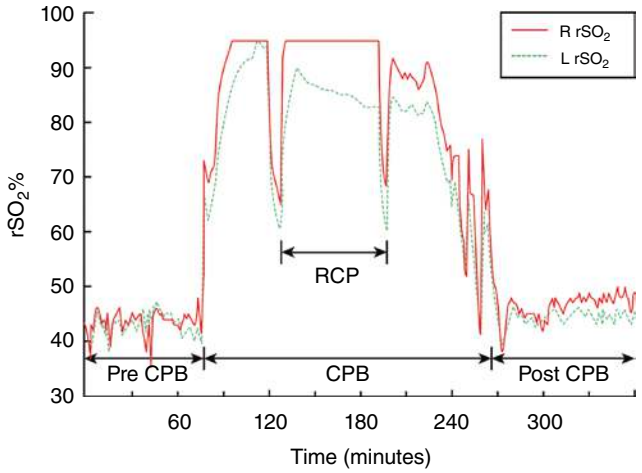

Figure 14.13 Bilateral regional cerebral oxygen saturation (rSO_2) in a neonate during stage I palliation for hypoplastic left heart syndrome. During pre-cardiopulmonary bypass (CPB) the baseline rSO_2 is low at 40–50% and similar in both frontal cerebral hemispheres. During CPB, cooling rSO_2 increases to greater than 90% bilaterally, decreasing briefly to 60–70% during deep hypothermic circulatory arrest (DHCA) for the atrial septectomy and increases again with left rSO_2 lower that right during regional cerebral perfusion (RCP). A brief period of DHCA to transfer the aortic cannula to the neoaorta is followed by increase to rSO_2 >85% and then decrease during rewarming on bypass. After bypass, rSO_2 is 45–50%.

Recent publications report additional surgical cohorts that associate low perioperative NIRS values with later decrements in neurodevelopmental outcomes. Carra and

colleagues studied 87 infants with median age of 4 months undergoing cardiac surgery with bypass and found that higher "dose" of cerebral desaturation below rSO_2 of 65% (% below 65% × minutes) in the first 24 hours after surgery was associated with lower IQ scores 2 years later [137]. In a cohort of 56 neonates with SV and 2V lesions studied by Andropoulos and colleagues, multivariable analysis of risk factors reported an association of lower preoperative rSO_2 values with lower cognitive and motor scores at 12 months [138]. Hoffman and colleagues reported that among 178 children undergoing SV or 2V cardiac surgery as neonates, lower baseline rSO_2, but not pulse oximeter-derived SpO_2, measured at the time of neurodevelopmental assessment, was a risk factor for lower motor scores from 6 to 36 months of age [139]. Aly and colleagues report 75 SV and 2V neonates who had Bayley Scales of Infant Development-II (BSID-II) testing at 6, 15, and 21 months after surgery. Patients with poor outcomes (death or a BSID-II score more than 2 SD below norms) had lower cerebral tissue oxygenation index at 60 minutes (48 vs. 58%, $p = 0.003$) and 24 hours after bypass (49 vs. 59%, $p < 0.01$) [140].

Monitoring and supporting cortical oxygenation during cardiac surgery are conceptually similar to "goal-directed therapy," used for shock management in the ICU [141, 142]. Recognition of cortical desaturation promotes interventions that increase oxygen delivery; thus, cerebral oximetry monitoring acts as a unidirectional influence on bypass practices toward higher hematocrit, higher flow rates, higher cerebral perfusion pressure, higher arterial carbon dioxide tension (pH-stat management), and the use of selective perfusion techniques [96]. Table 14.2 shows abnormalities associated with cortical desaturations and interventions performed at Texas Children's Hospital for cortical desaturation events.

Table 14.2 Causes and treatments of cortical desaturation used at Texas Children's Hospital

Abnormality	Principle	Intervention
Cerebral perfusion pressure	The brain is perfused by pressure, not cardiac output. However, our preference is to treat low pressure with cardiac output support, to avoid excessive vascular resistance and hypoperfusion of the noncerebral vascular beds.	During CPB: Increase flow rate and maintain afterload reduction. Vasopressor only if excessive vasoplegia is suspected. Check SVC and aortic cannulae. Off CPB: Administer volume judiciously with monitoring of atrial filling pressures. Inotropic support to improve stroke volume. Pacing for bradycardia. Vasopressors when excessive vasoplegia is suspected, and judiciously when volume is not tolerated and/or arrhythmia precludes beta agonist therapy.
Anemia	Low oxygen carrying capacity increases vulnerability to watershed white matter injury. The infant heart has low tolerance for the volume administration of transfusion immediately after bypass.	Avoid excessive hemodilution during hypothermia, typically 30–35%. Blood transfusion and hemofiltration during cardiopulmonary bypass to a hematocrit greater than 40% at separation. Higher hematocrit at separation allows for a volume-neutral exchange transfusion of platelets if needed.
Fever	High brain temperatures increase $CMRO_2$. High global extractions yield low mixed venous oxygen saturations, affecting arterial saturation in infants with mixing lesions.	Fevers are treated with antipyretics. Cooling is easily controlled on CPB. After separation and in the ICU, cooling can be accomplished to normothermia when needed with adequate sedation.
Hypoxia	Arterial hypoxia in the infant with a mixing lesion must be addressed systematically. Reflex administration of oxygen in this setting can result in systemic hypoperfusion.	Lung ventilation and perfusion: tracheal suction, recruitment maneuvers. Pulmonary to systemic flow ratio: evaluate for shunt occlusion, pulmonary vascular tone elevation. Mixed venous desaturation: see below
Mixed venous desaturation	Infants with mixing lesions are especially vulnerable to decrements of mixed venous oxygen content. Systemic vascular tone is the most common cause. Excessive work of breathing, agitation, shivering, and fever can contribute to low mixed venous saturation.	Alpha blockade is used for infants during cardiopulmonary bypass. Afterload reduction with milrinone, nipride, or ACE-inhibitors is a preferred first-line therapy after separation from CPB. Intubation, sedation, or paralysis may be necessary in the ICU depending on the acuity. Pressure support trials causing low mixed venous oxygen saturation and cortical desaturation should be terminated.
Hypocarbia	Arterial CO_2 diffuses freely into the CSF while soluble buffers do not. Cerebral blood flow is increased by acidic CSF (increased CO_2) and decreased by basic CSF (decreased CO_2). CSF buffering over several hours compensates acute changes cerebral blood flow caused by arterial CO_2 tension.	Whether pH-stat or α-stat methods of measuring arterial CO_2 tension are used, low cerebral blood flow can be mitigated during cardiopulmonary bypass by permissive hypercapnia.

AL Grawany

Frequency-domain NIRS and diffuse correlation spectroscopy

Frequency-domain NIRS combined with diffuse correlation spectroscopy (DCS) extends the capabilities of standard NIRS monitoring and can be utilized to measure cerebral oxygenation and hemodynamics noninvasively. CBF, cerebral blood volume (CBV), cerebral oxygen saturation (rSO_2), cerebral oxygen extraction fraction (OEF), and an estimation of cerebral metabolic rate for oxygen ($CMRO_2$) can be derived. Although primarily a research tool, its portable nature could potentially make it a clinical bedside/operating room modality, augmenting or replacing the NIRS monitors currently in use. Technical explanations of the FD-NIRS/DCS approaches are contained in recent reviews [143]. CBF measured by DCS also correlates with bypass pump flow, and TCD measured CBF velocity during full-flow bypass, low-flow bypass, selective cerebral perfusion, and DHCA [144].

Cheng and colleagues studied 31 CHD neonates (7 two-ventricle, 11 transposition of the great arteries (TGA), 13 SV) preoperatively and postoperatively and compared cerebral oxygenation and hemodynamics to 13 control neonates [145]. Preoperatively, all three CHD groups exhibited lower rSO_2 than normal controls, and the TGA and SV groups had increased OEF. The SV group had lower CBF than normal controls. Postoperatively, TGA patients had higher rSO_2 and lower CBF, OEF, and $CMRO_2$. The 2V patients had lower CBF, and the SV patients had lower rSO_2 (Figure 14.14). The same group utilized FD-NIRS/DCS to assess CBF and $CMRO_2$ during bypass in neonates and demonstrated that this noninvasive method documented the same uncoupling of CBF and $CMRO_2$ during deep hypothermia, as Greeley and colleagues measured over 30 years previously using invasive techniques (see above) [146] (Figure 14.15).

KEY POINTS: MONITORS OF CEREBRAL OXYGENATION

- NIRS technology is a well-established accurate monitor of cortical oxygen saturation.
- Accumulating data associates low rSO_2 in the perioperative period with worse neurodevelopmental outcomes.
- FD-NIRS/DCS is a noninvasive method used to assess cerebrovascular hemodynamics and $CMRO_2$.

Monitors of cerebral autoregulation

As described above, cerebral pressure and flow autoregulation is abnormal both during and after CPB in neonates and infants. Abnormal cerebrovascular pressure autoregulation in premature neonates and pediatric brain trauma patients is associated with further cerebral injury and poor outcomes [147, 148]. Outcome studies of cerebral pressure autoregulation in neonates and infants undergoing cardiac surgery with bypass are lacking, but recent developments may allow real-time bedside autoregulation monitoring and thus allow treatment strategies and facilitate outcome studies. NIRS can measure a blood volume index, which is the mathematical inversion of the optical density of light at 805 nm wavelength measure from the NIRS monitor (1-OD 805 nm). This parameter correlates with the total hemoglobin, i.e., blood volume, in the light path [149]. When correlated with mean arterial pressure derived from an arterial catheter, the hemoglobin volume index, HVx, can be derived to measure cerebral pressure autoregulation in real time, and this parameter demonstrates strong correlation with other measures of cerebral autoregulation, including laser Doppler and transcranial

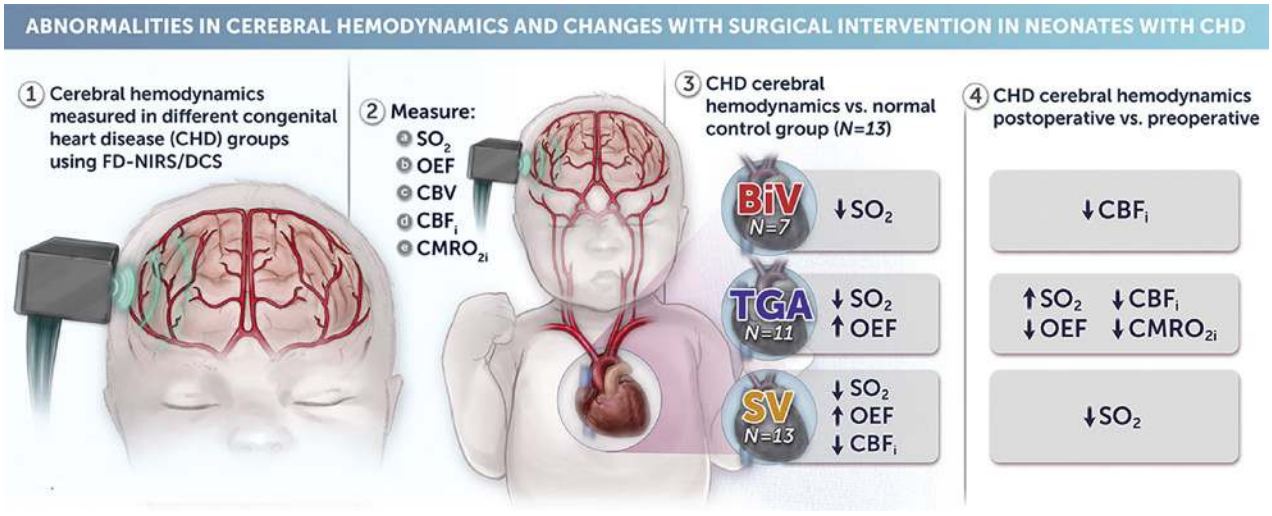

Figure 14.14 Noninvasive measures of cerebral hemodynamics and oxygenation FD-NIRS/DCS technology show significant differences between controls and CHD groups. Significant diagnosis-specific changes existed between preoperative and postoperative states. CHD, congenital heart disease; FD-NIRS, frequency-domain near-infrared spectroscopy; DCS, diffuse correlation spectroscopy; SO_2, cerebral oxygen saturation; OEF, cerebral oxygen extraction fraction; CBV, cerebral blood volume; CBFi, cerebral blood flow index; CMRO2i, ceragram metabolic rate for oxygen index; Bi-V, two-ventricle heart disease without transposition; TGA, D-transposition of the great arteries; SV, single ventricle. Figure 14.15 Coupling between cerebral blood flow and oxygen consumption during cardiac surgery. Mean nasopharyngeal temperature is overlaid at each stage. Note considerable increase in the CBFi/CMRO$_2$i ratio, or decrease in oxygen extraction, during deep hypothermia relative to the PI period. Error bars represent standard error of the mean values, blue shaded region are measurements during deep hypothermia, and red line is temperature. Asterisks denote significant differences from baseline. PI, postinduction; CBP1, first bypass period; RCP/CPB2, regional cerebral perfusion/second bypass period; RW, rewarming; PCPB, post bypass period. (Source: Ferradal et al. [146] / Springer Nature / CC BY 4.0.)

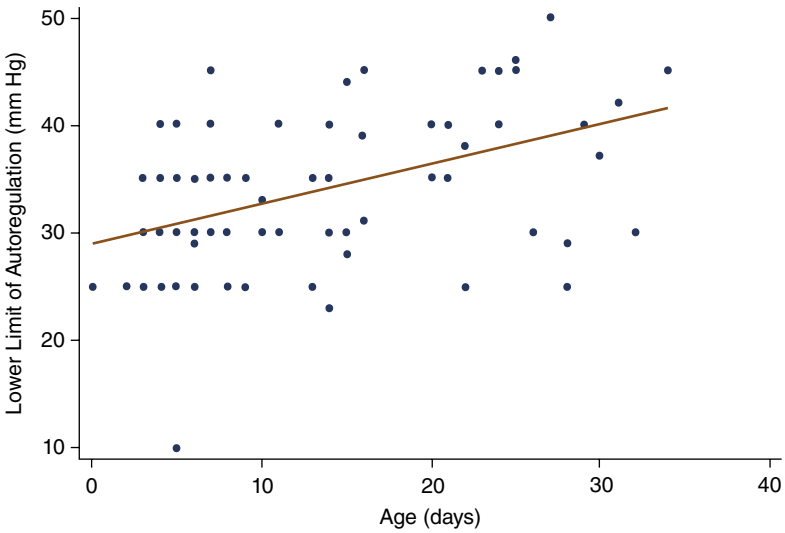

Figure 14.16 The upward trend in the first month of life for the average lower limit of autoregulation during cardiopulmonary bypass. (Source: Andropoulos et al. [151]. Reproduced with permission from Elsevier.)

ultrasound Doppler blood flow, in experimental animals [150]. HVx has a value of −1 to +1, and when autoregulation is functional, HVx has a value near zero or negative, because blood pressure and CBV are either poorly or negatively correlated. When blood pressure is outside the limits of autoregulation (either too high or too low), HVx is increasingly positive and approaches +1 because blood volume is pressure-passive, i.e., increases with increasing blood pressure and decreases with decreasing blood pressure. Because the blood volume index is already measured by NIRS monitors, efforts are under way for the FDA and other regulatory agencies to approve this monitoring modality; the advantage of this method is that no new monitoring equipment is needed, only the computer software to integrate the signals and display the HVx.

Smith and colleagues evaluated cerebral pressure autoregulation utilizing the HVx in 72 neonates undergoing surgery with bypass and assessed this parameter at different levels of hypothermia down to 18 °C [39]. Although HVx could be derived in all patients and dysautoregulation was demonstrated in all patients at hypothermia, this was confounded by the fact that mean arterial pressure decreased and exhibited collinearity with low temperature; thus, the effect of hypothermia on autoregulation could not be definitively established. In these patients, the lower mean arterial pressure limit of autoregulation ranged from 25 to 45 mmHg, with a trend upward in the first month of life [151] (Figure 14.16). Easley and colleagues measured HVx in 57 patients undergoing surgery with bypass aged from neonate to 17 years and demonstrated cerebral

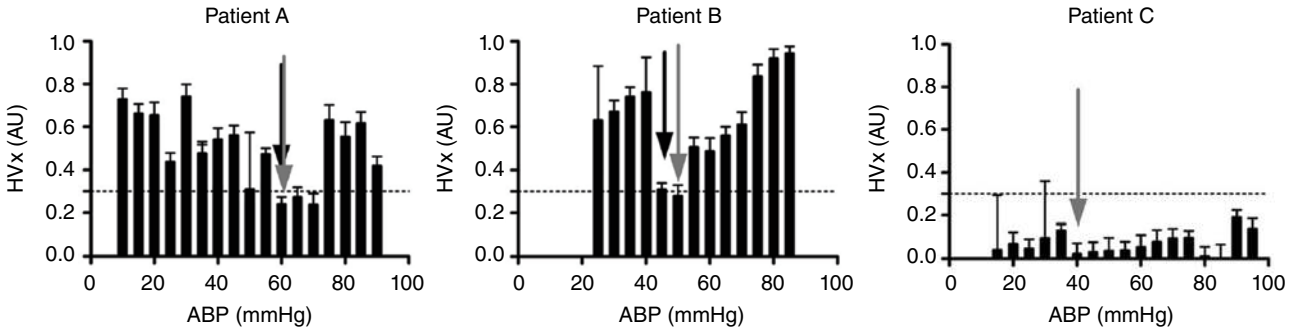

Figure 14.17 Examples of individual autoregulation curves for three different patients, one in each panel. In each graph, binned averages of the hemoglobin volume index (HVx) are plotted against arterial blood pressure (ABP) with their standard errors. The horizontal line at 0.3 for the HVx indicates the suspected threshold for loss of autoregulation. Patients were randomly selected to illustrate the identification of the lower limit of autoregulation (LLA) and the optimal arterial blood pressure (ABP opt) from the autoregulation curve. LLA is indicated with a black arrow and ABP opt with a gray arrow on each curve, as applicable. Patient A: A 7-month-old infant with Tetralogy of Fallot (TOF) undergoing complete repair. The figure demonstrates an individual's HVx curves that meet criteria for determining both an LLA and ABP opt. On the basis of the curve, the patient maintained autoregulation to an ABP of 60 mmHg, but then lost autoregulatory function with a further drop in ABP to 55 mmHg. The lowest HVx value (ABP opt) was also at 60 mmHg. Patient B: A 2-year-old child with heterotaxy undergoing bidirectional cavopulmonary shunt. The HVx curve demonstrates both LLA at 45 mmHg and ABP opt at 50 mmHg. Patient C: 3-month-old infant with TOF undergoing complete repair. This patient's HVx curve fails to meet criteria for demonstrating an LLA as all measurements demonstrate intact autoregulation. ABP opt was 40 mmHg. (Source: Easley et al. [149]. Reproduced with permission from Cambridge University Press.)

pressure dysautoregulation in many patients during CPB with an average lower limit of autoregulation of about 40 mmHg [149] (Figure 14.17). Patients with the highest peak glial fibrillary acidic protein (GFAP) (a marker of cerebral injury) values had higher peak values of the HVx, demonstrating a correlation between dysautoregulation and this marker of brain injury. Cabrera and colleagues studied 16 infants undergoing bidirectional cavopulmonary connection and reported that hypertension and elevated pulmonary artery pressure were associated with elevated HVx (cerebral pressure dysautoregulation) [152].

These studies demonstrate the potential to monitor real-time cerebral pressure autoregulation during pediatric cardiac surgery and make possible interventional outcome studies. A maneuver as simple as increasing or decreasing mean arterial pressure until intact autoregulation occurs can be compared in a randomized prospective trial to usual clinical management without autoregulation monitoring. Short-term outcomes such as neurological morbidity, MRI findings, and biomarkers of brain injury and long-term outcomes such as neurodevelopmental outcomes, can be studied. In the adult cardiac surgery population, a retrospective study demonstrated that increasing time with blood pressure below the lower limit of autoregulation was associated with major postoperative morbidity, including stroke and mortality [153]. Such a controlled trial has been performed in adults and demonstrates that when blood pressure is personalized to achieve cerebral pressure autoregulation, that postoperative delirium and memory dysfunction is reduced, although acute neurologic injury such as stroke, MRI change, and coma were not different [154]. The appeal of personalizing blood pressure to achieve autoregulation and improve outcomes is intuitive, but significant research must be done to determine whether this approach will improve neurological outcomes in infants and children [155].

KEY POINTS: MONITORS OF CEREBRAL AUTOREGULATION

- The HVx derived from NIRS can monitor pressure autoregulation in real time.
- The lower limit of autoregulation can be determined from HVx.
- Personalized blood pressure management can improve autoregulation.
- Outcome studies of autoregulation management are lacking.

Anesthetic and sedative neurotoxicity

More than 20 years ago, preclinical animal model data about neurotoxic effects of anesthetic and sedative agents that bind *N*-methyl-D-aspartate (NMDA) receptors as antagonists, and gamma-aminobutyric acid (GABA) receptors as agonists, was published [156, 157]. Increased neuroapoptosis in the developing nervous system is the predominant mechanism of injury, and this effect has been demonstrated in hundreds of preclinical publications in animal species ranging from nematodes, to rodents, to non-human primates [158]. Functional deficits in behavior, memory, and cognition have also been demonstrated. While the animal data is convincing, human data is mixed, with some observational and retrospective studies demonstrating neurodevelopmental deficits, while others do not. The recent GAS, PANDA, and MASK studies did not demonstrate a cognitive deficit (e.g., IQ) with volatile general anesthesia vs. controls for noncardiac surgery, but there were subtle decrements in behavior and executive function with a single brief exposure, and

differences in processing speed and executive function with multiple anesthetic exposure [159–162].

Primarily based on the preclinical animal data, the FDA issued a Drug Safety Communication (DSC) in 2016 warning that "repeated or lengthy (>3 hours) use of general anesthetic and sedation drugs during surgeries or procedures in children younger than 3 years . . . . may affect the development of children's brains" [162]. The labeling of all common anesthetic and sedative drugs, including volatile anesthetics, benzodiazepines, propofol, barbiturates, and ketamine, was updated to reflect this warning. Although this DSC has been controversial for many researchers and clinicians because of perceived paucity of human data, many congenital heart surgery patients are included this patient category of prolonged anesthesia at a young age. In addition, many patients receive prolonged sedation with GABA- and/or NMDA-binding agents postoperatively in the ICU. Dexmedetomidine has a different mechanism of binding as a presynaptic alpha-2 agonist and does not cause the same degree of neuroapoptosis at clinically relevant dose levels in the majority of animal studies, including non-human primates [163]. However currently, there are no published studies in infants and children to validate this experimental observation.

Data from three congenital heart surgery cohorts has been published to address the issue of anesthetic and sedative exposure and neurodevelopmental outcomes. The Texas Children's cohort of 59 neonates undergoing both SV and 2V repairs reported an association of larger total volatile anesthetic dose (MAC-hours) with lower neurodevelopmental scores at age 1 and 3 years [138]. The Children's Hospital Philadelphia cohort of 96 HLHS patients demonstrated an association with larger volatile anesthetic dose and lower full-scale IQ (FSIQ) and verbal IQ at 4 years [164]. Finally, the Western Canadian cohort of 95 neonatal cardiac surgery patients who underwent a comprehensive battery of neuropsychological tests at 4 years in multiple domains reported the number of days on chloral hydrate was associated with lower performance IQ and cumulative dose of benzodiazepines with lower visual motor integration scores [165, 166]. This study is limited primarily by the fact that drug exposure was calculated only for the first 6 weeks of life.

The large number of risk factors and the high incidence of neurodevelopmental deficits in the congenital heart surgery population make it difficult to design trials or studies of anesthetic and sedative neurotoxicity in this group because of the many confounders present in each of these patients. Whether alternative drug strategies, i.e., dexmedetomidine, would be associated with improved neurodevelopmental outcome, has yet to be studied. Despite its complexities, this area of research needs additional studies as potentially modifiable factors to improve neurodevelopmental outcome.

KEY POINTS: ANESTHETIC AND SEDATIVE NEUROTOXICITY

- GABA- and NMDA-binding sedatives and anesthetics cause neurodegeneration in animal models.
- Brief human noncardiac anesthetic exposures do not cause cognitive deficits, but have some associations with behavioral changes in some studies.
- There are two studies associating higher volatile anesthetic exposure in infancy with adverse neurodevelopmental outcomes in CHD.
- More data is needed, and the CHD population is difficult to study because of the multiple confounding factors.

Longer term neurodevelopmental testing outcomes after congenital heart surgery

The preceding discussion has focused on cerebrovascular physiology and neuromonitoring methods and acute or short-term neurological injury and outcomes. A number of longer term studies, e.g., 12 months to 16 years, have been published in the CHD population. These data are mostly generated from single-center cohorts of neonates and young infants studied prospectively after complex congenital heart surgery. There are several recent multicenter or combined studies that provide new data. These cohorts provide important insights into risk factors for the lower neurodevelopmental scores observed in 30–50% of neonates undergoing cardiac surgery, as they reach school age and beyond. The neurodevelopmental characteristics of this population often include deficits in cognitive, memory, language, fine motor, behavior, attention, and executive functioning domains, with a neurodevelopmental signature similar to that observed in former preterm infants [167]. Gross neurological deficits such as hemiparesis, choreoathetosis, and profound developmental delay are observed infrequently in the modern era [168, 169].

Boston circulatory arrest study

The BCAS is a landmark study initiated in the late 1980s that has set the standard for study of long-term neurodevelopment in a substantial cohort from a single center, with detailed neuropsychiatric testing and MRI brain imaging now reported in 16-year-old in the study. A total of 170 neonatal dextro-transposition of the great arteries (D-TGA) patients undergoing the arterial switch operation from 1988 to 1992 were enrolled and randomized to DHCA or low-flow CPB (50 mL/kg/min) as the predominant strategy. Alpha-stat management was used, and hematocrits were maintained at about 20%. The main immediate postoperative findings were a higher risk of clinical seizures (odds ratio 11.4), EEG seizures (odds ratio 2.5), longer recovery time to EEG reappearance, and higher creatine kinase brain isoform levels [54]. A total of 155 of these infants were tested at age 12 months with the Bayley Scales of Infant Development-I (Bayley-I), MDI (105.1 ± 15.0) (normal 100, SD ± 15), and PDI (95.1 ± 15.5). The use of DHCA was associated with a 6.5-point deficit on the MDI, and PDI was inversely proportional to the duration of DHCA [170]. EEG seizures were associated with lower PDI scores. At age 8 years, when multiple domains are testable, the 155 returning subjects had overall scores on the Wechsler Intelligence Scale for Children-III as follows: FSIQ, 97.1 ± 15.3; performance IQ, 94.9 ± 14.3; and verbal IQ, 99.8 ± 16.6. The presence of a VSD

was associated with lower verbal IQ scores. Academic achievement scores were generally in the normal range, although 37% were receiving remedial academic services and 10% had repeated a grade [6]. Performance on these tests was decreased when DHCA duration was >41 minutes (95% lower confidence limit, 32 minutes). The cohort as a whole was below expectations in terms of academic achievement, fine motor function, visual–spatial skills, working memory, attention, and higher order language skills. Of these subjects, 139 returned at age 16 years for further neuropsychological testing and brain MRI [71]; 65% of these adolescents utilized some form of specialized educational services, and most scores of academic achievement, memory, executive functions, visual–spatial skills, attention, and social cognition tests were all below reference population norms, mostly in the mid-90th percentile, with no association with DHCA vs. low-flow bypass group. Multivariable analysis revealed associations of parental IQ, DHCA duration, and EEG seizures with one or more neuropsychiatric outcomes. Structural MRI abnormalities, mostly evidence of remote ischemic hemorrhage, were present in 33% of the 111 subjects scanned. On quantitative MRI imaging, the arterial switch operation group as a whole demonstrated reduced fractional anisotropy in bilateral cerebral hemispheric, brainstem, and cerebellar white matter, signifying impaired microstructural development. Shorter cooling duration, higher nadir temperature, longer total ICU length of stay, and need for subsequent operations were all associated with impaired white matter development [171].

The wealth of information gleaned from the BCAS data set the standard for all subsequent single-center studies. The uniform patient group (all D-TGA, no genetic abnormalities) receiving a single corrective surgery is important for minimizing subsequent confounders. The prospective, randomized controlled intervention design, EEG, MRI, and careful serial neurodevelopmental outcomes in a large group with a high follow-up rate are unparalleled thus far in subsequent studies. BCAS also raises the issue that bypass management (i.e., alpha-stat management, rapid cooling, prolonged DHCA, hematocrit 20%) has changed significantly in many centers since the cases were done, and the long-term findings may not be the same with contemporary approaches. The infant outcome tests (e.g., Bayley Scales of Infant Development) have undergone revision and are now in their third version; there is no reliable method to translate results between versions.

Children's hospital of Philadelphia cohort

Gaynor and colleagues enrolled 550 neonates and infants <6 months of age undergoing complex CHD surgery from 1998 to 2003 in a prospective study of apolipoprotein E (APOE) genotype and neurodevelopmental outcomes [172]. APOE is important in neuronal repair and previously had been demonstrated to affect outcome in Alzheimer's disease. This cohort has yielded important information about not only APOE but also a number of other risk factors for impaired neurodevelopmental outcomes through school age. A variety of cardiac diagnoses were enrolled, including a substantial group of HLHS patients. In all 359 subjects tested at 1 year, MDI on the Bayley-II was 90 ± 15, and PDI was 78 ± 18 [173]. The APOE $\varepsilon 2$ allele was associated with significantly lower MDI and PDI scores after multivariable adjustment. Other risk factors were lower birth weight, preoperative intubation, lower hematocrit on CPB, longer postoperative length of stay, additional CPB operations, and genetic syndromes including chromosome 22q11.2 deletion syndromes. The use of DHCA was not associated with lower Bayley-II scores. At age 4 years, neurodevelopmental outcomes were tested in 381 subjects using a battery of standard tests; overall scores in the eight domains tested were within normal ranges; however, more patients had severe impairment in at least one domain than the general population. Cardiac diagnosis was demonstrated to be associated with outcomes, with HLHS patients performing worse than TGA, tetralogy of Fallot, or VSD patients without chromosomal anomalies in unadjusted analyses; these differences were less apparent after multivariable adjustment. In a separate report, EEG seizures in the perioperative period, which occurred in 11% of the cohort, were associated with worse executive function and impaired social interactions [174]. In another report of 92 of these infants who underwent DHCA, with a median of 36 minutes (range 1–132), DHCA was not associated with worse neurodevelopmental outcomes compared with those infants who had not undergone DHCA [175]. Finally, younger gestational age in this cohort was associated with worse outcomes, with 39–40 weeks' gestational age at birth performing better in multiple domains at age 4 years than those born at less than 39 weeks [176]. In a very important and novel report from this cohort, 21.6% of patients had hearing loss at age 4 years, an incidence 20-fold higher than expected in a normal population [177]. Hearing loss was associated with younger gestational age, genetic syndromes, and longer duration of hospital stay. The presence of hearing loss was associated with worse cognition, language, and attention. Possible causative factors included environmental noise in the ICU and ototoxic medications such as furosemide.

Western Canadian study

The Western Canadian Complex Pediatric Therapies Follow-up Group started prospective data collection of neonates and infants <6 weeks of age undergoing complex cardiac surgery in 1996–1999; this group has reported additional cohorts having surgery as late as 2003–2006. A variety of cardiac diagnoses were enrolled, including about one-third with HLHS and one-third with D-TGA. Their initial report of 85 infants included 67 survivors assessed at age 18–24 months with the Bayley-II [178]. The entire cohort has mean MDI of 84 ± 17 and PDI of 80 ± 22; chromosome anomaly conferred a major risk factor and was found in 10 of 67 patients, with mean MDI of 67 ± 16 and PDI of 61 ± 17. Twenty-two percent of the population had profound mental delay (MDI < 70), and 30% profound motor delay (PDI < 70). Associated factors in the multivariable analysis included duration of preoperative ventilation, chromosome anomaly, duration of DHCA and CPB, and low arterial pH and high serum lactate, all associated with significant delay on Bayley-II. This group also assessed 16 subjects with deletion of chromosome 22q11.2 (DiGeorge syndrome), matched for cardiac lesion, socioeconomic status, and year of operation, with 16 patients without 22q11.2 deletion [179]. The 22q11.2 deletion patients (six interrupted aortic arch, six truncus arteriosus, four tetralogy

of Fallot) had lower MDI (66.1 ± 10.6 vs. 86.3 ± 14.6, $P < 0.001$) and PDI (55.5 ± 9.4 vs. 82.3 ± 14.3, $P < 0.001$). In a separate report of this cohort in 61 patients at age 5 years, FSIQ was 89 ± 20, verbal IQ was 90 ± 20, performance IQ was 90 ± 20, and visual motor integration (VMI) was 87 ± 17 [180]. The MDI as assessed at 18–24 months strongly predicted the FSIQ at 5 years ($r = 0.817$).

The Western Canadian Group has also reported on a later cohort, with complex cardiac surgery <6 weeks of age from 2003 to 2006, associating sedative, anesthetic, and analgesic drug exposure and neurodevelopmental outcomes [165, 166]. They calculated the cumulative dose during the first 6 weeks of life for volatile anesthetics, opioids, benzodiazepines, ketamine, and chloral hydrate. At age 18–24 months, they administered Bayley-II or Bayley-III (Bayley-III after July 2004), and adaptive behavior and language were also assessed by parent questionnaire. Multivariable analysis with the drug exposure variables, as well as a number of patient and surgical variables, was performed, with primary outcome being significant mental or motor delay <70 on the Bayley scales, vocabulary delay <15th percentile, and adaptive behavior scores. In all, 135 subjects were enrolled in the study; 19 died, 16 had chromosomal anomalies, and five were lost to follow-up, leaving 95 with neurodevelopmental assessments. Forty-eight percent of patients were D-TGA having undergone arterial switch, 24% were HLHS patients, and the remainder were other 2V complete repairs. The overall cohort had mental and motor scores below the population norms but within 1 SD of normals; 11% had mental delay and 7% motor delay (in the normal population this is 2.5%), while 31% had vocabulary delay (normal is 15%). All patients received volatile agents, benzodiazepines (median 16 days), and opioids (median 15 days); 73% received chloral hydrate, and 56% received ketamine. There was no association with anesthetic or sedative drug dose and profound delays. Increasing days of ventilation, older age at surgery, lowest PaO_2, use of DHCA, and lower maternal education were all associated with significant delays.

Hearts and minds study

The Heart and Minds Study is a prospective longitudinal cohort study of infants <8 weeks of age undergoing cardiac surgery with or without CPB between 2005 and 2008 in Australia and New Zealand [22]. Subjects had preoperative and postoperative brain MRI, and there was data collection and 2-year neurodevelopmental outcome testing using the Bayley-III. About half of the patients were SV palliations, and half were complete 2V repairs. The overall neurodevelopmental scores of the 122 subjects with follow-up at age 2 years were as follows: cognitive, 94 ± 15; language, 94 ± 16; motor, 97 ± 12. The primary aim of the study was to determine the association of WMI with patient and surgical characteristics, and neurodevelopmental outcome. There was no association of WMI with Bayley-III scores; however, structural brain immaturity on MRI was associated with lower neurodevelopment.

Milwaukee cohort

Hoffman and colleagues reported on a cohort of HLHS patients undergoing stage I palliation in 2002–2005, and then neurodevelopmental assessment at age 4–5 years [181]. The primary aim of the study was to determine the association of perioperative regional cerebral oxygen saturation (rSO_2), measured by NIRS, with neurodevelopmental outcomes. Of 51 patients entering the study, 21 had complete neurodevelopmental assessment (48% of survivors). The composite neurodevelopmental outcome of cognition, language, attention, and VMI was 97.6 ± 9.6, was within normal population ranges, and with low performance frequencies also not different from reference population ranges. Patients demonstrating low or abnormal VMI had lower rSO_2 (63.6 ± 8.1 vs. 67.8 ± 8.1, $P = 0.026$) in the first 48 postoperative hours. They also spent more time at $rSO_2 < 55$ and 45% levels than those with normal VMI. Peripheral oxygen saturation (SaO_2) was also lower in these patients; however, other physiological variables (mean arterial pressure,41, SvO_2, central venous pressure, hemoglobin, blood gas parameters) were not different. The breakpoint for lower VMI score in the multivariate model was an rSO_2 of 55%. This team also reported 178 children from their institution followed for 36 months with the BSID-III performed at 6-month intervals after neonatal surgery. At 6 months, SV and 2V patients had Cognitive and Language scores in the normal range, with means below population norms, and these scores remained relatively constant through 36 months. Motor scores started at 0.5–1 SD below normal at 6 months but increased progressively for both SV and 2V patients and were in the normal range at 36 months. In contrast, patients with a genetic syndrome started 1–2 SD below normal in all three domains at 6 months; their Cognitive and Language scores decreased, and Motor scores were constant. By 36 months, all three means were about 2 SD below population norms [139] (Figure 14.18).

Texas children's hospital cohort

The Texas Children's Hospital cohort of neonates undergoing complex cardiac surgery at less than 30 days of age between 2005 and 2011 has been the subject of several neurodevelopmental outcomes publications [8, 18, 138, 182, 183]. Of 93 subjects entering two separate prospective studies, 59 (71%) survivors underwent 12-month Bayley-III testing; 47% of these patients had HLHS. Cognitive score was 102.1 ± 13.3, language score was 87.8 ± 12.5, and motor score was 89.6 ± 14.1. The major findings in these reports after multivariable analyses were as follows:

- Longer duration of regional cerebral perfusion was not associated with lower Bayley-III scores, but longer DHCA was associated with lower scores.
- New postoperative MRI brain injury, longer ICU length of stay, lower preoperative rSO_2, and chromosome anomalies were associated with lower Bayley-III scores.
- Larger volatile anesthetic agent exposure was associated with lower cognitive scores.

By age 36 months, Bayley-III testing of this cohort revealed Cognitive, Language, and Motor score means within normal ranges, with SV patient means for Motor still normal but about 5 points lower. By 5 years, on a full battery of tests, the mean IQ, language, and behavior scores were in the normal range; motor skills for SV patients were about 2/3 SD below normal means, and VMI about ½ SD below normal means [183].

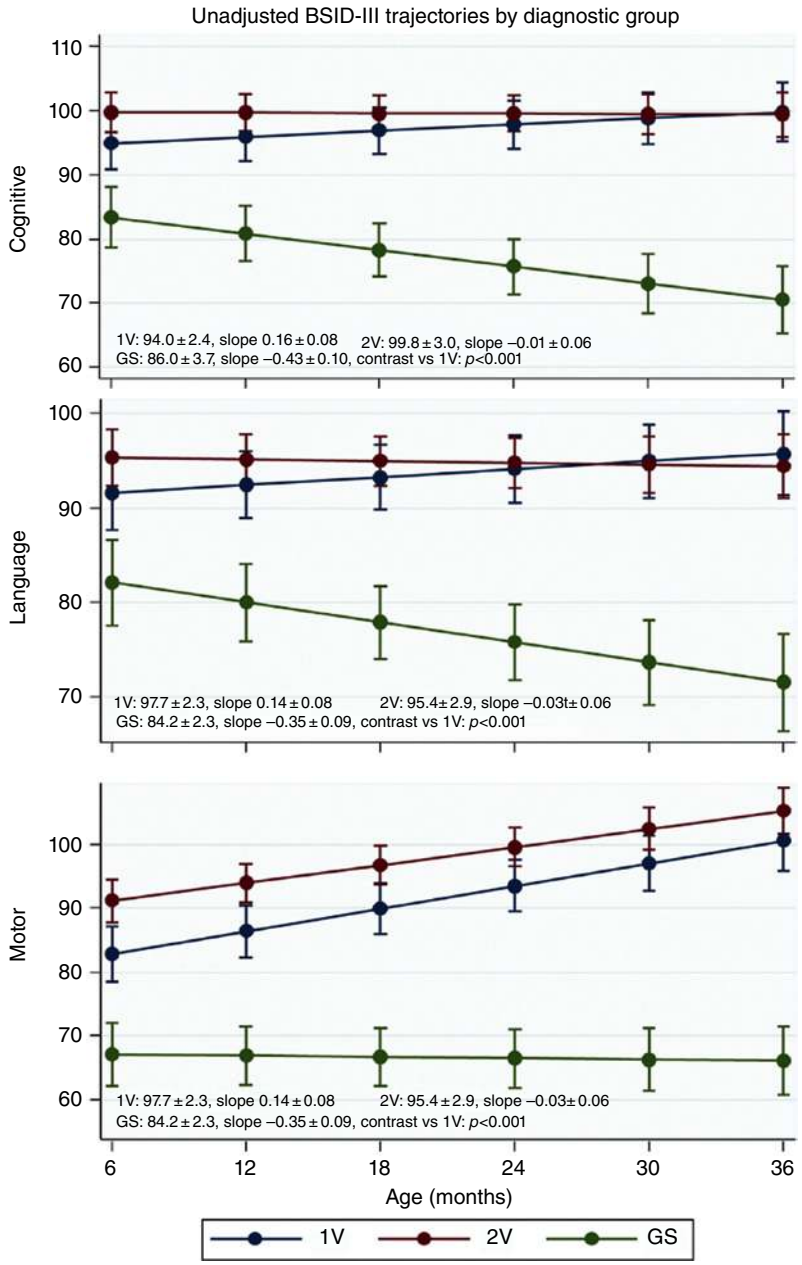

Figure 14.18 Change in Bayley Scales of Infant and Toddler Development, 3rd Edition (BSID-III) score over time by patient diagnostic category of 1 ventricle (1V, blue), two-ventricles (2V, red), and genetic syndrome (GS, green). The linear mixed-effect model parameter estimates and 95% confidence intervals are shown as symbols and range bars. (Source: Hoffman et al. [139]. Reproduced with permission from Elsevier.)

Single ventricle reconstruction trial

The Single Ventricle Reconstruction (SVR) Trial is a multicenter study of stage I palliation for HLHS randomizing surgery to systemic to pulmonary artery shunt vs. right ventricle to pulmonary artery shunt [184]. Operations were performed between 2005 and 2008 in 15 centers. Neurodevelopmental outcomes were assessed with the Bayley-II at a mean of 14.3 ± 1.1 months of age. In all, 314 patients were assessed at that time (86% of transplant-free survivors), and mean MDI was 89 ± 18 and PDI was 74 ± 19, both profoundly lower than reference population norms. Multivariable regression models determined that site of surgery, birth weight less than 2,500 g, longer length of stage I hospitalization, and greater number of complications were associated with lower PDI scores. Lower MDI scores were associated with lower birth weight, genetic syndrome or other anomalies, lower maternal education level, longer days on ventilation, and greater number of complications. Intraoperative variable data collection was limited, but none of these variables (DHCA vs. regional cerebral perfusion, alpha-stat vs. pH-stat, hematocrit) were associated with Bayley-II outcomes. By age 3 years,

mean scores for each domain on a parental questionnaire of neurodevelopment were significantly lower than those of the normal control population. The percentage of children with delayed scores (>2 SD below the mean) was 20% for the Communication Scale, 30% for the Gross Motor Scale, 35% for the Fine Motor Scale, 24% for the Problem Solving Scale, and 17% for the Personal-Social Scale (about 2% would be expected in a normal population). Delay was detected in at least one area for 51% of the cohort [185].

An assessment of behavioral outcomes at 6 years in the SVR cohort reported approximately three times higher risk of impaired adaptive behavior skills and that lower socioeconomic status was associated with lower fine motor, problem-solving, adaptive behavior, communication, and functional status [186, 187]. It should be noted that of 555 subjects entered into the SVR trial, 41% had died by age 6 years, and another 4% required cardiac transplantation; emphasizing the high-risk nature of this patient population for ongoing threats to normal neurodevelopment. Type of shunt does not appear to have any effect on any long-term clinical or neurodevelopmental outcome.

International cardiac collaborative on neurodevelopment (ICCON) investigators cohort

The ICCON Investigators group was recently formed and has pooled early neurodevelopmental outcomes results for complex neonatal and young infancy cardiac surgery with operations occurring between 1996 and 2009 [188]. Data were analyzed from 23 institutions utilizing Bayley-II testing performed on patients aged 6–30 months. The mean age of assessment was 14.5±3.7 months, and the overall scores for the 1,770 patients were MDI 88.2±16.7 and PDI 77.6±18.8. Important findings were that cardiac class IV (SV patients with aortic arch obstruction, e.g., HLHS) was significantly more common in the later years of the studies. In the multivariable analysis, patient factors were evaluated, and cardiac diagnosis (class IV), genetic anomaly, lower maternal education, male gender, and lower birth weight were all associated with lower scores. After this adjustment, mean Bayley-II scores did increase significantly over time, with mean MDI and PDI scores increasing by approximately 0.4 points/year over the 14 years represented in the study (Figure 14.19). Longer total support time (CPB, DHCA, and SCP), use of ECMO, need for cardiopulmonary resuscitation (CPR), and longer duration of ICU stay were all associated with lower MDI and PDI scores.

Zurich cohort

Latal and colleagues describe a single-center cohort of 233 patients undergoing SV and 2V surgery with bypass at median age 3–4 months, who had neurodevelopmental assessments at age 6 years [189]. Of these, 64 (27%) patients had a recognizable genetic syndrome, including trisomy 21, microdeletion of chromosome 22q11.2, VACTERL association, CHARGE syndrome, and others. Median total IQ for nongenetic disorder group was 95 (range 47–135), and

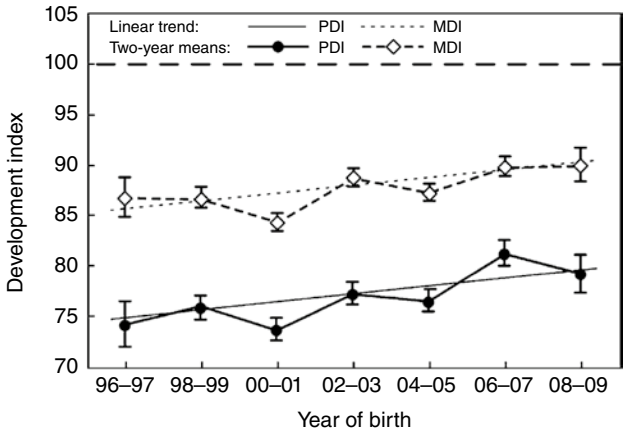

Figure 14.19 Standardized Psychomotor Development Index (PDI) and the Mental Development Index (MDI) using the Bayley Scales of Infant Development, 2nd Edition, from the ICCON Study. Means are displayed by year of birth category. The standardized means plot predicted PDI and MDI and standard error bars based on a model with year of birth category adjusting for center, patient and preoperative factors, operative management factors, and postoperative events at the mean value of the covariates. Overlaid are standardized means plots based on continuous year of birth. The dotted line represents the normative mean of 100 for both PDI and MDI. (Source: Gaynor et al. [188]. Reproduced with permission from Elsevier.)

for the genetic disorder group was 55 (range 17–115), $p < 0.01$. Median scores on tests of language, reasoning, processing speed, and number recall were in the normal range for nongenetic syndrome patients, and 0.6–1.2 SD below norms for the genetic syndrome patients, with all findings significantly different. In multivariable analysis, genetic syndrome, longer ICU stay, lower birth weight, postoperative seizures, and lower socioeconomic status were associated with poor neurodevelopmental outcomes.

The studies reviewed in this section give an emerging, if incomplete, picture of risk factors for the now very well-established lower neurodevelopmental outcomes in infants undergoing congenital heart surgery. Many recent reports emphasize significantly lower testing scores during infancy in most all cohorts; however, there are now more reports at age of school entry or later. These reports at older ages give a profile of the preschool or school-aged child with subtle impairment in a number of domains, including executive functioning, language, attention, fine motor function, VMI, and reasoning. As noted earlier, this profile is not dissimilar to the premature neonate. Both groups have in common structural and microstructural brain immaturity and a propensity to brain injury, with WMI being the most common. Comparison of outcomes over time is difficult because of different testing strategies utilized in different cohorts, [190] but there appears to be a trend of improving early outcomes, albeit in a patient population increasingly skewed toward more complex SV lesions. Debate is ongoing about the proportion of risk accrued to nonmodifiable (i.e., innate) patient factors vs. modifiable ones (i.e., CPB techniques, neurological monitoring, anesthetic and sedative

techniques, and ICU strategies). Interesting new data about association of potentially neurotoxic compounds in the perioperative environment (cyclohexanone, phthalates in plastics) with lower neurodevelopment scores after infant cardiac surgery bears further consideration [191, 192]. Finally, the effect of early childhood intervention and a stimulating home environment has begun to be studied as a means to take advantage of the potential for neuroplasticity in these infants [193, 194].

The multivariable models all have significant limitations, and the majority explain only 20–40% of the variation in the neurodevelopmental outcome scores; only a few models explain >50%. Further complicating the concepts of nonmodifiable factors may be emerging strategies for fetal intervention, by both catheter and medical interventions, that could improve both the cardiac and cerebral abnormalities observed in neonates with CHD. The very strong risk factor that most genetic syndromes confer for adverse neurodevelopmental outcomes is increasingly clear. This becomes more important as cardiac surgery is offered to a broader population of patients with genetic syndromes, i.e., trisomy 13 and 18; and as sophisticated genetic testing (whole exome and genome sequencing) uncovers additional abnormalities associated with neurodevelopmental problems [195]. (See Chapter 8, Genetic Syndromes). Newer approaches to modeling the many complex risk factors include artificial intelligence/machine learning algorithms that may be able to better account for small sample sizes with multiple risk factor variables [196]. Small single-center studies are still the predominant publication type for neurodevelopmental outcomes. The pitfalls of drawing conclusions from multivariable analyses, i.e., frequency of Type I and Type II errors, from small data sets, are evident. Multicenter databases, combined analyses, meta-analyses, and multicenter prospective studies with much larger sample sizes, and standardized outcome measures will be important to move this field forward with higher quality evidence to support beneficial treatment strategies. Table 14.3 summarizes data from the cohorts reviewed earlier, and Table 14.4 presents the modifiable vs. nonmodifiable risk factors published in the studies reviewed here, and lists possible strategies for intervention, where applicable [197, 198].

KEY POINTS: COHORT STUDIES OF NEURODEVELOPMENTAL OUTCOMES

- Most single-center cohort studies demonstrate decrements in motor performance which improves over time.
- Cognitive deficits are less severe, but performance is not normal in most cohorts.
- Language, executive function, and behavior are also not normal in most cohorts.
- Genetic syndromes are a significant risk factor for neurodevelopmental problems.
- Larger patient populations and standardized outcomes are needed to improve data quality.

Conclusions

> Truth in medicine is an unattainable goal, and the art as described in books is far beneath the knowledge of an experienced and thoughtful physician.
>
> Muhammad Ibn Zakariya Al-Razi, *c.* 900 BCE

The neurologic vulnerability of children with CHD has been well characterized. White matter lesions suggestive of impaired oxygen delivery to watershed regions of the brain are the most common perioperative-acquired injury seen on MRI. The neurodevelopmental abnormalities of children with CHD are often subtle disorders of intellect, attention, impulsivity, and executive functioning, which impact the quality of life of survivors of critical heart disease in infancy. The principles of CBF and oxygen delivery are equally well characterized, but the strategies to optimize these parameters during CPB are a subject of vigorous debate. A summary of the advantages and disadvantages of the neuromonitoring modalities discussed in this chapter is given in Table 14.5.

Does a neuroprotective strategy during CPB improve outcome?

Scientific investigation has failed to delineate an evidence-based neuroprotective practice for many of the most basic aspects of care during cardiac surgery and CPB, including the use of circulatory arrest or selective cerebral perfusion, and whether and how to monitor the brain during and after CPB. The perspective presented in this chapter emphasizes the physiologic principles relevant to neuroprotection, which are often the only available rationale for decisions that have to be made for critically ill children with CHD.

Single-center studies of cerebral oximetry where goal-directed therapy with cerebral oximetry monitoring is either embraced or rejected cannot show the effect of these practice shifts for lack of a comparison group. Outcomes from the Texas Children's Hospital for neonates requiring cardiac surgery have been studied for both MRI-detected injury and neurocognitive performance. The CPB strategy at Texas Children's Hospital is highly standardized to the use of goal-directed oxygen delivery support and selective perfusion techniques guided by multimodal neuromonitoring, including both reflectance NIRS and TCD insonation [199]. The rates of new neurologic injuries after surgery with this practice compare favorably with published studies of similar outcome measures. A varied critical lesion infant cohort, including HLHS, TGA, truncus arteriosus, and interrupted aortic arch, demonstrated a 36% new MRI injury rate, with only 16% showing new WMI (see Figure 14.2 for comparison data) [17]. For the highest -risk neonates requiring arch reconstruction, the duration of CPB and duration of selective perfusion were both free from association with low 12-month developmental score in any of the three domains tested: cognitive, motor, and language. The duration of circulatory arrest was, however, significantly associated with decreased cognitive performance at 12 months [8]. Thus, the goal-directed strategy, utilizing neuromonitoring, is a safe option for the management of CPB in neonates, but has not been shown to be superior to either circulatory arrest or nonmonitored management in a randomized setting.

Table 14.3 Summary of major neurodevelopmental outcomes Cohorts after complex infant cardiac surgery

Cohort (references)	N	Single (S) or multi-center (M)	Years of surgery	Age at follow-up	ND outcomes	Major associations
Boston circulatory arrest study [6, 54, 71, 170, 171]	155	S	1988–1992	1, 8, 16 years	MDI 105, PDI 95 (1); FSIQ 97, PIQ 95, VIQ 100; adolescents with most scores mid-90th percentile	Prolonged DHCA with outcomes at 1 and 4 years; parental IQ, DHCA duration, EEG seizures at 16 years
Philadelphia APOE study [172–177]	381	S	1998–2003	1, 4 years	MDI 90, PDI 78; 92–105 on 8 domains at 4 years, mean 97	APOE ε2 allele; lower BW, pre-op intubation, lower CPB hct, LOS, additional CPB operations, chromosome/genetic anomaly, EEG seizures, younger GA, cardiac diagnosis (HLHS), hearing loss; DHCA use not associated
Western Canadian Outcomes Group I [178–180]	61	S	1996–1999	18–24 months, 4–5 years	MDI 84, PDI 80; FSIQ 89, VIQ 90, PIQ 90, VMI 87	Chromosome anomaly, pre-op ventilation, duration of DHCA and CPB, acidosis, lactate
Western Canadian Outcomes Group II [165, 166]	95	S	2003–2006	18–24 months, 4–5 years	MDI 86, Cog 98; PDI 85, Motor 95	Days of ventilation, older age, low PaO_2, use of DHCA, lower parental education; days of chloral hydrate, cumulative dose benzodiazepines
Hearts and minds study [22]	122	M (2)	2005–2008	2 years	Cog 94, Lang 94, Motor 97	Brain immaturity
Milwaukee HLHS cohort [181]	21	S	2002–2005	4–5 years	Cognitive IQ 95, attention 107, language 95, VMI 93	rSO_2, SaO_2
Milwaukee cohort II-SV, 2V, genetic syndromes [139]	178	S	2007–2012	6–36 months	36 months outcomes: SV/2V Cog 100, Lang 94–95, Motor 100–105; Genetic Syndrome: Cog 70, Lang 72, Motor 67	rSO_2
Texas children's hospital cohort [8, 18, 151, 182, 183]	59	S	2005–2011	12 months, 36 months, 5 years	12 months: Cog 102, Lang 88, Motor 90; 36 months: Cog 97, Lang 95, Motor 98; 5 years: IQ 98, Lang 98, Motor 94, behavior 96	Volatile anesthetic exposure, ICU LOS, chromosome anomaly, MRI brain injury, rSO_2, DHCA; longer RCP not associated
Single ventricle reconstruction trial [184–187]	314	M (15)	2005–2008	14 months, 3 years, 6 years	MDI 89, PDI 74; 3–6 years: 10–15× higher percentage of delayed language, motor, problem-solving, social problems	BW, site of surgery, LOS, complications, chromosome anomaly, parental education, medical complications, SES
International cardiac collaborative on neurodevelopment [188]	1,770	M(23)	1996–2009	6–30 months	MDI 88, PDI 78	Later year of surgery, cardiac class, genetic anomaly, lower BW, parental education
Zurich cohort [189]	233	S	2004–2009	5–7 years	IQ 95 nongenetic, 55 genetic; Verbal, language, reasoning, processing speed: 93–103 nongenetic, 96–91 genetic	Longer ICU LOS, lower BW, seizures, lower SES

MDI, Bayley Scales of Infant Development-II Mental Development Index; PDI, Bayley Scales of Infant Development-II Psychomotor Development Index; Cog, Lang, Motor, Bayley Scales of Infant Development-III cognitive, language, and motor composite scores. (1) BCAS used Bayley-I. ICU, intensive care unit; LOS, length of stay: MRI, magnetic resonance imaging; EEG, electroencephalogram; rSO_2, regional cerebral oxygen saturation; BW, birthweight; GA, gestational age; VMI, visual motor integration; FSIQ, full-scale intelligence quotient; VIQ, verbal intelligence quotient; PIQ, performance intelligence quotient; DHCA, deep hypothermic circulatory arrest; RCP, regional cerebral perfusion; SES, socioeconomic status.

Table 14.4 Modifiable and Nonmodifiable Published Risk Factors for Lower Neurodevelopmental Outcome Scores after Infant Congenital Heart Surgery

Nonmodifiable Factors	Factor (Example)	Potential interventions
	Cardiac diagnosis (HLHS)	??Fetal catheter intervention; maternal O_2 administration
	Genetic anomaly (22q11.2)	
	Parental education/SES	
	Birthweight	
	Prematurity	
	Brain immaturity	??Maternal progesterone [197, 198]
	Gender	
Modifiable factors		
	Use and duration of DHCA	Avoid/limit DHCA duration [6]
	Use of RCP	Use RCP in lieu of DHCA [199]
	CPB hematocrit	Maintain >24% [46]
	Low rSO_2	Intervene <50%
	MRI brain injury	Avoid/limit DHCA duration [22]
	Elective delivery <39 weeks GA	Avoid [176]
	ICU LOS	Early extubation; minimize sedation [182]
	Seizures	Benzodiazepines [111]
	Anesthetic technique	Limit volatile anesthetic exposure, ??dexmedetomidine [182]
	Low cardiac output/acidosis/lactate	Surgical, anesthetic, ICU strategies
	Low PaO_2	Oxygen delivery strategies; early surgical intervention

Nonmodifiable factors could potentially be modifiable; experimental interventions are listed. HLHS, hypoplastic left heart syndrome; 22q11.2, partial deletion chromosome 22; SES, socioeconomic status; DHCA, deep hypothermic circulatory arrest; RCP, regional cerebral perfusion; rSO_2, regional cerebral oxygen saturation; MRI, magnetic resonance imaging; GA, gestational age; ICU, intensive care unit; LOS, length of stay.

Table 14.5 Practical advantages and disadvantages of specific neuromonitoring modalities

Monitor	Advantages	Disadvantages
Electroencephalograph	Detects subclinical seizures and confirms electrical silence during deep hypothermia.	Requires expertise for interpretation; cumbersome array of electrodes.
Transcranial Doppler	Allows for assessment of cerebral blood flow (velocity) during critical stages of cardiopulmonary bypass, especially selective perfusion.	Technically challenging; flow velocities are dependent on the angle of insonation, which can be difficult to stabilize.
Jugular venous oximetry	Gold standard measurement of cerebral venous oxygen content.	Requires expertise to place the catheter in the jugular bulb; invasive to the cephalad venous drainage system in pre-Glenn patients.
Near-infrared spectroscopy (NIRS)	Noninvasive measure of cortical blood oxygenation; technically easy to apply with a stable signal. Most widely used and familiar neuromonitor in the cardiac patient.	Practical limitations are rare; disposable sensors are costly. Most centers that do not use reflectance NIRS do so for lack of level III outcome evidence.

Introduction

Currently, most institutions use a combination of imaging modalities, including echocardiography, cardiac catheterization and angiography, computed tomography (CT), and cardiac magnetic resonance (CMR), for the comprehensive diagnostic evaluation of patients with congenital heart disease (CHD). Transesophageal echocardiography (TEE) has evolved over time to become a critically important cardiovascular imaging modality that has major benefits, particularly in the perioperative setting.

Since the introduction of TEE in the late 1980s, it has proven useful as a diagnostic and monitoring tool in adult patients during cardiac and noncardiac surgery. Until the early 1990s, intraoperative TEE in infants and small children was not feasible, as TEE probes of a suitable size were unavailable. Advances in ultrasonography technology, specifically the miniaturization of imaging probes, have since permitted the safe use of TEE in these patients.

Most cardiac centers currently consider TEE to be the standard of care for assessing the adequacy of surgical interventions in children and adults with CHD. This imaging approach can immediately detect suboptimal surgical results, thus improving clinical outcomes by avoiding subsequent reoperations and reducing overall morbidity, mortality, and costs. The use of TEE in environments such as the cardiac catheterization laboratory, electrophysiology suite, and intensive care unit (ICU) also significantly facilitates the management of patients with CHD. Although TEE is not commonly used for purely diagnostic indications in children, many adults with CHD and challenging images benefit significantly from this use of TEE.

Epicardial echocardiography (E-echo), which directly places the probe on the heart surface, provides an option to image the heart when TEE is unavailable or contraindicated, or when this modality can provide information that complements the TEE findings in the operating room or ICU.

This chapter focuses on the use of TEE and E-echo for monitoring and assessment in CHD patients, highlighting these modalities' many benefits and roles in clinical practice. The emphasis is on intraoperative use, as this is the most common application of the technology in CHD patients.

Indications for TEE in CHD

Echocardiography is the preferred imaging modality for the initial diagnostic assessment and serial follow-up of patients with CHD. Transthoracic echocardiography

Anesthesia for Congenital Heart Disease, Fourth Edition. Edited by Dean B. Andropoulos, Emad B. Mossad, and Erin A. Gottlieb.

(TTE) provides excellent definition of cardiovascular anatomy in most patients. In fact, the exceptionally high resolution of TTE imaging in infants and young children with CHD is often sufficient to plan medical and surgical management. Published standards exist for the echocardiographic assessment of pediatric and adult patients with CHD, including TTE, TEE, quantification, and 3D imaging [1–5].

Despite the merits of TTE, its technical limitations result in suboptimal imaging in patients with poor windows caused by obesity, mechanical ventilation, and prior or recent cardiac surgery. TEE overcomes many of these limitations and can be extremely helpful when other imaging approaches, including TTE, provide insufficient information or there is a need to answer important diagnostic questions. The portability of TEE makes it easy to perform in various settings. TEE in the patient with CHD is often an adjunct to other diagnostic studies and, as such, should complement, but not substitute for, a complete TTE examination.

Several professional societies in North America and other countries have proposed indications for the use of TEE [3, 6–9]. Guidelines published by the American Society of Echocardiography (ASE) in 2005 and 2019 address specific indications for TEE in pediatric patients and in all patients with CHD [5, 10]. These documents describe three major categories of indications for TEE in CHD patients: diagnostic assessment, perioperative evaluation, and related to percutaneous interventions (Table 15.1).

Outpatient TEE is a routine diagnostic tool used in many centers that care for adult patients with cardiovascular disease, including CHD, because transthoracic imaging becomes more challenging and less revealing as patients reach adulthood [11]. The TEE modality plays an important role in this setting, as congenital anomalies are highly variable in presentation. The benefits of TEE include the detailed evaluation of primary structural malformations, secondary compensatory cardiovascular changes, associated complications, and functional and hemodynamic consequences. The proximity of the imaging probe to the back of the heart provides optimal visualization of cardiovascular structures. Overall, TEE is superior to TTE for diagnosing specific pathologies involving the aorta (Ao) and left atrial appendage (LAA) and for evaluating prosthetic heart valves, native valve masses, and complications resulting from endocarditis, including vegetations, abscesses, and fistulae [3]. It is the imaging approach of choice to exclude thrombus before performing elective cardioversion in most patients with atrial rhythm disturbances. The TEE imaging approach is also useful in evaluating potential cardiac sources of embolism, such as a patent foramen ovale (PFO) [12]. The modality can also enhance the assessment of intracardiac or extracardiac baffles in patients who have undergone Fontan, Senning, or Mustard procedures [13, 14].

Intraoperative evaluation represents a frequent application of TEE and has the following goals [15]:

- Confirm and refine the preoperative diagnosis
- Detect new or unsuspected pathology
- Adjust the anesthetic and surgical plan
- Assess the results of the surgical intervention

Table 15.1 Indications for transesophageal echocardiography (TEE) in the patient with congenital heart disease (CHD)

Diagnostic indications
• Patient with suspected CHD and nondiagnostic transthoracic echocardiography (TTE)
• Presence of patent foramen ovale (PFO) with and without agitated saline contrast and direction of shunting as possible etiology for stroke
• Evaluation for cardiovascular source of embolus with no identified noncardiac source
• Evaluation of intracardiac or extracardiac baffles after the Fontan, Senning, or Mustard procedure
• Suspected acute aortic pathology, including, but not limited to, dissection/transection (e.g., Marfan syndrome, bicuspid aortic valve, coarctation of the aorta)
• Intracardiac evaluation for vegetation or suspected abscess
• Evaluation for intracardiac thrombus prior to cardioversion for atrial flutter/fibrillation and/or radiofrequency ablation
• Pericardial effusion or cardiac function evaluation and monitoring postoperative patient with open sternum or poor acoustic windows
• Evaluating status of prosthetic valve in the setting of inadequate TTE images
• Reevaluation of prior TEE finding for interval change (e.g., resolution of thrombus after anticoagulation, resolution of vegetation after antibiotic therapy)
Perioperative indications
• Immediate preoperative definition of cardiac anatomy and function
• Postoperative surgical results and function
• Intraoperative monitoring of ventricular volume and function
• Monitoring of intracardiac/intravascular air and adequacy of cardiac de-airing
TEE-guided interventions
• Guidance for placement of occlusion device (e.g., septal defect, Fontan or intra-atrial baffle fenestration)
• Guidance for blade or balloon atrial septostomy
• Guidance for creation/stenting of interventricular communication
• Guidance during percutaneous valve interventions
• Guidance during radiofrequency ablation procedure
• Assessment of results of minimally invasive surgical incision or video-assisted cardiac procedure
• Guidance during placement of catheter-based cardiac assist device (e.g., Impella heart pump)

Source: Puchalski et al. [5]. Reproduced with permission of Elsevier.

A summary of the indications in both adults and children with CHD includes [5]:

- All open-heart and most thoracic aortic surgical procedures
- Surgical repair of most congenital heart lesions that require cardiopulmonary bypass (CPB)
- Surgery to treat significant residual abnormalities, such as outflow tract obstruction, valve regurgitation or stenosis, or intracardiac communications

TEE may provide significant benefits in patients with CHD undergoing cardiac catheterization procedures, such as device closure of intracardiac communications (atrial septal defects [ASDs] or ventricular septal defects [VSDs]), balloon valvuloplasty, perforation of the atretic pulmonary valve, and atrial septostomy [16–19]. Likewise, TEE can be extremely

AL Grawany

useful during electrophysiologic procedures by guiding catheter placement and assisting with ablation therapies [20, 21]. In these various applications, TEE can offer valuable information that facilitates planning, refinement, and, upon completion of the intervention, real-time assessment of the results.

Despite its considerable merits, TEE has inherent limitations, including the following:

- Imaging constraints within the gastrointestinal tract, resulting, in some cases, in suboptimal evaluation of structures or Doppler angles of interrogation
- Reduced far-field imaging of anterior structures compared with TTE
- Semi-invasiveness, often necessitating sedation or general anesthesia, with associated risks
- Suboptimal examination conditions related to patient or environmental factors, such as limited time to perform a comprehensive study, ambient lighting, and electrocautery interference

KEY POINTS: INDICATIONS FOR TEE

- TTE adequately characterizes congenital cardiovascular malformations in most patients, particularly in children.
- TEE overcomes many of the limitations of TTE imaging, including suboptimal windows caused by obesity, mechanical ventilation, and previous cardiac surgery.
- The main indications for TEE include diagnostic assessment, perioperative evaluation, and guiding percutaneous interventions.
- Perioperative use represents the most common application of TEE in the patient with CHD.
- In the patient with CHD, TEE should complement, not replace, a complete TTE examination.

Contraindications to TEE

Before using transesophageal imaging, it is prudent to carefully consider the indications, exclude contraindications, obtain informed consent, and completely review relevant clinical information, including all available echocardiographic studies and other diagnostic data. Given the potential risks associated with this semi-invasive procedure, the need for TEE requires judicious decision-making for every patient. In any clinical situation in which safety concerns exist, one should consider alternate imaging modalities such as E-echo, discussed later in this chapter.

General contraindications to TEE include esophageal pathology, severe respiratory decompensation, and inadequate control of the airway (Table 15.2) [3, 5]. The risk-to-benefit ratio for TEE warrants cautious assessment in patients with cervical spine injury or deformity and those with severe coagulopathy. The presence of a gastrostomy feeding tube often necessitates deferring the transgastric (TG) and deep transgastric (DTG) examinations. Although there is no established timing for safe esophageal instrumentation after esophageal surgery, anecdotally, many children have undergone TEE imaging several months or years later without notable ill effects.

Table 15.2 Contraindications to transesophageal echocardiography

Absolute
• Unrepaired tracheoesophageal fistula
• Esophageal obstruction or stricture
• Perforated hollow viscus
• Active gastric or esophageal bleeding
• Poor airway control
• Severe respiratory depression
• Uncooperative, unsedated patient
Relative
• History of esophageal or gastric surgery
• History of esophageal cancer
• Esophageal varices or diverticulum
• Recent gastrointestinal bleeding
• Active esophagitis or peptic ulcer disease
• Vascular ring or aortic arch anomaly with or without airway compromise
• Oropharyngeal pathology
• Severe coagulopathy
• Significant thrombocytopenia
• Cervical spine injury or anomaly
• Post-gastrostomy or fundoplication surgery limits imaging to esophageal windows

Source: Puchalski et al. [5]. Reproduced with permission of Elsevier.

KEY POINTS: CONTRAINDICATIONS TO TEE

- TEE is a semi-invasive procedure with associated risks.
- The use of TEE requires considering the indications and contraindications, reviewing all available patient data, and obtaining informed consent.
- One should consider the absolute and relative contraindications for TEE and perform it only after a careful risk–benefit assessment.

TEE hardware

Using echocardiography requires knowing the science of ultrasound and the many important principles involved. The application of TEE assumes a thorough understanding of the instrumentation needed to perform the examination. This chapter cannot address these aspects of echocardiography and TEE practice, even in an abbreviated form; the interested reader is referred to detailed resources on the subject [22–28].

Echocardiographic system

Ultrasonography machines suitable for echocardiography incorporate multiple modalities for image and signal processing during interrogation of the heart and vasculature.

Modern systems integrate components such as a high-resolution display, a console with hard keys, connection ports for transducers, ports for physiologic monitors (e.g., electrocardiogram), and a computer with software for processing data and network ports.

Controls and their layout on the machine vary by manufacturer; nonetheless, some common features among systems merit a basic understanding of their function. By manipulating various knobs, one can adjust image quality, activate different modes, record images, and perform other functions. Understanding how the machine operates is essential for acquiring images of diagnostic quality. Discussions of these important aspects of echocardiography are available in print [25, 26] and in a number of web-based resources.

TEE imaging probes

Several TEE probes are commercially available for clinical use (Table 15.3). In general, probes are not interchangeable among different echocardiographic systems and may not even be compatible between machines across the same platform. Using a TEE probe in a particular system requires not only appropriate hardware compatibility but also specific software to interface the imaging device with the echocardiography machine.

The evolution of transducer technology has produced TEE probes that have higher resolution than the first probes, as well as enhanced image plane options and additional modes to better assess the cardiovascular system. These advances represent major improvements in our ability to evaluate complex disease comprehensively.

Early *monoplane* (single-plane) TEE probes provided imaging only in the transverse orientation or horizontal plane (0°) [29]. *Biplane* probes incorporated a second scanning crystal that enabled, in addition, imaging in the longitudinal orientation or vertical plane (90°), thereby providing information in planes perpendicular to each other (i.e., orthogonal planes) [30–34]. The introduction of *multiplane* (omniplane) probes permitted interrogation of cardiovascular anatomy in any plane between 0° and 180° [35–38]. These flexible devices all contain phased-array transducers that produce "pie-shaped" or sector images. Sophisticated multiplane probes with many imaging planes to visualize most cardiac structures have largely replaced monoplane and biplane devices (Figure 15.1).

Three-dimensional (*3D*) *volume* TEE and TTE scanning involves using a specialized matrix array probe to display a selected volume of the heart as a real-time 3D data set [39]. Manipulating the data in real time can display anatomy from any perspective, including the surgical orientation [40, 41]. This latest advance replaces previously available 3D technology, which relied on off-line reconstruction of sequentially acquired two-dimensional (2D) image planes, thus limiting its use in the operating room.

Device selection

Unlike the almost "one-size-fits-all" approach to selecting a TEE probe in an adult, choosing among available TEE devices adds another layer of complexity and sometimes even inconvenience to imaging pediatric patients (Figure 15.2). Two parameters guide the selection of an appropriate probe in the pediatric age group: patient weight and probe size (Table 15.4).

At this time, it is rare to use monoplane and biplane TEE probes, as these may no longer be serviced by their respective manufacturers. However, several centers worldwide, mainly in countries with limited resources, still perform biplane and even monoplane TEE imaging in infants and children.

The *pediatric multiplane probe* (*mini-multiplane*) has allowed safe TEE imaging for many years in infants and small children weighing more than 3 kg. The availability of an even smaller device, a neonatal *micro-multiplane probe*, allows the use of this imaging modality in tiny neonates weighing as little as 2.5 kg [42]. These TEE probes incorporate full 2D and Doppler capabilities [43]. In clinical practice, the use of both pediatric and neonatal TEE probes occurs in even smaller patients than recommended by the equipment manufacturers [44, 45].

Table 15.3 Currently available multiplane transesophageal echocardiography (TEE) probes for clinical use

TEE device	Tip dimensions (W × H × L, in mm)	Shaft dimensions (W × L, mm × cm)	Number of elements	Imaging frequencies (MHz)
Philips				
Neonatal or micro-multiplane (S8-3t)	7.5 × 5.5 × 18.5	5.2 × 88	32	3.0–8.0
Pediatric or mini-multiplane (S7-3t)	10.7 × 8.0 × 27	7.4 × 70	48	3.0–7.0
Adult 2D multiplane (S7-2t)	15.0 × 12.5 × 35	10.0 × 90	64	2.0–7.0
Adult 3D (X8-2t)	17.0 × 13.4 × 38	10.0 × 100	2,500 matrix	2.0–8.0
Siemens				
Pediatric multiplane (V7M)	10.7 × 8 × 36*	7.0 × 70	48	4.0–8.0
Adult multiplane (V5M)	14.5 × 11.5 × 45	10.5 × 110	64	3.5–7.0
Adult 3D/4D (Z6Ms)	15.0 × 12.0 × 40	10.2 × 100	2,304 matrix	
General Electric				
Neonatal or micro-multiplane (10T-D)	7.6 × 5.6 × 16	5.6 × 90	32	3.3–10.0
Pediatric micro-multiplane (9T, 9Tc, 9T-RS)	10.9 × 8.4 × 35.2	7.0 × 70	48	3.0–10
Adult multiplane (6T, 6Tc, 6Tc-RS))	14.0 × 12.5 × 45	10.5 × 110	64	3.0–8.0
Adult 3D/4D (6VT-D)	14.3 × 12.7 × 44.8	10.5 × 110	2,500 matrix	3.0–8.0

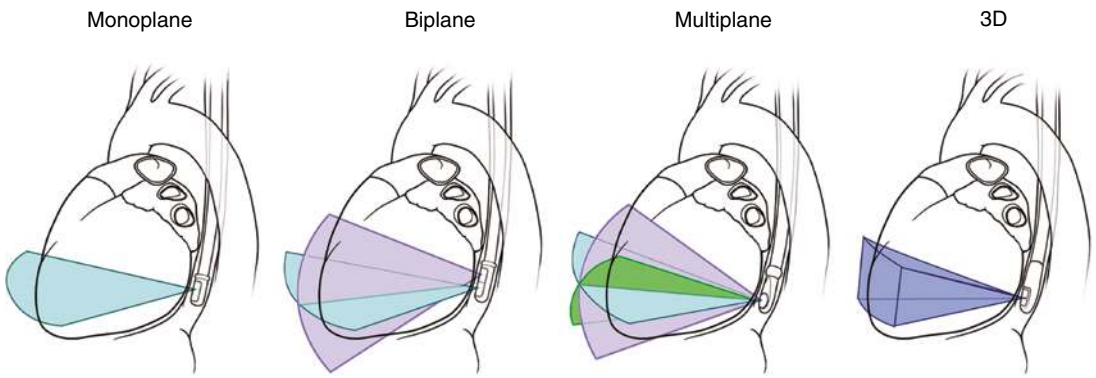

Figure 15.1 *Evolution of TEE imaging hardware*. The graphic displays the evolution of TEE imaging technology from monoplane to biplane, to multiplane, to 3D devices. (Source: Texas Children's Hospital. Reproduced with permission.)

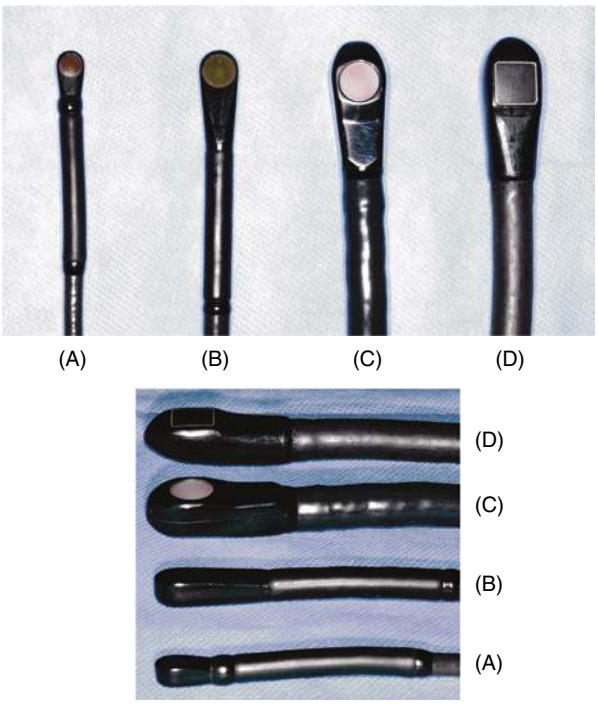

Figure 15.2 *TEE multiplane probes*. The photograph shows four currently available TEE multiplane imaging devices. (A) Neonatal probe; (B) pediatric probe; (C) "adult" 2D probe; (D) "adult" 3D probe.

Table 15.4 Manufacturer recommendations for multiplane transesophageal echocardiography (TEE) probe selection according to patient weight

TEE multiplane probe	Minimum patient weight (kg)
Neonatal	2.5
Pediatric	3.5
Adult (2D)	25
Adult (3D)	30

2D two-dimensional; *3D* three-dimensional

In older children, the preference is to use multiplane imaging with an adult-sized TEE probe, if feasible. Current 3D TEE probes have slightly larger dimensions than available adult 2D TEE probes, rendering them unsuitable for use in most young children. Although manufacturers suggest a patient weighing greater than 25 kg to use an adult 2D TEE probe or greater than 30 kg for a 3D TEE probe, in clinical practice, the usage of these devices often occurs in children weighing less than this. In general, these probes have more piezoelectric crystals than equivalent pediatric devices, and their larger size may improve contact with the esophagus; both features enhance the overall image resolution.

Intracardiac echocardiography (ICE) catheters (8–10 F) inserted via the transesophageal approach can provide 2D imaging in a single, longitudinal plane in neonates and small infants [46–48]. Although these catheters are not formally marketed for this specific application, reports indicate that they deliver clinically useful information in some cases, albeit with several limitations.

Probe insertion

In the operating room, TEE probe insertion occurs after induction of general anesthesia, endotracheal intubation, and arterial catheter placement. Although aspirating gastric contents is standard anesthetic practice in many centers, it does not reliably enhance TEE image quality [49]. In pediatric patients, some providers prefer nasal rather than oral endotracheal intubation to better stabilize the endotracheal tube (ETT), which reduces the risk of inadvertent extubation or movement during TEE probe manipulation. This practice, however, is variable. Regardless of the intubation route, securely taping the ETT should minimize the risk of displacement.

Blind positioning of the lubricated probe tip in the oropharynx with gentle advancement into the esophagus should occur with the patient's head in the midline position. The probe control for transducer tip flexion should remain unlocked at this time to allow free movement.

Slight anterior flexion of the probe tip, forward thrusting of the mandible, and device guidance with a gloved finger can aid advancement of the probe along the contour of the posterior pharynx, thereby minimizing trauma. Alternatively, laryngoscopy can be used initially with direct visualization during probe insertion or after a difficult blind probe insertion [50].

In children, positioning the head to the side may facilitate the probe's passage, as this position reportedly results in closure of the ipsilateral pyriform sinus, where the probe may

encounter obstruction [51]. After placing the transducer behind the heart, repositioning the patient's head avoids interference with the surgical field during probe manipulation. Independent factors that render probe insertion difficult in infants weighing 4 kg or less include lower weight, abnormal craniofacial anatomy, prematurity, a diagnosis of 22q11 deletion [52], and, possibly, Down syndrome.

Probe placement is an essential skill in the practice of TEE. Distinguishing expected from excessive resistance requires thorough expertise and ongoing experience with the technique [53]. Although esophageal intubation requires some degree of effort, it is important never to force the probe against resistance. Manufacturers recommend insertion of the TEE probe through a bite block (also referred to as bite guard), which is positioned between the patient's teeth to provide safe passage through the patient's mouth, prevent damage to the TEE probe, and maintain the probe warranty. In clinical practice, this is more commonly used when imaging is done under sedation than with general anesthesia and more likely to be used in adults versus children.

Probe insertion and manipulation can be significantly stimulating and requires an adequate level of patient sedation or anesthesia and even neuromuscular blockade in most children before placement. These maneuvers can also elicit clinically significant hemodynamic and/or respiratory changes, particularly in patients with specific anomalies with known significant potential risks of TEE (e.g., anomalous pulmonary venous drainage, vascular rings or slings); thus, vigilance is imperative [54]. In the event of acute hemodynamic or airway compromise, the probe should be repositioned or removed immediately.

Outpatient TEE is performed often in adults but rarely in children, because the excellent image quality of TTE in the pediatric population provides adequate information as previously noted. In most cases, TEE is used to address a specific question, such as assessing for a thrombus in the LAA. A combination of oropharyngeal topical anesthesia and intravenous sedation may be sufficient for TEE imaging in the adolescent or adult. In younger patients, some adolescents, and a few adults, deep sedation or general anesthesia with endotracheal intubation may be necessary to overcome lack of cooperation, avoid respiratory compromise, and provide adequate time for a complete study.

The facility where TEE occurs should be equipped with oxygen, suction capabilities, drugs, and equipment for cardiopulmonary resuscitation and other emergency therapies. Standard cardiorespiratory monitoring during the procedure includes intermittent blood pressure measurements, electrocardiography, pulse oximetry, and capnography. Patients with CHD may have significant hemodynamic alterations with marginal compensation, requiring the judicious, titrated administration of pharmacologic agents [55]. Patients with cyanotic heart disease are at additional risk for paradoxical air embolism during the administration of intravenous fluids or drugs. Decreases in systemic vascular resistance associated with a sedative or anesthetic agent can worsen right-to-left shunting and exacerbate underlying systemic arterial desaturation, necessitating careful observation of drug responses.

Instrument manipulation and probe controls

Manipulating the TEE probe in several directions aids in imaging cardiovascular structures relative to the sagittal plane (Figure 15.3). The probe shaft can be pushed in (advanced) or pulled back (withdrawn) and can be turned to the right (clockwise) or to the left (counterclockwise). Wheel controls on the probe handle manipulate the probe tip, which can be flexed anteriorly (anteflexed) or posteriorly (retroflexed) and to the right or left (Figure 15.4). Pediatric TEE probes may lack the right-to-left flexion control, seldom a limitation, because only minimal adjustments in the probe's position are needed to navigate from view to view. The imaging plane of a stationary, multiplane transducer can be rotated between angles of 0° and 180°, without the maneuvers required by monoplane and biplane devices to obtain equivalent views [56]. The control to change the multiplane

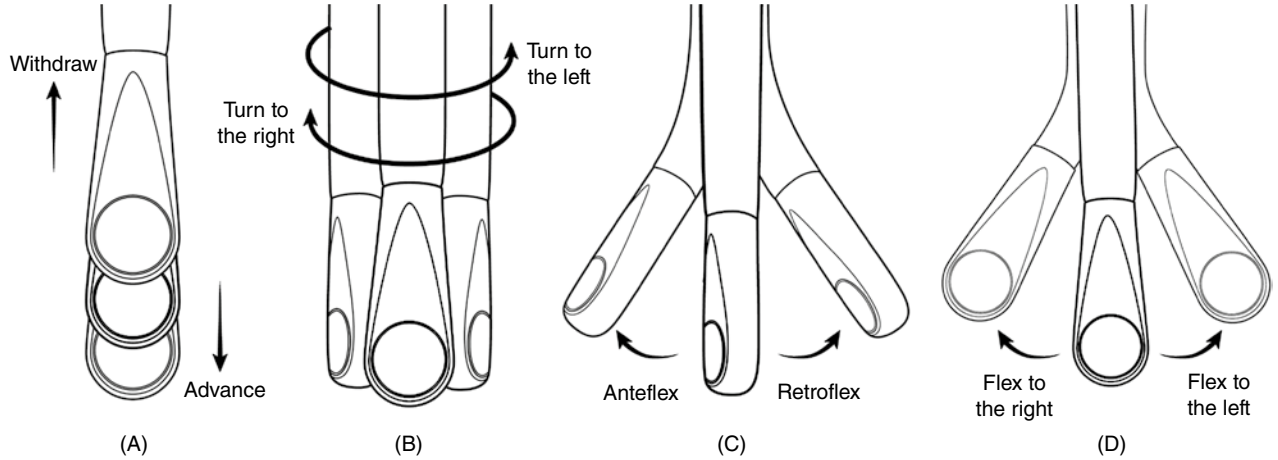

Figure 15.3 *TEE probe manipulation*. The graphic displays the terminology corresponding to the various TEE probe manipulation options. (A) Advance/withdraw; (B) turn to the right/left; (C) anteflex/retroflex; and (D) flex to the right/left. Note that the first two maneuvers (shown in panels A and B) require movement of the entire probe shaft, while performing the second two (depicted in panels C and D) is by special controls that move only the probe tip. Figure 15.4 *Adult multiplane TEE probe controls.* This photograph shows three different types of commercially available multiplane TEE adult probes with their respective flexion (anterior/posterior, right/left) and multiplane angle controls.

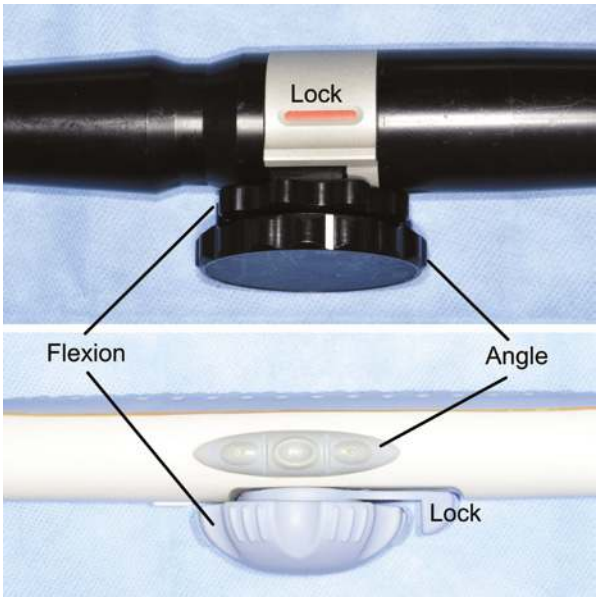

Figure 15.5 *Pediatric multiplane TEE probes.* The photograph displays two commercially available pediatric multiplane TEE probes to highlight differences in the multiplane angle control (mechanical in top panel vs. electronic in lower panel), the wheel control for flexion (anteflexion/retroflexion), and the probe tip locking mechanism.

angle in adult devices is electronic, whereas it can be either mechanical or electronic in pediatric devices (Figure 15.5).

KEY POINTS: TEE HARDWARE

- The TEE technology has evolved from monoplane, to biplane, to multiplane, to recent 3D-live imaging devices.
- Currently, there are four available multiplane probes for TEE imaging in patients with CHD (i.e., neonatal, pediatric, adult 2D, and adult 3D TEE probes).
- All multiplane probes include 2D, M-mode, spectral Doppler, and color Doppler capabilities.
- Two main factors guide device selection: probe size and patient weight.

TEE examination in CHD

Structural examination

The echocardiographic evaluation of the patient with CHD presents many challenges because of factors such as the wide spectrum of lesions; the myriad of anatomic variants, each with specific physiologic alterations; the frequent presence of coexistent pathologies; and the complexity of many defects [1]. Compounding these considerations is the need to be able to reconstruct the 3D anatomy of the congenitally malformed heart while relying primarily, and in most instances exclusively, on 2D imaging. Despite these challenges, TEE permits excellent visualization of cardiovascular structures and provides significant benefits.

A comprehensive TEE examination in the patient with CHD can employ different approaches. Each approach has specific advantages and some potential disadvantages, as described briefly in the sections that follow.

View-based approach

The "view-based" TEE examination relies on obtaining several specific predefined cross sections by moving the probe to various locations within the esophagus or stomach. Initial guidelines by the ASE and Society of Cardiovascular Anesthesiologists (SCA) suggested a set of 20 TEE views for a comprehensive examination. This widely adopted approach became standard practice for the TEE examination of the adult patient with an anatomically normal heart [57]. Subsequently, updated recommendations incorporated 8 additional cross sections, for a total of 28 TEE views (Figure 15.6) [3]. Recent ASE TEE guidelines specifically addressing children and all patients with CHD recommend 28 views for a comprehensive examination [5]. Most of these views are the same described for imaging of the adult heart, but a few were added in recognition of the need for examination of specific structures or pathologies commonly seen in the pediatric age group or the congenital population (Figure 15.7). Selected adult TEE views were correspondingly excluded to maintain the same overall number of cross sections. A more detailed description of views useful in imaging CHD appears in the subsequent sections. During a complete TEE examination, obtaining most or all these views, regardless of sequence, provides comprehensive anatomic, functional, and hemodynamic information. This approach helps the practitioner learn the basic principles of TEE and represents an excellent foundation on the subject. The reader is referred to the outstanding web-based educational resources of the Toronto General

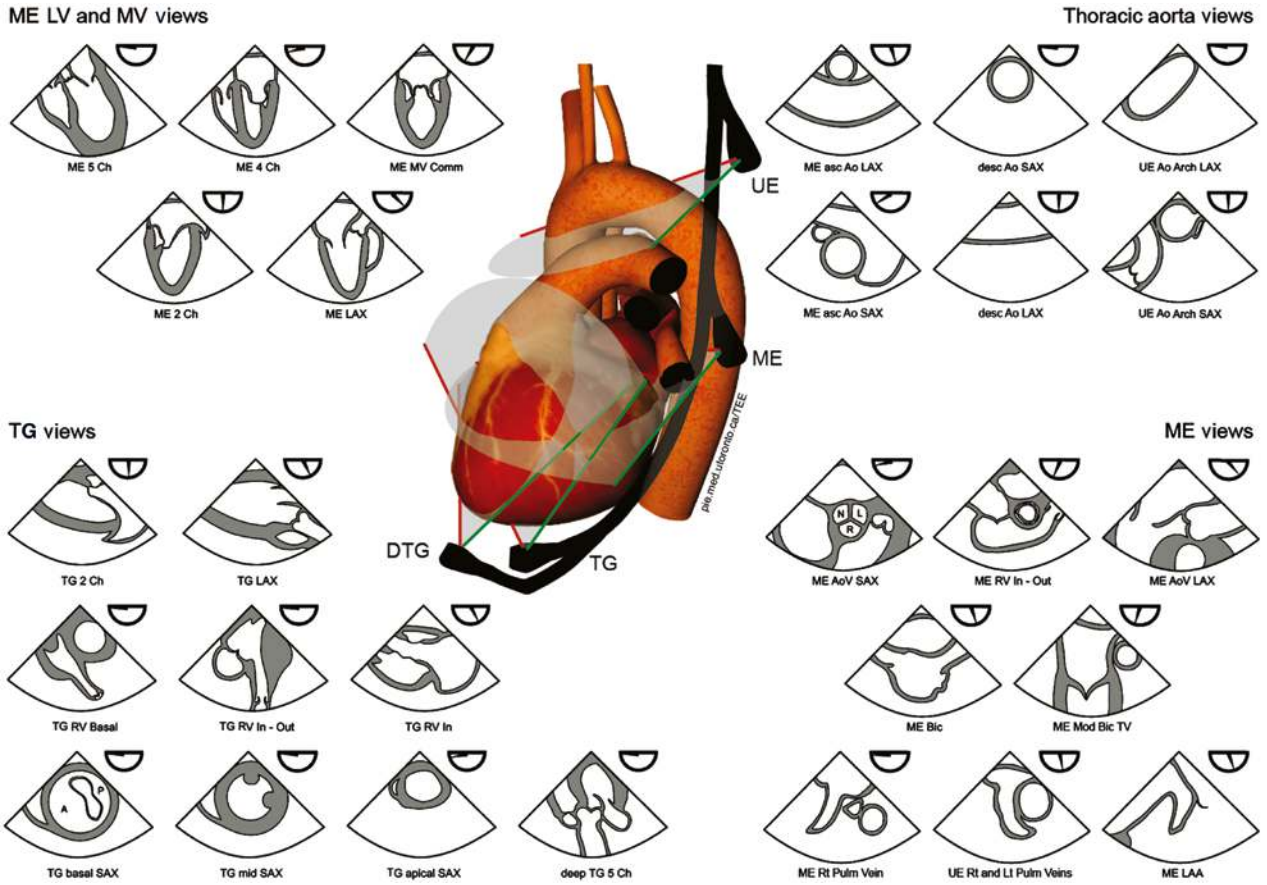

Figure 15.6 *TEE views in the comprehensive adult examination*. This graphic displays the suggested 28 views in the adult guidelines for a comprehensive TEE examination [3]. The TEE probe positioned at the upper esophageal (UE), midesophageal (ME), transgastric (TG), and deep transgastric (DTG) levels can attain these cross sections. The grouping of the views in this graphic is by the structures being interrogated or the specific TEE window. The reader is referred to this publication for a detailed description of each of these views. *A* anterior; *L* left coronary cusp; *LV* left ventricle; *MV* mitral valve; *N* con coronary cusp; *P* posterior; *R* right coronary cusp. Hospital (www.pie.med.utoronto.ca/TEE/) for interactive modules on the standard adult TEE examination.

The view-based TEE examination has substantial benefits, not only as a standardized method of performing the evaluation but also in terms of facilitating teaching, archiving, and reporting of the study, as well as quality assurance. Familiarity with these views, including the nomenclature, where and how to obtain each, the structures displayed by each, and the information derived, enhances one's ability to perform a detailed examination and to communicate the findings to others.

However, this approach has several limitations. The most recent pediatric and congenital TEE guidelines highlight two of them. First, the suggested TEE views were aimed primarily at the intraoperative interrogation and excluded views that may be necessary in nonoperative settings. Second, the outlined TEE examination was not diagnosis based, potentially excluding important views in the evaluation of specific cardiac conditions. These limitations are particularly relevant to the assessment of CHD, because a strict view-based approach is inadequate for the detailed evaluation of structural abnormalities in many patients. Standard TEE views may not allow imaging of the complex anatomic relationships that characterize congenital pathology. Of critical relevance is that comprehensively evaluating many structural anomalies requires not only single views but also sweeps between multiple planes, some modified or nonstandard, aimed at building a 3D construct of the anatomic abnormalities.

Structure-based approach

The "structure-based" examination focuses on detailed TEE imaging of cardiovascular structures of interest by using complementary views to permit their in-depth examination. Specific structural imaging in the adult has been described, for example, in the detailed evaluation of cardiac valves, the Ao, and the LAA, among other regions [3, 58–64]. A similar type of approach has been extremely helpful in characterizing specific anatomic and functional abnormalities in the patient with CHD, such as defects that involve the atrial or ventricular septum, pulmonary veins, and other structures [65–67].

This type of image-acquisition paradigm may be preferable when, for various reasons, a focused TEE examination needs to address only a specific pathology of concern. One potential limitation of this approach in CHD is that by targeting only particular cardiac structures or pathologies, one may overlook relevant coexisting

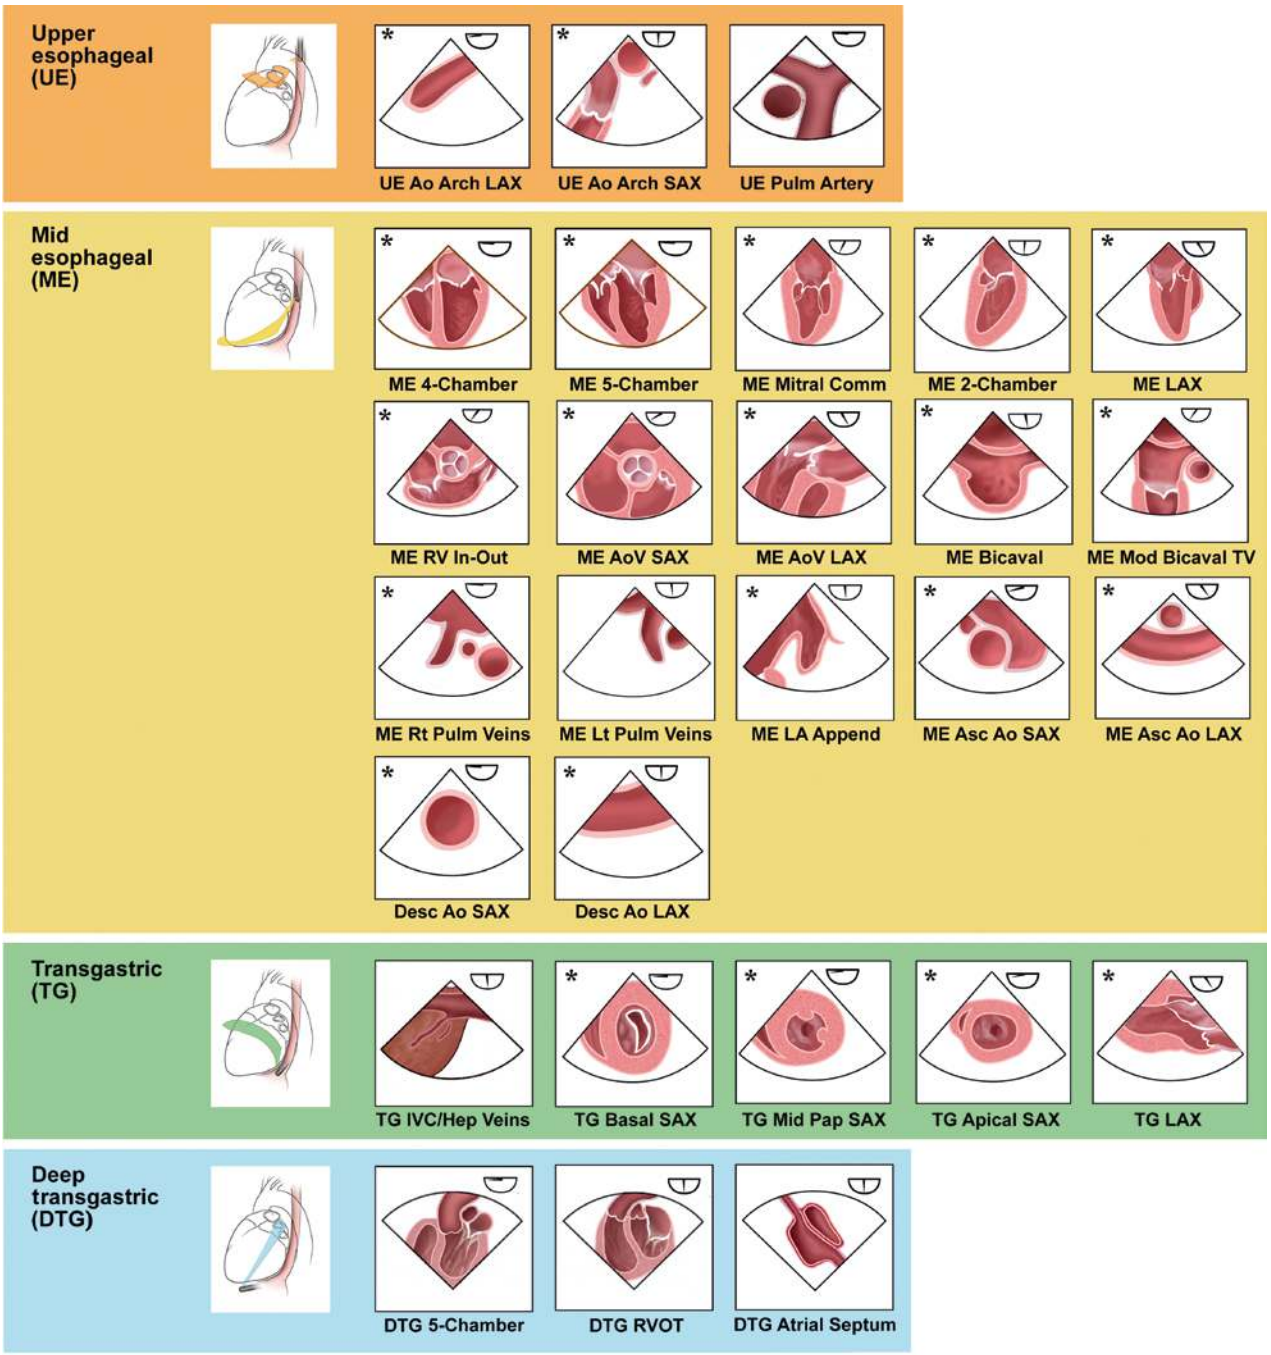

Figure 15.7 *TEE views in the comprehensive pediatric and congenital TEE examination*. The graphic displays the 28 recommended TEE views as a starting point in the guidelines addressing the comprehensive examination in children and all patients with CHD [5]. The grouping of the views in this figure is by the specific TEE window that the views can be obtained. The reader is referred to this publication for a detailed description of each of these views. (Sources: Texas Children's Hospital. Reproduced with permission; panels marked by asterisk from Hahn et al. [3]. Reproduced with permission of Elsevier.)

abnormalities or anatomic variants. However, by examining all relevant structures, this is the favored examination approach in CHD [5].

Sequential segmental approach

The "sequential segmental" analysis has been proposed as the foundation of complete anatomic assessment in CHD [68–71]. This approach involves a well-organized, methodical interrogation of the three major cardiac segments (i.e., atria, ventricles, and great arteries) and their relationships to each other (connections or alignments between the segments), to define a patient's anatomy and any abnormalities (Figure 15.8; also refer to Chapter 7). The incorporation of this type of analysis into many diagnostic imaging modalities in CHD is key in echocardiographic assessment (TTE and fetal imaging) [72–75].

The fundamental principle of this methodology is the identification of specific cardiac chambers by their characteristic

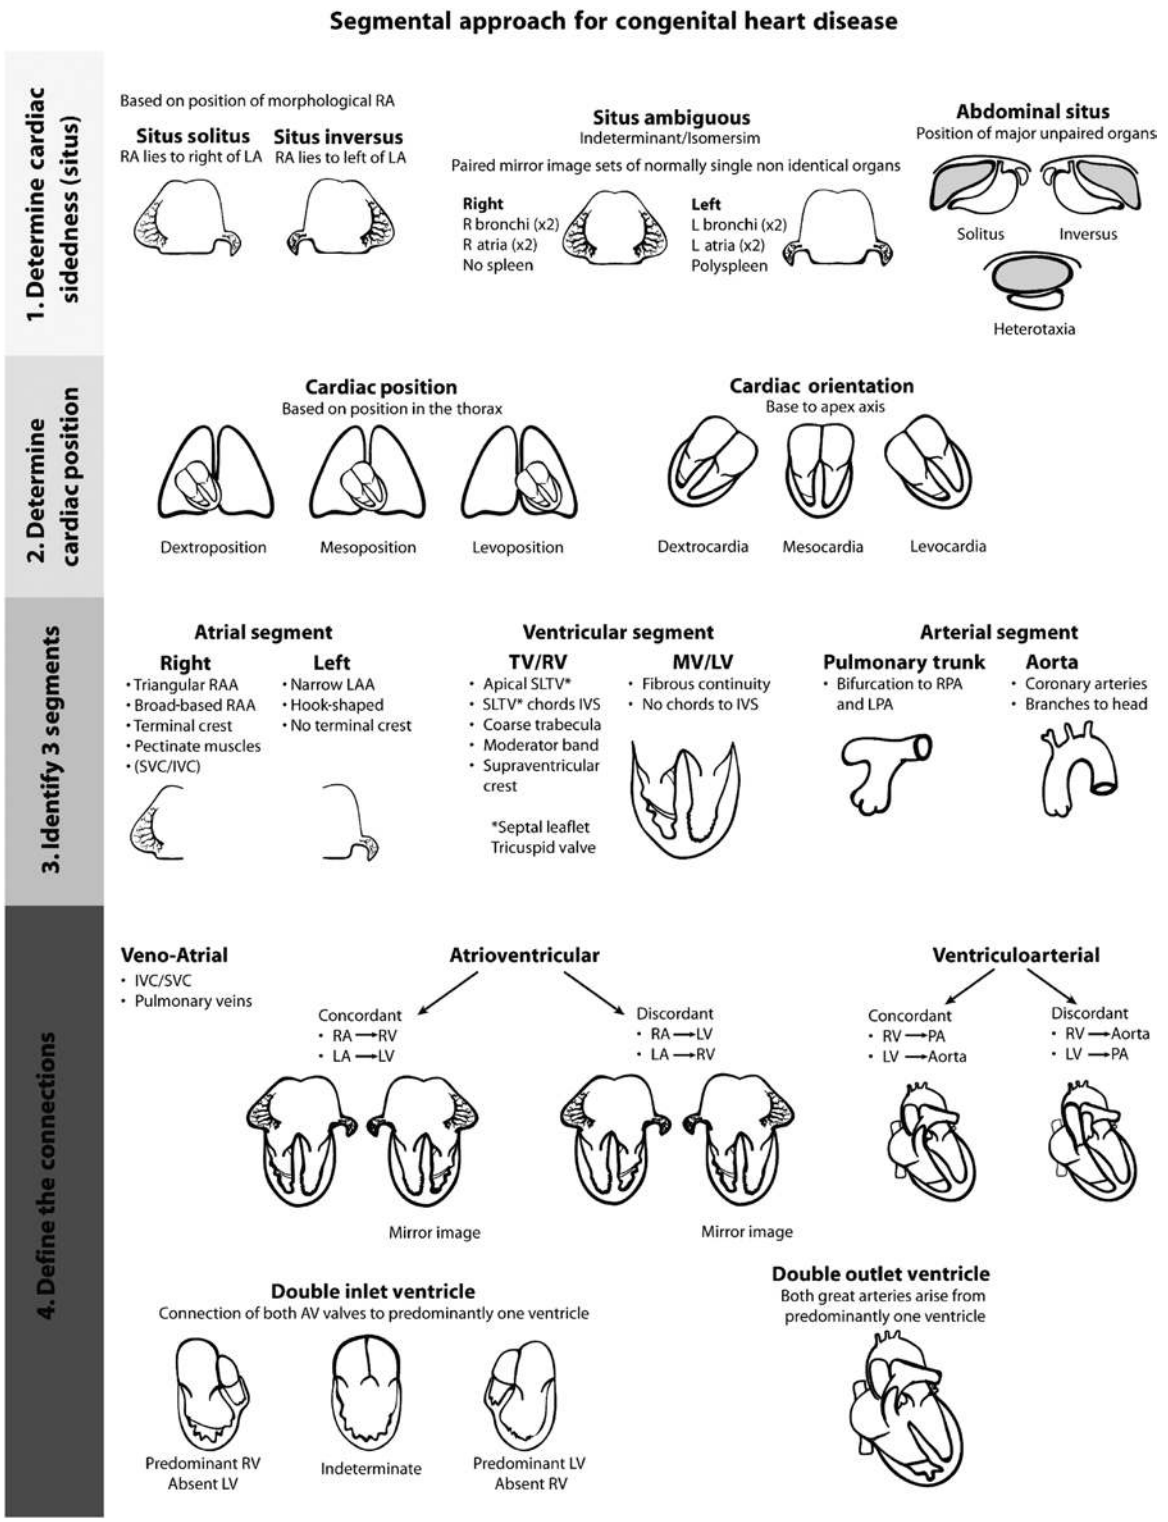

Figure 15.8 *Sequential segmental analysis*. The graphic illustrates the steps involved in the diagnostic analysis of CHD. The approach examines the following: cardiac situs; position of heart in the thorax and base to apex orientation; all segments and connections; and the cardiac defects. *AV* atrioventricular; *IVC* inferior vena cava; *IVS* interventricular septum; *L* left; *LA* left atrium; *LAA* left atrial appendage; *LPA* left pulmonary artery; *LV* left ventricle; *MV* mitral valve; *PA* pulmonary artery; *R* right; *RA* right atrium; *RAA* right atrial appendage; *RPA* right pulmonary artery; *RV* right ventricle; *SVC* superior vena cava; *TV* tricuspid valve. AL Grawany

morphologic properties, rather than by their positions within the body. The suggested practice examines the arrangement of the thoracoabdominal organs or situs, atrial structures, ventricles, and great arteries, as well as the connections between the segments, namely, the atrioventricular (AV) and ventriculoarterial (VA) connections [76, 77]. This approach has significant merit as congenital heart lesions can have normal or abnormal relationships among chambers, valves, and vessels (refer to Chapter 7).

The sequential segmental analysis overcomes the limitations of a purely structure-based approach, as careful interrogation and identification of all cardiovascular structures ensures a thorough TEE assessment. Despite these advantages, for those unfamiliar with segmental anatomy, the methodology involved may be less intuitive and more time-consuming. However, this approach is very useful, particularly in a preoperative study performed to characterize or confirm the anatomic abnormalities.

The TEE examination

Guidelines and recommendations exist for the application of TTE and TEE imaging in CHD [1, 3, 5–8]. Previous publications have addressed applications of TEE in CHD [10, 78], with the most recent guidelines outlining in detail the comprehensive and systematic examination in these patients [5]. Providing details of the TEE examination in CHD is beyond the scope of this chapter, so we review only selected aspects, and the reader should look to other publications for an exhaustive discussion on the subject [5, 28, 79, 80].

Although there is no predetermined sequence for the order of acquisition of information during a TEE examination in CHD, and one should not be inferred from the following outline, it is valuable for individuals to develop their own organized approach to performing a complete and expeditious interrogation. Unique patient conditions or specific circumstances, such as hemodynamic instability or respiratory impairment by TEE probe manipulation, may shorten the examination.

The sections that follow on imaging windows and planes provide a brief overview of selected TEE views frequently obtained during CHD evaluation. The examination assumes levocardia (heart in the left thoracic cavity with apex pointing to the left) and normal segmental anatomy: in other words, visceroatrial situs solitus (stomach on the left, liver on the right, and normal atrial arrangement), concordant AV and VA connections, normal ventricular topology, and great artery spatial orientation. It may not be possible to obtain all views in all patients, nor will the planes and angles of interrogation necessarily conform to each patient's unique anatomy. The variety of structural cardiovascular malformations dictates a modified scheme in many cases.

The comprehensive TEE examination in CHD includes detailed 2D imaging and meticulous spectral and color-flow Doppler interrogation. Contrast echocardiography using an injection of agitated saline or 5% albumin into a peripheral or central vein can detect small intracardiac shunts, further delineate anatomy (e.g., persistent left superior vena cava [SVC]–to–coronary sinus connection), and identify pathology such as atrial baffle leaks [81, 82].

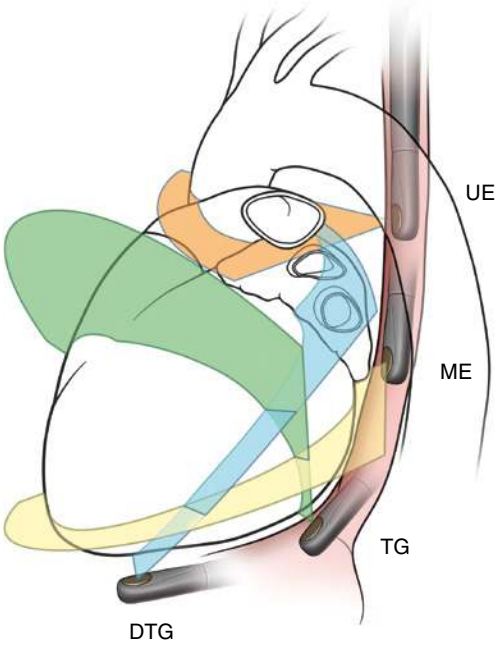

Figure 15.9 *TEE imaging windows*. The standard TEE imaging windows and representative imaging planes are shown. *DTG* deep transgastric; *ME* midesophageal; *TG* transgastric; *UE* upper esophageal positions. (Source: Texas Children's Hospital. Reproduced with permission.)

Imaging windows

During a TEE examination in CHD, imaging of the heart and related vascular structures occurs at multiple levels: upper esophageal (UE), midesophageal (ME), TG, and DTG (Figure 15.9). Different transducer angles are used to obtain specific cross sections. These diverse TEE windows complement each other and provide information that is not otherwise obtainable in some views. The TG and DTG views, for example, provide favorable alignment of the Doppler angle of interrogation to the outflow tracts, optimizing spectral Doppler signals and the assessment of gradients.

Multiplane imaging views

The guidelines for performing a comprehensive TEE examination in children and all patients with CHD describe in detail the recommended 28 tomographic views, acquisition protocol, and structures imaged in each of these cross sections (Figure 15.7). The reader is referred to this document for further information [5]. Table 15.5 highlights how these multiplane TEE views can be obtained (note that this is a succinct guide, as there are several approaches), structures displayed, and relevant features of each. As emphasized in the guidelines document, these views are only a starting point, as additional, modified, nonstandard cross sections may be necessary to define the anatomy of a given patient. This is particularly important in patients with complex anatomy, such as seen in heterotaxy, and in patients with cardiac malpositions, for whom the multiplane transducer angles for the standard views may need to be significantly altered.

Table 15.5 Transesophageal echocardiography (TEE) views for a comprehensive examination in children and all patients with congenital heart disease

View (*abbreviation*)	Acquisition details	Structures imaged and assessment
Midesophageal views		
ME Four-chamber view (*ME 4-Ch*)	Neutral probe position, transducer angle of ~0°–10° Equivalent to TTE apical 4-Ch view	All four cardiac chambers, AV valves, atrial and ventricular septa, CS
ME Five-chamber view (*ME 5-Ch*)	From ME 4-Ch view probe tip anteflexion or probe withdrawal	In addition to structures in the ME 4-Ch view, LVOT, proximal Ao
ME Mitral valve view (*ME Mitral*)	From ME 4-Ch view increase transducer angle to ~50°–70°	LA, LV, MV (segments, commissures), tensor apparatus, papillary muscles, CS
ME Two-chamber view (*ME 2-Ch*)	From ME 4-Ch view increase transducer angle ~80°–100° Orthogonal to the ME 4-Ch view	LA, LAA, MV, LV, CS
ME Long-axis (*ME LAX*)	From ME 4-Ch view increase transducer angle to ~120°–140°	LA, LV, RVOT, LVOT, MV, AoV, prox Asc Ao aorta
ME Aortic valve long-axis (*ME AoV LAX*)	From ME LAX view reduce image depth	Focused view of LVOT, AoV, prox Asc Ao
ME Aortic valve short-axis (*ME AoV SAX*)	From ME 5-Ch view keep Ao root in focus, withdraw probe, adjust transducer plane to 25°–45° Orthogonal to ME AoV LAX view	AoV morphology (number of cusps, commissures), function, localization of pathology (stenosis, regurgitation)
ME Ascending aorta long-axis (*ME Asc Ao LAX*)	From ME LAX view withdraw probe, adjust transducer angle to ~90°–110°	Asc Ao in long axis, RPA Allows for assessment of proximal to mid ascending aortic pathology
ME Ascending aorta short-axis (*ME Asc Ao SAX*)	From ME Asc Ao LAX view decrease transducer angle to ~0°–30° Orthogonal to ME Asc Ao LAX view	Prox Asc Ao (short axis), MPA (long axis), RPA, SVC Allows for Doppler assessment of MPA
ME Right ventricular inflow-outflow (*ME RV In-Out*)	From ME 4-Ch, ME 5-Ch, or ME AoV SAX anteflex probe tip, rotate transducer angle to ~50°–70° Mimics inverted TTE parasternal SAX view at base of heart	RA, LA, IAS, TV, PV, AoV, MPA, inflow and outflow of RV Useful to assess VSDs, TR jets, RV size, function, and obstruction
ME Bicaval view (*ME Bicaval*)	Transducer angle of 90°–110° Orthogonal to ME 4-Ch view	SVC and IVC entry to RA, RAA, IAS; useful to assess IAS, central catheter tip position
ME Modified Bicaval tricuspid valve (*ME Mod Bicaval TV*)	Transducer angle of 50°–70° or from ME Bicaval view turn probe to the right	TV (anatomy, regurgitation severity, regurgitant Doppler peak velocity), LA, RA
ME Left atrial appendage view (*ME LAA*)	Transducer angle of ~90°–110° LAA also seen in ME 4-Ch view with LA centered and probe shaft turned to left	LAA, variable anatomy of LAA requires multiple views for a detailed examination
ME Right pulmonary veins (*ME Rt Pulm veins*)	From ME 4-Ch view, turn probe shaft to right at transducer angle 0°, adjusting to 30°–50° may display all right-sided pulmonary veins Alternate approach is to turn the probe to the right from the ME Bicaval view	Right pulmonary veins, SVC, Mid Asc Ao
ME Left pulmonary veins (*ME Lf Pulm veins*)	After centering LA in screen rotate transducer angle to 90°–110° and turn probe shaft to the left Alternate approach is from the ME 4-Ch view to turn probe to the left to image the LAA, and slowly advance–withdraw the probe	Left pulmonary veins, LPA
Transgastric views		
TG Basal short-axis (*TG Basal SAX*) TG Mid-papillary short-axis (*TG Mid Pap SAX*) TG Apical short-axis (*TG Apical SAX*)	Gently advance TEE probe into the lower esophagus/stomach, with slight anteflexion at transducer angle of ~0°–20°	Multiple cross-sectional short-axis views of LV at basal, mid-papillary, and apical levels TG Mid Pap SAX view extremely helpful in evaluating LV function (global and segmental), LV preload
TG Long-axis (*TG LAX*)	From TG Mid Pap view increase transducer angle to ~120°–140°	LV (long axis), LVOT, AoV Useful for Doppler evaluation of Ao outflow

AL Grawany

Table 15.5 (Continued)

View (*abbreviation*)	Acquisition details	Structures imaged and assessment
TG Inferior vena cava/Hepatic veins (*TG IVC/Hep veins*)	From ME Bicaval view advance probe into the distal esophagus or upper gastric region at transducer angle of ~80°–100°	IVC, hepatic veins, RA Useful to assess situs and evaluate flow in venoatrial connection (IVC–RA), hepatic veins, anomalous pulmonary veins
Deep transgastric views		
DTG Five-chamber view (*DTG 5-Ch*)	Advance probe further into stomach with transducer angle of 0°–20° and variable degrees of tip anteflexion LV is displayed from base at top to apex at bottom of image (in contrast to standard adult TEE view) Nearly equivalent to ME 5-Ch view	Ventricles, LVOT, Ao root, IVS, MV
DTG Right ventricular outflow tract (*TG RVOT*) Not a standard view in the adult TEE guidelines	From DTG 5-Ch view rotate transducer angle to ~50°–90° At times, rightward probe shaft rotation can be helpful	Ventricles, RVOT, MPA, IVS, MV
DTG Atrial septal (*TG Atr Sept*) Not a standard view in the adult TEE guidelines	From the DTG RVOT view turn probe shaft right with a transducer angle to ~80°–90° Simulates TTE subcostal bicaval view	Excellent delineation of IAS and systemic venous connections Visualizing the IVC may require a transducer angle of ~100°–120°)
Upper esophageal views		
UE Pulmonary artery view (*UE PA*) Not a standard view in the adult TEE guidelines	From ME 4-Ch view withdraw TEE probe, anteflex tip, turn shaft left at a transducer angle of ~0°–20° Alternatively, from ME RV In-Out view withdraw probe and adjust transducer angle	MPA and branches Useful to assess main PA, bifurcation, proximal branches, and to perform Doppler exam Interposition of left mainstem bronchus, makes imaging LPA difficult
UE Aortic arch long-axis (*UE Ao Arch LAX*)	Position probe in upper esophagus with transducer angle of ~0°–10°	Aortic arch (long axis), innominate vein
UE Aortic arch short-axis (*UE Ao Arch SAX*)	From UE Ao Arch LAX increase transducer angle to ~70°–90° Orthogonal to UE Ao Arch LAX	Aortic arch (short axis), innominate vein, PV, MPA and branch PAs (with probe shaft rotation)
Aorta views		
Descending aorta in short-axis (*Desc Ao SAX*)	From ME 4-Ch view rotate probe shaft left to display the left-sided pulmonary veins and LAA, turning probe further posteriorly shows the Desc Ao SAX at a transducer angle ~0°–10°	Desc Ao (short axis)
Descending aorta in long-axis (*Desc Ao LAX*)	From desc Ao SAX view increase transducer angle to ~90°–100° (orthogonal to Desc Ao SAX view)	Desc Ao (long axis)

Abbreviations: *Ao* aorta; *AV* atrioventricular; *Asc* ascending; *CS* coronary sinus; *Desc* descending; *IAS* interatrial septum; *IVC* inferior vena cava; *IVS* interventricular septum; *LA* left atrium; *LAA* left atrial appendage; *LPA* left pulmonary artery; *LV* left ventricle; *LVOT* left ventricular outflow tract; *MPA* main pulmonary artery; *MV* mitral valve; *PA* pulmonary artery; *PV* pulmonary valve; *Prox* proximal; *RA* right atrium; *RAA* right atrial appendage; *RPA* right pulmonary artery; *RV* right ventricle; *RVOT* right ventricular outflow tract; *SVC* superior vena cava; *TR* tricuspid regurgitation; *TTE* transthoracic echocardiography; *TV* tricuspid valve; *VSD* ventricular septal defect

In general, the views can be considered as follows:

ME views

A significant amount of TEE imaging takes place in the ME region; in fact, this window allows acquisition of more than half of the suggested views (15/28) for a comprehensive pediatric or adult CHD examination. The *ME four-chamber view (ME 4-Ch)* is considered the starting view or "home base," as it acts as a reference point for obtaining other views by manipulating the probe (tip or shaft adjustments) or adjusting the transducer angle on a multiplane probe.

TG views

The TG views include five cross sections of the heart. Transverse plane imaging shows the ventricles in short axis at various levels from base to apex. Longitudinal plane imaging shows the left ventricle (LV) and right ventricle (RV) and the inferior cavoatrial region.

DTG views

Advancing the probe into the fundus of the stomach obtains the three DTG views. Up-down inversion displays the TEE images in an anatomic orientation (base of the heart at the

top of the sector and apex at the bottom), which assists tremendously in the understanding of complex disease and correlates to TTE imaging and other diagnostic modalities. This convention is not applied to standard adult TEE DTG imaging, or to equivalent apical or subcostal views obtained by surface imaging in the adult patient. The DTG views of the semilunar valves or ventricular outflow tracts provide excellent angles of spectral Doppler interrogation, thereby allowing optimal alignment of the cursor parallel to the direction of blood flow. These views also significantly contribute to the evaluation of VA connections in CHD.

UE views

These three views allow imaging of vascular structures (e.g., pulmonary artery [PA], aortic arch, variants or anomalies).

Aortic views

The views of the thoracic descending Ao can be obtained at various levels by withdrawing and advancing the imaging probe. The level of the Ao in these views can be difficult to interpret because of the lack of landmarks.

Three-dimensional TEE

Ease of acquisition with rapid online display of detailed dynamic images has increased the use of real-time 3D TEE in the perioperative period to assess cardiac anatomy and function [4, 40, 41, 83–85]. Special matrix array ultrasonography probes acquire raw data by volume scanning, and integrated ultrasonography machine software processes the 3D data sets. These TEE probes perform all standard 2D functions, include motion mode (M-mode) and all Doppler modalities (e.g., spectral, color, tissue), and have the additional feature of multiplane mode (X-plane) to simultaneously display independent 2D scanning planes during the same heartbeat. Single-button activation of specific 3D imaging modes for both TEE and TTE matrix array probes include live, zoom, full volume, and color Doppler full volume, allowing for real-time imaging of cardiac structures (Table 15.6). Using these modes, one can define a specific region of interest to obtain a 3D volume of varying sizes. Newer software can display all 3D data sets in real time, such that moving the probe will immediately affect the 3D volume on the display.

Currently, all real-time 3D imaging modes appear as a volume-rendered 3D object with full details of the surface and inner structure. The free rotation of any rendered 3D object on the screen allows its display from any orientation, including the surgeon's perspective.

Cropping permits a "virtual dissection" of the 3D object that examines all its details. The 3D technology has proven superior to 2D echocardiography for assessing the LV (volume, ejection fraction [EF], mass, and dyssynchrony) and the mitral valve (MV) [86]. *En face* views of the MV, for example, when displayed in the surgeon's orientation viewed from the left atrium (LA), show the anatomical details of the leaflets and define leaflet pathology of prolapse, clefts, and perforations [87, 88]. Thus, the use of this modality has become well accepted for adult patients undergoing cardiothoracic surgical interventions and catheter-based procedures. The excellent detail of 3D imaging provides more information about cardiac anatomy and spatial relationships than 2D echocardiography, clearly a merit of the technology in evaluating CHD. Real-time 3D TEE can better show the intricate relations of cardiac structures in patients with complex CHD. While multiple 2D views were previously necessary to assess pathology, 3D imaging can show the entire heart in a single screen display. In assessing CHD, 3D TEE has a major role in evaluating defects in both the atrial and ventricular septum and valvular pathologies of the MV and aortic valve (AoV) [4, 89]. Current recommendations for 3D TEE imaging in CHD appear in Table 15.7 [5].

Although experience with real-time 3D TEE in children with CHD is limited by the lack of suitable imaging devices, applications of the technology have shown extremely favorable results [4, 21, 65, 66, 89–95], mirroring the reported 3D TTE experience in CHD [96, 97]. It is reasonable to consider this modality in cases for which a 3D perspective may offer additional benefits over routine 2D TEE in the patient suitable for 3D TEE imaging with currently available devices.

Similar to 2D TEE, structures closest to the probe are easily imaged in 3D, enabling the evaluation of clinically relevant issues in real time. The thin interatrial septal (IAS) and distant structures (AoV and pulmonary valve [PV]) remain difficult to image by 3D TEE in some patients. Despite recommendations

Table 15.6 Real-time three-dimensional transesophageal echocardiography imaging

Structure	2D view for 3D acquisition	3D mode	Clinical utility
Mitral valve	ME 4-Ch (0°), ME MV Comm (60°), ME 2-Ch (90°), ME LAX (120°); ± CD for all views	Zoom, FV	Morphology, function, quantification (effective regurgitant orifice area, MV area)
Aortic valve	ME AoV SAX (30°–60°), ME AoV LAX (120°); ± CD for all views	Zoom	AoV area, TAVI
Tricuspid valve	ME 4-Ch (0°–30°), TG (40°); ± CD for all views	Zoom	Unstudied
Pulmonary valve	UE Ao Arch SAX (90°) ± CD	Zoom	TEE has limited views
Interatrial septum	ME 4-Ch (0°), ME Bic (90°); ± CD for all views	Zoom, FV	ASD
Left ventricle	ME 4-Ch (0°), ME 2-Ch (90°), ME LAX (120°)	FV	Volume, mass, ejection fraction, dyssynchrony
Right ventricle	ME 4-Ch (0°), ME 2-Ch (90°), ME LAX (120°)	FV	Volume, ejection fraction
Left atrial appendage	ME 4-Ch (0°), ME MV Comm (60°), ME 2-Ch (90°), ME LAA (110°)	Live, Zoom	Thrombus

The standard 2D transesophageal echocardiography (TEE) view is used with different 3D imaging modes to scan a region of interest and obtain a volume of tissue. This volume or block of tissue can be cropped, rotated, and displayed in any orientation to show normal and pathologic findings.
Abbreviations: 2D two-dimensional; *3D* three-dimensional; *AoV* aortic valve; *ASD* atrial septal defect; *Bic* bicaval; *CD* color Doppler; *Comm* commissural; *FV* full volume; *LAA* left atrial appendage; *LAX* long-axis; *ME* midesophageal; *MV* mitral valve; *SAX* short-axis; *TAVI* transcatheter AoV implantation; *TG* transgastric; *UE Ao Arch* upper esophageal aortic arch; *2-Ch* two-chamber; *4-Ch* four-chamber

Table 15.7 Clinical use of three-dimensional (3D) transesophageal echocardiography (TEE) in congenital heart disease

3D TEE has been recommended for
- ASD device closure guidance
- VSD device closure guidance
- Visualization of catheters, delivery systems, and devices
- Measurement of defects visualized in *en face* views
- Analysis of the anatomy and function of atrioventricular valves
- Visualization of the aortic valve and left ventricular outflow tract

3D TEE has been used effectively during
- Fontan fenestration closure
- Ruptured sinus of Valsalva aneurysm device closure
- Coronary artery fistula device closure
- Prosthetic valve paravalvular leak device closure
- Atrial switch baffle leak device closure and baffle obstruction stenting
- Atrial septum transseptal puncture during various procedures
- Biventricular pacemaker synchrony assessment and lead placement guidance

Abbreviations: *ASD* atrial septal defect; *VSD* ventricular septal defect-

for 3D echocardiographic image acquisition and display, a consensus statement on 3D imaging in CHD, and the reported clinical use of 3D TEE in the pediatric and CHD TEE guidelines, there remains no standardized protocol for the use of intraoperative real-time 3D TEE in everyday practice [4, 5, 83]. Although 3D image acquisition is rapid, processing the 3D data sets with analytical software can be time-consuming and challenging in the hectic intraoperative environment.

Functional assessment

Assessment of ventricular function is an important component of a comprehensive TEE examination. While it is common to evaluate systolic function, evaluating diastolic function is an area of growing interest because there is increasing recognition of the role that diastolic dysfunction plays in clinical outcomes [98].

The ventricles differ in geometry, systolic contraction pattern, and load conditions, requiring different methods to assess each chamber. Quantitative assessment of LV systolic function by echocardiography relies on geometric models that may not be applicable to the unusual ventricular geometries typical of CHD [2, 99]. In patients with CHD, the extents of RV enlargement and deterioration of function often determine the need for clinical intervention [100]. Currently, CMR is the gold standard for assessing RV systolic function [101], whereas real-time 3D echocardiography is comparable to CMR in assessing LV function [83].

Newer echocardiographic techniques can quantify subtle changes in regional and global ventricular function, independent of ventricular morphology, and are less affected by loading conditions [102]. *Tissue Doppler imaging* (TDI), also referred to as *Doppler tissue imaging*, provides a reproducible, clinically valid, and easily obtainable nongeometric quantitative method to assess both systolic and diastolic ventricular function [103]. *Strain* and *strain rate imaging* can provide global and regional assessment of ventricular function that is independent of geometry and less affected by loading conditions [104–106]. Improved ultrasonography technology has simplified techniques such as TDI, 3D EF, and tissue tracking for strain and strain rate to better quantify systolic function in the operative setting [107, 108]. For many of these techniques, there are reference values for normal adults and children, most often established by TTE [2, 99, 109, 110]. These values vary greatly according to age and lack validation by TEE. The discussion that follows highlights general concepts regarding selected approaches for assessing ventricular function by echocardiography.

LV systolic function

Normal LV function involves complex 3D movements during the cardiac cycle. Systolic function depends on heart rate, myocardial contractility, and loading conditions. Typically, quantitative echocardiographic assessment of LV function measures changes in LV volume by calculating stroke volume (SV), LV ejection fraction (LVEF), and cardiac output (CO). However, these quantitative measures are time-consuming, limited by loading conditions, and affected by alterations in geometric shape. Technical concerns when using TEE, such as chamber foreshortening and poor endocardial definition, further complicate the acquisition of quantitative information. Thus, intraoperative ventricular systolic performance is often assessed qualitatively, most commonly by "eyeballing" and at times by using methods such as simple linear (shortening fraction [SF]) and area (fractional area change [FAC]) measurements.

"Eyeballing" of wall motion and thickening in the ME 4-Ch, TG Mid Pap SAX, and TG LAX views (refer to Figure 15.7 and Table 15.5) can be used to qualitatively assess ventricular systolic function. Although used ubiquitously, this subjective technique lacks standardization, depends on experience, and has significant inter- and intra-observer variability. The TG Mid Pap SAX view is often used but examines only a portion of the LV (six segments) and may not reflect global systolic function in hearts with an abnormal geometric shape or regional wall motion abnormalities.

SF estimates LV systolic function from linear measures of end-diastolic diameter (LVEDD) and end-systolic diameter (LVESD) by using M-mode in a TG Mid Pap SAX view of the LV (Figure 15.10A). The superior temporal resolution of M-mode echocardiography can capture the movement of structures over time. The SF as a percentage (normal: 26–45%) is determined by the following formula:

$$\mathrm{SF}(\%) = \frac{(\mathrm{LVEDD} - \mathrm{LVESD}) \times 100}{\mathrm{LVEDD}}$$

FAC estimates global LV systolic function by using area measurements; thus, it differs from the LVEF, as it is not a volume measurement. Tracing the LV endocardial border obtains an area at end-diastole (LVEDA) and end-systole (LVESA) from LAX (ME view) or SAX (TG view) LV cross sections (Figure 15.10B). The LVFAC expressed as a percentage (normal: 45%) is determined by the following formula:

$$\mathrm{LVFAC}(\%) = \frac{(\mathrm{LVEDA} - \mathrm{LVESA}) \times 100}{\mathrm{LVEDA}}$$

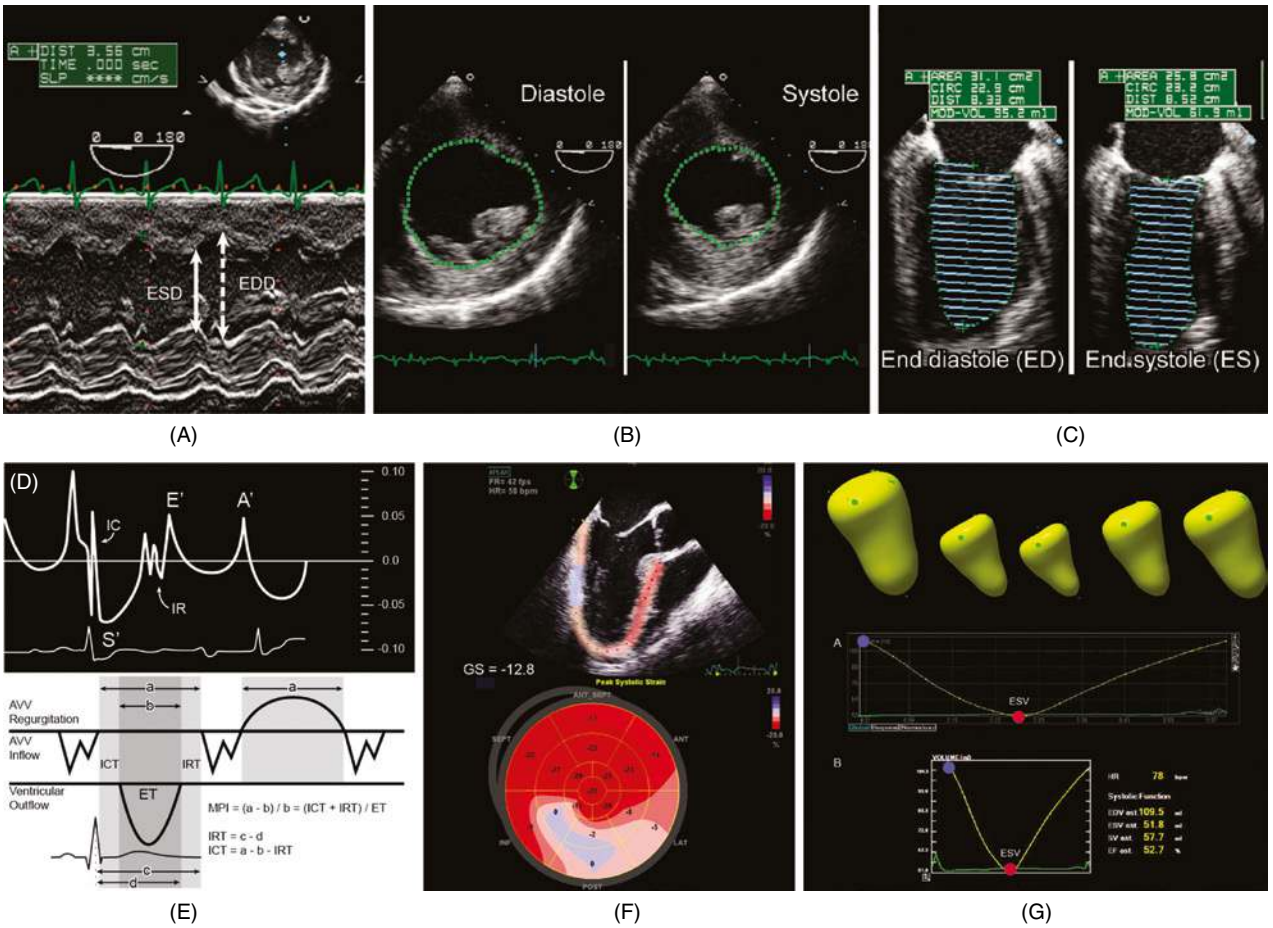

Figure 15.10 *Echocardiographic evaluation of left ventricular (LV) function*. This graphic displays the assessment of LV function using different techniques. (A) *Shortening fraction* estimates systolic function using linear measurements of LV end-diastolic (*EDD*) and end-systolic (*ESD*) chamber dimensions from a TG Mid Pap SAX view. (B) *Fractional area change* measures LV EDD and ESD chamber areas from a TG Mid Pap SAX view. (C) *Ejection fraction* measurement with Simpson's method of discs uses ME 4-Ch and/or ME 2-Ch views to trace the LV endocardium at *EDD* and *ESD*. Integrated machine software divides the LV into slices to calculate the volume. (Sources for A–C: Vegas [111, 112]. Reproduced with permission of Springer Nature.) (D) *Tissue Doppler imaging* of the lateral mitral valve annulus demonstrates a systolic velocity (*S'*) and two opposite-directed velocities, in early diastole (*E'*) and late diastole (*A'*) (graphic representation from a midesophageal window). The S' wave velocity provides an estimate of LV ejection fraction. *IC* isovolumetric contraction; *IR* isovolumetric relaxation. (E) *Myocardial performance index* is measured using spectral Doppler of the aortic outflow and mitral inflow as described in the text. (F) *Speckle tracking* can easily measure strain and strain rate (shown here for a ME LAX view) and peak systolic strain displayed in a bull's-eye format. (G) *3D assessment* of an endocardial cast derived from a 3D data set can be analyzed to estimate LV volumes and ejection fraction. (Source: Vegas [112]. Reproduced with permission of Springer Nature.) *ESV* end-systolic volume.

EF represents the most common measure of ventricular systolic function by echocardiography. The calculation of LVEF as a percentage (normal range: 56–78%) is as follows:

$$\text{LVEF}(\%) = \frac{(\text{LVEDV} - \text{LVESV}) \times 100}{\text{LVEDV}}$$

The end-diastolic volume (EDV) and end-systolic volume (ESV) of the LV can be determined by using 2D geometric methods and, more recently, from 3D volumes. The *Simpson method of discs* (MOD) in the ME 4-Ch and ME 2-Ch views (single or biplane method) divides the LV into slices of known thickness, whereby the sum of the slices represents the LV volume. The technique requires tracing the LV cavity at end diastole and end systole and determining the LV length through the apex (Figure 15.10C). The ultrasonography machine software automatically determines the LV volumes, SV, and LVEF.

A full volume data set acquired by 3D imaging can assess LV volume using two methods: 3D-guided biplane analysis and direct volumetric analysis. The 3D-guided biplane method minimizes foreshortening of the LV by positioning two perpendicular 2D planes accurately through the LV apex, thereby creating ideal ME 4-Ch and ME 2-Ch views. The LV volumes, LVEF, and mass are calculated by applying the modified Simpson biplane MOD. Direct volumetric analysis, performed with specialized software available on the ultrasonography system, measures LV volume throughout the cardiac cycle from a 3D surface-rendered cast of the LV cavity (Figure 15.10G). The software measures the EDV and ESV and calculates the SV and LVEF. This method accurately measures LV volumes, particularly in patients with an abnormal ventricular shape or regional wall motion abnormalities. The benefit of this analysis technique relates to better alignment of imaging planes through the cardiac apex, inclusion of more endocardial surface during

AL Grawany

the analysis, and the lack of geometric shape assumption. LV and RV volumes measured by 3D TTE are comparable to 2D TTE, CMR, and CT techniques. Assessing ventricular function with 3D technology is of great benefit in CHD, particularly in patients with single ventricle anatomic variants.

Doppler estimation of *SV and CO* uses the spectral Doppler mode. Any intracardiac site where recording both the cross-sectional area (CSA) and the flow velocity time integral (VTI) can be used to determine SV, as SV = CSA × VTI. An easy application of this method involves measuring the diameter of the AoV annulus (ME AoV LAX view) and flow through the valve (DTG 5-Ch view). Because the CSA of the AoV annulus does not usually change, serial monitoring of SV (and CO) mirrors changes in the VTI. The product of SV and heart rate represents the CO.

TDI records and displays pulsed-wave Doppler signals produced by the low-velocity movement of tissue. Positioning the sample volume at the lateral or septal mitral annulus measures and displays peak myocardial velocity (Figure 15.10D). Obtaining an optimal spectral trace depends on parallel Doppler alignment and tissue devoid of artifacts from reverberation, side lobes, or dropout. The TDI spectral display of the mitral annulus comprises a systolic velocity (S′) and two opposite-directed velocities recorded in early diastole (E′) and late diastole (A′). The S′ velocity is an estimate of LVEF, but not specifically a measure of contractility. Normal values for TDIs in pediatric and adult patients differ with heart rate, age, ventricular morphology, and loading conditions. These velocities are now routinely part of ventricular functional assessment by transthoracic imaging [109].

The *myocardial performance index (MPI)*, or *Tei index*, is a Doppler-derived measure of global ventricular function. It incorporates both systolic and diastolic time intervals and thus represents both systolic and diastolic performance [113]. The MPI is defined as the sum of isovolumic contraction time (ICT) and isovolumic relaxation time (IRT) divided by ejection time (ET):

$$\text{MPI} = \frac{\text{ICT} + \text{IRT}}{\text{ET}}$$

The longer the isovolumic times, the higher the MPI and the worse the ventricular performance.

Pulsed-wave Doppler interrogation of the respective AV valve and outflow tract can easily measure components of the index for either the LV or the RV (Figure 15.10E). TDI derives the MPI over a single cardiac cycle, making it more accurate than the conventional Tei index. Studies have established normal MPI values for both adults and children (normal values in adults: LV, 0.39 ± 0.05 and RV, 0.28 ± 0.04; normal values in children: LV, 0.35 ± 0.03 and RV, 0.32 ± 0.03) [114, 115]. This index has been applied to the assessment of LV and RV function in patients with CHD, as well as to the evaluation of complex ventricular geometries [115–117]. It has also been used in the intraoperative setting to study the cardiovascular effects of anesthetic agents in children with CHD [118].

Strain and strain rate imaging are newer echocardiographic modalities that offer an enhanced approach to evaluating regional myocardial contraction and relaxation. During systole, the actual volume of myocardial tissue remains unchanged, but the myocardium changes in shape or deforms in three dimensions: longitudinal (shortening), radial (thickening), and circumferential (shortening and torsion). Strain and strain rate analyze ventricular deformation to quantify global and regional ventricular function more accurately than other functional indexes [104, 105, 110, 119–121]. Strain is a single, dimensionless (%) parameter that examines the motion deformation between two points in the myocardial wall. Total deformation in all dimensions represents a percentage change from the initial length. Negative strain implies that the fibers shorten (circumferential plus longitudinal) or thin (radial), whereas positive strain indicates that the fibers lengthen (circumferential plus longitudinal) or thicken (radial). End-systolic strain estimates LVEF. Strain rate is the speed of deformation or the change in strain over time (1/s). Peak systolic stain rate is a measure of contractility.

Two methods can assess myocardial deformation: TDI and speckle tracking. *Speckle tracking* of myocardium from a standard 2D image quantifies myocardial deformation without the limitations of angle dependence associated with TDI. Speckle tracking involves frame-by-frame analysis of the movement of a region of speckles of the myocardium to derive their direction and velocity (shift over time) of tissue movement relative to each other. Speckle tracking is less influenced by artifacts, although reverberations and dropout of myocardial tissue are problematic. Speckle tracking displays peak strain as an average value for each regional wall. Averaging these peak strain values provides the *global longitudinal peak systolic strain* (GLPSS), a measure of global systolic function. A colorized bull's-eye format displays the distribution of regional peak systolic and global systolic strain (Figure 15.10F). The analysis of myocardial deformation has been applied to various cardiovascular diseases, including cardiomyopathy, myocarditis, and valve pathology, among many other conditions. The use of TEE for this purpose has been extended to the perioperative setting, but experience with this application remains limited [106, 107].

Regional wall motion

Dividing the LV into segments better describes regional wall motion abnormalities and correlates them with coronary artery anatomy. Analysis of LV segmental function is based on a qualitative visual assessment for motion or thickening of a segment during systole. The ASE and SCA use a *17-segment LV model* that divides the basal and mid-levels into six segments each and the apex into four; the 17th segment is an apical cap (devoid of LV cavity) [99, 122]. TG SAX views show one LV level at a time, but these views have the advantage of simultaneously showing portions supplied by all major coronary arteries (right, left anterior descending, and circumflex vessels). Using other ME TEE views complements this assessment by showing additional LV wall segments (Figure 15.11).

Regional wall motion abnormalities detected by TEE in pediatric patients, like those in adult patients, have been considered markers of compromised myocardial blood flow [124, 125]. Segmental abnormalities can occur from surgical manipulations that alter coronary blood flow, either from coronary dissection, interventions involving the Ao or coronary arteries, intracoronary air, or localized reperfusion injury during cardiac surgery.

RV systolic function

The echocardiographic assessment of RV systolic function is complicated by the nongeometric, asymmetric, crescent shape of the ventricle, which precludes easy application of

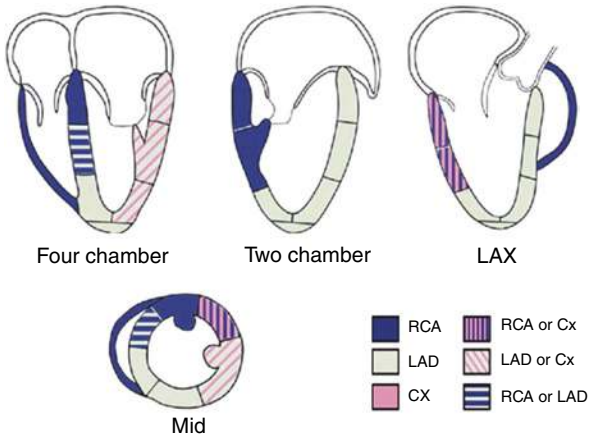

Figure 15.11 *Myocardial blood supply and corresponding TEE views.* The typical distributions of the right (*RCA*), left anterior descending (*LAD*), and circumflex (*CX*) coronary arteries as assessed by TEE imaging is shown. The coronary arterial distribution varies among patients. Some segments have variable coronary perfusion. (Source: Reeves et al. [123]. Reproduced with permission of Elsevier).

quantitative methods [126, 127]. Despite these challenges, several echocardiographic approaches can assess RV function [128–130]. The most commonly used of these approaches are *RV FAC* and *tricuspid annular plane systolic excursion (TAPSE)*. Tissue Doppler and strain echocardiography following the same principles described earlier can evaluate the RV as well as the LV [131]. Doppler measurement of the *RV myocardial performance index* (RV MPI) can augment the qualitative assessment of RV size and function. As previously mentioned, CMR is the current reference standard for assessing RV volume and systolic function.

The *RV FAC* is computed with a formula of area measurements like that for the LV FAC; these measurements are made by tracing the endocardial border of the RV during systole and diastole from the ME 4-Ch view. The normal range of values for RV FAC is 35–60%; values of 25–35% indicate mild dysfunction, 18–24% moderate dysfunction, and <17% severe dysfunction.

TAPSE is the distance of systolic excursion of the lateral tricuspid valve (TV) annulus in a longitudinal plane, often measured by using M-mode. It is a surrogate measure of global RV function (normal: 16–30 mm in adults) that correlates with angiography, biplane MOD, and FAC. Unlike TTE, TEE does not easily achieve parallel alignment in the ME 4-Ch view for this M-mode assessment; as an alternative, the TG RV Inflow view (a cross section included in the adult but not pediatric and congenital comprehensive TEE guidelines) may offer better alignment.

Evaluation of diastolic function

Diastolic dysfunction plays a major role in cardiovascular disease and is a risk factor for adverse clinical outcomes in all patients, including pediatric and adult patients with CHD [132]. The literature and ASE guidelines extensively detail the echocardiographic assessment of diastolic function [133–136]. The evaluation of LV diastolic function uses transmitral inflow Doppler indices (E, A, deceleration time) and tissue Doppler diastolic mitral annular velocities (E′, A′) at the lateral mitral annulus [137]. Combining these values, along with other Doppler echocardiographic variables (e.g., pulmonary venous flows), can classify patterns of diastolic dysfunction and assess disease progression. In a similar way, evaluating RV diastolic function involves TDI of tricuspid annular velocities.

Unfortunately, evaluating diastolic function in pediatric patients is complicated by the many confounding variables that influence Doppler assessment and interpretation of findings [138]. Although reports exist of the perioperative evaluation of diastolic function in adult patients undergoing cardiac surgery [137, 139–141], concerns remain about applying values derived from TTE performed in awake patients to TEE performed on patients under general anesthesia [142]. To the best of our knowledge, no formal studies have extensively explored diastolic function with TEE in children or, specifically, in the CHD population.

Hemodynamic evaluation

Echocardiography is an excellent noninvasive tool to obtain semiquantitative and quantitative hemodynamic information in CHD [143]. Doppler assesses blood flow and displays it as color superimposed over a 2D image (color Doppler) or as a spectral graph of velocity over time (spectral Doppler). Information obtained from Doppler can derive measures of pressure, volume, and flow [144].

Spectral Doppler measures the velocity of blood at a specific position, using a sample volume of *pulsed-wave Doppler* or along a sample line with *continuous-wave Doppler*. Doppler measurements require adequate alignment of spectral Doppler sampling to the direction of blood flow to minimize underestimation. Tracing the spectral Doppler display yields values for peak and mean velocities and the area under the curve (i.e., the flow VTI). The display of Doppler waveforms at a sweep speed of 100–150 mm/s can help identify temporal changes in the velocity flow profile, particularly in children with fast heart rates.

The complete *Bernoulli equation* is a complex formula that incorporates Doppler velocity measurements, flow acceleration, and viscous friction (blood viscosity) to estimate the *peak instantaneous pressure gradient* (PG) across an orifice. In clinical practice, a simplified version of the Bernoulli equation is sufficient in most cases to estimate the PG from the measured peak velocity (V) as follows:

$$\mathrm{PG}\,(\text{in mmHg}) \text{ or } \Delta P = 4V^2$$

Good correlation exists between Doppler estimates of PGs and direct pressure measurements. Preoperative PG estimates obtained when patients are awake or lightly sedated may differ from those obtained in the operating room under general anesthesia and conditions that may influence ventricular loading and systolic function.

No echocardiographic technique measures intracardiac pressures directly. Instead, it is necessary to use Doppler velocity measurements of regurgitant jets or across structures and apply the modified Bernoulli equation $\left(\Delta P = P_1 - P_2 = 4\left(V_2^2 - V_1^2\right)\right)$ to determine the pressure drop or gradient. In most cases, V_2 is much higher than V_1, so one can usually neglect the V_1 component of this equation. This technique is particularly valuable for estimating RV systolic pressure (RVSP), which should reflect the PA systolic pressure (PASP) in the absence of obstruction to RV outflow and which can be used to identify pulmonary hypertension. Estimating RVSP uses measurements of the peak

velocity of the tricuspid regurgitant (V_{TR}) jet along with an estimate of right atrial pressure (RAP) in the following equation:

$$\text{RVSP (in mmHg)} = 4V^2_{TR} + \text{RAP}$$

Color Doppler facilitates the detection of abnormal flows and, along with other parameters, can assess disease severity (Table 15.8). Measurements of the jet area, vena contracta, and the region of flow acceleration can be combined to grade the severity of regurgitant valvular lesions [145–147]. In the operative setting, however, most of this evaluation is qualitative.

Shunt fractions can be calculated by measuring flow (Q) through the pulmonary (Qp) and systemic (Qs) circulations. Typically, measurement of flow is across the PV and AoV from the Doppler-derived VTI and the CSA of each arterial root as:

$$Q = \text{VTI} \times \text{CSA}$$

TEE is a reliable monitor of LV filling (preload) changes in all age groups. In pediatric patients, experienced echocardiographers can identify with high sensitivity and specificity mild reductions in blood volume by changes in LVEDA by using TEE in the TG Mid Pap SAX view [148]. A marked decrease in both EDA and ESA suggests hypovolemia. Patients with conditions such as arterial vasodilatation, severe aortic regurgitation, mitral regurgitation, and VSD may have a reduced ESA but typically have a normal-to-increased EDA in this TEE view.

KEY POINTS: TEE EXAMINATION IN CHD

- TEE plays a critical role in CHD not only in characterizing the structural abnormalities but also in the functional and hemodynamic evaluation.
- The TEE examination in CHD requires navigating different windows in the esophagus and stomach to obtain cross-sectional images of structures in multiple planes.
- The examination in children and all patients with CHD should include, in most cases, the 28 views suggested in the TEE guidelines addressing these patient populations and additional modified planes as necessary.
- There is no specific recommended sequence for the TEE examination in the patient with CHD.
- In addition to the interrogation in specific 2D views, the comprehensive examination in the patient with CHD requires the use of sweeps between various planes to allow a 3D reconstruction of the anatomy and related abnormalities by the examiner.
- 3D TEE provides more information about cardiac anatomy and spatial relationships than 2D TEE; however, the size of the current adult devices limits their use to older children.
- Benefits of the real-time 3D TEE technology include the ability to freely rotate a volume-rendered 3D object in the display to be viewed from any orientation with the possibility for dissection to provide detailed information.

Table 15.8 Doppler parameters in severe valvular disease (Adult Values)

	Aortic	Mitral	Tricuspid	Pulmonic
Severe regurgitation				
CW Doppler signal strength	Dense	Dense	Dense	Dense
JA mapping (cm^2) or JA/LVOT area (%)*	>60	>10	>10	
JA/atrial area or JH/LVOT height (%)**	>65	>40		Large
Doppler flow reversal	Desc aorta	S pulmonary vein	S hepatic vein	PA
Regurgitant volume (ml)	≥60	≥60	≥60	≥60
Regurgitant fraction (%)	≥50	≥50	≥50	≥50
Vena contracta width (mm)[a]	6	≥7	>7	
Effective regurgitant orifice area (cm^2)	≥0.30	≥0.4	≥0.4	
PISA radius (mm)[b]		>10	>9	
PHT (ms)	<200–300			
Severe stenosis				
Velocity (m/s)	>4	>3	>1.5	>4
Mean pressure gradient (mmHg)	>40	>10	>5	See note
Valve area (cm^2)	<1	<1	<1	<0.5
PHT (ms)		>220	>195	

The severity of valve regurgitation or stenosis can be assessed by using different spectral and color Doppler modalities. Adult values for severe disease of different cardiac valves are shown. *Valvular regurgitation*: color Doppler can be used to map the area of a regurgitant jet, measure the vena contracta or narrowest region of the regurgitant jet (corresponds to the diameter of the regurgitant orifice area), and determine the PISA radius (based on the principle of a flow convergence zone corresponding to regurgitant flow). Spectral Doppler of the regurgitant jet signal strength by CW, systolic flow reversal in major vessels, and PHT (time needed for the peak transvalvular pressure gradient to fall to half its value) can be evaluated to assess severity. The regurgitant volume, fraction, and effective regurgitant orifice area can be calculated. *Valvular stenosis*: spectral Doppler allows assessment of velocity and pressure gradient, calculation of valve area, and measurement of PHT. *CW* continuous-wave; *desc* descending; *JA* jet area; *JH* jet height; *LVOT* left ventricular outflow tract; *PA* pulmonary artery; *PISA* proximal iso-velocity surface area; *PHT* pressure half-time. Note: For the pulmonic (pulmonary) valve, peak pressure gradient (mmHg) >64.

Nyquist limits:

[a] 50–60 cm/s

[b] 40 cm/s

* JA mapping (cm^2) applies to the mitral and tricuspid valves and JA/LVOT area (%) to the aortic valve.

** JA/atrial area applies to the mitral valve and JH/LVOT height (%) to the aortic valve

Applications of TEE in CHD

Intraoperative setting

The benefits of using TEE during surgery for CHD include monitoring, assessing the adequacy of cardiac de-airing, detecting complications, and guiding the placement of intravascular or intracardiac catheters [149–151]. TEE also influences anesthetic management in CHD by guiding changes in inotropic strategy and volume replacement [152, 153].

Intraoperative TEE influences surgical management in 3–15% of cases; the results alter the preoperative diagnosis in 3–5% of cases and prompt a return to CPB in 3–7% [153–155]. A report on intraoperative TEE during congenital heart surgery in a wide range of patients (aged 2 days to 85 years) stated that using TEE resulted in major changes to treatment in 13.8% of the patients [156]. These changes were most frequent during reoperations, valve repairs, and complex outflow tract reconstructions.

A critical role of intraoperative TEE is assessing the adequacy of the surgical intervention and detecting residual abnormalities that may require immediate revision [29, 157–163]. This feature represents a major benefit of intraoperative TEE, as it can positively influence clinical patient outcomes. In return-to-CPB situations, factors such as the level of inotropic support, loading conditions of the ventricle, and myocardial function can influence the echocardiographic findings, potentially underestimating or overestimating the hemodynamic severity of the condition. Consequently, decisions regarding return to CPB should be interpreted in this context and in consideration of the overall risk-to-benefit ratio.

In a study of TEE in 230 patients, detecting and surgically revising residual abnormalities improved outcomes, whereas the patient's course was suboptimal if the residual defect remained [161]. In addition to the patient benefits afforded by this imaging modality, routine TEE during congenital and pediatric heart surgery appears to be cost-effective [164, 165]. The experience regarding the value of intraoperative TEE has been so compelling that, at many centers, it has become the standard of care.

Cardiac catheterization laboratory

During the past several decades, transcatheter-based therapies and interventional procedures have become increasingly used in the nonsurgical management of congenital cardiovascular anomalies. Many of these approaches have extended from the cardiac catheterization laboratory to the operating room (and vice versa) as combined efforts of interventional cardiologists and cardiothoracic surgeons. TEE allows safer and more effective application of these interventions by decreasing radiation exposure, reducing the amount of contrast agents administered, and limiting the duration of the procedure [166]. As with intraoperative TEE, major benefits include acquisition of detailed anatomic and hemodynamic data before and during the procedure; real-time evaluation of catheter and device placement across structures while assisting in procedural guidance; immediate assessment of the intervention; and monitoring for procedural complications. The high success rate and low incidence of complications with these procedures are a testament to the refinement of interventional techniques coupled with advances in TEE [21].

Intensive care unit

Echocardiography remains an important diagnostic tool in the ICU to manage postoperative cardiac surgical patients [167]. Bandages, chest tubes, mediastinal air, positive pressure ventilation, and even an open sternum frequently render TTE imaging challenging and, at times, infeasible. Thus, alternate imaging approaches such as TEE or, at times, epicardial imaging in patients with an open sternum may be the preferred imaging modality to address important clinical questions, particularly in ventilated patients [48, 168]. In the hemodynamically unstable patient in the ICU, TEE can help identify problems related to preload, myocardial function, afterload, and cardiac tamponade. In the absence of the classic clinical finding of tamponade, TEE can diagnose localized cardiac compression from a loculated collection or even "dry" tamponade. New findings related to outflow tract obstruction, significant native or prosthetic valve dysfunction, or regional wall motion abnormalities may prompt surgical reintervention. Additional applications of TEE in the ICU include investigating possible occult shunts, evaluating mechanical circulatory support devices, and facilitating support weaning.

KEY POINTS: APPLICATIONS OF TEE IN CHD

- For CHD patients, TEE is most likely to be used in the operating room, cardiac catheterization or electrophysiology laboratory, and critical care setting.
- Preoperative TEE permits the baseline evaluation of anomalies, confirms preoperative diagnoses, identifies new or different pathology, excludes defects, and refines the surgical and anesthetic plans.
- Major roles of postoperative TEE include assessing the adequacy of the intervention, guiding the revision of the repair if necessary, and identifying problems associated with weaning from CPB.
- Several factors can influence the echocardiographic findings, potentially underestimating or overestimating the severity of the condition, which warrants their consideration in return-to-CPB decisions.
- TEE facilitates procedures in the catheterization or electrophysiology laboratory, may enhance their safety, and limits the duration of the intervention.
- In the ICU, TEE can address important clinical questions when other imaging modalities cannot be used or cannot provide the required information; in the hemodynamically unstable patient, TEE can help identify the cause of the instability.

AL Grawany

TEE safety and complications

Although complications related to transesophageal instrumentation occur at a rate of 1–3%, extensive clinical experience indicates that serious TEE complications are rare [169–172]. Probe manipulation can affect hemodynamic and respiratory parameters; this requires attentiveness, particularly in small infants [173, 174]. Aortic compression can influence blood pressure readings, depending on the location of the arterial monitoring line.

In the patient with an aberrant origin of a subclavian artery with a retroesophageal course, the arterial pressure monitoring line should be placed in an extremity not supplied by the anomalous vessel, as the pressure tracing may be lost with insertion or manipulation of the TEE probe. This occurs because the probe compresses the vessel as it courses behind the esophagus. In fact, placing a TEE probe occasionally detects this vascular anomaly [175, 176]. TEE is of little benefit in the surgical management of isolated vascular malformations, such as vascular rings, and it may in fact be risky, as probe insertion can significantly compromise respiratory function [177]. In infants with anomalous pulmonary venous connections, compression of a posteriorly located pulmonary venous confluence by the TEE probe can cause detrimental hemodynamic effects (Figure 15.12) [54]. In such patients, inserting the TEE probe after sternotomy may be safer [178].

Respiratory compromise can result from displacement of the ETT or accidental extubation. Capnography can help identify these complications. If desaturation occurs acutely, the position of the TEE probe tip should be immediately adjusted to neutral, and the position of the ETT should be checked. During removal of the TEE probe, holding the ETT firmly prevents inadvertent extubation. Airway compression during manipulation of the imaging probe can also result in ventilatory difficulties.

TEE can cause dysphagia, resulting from mild mucosal injury detectable by flexible esophagoscopy in some patients [179–181]. Unrecognized esophageal perforation during intraoperative TEE has been reported in a small infant [182]. Inadvertent laceration of the stomach has been described from the surgical incision extending into the xyphoid region, while the abdominal wall protruded anteriorly during TG imaging [169]. These cases underscore the need to exercise meticulous care during the insertion and manipulation of TEE probes, particularly in the critically ill neonate.

Endocarditis has been temporally related to TEE examination. However, the incidence of positive bacterial blood cultures immediately after TEE is extremely low and within the expected rate of false-positive results. The American Heart Association guidelines do not recommend administering antibiotics solely to prevent endocarditis in patients who undergo gastrointestinal tract procedures, which would include TEE [183].

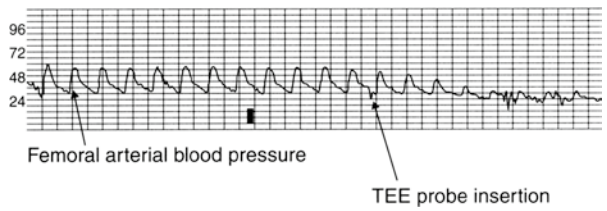

Figure 15.12 *Hemodynamic changes related to TEE probe.* The figure displays an acute decrease in systemic arterial blood pressure, as recorded from a femoral arterial line, related to TEE probe insertion in a neonate with total anomalous pulmonary venous return. The hypotension was likely the result of probe compression of the pulmonary venous confluence.

KEY POINTS: TEE SAFETY AND COMPLICATIONS

- Serious complications related to TEE have been reported, but these are fortunately rare.
- Infants are at elevated risk of TEE complications, including respiratory and hemodynamic compromise.
- Anomalies such as vascular rings and anomalous pulmonary venous drainage may preclude TEE imaging.
- When TEE imaging is planned, the ETT should be well secured to prevent dislodgement or inadvertent tracheal extubation.
- A low threshold to adjust the TEE probe position, pause or discontinue imaging, or remove the device is warranted in cases of acute arterial desaturation or potentially adverse hemodynamic changes.

Evaluation of selected congenital heart defects before and after intervention

In the perioperative setting, echocardiographic assessment during the pre-CPB period confirms the presence of the operative lesion(s), documents associated findings, and assesses cardiac function. Post-CPB evaluation focuses on determining the adequacy of the repair, mainly by identifying residual intracardiac shunts, outflow tract obstructions, and valvular regurgitation and by assessing ventricular performance [159, 161, 184]. Numerous educational resources provide comprehensive reviews on TEE imaging and hemodynamic assessment in CHD [28, 80, 184–186]. The following sections present an overview of pertinent TEE findings in selected anomalies and a summary of relevant aspects of the pre- and post-CPB examination (Table 15.9). The reader should refer to other chapters throughout this textbook that address in further detail each of the highlighted congenital lesions which follow.

Table 15.9 Transesophageal echocardiography examination (TEE) in selected congenital heart defects

	Pre–cardiopulmonary bypass TEE	Post–cardiopulmonary bypass TEE
Aortic stenosis	• Define aortic valve anatomy • Evaluate location (subvalvular, valvular, supravalvular) and severity of the obstruction • Characterize the pathology • Evaluate for aortic regurgitation • Determine presence of LV hypertrophy and assess function	• Assess for residual outflow obstruction • Evaluate for aortic regurgitation • Examine for the presence of new VSD • Examine for mitral regurgitation • Assess ventricular function • Evaluate prosthetic valve function (if applicable) • After a Ross procedure, assess autograft and RV-to-PA conduit

Atrial septal defect (ASD)	• Define location and size of defect
	• Examine defect rims for catheter-based interventions
	• Assess AVV regurgitation
	• Determine RA and RV sizes
	• Assess baseline ventricular function
	• Estimate RVSP (PASP) from TR jet velocity
	• Identify associated anomalies
	  ○ MV prolapse
	  ○ Cleft AVV
	  ○ Partial anomalous venous drainage
		After repair of all ASDs:
		• Assess for residual shunting
		• Evaluate ventricular function
		After repair of secundum and primum defect:
		• Examine for AVV regurgitation
		After repair of sinus venosus defect:
		• Evaluate for SVC obstruction
		• Assess for pulmonary venous obstruction (if associated anomalous pulmonary venous return)

Atrioventricular septal defect (AVSD)	• Define location, size, and type of defects
	• Characterize shunting across defects
	• Evaluate for additional septal defects
	• Assess AVVs
	  ○ Rastelli type in complete defect
	  ○ AVV regurgitation
	  ○ Relation of valvular structures to ventricles
	  ○ Balanced vs. dominant type
	  ○ Valvular support apparatus
	• Interrogate ventricular outflows (obstruction)
	• Assess baseline ventricular function
	• Estimate RVSP/PASP
		After repair of all AVSDs:
		• Assess for residual shunts
		• Evaluate for LVOT obstruction
		• Evaluate ventricular function
		After repair of partial AVSD/cleft MV closure:
		• Evaluate for residual or new AVV regurgitation (mild regurgitation may be acceptable)
		• Examine for mitral inflow obstruction (if mitral cleft closed)
		After repair of complete AVSD:
		• Examine for AVV stenosis (particularly if annuloplasty or left-sided cleft closure performed) and regurgitation

Congenitally corrected transposition (L-TGA)	• Confirm anatomy • Confirm AV and ventriculoarterial relationships • Evaluate AVV function • Assess ventricular sizes and function	• Assess for AVV regurgitation • Examine outflow tracts for patency/obstruction • Determine adequacy of the intervention (PA banding, classic repair, or double switch operation) • Assess ventricular function
Double-outlet right ventricle	• Evaluate septal defects (size, location, shunt direction) • Assess relation of VSD to great arteries • Assess physiology from anatomic findings (i.e., VSD, transposition or Taussig-Bing, tetralogy type) • Determine great artery relationship (normal, malposed) • Evaluate for outflow tract obstruction • Evaluate ventricular sizes and function • Evaluate associated defects	• Evaluate for residual intracardiac shunts • Assess for outflow tract obstruction • Examine AVVs and semilunar valves for regurgitation/stenosis • Depending on the procedure interrogate LV-to-Ao baffle and RV-to-PA conduit function as applicable • Assess ventricular function
Pulmonary stenosis	• Define pulmonary valve anatomy • Evaluate location (subvalvular, valvular, supravalvular) and severity of the obstruction • Characterize the nature of the pathology • Determine size of the PAs • Evaluate for intracardiac shunts • Evaluate for RV hypertrophy and function	• Examine for residual outflow obstruction • Assess for pulmonary regurgitation • Investigate for new VSD • Examine for TR • Assess ventricular function • Assess conduit or prosthetic valve function as applicable

AL Grawany

Table 15.9 (Continued)

	Pre–cardiopulmonary bypass TEE	Post–cardiopulmonary bypass TEE
Tetralogy of Fallot	• Define size and location of septal defects • Examine for additional VSDs or associated anomalies • Evaluate RVOT (subvalvular, valvular, supravalvular regions) ○ Define morphology, obstruction, gradients • Determine size of pulmonary arteries • Assess Ao override/ root size, AoV competence • Identify origin and course of coronary arteries • Evaluate baseline ventricular function	• Evaluate for residual VSD • Assess RVOT velocity/gradient • If there is residual obstruction, define type (fixed vs. dynamic) and severity • Evaluate for pulmonary regurgitation • Estimate RVSP (from TR jet) • Evaluate RV and LV function • Examine conduit or prosthetic valve function in pulmonary position
Transposition of great arteries (D-TGA)	• Confirm anatomy and ventriculoarterial relationships • Assess intracardiac shunts (location, size, flow direction, relation to outflows) • Assess for outflow tract obstruction • Evaluate AVVs and semilunar valves • Identify origin and course of the coronary arteries • Assess ventricular sizes and function • Assess septal geometry (indicator of ventricular pressures)	*After the arterial switch operation (Jatene procedure):* • Interrogate the neoaortic and pulmonary anastomoses (for stenosis) • Evaluate for semilunar valve competence • Assess patency of outflow tracts • Assess for AVV regurgitation • Evaluate for residual intracardiac shunts • Examine coronary blood flow • Assess global and segmental LV function
Truncus arteriosus	• Assess the truncal valve (for morphology, stenosis, and regurgitation) • Identify septal defects (size, location) • Determine the origin of the pulmonary arteries ○ Type of truncus ○ Pulmonary blood flow • Assess ventricular function	• Examine the truncal (aortic valve) for stenosis and regurgitation • Evaluate the RV-to-PA conduit (for stenosis or regurgitation) • Evaluate for residual VSD shunting • Assess for AVV regurgitation • Estimate RVSP (PASP) from TR jet • Assess ventricular function, including segmental wall motion (coronary arteries)
Single ventricle	• Evaluate morphologic type • Assess AVVs and semilunar valves, inflows, and outflows • Assess adequacy of the interatrial communication • Evaluate prior surgical interventions • Assess ventricular function	*After Fontan or Glenn procedure:* • Flow in Fontan or Glenn connections • Evaluate Fontan fenestration, if performed • AVV regurgitation • Atrial septal shunting for evidence of obstruction (if stenosis or atresia of AVV) • Assess ventricular function
Ventricular septal defect (VSD)	• Determine location and size of defect(s) • Evaluate for additional intracardiac shunts • Investigate for associated pathology: ○ AVV regurgitation ○ Aortic valve cusp herniation or prolapse ○ Aortic regurgitation ○ Subaortic membrane ○ Pulmonary valve stenosis ○ Double-chamber RV • Assess baseline ventricular function • Estimate RVSP (PASP) from TR jet or VSD peak velocity	*After repair of all VSDs:* • Evaluate for residual shunting (tiny patch leaks are acceptable) • Estimate RVSP from TR jet • Assess ventricular function *After repair of perimembranous defect:* • Evaluate for AVV regurgitation (TR in particular) • Assess for aortic regurgitation *After repair of supracristal (subarterial, doubly committed) defect:* • Evaluate for new aortic regurgitation • Evaluate for pulmonary regurgitation *After repair of muscular or inlet defect:* • Evaluate for AVV regurgitation

Abbreviations: *Ao* aorta; *AoV* aortic valve; *AV* atrioventricular; *AVV* atrioventricular valve; *LV* left ventricle; *LVOT* left ventricular outflow tract; *MV* mitral valve; *PA* pulmonary artery; *PASP* pulmonary artery systolic pressure; *RA* right atrium; *RV* right ventricle; *RVOT* right ventricular outflow tract; *RVSP* right ventricular systolic pressure; *SVC* superior vena cava; *TR* tricuspid regurgitation

Atrial septal defects

Anatomic and physiologic features

Interatrial communications allow blood to flow between the atria. By definition, a true ASD is a gap in the IAS tissue that permits shunting of blood between the atrial chambers. Other types of atrial communication do not necessarily result from a deficiency of IAS tissue. Typically, ASDs are classified into four types, although not all represent a "true" ASD. The defect location defines each type, which may be associated with other cardiac anomalies.

An *ostium secundum defect* (80% of ASDs) is a tissue defect that arises at or near the center of the IAS in the region of the fossa ovalis (septum primum). The defect usually has a complete surrounding rim of septal tissue, although portions of the tissue rim(s) are deficient in some cases. A secundum ASD can coexist with other congenital heart lesions and, in 30% of cases, with MV prolapse. An *ostium primum defect* (15% of ASDs) is a tissue defect in the inferior aspect of the IAS near the AV valves and is part of the spectrum of atrioventricular septal defects (AVSDs). The *sinus venosus defect* (5% of ASDs) is a tissue deficiency in the sinus venosus septum that occurs near the caval veins (superior vena cava and inferior vena cava [IVC] types). Sinus venosus defects are associated with partial anomalous pulmonary venous connection (PAPVC) or drainage. A *coronary sinus defect* is a rare atrial communication that frequently includes the coronary sinus orifice. This defect is a deficiency in the common wall that separates the coronary sinus from the LA. Left-to-right shunting occurs most commonly from the LA to the right atrium (RA) through the partially or completely unroofed coronary sinus, but the direction of shunting may be variable as influenced by atrial hemodynamics. These defects are frequently associated with persistent drainage of a left-sided SVC (LSVC) into the coronary sinus. A *PFO* represents a flap that arises from failure of the septum primum to adhere to the limbus of the septum secundum. There is no deficiency in septal tissue, though this interatrial communication can cause shunting under certain conditions.

The clinical manifestations of an ASD primarily relate to the magnitude of atrial-level shunting, which depends on the defect size, ventricular compliances, and PA pressures. An ASD, particularly a small defect, may represent an incidental finding on echocardiography. A large defect causes pulmonary overcirculation that results in symptoms of right-sided volume overload. Over time, atrial arrhythmias and heart failure can develop. Although older patients can have evidence of elevated PASP, they rarely have severe pulmonary hypertension.

Highlights of the TEE examination

Multiple ME views are necessary to completely assess the relatively thin IAS [187]. The perpendicular alignment of the imaging plane in the ME Bicaval view most reliably images the IAS. In the ME 4-Ch view, the imaging plane is parallel to the IAS; hence, a false "absence of tissue" may occur from dropout. Other helpful views include the DTG Atr Sept view. Measuring the gap in the septal tissue determines the size of the atrial communication. Communications at the atrial level as displayed by TEE appear in Figure 15.13.

Color and spectral Doppler interrogation can easily detect abnormal blood flow across the IAS. Left-to-right shunting is usual in an isolated ASD, but it may be right-to-left or bidirectional in patients with certain conditions (e.g., pulmonary hypertension) or coexistent defects. The peak velocity across the defect is inversely proportional to the defect's size, with a larger defect having lower velocity laminar flow. If there is a tricuspid regurgitation (TR) jet, it can estimate the PASP, as previously discussed.

TEE with saline contrast is the most sensitive method to detect interatrial shunts that are not evident by 2D or Doppler techniques. A contrast study involves vigorously agitating saline (3–10 mL) with <1 mL of air and injecting it rapidly into a central or arm vein. A better alternative may be aspirating the patient's blood and mixing it with saline or albumin. A negative study reveals no flow of bubbles across the IAS. A positive study indicates right-to-left shunting, with microbubbles present in the LA within five heartbeats of injection. A false-positive study can result from pulmonary arteriovenous malformations. Additionally, the appearance of noncontrasted blood in the contrast-filled RA can help identify left-to-right shunting. Saline contrast improves PFO detection, both at rest and with raised RAP [188]. A Valsalva maneuver can enhance the recognition of a small or intermittent right-to-left interatrial shunt. In the intubated patient, sustained lung inflation to a positive inspiratory pressure of about 25 mmHg for approximately 10 seconds can simulate a Valsalva maneuver.

The *preoperative TEE* examination for an ASD should confirm the location of the defect, its size, and the direction of the shunt. Guided by the specific type of defect, the TEE study should evaluate for existing or potential MV prolapse (secundum defect), cleft MV (primum defect), PAPVC (sinus venosus defect), and LSVC-to-coronary sinus connection (coronary sinus defect). Additional aspects of the TEE study in all defects include evaluating AV valve competence, associated anomalies, and ventricular function. Atrial communications with significant left-to-right shunting can cause right atrial and RV enlargement and diastolic flattening with paradoxical motion of the interventricular septum (IVS). The *postsurgical TEE* examination should evaluate the IAS for residual shunting, valvular competence, ventricular function, and flow across the systemic and pulmonary veins, depending on the defect and the type of intervention undertaken.

Transcatheter closure with an occluding device may be an option for selected secundum defects [19]. TEE assists in patient selection, procedural guidance, and immediate assessment of success and complications. Essential components of the TEE examination that contribute importantly to decision-making include determining the size and location of the defect, characterizing the orifice (single vs. multiple), evaluating the dimensions and adequacy of septal rims, and assessing the relationship of the defect to surrounding structures [189–193]. Advocates suggest routinely using 3D TEE during transcatheter closure when the patient's size allows it.

Postdeployment TEE assesses the device (integrity, position, and stability) and possible residual shunt, and identifies complications (Figure 15.14) [19, 194]. Placing a device can affect surrounding structures, resulting in compromised inflow from the caval veins, coronary sinus, or pulmonary veins; interference with valve function; and pericardial effusion.

AL Grawany

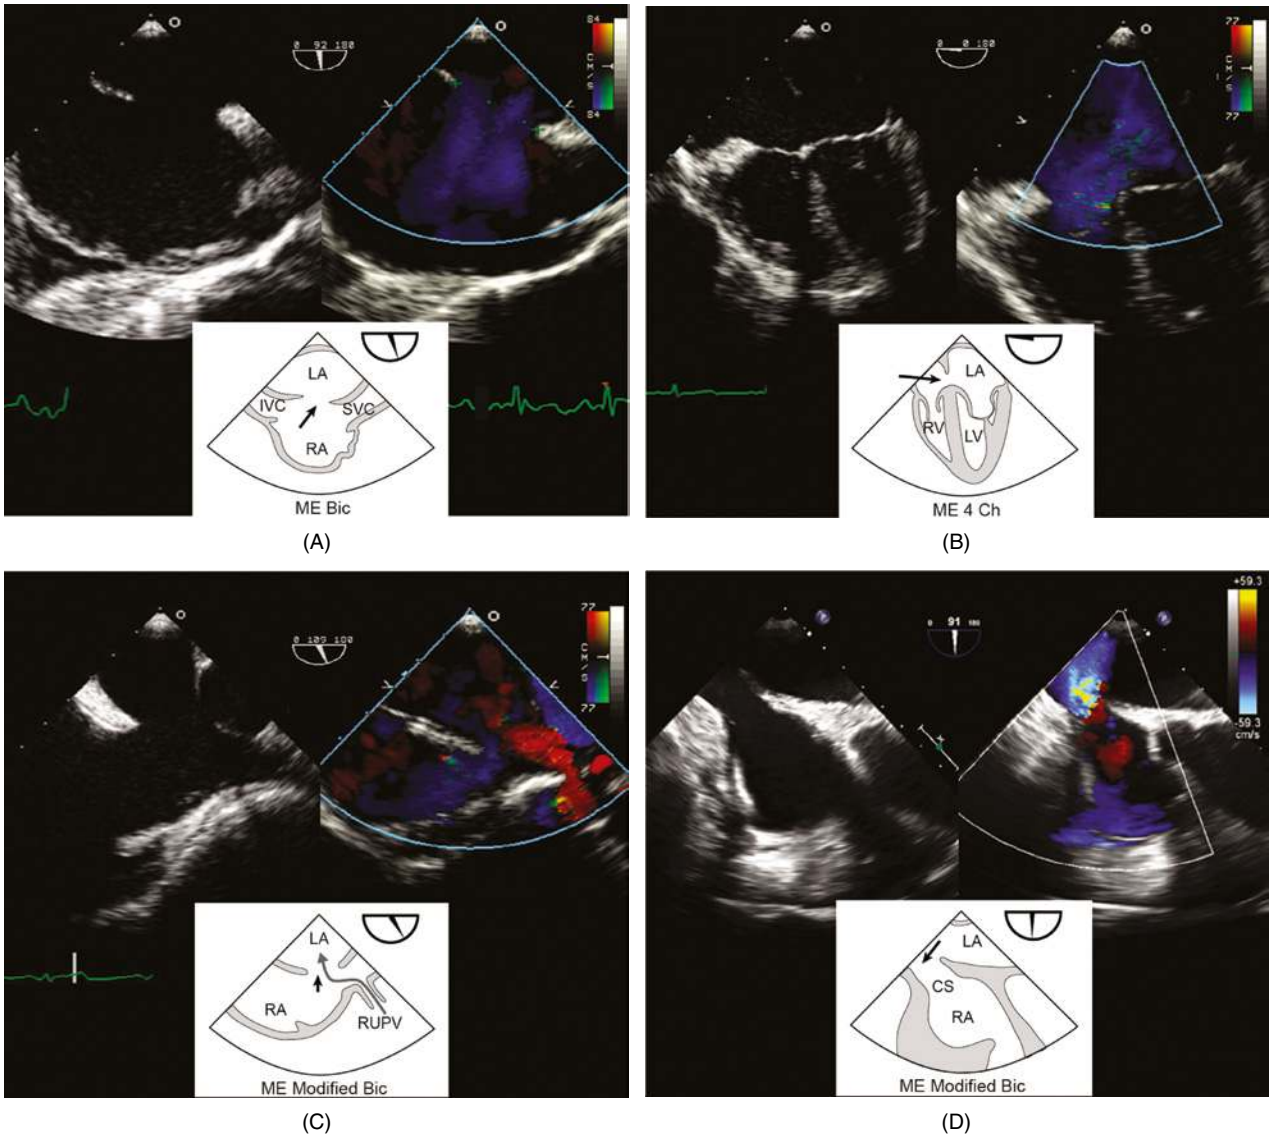

Figure 15.13 *Atrial septal defects (ASDs)*. (A) *Secundum ASD*. ME Bic view depicts a centrally located septal deficiency in this defect within the region of the fossa ovalis (*arrow*) and adjacent interatrial septal (IAS) rims. Comprehensive septal rim assessment requires multiple views. (B) *Ostium primum ASD*. ME 4-Ch view shows the inferior communication in the IAS in this defect (*arrow*). Note insertion of both atrioventricular valves (AVVs) into the interventricular septum at the same level. A cleft or commissure in the anterior mitral valve leaflet, also referred to as zone of apposition of the left AVV, is best seen in the TG Basal SAX view. The assessment of mitral regurgitation can be performed in the ME 4-Ch, ME 2-Ch, ME Mitral Comm, and ME LAX views. Mitral valve chordal attachments to the interventricular septum, when present, can be defined in the ME 5-Ch, ME LAX, TG LAX, and DTG 5-Ch views and assessed for related left ventricular (*LV*) outflow tract obstruction. (Source: Vegas [112]. Reproduced with permission of Springer Nature.) (C) *Sinus venosus ASD*. The ME Bic or modified views with slight probe withdrawal optimally images the superior type of defect (*small arrow*) and the superior vena cava (*SVC*) as it drains into the right atrium (*RA*). Anomalous drainage of the right upper pulmonary vein (*RUPV*) in the SVC-type defect (*long arrow*) results from unroofing of the wall that separates the RUPV from the left atrium (*LA*) as shown by color Doppler of pulmonary venous flow. Advancing the probe to the TG IVC/Hep Veins view in an inferior defect displays the atrial communication and region where the inferior vena cava (*IVC*) joins the RA. (D) *Coronary sinus ASD*. The examination of the coronary sinus (*CS*) is optimal in views that display this structure in both its long and short axes. A dilated CS is best imaged by probe retroflexion in the ME 4-Ch view or slight advancement towards the lower esophagus. Unroofing of the CS in this defect is demonstrated by echo dropout in the wall that separates the LA from the CS in the ME (4-Ch, 2-Ch, MV Comm, and LAX) views. Probe angulation between 90° and 120° assisted by color-flow Doppler in a modified ME Bic view depicts the defect and flow from the CS into the RA in the inferior portion of the atrium (*arrow*) as shown. A persistent left SVC, if present, appears in the ME MV Comm view as a wedge-shaped echo-free space between the left upper pulmonary vein and left atrial appendage or at the level of the AV junction in the ME 4-Ch and ME 2-Ch views. *RV* right ventricle. Diagrams courtesy of Ms. Willa Bradshaw.

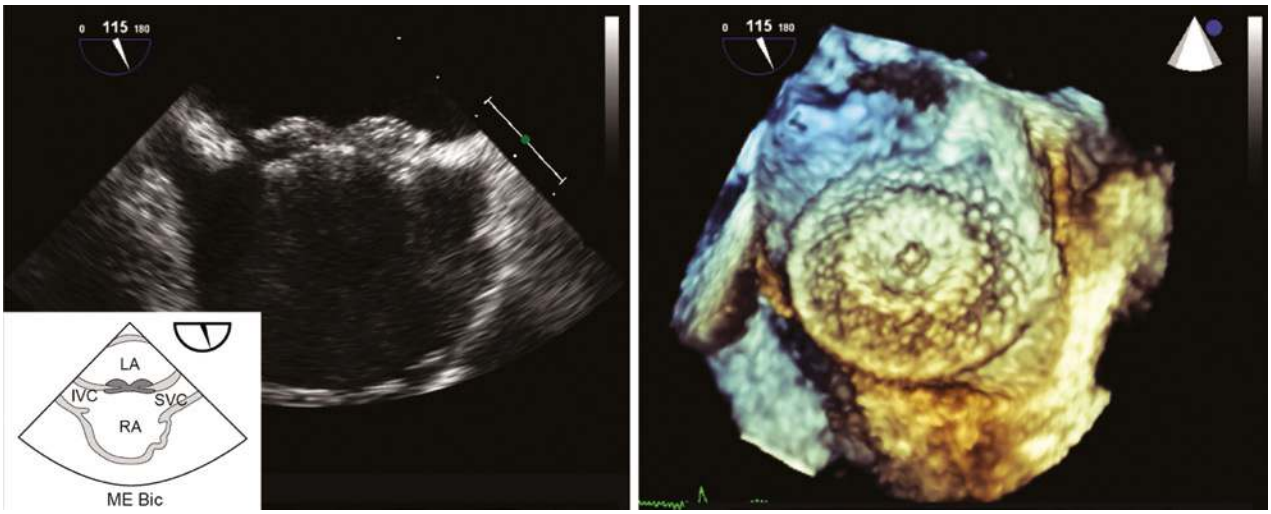

Figure 15.14 *Device occlusion of secundum atrial septal defect (ASD).* (A) ME Bic view depicts an Amplatzer™ ASD occluder device well positioned across the interatrial septum. (B) 3D TEE view from the right atrium (*RA*) depicts the details of the device in an *en face* perspective. *IVC* inferior vena cava; *LA* left atrium; *SVC* superior vena cava. (Source: Vegas et al. [41]. Reproduced with permission of Springer Nature.) Diagram courtesy of Ms. Willa Bradshaw.

Ventricular septal defects

Anatomic and physiologic features

The ventricular septum is a complex 3D structure formed by morphologically distinct subunits that can have tissue deficiencies that result in defects. The categorization of VSDs has been the subject of ongoing debate [195]. In this chapter, we use the classification scheme based on the location of the defect within the ventricular septum as follows: membranous, muscular, inlet, or subarterial. *A perimembranous defect* (70% of VSDs), also referred to as membranous, paramembranous, conoventricular, or infracristal, involves the thin membranous portion of the IVS adjacent to the TV and AoV. *A muscular defect* (20% of VSDs) can occur anywhere in the trabecular septum (mid, apical, anterior, and posterior regions) and is bound entirely by muscle. Single or multiple defects can be present. An *inlet defect* (5% of VSDs), also referred to as the "canal type of defect," results from incomplete formation of the central fibrous body or AV canal septum (see AVSD below). This communication is located at the crux of the heart, adjacent to the MV and TV annuli. An *outlet defect* (5% of VSDs), also described as infundibular, conal, subpulmonary, supracristal, doubly committed, or subarterial, occurs in the muscular portion of the septum that separates the outflow tracts. The various types of VSDs frequently overlap, as they can extend from one primary region to another. Associated lesions are identified in some cases, including patent ductus arteriosus (PDA; 6%) and coarctation of the Ao (CoA; 5–10%).

Highlights of the TEE examination

Systematically interrogating the entire IVS requires multiple TEE views [196]. The use of 2D imaging can identify each type of VSD (Figure 15.15), although small defects may require superimposed color Doppler to define their location and optimize spectral Doppler alignment. Contrast injection can be helpful to detect a defect that may be otherwise difficult to identify. In isolated defects, spectral Doppler interrogation shows systolic left-to-right shunting across the ventricular septum, with a peak jet velocity inversely proportional to defect size. Turbulent color Doppler flow characterizes a small restrictive VSD, with a high peak velocity consistent with a ventricular gradient. A large, unrestrictive VSD equalizes pressures between the ventricles and elevates PASP. A significant left-to-right shunt causes left-sided volume overload, dilatating the LA and LV. *Eisenmenger syndrome*, rarely seen today, results from unrestricted interventricular shunting that alters the pulmonary vasculature and thereby increases arteriolar resistance and reverses the shunt direction from left-to-right to right-to-left. The peak velocities of the TR or VSD jets can provide an estimate of RVSP (or PASP).

The *preoperative TEE* examination should, in all cases, confirm the location, size, and number of defects; assess the chamber and PA sizes; and evaluate ventricular function [196]. Spectral Doppler interrogation can determine shunt direction and magnitude and the degree of pressure restriction and provide an estimate of PA pressures. The examination should also assess for associated cardiac anomalies, valvular competence, and outflow tract obstruction. The *post-CPB TEE* study focuses on evaluating residual shunting, PASP, and ventricular function [197]. One should note that a large proportion of residual VSD shunts are trivial and resolve spontaneously [198]. The type of VSD suggests the need for further evaluation for associated pathology, such as outflow tract obstruction, valvular regurgitation, and the adequacy of the intervention for concomitant lesions. TEE is also helpful for monitoring, guiding, and documenting the appropriate position of transcatheter muscular VSD occluder devices in the cardiac catheterization laboratory and during periventricular interventions (Figure 15.16). In fact, a recent report describes the exclusive use of TEE without fluoroscopy during transcatheter occlusion procedures [200].

AL Grawany

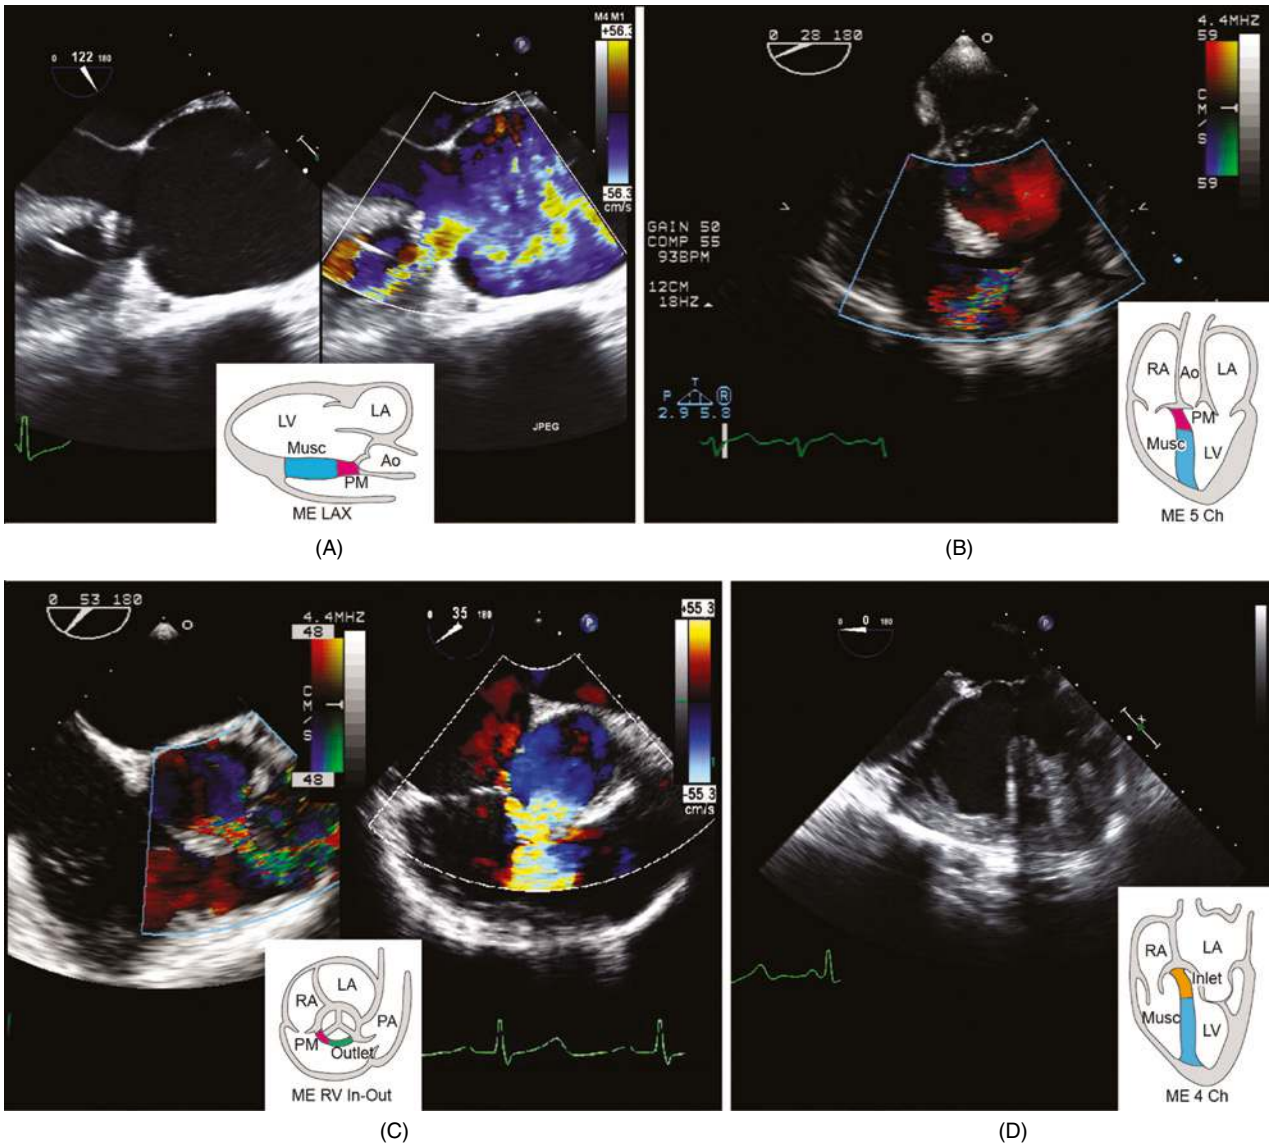

Figure 15.15 *Ventricular septal defects (VSDs)*. (A) *Perimembranous* (*PM*) *VSD*. The defect appears in cross sections that display the tricuspid valve (TV) and/or aortic valve (AoV) at the level of the midesophagus, such as ME 5-Ch, ME AoV LAX (shown), ME LAX, and right ME RV In-Out views. Associated TV abnormalities may be present (aneurysmal septal tissue partially occluding the VSD), AoV cusp prolapse, or subaortic stenosis requiring additional views for evaluation. (B) *Muscular* (*Musc*) *VSD*. The examination for this defect uses sweeps of the entire ventricular septum to identify deficiencies surrounded exclusively by muscle rims. The ME 4-Ch (shown), ME LAX, and the TG/DTG views best display this communication. Color Doppler may be necessary to demonstrate small serpiginous or, on occasion, multiple adjacent muscular defects ("Swiss cheese septum"). (C) *Outlet VSD*. The ME RV In-Out view is particularly helpful in determining the type of VSD, as a septal deficiency close to the pulmonary valve indicates an outlet VSD (*left panel*), in contrast to a PM defect located near the TV valve (*right panel*). An outlet VSD may potentially result in AoV cusp prolapse (usually of the right coronary cusp) with associated regurgitation. This is optimally examined in the ME AoV LAX view by 2D imaging and color-flow mapping. (Source: Vegas [112]. Reproduced with permission of Springer.) (D) *Inlet VSD*. The identification of this defect in the superior aspect of the muscular septum is optimal in a ME 4-Ch view that shows the region where the atrioventricular valves would normally join the interventricular septum (crux of the heart) as shown. Inlet defects are located more superiorly in the muscular septum than posterior muscular VSDs. *Ao* aorta; *LA* left atrium; *LV* left ventricle; *PA* pulmonary artery; *RA* right atrium. (Source: Diagrams courtesy of Ms. Willa Bradshaw.)

Atrioventricular septal defects

Anatomic and physiologic features

The characteristics of AVSDs, also referred to as *common AV canal* or *endocardial cushion* defects, relate to deficiencies of the AV septum and abnormalities of the AV valves. Although a well-known classification scheme recognizes only two categories of AVSDs, i.e., the complete and partial forms [201], the description of additional forms may lead to confusing nomenclature [202]. The various categories are as follows:

- *Complete defect*, characterized by a single valve annulus, common AV valve with usually five leaflets, and contiguous communications at the atrial (primum ASD) and ventricular (inlet VSD) levels

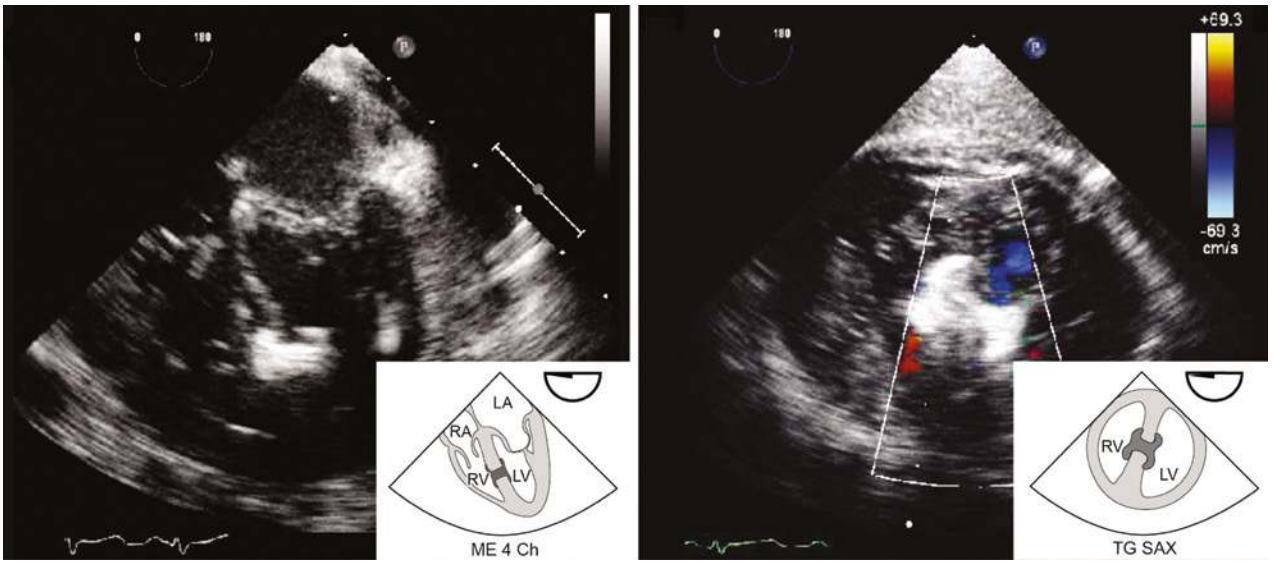

Figure 15.16 *Device occlusion of muscular ventricular septal defect (VSD).* (A) ME 4-Ch image depicts the appearance of a muscular VSD occluder device in the mid septum. (B) TG Mid Pap SAX complementary image demonstrates the position of the occluder device. *LA* left atrium; *LV* left ventricle; *RA* right atrium; *RV* right ventricle. (Source Motta and Miller-Hance [199]. Reproduced with permission of Wolters Kluwer Health, Inc.). Diagrams courtesy of Ms. Willa Bradshaw.

- *Intermediate defect*, described as having a primum ASD, large nonrestrictive VSD, and common AV valve annulus separated by a "tongue" of tissue into two valvular orifices
- *Partial defect*, consisting of a primum ASD and cleft in the left AV valve (MV). An alternative term for the cleft is the "zone of apposition."
- *Transitional defect*, having in addition to a primum ASD a small inlet VSD due mostly to obliteration by right-sided or TV valve chordal attachments to the ventricular septum

Complete defects are usually associated with significant intracardiac shunting, resulting in pulmonary overcirculation and left-sided volume overload. Intermediate defects physiologically resemble the complete form of the defect. Partial and transitional defects essentially behave as an ASD. Associated defects in the patient with an AVSD may include tetralogy of Fallot (TOF), double-outlet RV (DORV), and total anomalous pulmonary venous drainage or pulmonary atresia in more complex, heterotaxy-type defects.

Highlights of the TEE examination

The ME 4-Ch view best shows these types of defects (Figure 15.17). The comprehensive *pre-CPB TEE* assessment of these anomalies uses multiple planes of interrogation and a combination of all Doppler modalities for a detailed evaluation [203, 204]. Initial experience has shown real-time 3D TEE to be extremely helpful in revealing the anatomic features of AVSDs [92]. The *post-CPB TEE* examination should evaluate for residual intracardiac shunts, AV valve dysfunction (regurgitation or stenosis), subaortic obstruction, PASP elevation, and ventricular function.

LV outflow obstruction

Anatomic and physiologic features

Obstruction along the LV outflow tract (LVOT) can occur at the subvalvular, valvular, or supravalvular levels, or it can be more distally situated (as in CoA or aortic arch interruption). *Subvalvular aortic stenosis* arises from a discrete membrane, fibromuscular ring, or muscular tunnel obstruction, with associated lesions such as CoA and MV abnormalities. Shone complex consists of a subaortic membrane, bicuspid AoV (BAV), supravalvular mitral ring, and CoA. *Valvular aortic stenosis* can arise in association with a BAV from valve thickening or progressive calcification. Coexisting lesions can include PDA, CoA, and other left-sided obstructive pathology. BAV is associated with the potential for valvular regurgitation or aortic root dilatation from an ascending aortopathy. *Supravalvular aortic stenosis* involves narrowing of the ascending Ao at the sinotubular junction, a pathology most commonly afflicting children with Williams syndrome. An obstructive arteriopathy can affect various regions of the Ao, aortic arch vessels, and even the coronary arteries in some cases. The physiological repercussions of any form of LVOT obstruction relate to impedance of LV ejection, resulting in elevation of systolic pressure, a gradient between the proximal and distal regions across the obstruction, increased myocardial force, and LV wall stress.

Highlights of the TEE examination

2D and real-time 3D TEE can adequately characterize anatomy and identify pathology in the outflow tract, AoV, and aortic root [205–209]. Alternate imaging modalities such as CMR or CT may be needed to define the anatomy of the Ao

AL Grawany

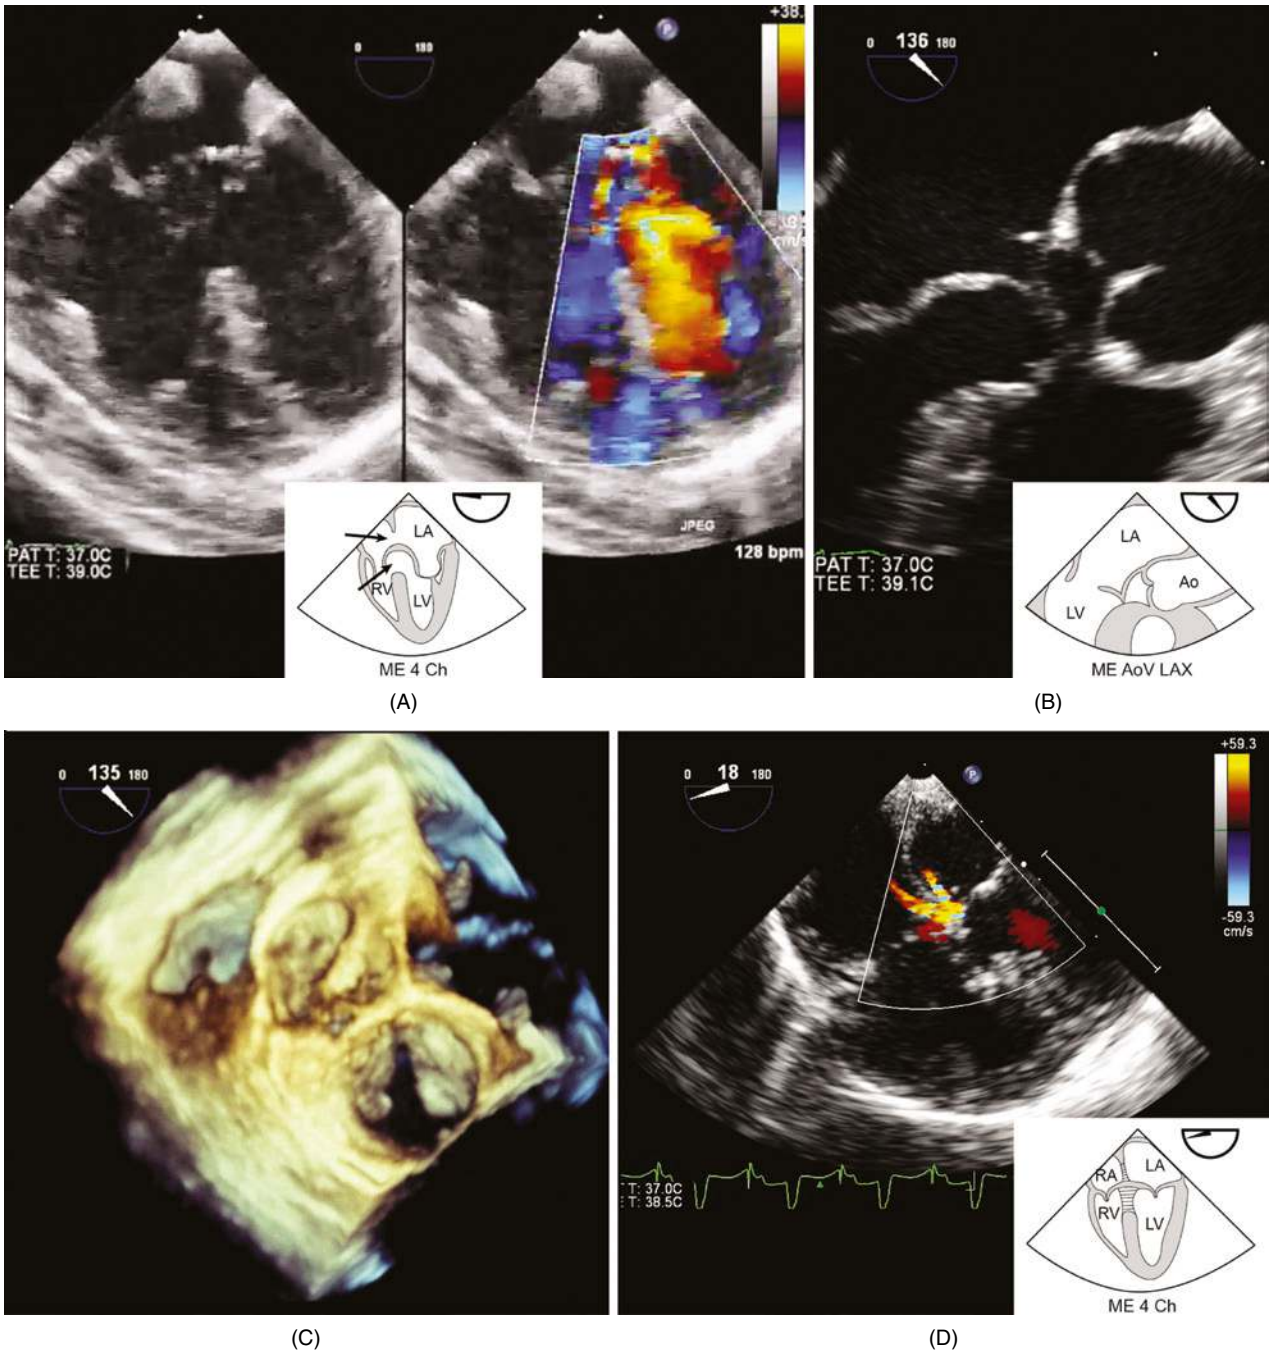

Figure 15.17 *Atrioventricular septal defect (AVSD)*. (A) *Septal defects*. ME 4-Ch views depict a primum atrial septal defect and an inlet ventricular septal defect in an AVSD (*arrows*). Additional aspects of the evaluation should include determination of shunt flow by color Doppler, morphology and function of valvular structures, and ventricular size and function. (B) *Subaortic stenosis*. Left ventricular (*LV*) outflow tract obstruction may be caused by atrioventricular valve (AVV) attachments to the interventricular septum or elongation of the outflow related to LV inlet–outlet disproportion. This is best displayed in the ME 5-Ch, ME LAX (shown), TG LAX, and DTG 5-Ch views. (C) *Left AVV cleft*. An *en face* view clearly displays a cleft in the left AVV by 3D TEE imaging. Superimposed color Doppler permits characterization of associated regurgitant jets. (D) *Post–cardiopulmonary bypass examination*. The postrepair evaluation focuses on the assessment of AVV function to exclude significant regurgitation or stenosis and the presence of residual intracardiac shunts. A ME 4-Ch image depicts a tiny LV to right atrial (*RA*) shunt and a trivial amount of regurgitation at the septal aspect of the left AVV (base of the cleft). *Ao* aorta; *LA* left atrium; *RV* right ventricle. Diagrams courtesy of Ms. Willa Bradshaw.

and its branches more precisely in selected cases. Regardless of the specific cause of the obstruction, the TEE examination should include assessment of AoV morphology and function, aortic annulus and root size, and the LV to determine its size, wall thickness, and function (Figure 15.18). Depending on the type of obstructive pathology, details of relevance in the TEE examination include the presence and severity of associated aortic annular or root hypoplasia, aortic root dilation (poststenotic or otherwise), and other coexisting lesions. Cross sections in the mid- and upper esophagus facilitate the examination of the mid-ascending Ao (ME Asc Ao LAX) and aortic arch (UE Ao Arch LAX and SAX views). Transgastric (TG LAX) and DTG (DTG 5-Ch) imaging is extremely useful in assessing outflow tract gradients as these windows allow Doppler interrogation parallel to the direction of flow.

The interventions for LVOT pathology involve a variety of approaches that aim to alleviate the obstruction. The specific intervention, operation, or catheter-based procedure dictates how the TEE examination is performed, but it often consists of determining the residual severity of any outflow obstruction and evaluating AoV competency [161]. After a subaortic resection, it is important to exclude the presence of an iatrogenic VSD or damage to the MV. In the case of autologous PV replacement of a diseased AoV (Ross procedure), relevant aspects of the examination include assessing graft function (autograft and PV allograft) and analyzing segmental wall motion to identify complications related to coronary reimplantation. A similar approach is warranted for Ao root replacement. Evaluating prosthetic valve function and excluding paravalvular leakage are essential after AoV replacement.

RV outflow obstruction

Anatomic and physiologic features

As in the case of LVOT obstructive lesions, those that affect the RV outflow tract (RVOT) may be isolated to the subvalvular, valvular, or supravalvular levels, or they may concomitantly involve multiple regions. Pulmonary (or pulmonic) valve stenosis (PS) is the most common lesion and is characterized by leaflet thickening or fusion resulting in valvular narrowing. The variable size of the valvular orifice accounts for the severity of the obstruction. Less frequently, valvular dysplasia causes the stenosis. Associated defects include ASD, VSD, and obstructive subpulmonary hypertrophy.

Obstruction of the RVOT results in an elevated RVSP and wall hypertrophy, usually proportional to the degree of obstruction. Severe pressure loads can, in some cases, result in RV dilation and failure.

Highlights of the TEE examination

The best views for examining the malformation that causes severe valvular PS include the ME RV In-Out, ME PA, ME Asc Ao SAX, and UE Ao Arch SAX views (Figure 15.19). Typical findings include valvular doming and reduced systolic leaflet excursion. Color Doppler shows turbulent antegrade flow at the level of the valve and, depending on associated pathology, in adjacent subvalvular or supravalvular regions [210]. Pulmonary regurgitation can also be present. Pulsed-wave Doppler can establish the level, and continuous-wave Doppler can determine the pressure gradient across the obstruction. As in the case of LVOT obstruction, TG and DTG views may permit better Doppler alignment, particularly if the UE views are unobtainable. Estimating RVSP from the peak velocity of the TR jet provides another parameter to determine the severity of the obstruction. Severe PS causes RV hypertrophy, as detected in the ME 4-Ch and ME RV In-Out views and in cross sections that display the RV in the TG and DTG windows. Systolic interventricular septal flattening appears in most cases of severe valve obstruction with preserved RV function. Poststenotic dilatation of the main PA may be present.

In most cases, catheter interventions can manage isolated valvular PS. Real-time 3D TEE can enhance monitoring during percutaneous valvuloplasty in anesthetized patients [211]. In those undergoing surgery for pathology that affects the valve itself, adjacent regions, or multiple levels, after the obstruction is relieved, the *post-CPB TEE* examines the residual outflow PG, determines the severity of any pulmonary regurgitation, identifies new pathology (VSD, TR), and assesses biventricular function. The need to address associated lesions guides any additional applications of TEE.

Tetralogy of Fallot

Anatomic and physiologic features

In the classic lesion, the four components of TOF consist of a large VSD, RVOT obstruction, aortic override, and RV hypertrophy. The diverse clinical manifestations in this lesion relate to its variable anatomic features, particularly the severity of the RVOT obstruction. Associated findings may include an atrial-level communication (PFO or ASD), additional VSDs, an LSVC-to-coronary sinus connection, coronary artery anomalies, and variants of aortic arch sidedness or branching pattern. Concomitant lesions such as an AVSD (colloquially referred to as "tet-canal" defect) are found in some cases. Pulmonary atresia with a VSD represents a severe form of disease in TOF.

Highlights of the TEE examination

The abnormalities that comprise the TOF spectrum are easily identifiable by TEE (Figure 15.20) [199]. The TEE examination requires detailed interrogation of the RVOT and the main and proximal branch PAs from the UE, ME, and DTG levels. Spectral and color Doppler are essential for determining the level and severity of the obstruction. Examining the ventricular septum requires multiple views that display the VSD and excludes additional communications at the ventricular level as described in the prior section on VSDs. The ME 4-Ch, TG, and DTG views can assess RV size, chamber hypertrophy, and function. Additional TEE planes of interrogation are necessary to assess associated defects.

Postoperative TEE after complete repair of TOF evaluates for residual RVOT obstruction, PV competence, VSD patch leak, and ventricular function [79, 212–214]. Patients who have undergone TOF repair in infancy or childhood present most often in late adolescence or adulthood with pulmonary regurgitation and the effects of chronic volume overload to the right heart. In some cases, the RV and even the LV have detectable systolic impairment. Residual RVOT obstruction and intracardiac shunts should be explored by using similar TEE views to those used to evaluate the uncorrected lesion.

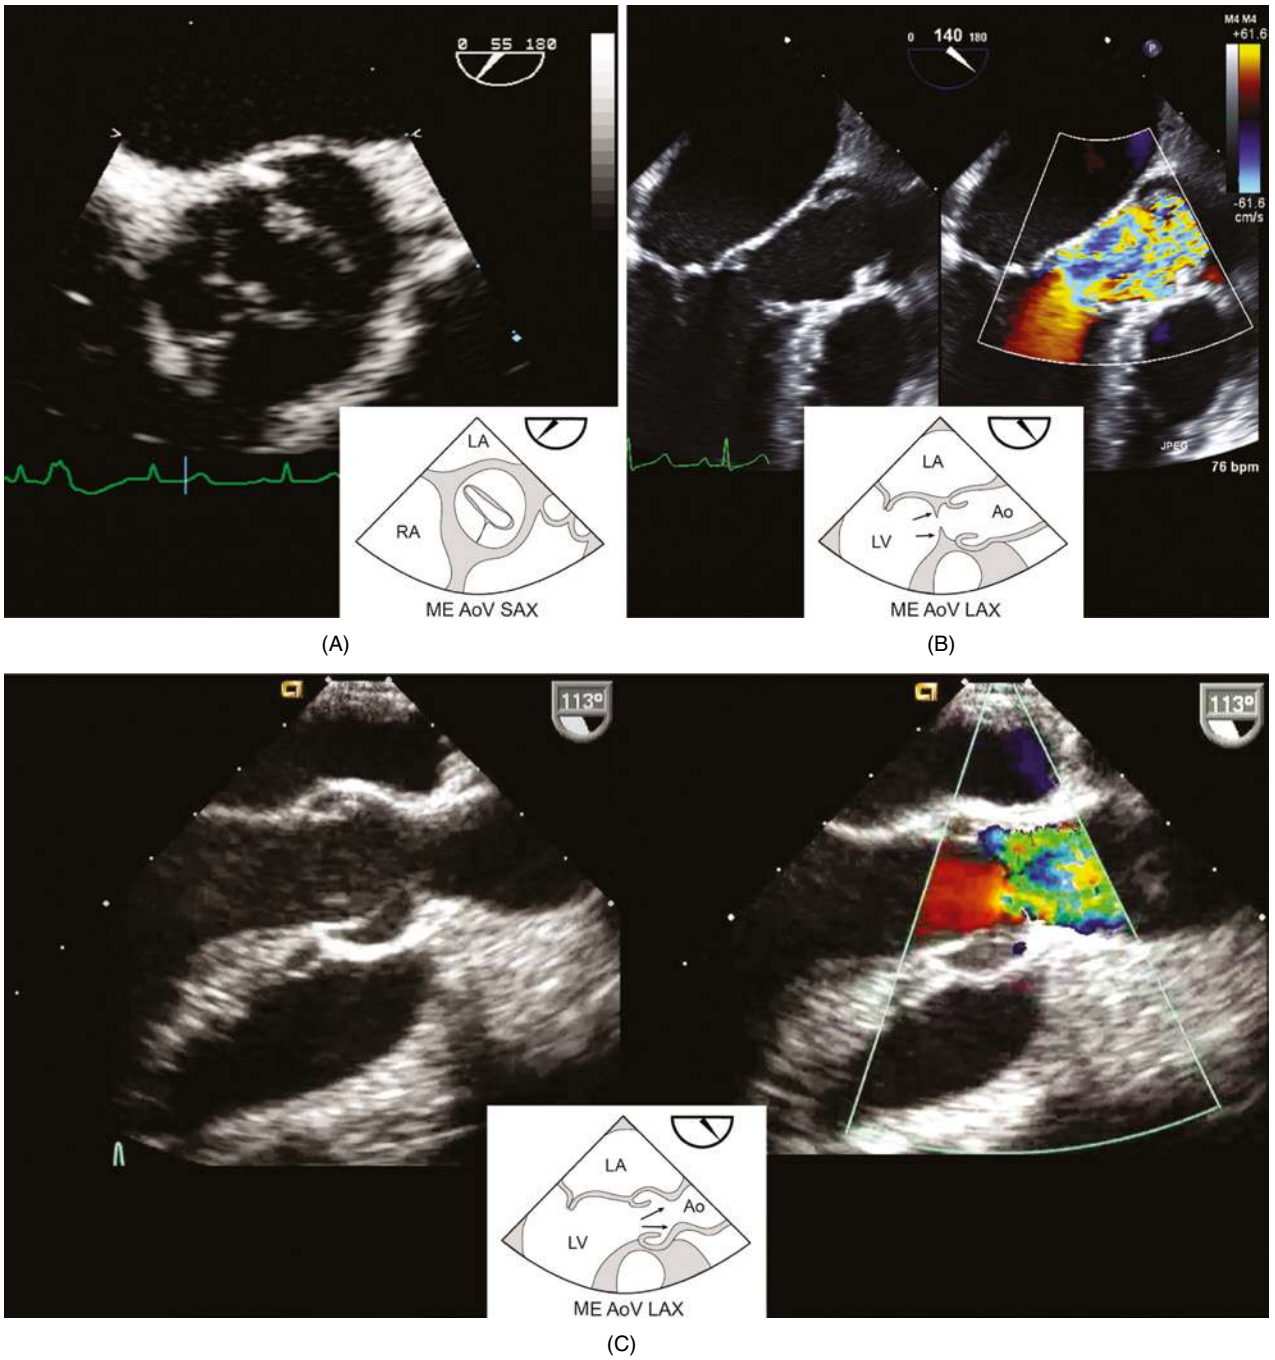

Figure 15.18 *Left ventricular outflow tract (LVOT) obstruction*. (A) *Valvular aortic stenosis*. In aortic valve (AoV) stenosis, the number and mobility of the leaflets and the qualitative severity of the obstruction are best appreciated in the ME AoV SAX and ME AoV LAX views. The ME AoV SAX image shows a systolic frame of a functionally bicuspid AoV; note the presence of commissural fusion. (B) *Subaortic stenosis*. 2D and color Doppler interrogation of a fibromuscular membrane (*arrows*) causing subaortic stenosis in the ME AoV LAX view. This cross section, in addition to the ME 5-Ch, TG LAX, and DTG 5-Ch views, is essential in defining the level and nature of the obstruction in any of the lesions that affect the LVOT. Superimposed color-flow Doppler demonstrates turbulence at the level of the obstruction (as shown) and permits evaluation of AoV function. Continuous-wave Doppler interrogation in the TG and DTG views can determine the pressure gradient across the region, whereas pulsed-wave Doppler defines the level of obstruction. Abnormal AoV systolic closure and/or fluttering of the valvular cusps, if present, are best shown in the ME AoV SAX and LAX views. (Source: Vegas et al. [41]. Reproduced with permission of Springer Nature.) (C) *Supravalvular aortic stenosis*. The typical hourglass deformity (*arrows*) at the Ao sinotubular junction appears in the ME AoV LAX view (as shown) by 2D imaging and color-flow Doppler (note the site of color aliasing). Dilation of the coronary arteries may result from exposure to high left ventricular (*LV*) pressures (best seen in the ME AoV SAX and ME AoV LAX views with multiplane angle adjustments). The potential for myocardial ischemia from compromised coronary blood flow in this lesion can manifest on TEE as segmental wall motion abnormalities and requires a combination of views that display the various regions of the myocardium (refer to Figure 15.11). *Ao* aorta; *LA* left atrium; *RA* right atrium. Diagrams courtesy of Ms. Willa Bradshaw.

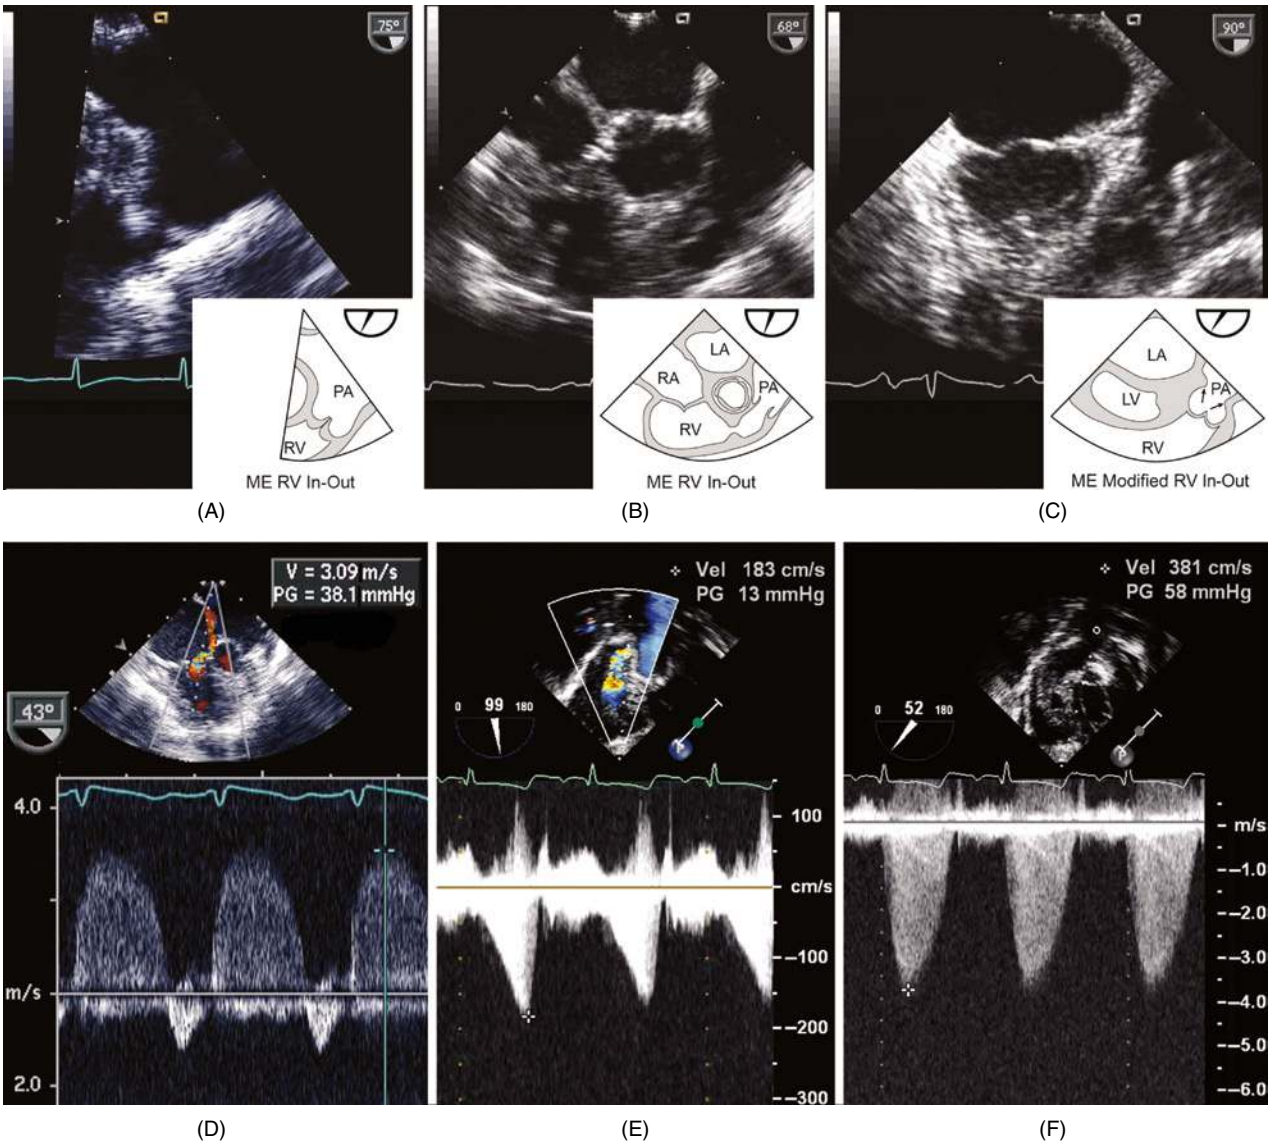

Figure 15.19 *Right ventricular outflow tract (RVOT) obstruction*. (A) *Valvular pulmonary stenosis (PS)*. Stenosis of the pulmonary valve (PV) can be due to valvular thickening, commissural fusion, and/or valvular dysplasia. The malformation is best examined in the ME RV In-Out, UE PA, ME Asc Ao SAX, and UE Ao Arch SAX views. Typical findings include valvular doming and reduced systolic leaflet excursion. The zoomed view shown in a ME In-Out view depicts a thickened PV and associated poststenotic dilation of the main pulmonary artery (*PA*) in a patient with valvular stenosis. (B) *Subvalvular PS*. Muscular hypertrophy of the subvalvular pulmonary region can occur in isolation or may be present in association with valvular PS. The narrowing of this region of the right ventricle (*RV*) can be fixed or dynamic in nature. The ME RV In-Out image displays severe subvalvular narrowing. (C) *Supravalvular PS*. Discreet narrowing of the supravalvular region occasionally occurs in association with valvular PS or the pathology can be found in isolation. This is best examined in views that display the pulmonary outflow tract in its long axis, as shown in a modified ME RV In-Out view (*arrows*). (D) *Estimation of right ventricular systolic pressure* (*RVSP*). Moderate-to-severe RVOT obstruction is frequently associated with some degree of tricuspid regurgitation (TR). The peak velocity of the TR jet, as shown, allows estimation of the RVSP, providing another parameter to assess the severity of the outflow obstruction. In this example, the RVSP, as derived from the simplified Bernoulli equation, is ~48 mmHg calculated as follows: [(3.09)^2 + right atrial (*RA*) pressure (assumed ~10 mmHg)]. The RVSP in this case does not reflect the pulmonary artery systolic pressure. (E) *Spectral Doppler*. Interrogation using spectral Doppler from the DTG RVOT view depicts the late systolic, "dagger-shaped" signal, that characterizes dynamic obstruction. (F) *Continuous-wave* (*CW*) *Doppler*. The image depicts the optimal cursor alignment for spectral Doppler interrogation that can be obtained from DTG imaging. In this example, CW Doppler measures the peak systolic pressure gradient between the RV and the PA (58 mmHg) and is able to estimate the severity of the RVOT obstruction. *LA* left atrium; *LV* left ventricle. Diagrams courtesy of Ms. Willa Bradshaw.

Double-outlet right ventricle

Anatomic and physiologic features

A DORV refers to a VA connection in which there is near or complete alignment of both great arteries to the RV. The exact diagnostic criteria for DORV are controversial. It does not represent a single disease but rather a spectrum of pathologies that may share features with other lesions such as TOF and transposition [215]. A VSD is almost always present. The location of the VSD and its relation to the great vessels play a critical role in the physiology and can be subaortic (most

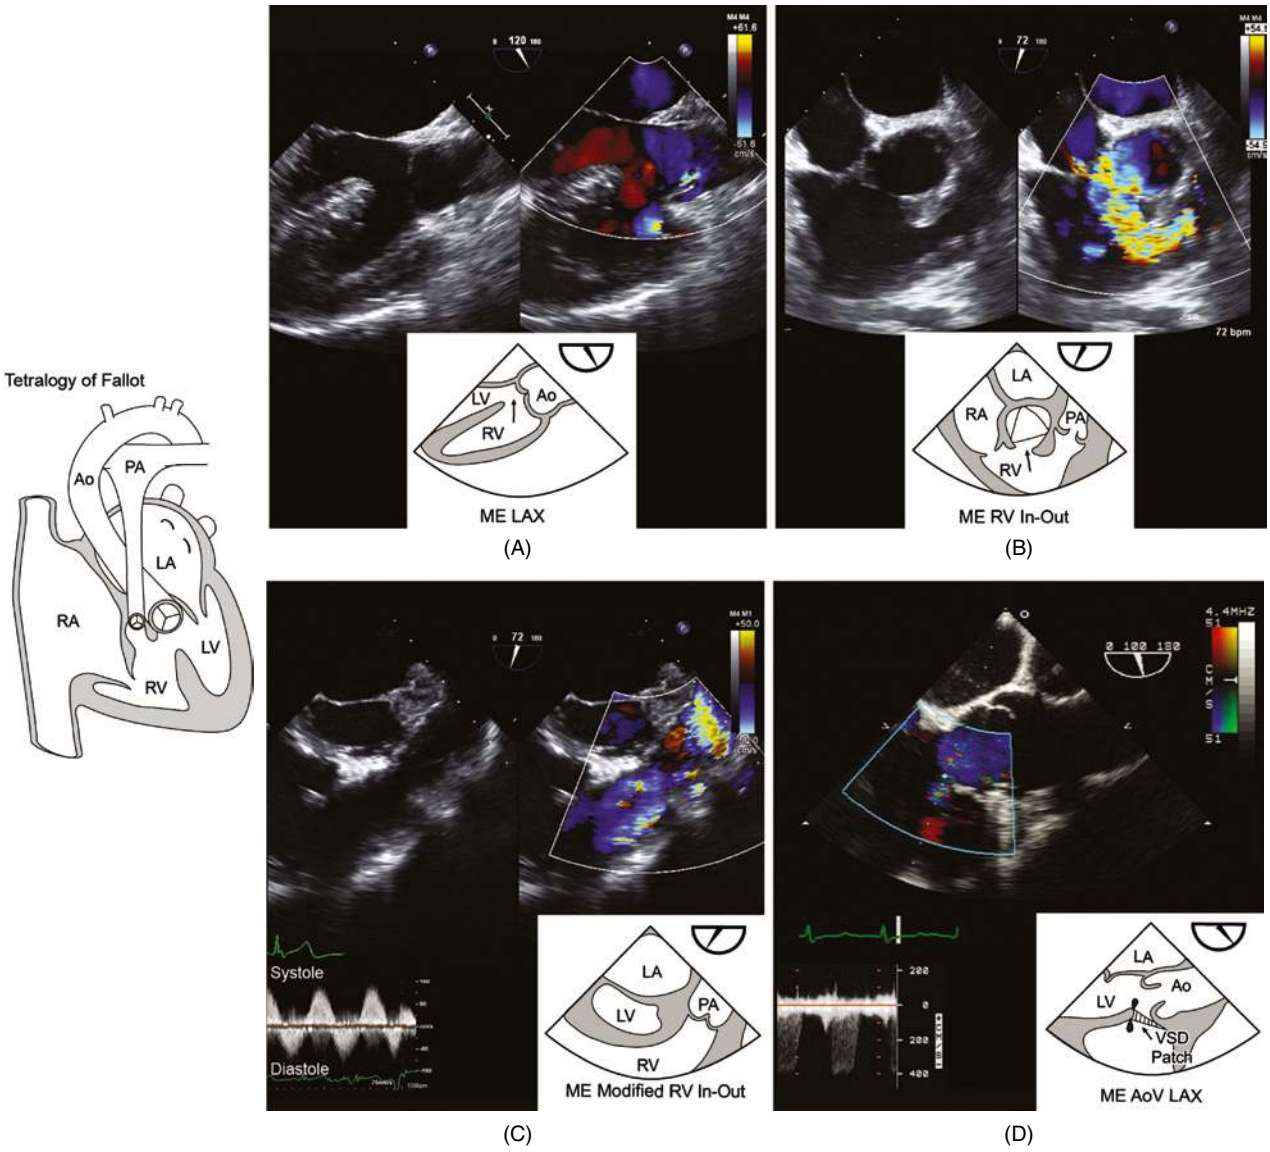

Figure 15.20 *Tetralogy of Fallot (TOF)*. (A) *Conoventricular ventricular septal defect* (*VSD*). The large VSD in TOF (*arrow*) is optimally displayed in the ME LAX (shown), ME 5-Ch, ME RV In-Out; panel B), and DTG views. These same views display the aortic (*Ao*) override over the VSD. Color Doppler facilitates assessment of defect size and direction of shunting. (B) *Right ventricular outflow tract* (*RVOT*) *obstruction*. The RVOT (subvalvular, valvular, and supravalvular areas) is best evaluated in the ME RV In-Out view. The typical anterior and leftward deviation of the conal or infundibular septum that causes subpulmonary muscular dynamic obstruction, as well as the VSD (*arrow*), can be optimally displayed in this view as shown. (C) *Pulmonary regurgitation*. Transannular patch repair in TOF resulting in pulmonary regurgitation is best evaluated in views that display the RVOT in long axis as shown. Note the blue color Doppler jet representing flow into the right ventricle (*RV*) during diastole and the to-and-fro flow across the RVOT by spectral Doppler. (D) *VSD patch leak*. Assessment of residual ventricular level shunting is an important component of the postrepair TEE examination after corrective surgery and during subsequent reoperations in TOF. The ME AoV LAX view shown depicts a VSD patch (*arrow*) with a small leak by color Doppler and associated high-velocity left-to-right shunting by spectral Doppler. *LA* left atrium; *LV* left ventricle; *PA* pulmonary artery; *RA* right atrium. Diagrams courtesy of Ms. Willa Bradshaw.

commonly), subpulmonary (i.e., Taussig-Bing anomaly), doubly committed, or noncommitted (remote). The spatial orientation of the great vessels is frequently abnormal and can be side by side or in the configuration of D-transposition of the great arteries (D-TGA). The physiologic manifestations are variable and can mimic those of an isolated VSD, TOF, D-TGA, or single ventricle. Lesion heterogeneity necessitates careful preoperative assessment and surgical planning.

Highlights of the TEE examination

Preoperative TEE evaluates the location and size of the VSD and its relationship to the great arteries (Figure 15.21). The spectral and color Doppler modalities are important in assessing flow out of the LV and across the VSD when the defect is subaortic in location. These modalities are essential in evaluating the severity of associated outflow tract obstruction (right and left) and valvular function (stenosis or regurgitation).

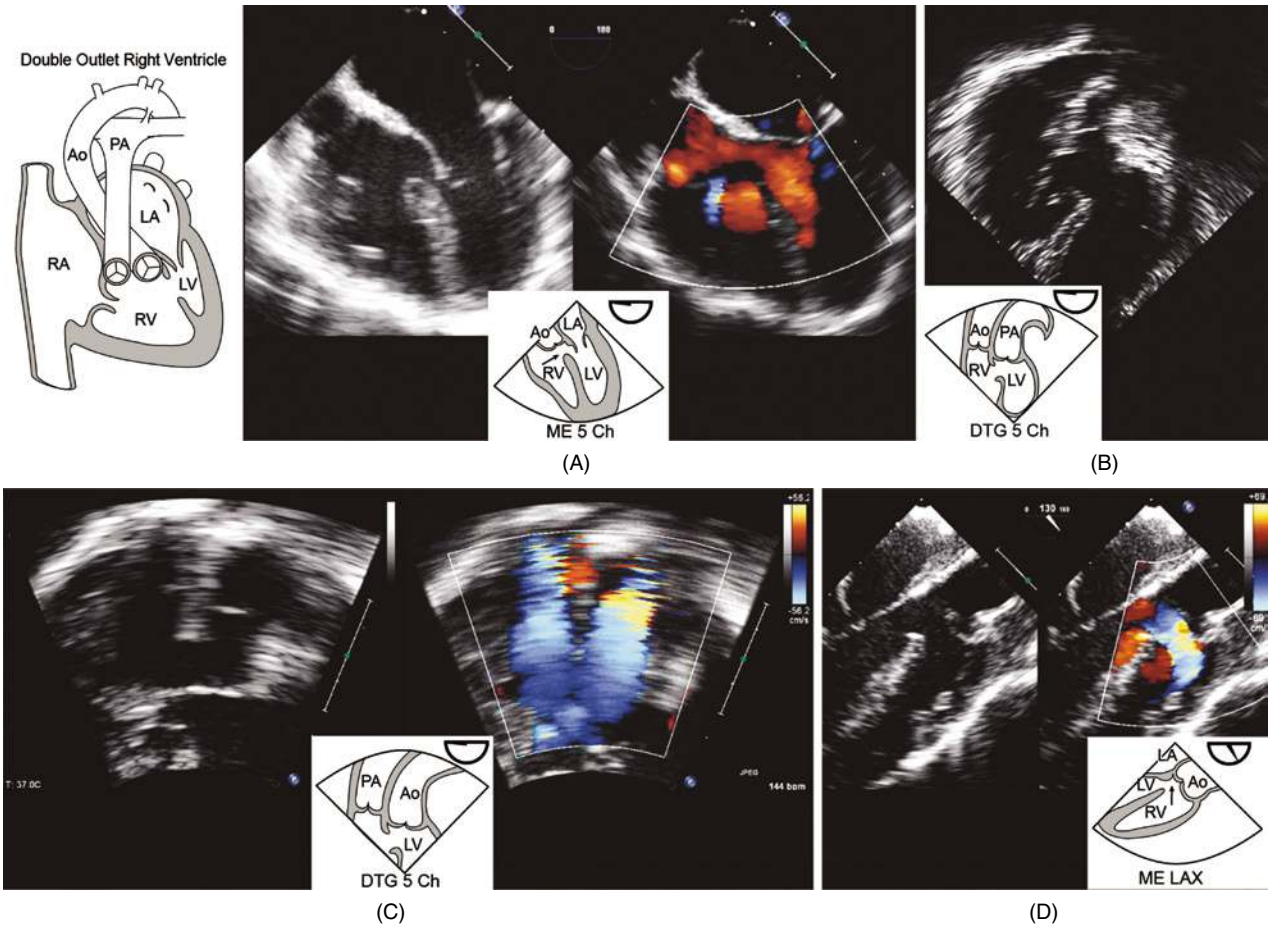

Figure 15.21 *Double-outlet right ventricle (DORV)*. (A) *Subaortic ventricular septal defect (VSD)*. *Left panel*: ME 5-Ch view depicting the most common variant of DORV with a malalignment VSD in subaortic location. Note the ventricular communication (*arrow*), the abnormal relationship of the aorta (*Ao*) over the right ventricle (*RV*), and the presence of a muscular conus resulting in mitro-aortic discontinuity. Color and spectral Doppler in the ME views (4-Ch, 5-Ch, LAX) outline the direction and pattern of shunting across the VSD. R*ight panel*: the unusual long pathway of blood flow from the left ventricle (*LV*) to the Ao, as shown by color Doppler, represents a substrate for potential subaortic stenosis after the repair. (B) *Subpulmonary VSD*. DTG 5-Ch view in the Taussig-Bing anomaly depicting the relationship of the great arteries in this defect and the subpulmonary location of the VSD accounting for preferential flow of LV blood into the pulmonary artery (*PA*) and the physiology of D-transposition of the great arteries. (C) *Side-by-side great arteries*. The abnormal side-by-side spatial orientation of the great arteries in DORV (patient with a subaortic VSD) is noted in these zoomed 2D and color Doppler images. This relationship contrasts with their crisscross orientation in the normal heart. (D) *VSD flow*. ME LAX view in same patient as in panel C with DORV depicting the relationship of the VSD to the Ao and evaluation of VSD flow by color-flow Doppler (*arrow*). *LA* left atrium; *RA* right atrium. Diagrams courtesy of Ms. Willa Bradshaw.

In most instances for which a biventricular repair is feasible, surgery aims to restore normal anatomy by establishing continuity between the ventricles and corresponding great arteries using various surgical techniques. In cases involving pulmonary stenosis, distinguishing this anomaly from TOF is important. Although the physiology of the two lesions is similar, a subaortic conus in the patient with TOF-like DORV represents a substrate for subaortic stenosis after the repair, a rare occurrence in TOF. All TEE views that display the pathway of the blood flow between the LV and the Ao (e.g., ME 5-Ch, ME LAX, TG LAX, and DTG 5-Ch) should explore this potential problem. In addition, *postrepair TEE*, depending on the details of the anatomy and type of the intervention, should exclude residual intracardiac shunting, evaluate for any other forms of outflow tract obstruction and valvular regurgitation, and assess ventricular function.

Transposition of the great arteries

Anatomic and physiologic features

In D-TGA, the AV connections are concordant and the VA connections are discordant. The segmental anatomy as per the Van Praagh short-hand notation in most cases is that of {S,D,D}, meaning normal visceroatrial arrangement or visceroatrial situs solitus, D-loop ventricles, and D-transposition (denoting the position and relationship of the great arteries). Whereas in the normal heart the Ao is posterior and rightward of the anterior and leftward PA, in this arrangement the Ao originates from the RV anteriorly and to the right of the posterior and leftward PA. Separate parallel circulations characterize the physiology. A communication, usually an ASD or a PDA, is essential for intercirculatory mixing and to allow partially oxygenated blood to reach the systemic circulation. In most cases, the ventricular septum is intact, but VSDs of various sizes can be present. Associated

AL Grawany

findings can include pulmonary outflow obstruction, coronary artery variants, and aortic arch anomalies.

Highlights of the TEE examination

The TEE evaluation in the patient with D-TGA requires proper 2D identification of cardiac chambers and connections (Figure 15.22). Additional indispensable TEE information includes confirming the segmental venoatrial connections (ME Bicaval, TG IVC/Hep veins); evaluating the AV valves, ventricular septum, and ventricular function (ME views: 4-Ch, 2-Ch, 5-Ch, LAX; TG views: Basal SAX, Mid Pap SAX, Apical SAX); assessing the LVOT and PV (ME views: LAX, 5-Ch, AoV SAX, and AoV LAX; TG LAX; DTG 5-Ch); examining the RVOT and AoV (ME RV In-Out and DTG RVOT views); and interrogating the IAS (ME 4-Ch, ME Bicaval, and DTG Atr Sept). In addition to the 2D evaluation, the examination should include interrogation of the outflow tracts for obstruction, the semilunar valves for stenosis or regurgitation, and the origin of the coronary arteries. A comprehensive assessment of the aortic arch may not be feasible with TEE, but a combination of views at the UE and ME levels may offer limited interrogation. If necessary, epicardial imaging can provide additional views.

Surgical correction of D-TGA aims to restore the proper sequence of blood flow. The favored surgical approach is the *arterial switch operation* (ASO), an anatomic correction that restores the normal VA relationships. It involves transecting and anastomosing the great arteries to their respective appropriate ventricles and translocating the coronary arteries. TEE can reveal immediate complications after the ASO, including anastomotic site stenosis causing supravalvular obstruction in the PA or Ao [216]; ASD or VSD patch leaks, valve regurgitation, and ventricular dysfunction [216]. Coronary complications should be suspected if global systolic function is impaired or segmental wall motion abnormalities are present [124, 125]. Both TEE and E-echo have been shown to be of benefit in evaluating segmental wall motion abnormalities

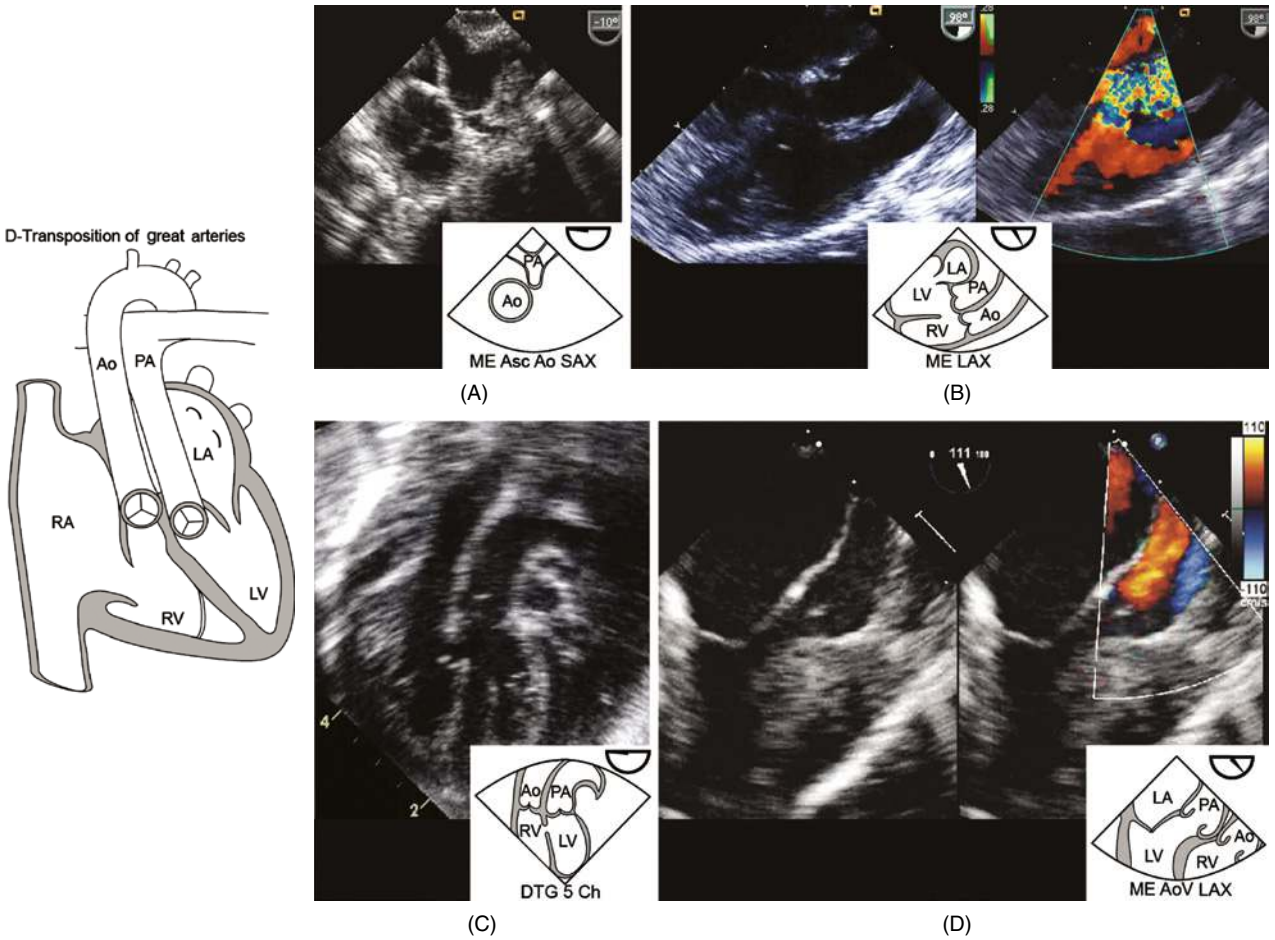

Figure 15.22 *D-Transposition of the great arteries (D-TGA).* (A) *Orientation of the great arteries*. ME Asc Ao SAX view displaying the anterior and rightward aorta (*Ao*) with respect to the posterior and leftward bifurcated pulmonary artery (*PA*) in D-TGA. (B) *Ventricular septal defect* (*VSD*). 2D and corresponding color Doppler images in the ME LAX view in an infant with D-TGA and associated VSD. Note the abnormal parallel orientation of the great arteries (in contrast to their normal crisscross relationship) and flow from the higher pressure right ventricle (*RV*) across the VSD into the left ventricle (*LV*) and PA (red flow). (C) *Ventriculoarterial* (*VA*) *connections*. DTG 5-Ch view depicting the discordant VA connections in D-TGA (Ao from the RV and PA from the LV). A perimembranous VSD is readily appreciated in this 2D image. This view permits optimal spectral Doppler alignment across the outflow tracts and great vessels for assessment of patency/obstruction. (D) *Patent ductus arteriosus (PDA)*. ME LAX 2D and color Doppler images displaying the outlet of the LV into the PA. Note the PDA flow (blue signal away from the transducer) into the PA. *LA* left atrium; *RA* right atrium. Diagrams courtesy of Ms. Willa Bradshaw.

and coronary artery patency [125, 217, 218]. Excellent agreement has been reported between TEE and E-echo coronary Doppler flow patterns, as importantly, abnormalities have been correlated with adverse myocardial events [219]. The atrial switch (Senning and Mustard operation) provides physiologic correction by using intra-atrial baffles to allow deoxygenated blood to reach the PAs and the ejection of oxygenated blood into the Ao (Figure 15.23). It is no longer the surgical intervention of choice because the morphologic RV remains as the systemic pump for life. Most patients who have undergone this procedure are adult survivors of CHD. In patients with prior *Rastelli-type operation*s, which route the LV output to the Ao across a baffle and place an RV-to-PA conduit, color and spectral Doppler can assess outflow obstruction, pulmonary or aortic regurgitation, and residual VSD and estimate PASP.

Congenitally corrected transposition of the great arteries

Anatomic and physiologic features

In congenitally corrected transposition of the great arteries (CCTGA), also referred to as physiologically corrected transposition, the AV and VA connections are both discordant (double discordance). The ventricles and great vessels are malpositioned, with inversion of the ventricles and transposition of the great arteries. Although the anatomy is variable, in most cases, it consists of levocardia and visceroatrial situs solitus, with systemic veins draining into a right-sided RA connected to a right-sided morphologic LV that ejects across a rightward and posterior PA; the pulmonary veins drain into a left-sided LA, which is connected to a left-sided morphologic RV (L-ventricular loop that ejects across a leftward and anterior Ao (L-positioned great arteries). This segmental anatomy is referred to as {S,L,L} or simply as L-TGA. In this malformation, the morphologic LV represents the venous, pulmonary ventricle, and the morphologic RV functions as the arterial, systemic ventricle. The physiology is correct as desaturated blood reaches the pulmonary circulation and saturated blood enters the systemic circulation. Associated anomalies can include a VSD, pulmonary stenosis or obstruction to morphologic LV outflow, and abnormalities of the TV (Ebstein-like anomaly and others). The patient with CCTGA may present late in adulthood with TR and systemic RV failure or complete heart block.

Highlights of the TEE examination

Diagnosis of CCTGA relies on the accurate identification of cardiac chamber morphology (Figure 15.24). In addition to confirming the anatomy, an important role of TEE in this defect is assessing TV competence (systemic or left-sided AV valve), evaluation of associated defects, and determination of the functional status of the RV.

Depending on the type of surgical intervention for this lesion (e.g., conduits, baffles, and switches), TEE assists in the *post-CPB* assessment by excluding hemodynamically significant residual lesions that may necessitate revision and evaluating AV and semilunar valve competence, outflow tract obstruction, and ventricular function.

Truncus arteriosus

Anatomic and physiologic features

Truncus arteriosus refers to the anomaly that has a single arterial trunk from which both the PA and the Ao (with coronary arteries) originate. Both ventricles have a single, common outlet, and the truncal root overrides a VSD. Hypoxemia results from complete admixture of deoxygenated and oxygenated blood. Various classification schemes describe this lesion. Classification of this defect into three types (i.e., I, II, and III) in the Collet and Edwards scheme is based on the origin of the PAs from the truncal root. The clinical manifestations of this lesion depend largely on the status of the pulmonary vascular resistance and the presence of any intrinsic stenosis in the PAs. Associated findings can include truncal valve anomalies, right aortic arch, interrupted aortic arch, and coronary ostial anomalies.

Highlights of the TEE examination

The common arterial trunk has a single semilunar valve that can have variable cusp number and morphology and can be stenotic or regurgitant (Figure 15.25). A comprehensive *pre-CPB TEE* examination includes assessing truncal valve function and other coexistent lesions.

Corrective surgery for this lesion involves closing the VSD, detaching the main PA segment or individual branches from the truncal root and repairing the wall defect, and establishing continuity between the RV and the PA, usually by placing a conduit. Interventions on the truncal valve may be necessary during the initial operation or subsequently. *Post-CPB TEE* excludes residual VSD shunting and assesses the function of the truncal valve, the RV-to-PA conduit, and both ventricles. Coronary artery perfusion may be compromised preoperatively and postoperatively, resulting in global or regional wall motion abnormalities. The RV may dilate and underperform in the face of increased PASP as assessed from estimates of RVSP. In the long term, issues associated with conduit stenosis or regurgitation or truncal valve problems may lead to reoperation. The role of TEE in this scenario, in addition to assessing the specifics of the intervention, is similar to its role immediately after the initial corrective procedure.

Single ventricle

Anatomic and physiologic features

The single ventricle (univentricular heart) spectrum comprises lesions with an atretic AV valve (MV or TV), hypoplastic ventricle (e.g., hypoplastic left heart syndrome and double-inlet LV), and others for which physiologically a biventricular repair is not feasible or desirable (e.g., functional single ventricle). Frequently, a characteristic of this broad group of lesions is complete admixture of systemic and pulmonary venous blood at the atrial or ventricular level. Another common finding is systemic or pulmonary outflow obstruction.

Highlights of the TEE examination

A complete and systematic TEE examination should be the goal in all cases. However, considering the many defects that fit into the single ventricle category, the evaluation should be

AL Grawany

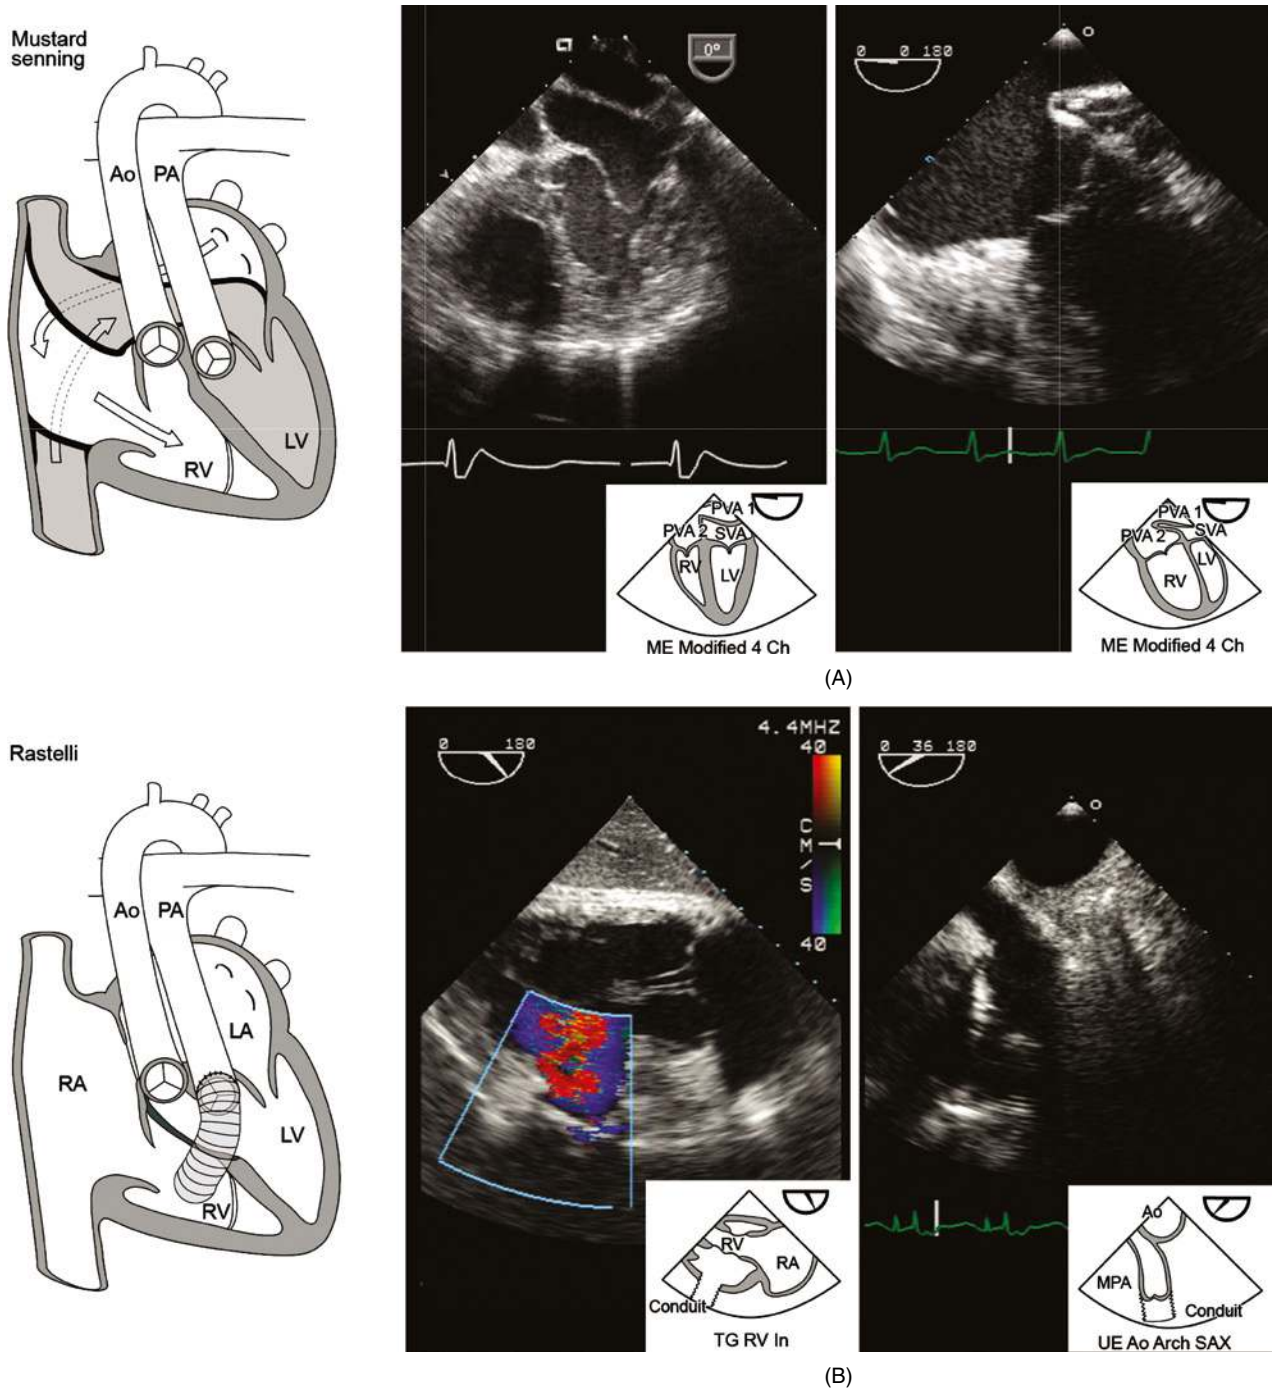

Figure 15.23 *D-Transposition of the great arteries (D-TGA) post-Senning and post-Rastelli operations*. (A) *D-TGA after Senning procedure*. TEE assessment of atrial pathways requires multiple views and sweeps between several planes to trace the course of the blood flows and provide information about atrial anatomy and the presence of baffle pathology (leak or obstruction). *Left panel*: modified ME 4-Ch view depicts the systemic venous atrium (*SVA*), which receives the systemic veins (not shown), and the region of the pulmonary venous atrium where the pulmonary veins drain (*PVA 1*). Note the portion of the baffle that separates the SVA from the PVA 1. *Right panel*: as the TEE probe shaft is turned rightwards, the pathway of pulmonary venous flow can be examined to exclude obstruction from PVA 1 to the region of the pulmonary venous atrium above the tricuspid valve (*PVA 2*). In patients who have undergone atrial baffle procedures, these views in combination with additional TEE cross sections assist in the assessment of systemic right ventricular (*RV*) function, grading severity of tricuspid regurgitation, and evaluating potential intracardiac thrombus related to rhythm abnormalities or pacing leads. (B) *D-TGA post-Rastelli operation*. In the patient with D-TGA and associated ventricular septal defect (VSD) and pulmonary stenosis, a Rastelli-type repair may be favored, where the left ventricular (*LV*) output is re-routed to the aorta (*Ao*) across a VSD patch that serves as a baffle, and an extracardiac conduit is placed between the RV and main pulmonary artery (MPA). *Left panel*: TG RV In view (adult TEE cross section) with color Doppler displays the proximal conduit. *Right panel*: UE Ao Arch SAX view as shown is particularly helpful in the examination of the distal conduit. A combination of TEE modalities that may include 2D, 3D, color, and spectral Doppler in multiple views can assess outflow obstruction, conduit/aortic regurgitation, residual VSD, and estimate RV systolic pressure in the postoperative patient. *LA* left atrium; *PA* pulmonary artery; *RA* right atrium. Diagrams courtesy of Ms. Willa Bradshaw.

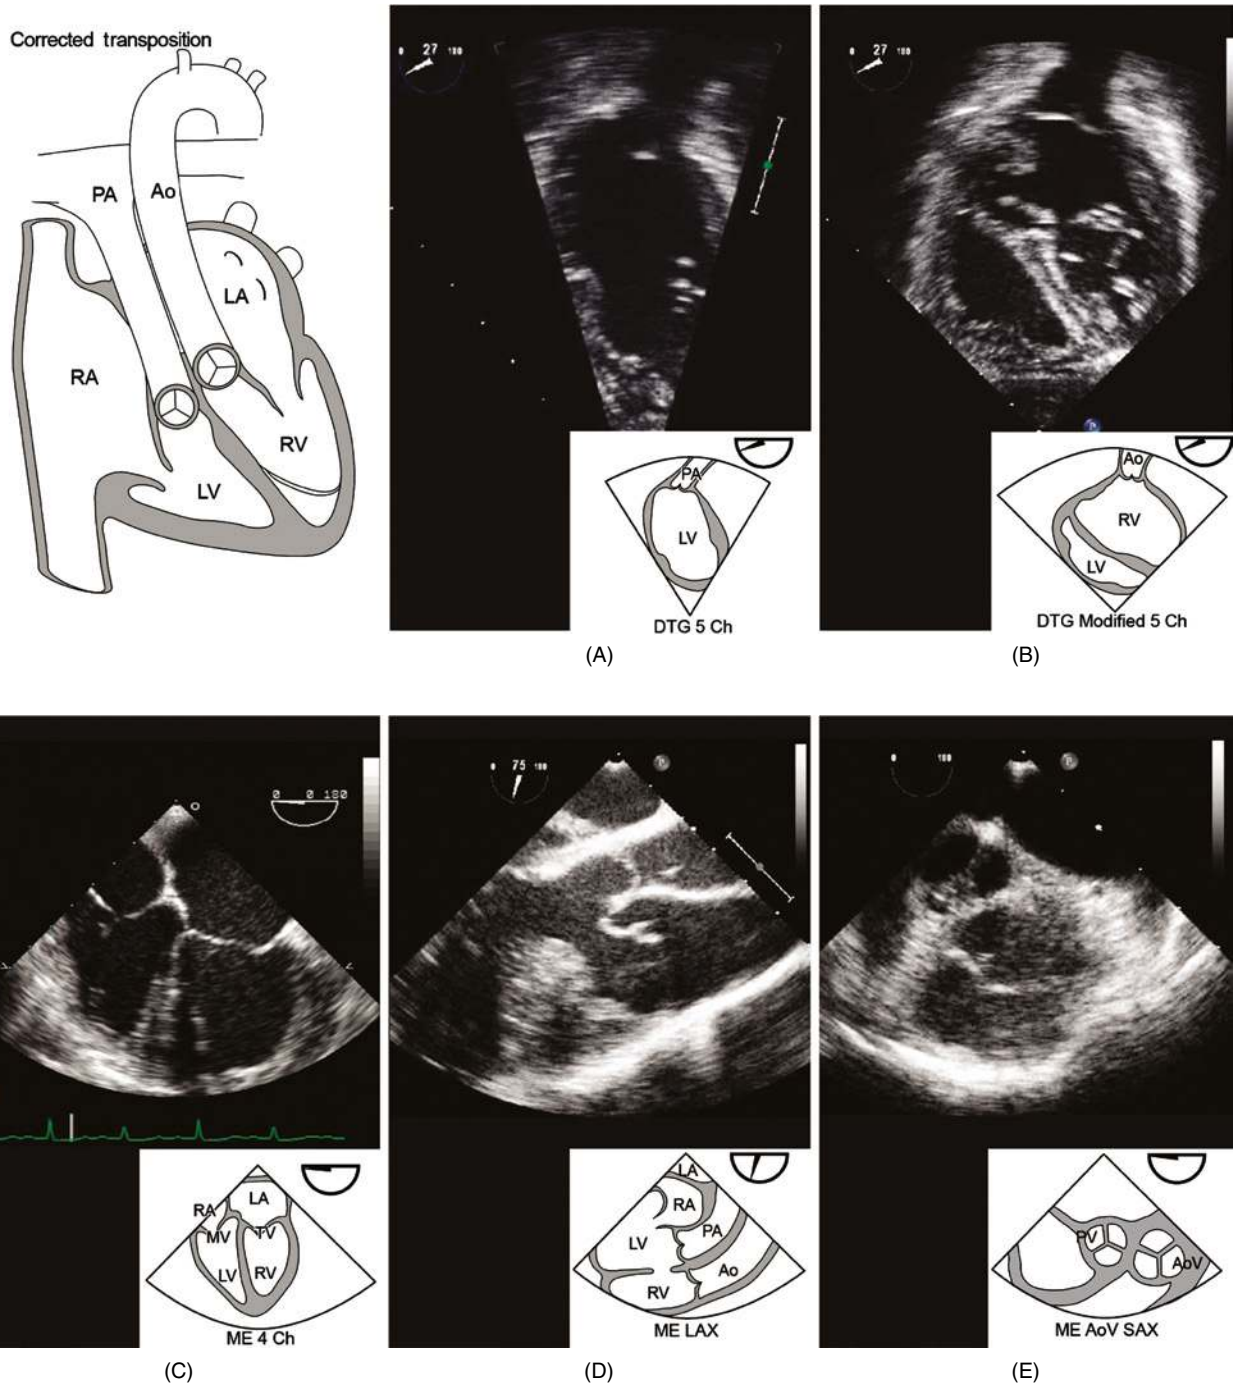

Figure 15.24 *Congenitally corrected transposition (CCTGA)*. (A) *Ventriculoarterial* (*VA*) *discordance* (*left ventricle* [*LV*] *to pulmonary artery* [*PA*] *connection*). The DTG views are essential in the TEE evaluation of CCTGA (also referred to as L-transposition of the great arteries [L-TGA]). The examination requires not only single views but sweeps between planes to assess ventricular morphology, their arrangement, and connections between these and the arterial trunks. The discordant connection between the smooth-walled LV and PA are shown in a DTG view. (B) *VA discordance* (*right ventricle [RV] to aorta* [*Ao*] *connection*). DTG view with anterior probe angulation in the same patient depicted in panel A displays the origin of the Ao from the trabeculated left-sided RV. The smooth-walled LV is to the right of the morphologic RV. (C) *Atrioventricular* (*AV*) *discordance*. Evaluating ventricular morphology and AV connections in CCTGA requires imaging in multiple views at the ME, TG, and DTG levels. As displayed in this ME 4-Ch image, the discordant AV connections are evident as the left atrium (*LA*) opens into a chamber of RV morphology and the right atrium (*RA*) drains into the LV. The identification of the RV is by its trabeculated endocardial surface, the presence of a moderator band, and a septophilic tricuspid valve (*TV*) that is more apically positioned on the interventricular septum relative to the mitral valve (*MV*). The subpulmonary ventricle displays a smooth surface and two papillary muscles (not shown). Various cross sections allow examination of the RV, which often dilates and functions poorly over time, resulting in TV regurgitation. (Source: Vegas [112]. Reproduced with permission of Springer Nature.) (D) *Orientation of the great arteries*. The parallel orientation of the great arteries, with the Ao more anterior, is confirmed in cross sections that display the outflow tracts in their long axes (ME LAX, ME 5-Ch, DTG 5-Ch, and DTG RVOT views). The ME LAX image shown displays this parallel orientation. Note associated pulmonary stenosis (small posterior valvular annulus, stenotic doming leaflets) and the presence of a ventricular septal defect in this case. (E) *Coplanar semilunar valves*. This cardiac lesion makes the aortic valve (*AoV*) and pulmonary (pulmonic) valve (*PV*) appear coplanar (both valves in their short axes seen at the same level), with the PA spatially positioned posteriorly and to the right (in the center of the image), relative to the anterior and leftward Ao. This abnormal orientation is best seen in the ME AoV SAX (shown), ME Asc Ao SAX), and ME RV In-Out views. In this example, the PV appears to have possible commissural fusion. Diagram courtesy of Ms. Willa Bradshaw.

AL Grawany

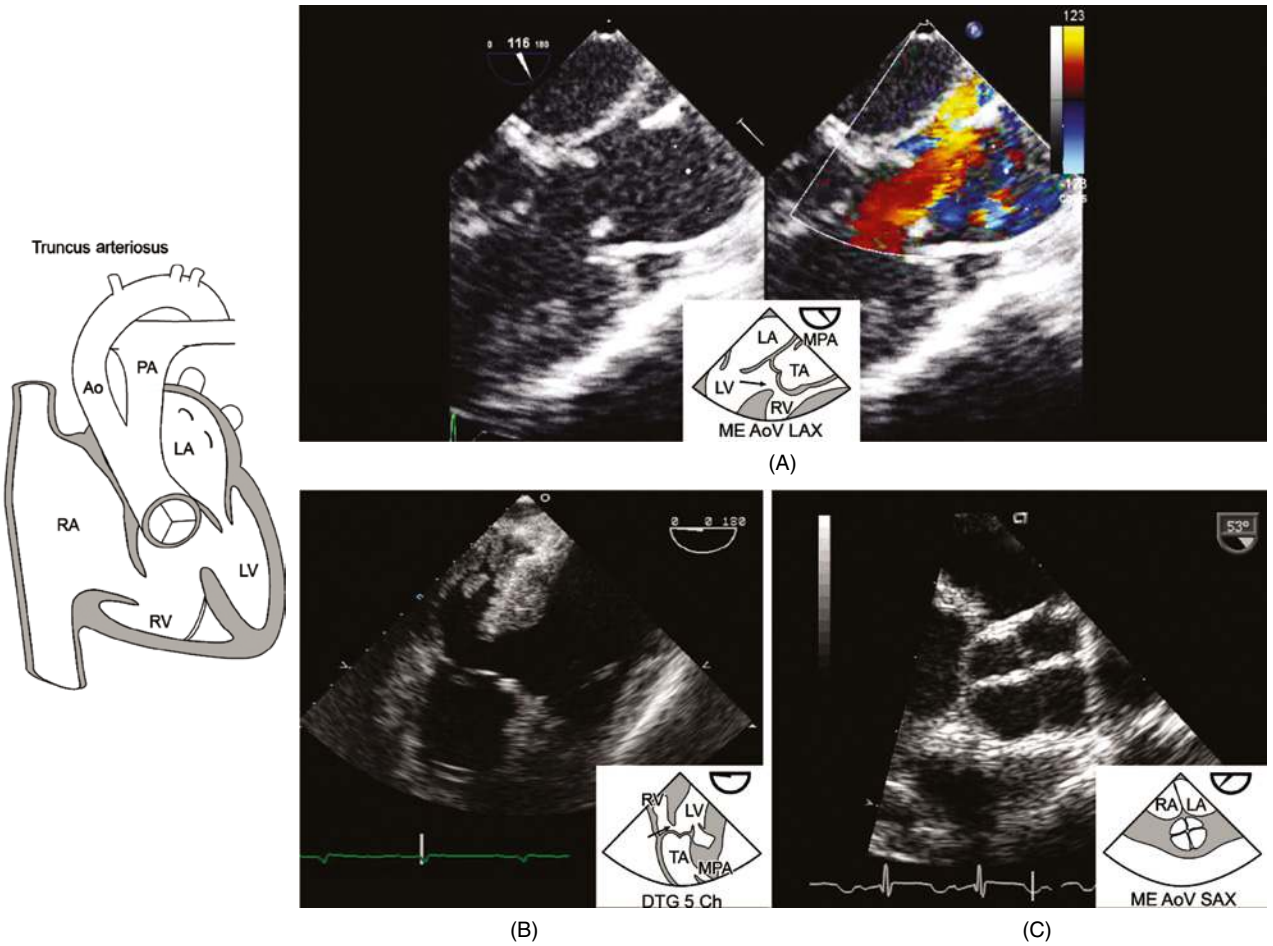

Figure 15.25 *Truncus arteriosus (TA)*. (A) *Truncal root*. The origin and proximal course of the pulmonary arteries (*PAs*) from the arterial trunk can be defined by 2D imaging and color-flow Doppler by adjusting the TEE probe position in the ME Asc Ao SAX, ME Asc Ao LAX (shown), UE PA, and modified UE views. The ventricular septal defect (*arrow*) can also be examined in ME views. (B) *Single outlet*. The assessment of this lesion requires a combination of planes that display the truncal root in short and long axes (ME AoV SAX and LAX), and DTG views. These same cross sections may allow for evaluation of shunting by color and spectral Doppler across the ventricular septal defect. Characteristically a single outlet is identified as displayed in this DTG 5-Ch view (note the nonstandard anatomic orientation of this TEE image with the ventricular apex at the top of the image display and outflow tract at the bottom). (C) *Truncal valve*. Evaluating truncal valve morphology and presence/severity of stenosis and/or regurgitation are important components of the examination. Frequently, a quadricuspid truncal valve is present as shown in this ME AoV SAX view. *Ao* aorta; *LA* left atrium; *LV* left ventricle; *MPA* main pulmonary artery; *RA* right atrium; *RV* right ventricle. Diagram courtesy of Ms. Willa Bradshaw.

aimed at the structural abnormalities and associated hemodynamic and functional alterations. Although rarely diagnostic, an essential aspect of the examination is including views that confirm the anatomic abnormalities. Occasionally, this interrogation reveals new findings or modifies previous ones. Depending on the morphologic substrate, the TEE examination should show the anatomic or functional features that merit a single ventricle management strategy, such as a hypoplastic ventricle with an atretic or severely stenotic inflow or outflow, or a single (common or rudimentary) ventricle with two separate atria that may communicate through an ASD (Figure 15.26). The morphology of the often-enlarged single ventricle may be right, left, or indeterminate. The ME level is suitable for evaluating most of these features. An initial useful cross section is the ME 4-Ch view, which serves as a reference point from which adjusting the multiplane angle optimizes visualization of the various structures of interest. If a patient with a two-ventricle heart is unable to undergo a biventricular repair but instead has a single ventricle management strategy, the examination should identify features of the anatomy that indicate this approach.

In single ventricle variants and two-ventricle hearts not amenable to a biventricular repair, the evaluation of ventricular morphology, size, and function is facilitated by 2D imaging in the ME 4-Ch and ME 2-Ch views, cross sections at the TG and DTG levels, and, if helpful, UE views. Assessment of the AV valves determines their type as single, double, or common and their relationship to the ventricles (straddling and override), patency, and functionality (stenosis or regurgitation). This interrogation is best performed at the ME (4-Ch, 2-Ch, RV In-Out, and Mod Bicaval TV) level. Evaluation of the outflows examines the relation between the ventricles and the arterial roots, their patency, and the semilunar valves. This assessment requires multiple views and

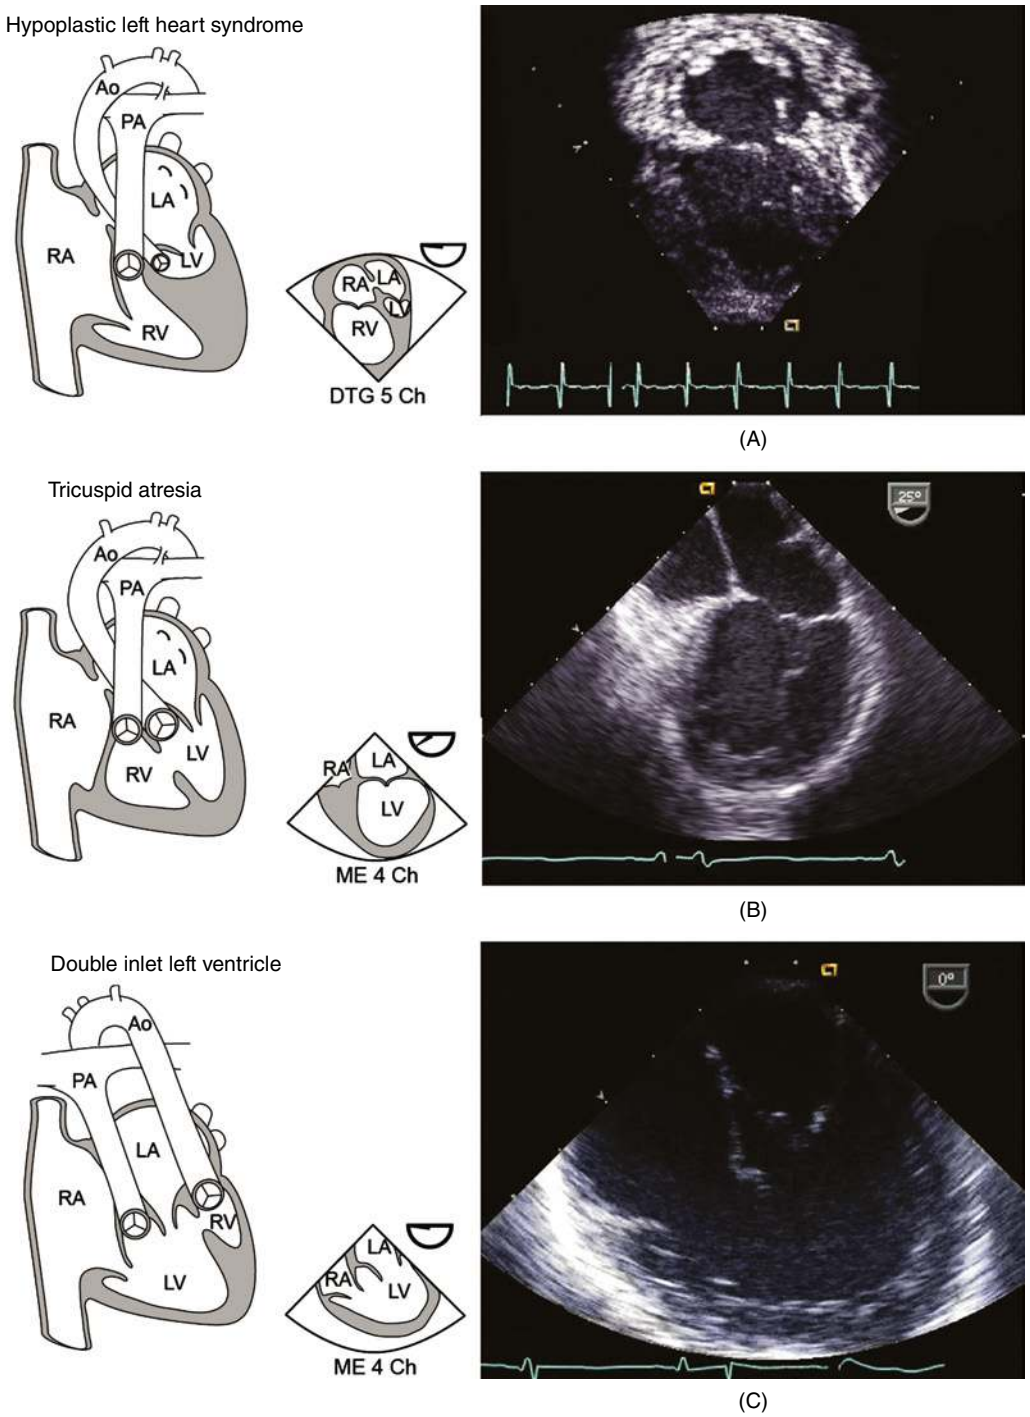

Figure 15.26 *Single ventricle variants*. (A) *Hypoplastic left heart syndrome* (*HLHS*). DTG 5-Ch view showing the characteristic features of HLHS. Note the nonexistent left ventricular (*LV*) cavity, small mitral valve, and tiny left atrium (*LA*). An atrial communication is also seen. (B) *Tricuspid atresia*. ME 4-Ch view displaying the atretic valve in tricuspid atresia and hypoplastic right ventricle (*RV*). (Source Motta and Miller-Hance [199]. Reproduced with permission of Wolters Kluwer Health, Inc.). (C) *Double-inlet left ventricle* (*DILV*). ME 4-Ch view depicting two atrioventricular valves opening into a large ventricular chamber, consistent with the diagnosis of DILV. *Ao* aorta; *PA* pulmonary artery; *RA* right atrium; *RV* right ventricle. Diagrams courtesy of Ms. Willa Bradshaw.

sweeps obtained at the ME (5-Ch, LAX, AoV LAX, AoV SAX, Asc Ao SAX), TG (LAX), and DTG (5-Ch and RVOT views) levels. The adequacy of systemic or pulmonary venous admixture or drainage (ME 4-Ch, ME Bicaval, ME Rt Pulm veins, ME Lf Pulm veins, TG IVC/Hep veins, and DTG Atr Sept views) should also be established. This comprehensive evaluation in the single ventricle patient also requires the use all available Doppler modalities.

Single ventricle surgical management often involves sequential palliative stages. Depending on the anatomy, *stage I palliation* may consist of a surgical technique aimed at providing for or improving systemic (e.g., Norwood procedure)

AL Grawany

or pulmonary blood flow (e.g., systemic to pulmonary artery shunt) or limiting pulmonary overcirculation (i.e., PA banding) to balance pulmonary and systemic blood flows. The *preoperative TEE* examination confirms the anatomy by evaluating the AV and VA connections; AV valve morphology and function; the degree of outflow tract obstruction; size, morphology, and function of the ventricle; and adequacy of the interatrial communication. The *post-CPB TEE* examines the adequacy of the specific intervention, AV valve competence, and ventricular function. *Stage II palliation* usually consists of a bidirectional superior cavopulmonary connection (Glenn shunt or hemi-Fontan procedure). *Postoperative TEE* evaluates patency of the anastomosis, AV valve competence, and ventricular function. The last step or the *stage III operation* is the *Fontan procedure* or *total cavopulmonary connection* using either an intracardiac lateral tunnel or an extracardiac conduit to route blood from the IVC into the PA (Figure 15.27). Creating a fenestration allows blood from the venous system to enter the systemic circulation to maintain CO without depending on passage through the pulmonary circulation. In addition to the anatomic and functional assessment previously mentioned for earlier palliative stages, the *post-CPB TEE* evaluates the Fontan circuit for obstruction, leaks, and patency of any fenestration [14, 220, 221]. There should be low-velocity phasic flows into the PAs and across the Fontan pathway as shown in the ME and DTG views. Spontaneous contrast often appears in the Fontan circuit and represents slow flow along this venous pathway. TEE is particularly helpful in identifying thrombus formation along the Fontan pathway and during cardiac catheterization procedures aimed at creating, enlarging, or occluding a fenestration [222]. Adult patients who have undergone prior Fontan procedures may need revision of the intervention for either thrombotic complications or other problems. The Fontan conversion procedure aims for a more favorable hemodynamic modification.

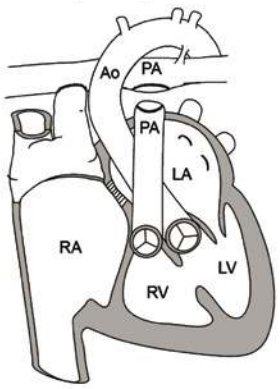
KEY POINTS: EVALUATION OF SELECTED CONGENITAL HEART DEFECTS BY TEE

- The TEE evaluation of CHD assumes an understanding of the anatomic abnormalities and physiologic repercussions of the various defects.
- The review of information obtained in all prior diagnostic studies, but particularly the TTE findings, is critical before undertaking TEE.
- The comprehensive TEE evaluation in CHD requires the use of all modalities that include 2D and, in selected cases, real-time 3D imaging, spectral Doppler, and color-flow interrogation.
- The examination benefits from the use of multiple TEE planes in all available windows.
- The intraoperative assessment of any defect aims to characterize the abnormalities in question, assess disease severity, and evaluate functional aspects related to the AV valves, semilunar valves, and myocardium, which may affect the clinical course.

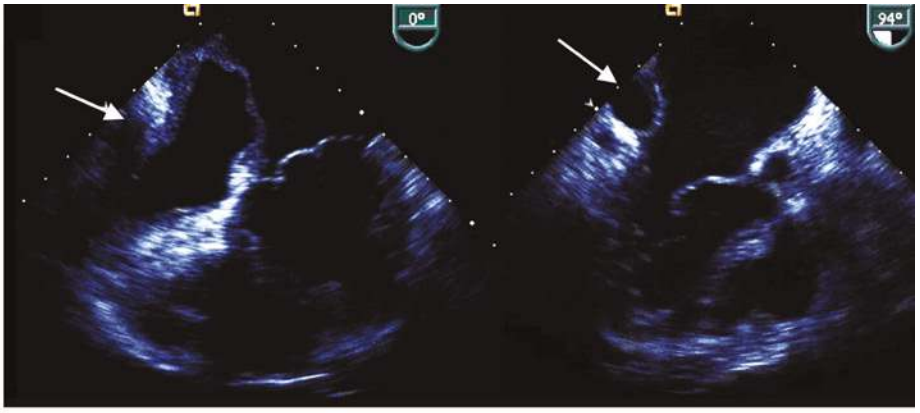
Applications of TEE during mechanical support

The options for mechanical circulatory support as a bridge to transplant, and to a lesser extent destination therapy, are growing in CHD populations as experience with these devices increase [223–228]. The spectrum of mechanical support ranges from full support with extracorporeal membrane oxygenation (ECMO) to supporting one or both ventricles with intracorporeal or paracorporeal ventricular assist devices. In addition, some patients with congenital or acquired cardiovascular conditions may benefit from the use of temporary assist devices while cardiac function recovers. Echocardiography plays important roles in the selection, intraprocedural insertion of the device, perioperative management, and postprocedural monitoring in patients with mechanical support [15, 229–236]. Important aspects of the examination are noted in Table 15.10.

Epicardial echocardiography



Currently, E-echo is mostly reserved for patients in whom TEE probes cannot be used because of contraindications to esophageal instrumentation (see Table 15.2), size constraints, or the potential for hemodynamic or respiratory compromise, or when TEE hardware is not available. Additional indications for an epicardial study include difficult patient anatomy, poor TEE image quality, and inability to adequately image structures [237–241]. Therefore, E-echo should be considered complementary to TEE in most cases.



Intraoperative E-echo also provides an alternative technique to image the heart during cardiac surgery and can aid surgical decision-making. Critically ill pediatric patients with an open chest and those on ECMO may also benefit from E-echo in the ICU. In the recent era of the coronavirus disease pandemic, E-echo has been proposed as a possible safer alternative to TEE because it avoids (i) aerosolization, (ii) direct contact between the imaging probe and body fluids (if a probe protective cover is not used), and (iii) the need for special preparation [242].

This technique uses a standard TTE probe placed in a sterile sheath with acoustic gel like that used for percutaneous line insertion [243]. These are lower frequency probes, with good tissue penetration. Image quality can be improved by filling the field with saline or using a saline-filled sterile glove to provide a stand-off between the probe and the structure being imaged. Directly placing the probe on anterior structures like the pulmonary valve provides better image quality than TEE does.

The surgeon or operator manipulates the probe directly on the surface of the heart and great vessels (Figures 15.28 and 15.29). In 2007, the ASE, in conjunction with the SCA, published guidelines for performing a comprehensive E-echo examination and recommended seven views for this examination [244]. The standard views obtained are analogous to standard transthoracic views. In most cases when using this modality in CHD, the imaging examination focuses on addressing specific issues or questions and additional views may be used (Figure 15.30). The freehand

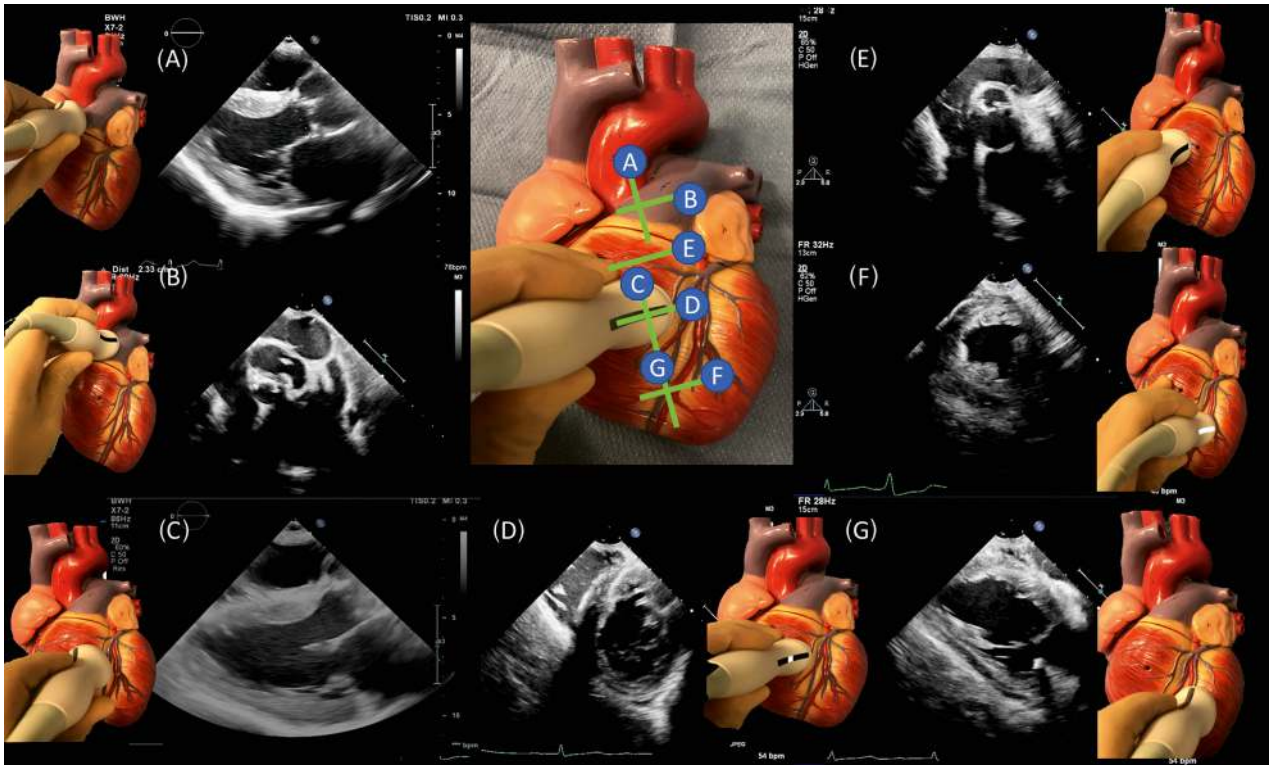

Figure 15.28 *Standard epicardial echocardiography views*. Similar to transthoracic echocardiography, for epicardial imaging the probe is positioned on the surface of the heart with the probe marker pointing cephalad or to the left of the patient. Most views are orthogonal to each other, so obtaining a long- or short-axis view and rotating the probe 90° shows the other view at the same heart level. Slight tilting and rotation of the probe can help optimize each view. (A) *Aortic valve (AoV) long-axis (LAX) view*. The probe position aligns parallel to the long axis of the ascending aorta with the marker pointing cephalad. This view shows the AoV and left ventricular outflow tract (LVOT) permitting color and spectral Doppler interrogation. (B) *AoV short-axis (SAX) view*. The probe is rotated 90° clockwise from the AoV LAX view with the probe marker to the patient's left. This view shows the short axis of the aortic root at the level of the aortic sinuses. (C) *Left ventricular (LV) LAX view*. The probe is positioned in the middle of the right ventricular (RV) free wall aligned with the long axis of the Ao with the marker pointing cephalad. This view shows the entire LV in long axis and mitral valve. (D) *LV basal SAX view*. The probe is rotated 90° clockwise from the LV LAX view with the probe marker pointing leftward, until the MV leaflets appear in short axis ("fish-mouth" view) and the RV is in the near-field with the tricuspid valve on the left of the image. (E) *RV inflow-outflow view*. The probe is positioned over the RV outflow tract (RVOT) with superior angulation and the probe marker to the left. The RVOT appears in the near-field, the AoV in the center, the pulmonary valve (PV) in long axis on the screen right, and the proximal main PA below. This view allows for color-flow Doppler assessment of the PV and depending on angle alignment, may facilitate measurements of RVOT and PV gradients. (F) *LV mid-SAX*. From the LV basal SAX view, angulation or moving the probe inferiorly with the probe marker to the left, displays the LV in SAX at the level of the papillary muscles. (G) *LV two-chamber* view. The probe is rotated 90° counter-clockwise from the LV mid-SAX view with the probe marker pointing cephalad, shows the long axis of the LV.

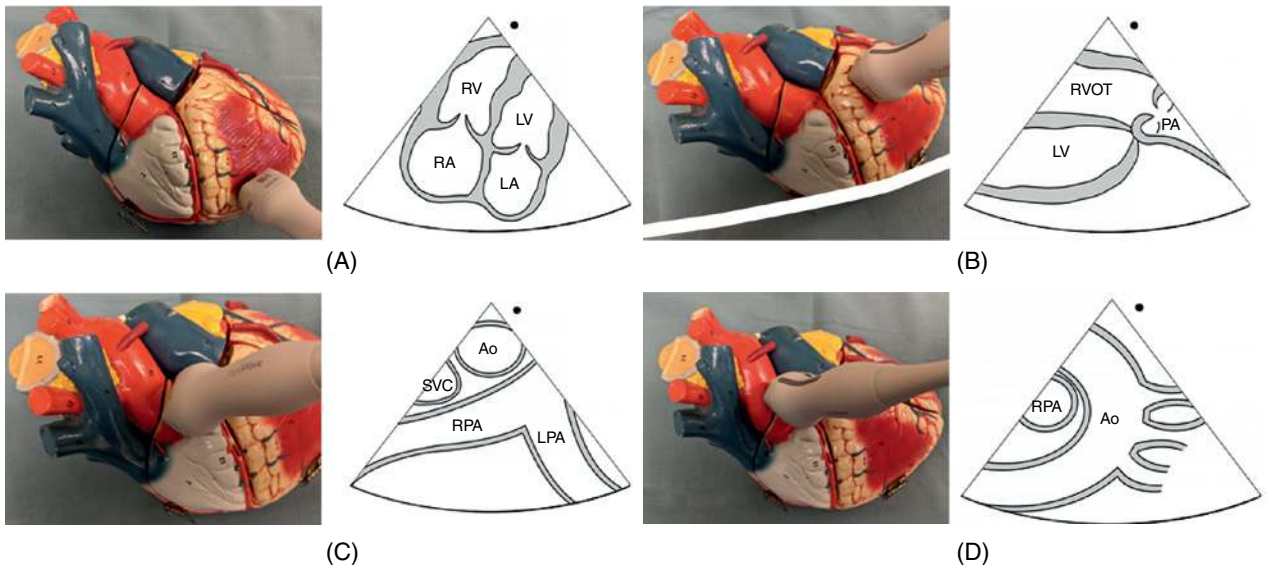

Figure 15.29 *Additional epicardial echocardiography views in congenital heart surgery*. (A) *Subxiphoid equivalent modified apical four-chamber view*. By positioning the probe over the inferior border of the right ventricle (RV) with slight clockwise rotation and the marker pointing to the left, a modified four-chamber view is obtained as shown allowing for visualization of the RV, left ventricle (LV), left atrium (LA), right atrium (RA), interatrial septum, a portion of the interventricular septum, as well as assessment of atrioventricular valve function. (B) *RV outflow tract view*. The probe is positioned over the RV outflow with the marker pointing to the patient's left shoulder. The view shows the right ventricular outflow tract (RVOT), pulmonary valve, main pulmonary artery (PA), and a portion of the LV. (C) *Branch PA view*. The probe is positioned over the ascending aorta or main pulmonary artery bifurcation, with the marker pointed to the left shoulder. The view images the main and branch pulmonary arteries. (D) *Aortic arch view*. The probe is positioned over the distal ascending aorta (Ao) aligned along the long axis of the aortic arch with the marker pointed to the patient's left. This view shows the aortic arch and arch vessels. *LPA* pulmonary artery; *RPA* right pulmonary artery; *SVC* superior vena cava.

manipulation of the probe by the operator permits off-axis imaging to evaluate the anatomic variations unique to each CHD patient. Color-flow Doppler can assess the surgical result. Visualizing all four chambers and valves of the heart, as well as the great vessels, is feasible in most patients, although apical views may not be obtainable. Structures that are particularly well imaged with E-echo include the aortic arch, branched pulmonary arteries, and coronary vessels. Recent reports suggest that 3D epicardial imaging is beneficial in CHD [245].

Drawbacks of E-echo relate to the risk of infection and the consequent need for sterility, limited windows of interrogation, interruption or distraction from the surgical procedure, and the need for a skilled operator. Furthermore, compression of structures during E-echo can cause arrhythmias and hemodynamic instability. In the operating room, a second, unsterile operator is needed to operate the ultrasonography machine and archive the images. Cooperation among the operative team is essential for the safe incorporation of this practice into the procedural workflow.

Summary

Over the years, TEE has become a valuable adjunct to surgical, hemodynamic, and anesthetic management in the patient with CHD. In the intraoperative setting, TEE confirms the diagnosis, facilitates planning or refinements of the intervention, and immediately evaluates the operative results. TEE can detect suboptimal surgical results or complications, thereby often preventing the need for subsequent reoperations and reducing overall morbidity, mortality rates, and costs. The contributions of TEE to anesthetic care include real-time monitoring of ventricular filling and cardiac function, ensuring adequate cardiac de-airing, and facilitating the optimization of hemodynamic management strategies. In the cardiac catheterization laboratory, TEE provides guidance of interventional procedures, assesses the success of the intervention, identifies complications, and enhances overall patient safety.

The overview presented in this chapter regarding the contributions of TEE in patients with CHD reflects the impact of the technology on clinical care and its positive influence on outcomes. Most centers consider the TEE imaging approach as the standard for intraoperative assessment during cardiac surgery and many interventions in the cardiac catheterization laboratory. As TEE technology continues to evolve, additional applications and contributions will probably be recognized for both children and adults with CHD. Epicardial imaging is now a well-established intraoperative option in patients in whom TEE is not feasible or when additional information is necessary by using this imaging approach as a complement to TEE.

Acknowledgments

We would like to acknowledge Ms. Willa Bradshaw, BSc, MScBMC, and Ms. Elizabeth (Beth) E. Sumner, MA, medical illustrators, for their outstanding graphic contributions to this chapter. Introduction

Pediatric cardiac surgery is associated with a substantial risk of bleeding, frequently requiring the administration of allogeneic blood products. The anemia and coagulopathy observed in neonates and children perioperatively are complex and multifactorial. Efforts to optimize preoperative hemoglobin, understand and correct coagulopathy, and incorporate blood conservation strategies to reduce bleeding are integral parts of pediatric cardiac anesthesiology and surgery. In this chapter, we will begin by reviewing the coagulation pathway, its maturation, and alterations associated with the pathophysiology of congenital heart defects (CHD). We will address preoperative optimization and blood conservation techniques, issues involved with the management of the coagulation system during and after cardiopulmonary bypass (CPB), and modalities for treating coagulopathy and bleeding in the perioperative period.

Coagulation

Mechanisms of hemostasis

Hemostasis is a complex physiologic process that regulates the formation and dissolution of a fibrin network through (i) platelet activation and aggregation, (ii) thrombin generation and fibrin clot formation, and (iii) fibrinolysis. The normal hemostatic mechanism that is triggered after vascular injury initiates a complex cascade of biochemical signaling and interactions between platelets, coagulation proteins, proteolytic enzymes, and fibrinolytic mechanisms. All of these actions are tightly regulated so that clotting occurs only at the site of vascular injury while maintaining blood flow in other parts of the circulation. The three phases of hemostasis are (i) primary hemostasis (formation of the platelet plug), (ii) secondary hemostasis (coagulation), (iii) tertiary hemostasis (fibrinolysis) (Figure 16.1).

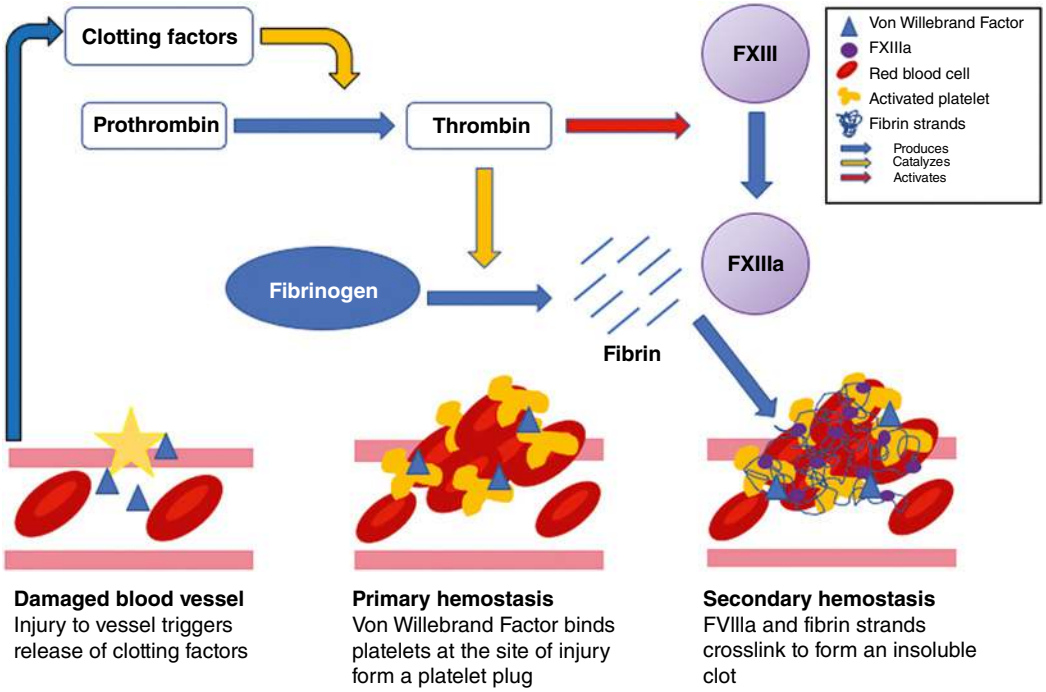

Figure 16.1 Simplified mechanisms of hemostasis including primary hemostasis and secondary hemostasis.

Primary hemostasis

Primary hemostasis reduces bleeding after vessel damage by inducing vasoconstriction at the site of injury and initiating platelet adhesion, activation, and aggregation to form a platelet plug. First, damage to the blood vessel walls exposes subendothelial collagen, which then binds circulating von Willebrand factor (vWF). Platelets *adhere* to the exposed vWF via glycoprotein 1b (GPIb) receptor on platelet surfaces. The binding of platelets to the subendothelial collagen-vWF complex triggers platelet *activation*. Upon activation, platelets release thromboxane A2 (TXA_2) and adenosine diphosphate (ADP) from their granules. These hemostatic mediators strengthen interactions between adherent platelets and promote the recruitment of additional circulating platelets to the growing platelet plug. Subsequently, negatively charged phospholipids are expressed on the surface membrane of activated platelets, which create an active surface on which coagulation proteins interact. Finally, the platelet glycoproteins GpIIb/IIa are converted to the active form and bind both fibrinogen and vWF to promote aggregation. The process of platelet *aggregation* is further modulated by the microenvironment. At low shear rates, platelet aggregation occurs predominately via $(alpha)_{IIb}ß_3$ integrin and fibrinogen interactions, while at higher shear rates, platelets aggregate increasingly in a vWF-dependent manner. Further aggregation and platelet plug development occur as surrounding platelets are activated by serotonin, TXA2, and ADP released by other platelets [1]. This local process is tightly controlled to prevent the propagation of the platelet plug beyond the site of injury by power platelet aggregation inhibitors and vasodilators produced by non-injured endothelial cells.

Secondary hemostasis

Secondary hemostasis leads to the formation of a fibrin clot by sequentially activating circulating coagulation factors to finally form insoluble fibrin. Our understanding of this "coagulation cascade" has evolved from the traditional description of independent "intrinsic" and "extrinsic" pathways being activated in plasma to a "cell-based" concept of coagulation factors interacting on the surface of tissue factor (TF)-bearing cells and activated platelets at the site of vascular injury [2].

The cell-based model describes three overlapping phases of coagulation: *initiation* of coagulation factors on TF-bearing cells, *amplification* of coagulation by thrombin generated on these TF-bearing cells, and *propagation* of thrombin generation on platelet surfaces. TF, exposed in the vascular subendothelium after injury, is the primary physiologic initiator of coagulation [2].

Initiation of coagulation occurs when plasma factor VII (FVII) binds tightly to TF and is rapidly activated to FVIIa. This FVIIa-TF complex catalyzes the activation of coagulation factors, FX and FIX. The FXa on the surface of TF-bearing cells binds with FVa to produce small amounts of thrombin (II). This initial amount of thrombin, though insufficient to initiate fibrin formation, plays an important role in subsequently activating platelets and FVIII during the amplification phase [2].

During the *amplification* phase, the small amount of thrombin generated on TF-bearing cells amplifies the initial procoagulant signal by enhancing platelet adhesion, activating platelets, and activating factors V, VIII, and XI. Thus, thrombin acts on the platelet surface to "set the stage" for procoagulant complex assembly [2]. On the activated platelet surface, FIXa joins with FVIIIa to form the "tenase" complex (FVIIa/FIXa). The complex activates large amounts of FXa which joins with

AL Grawany

its cofactor, FVa, to form the "prothrombinase" complex (FXa/FVa). During the *propagation* phase, the "tenase" and "prothrombinase" complexes are assembled on the platelet surface to generate a large-scale conversion of prothrombin into thrombin. Unlike the small amount of thrombin produced in the initiation phase, this quantity of thrombin is sufficient to cleave fibrinogen to fibrin strands that are necessary for clot formation [2].

Tertiary hemostasis

The final phase of hemostasis, termed *fibrinolysis*, involves fibrin clot maturation and fibrinolysis. Activated factor XIII cross-links the fibrin monomers and acts as "mortar" that cements the platelet plug to form a stable clot. After clotting has occurred and bleeding has stopped, activation of the fibrinolytic system breaks down the thrombus in order to re-establish normal blood flow. Circulating plasminogen binds to fibrin within the clot. Tissue plasminogen activator (tPA) released from endothelial cells also complexes with fibrin and converts the bound plasminogen to its active form, plasmin, leading to the enzymatic dissolution of the thrombus. This stage is critical to maintaining and restoring the patency of the involved blood vessel so that blood flow can be restored, and wound healing can proceed.

Hemostatic homeostasis

The hematological system constantly balances the ability to keep blood flowing through undamaged vessels with the ability to stop bleeding from damaged blood vessels. Under normal circumstances, blood vessels are non-thrombogenic because of intact endothelial surfaces and circulating activated protein C, with its cofactor protein S inactivating any circulating FVa and FVIIIa to attenuate thrombin generation. Antithrombin (AT) neutralizes circulating FXIa, FXa, FXIa, and thrombin to prevent fibrin formation. Circulating nitric oxide and prostacyclin inhibit platelet activity and release tPA to promote fibrinolysis. Thus, clot formation is prevented in undamaged blood vessels while vascular damage disrupts these homeostatic mechanisms to create an environment conducive to clot formation. Furthermore, when vascular damage does occur, the coagulation process is restricted only to the injured vessels because the coagulation process-inducing TF is expressed on damaged vessels and also because a host of circulating anticoagulants keeps the actions circulating activated coagulation factors in check. Under normal conditions, coagulation and fibrinolysis occur only where they are needed and are prevented from becoming pathological generalized problems by procoagulant and anticoagulant factors that delicately balance the system.

KEY POINTS: MECHANISMS OF HEMOSTASIS

- Primary hemostasis involves platelet adhesion, activation, and aggregation to form a platelet plug at the site of injury.
- Secondary hemostasis involves coagulation factor activation and fibrin clot formation.
- Tertiary Hemostasis involves cross-links of fibrin strands and break down of the clot through fibrinolysis.

Developmental hemostasis

Like most organ systems in the newborn, the hematologic system is not fully developed at birth but matures over the first year of life. In the late 1980s, Dr. Maureen Andrew termed the age-related changes of the hemostatic system *developmental hemostasis* [3]. This parallel maturation of the coagulation and fibrinolytic systems maintains the delicate hemostatic balance between thrombosis and bleeding in healthy neonates and infants. An understanding of these changes in the coagulation system is critical for practitioners involved in caring for pediatric cardiac patients.

Although maternal coagulation factors do not cross the placenta, the synthesis of coagulation proteins begins at approximately 11 weeks gestation. Levels of coagulation factors are dependent on the gestational age of the neonate, with major increases in both procoagulant and anti-coagulant factors occurring between 30 and 40 weeks of gestation and reaching adult levels by 1 year of age [3–5]. In contrast, levels of fibrinogens, FV, VIII, FXIII, vWF, and platelet counts are comparable to adult values on the first day of life. In addition to these quantitative differences, recent studies have demonstrated qualitative differences in several hemostatic components, which manifest throughout the three stages of hemostasis (Table 16.1).

Platelet counts in neonates are similar to those found in older children and adults, but neonatal platelets show a qualitative decrease in function for the first 2–4 weeks of life. However, the literature regarding neonatal platelet function is conflicting, with some studies demonstrating platelet hyporeactivity and others demonstrating accelerated coagulation [6–13]. The *in vitro* activation of neonatal platelets is decreased to a variety of standard agonists including

Table 16.1 Differences in coagulation components between neonates and adults

Component	Neonatal versus adult levels
Primary hemostasis	←→ Platelet Count
	↑ vWF
Coagulation factors	↓ FII, FVII, FIX, FX
	↓ FXI, FXII
	↓ to ←→ FVI, FXIII
	←→ Fibrinogen
	↑ FVIII, vWF
Anticoagulation factors	↓ PC, PS, AT, TFPI
	↑ alpha2M
Fibrinolysis	↓ Plasminogen
	↓ to ←→ PAI

vWF = von Willebrand factor; F = factor; TFPI = Tissue factor pathway inhibitor; AT = antithrombin; PC = Protein C; PS = Protein S; alpha2M = alpha2-macroglobulin; PAI = Plasminogen activator inhibitor.
Source: Adapted from Anderson et al. [3–5].

epinephrine, ADP, collagen, and thrombin [10, 14]. This hyporeactivity manifests in several ways: (i) a decrease in platelet granule secretion; (ii) decreased expression of fibrinogen-binding sites on platelet surfaces; (iii) deficiencies in neonatal phospholipid and calcium metabolism that impair platelet activation; and (iv) immature signal transduction pathways and reduced platelets surface receptors that impair platelet aggregation [6, 15]. As such, Caparros-Peres and colleagues report *reduced* platelet adhesion and aggregation in a plasma-free medium [11]. Despite the impaired function in *in vitro*, most *in vivo* assays of platelet function show adequate neonatal platelet function. For example, bleeding time (BT) and platelet closure time (PFA-100) have been shown to be shorter than adults, suggesting *increased* adhesion and aggregation [12]. Similarly, viscoelastic testing often demonstrates normal or accelerated coagulation in this population [7]. Interestingly, when adult platelets were placed into neonatal blood, bleeding times were dramatically shorter when compared with adult platelets added to adult blood [13]. These *in vivo* assays may be explained by the prominent role that plasma proteins play in neonatal hemostasis. In fact, neonates have a higher concentration of plasma vWF and a greater percentage of the ultra-large vWF necessary for improved platelet adhesion. Despite these conflicting studies, primary hemostasis appears to remain intact in healthy neonates and children.

At birth, many of the coagulation factors involved in secondary hemostasis are quantitatively lower than adults. In newborns, mean levels of the vitamin K-dependent procoagulant factors (II, VII, IX, X) and contact factors (XI, XII, PK, and HMWK) are about 70% of adult levels (Figure 16.2) [3]. This can be attributed to the immature fetal liver, which has reduced ability to provide the gamma-carboxylation needed to produce vitamin K-dependent factors [16]. This is partially counterbalanced by higher levels of vWF and ultra-large vWF, which improve adherence between platelets and injured vessels [17] (Figure 16.3). Neonatal hemostasis is balanced by having concurrent lower levels of the anticoagulants antithrombin (AT), Protein C, and Protein S, and fibrinolytic factors (plasminogen and tPA) (Figure 16.4) [3–5]. The higher levels of thrombin inhibitor alpha2-macroglobulin counteract lower levels of other anticoagulants. In the presence of these quantitative and qualitative factor deficiencies, neonates tend to generate significantly less thrombin than adults.

In addition to lower levels of clotting factors, the existence of neonatal forms of clotting proteins has been described. Most notably, Brown and colleagues demonstrated an immature form of fibrinogen [18], which has differing phosphorus and sialic acid content than adult fibrinogen [19]. These differences lend unique properties to the differences in clot formation between neonatal and adult fibrinogen [18, 20]. Clots formed from adult fibrinogen display higher fiber density and significant three-dimensional branching structure. In contrast, clots formed from neonatal fibrinogen display a more linear, two-dimensional structure with increased porosity and less branching [18]. Clots formed from neonatal fibrinogen display a significantly faster degradation rate than their adult fibrinogen counterparts [18]. However, when adult and neonatal fibrinogen are mixed, simulating a transfusion event, neonatal and adult fibrinogen do not integrate completely during the process of fibrin formation (Figure 16.5). Even more concerning, these mixed clots have a slower degradation time than clots formed from neonatal fibrinogen alone. This data suggests neonatal clots may be more susceptible to fibrinolysis, but differences in the neonatal fibrinolytic proteins may help maintain the hemostatic balance.

Tertiary hemostasis mainly involves the breakdown of the fibrin clot by plasmin. Neonatal plasminogen levels are about 25–50% of adult levels until about 6 months of age [21, 22]. Since plasminogen's *in vivo* activator, tPA, is comparably low in neonates, the rate of conversion from plasminogen to plasmin is also decreased in neonates relative to adults. In contrast, the activity of plasminogen activator

inhibitor type 1 (PAI-1), the major inhibitor of plasminogen activation, is similar in neonates and adults [22]. Due to these imbalances and a qualitatively dysfunctional form of plasminogen, plasmin is generated at much slower rates in neonates [21]. Overall, the balance of factors favors a reduction in fibrinolytic activity.

In spite of these quantitative and qualitative differences in neonatal hemostasis, healthy neonates rarely suffer from spontaneous hemorrhage or thrombosis. This suggests that the maturation of procoagulants and anti-coagulant factors maintain a relative balance in healthy neonates. However, thrombotic complications are more common in neonates, and thromboelastography (TEG) has shown that neonates and infants actually clot faster and have increased clot strength compared with adults [7]. For patients undergoing cardiac surgery, this balance can be easily disrupted and these patients can be placed at risk for both bleeding and thrombotic complications.

KEY POINTS: DEVELOPMENTAL HEMOSTASIS' EFFECT ON COAGULATION

- At birth, many pro- and anti-coagulation factors are quantitatively and quality deficient, but reach adult levels and function by 1 year of age.
- The parallel maturation of coagulation and coagulation inhibitors maintain the delicate balance between thrombosis and bleeding in infants.

Influence of congenital heart disease on coagulation

In addition to the age-related effects on coagulation factor levels and function, children with congenital heart disease (CHD) have complex alternations in their whole blood

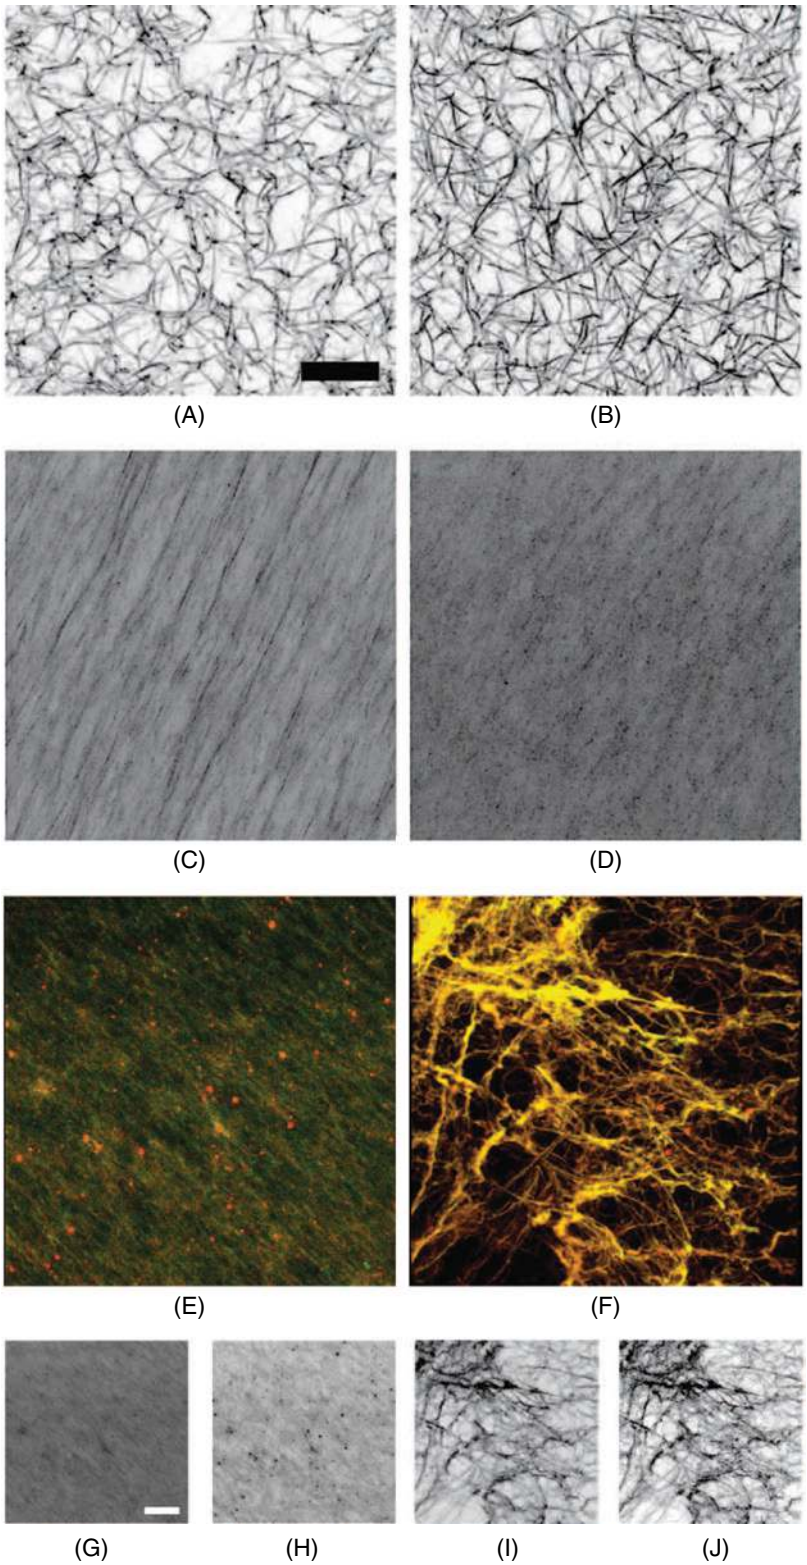

Figure 16.5 Confocal microscopy analysis of clots constructed from both purified neonatal and adult fibrinogen. Clots were formed from purified adult (A, B) or neonatal (C, D) fibrinogen at a concentration of 2.5 (A, C) or 3.5 mg/mL (B, D) fibrinogen in the presence of 10 μg/mL thrombin. Clots were also formed by combining neonatal and adult fibrinogen in a 2.5 : 1 (E, G, H) or 1 : 2.5 (F, I, J) ratio to create clots simulating conditions observed after transfusion with a total fibrinogen concentration of 3.5 mg/mL in the presence of 10 μg/mL thrombin. Neonatal fibrinogen was labeled with Alexa-Flour 488 (green) to allow for separate visualization of adult and neonatal fibrinogen labeled with Alexa-Flour 555 (red). Representative images are presented. For combined fibrinogen samples, overlaid neonatal and adult fibrinogen channels (E, F) and corresponding individual neonatal (G, I) and adult fibrinogen (H, J) channels are presented. AL Grawany

composition and coagulation profile, even more so in the presence of long-standing hypoxemia. Since the current practice of pediatric cardiac surgery is to perform corrective procedures in infancy, most of the studies on the effects of long-standing hypoxemia are several decades old. However, children with delayed surgical repair or single ventricle physiology (SVP) who live with chronic hypoxemia will develop cardiac pathophysiology-induced coagulation abnormalities that affect the hematologic, endothelial, and hemostatic systems. These patients are at increased risk for perioperative bleeding and clotting due to the complex interplay of coagulation abnormalities including secondary erythrocytosis, thrombocytopenia, impaired platelet function, deficiency of vWF multimers, and a range of clotting deficiencies.

Erythrocytosis and hemostasis

Irrespective of the primary cardiac lesions, patients with chronic hypoxemia often develop *secondary erythrocytosis*, which refers to an isolated increase in red blood cells (RBCs). This is in contrast to polycythemias that result in a marked increase in all three blood cell lines (RBCs, white blood cells, and platelets). In cyanotic heart disease, long-standing hypoxemia and reduced tissue oxygenation stimulate the kidneys to produce erythropoietin (EPO). This secondary erythrocytosis is an adaptive physiologic mechanism designed to compensate for inadequate oxygenation. However, in the presence of a persistent right-to-left shunt causing chronic hypoxemia, tissue oxygenation cannot improve beyond a certain point. Nevertheless, the kidneys continue to secrete EPO, leading to a further increase in red cell mass and blood viscosity. As blood viscosity increases with the higher number of hematocrits, blood flow may become sluggish and increase the risk of thrombosis and infarction. In fact, the increased mass has been linked with an increased risk of cerebrovascular events in neonates and infants with cyanotic heart disease [23].

In addition to secondary erythrocytosis, many patients with CHD demonstrate abnormal hemostatic profiles. While this is multi-factorial, qualitative and quantitative deficiencies in both platelets and fibrinogen are implicated. Patients with hematocrits above 60–65% often have decreased platelet counts. The thrombocytopenia seen in CHD patients is due to both decreased platelet production and increased peripheral destruction due to platelet activation from the high shear stress generated by increased blood viscosity [24]. Recent studies using TEG suggest that despite normal to elevated fibrinogen concentration, the fibrinogen function may be impaired. Cui and colleagues found that baseline tracings in patients with preoperative hematocrits >54% have decreased peak amplitude on TEG and TEG-functional fibrinogen when compared to normal patients [25]. Similarly, Jensen and colleagues demonstrated that patients with a preoperative hematocrit >57% have a smaller angle (alpha), primarily representative of the fibrinogen contribution to clot formation [26]. In addition, many patients with CHD have reduced levels of vitamin K-dependent factors (II, V, VII, X) likely due to chronic hypoxia and chronic passive congestion of the liver [27]. Finally, these patients appear to have accelerated fibrinolysis based on increased levels of D-dimers and elevated plasminogen activator inhibitor type **1** (PAI-1). However, it is unclear if the accelerated fibrinolysis is due to low-grade intravascular thrombosis, increased fibrinolysis, or increased turnover of fibrinogen [28].

Table 16.2 Coagulation factor levels (mean ± SD) over time for the subgroup of 17 patients who had complete samples drawn at each stage

Variable	Stage I	Pre-BDG	Pre-Fontan	Post-Fontan
Fibrinogen (mg/L)	200.5 ± 70	203.5 ± 86	292.8 ± 76	350.5 ± 93
Antithrombin (%)	36.8 ± 12	75.4 ± 18[a]	93.1 ± 16[b]	56.9 ± 15
Protein C (%)	17.7 ± 9	43.2 ± 12[a]	60.2 ± 16[b]	56.9 ± 15
Protein S (%)	34.1 ± 17	81.3 ± 16[a]	71.1 ± 18	76.3 ± 19
Factor II (%)	37.5 ± 14	64.7 ± 15[a]	77.8 ± 13	81.9 ± 11
Factor V (%)	67.9 ± 19	79.1 ± 15	86.9 ± 21	71.8 ± 19
Factor VII (%)	32.7 ± 14	49.3 ± 13[a]	57.9 ± 15	49.2 ± 14
Factor VIII (%)	50.3 ± 21	63.5 ± 26	90.9 ± 36	175.5 ± 89[c]
Factor IX (%)	32.5 ± 14	47.2 ± 17	62.9 ± 13	72.5 ± 18

Adapted from Odegard and colleagues [29]

While chronic hypoxemia affects multiple aspects of the coagulation system, a prospective longitudinal study of coagulation factors in 20 neonates with hypoplastic left heart syndrome (HLHS) at each stage of their palliation highlighted the complexity of hemostatic changes in congenital cardiac patients. In these children, significantly decreased levels of fibrinogen, vitamin K-dependent factors (II, VII, XI, and X), factors V and VII, as well as anti-coagulation factors (anti-thrombin, Protein C, Protein S, and plasminogen) were noted after initial palliation. These abnormalities persist through the bidirectional cavopulmonary anastomosis and just prior to the Fontan completion. Even after Fontan completion, many of these abnormalities persist, with the exception of an increase in FVIII levels and activity (Table 16.2). It is likely that the imperfect balance of procoagulant and anticoagulant factors contributes to the significant incidence of thrombotic events that occur in these patients [29].

In summary, the hemostatic abnormalities in patients with CHD are complex and include secondary erythrocytosis, thrombocytopenia, impaired fibrinogen function, and multiple coagulation factor deficiencies. Despite our best efforts at minimizing the effects of cardiac surgery on hemostasis, the underlying qualitative and quantitative hemostatic changes related to CHD itself predispose these patients to both bleeding and thrombosis.

KEY POINTS: INFLUENCE OF CONGENITAL CARDIAC PATHOPHYSIOLOGY ON COAGULATION

- Children with CHD have complex alterations in their coagulation profile due to long-standing hypoxemia and liver congestion.

- Children with chronic hypoxemia develop secondary erythrocytosis which results in elevated hematocrit levels, decreased platelet count and function, and impaired fibrinogen function.
- Coagulation abnormalities persist in children with single-ventricle anatomy and physiology through all stages of palliation.

Preoperative considerations

Predictors of bleeding post-CPB

Bleeding in the perioperative period of cardiac surgery is associated with increased incidence of postoperative complications and mortality, both from the direct effects of bleeding and from the therapies deployed to restore hemostasis. As an example, blood transfusion has been shown to be associated with a dose-dependent increased risk of postoperative infection and mortality in pediatric surgical patients [30]. Several studies have suggested that the increased bleeding risk observed in patients with CHD may be attributable to multiple contributing factors including both quantitative and qualitative differences in coagulation factors, relative immaturity of the coagulation system, endothelial dysfunction, intrinsic risk of surgical procedures, associated comorbidities (e.g., liver dysfunction), and iatrogenic factors (e.g., anticoagulation therapies, central venous access) [26, 31, 32]. Among children with CHD undergoing surgery, those with cyanotic heart disease (e.g., single ventricle physiology) are considered at higher risk for both intraoperative bleeding and postoperative thrombotic complications [29, 33]. Although the exact mechanisms for bleeding and thrombotic risks in children with CHD remain poorly understood, a complex multifactorial etiology including modifiable and non-modifiable factors is hypothesized.

Figure 16.6 summarizes the risk factors reported in the literature and that are discussed throughout this chapter. Patient-risk factors are mainly related to the age of the patient at the time of surgery. Several authors have reported a strong association between age and the incidence of bleeding, with the highest risk of hemorrhage being reported in neonates [35, 36]. Age at the time of surgery is also associated with surgery-specific risk factors as neonates often require complex surgical procedures involving prolonged CPB duration sometimes associated with deep hypothermic cardiac arrest (DHCA) [37]. Another surgery-related risk factor is the timing for surgery (i.e., need for urgent or emergent surgery) which often mean hemodynamic instability (i.e., heart failure sometimes requiring extracorporeal membrane oxygenation [ECMO]), high requirement of ventilatory or inotropic support, and presence of multiple organ failure (i.e., acute kidney injury, liver failure, pulmonary edema). As discussed above, different bleeding risks have been reported according to the type of CHD. The presence of cyanosis will have an impact on coagulopathy, fibrinogen polymerization, and platelet function [26, 38]. Patients with cyanotic heart disease often require multiple surgical procedures, also increasing the bleeding risk.

Although several authors have studied the predictive values of preoperative coagulation testing (i.e., standard laboratory tests, viscoelastic tests, thrombin generation, or platelet function), none of these tests have been shown to accurately predict perioperative bleeding, a testimony to the complexity and the multifactorial nature of perioperative bleeding [39, 40].

Although most risk factors are non-modifiable, it is important to estimate the risk before surgery in order to choose the appropriate tools to monitor and treat coagulopathy using a

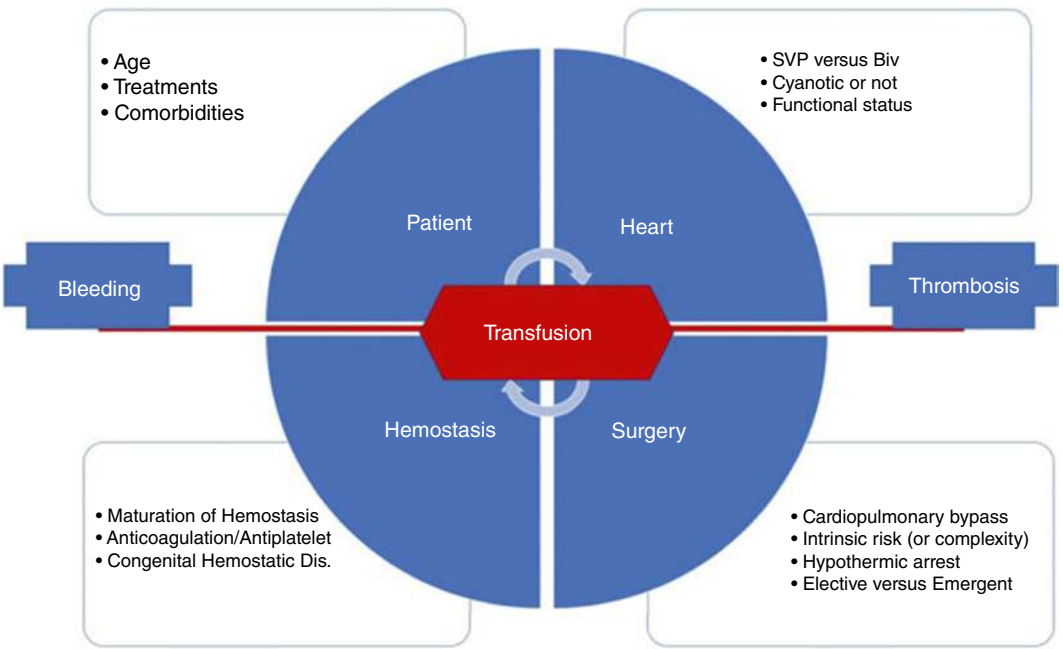

Figure 16.6 Factors affecting perioperative hemostasis in pediatric cardiac surgical patients. (Source: Cohen et al. [34]. Reproduced with permission of Cambridge University Press.)

AL Grawany

standardized and targeted transfusion algorithm that we will discuss later in this chapter.

KEY POINTS: PREDICTORS OF BLEEDING POST-CPB

- Bleeding in the perioperative period of cardiac surgery is associated with an increased incidence of postoperative complications and mortality.
- Although the exact mechanisms for bleeding and thrombotic risks in children with CHD remain poorly understood, a complex multifactorial etiology including modifiable and non-modifiable factors is hypothesized.
- Preoperative coagulation tests have not been shown to accurately predict perioperative bleeding.

Preoperative laboratory testing

During the preoperative evaluation of patients coming for cardiac surgery, practitioners should perform a complete history and physical examination to determine what laboratory testing is necessary. Patients with cyanotic heart disease may have secondary erythrocytosis, thrombocytopenia, abnormal levels of fibrinogen, and other coagulation factors. In addition, these children often have abnormal liver function tests secondary to systemic hypoperfusion, heart failure, hypoxemia, and hyperviscosity. Because the detection of these abnormalities and correction may help minimize the risk of bleeding during the intraoperative period, it is recommended that a basic electrolyte panel, complete blood cell count with differential, coagulation profile, a type and crossmatch, and liver function tests be obtained [41]. Practitioners should also question the patient and family members about bleeding or thrombotic events to determine if further hematology work up is necessary.

For outpatients with acyanotic heart disease, several institutions have adopted strategies aimed at minimizing preoperative laboratory testing to reduce patient stress related to blood draws, minimize the risk of iatrogenic anemia, and reduce additional costs. In a survey of 12 congenital cardiac surgical programs, 11 institutions still send most baseline laboratory testing. However, many practitioners reported that in the year following the original survey, no cases were canceled or their management changed because of these laboratory results. While most practitioners agreed that a type and screen and complete blood count would be sufficient to manage outpatients, only one institution has implemented these changes thus far [42].

KEY POINTS: PREOPERATIVE LABORATORY TESTING

- A complete blood count, a basic electrolyte panel with liver function tests, coagulation profile and a type and cross are recommended for most patients presenting for cardiac surgery.
- A thorough history and physical examination will determine if additional laboratory testing is necessary to screen for potential bleeding or thrombosis risks.

Preoperative anemia

One of the cornerstones of modern Patient Blood Management protocols is the identification and the treatment of preoperative iron deficiency with or without anemia. Pediatric cardiac surgical patients can range from newborns to adolescents, suffering from cyanotic or non-cyanotic cardiac defects, which result in varying baseline hemoglobin (Hb) concentrations and ferritin levels. The optimal preoperative Hb values for pediatric cardiac surgery remain to be determined as the World Health Organization (WHO) definition of anemia for pediatric patients does not apply to neonates and children with variable degrees of cyanosis and secondary erythrocytosis. However, one could argue that any pediatric cardiac surgical patient with a preoperative Hb below 11 g/dL should be considered anemic and might be suitable for preoperative anemia study and therapy. Higher thresholds might be worth consideration, especially in children with cyanotic heart defects. If a Hb of 11 g/dL is chosen as a threshold for intervention, up to 50% of patients with CHD would be diagnosed with preoperative anemia and should therefore be started on iron therapy before their procedure. In neonates and children undergoing noncardiac surgery, preoperative anemia was associated with an increased risk of mortality and postoperative complications [43, 44]. In cardiac patients, preoperative anemia was associated with an increased risk of perioperative acute kidney injury (AKI) in a retrospective cohort study of 220 patients undergoing cardiac surgery [45]. In addition, preoperative anemia has been shown to increase the risk of allogeneic transfusion in children undergoing noncomplex cardiac surgery (i.e., repair of ventricular or atrioventricular septal defects) [46]. Therefore, similar to adult patients, assessment of preoperative anemia and appropriate treatment should be recommended to avoid complications associated with perioperative and reduce the need for avoidable allogeneic blood transfusions.

Iron deficiency is present in an estimated 70–80% of pediatric patients with inflammatory bowel disease and has been shown to impair health-related quality of life [47]. Iron deficiency is also common in patients with chronic kidney disease and renal failure and is associated with increased all-cause and cardiovascular mortality [48]. Iron deficiency was recently studied in children with heart failure [49]. In this cohort, the authors found that 56% of children with heart failure presented with iron deficiency. They also found that iron deficiency was associated with greater risks of ventricular assist device implantation, heart transplantation, or death. In adults, iron deficiency has been repeatedly shown to be associated with greater cardiovascular and all-cause mortality, poorer functional capacity, lower health-related quality of life, and greater readmission rates in patients with chronic heart failure. Multiple randomized controlled trials have shown that treating iron deficiency with intravenous iron improves each of these outcome measures [50, 51].

Keeping that in mind, preoperative treatment of iron deficiency anemia is recommended in some adult and pediatric guidelines for the management of heart failure [52] or blood conservation in adults and pediatric cardiac surgical populations [53, 54]. In children undergoing cardiac surgery, the optimal approach for preoperative treatment of iron deficiency anemia has never been appropriately studied. For the preoperative administration of iron, only a very limited number of studies exist, most of them looking at oral iron

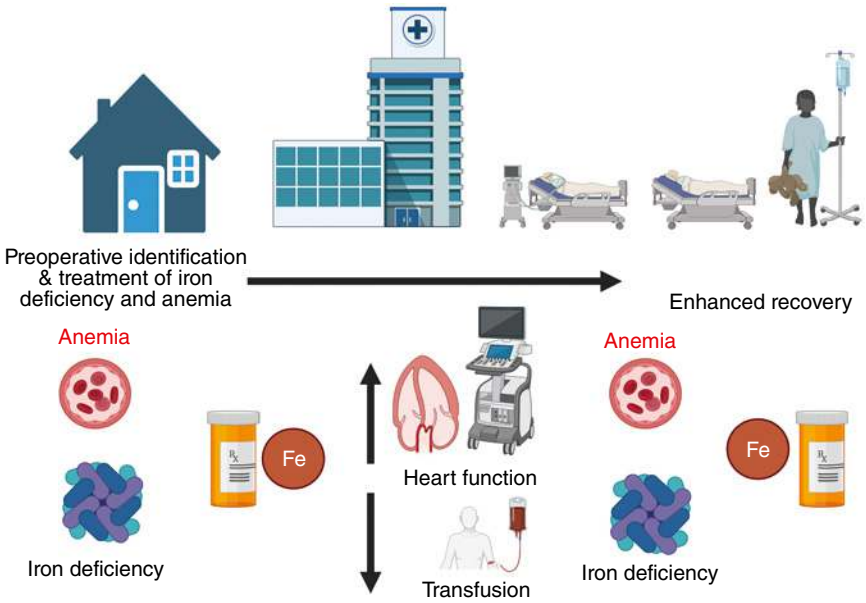

Figure 16.7 Integration of iron deficiency and anemia management into guidelines for enhanced recovery following pediatric cardiac surgery. (Source: made in ©BioRender - biorender.com.)

supplementation [55]. The largest study using intravenous iron has been published by Hassan and colleagues in 2017 in which the authors demonstrated that Ferumoxytol was effective in treating iron-deficiency anemia in a small retrospective cohort of 54 patients [56]. The members of this group pointed out that a slow infusion rate and close monitoring allowed early detection of the infrequent adverse drug reactions. Although the concomitant administration of EPO has sometimes been suggested, data supporting the efficacy and safety of EPO in pediatric cardiac patients is sparse. In a small retrospective study, Shimpo and colleagues demonstrated that the administration of up to 300 IU/kg EPO was effective as an adjuvant therapy for open-heart surgery [57]. However, the appropriate dosing regime has not been determined thoroughly. Appropriately designed studies are urgently needed to define the optimal treatment strategy (oral vs. intravenous iron), the dose, the duration, and to understand whether the addition of EPO would sometimes be beneficial.

Although one of the challenges often reported for preoperative assessment and treatment of anemia in adult cardiac surgical patients is the short window between the initial patient assessment and the time of surgery, this is often not an issue in infants and children who usually have to wait weeks, sometimes months, before their surgical procedure. We should therefore take advantage of the wait time to correct iron deficiency and anemia. In addition, postoperative iron deficiency and hospital-acquired anemia are also important issues that require our attention, and efforts should be undertaken to reduce unnecessary blood sampling and treatment of iron deficiency anemia should be initiated or resumed in the postoperative period before hospital discharge. The development of enhanced recovery after surgery (ERAS) protocols, as recently emphasized by the members of the American Association of Thoracic Surgeons' Cardiac Clinical Practice Standards Committee [58], is an excellent opportunity to integrate perioperative management of iron deficiency and anemia integrated into the multimodal protocol to optimize enhanced recovery following pediatric cardiac surgery (Figure 16.7).

KEY POINTS: PREOPERATIVE ANEMIA

- Preoperative anemia and iron deficiency are prevalent in the pediatric cardiac surgical population.
- Anemia and iron deficiency should be evaluated and treated preoperatively.
- The optimal therapeutic strategy (e.g., oral vs. intravenous iron, with or without EPO) remains to be determined.

Autologous donation

Preoperative autologous donation (PAD) refers to the collection and anticoagulation of whole blood from a patient for anticipated perioperative transfusion. The amount of blood collected from a single donation is limited to about 10% of the patient's total blood volume. While it may eliminate the risk of blood-borne infections and may diminish immune modulation, PAD remains controversial due to issues with safety, cost, logistics around surgical scheduling, and the potential pathophysiologic effects on a child with complex CHD. Therefore, this practice is generally reserved for relatively healthy adolescent patients with simple cardiac anomalies.

In contrast, autologous intraoperative blood collection and retransfusion have become more popular in order to minimize the risks associated with PAD. Acute normovolemic hemodilution (ANH) is the removal of whole blood from the patient before CPB while maintaining normovolemia through the infusion of crystalloids or colloids and then transfusing the blood after CPB. Patient selection depends on baseline hematocrit and hemodynamic stability,

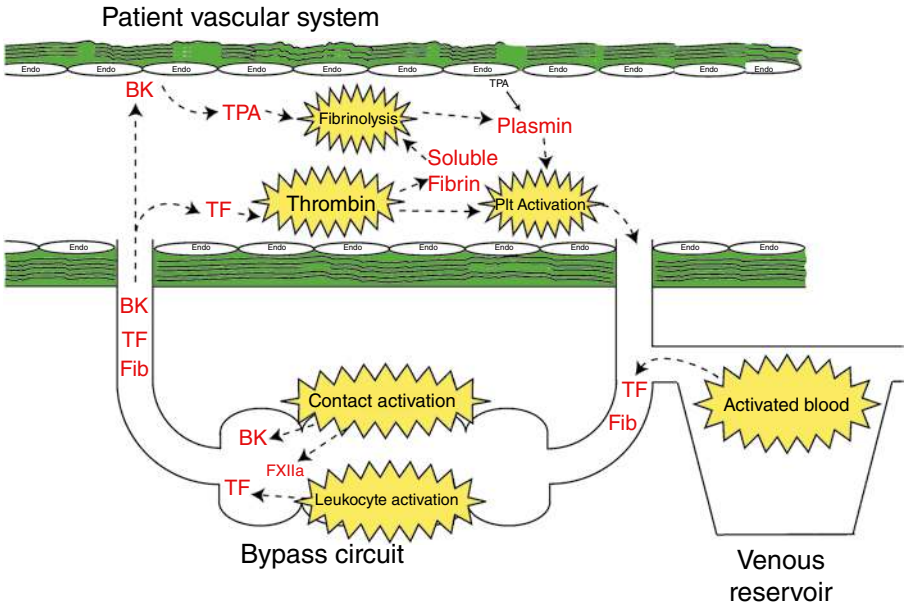

Figure 16.8 Summary of hemostatic activation mechanisms on cardiopulmonary bypass. BK = bradykinin; FXIIa = activated factor XII; TF = tissue factor; TPA = tissue plasminogen activator; Plt = platelets; Fib = fibrin degradation products; Endo = endothelium. (Source: Sniecinski et al. [62]. Reproduced with permission of Wolters Kluwer Health, Inc.)

the composition of the CPB prime, and the targeted hematocrit on CPB. A retrospective study of 209 pediatric patients undergoing cardiac surgery (with ANH when appropriate), showed that 59.6% of patients >6 kg did not receive any blood transfusions, while all patients under 6 kg received a blood transfusion. Another study of 36 patients <10 kg matched 1:1 for intraoperative autologous blood collection and retransfusion vs. standard practice, demonstrated that patients in the study group received fewer blood products overall (47 mL/kg vs. 68 mL/kg) without increased 24 hours chest tube output, mechanical ventilation, or intensive care units (ICU) length of stay. Of note, platelet count and fibrinogen levels were significantly lower in the study group compared to the control group. While these studies show that the practice is relatively safe, this practice does not necessarily reduce overall blood transfusions in patients under 18 kg [59–61].

KEY POINTS: AUTOLOGOUS DONATION

- PAD is the collection and anticoagulation of whole blood from a patient for anticipated perioperative transfusion.
- While PAD has fallen out of favor, intraoperative autologous blood collection and re-transfusion may reduce blood transfusions in patients >6 kg without increased risks.

CPB-associated coagulation changes

Exposure to CPB circuit

Cardiopulmonary bypass (CPB) is a unique scenario when the patient's blood is exposed to non-endothelial/non-physiologic surfaces leading to a widespread activation of the coagulation, fibrinolytic, and inflammatory systems (Figure 16.8).

Several mechanisms are involved in the hemostatic activation induced by CPB [62, 63]. The contact system (bradykinin system) is activated immediately when blood is in contact with the CPB artificial surfaces. In addition, factor XII autocleaves itself upon contact with a variety of anionic surfaces leading to activated FXII, which converts prekallikrein into active kallikrein. Plasma kallikrein creates a positive feedback loop by producing more activated FXII, as well as producing bradykinin from high-molecular-weight kininogen (HMWK) [64]. Bradykinin levels increase 10-fold due to increased HMWK cleavage as well as reduced lung clearance secondary to minimal pulmonary blood flow [65]. This has important implications for fibrinolysis because elevated bradykinin levels induce secretion of tPA. The role of thrombin generation during CPB is well-documented, even in the presence of adequate anticoagulation [66]. The activation of the contact system, as well as the exposure of TF on the membrane of traumatized cells by aspiration of the surgical field and CPB, expression of TF due to inflammation and due to the generated thrombin will promote a vicious circle of activation of the hemostatic and fibrinolytic system. Endothelial cells release tissue-type plasminogen activator (tPA), a major activator of plasminogen leading into fibrin-degrading plasmin. In the setting of CPB, soluble and circuit-bound fibrin provides a huge surface for plasminogen activation to occur. There is a 10- to 100-fold increase in plasmin generation shortly after the commencement of CPB, and plasmin generation, along with fibrin degradation, remains increased 10- to 20-fold throughout the duration of CPB [67]. During CPB, fibrin formation and degradation rates are nearly equal, indicating that much of the fibrin degradation is not at the sites of vascular injury. This hyperfibrinolytic state consumes fibrinogen, leaving less

available for coagulation postoperatively. After CPB, platelet adhesion is decreased to the destruction of GPIb receptors by plasmin and by the shear stress. In addition, platelet aggregation is also decreased by thrombin, plasmin, and fibrin degradation products. Altogether, these processes lead to a quantitative and qualitative consumption of coagulation factors and platelets during CPB.

Because coagulation and immune systems are associated, inflammation has multiple mediators that can create profound amplification in coagulopathy. A sepsis-like clinical picture, named systemic inflammatory response syndrome (SIRS), often results from CPB and can be linked to the close relationship between inflammation and coagulation. Leukocytes, including neutrophils and monocytes, bind to and are activated by the surface of the CPB, which leads to an increase in tissue expression, procoagulant activation, and thrombin generation. The generation of inflammatory cytokines leads to increased vascular permeability, neutrophil infiltration into the tissue, and production of acute-phase proteins.

In addition, CPB needs to be primed with blood, fluid, or a combination leading to a variable degree of hemodilution promoting even more than coagulopathy.

Hemodilution and CPB prime

Postoperative hemostasis is greatly influenced by the degree of hemodilution that occurs as a result of CPB. The effect of dilution depends on the patient's blood volume, the baseline blood concentrations (hematocrit, coagulation factors, platelets), and the volume and components of the CPB circuit prime. In children, hemodilution is an independent predictor of increased transfusions. As a result, smaller circuits have become more popular in order to minimize hemodilution, reduce the inflammatory response induced by CPB components, and decrease overall blood transfusions. Miniaturizing the CPB circuit is achieved by the elimination of non-essential components, using small-volume circuit components (oxygenator, filters, cannulae), decreasing the length and diameter of circuit tubing, using a remote pump head, assisted venous drainage, retrograde autologous circuit priming, and microplegia techniques [68]. As a result, some institutions report prime volumes of 95–110 mL for infants <5 kg. However, efforts to reduce the prime volumes require careful planning and meticulous management of bypass to mitigate risks.

Dilutional anemia

Originally, hemodilution during hypothermic CPB was used to reduce the use of blood products, promote microcirculatory flow and improve tissue perfusion. However, concerns emerged about postoperative cognitive impairment from reduced perfusion pressure, decreased oxygen-carrying capacity, and increased cerebral blood flow causing an increased risk for cerebral microemboli. Subsequent studies have demonstrated that for infants undergoing biventricular repair, a hematocrit ~ 24% or higher at the onset of low-flow CPB is associated with higher Psychomotor Development index scores at 1 year, reduced lactate levels, and improved fluid balance [69]. Some studies suggest that lower hematocrit levels are safe if mixed venous oxygen saturation, near-infrared spectroscopy cerebral oxygen saturation, and lactate levels are maintained within the normal range [70]. Unfortunately, most of the studies evaluating lower hematocrits on CPB contain a small heterogeneous population and the nadir hematocrit was ~22%. In summary, due to differences in diagnosis, age at operation, and CPB management, it is unlikely that hematocrit alone can indicate when the benefits of RBC transfusion outweigh the risks of hemodilution.

Dilution of coagulation factors

In addition to dilutional anemia, many coagulation factors have been noted to decrease at the initiation of CPB. Brown and colleagues demonstrated a decrease in both fibrinogen and FXIII due to hemodilution, which were restored to baseline levels after the transfusion of cryoprecipitate [18]. Of particular importance, the hemodilutional effects of CPB in neonates and infants often result in low fibrinogen levels that lead to impaired fibrin formation, inadequate clot formation, and increased risk of post-CPB bleeding [18, 71–73] (Figure 16.9).

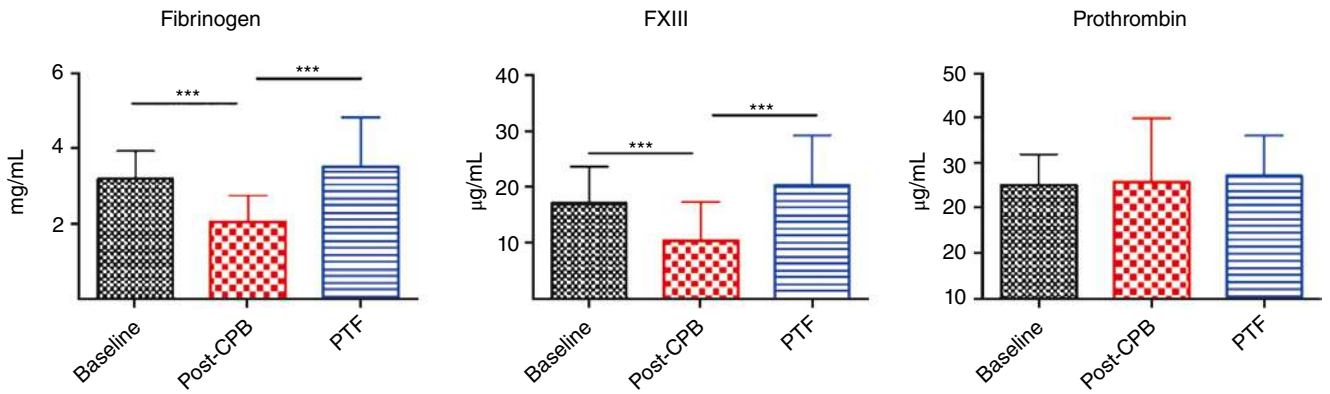

Figure 16.9 Effects of hemodilution on coagulation factors in neonates undergoing cardiopulmonary bypass. Post-CPB = cardiopulmonary bypass, F = Factor; PTF = Post Transfusion. (Source: Brown et al. [18]. Reproduced with permission of Wolters Kluwer Health, Inc.)

Composition of CPB prime

In addition to miniaturizing the circuit volumes for pediatric patients, the prime composition is often adapted to the particular requirements of the patient and the operation. That being said, the majority of institutions still use a blood prime for infants and neonates. The lower the blood volume and hematocrit of the patient, the more banked blood needs to be added into the prime. While several institutions have access to fresh whole blood (<48 hours after donation), the majority of institutions use reconstituted whole blood (fresh frozen plasma (FFP) plus RBCs). Advocates for fresh whole blood prime believe that it reduces coagulopathy and also CPB-mediated inflammation. However, Mou and colleagues performed a randomized trial in children <1 year of age comparing fresh whole blood with reconstituted blood. The authors found that patients who received fresh whole blood had increased ICU length of stay and more fluid overload [74]. In contrast, several other studies have demonstrated that patients receiving whole blood received fewer transfusions, significantly less chest tube output, and shorter length of mechanical ventilation and ICU stays [75–77]. Furthermore, adequately powered studies performed in the context of the current multimodal strategy to manage coagulopathy are required before the safety and efficacy of fresh whole blood can be determined.

While most institutions still use RBCs and FFP in the CPB prime for neonates, there is little high-grade evidence to support its use in older patient populations. Some institutions use albumin to maintain oncotic pressure and reduce fluid accumulation, while proponents of FFP argue that in addition to maintaining oncotic pressure, FFP increases the level of coagulation factors and reduces intraoperative transfusion requirements in complex neonatal and cyanotic patients. In a study of 60 patients weighing 7–15 kg randomized to FFP or crystalloid prime, Dieu and colleagues did not report any significant differences in median postoperative blood loss or transfusion requirements [78]. Other studies have demonstrated that patients with FFP prime have higher fibrinogen concentrations and improved TEG values at the end of CPB, but this was not associated with a decrease in postoperative transfusions. Unfortunately, the composition of the prime is often a matter of opinion and institutional practice and differs widely across institutions. The only consensus regarding CPB prime is minimizing transfusion requirements and hemodilution. Additional pediatric-specific trials are needed to determine the optimal CPB prime composition.

KEY POINTS: HEMODILUTION AND CPB PRIME

- Significant hemodilution of hematocrit and coagulation factors due to the CPB circuit contributes to post-bypass coagulopathy in patients undergoing congenital cardiac surgery.
- The degree of hemodilution depends on the patient's blood volume, baseline hematocrit, and the volume of the CPB circuit and its components.
- Due to significant hemodilution in neonates, many institutions still use either whole blood or reconstituted blood (FFP and RBCs) in their circuit prime.

Anticoagulation

Anticoagulation during CPB is necessary to prevent thrombin formation and subsequent clotting as blood comes into contact with the non-endothelial CPB surfaces. Unfractionated heparin is the primary anticoagulant used to inhibit not only the formation of thrombin but also the activity of circulating thrombin through its binding to AT [79]. Unfractionated heparin is usually administered at the dose of 300–400 IU/kg. The administration of 400 U/kg of heparin has been shown to produce adequate prolongation of activated clotting times (ACT) >480 s. However, a word of caution is required for neonates where standard weight-based doses have been shown to inadequately suppress thrombin generation and activity. Consequently, some centers have adopted patient-specific heparin concentration-based heparin management protocols in infants aged <6 to 12 months [80–82]. Individualized heparin doses based on heparin dose-response analysis have been used in some studies [83]. However, in a recent large cohort of children who received unfractionated heparin for CPB, Nakamura and colleagues found that heparin responsiveness before CPB was not reliably predicted by either *in vitro* heparin dose-response slopes estimated by the HMS Plus System (Medtronic, Minneapolis, MN) or regression models using commonly available preoperative clinical and laboratory data [84]. The strength of the correlation between predicted and observed heparin responsiveness was found to be at best moderate for young children <5 years. Different techniques have been used to monitor anticoagulation intraoperatively. Standard whole blood clotting time is still routinely used to monitor anticoagulation in children undergoing cardiac surgery. However, some centers have recommended monitoring heparin concentration along with the ACT as a more accurate guide for the administration of heparin to infants during CPB [85].

Despite the use of anticoagulation monitoring, anticoagulation using unfractionated heparin remains challenging in neonates and infants. Differences between commercialized heparin manufacturers and others have also been reported, which highlights the need for appropriate monitoring of anticoagulation.

Another reason for the difference in heparin sensitivity in the pediatric population may be related to the anticoagulation activity of AT, which can be influenced by age, heart failure, liver dysfunction, and inflammation. In a study by Manlhiot and colleagues, low circulating AT activity was associated with lower heparin efficacy, which ultimately leads to a decreased ability to suppress thrombin generation during CPB [86]. Determination of risk factors for heparin resistance, and potentially, AT supplementation, may individualize and improve anticoagulation treatment. In the presence of AT deficiency, FFP is usually administered because of its frequent availability in the operating room. Even though AT concentrate has sometimes been used in children supported with ECMO, there is a paucity of studies assessing the efficacy and safety of AT supplementation in neonates and children undergoing cardiac surgery. In a small cohort of infants and children with an inadequate response to heparin, Lopez and colleagues reported that 50 ± 6 U/kg of AT was effective in achieving adequate anticoagulation [87]. AT levels are sometimes included as part of the

preoperative laboratory testing. Because of the low prevalence of congenital AT deficiency, routine measurement of AT levels is not recommended. However, preoperative measurement of AT level should be considered in the presence of risk factors (e.g., neonates exposed to preoperative heparin infusion).

After a patient is weaned off CPB, protamine is administered to neutralize the effect of heparin. The protamine dose is usually based on the total amount of heparin administered during CPB. However, both residual heparin and protamine overdose are associated with increased postoperative bleeding. Most centers use a protamine-to-heparin ratio of 1:1. Based on the pharmacokinetic of heparin, a 1:1 ratio could lead to protamine overdose and bleeding; it is often recommended to use a protamine-to-heparin ratio of 1:2 ratio. Protamine dose can also be estimated based on heparin concentration monitoring [81, 83].

KEY POINTS: ANTICOAGULATION

- ACT is a whole blood test, and the clotting time obtained from an ACT is not specific to anticoagulation and any prolongation could be explained by the underlying coagulopathy.
- The baseline ACT, although routine in most cardiac programs, is of little value as it has never been shown to predict heparin resistance.
- After protamine, ACT returning to the baseline value does not make sense due to the non-specificity of ACT. The ideal method to assess the presence of residual heparin is through the use of heparinase tests and the ratio between clotting time with and without heparinase. This could be achieved using ACT or viscoelastic tests [88]. It is usually accepted that a difference of >10% between clotting times with and without heparinase is subjective of residual heparinization.
- The optimal protamine-to-heparin ratio remains to be determined, but 1:1 increases the risk of overdosage and bleeding.

Heparin-induced thrombocytopenia and alternatives to heparin

Prolonged administration of heparin can lead to heparin-induced thrombocytopenia (HIT). HIT is an immune-mediated syndrome manifesting as a drop in platelet count to >50% and life-threatening vascular thromboses (incidence: 30–75%) and can even be associated with mortality in 20–30% of cases. HIT has been reported in adults undergoing cardiac surgery, as well as in children and neonates. Figure 16.10 summarizes the

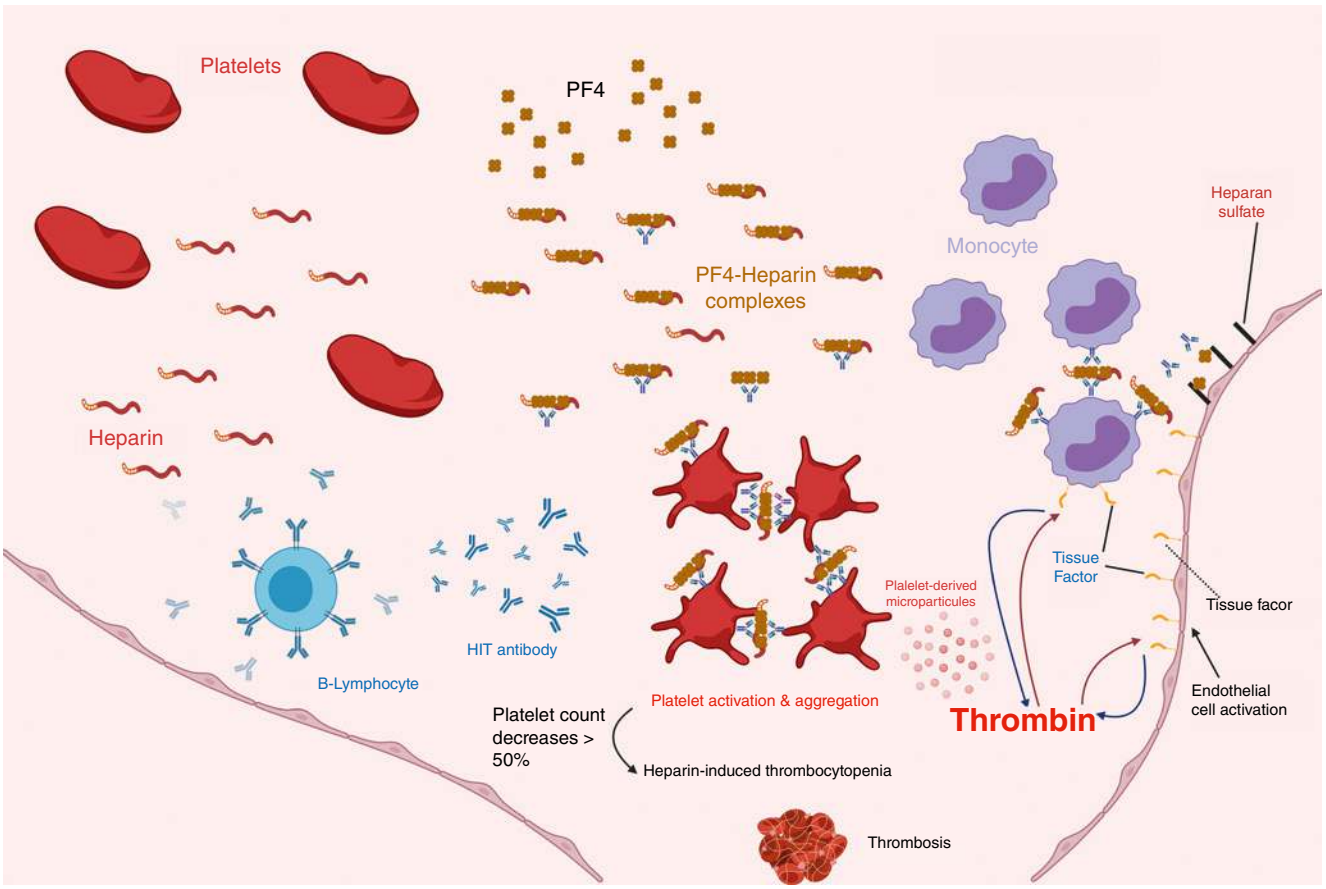

Figure 16.10 Heparin-induced thrombocytopenia. (Source: made in ©BioRender - biorender.com.)

pathogenesis of HIT. The central concept if the formation of heparin-dependent IgG that activates platelets after binding to multimolecular complexes of heparin and platelet factor 4 (PF4) leading to a self-perpetuating cycle of platelet activation, thrombin generation, and further release of PF4 from platelet granules. Endothelial cells and monocytes are also activated by the antiheparin/PF4 IgG resulting in the expression of circulant TF further promoting thrombin generation. The diagnosis of HIT relies on a combination of clinical signs and laboratory criteria. Clinical criteria include thrombocytopenia with a ≥50% platelet count drop or a platelet count decreases <150,000/mm^3, with or without venous or arterial thromboses. Laboratory criteria include the detection of antibodies to heparin/PF4 complexes and positive functional tests of platelet activation or aggregation.

In the pediatric population, the incidence of HIT is around 2–3% of patients receiving heparin anticoagulation. The main risk factor in the pediatric population is the use of intravascular catheters and heparin flushes in neonates and infants.

Three scenarios have been described for HIT. The "typical" onset HIT is seen in about two-thirds of cases and presents about 5 to 10 days after the initiation of heparin administration. The "rapid" onset HIT is seen in about 30% of the cases when HIT develops within hours or the first day of heparin administration. The pathophysiology of the "rapid" onset HIT is thought to be explained by the presence of preexisting heparin/PF4 antibodies due to previous exposure to heparin within 100 days. Finally, "delayed" onset HIT is rare but presents up to 3 weeks after discontinuation of heparin. The pathophysiology is explained by the presence of persistent antibodies that can activate platelets without the presence of heparin.

When HIT is suspected, the assessment begins with the calculation of the pretest probability using the "four Ts": thrombocytopenia, the timing of platelet drop, thrombosis, and other causes of thrombocytopenia (Table 16.3) [89]. In the pediatric cardiac surgical population, the number of etiologies for thrombocytopenia are numerous. It is therefore important to dissociate HIT with other causes of thrombocytopenia. Based on the scoring system in Table 16.3, the decision to proceed with only antigen testing (score 6–8), a positive antigen and functional assays (score 4–5), no laboratory testing when the probability of HIT is low (score 0–3). Antigen assays are used to detect the presence of IgG antibodies to heparin/PF4 complexes, as well as IgA and IgM. Although IgA and IgM can be detected, it seems unlikely that HIT can be developed without the presence of IgG which explains the discrepancy between the presence of detectable heparin/PF4 antibodies in adults treated with heparin (±50%) but only 1–5% develop HIT. Functional tests detect the ability of the heparin/PF4-IgG complex to activate platelets and cause thrombosis. Functional assays are time-consuming, require donor platelets, and are performed only in reference laboratories.

The treatment of clinically suspect HIT requires the interruption of any exposure to heparins, which not only includes unfractionated heparin but also LMWH and heparin-coated materials. The administration of non-heparin anticoagulants is recommended, like direct thrombin inhibitors (bivalirudin or argatroban) or direct Xa inhibitors (fondaparinux).

In contrast to heparins that require antithrombin (AT) to inhibit thrombin, argatroban and bivalirudin are direct thrombin inhibitors (DTIs) that bind to thrombin independent of antithrombin. DTIs, unlike unfractionated heparin (UFH), inhibit both plasma and fibrin-bound thrombin (Figure 16.11). Fibrin-bound thrombin activates platelets in the forming thrombus for clot stabilization. DTIs inhibit clot-bound thrombin, decrease clot stabilization, and promote thrombolysis.

In addition, recent data indicate that argatroban and bivalirudin increase the fibrin network permeability, rendering it less resistant to fibrinolysis. However, in conjunction with the lack of a reversal agent, these effects may contribute to potentially severe bleeding complications within the context of high-dose administration as used during cardiac surgery. There are limited data with regard to the use of argatroban during cardiac surgery, particularly during CPB. Bivalirudin has been studied in a few randomized controlled trials in adults undergoing cardiac surgery. Argatroban and bivalirudin are important anticoagulation alternatives for patients with HIT who require urgent surgery and/or perioperative anticoagulation. Although both argatroban and bivalirudin being employed for more than a decade in the complex setting of cardiac surgery, scientific data are limited to a restricted number of smaller prospective and retrospective, mostly single-center studies, and rarely involving pediatric patients. The unique pharmacokinetics of bivalirudin makes this agent an interesting option, particularly for a short-term, high-dose anticoagulant effect, as needed during cardiac surgery. However, limitations are the lack of a standardized

Table 16.3 Estimating the Pretest Probability of Heparin-Induced Thrombocytopenia: the "four Ts"

	2	1	0
Thrombocytopenia	>50% platelet fall (nadir ≥ 20,000/mm^3)	30–50% platelet fall (or >50% fall due to surgery) or nadir 10–19,000/mm^3	<30% platelet fall or nadir <10,000/mm^3
Timing of platelet count fall or thrombosis	Clear onset between days 5 and 10 or ≤1 day (if heparin exposure within the past 30 days)	Consistent with day 5–10 fall, but not clear (e.g., missing platelet count) or ≤1 day (heparin exposure within the past 31–100 days) or platelet fall after day 10	Platelet count fall ≤4 days without recent preceding heparin exposure
Thrombosis or other sequelae (e.g., skin lesion)	New thrombosis, skin necrosis, post heparin bolus acute systemic reaction	Progressive recurrent thrombosis, erythematous skin lesions, suspected thrombosis not yet proven	None
Other causes of thrombocytopenia not evident	No explanation (besides HIT) for platelet count is evident	Other possible cause is evident	Definite, other cause present

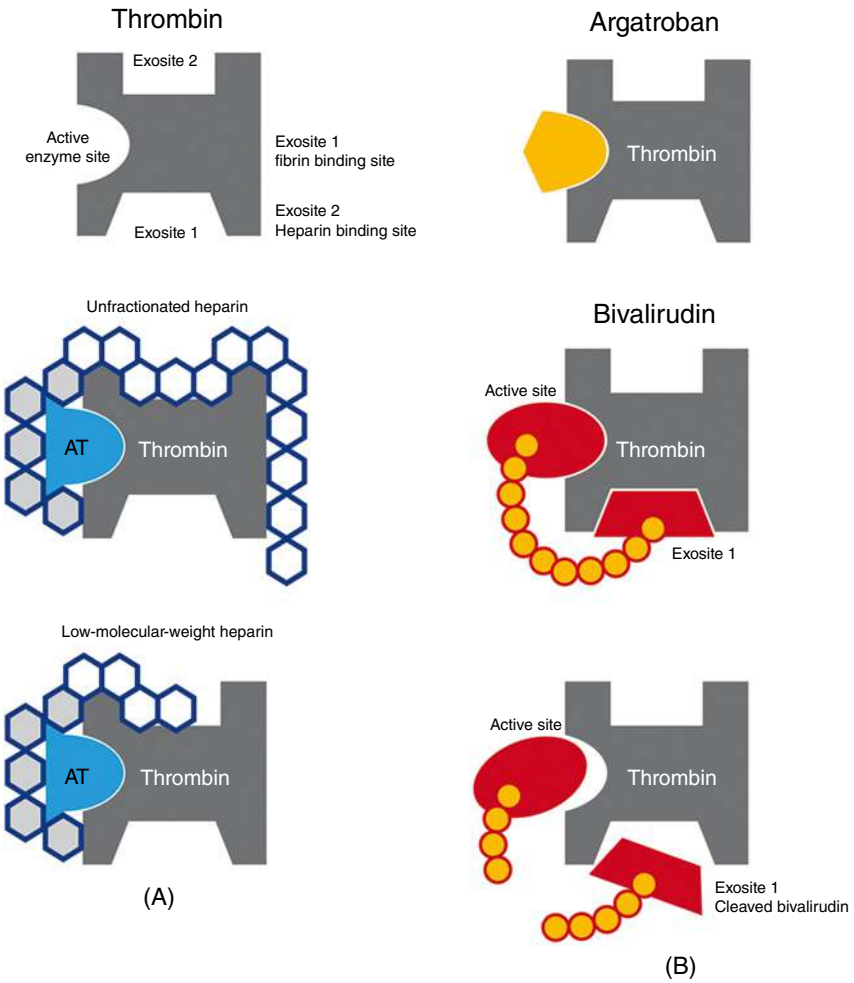

Figure 16.11 Mechanism of action of argatroban and bivalirudin. (A) Indirect inhibition of thrombin by antithrombin, which is activated via unfractionated or low molecular weight heparin. (B) Direct inhibition of thrombin by argatroban and bivalirudin. Bivalirudin is cleaved by thrombin via proteolysis. This represents the major elimination mechanism of bivalirudin. AT = antithrombin. (Source: Koster et al. [90]. Reproduced with permission of Wolters Kluwer Health, Inc.)

reliable point-of-care monitoring during CPB, as well as a reversal agent. The use of bivalirudin was recently studied in a small randomized controlled trial and compared to heparin in children with non-cyanotic heart disease undergoing cardiac surgery [91]. In the absence of a recommended safe dose for children, the adult dose regimen of 1 mg/kg followed by 2.5 mg/kg/hour infusion was used for all children, although 54% of children required an escalation in the dose to maintain an ACT of >480 seconds. The dose required to maintain ACT >480 seconds was 1.7 ± 0.2 mg/kg followed by 3.0 ± 0.7 mg/kg/hour infusion. Bivalirudin did not increase postoperative bleeding and transfusion requirement. In a recent research report, Wolstencroft and colleagues suggested that bivalirudin infusion in children should be started after a loading dose at rates greater than those used in adults [92]. Dose in neonates remains undefined because neither pharmacokinetics nor coagulation pharmacodynamics has been adequately characterized. An infusion rate of 4.5 mg/kg/hour in a 10 kg infant, 4 mg/kg/hour in a 20 kg child, and 3.5 mg/kg/hour in a 30–40 kg child will target an activated clotting time slower than 400 seconds. Adult regimens could be used in those children heavier than 50 kg. In a review article published in 2019, Zaleski and colleagues from Boston Children's Hospital summarized their experience with bivalirudin in the context of HIT [93]. The authors described their dose regimen as well as modifications required when the DTI is used. The authors suggest starting with a loading dose of 1 mg/kg followed by an infusion of 2.5 mg/kg/hour. They also recognized the need for close monitoring with repeated ACTs and dose adjustments with additional boluses of 0.5–1 mg/kg and increases in continuous infusion. That includes the following changes in CPB. The anesthesiologists must be aware that the bypass cannulas and pump suckers will be removed within a set timeframe after the discontinuation of bivalirudin. This is done to minimize the chance of blood stagnation that would lead to bivalirudin proteolysis and result in thrombosis. Because of this, blood products (cell salvage or otherwise) must be readily available for transfusion in the period immediately after separation from CPB. Modified ultrafiltration (MUF) has been safely used in several of the reported cases and should be considered when clinically appropriate; care must be taken to prevent blood stasis in the hemoconcentrator once incorporated. When used for cardiac catheterization, the authors suggest starting with a loading dose of 0.75 mg/kg

AL Grawany

followed by an infusion of 1.75 mg/kg/hour. It is also important to remember that although ACT is frequently used to monitor anticoagulation with DTIs, sensitivity-improving modifications are available either as point-of-care tests (e.g., Ecarin–thromboelastography) or quantitative, drug-calibrated assays (e.g., ecarin clotting time, dilute thrombin time, and chromogenic anti-IIa assays). However, these tests and assays have not been validated in the pediatric population for this application and thus should be used with caution, if at all.

In case a patient with a history of HIT requires an elective surgery, all efforts should be made to postpone the surgery until the heparin/PF4 antibody levels have become negative (±85 days). Although some experts advise not to expose those patients again to heparin, most suggest that it is safe to use heparin again due to the limited immune memory in HIT.

KEY POINTS: HEPARIN-INDUCED THROMBOCYTOPENIA

- HIT is an immune-mediated syndrome manifesting as a drop in platelet count >50% and life-threatening vascular thromboses (incidence: 30–75%)
- Clinical criteria include thrombocytopenia with a ≥50% platelet count drop or a platelet count decreases <150,000/mm^3, with or without venous or arterial thromboses.
- The treatment of clinically suspect HIT requires the interruption of any exposure to heparins, which not only includes unfractionated heparin but also LMWH and heparin-coated materials. Bivalirudin is a frequently used alternative.
- Most authors suggest that it is safe to use heparin again due to the limited immune memory in HIT.

Ultrafiltration

Ultrafiltration has been used in neonates and children undergoing cardiac surgery for many year and has been designed to minimize fluid overload, decrease the need for blood product transfusion, and reduce the plasmatic concentration of inflammatory mediators [94]. Ultrafiltration is a hemofiltration technique that passes blood through a semipermeable membrane filter and, according to a transmembrane pressure gradient, removes water, electrolytes, and other substances of small molecular size. Conventional ultrafiltration (performed during CPB) in children is associated with a statistically significant, but clinically modest, increase in the concentrations of fibrinogen and other coagulation factors [95]. MUF, which is performed after weaning from CPB, has been demonstrated to increase plasma protein concentrations and decrease postoperative bleeding and transfusion requirements [96, 97]. The efficacy of the two techniques has been discussed in a good number of articles [98–101]. In 2006, Williams and colleagues first compared clinical outcomes after heart surgery between three groups of infants with CHD that received dilutional conventional ultrafiltration, MUF, or a combination of both [102]. This study reported that the combination of MUF and dilutional conventional ultrafiltration afforded no additional benefit in terms of patient outcome relative to either dilutional conventional ultrafiltration or MUF alone. A meta-analysis of the currently available randomized controlled trials that examined the clinical benefits of MUF over conventional ultrafiltration in pediatric cardiac surgery indicated that MUF resulted in significantly higher post-CPB hematocrit levels and higher mean arterial blood pressure [103]. However, the analysis failed to show a positive impact of MUF on postoperative clinical parameters, including postoperative blood loss, ventilator time, and ICU time. These findings suggested that both MUF and conventional ultrafiltration could improve clinical conditions in the immediate post-CPB period. The benefit of MUF over continuous ultrafiltration on patient overall outcome might not be significant. In a more recent prospective randomized study, MUF was applied to all patients following the termination of CPB for either 10, 15, or 20 minutes [104]. In that study, MUF acutely improved the pulmonary compliance and gas exchange in all three groups and when lasting longer than 10 minutes acutely increased hematocrit levels and blood pressure measurements. However, there were not any additional contributions to the pulmonary, hemodynamic, and clinical measurements in the intensive care unit. Most recent guidelines recommend conventional ultrafiltration or ≥10 minutes of MUF to maximize hemoconcentration and facilitate early modification of systemic inflammatory response syndrome for neonates and infants undergoing cardiac surgery with CPB [54].

KEY POINTS: ULTRAFILTRATION

- Conventional ultrafiltration or ≥10 minutes of MUF to maximize hemoconcentration and facilitate early modification of systemic inflammatory response syndrome for neonates and infants undergoing cardiac surgery with CPB.

Management of bleeding

Cell salvage

Blood shed intraoperatively can be collected into an automated centrifuged-based blood salvage instrument that produces a heparin-free suspension of washed and concentrated RBCs. This technique can also be used to process the blood left in the CPB circuit after separation from CPB. Several meta-analyses have been published, clearly suggesting the utility of cell salvage in reducing perioperative transfusion needs in adult cardiac surgery [105, 106]. In pediatric cardiac surgery, technical limitations prevented cell salvage in smaller patients for many years. Due to the low blood volumes harvested during pediatric cardiac surgery, many commercialized cell salvage devices failed to process this low amount of blood adequately. However, recent technical advancements have made cell savers feasible for the small volume requirements of neonates and infants; therefore, cell salvage devices are now routinely used in pediatric cardiac

surgery. Two randomized clinical trials have been published and they have demonstrated the clinical utility of cell salvage in pediatric cardiac surgery through a reduction in perioperative transfusion needs [107, 108]. In addition, cell salvage has also been found to be cost-effective in pediatric cardiac surgery [109].

In clinical practice, the most common indications for the use of cell salvage are patients undergoing surgery with a high bleeding risk (e.g., re-sternotomy) and patients in which allogeneic blood transfusion is not an option (e.g., Jehovah's Witness). Some programs use cell salvage routinely and take advantage of the cell salvage technology to process CPB blood left after CPB separation. This approach is attractive as the blood at the end of CPB is usually poor-quality heparinized blood with a relatively low level of hematocrit. Processing blood with the cell salver will therefore concentrate the RBCs to higher hematocrit and eliminate heparin allowing the reinfusion of concentrated RBCs. It is however important to keep in mind that fibrinogen, platelets, and other coagulation factors will be lost in the process and will have to be replaced using the appropriate products or factor concentrates. Cell salvage can also be used to wash irradiated RBCs to reduce potassium and lactate loads and prevent hyperkalemia during CPB [110]. However, since the use of irradiated blood has been declining due to the effectiveness of leukocyte depletion, this indication has become less important during the past years.

Use of coagulation tests and transfusion algorithms

Intraoperative monitoring of hemostasis before, during, or after CPB has been studied for over 60 years. Several assays have been used either to predict bleeding or to treat coagulopathy in bleeding patients. Standard coagulation assays (e.g., activated partial thromboplastin time, aPTT; partial thromboplastin time, PTT; international normalized ratio, INR) were developed originally for the diagnosis of congenital factor deficiencies, and later the INR was formatted to guide the administration of vitamin K antagonists in both adults and children [111]. Although considered the "gold standard" of coagulation tests, these tests were not designed to monitor perioperative coagulopathy, nor to guide the administration of hemostatic agents in bleeding situations. As it usually takes 30–45 minutes to organize testing to be performed in the local hemostasis laboratory, limited information is obtained from these tests in the context of acute bleeding. In addition, standard laboratory tests are performed on platelet-poor plasma (PPP) and do not allow for a global assessment of coagulation (e.g., do not assess platelet function and fibrinolysis). Over the past decade, viscoelastic hemostatic tests have been increasingly used in different clinical conditions and are now integrated into all recent guidelines for management in adults during CPB [112–114]. Viscoelastic hemostatic assays are point-of-care tests that allow for a global assessment of coagulation at the bedside using whole blood. The technology to allow this assessment has evolved from the original thromboelastography (TEG®, Haemonetics Corp. Boston, MA) to now include thromboelastometry (ROTEM®, Instrumentation Laboratory, Bedford, MA), and, most recently, the Quantra® Hemostasis Analyzer (Hemosonics Corp., Charlottesville, VA).

In the TEG system, a cylindrical cup containing a 340 microliter whole blood sample oscillates under constant force. A pin on a torsion wire is suspended in the blood. As the viscoelastic strength of the clot increases progressively more rotation is transmitted to the torsion wire and this is detected by an electromagnetic transducer. The TEG 6s uses resonance-frequency viscoelasticity measurements and a disposable multichannel microfluidic cartridge, which decreases vulnerability to vibration and reduces user errors (Figure 16.12). In addition to the standard Global Hemostasis Cartridge, TEG 6s also includes a TEG PlateletMapping cartridge. Although the use of TEG PlateletMapping may be considered a useful supplement to the existing platelet function tests (e.g., PFA-100®, Seimens Medical Solutions, Malvern, PA; VerifyNow

AL Grawany

System™, Instrumentation Laboratory, Bedford, MA: Multiplate® Electrode Aggregometry, Roche Diagnostics, Indianapolis, IN) [115], further clinical validations will be required to define the clinical applications of TEG PlateletMapping [116].

ROTEM® uses a pin suspended on a ball bearing mechanism in which the pin oscillates through the application of a constant force. As the viscoelastic strength of the clot increases the rotation of the pin is progressively impeded and this is detected optically using a charge-coupled device (CDD) image sensor system. Different tests can be conducted simultaneously on each of the four channels of the analyzer (Table 16.4). The most recent analyzer, ROTEM® Sigma, and cartridges that contain different reagents in freeze-dried pellet form are represented in Figure 16.13.

The Quantra® QPlus System is a cartridge-based device consisting of the Quantra® Hemostasis Analyzer and single-use cartridges (QPlus Cartridge and QStat Cartridge) (Figure 16.14) [117]. The device measures shear modulus expressed in units of hectopascals (hPa) as a metric of clot viscoelastic properties during the coagulation process. This is accomplished using ultrasound generation and detection of resonance using the non-contact method of SEER (Sonic Estimation Elasticity via Resonance) Sonorheometry [118, 119]. An ultrasound pulse is sent into the blood sample causing it to resonate generating a shear wave. As the clot vibrates during resonance, returning ultrasound tracking pulses are used to measure the sample motion and create a time–displacement curve every 4 seconds. As the clot progressively stiffens the frequency of oscillations increases. The time–displacement curve at a specific point in time can be compared to theoretical models to determine the actual shear modulus.

Figure 16.15 offers a schematic representation of the TEG® and ROTEM® trace and the definition of the most important parameters are summarized in Table 16.5. Viscoelastic tests are available at the bedside and the use of TEG (TEG®, Haemonetic, Boston, MA) or ROTEM (ROTEM®, Instrumentation Laboratory, Bedford, MA) early parameters (as soon as 5 minutes after clotting time) allows for an implementation of early goal-directed hemostatic therapy in bleeding children [121]. A good correlation between viscoelastic tests and standard coagulation assays has been demonstrated in children undergoing cardiac surgery [73, 122, 123].

Diagnosis and treatment algorithms incorporating viscoelastic hemostatic tests for bleeding patients in a variety of clinical situations have now been developed. In adult cardiac surgical patients, Karkouti and colleagues conducted a pragmatic multicenter stepped-wedge cluster randomized controlled trial of a point-of-care–based transfusion algorithm in consecutive patients undergoing cardiac surgery with CPB at 12 Canadian hospitals from October 6, 2014, to May 1, 2015 [124]. In their study, the authors found that implementation of point-of-care hemostatic testing within the context of a simple, integrated transfusion algorithm across 12 hospitals reduced RBC transfusions, platelet transfusions, and major bleeding following cardiac surgery. These findings suggest that the use of point-of-care hemostatic testing improves the management of coagulopathy in cardiac surgery and support their broader adoption into clinical practice.

However, it is recognized that children, especially neonates and infants, pose different hemostatic problems on CPB when compared to adults. Of note, critical levels of hypofibrinogenemia and thrombocytopenia have been seen in infants and children, whereas this is rare in adult cardiac surgery. The efficacy of viscoelastic tests to predict bleeding in children undergoing cardiac surgery has been assessed in retrospective studies [39, 40, 125–130]. Overall, the value of intraoperative monitoring of hemostasis in predicting perioperative bleeding is weak and the vast majority of studies have failed to establish a correlation between intraoperative hemostasis parameters and the incidence of perioperative bleeding. The absence of predictive value can easily be explained by the multifactorial etiology of coagulopathy and bleeding in infants and children undergoing cardiac surgery as well the heterogeneity in terms of perioperative management, patients' co-morbidities, surgical complexity, and surgeons' individual skills and experience. The use of viscoelastic tests integrated into a well-defined algorithm to guide the use of blood products has been shown to significantly reduce blood product transfusion [131, 132]. To date, however, the efficacy of viscoelastic testing has only been studied in one prospective randomized study [133]. In this study, the

Table 16.4 ROTEM® assays and their clinical indications

Assay	Activators	Clinical indications
EXTEM	$CaCl_2$ and tissue factor	Deficiency of the factors of the extrinsic pathway.
FIBTEM	$CaCl_2$, tissue factor, and cytochalasin D	Fibrin polymerization, fibrinogen level

authors randomized 100 children to be managed using a conventional transfusion protocol based on routine practice ($n = 50$) or a ROTEM®-based algorithm specifically designed in that center ($n = 50$). The authors demonstrated that the application of a ROTEM®-based algorithm was associated with a significant reduction in the total amount of chest tube drainage measured at 12 hours ($p < 0.001$) and 24 hours ($p = 0.002$) after intensive care admission, and a significant reduction of the intraoperative amount of FFP and platelet concentrate administered. The authors concluded that hemostatic therapy for pediatric patients based on post-CPB thromboelastometry measurements reduced postoperative blood loss and blood product transfusion.

Only a few studies have looked at platelet function assays [9, 10, 134–137] and thrombin generation [138–140] in children undergoing cardiac surgery. None of those studies were adequately designed to assess the relationship between the intraoperative determination of platelet dysfunction or decrease in thrombin generation and transfusion or bleeding in neonates and children. Although the development of point-of-care devices to monitor platelet function (e.g., TEG® PlateletMapping cartridge) and thrombin generation could be a promising addition for intraoperative monitoring of hemostasis, further well-designed studies will be required to determine if the integration of those parameters into current transfusion algorithms could help improve perioperative management of coagulopathy and bleeding in infants and children undergoing cardiac surgery.

In the presence of ongoing bleeding, it is recommended to use intraoperative monitoring of hemostasis to guide the administration of blood products. Viscoelastic tests are better alternatives to standard coagulation assays for intraoperative bleeding management because (i) results can be obtained at the bedside within 5–10 minutes and (ii) they allow for a global assessment of clot activation, firmness, and stability [54]. Institutional algorithms should be designed based on the tests available and the availability of blood products and coagulation factor concentrates [120]. Overall, the concept of targeted therapy resides in the assessment of three components of the coagulopathy:

1. *Clot initiation* is assessed by the R time of TEG, the clotting (CT) of ROTEM®, or CT of Quantra®. Clotting times in the presence of heparinase can be used on the three devices (heparinase TEG®, HEPTEM for ROTEM®, and Clotting Time with Heparinase (CTH) of Quantra® QPlus cartridge. Those parameters can be used to estimate clotting factor deficiency and the degree of anticoagulation, including residual heparinization.
2. *Clot strength* is assessed by the clot amplitude obtained from any of those devices. The amplitude on EXTEM provides an estimate of the platelet count and fibrinogen level, the amplitude of FIBTEM provides an estimate of the fibrinogen level, and the difference between clot amplitude on EXTEM and FIBTEM provides an estimate of the platelet count. The same can be obtained from TEG® and functional fibrinogen TEG®, and the Clot Stiffness (CS) and the fibrinogen to clot stiffness (FCS) on the Quantra®.
3. *Clot lysis* can be assessed using the lysis parameters on TEG® (LY30) and ROTEM® (LI30, LI60, ML). For the Quantra®, The QStat cartridge will be needed to obtain the Clot Stability Lysis (CSL). The latter is being validated in a trauma patient [141]. It is, however, important to note that TEG® and ROTEM® are sensitive enough to detect the physiologic degree of fibrinolytic activation [142, 143], and therefore not to guide the administration of antifibrinolytic agents.

KEY POINTS: TRANSFUSION ALGORITHMS

- Although considered the "gold standard," standard coagulation tests were not designed to monitor perioperative coagulopathy, nor to guide the administration of hemostatic agents in bleeding situations.
- Viscoelastic hemostatic assays are point-of-care tests that allow for a global assessment of coagulation at the bedside using whole blood.
- Viscoelastic tests are better alternatives to standard coagulation assays for intraoperative bleeding management because (i) results can be obtained at the bedside within 5–10 minutes and (ii) they allow for a global assessment of clot activation, firmness, and stability.
- Institutional algorithms should be designed based on the tests available and the availability of blood products and coagulation factor concentrates.

Blood transfusion

The current standard of care for post-bypass bleeding includes the transfusion of adult blood products to restore hemostasis, such as packed RBCs, FFP, cryoprecipitate, and

platelets. While whole blood is available in some institutions, the transfusion of individual coagulation components is the primary treatment for post-CPB coagulopathies at most centers.

Whole blood

Historically, fresh whole blood (collected less than 24–48 hours) was used to correct the coagulopathies associated with CPB. While this practice has mostly been replaced by component therapy, there is some evidence that whole blood may be superior to component therapy in controlling bleeding after complex cardiac surgeries in children under 2 years old [35]. However, access to whole blood has been made increasingly difficult due to the techniques aimed at separating units into different components to maximize the impact of each unit. Other barriers are the logistics of timely acquiring, testing, and transporting fresh whole blood so that it is available within 48 hours of its collection.

Red blood cells

RBC transfusions are indicated for the treatment of decreased oxygen-carrying capacity causing end-organ dysfunction. This is particularly relevant for patients with congenital cardiac disease due to chronic hypoxemia (right-to-left shunting), elevated cardiac output (Qp>Qs), elevated metabolic rates, and finally the effects of surgery and CPB including hemodilution and surgical bleeding. In fact, RBC transfusions in children undergoing cardiac surgery account for more than half of all perioperative RBC transfusions.

Although RBC transfusions can be lifesaving, many studies have demonstrated an increase in morbidity and mortality associated with increasing blood transfusions. Increasing transfusions are associated with increased respiratory complications, prolonged ICU and hospital stays, decreased graft survival, increased acute kidney injury, increased thrombotic events, and immune modulation [144–148]. However, the optimal hemoglobin values for congenital cardiac surgery are not known and likely vary depending on age, degree of cyanosis, and complexity of the surgical procedure. Multiple studies have demonstrated that a restrictive transfusion practice does not increase morbidity or mortality in pediatric ICU patients, congenital cardiac patients, and preterm neonates [149–152]. However, many of the studies exclude neonates or patients with single ventricle physiology. One of the few studies examining the impact of a restrictive (hemoglobin 11.1 g/dL) vs. liberal (13.9 g/dL) RBC transfusion strategy in children with single-ventricle physiology after cavopulmonary anastomosis found no difference between the two study groups [149].

Platelet transfusion

Thrombocytopenia and platelet dysfunction are common causes of post-bypass coagulopathies and significantly increase the risk of bleeding and transfusion requirements in pediatric patients undergoing cardiac surgery. Platelet count and function in infants and children undergoing cardiac surgery are affected by CPB duration and degree of hemodilution [9, 10, 137, 153], whereas hypothermia correlates with platelet dysfunction alone [137]. A few studies suggest that the effect of CPB on platelet count and function may be age-related, with great platelet dysfunction (either activation or hypoactivity) in neonates and younger children compared with older children (Figure 16.16).

Few studies have assessed the effect of platelet transfusion on post-operative bleeding, although Romlin and colleagues completed a prospective study of 100 patients undergoing cardiac surgery comparing thromboelastography-guided transfusions versus standard management. These authors concluded that routine use of thromboelastography reduced RBC and FFP transfusions, though the rates of platelet and fibrinogen increased [131], suggesting that the primary post-CPB coagulopathies are related to platelet dysfunction. No studies to date have compared different volumes and types of platelet transfusions (e.g., concentrated or cold platelets) on post-operative bleeding. Thus, the recommendations for platelet transfusion are mainly expert consensuses, taking into account adult cardiac and pediatric transfusion guidelines [54].

Fibrinogen supplementation

A growing body of literature suggests that fibrinogen is the first coagulation factor to decrease during massive bleeding and that critically low levels are associated with post-operative blood loss and transfusion requirement in infants and children undergoing cardiac surgery [73]. During CPB, fibrinogen levels decrease up to 40% below baseline levels. However, no pediatric studies have identified the minimal plasma concentration required for adequate hemostasis. A retrospective study by Faraoni and colleagues demonstrated that plasma fibrinogen concentrations <150 mg/dL and a maximal clot firmness (MCF) on FIBTEM <3 mm predicted post-operative bleeding pediatric cardiac surgery patients [73]. Fibrinogen can be supplemented by the administration of cryoprecipitate or fibrinogen concentrate.

Although FFP can be used to replenish coagulation factors, large volumes (up to 15–30 mL/kg) are required to increase coagulation factors by as little as 20%. Such a large volume load is often not tolerated immediately after CPB in small children and may compound the coagulopathy due to further dilution of hemoglobin and platelets. As such, FFP does not contain enough fibrinogen to raise a low fibrinogen concentration to an adequate level in a child.

Cryoprecipitate is prepared by controlled thawing of FFP to precipitate and extract the coagulation factors. Cryoprecipitate contains fibrinogen (~150–700 mg/unit) as well as FVIII, FXIII, fibronectin, and vWF and has been the preferred option for fibrinogen replacement in the United States and the United Kingdom. Typically, one unit of cryoprecipitate is transfused per 5 kg of body weight and should increase the fibrinogen level by approximately 100 mg/dL [154]. In older children, 1 unit/10 kg should increase the fibrinogen concentration by approximately 50–70 mg/dL [155]. Although the risk of viral transmission is low with a single unit, the cumulative exposures needed to raise the fibrinogen level increases this risk.

An alternative to cryoprecipitate is fibrinogen concentrate (FC), a purified form of fibrinogen derived from pooled human plasma, which undergoes pasteurization to minimize

AL Grawany

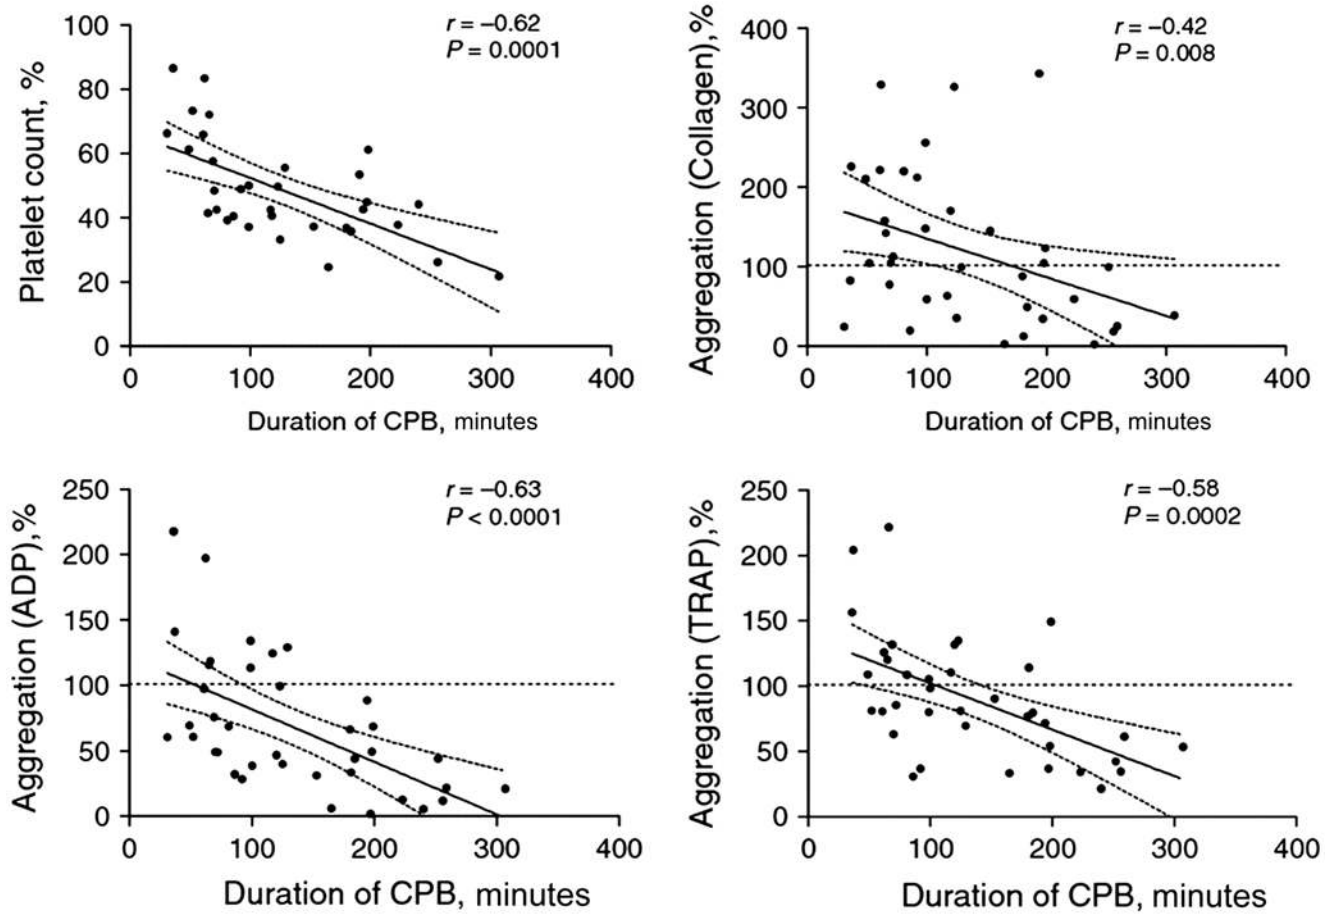

Figure 16.16 Platelet count and function decrease with increasing CPB time in pediatric patients having cardiac surgery. Platelet count and platelet aggregation after cardiopulmonary bypass. the risk of immunologic and allergic reactions. In pediatric patients, FC may have several advantages over cryoprecipitate: (i) small volume, (ii) accurate dosing, (iii) immediately available, (iv) lower infectious risk, and (v) reduced allergic or immunologic reactions (Table 16.6).

Currently, FC is being used off-label to replace low fibrinogen levels associated with bleeding in adult and pediatric surgical patients. Two small studies have investigated the efficacy and safety of FC. In a small pilot study, Galas and colleagues randomized 63 pediatric patients with a median age of 3.5 months [1–51.6 months] to receive either fibrinogen concentrate (60 mg/kg) or cryoprecipitate (10 mL/kg) after weaning from bypass if the fibrinogen levels were less than 100 mg/dL. Neither the median amount of blood loss in the first 48 hours after surgery nor the amount of allogenic blood product transfusions was significantly different between the two groups [72]. In another prospective study, Downey and colleagues randomized 60 patients <12 months undergoing cardiac surgery with CPB to receive either cryoprecipitate (2 units) or fibrinogen concentrate (target fibrinogen level ~300 mg/dL). This study demonstrated that the use of fibrinogen concentrate reduced donor exposures by 1.79 units (95% CI, 0.64–2.93) in the intent-to-treat population and 2.67 units

Table 16.6 Comparison between cryoprecipitate and fibrinogen concentrate

	Cryoprecipitate	Fibrinogen concentrate
Fibrinogen content	300–450 mg per unit	900–1100 mg/vial
Volume per unit	~300–450 mg/20 mL unit	1 g fibrinogen per 50 mL
Contents	Fibrinogen Factor VIII Factor XIII vWF	Fibrinogen
Preparation process	Stored Frozen and requires thawing ~15–17 minutes	Lyophilized powder, reconstituted with 50 mL diluent
ABO blood group Matching	Required	Not required
Viral Transmission Risks	Dependent on donor testing, no viral inactivation	Heat-treated for viral inactivation
Immune reaction risk	High – contains Immunoglobins, cytokines, cell debris	Low – Minimal immunoglobulins (low TRALI risk)

	Overall[a]	Cryo[a]	FC[a]	D

(95% CI, 1.75–3.59) in the per-protocol analysis without a significant difference in adverse events, length of stay, postoperative thrombosis, or death. The authors suggest that FC may be an adequate alternative to cryoprecipitate for pediatric patients undergoing cardiac surgery (Figure 16.17) [71]. Subsequently, the FIBRES study, involving 11 Canadian institutions, demonstrated that FC was non-inferior to cryoprecipitate in adults undergoing cardiac surgery [156].

Recommendations

- In bleeding neonates and children, guidelines recommend hypofibrinogenemia (diagnosed by either Clauss method (<150 g/dL) or viscoelastic testing) should be treated either with cryoprecipitate or FC.
- FC can be dosed in two ways:
  - 70 mg/kg or
  - Using the package insert equation to reach a target fibrinogen level:

$$\text{FC dose (mg)} = \frac{(\text{target fibrinogen} - \text{measured fibrinogen})}{1.7} \times \text{weight (kg)}$$

- Guidelines suggest that FFP should be considered for treating hypofibrinogenemia in bleeding neonates and children only when cryoprecipitate or FC is not available.

Recombinant factor VIIa

Recombinant VIIa (rFVIIa; NovoSeven® RT, Novo Nordisk, Bagsvaer, Denmark) is U.S. FDA approved for the treatment of hemophiliac patients who develop antibodies to clotting factors VII and IX. Administration of rFVIIa enhances

thrombin generation at the site of injury to facilitate the formation of a stable fibrin clot [157]. Since rFVIIa is not derived from human blood products, it has been an attractive therapeutic option for treating excessive bleeding. In fact, rFVIIa has been used "off-label" to treat excessive bleeding in a variety of clinical scenarios, including cardiac surgery.

In adults, the perioperative administration of rFVIIa after cardiac surgery has been shown to increase the risk of arterial thrombotic events [158] and in-hospital mortality [159]. In pediatric patients, rFVIIa was primarily utilized as a rescue for excessive blood loss following CPB. However, no controlled trials have been performed to assess the safety and efficacy of rFVIIa use in pediatric patients. The Congenital Cardiac Anesthesia Society organized a task force to review the literature with the intent to determine the indications for use, efficacy, safety, and appropriate dosing. Despite this large systematic review of more than 40 studies, the task force found insufficient evidence to support the use of prophylactic or routine use of rFVIIa in this patient population [160]. While rFVIIa is still used for rescue therapy at some institutions, its significant cost and lack of an established safety profile limit this appeal.

The major risk associated with rFVIIa administration is thromboembolic events. Theoretically, enhanced thrombin generation after rFVIIa is limited to the sites of vascular injury, but the thrombotic rates after "off-label" rFVIIa administration are up to 57% [160–162]. In a retrospective propensity-matched study of congenital cardiac surgery patients, those who received rFVIIa had a significantly higher thrombotic rate than those who did not (20% vs 8%) (Figure 16.18) [161]. Due to this increased risk, most guidelines recommend that the administration of rFVIIa should be restricted to rescue therapy when traditional options have been exhausted.

Recommendations

- Expert consensus recommends caution when using the administration of rFVIIa due to the thromboembolic risk.
- The recommended dosing regimen is up to two doses of 90 ug/kg administered two hours apart. Others have reported efficacy with lower doses [160, 163].

Factor concentrates

Prothrombin Complex Concentrates (PCCs) are derived from human plasma and contain coagulation factors to promote thrombin generation. They enhance coagulation by increasing the *in vivo* content of coagulation factor(s), particularly prothrombin or FII. There are approximately 15 different PCCs manufactured worldwide, but there are two main categories of PCC: 4-factor (4F) (II, VII, XI, and X) and 3-factor (3F) (II, XI, X, and very low FVII) PCC. The specific composition and amount of each clotting factor will depend on the manufacturer (Table 16.7). PCCs are approved for coagulation factor replacement therapy in patients with congenital or acquired coagulation factor deficiencies, but similar to rFVIIa, these products have been used "off-label" to manage post-CPB bleeding in pediatric cardiac patients.

In the 2005 update on oral anticoagulation guidelines, the British Committee for Standards in Hematology recommended 4F-PCC as preferential to FFP for reversing anticoagulation in patients with major bleeding [164]. In 2013, the FDA approved and recommended 4F-PCC (K-Centra, CSL Behring, King of Prussia, PA), for the reversal of vitamin K antagonists. While a few observational studies are reporting reduced bleeding and transfusion requirements after CPB in adult cardiac surgery patients, there are few studies examining this in pediatric cardiac patients. In 2020, Sisti and colleagues reported a retrospective study of 27 patients with a ventricular assist device (VAD) comparing FFP to 4F-PCC for warfarin reversal in pediatric patients undergoing orthotopic

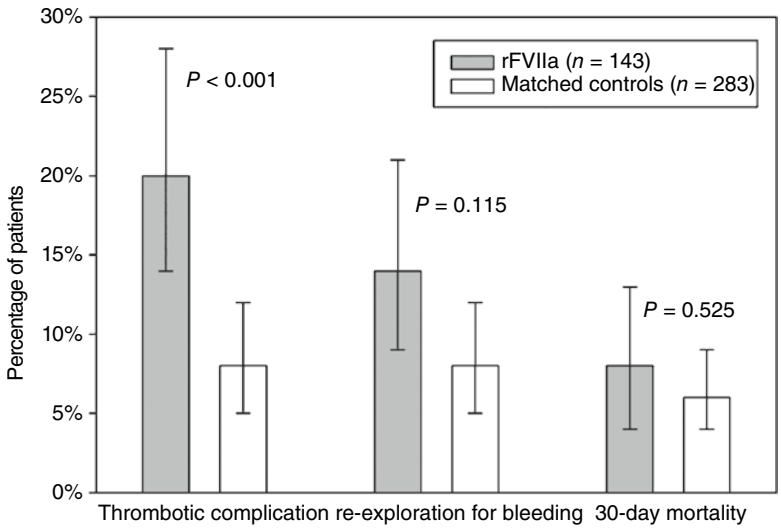

Figure 16.18 Recombinant Factors VIIa is associated with increased thrombotic complications in pediatric cardiac surgery patients. Risks of thrombotic complications, re-exploration for bleeding, and 30-day mortality. Outcome variables were compared using logistic regression analysis based on GEE to adjust for matched pairs and are reported as incidence (%) with 95% CI. $P<0.05$ was considered significant. CI = confidence interval; GEE, generalized estimating equations. (Source: Downey et al. [161]. Reproduced with permission of Wolters Kluwer Health, Inc.)

heart transplantation. The authors report that patients who received 4F-PCC pre-CPB received less PRBC and FFP transfusions than the control group with no difference in overall chest tube output or length of stay [165].

3F-PCC was originally approved for the repletion of factor IX in patients with hemophilia B, Factor VIII inhibitor bypassing activity (FEIBA) is a 4F-PCC with small amounts of activated FVII that was developed for hemophilia patients who developed antibodies to FVIII and FIX. Two *ex vivo* studies have looked at the effect of PCCs on optimizing thrombin generation in neonatal plasma [140, 166]. They report that 3F-PCC significantly shortened the time to initiate thrombin generation (lag time) and increased the peak amount of thrombin generated better than rFVIIa [140]. In a second study, thrombin generation in neonatal plasma was augmented by the addition of two 4F-PCC preparations (one non-activated and one activated (FEIBA)). Both PCC formulations enhanced the rate and peak amount of thrombin generation, but only activated 4F-PCC was capable of restoring lag time back to baseline values [166]. Despite these promising *ex-vivo* studies, little is known regarding the efficacy and safety of PCC use as a hemostatic agent in pediatric cardiac patients.

Although PCCs may offer several advantages, including small volumes, less immune modulation, decreased infectious risk, and improved clot formation, there are only a few published studies evaluating their clinical use in pediatric patients after CPB. In 2014, Giorni and colleagues compared the effect of PCC administered in 14 infants younger than 1 year with non-surgical post-CPB bleeding with 11 matched controls [167]. The authors showed that PCC reduced post-operative bleeding and decreased RBC transfusions without major post-operative complications. In a small case series published by Jooste et al., 3F-PCC was administered to six infants as rescue therapy for excessive post-CPB bleeding. The authors reported that PCC subjectively reduced clinically evident bleeding [168]. In 2020, Harris and colleagues published a retrospective propensity-matched study, evaluating adverse effects in patients who received 3F-PCC versus matched controls. These authors found no significant difference in the incidence of thrombosis, ECMO, or mortality. They demonstrated that platelets and cryoprecipitate administered were significantly less after the administration of 3F-PCC [169]. While all of these studies report a positive effect, questions remain regarding appropriate dosing regimens, efficacy, and safety concerns. Further clinical studies are needed before their use can be recommended in this population.

Recommendations:

- 4F-PCC should be used to reverse vitamin K antagonists in the setting of urgent or emergent surgery. Dosing regimens should follow the package insert.
- 3F- and 4F-PCC should be used for patients with congenital or acquired factor deficiencies requiring cardiac surgery with hematology consultation.
- 3F- and 4F-PCC should be used with caution in congenital cardiac surgery due to the thrombotic risk. Reported doses start at 5 mg/kg, with average doses ~10–20 mg/kg.

KEY POINTS: MANAGEMENT OF BLEEDING AFTER CPB

- Hypofibrinogenemia and platelet dysfunction are the most common causes of post-CPB bleeding.
- Treatment of post-CPB coagulopathies includes platelet transfusions and fibrinogen replacement with either cryoprecipitate or fibrinogen concentrate.
- Restrictive RBC transfusion strategies limit donor exposures and may reduce morbidity and mortality.
- rFVIIa is used off-label to enhance thrombin generation and clot formation in patients with post-CPB bleeding with anecdotal success.
- rFVIIa may be associated with an increased risk of thromboembolic events and should be used with caution.
- PCCs contain vitamin K-dependent coagulation factors in different concentrations.
- Other PCCs are being used off-label to treat excessive post-CPB bleeding, but little published data are available concerning their safety and efficacy.

AL Grawany

Pharmacologic therapies

Antifibrinolytics

The activation of the fibrinolytic pathway plays an important role in the coagulopathy observed during and after cardiac surgery and has prompted the prophylactic administration of antifibrinolytic agents in neonates and children undergoing cardiac surgery with CPB. During cardiac surgery, a large amount of thrombin is generated which promotes fibrinogen polymerization and thrombus formation. Thrombin also causes a conformational change such that factor XIII, α2-plasminogen inhibitor, and tissue-type plasminogen activator (t-PA) become attached to fibrin. Fibrin stimulates t-PA synthesis by endothelial cells and urokinase plasminogen activator (u-PA) synthesis by monocytes, macrophages, and fibroblasts. Both t-PA and u-PA activate plasminogen. Plasminogen can also be activated by the factor XIIa formed during the contact phase of coagulation. Plasmin is an endopeptidase that cleaves both fibrinogen and fibrin, disrupting them into fibrin degradation products (FDPs) without clotting ability. Plasmin also interacts with the inflammatory system stimulating the complement and kallikrein pathways. Fibrinolysis is inhibited by PAI 1 and PAI 2, and by thrombin binding to thrombomodulin to release and activate thrombin-activatable fibrinolysis inhibitor (Figure 16.19). Thrombin-activatable fibrinolysis inhibitor (TAFI) is the precursor of an enzyme (TAFIa) with basic carboxypeptidase activity that attenuates the lysis of fibrin clots by removal of the C-terminal lysine residues from partially degraded fibrin that mediates positive feedback in the fibrinolytic cascade [170]. Activation of fibrinolysis at CPB initiation is mainly limited to FXIIa-induced activation caused by contact of the patient's blood with the non-endothelial CPB surfaces. Fibrinolysis then becomes activated by the release of t-PA from the vascular walls. Overall, CPB results in an increase in t-PA, D-dimer, t-PA–PAI-1 complexes and a decrease in PAI-1 levels, indicating an activation of the fibrinolytic pathway and the consumption of its natural inhibitors. The degree of fibrinolytic activation is significantly correlated to the degree of thrombin generation, suggesting a strong interaction between activation of the coagulation and fibrinolytic pathways. In addition to thrombin, inflammatory markers such as cytokines and endotoxin are also able to promote the activation of plasminogen and its inhibitors. Because both plasmin and t-PA are known to interact with platelets, and vice versa, fibrinolytic activation is also associated with platelet activation [171].

Overall, fibrinolysis can be considered as a protective physiologic response that limits clot growth within a physiologic range. However, after major tissue damage and activation of CPB-induced coagulopathy, fibrinolytic activation may partially contribute to bleeding. Understanding the importance of the fibrinolytic system in CPB-induced coagulopathy and bleeding is crucial because agents capable of inhibiting fibrinolysis are available and can be administered prophylactically to avoid initiation of the fibrinolytic activation.

Antifibrinolytic agents include aprotinin and the lysine analogs (ε-aminocaproic acid [EACA] and tranexamic acid

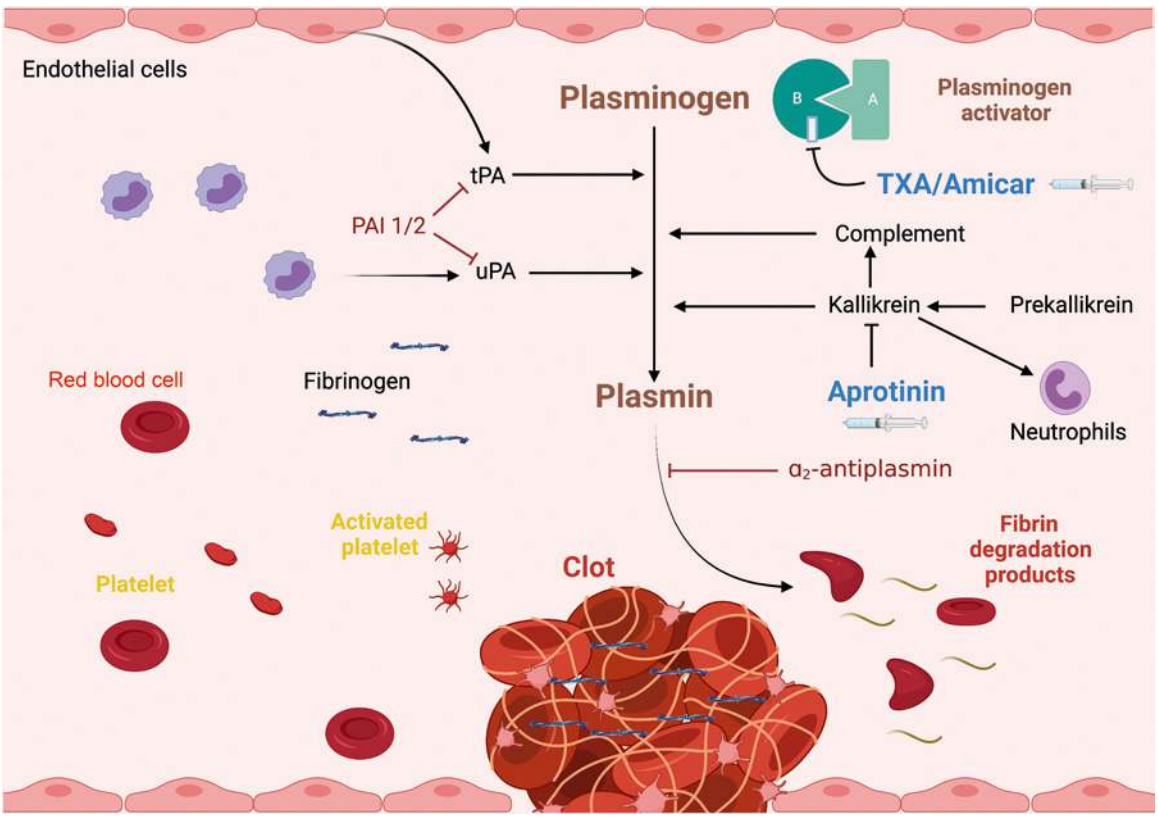

Figure 16.19 – Fibrinolysis. (Source: made in ©BioRender - biorender.com.)

[TXA]). Aprotinin is a protease inhibitor isolated from the bovine lung that is structurally similar to a tissue factor pathway inhibitor. Aprotinin is a broad-spectrum protease inhibitor that reversibly complexes with the active serine residue in various proteases in plasma (e.g., trypsin, kallikrein, plasmin, elastase). Aprotinin offers the most complete and potent fibrinolytic inhibition. Apart from these direct effects on the plasmatic coagulation system, aprotinin also inhibits the protease-activated receptor 1 thrombin receptor involved in both coagulation and inflammation. Lysine analogs, TXA and EACA, are currently the most extensively used antifibrinolytic agents. Activation of plasminogen by endogenous plasminogen activators results in plasmin, which causes degradation of fibrin. The binding of plasminogen to fibrin makes this process more efficient and occurs through lysine residues on fibrin that bind to the lysine-binding site on plasminogen. In the presence of lysine analogs, these lysine-binding sites are occupied which results in an inhibition of fibrin binding to plasminogen and endogenous fibrinolysis. Because plasmin generation after tissue injury can induce many other responses, including thrombin generation, complement activation, and activation of monocytes, neutrophils, and platelets, attenuation of these pathophysiologic responses with lysine analogs might provide additional benefits in restoring hemostatic balance, plasmin generation, and fibrinolysis.

Until 2007, aprotinin was the most frequently used antifibrinolytic agent. In 2007, the efficacy of aprotinin and other lysine analogs was summarized in a Cochrane systematic review and meta-analysis [172]. When compared to placebo, both aprotinin (77 studies), TXA (29 studies), and EACA (10 studies) significantly reduced the exposure to allogeneic blood products in adults undergoing cardiac surgery. Even though a trend in favor of aprotinin was observed, no statistical difference was reported when aprotinin was compared to TXA. No difference in terms of adverse events was reported when antifibrinolytic agents were compared to placebo or to each other, but none of the studies were actually designed to assess the safety of the drugs. Prospective studies that assessed the efficacy and safety of aprotinin in neonates and children undergoing cardiac surgery are rare. In a meta-analysis published by Schouten and colleagues in 2009, 18 studies were identified but only one study compared the efficacy of aprotinin and EACA [173]. Other authors have compared TXA and aprotinin in children but failed to demonstrate the superiority of one drug among the other.

In 2007, the results of the Blood Conservation Using Antifibrinolytics in a Randomized Trial (BART) study, a prospective study performed in high-risk patients undergoing cardiac surgery, were published [174]. This study reported an increased incidence of mortality associated with aprotinin (6% 30-day mortality for aprotinin) when compared to lysine analogs (3.9% for TXA and 4% for EACA). The publication of the study was followed by an FDA warning and in November 2007, Bayer Health- care (Leverkusen, Germany) announced the withdrawal of aprotinin from the market.

Several respective studies looked at the effect of aprotinin on the incidence of postoperative renal dysfunction or mortality in neonates and children. Among all those studies, two large retrospective analyses failed to demonstrate any evidence of increased mortality or renal failure in children undergoing cardiac surgery. While aprotinin appeared to be non-superior to EACA, TXA was shown to be superior to aprotinin in terms of transfusion with less morbidity. The safety of aprotinin was re-evaluated in several retrospective studies in adult cardiac surgery with conflicting results, but the overall impression is that the risk of adverse events is essentially observed when aprotinin was administered in a subset of the cardiac population and that the drug remains beneficial when used in patients undergoing procedures with high bleeding risk. In September 2011, Health Canada and in February 2012, the European Medicines Agency (EMA) lifted the suspension of aprotinin from the market. Aprotinin should only be given during primary coronary artery bypass grafting surgery and should be avoided in patients with preoperative renal dysfunction due to increased risks of postoperative renal failure and the requirement for renal replacement therapy. To date, no decision has been taken regarding the use of aprotinin in neonates and children undergoing complex cardiac surgery. However, in the absence of evidence regarding the safety of the drug in the pediatric cardiac population, lysine analogs should be preferred.

The efficacy of prophylactic administration of the lysine analogs in neonates and children undergoing cardiac surgery with CPB has been studied in several small prospective studies. In a systematic review and meta-analysis that compared TXA to placebo, prophylactic administration of TXA reduced the need for blood product transfusion [175]. All the prospective studies published to date have included a relatively small number of patients presenting with heterogeneous congenital heart diseases and undergoing procedures of variable complexities. Significant variability in dosages has been reported, with some centers using three boluses of 10 to 100 mg/kg, while others used a 10 to 100 mg/kg loading dose followed by a continuous infusion. Another important limitation of the current literature is the absence of safety assessment when sometimes large doses of antifibrinolytics are administered. To date, adverse reactions have only been reported in small retrospective studies while none of the prospective studies were designed or powered to look at the incidence of side effects. If no risk of thrombotic complication has been reported in the adult or pediatric literature, an increased risk of clinical seizures has been described following the administration of high-dose TXA. Lecker and colleagues showed that TXA inhibits neural glycine receptors, whereas inhibition of the inhibiting neurotransmitter glycine is an established cause of seizures [176]. Viewing the similarities in the chemical structures of TXA, gamma-aminobutyric acid (GABA), and glycine, it is conceivable that the interaction of TXA with both GABA and glycine receptors contributes to the increase in clinical seizures observed when TXA is given. Interestingly, the TXA peak concentration observed in the cerebral spinal fluid was reached approximately 5 hours after the plasma peak concentration (Figure 16.20), which might explain the delay reported between TXA administration and the development of clinical seizures after cardiac surgery. Similar concerns have also been described with equipotent concentrations of EACA, which might be explained by the fact that EACA is a competitive agonist of glycine receptors. Understanding pharmacology is crucial, and the use of a pharmacokinetic/pharmacodynamic-based dose regimen should be promoted.

(B) Average TXA concentration in the serum and CSF during key surgical events (n = 4). Data are mean ± SEM. (Source: Lecker et al. [176]. Reproduced with permission.)

The gap in our understanding of the pharmacokinetics of lysine analogs in neonates and children has been partially filled by the publication of a few pharmacokinetic studies [177]. In 2002, Ririe and colleagues studied the pharmacokinetics of EACA in 8 patients aged between 9 months and 4 years [178]. As a result, the authors suggested a dosing regimen of 75 mg/kg over 10 minutes, 75 mg/kg on CPB, and 75 mg/kg/hour infusion started at the end of the initial bolus. This regimen was derived and simulated to maintain serum concentration at two times the serum levels to produce 95% efficacy (260 μg/mL). In 2015, Eaton and collaborators studied the PK of EACA in 10 neonates undergoing cardiac surgery with CPB [179]. Simulations were performed to maintain plasmatic concentrations of 50 μg/mL, leading to the recommendation of a 40 mg/kg loading dose followed by a 30 mg/kg/hour infusion. The authors suggested the administration of 10 mg of EACA per liter of CPB prime. Those two dosing regimens demonstrated the large variability in targeted plasma concentrations (50 μg/mL vs. 260 μg/mL) and the need for further studies to determine the optimal plasma concentration to be targeted to safely inhibit fibrinolytic inhibition using EACA in neonates and children. One of the first pediatric cardiac TXA PK studies was published by Grassin-Delyle and colleagues in 2013 [180]. In their study, the authors randomized 21 patients to receive either a continuous infusion (10 mg/kg followed by a 1 mg/kg/hour with 10 mg/kg at CPB initiation) or discontinuous infusion (10 mg/kg, then 10 mg/kg into the CPB and 10 mg/kg/hour initiated at the end of CPB). From their pharmacokinetic modeling, the authors determined the most appropriate dosing scheme to obtain a given target concentration of 20 μg/mL in children weighing 5 to 40 kg. The recommended 6.4 mg/kg loading dose is identical for all children, whereas the infusion rate decreases with weight from 3.1 mg/hour/kg to 2.0 mg/hour/kg for children between 5 and 40 kg, respectively. In 2015, the second pharmacokinetics (PK) study was published by Wesley and colleagues [181]. In their study, the authors included 55 patients ranging from 2 days to 4 years old and categorized them into three groups: children less than 2 months old, infants 2 months to 1 year old, and children greater than 1-year-old and weighing up to 20 kg. The authors described three different dose regimens based on targeted plasmatic concentrations (e.g., 20, 60, or 150 μg/mL). In order to maintain a plasmatic concentration of 60 μg/mL, a loading dose of 50 mg/kg followed by a continuous infusion of 7 mg/kg/hour was suggested in neonates and infants <2 months of age, a loading dose of 26 mg/kg followed by a continuous infusion of 6 mg/kg/hour was suggested in infants aged from 2 to 12 months, and a loading dose of 13 mg/kg followed by a continuous infusion of 5.5 mg/kg/hour was suggested in children >12 months and ≤20 kg. An additional bolus of 60 mg/mL of prime volume was also suggested (Table 16.8).

Despite the major advances made in the understanding of lysine analogs PK in neonates and children undergoing cardiac surgery, the readers will appreciate the persisting variability among the different PK-based dose regimens. This variability is mainly explained by the lack of knowledge regarding the minimal concentration required to inhibit

Table 16.8 Summary of the dose regimens suggested in pharmacokinetics studies

Study	Population	Targeted concentration	Loading dose	Infusion	CPB
1. ε-aminocaproic acid					
Eaton [179]	2.7–3.7 kg	50 μg/mL	40 mg/kg	30 mg/kg/hour	10 mg/L
Ririe [178]	9 months–4 years	260 μg/mL	75 mg/kg	75 mg/kg/hour	75 mg/kg
2. Tranexamic acid					
Grassin-Delyle [180]	5–40 kg	20 μg/mL	6.4 mg/kg	2.0 to 3.1 mg/kg/hour	NA
Wesley [181]	0–2 months	20 μg/mL	15 mg/kg	2.5 mg/kg/hour	20 mg/L
	2–12 months	20 μg/mL	9 mg/kg	2 mg/kg/hour	20 mg/L
	>12 months (Max 20 kg)	20 μg/mL	4 mg/kg	2 mg/kg/hour	20 mg/L
	0–2 months	60 μg/mL	50 mg/kg	7 mg/kg/hour	60 mg/L
	2–12 months	60 μg/mL	26 mg/kg	6 mg/kg/hour	60 mg/L
	>12 months (Max 20 kg)	60 μg/mL	13 mg/kg	5.5 mg/kg/hour	60 mg/L

fibrinolytic activation in children undergoing cardiac surgery with CPB. On the basis of the initial investigations published in the 1970s, two basic target concentrations have been identified. A lower concentration of approximately 10–20 μg/mL, which is thought to inhibit approximately 80% of fibrinolysis, and a high concentration of approximately 100 μg/mL, which should completely inhibit fibrinolysis. For several reasons, and in particular the difficulty of accurately measuring fibrinolytic activation in-vivo, those plasmatic concentrations have never been clinically validated. To date, only *ex-vivo* t-PA-activated models of hyperfibrinolysis have been used to estimate the plasmatic concentration required to completely inhibit fibrinolytic activation in neonates and children [182, 183]. If the plasmatic concentrations obtained from those *ex-vivo* models appeared to be significantly lower than the one described in the 1970s (<20 μg/mL), further studies are needed to further validate the findings in neonates and children undergoing cardiac surgery.

Based on the existing literature, a TXA loading dose of 30 mg/kg followed by a continuous infusion of 10 mg/kg/hour can be used in children <1 year of age, while loading dose of 10 mg/kg followed by a continuous infusion of 10 mg/kg/hour can be used afterward. For EACA, a loading dose of 40 mg/kg followed by a 30 mg/kg/hour infusion is recommended [54].

Desmopressin

Desmopressin (DDAVP) is a vasopressin analog that increases circulating levels of coagulation factor VIII and von Willebrand factor (vWF) by stimulating the release of stored vWF from the Weibel Palade bodies in the endothelium. It has been hypothesized that DDAVP favors the hemostatic process not only by inducing the release of vWF from endothelial cells but also by enhancing the procoagulant activity of platelets [184]. When platelets encounter a damaged vessel wall, they immediately recognize and adhere to exposed collagen and other subendothelium proteins. The adherent platelets become activated and recruit other platelets to the site of vascular injury. Meanwhile, the initiation of the coagulation cascade generates thrombin, which further activates platelets. By the combined action of thrombin and collagen, platelets express on their surface a number of specific molecules that promote both thrombin formation and cell-cell interactions (COAT platelets). It has been suggested that desmopressin infusion enhances the formation of COAT platelets and thus improves the hemostatic activity of platelets [185].

Desmopressin is used mainly to improve hemostasis in patients with von Willebrand disease, hemophilia A and certain inherited disorders of platelet function. In a recent Cochrane review, 39 studies were identified in the adult cardiac population where DDAVP was administered after cardiopulmonary bypass. In adults undergoing cardiac surgery, the reduction in the volume of RBCs transfused and total blood loss was small and was unlikely to be clinically important [186]. The efficacy of desmopressin in reducing bleeding and transfusion in children undergoing cardiac surgery has only been assessed in 3 studies [187–189]. The administration of DDVAP was not associated with a significant reduction in blood loss or blood product transfusion. However, the studies published to date preferred a prophylactic administration of DDAVP without estimation of the bleeding risk, the platelet count, vWF levels, and platelet function. Further studies are needed to study the effect of DDAVP administration post-CPB in children with normal platelet count ($\geq 150 \times 10^9$/L) but with decreased platelet function and/or in patients with acquired vWF deficiency.

KEY POINTS: PHARMACOLOGIC THERAPIES

- Prophylactic administration of antifibrinolytic drugs helps decrease bleeding and transfusion in pediatric cardiac surgery.
- High doses should be avoided to decrease the risk of side effects, especially clinical seizures with TXA.
- Further studies are needed to study the effect of DDAVP administration post-CPB in children with normal platelet count ($\geq 150 \times 10^9$/L) but with decreased platelet function and/or in patients with acquired vWF deficiency.

Sickle cell disease

Sickle cell disease (SCD) is a genetic disorder of hemoglobin and is characterized by hemolysis and recurrent vaso-occlusive episodes that cause severe pain "crises" and lead to progressive

AL Grawany

organ dysfunction. Patients with SCD only produce Hemoglobin S (HbS), which contains abnormal beta chains. Unlike normal adult Hemoglobin A (HbA), HbS is unstable in hypoxic conditions and polymerizes into the long helical strands that give affected RBCs the "sickled" appearance. These sickled RBCs have a shorter life span (10–12 days) than normal RBCs (120 days), which leads to chronic hemolytic anemia. During periods of dehydration, physical exertion, infection, or the stress of surgery can precipitate a sickle cell crisis. These "sickled" RBCs occlude blood flow to organs and lead to vaso-occlusive events (pain crises) and end-organ damage. Long-term complications from SCD include chronic anemia, pulmonary hypertension, or ischemic strokes.

Cardiac surgery presents numerous challenges that require special consideration for SCD patients due to hypothermia, CPB circuit primes, and prolonged NPO times. However, cardiac surgery with CPB has been undertaken successfully in SCD patients. Patients scheduled for cardiac surgery should have an outpatient visit with a hematologist 2–4 weeks prior to the procedure for evaluation and transfusion planning.

Preoperative laboratory studies should include at least a CBC and type and screen. In addition to a type and screen, consider obtaining an RBC genotype testing for extended antigen matching, as it can be challenging to find appropriate blood products for patients receiving chronic transfusions. Prior to surgery, it is important to communicate to ensure that appropriate blood is available for the procedure. Some institutions will send hemoglobin electrophoresis and reticulocyte count. Patients with an HbS ≥30% or a total hemoglobin <10 g/dL, these patients may require preoperative admission for hydration and an exchange transfusion.

The goal of intraoperative management is to avoid conditions that would result in sickling of the RBCs, such as hypoxia, hypothermia, or emotional stress. The goal is to minimize the percentage of HbS to ≤30% to reduce the risk of sickling. Therefore, patients with elevated HbS may require an exchange transfusion at the initiation with cardiopulmonary bypass. Prior to the exchange transfusions, it is important to maintain adequate oxygenation and maintain normothermia. Other considerations to minimize RBC trauma include maintaining bypass flow, minimizing pump sucker trauma, and vasodilating the patients with isoflurane or phentolamine as tolerated. Although systemic hypothermia and cold cardioplegia have been used, normothermia is preferred when possible. Finally, adequate post-operative pain management is critical but can be challenging in SCD patients. A multi-modal approach that includes opioids, acetaminophen, and Non-steroidal anti-inflammatory drugs (NSAIDs) should be employed. Consider regional anesthesia if possible.

KEY POINTS: SICKLE CELL PATIENTS FOR CARDIAC SURGERY

- SCD is a genetic disorder of hemoglobin (homozygous HbS) that is characterized by vaso-occlusive episodes that result in pain crises and end-organ damage.
- Dehydration, hypoxia, infection, physical exertion, hypothermia, or the stress of surgery can all precipitate a sickle cell crisis.
- For patients coming for cardiac surgery, the goal of management is to avoid or minimize factors that may precipitate a sickle cell crisis. Patients may require an exchange transfusion to decrease the percentage of HbS ≤30%.
- These patients often present with preoperative anemia; it may be difficult to find cross-matched blood due to chronic transfusions and alloimmunization.

Summary

Perioperative management of coagulopathy and hemostasis in neonates and children undergoing cardiac surgery is complex. Preoperative optimization of RBC mass should be promoted, as well as the implementation of blood conservation techniques. Maintenance of adequate anticoagulation during CPB, rapid assessment of coagulopathy, and the implementation of transfusion institutional algorithms based on monitoring of coagulopathy and the use of targeted therapy are keys. Despite the progress made in the last decades, further clinical studies are urgently needed to assess the safety and efficacy of the most recent diagnostic and therapeutic options.

Introduction

Use of point-of-care ultrasound (POCUS) in acute care practice has expanded to include a variety of applications from ultrasound-assisted physical examination to assessment of hemodynamic states as well as guidance for procedures. Within anesthesia practice, POCUS may be used to guide management at all stages of perioperative care [1]. While the list of applications for POCUS within anesthesia practice is growing, this chapter focuses on the cardiac and lung POCUS with an emphasis on patients with congenital heart disease (CHD). See Chapter 13 for a discussion of ultrasound-guided vascular access and Chapter 24 for a presentation of ultrasound-guided regional anesthesia.

What is POCUS?

POCUS is the systematic application of ultrasound performed at the bedside to evaluate specific structures, generally using a limited number of ultrasound views [2]. Clarity of language is paramount when describing the various ultrasound modalities examining the heart. Ultrasound evaluation of the heart has become a continuum of imaging devices and strategies ranging from limited evaluations with miniaturized handheld devices to comprehensive imaging of the heart with large cart-sized devices on wheels with the highest resolution medical ultrasound technologies [3]. Some consider the very limited evaluations of the ultrasound of the heart to be more like an extension of the physical examination rather than a stand-alone imaging test [4]. In many ways, these distinctions are still being created in modern cardiac imaging, but standard echocardiography remains the most comprehensive ultrasound-based evaluation of cardiac anatomy and function [5]. Cardiac POCUS and focused cardiac ultrasound seem to be the best terms, which are currently being used interchangeably to describe more targeted cardiac ultrasound evaluations. For consistency, the authors are using the term cardiac POCUS.

During this imaging strategy, a bedside clinician (most often a noncardiologist) uses ultrasound to examine the heart in a limited fashion with a goal to identify a limited number of specific ultrasonographic signs that are which could be associated with the clinical situation of interest or a specific pathology [6]. While cardiac POCUS is almost always performed with a smaller, more portable ultrasound machine

with limited functionality, it should be defined by the imaging technique rather than the machine used [7, 8]. Since cardiac POCUS has narrowed diagnostic targets with focused questions, it is important to clearly distinguish it from comprehensive standard echocardiography during medical documentation or communication between providers. Confusion can be created if ambiguous terms, such as "bedside echo or limited echo," are used to describe clinician-performed cardiac POCUS. The term echocardiography (or similar forms) should be reserved for more comprehensive evaluations, usually performed by a cardiac sonographer and often include quantitative measurements. Whereas cardiac POCUS should be limited to a few predefined views where the clinician can make qualitative assessments. With non-precise language, the assumptions of broader diagnostic targets or evaluations can occur creating misunderstanding or false reassurances. See Chapters 15 and 18 for further discussion of comprehensive echocardiography.

Pediatric cardiac POCUS

The evidence supporting the accuracy of cardiac POCUS by noncardiologists in pediatrics comes predominantly from small single center studies with mostly structurally normal hearts [9–13]. The identification of severely depressed systolic function and larger effusions are the most reliable findings [14]. Given how cardiomyopathy and severely depressed ventricular systolic function can present in pediatrics with insidious onset and/or with misleading chief complaints, cardiac POCUS seems to have a valuable role to play in the early identification of severely depressed left ventricular systolic function [15]. However, borderline systolic dysfunction is the area of significant weakness [9, 16]. Some argue that borderline systolic dysfunction may be out of the scope of pediatric cardiac POCUS [13]. Users of pediatric cardiac POCUS should be keenly aware of this weakness of the modality. This is particularly important in pediatrics since borderline depressed function in a previously healthy child is often a harbinger of rapidly progressive cardiogenic shock, especially in infectious myocarditis or inflammatory disorders [17, 18]. There is scant evidence supporting cardiac POCUS in more complex CHD, and its use in this population should be limited to those with extensive training and experience in CHD training and/or pediatric echocardiography. Additionally, the use of cardiac POCUS as *a screening tool* for CHD is likely counterproductive and it is likely contraindicated for this purpose [14].

The diagnostic targets for pediatric cardiac POCUS are typically limited to the assessments of ventricular size, qualitative ventricular systolic function, right ventricular systolic pressure, and the pericardial space [14]. Evaluation of diagnostic targets is performed in a qualitative or semiquantitative manner, typically using an "eyeball" method [2, 8, 14]. These assessments are usually binary, i.e., is there pathology present or is there not? Declaration of uncertainty is often the correct approach in POCUS if the diagnostic targets are not well visualized, particularly given the inherent nature of POCUS. Cardiac POCUS image acquisition and interpretation are performed rapidly (less than 5 minutes) and usually in suboptimal imaging conditions. Quality improvement work in pediatric transthoracic echocardiography has shown that the conditions in which POCUS is performed – incomplete examinations outside the echocardiography laboratory, in poor ambient light conditions via lower end machines with increased acoustic artifacts – are the exact setup for diagnostic errors [19]. Therefore, a low threshold for referral for standard echocardiography seems reasonable when using cardiac POCUS to clarify equivocal imaging or to evaluate persistent symptoms after an unrevealing cardiac POCUS. Inability to diagnose disease using substandard imaging equipment in suboptimal imaging conditions does not prove the absence of disease.

Basic physics of POCUS

The ultrasound technology for POCUS is based on the same principles of physics as routine ultrasonography. The top of the ultrasound probe contains crystals (piezoelectric crystals) in various configurations based on the type of probe and its intended clinical use. The ultrasound machine transmits an electrical impulse, which results in vibration of these crystals. It is this vibration that emits a sound wave that travels into the adjacent tissue. Sound is absorbed, scattered, and reflected by the tissues. Sound reflected by the tissues returns to the probe where it results in vibration of the crystals. This mechanical vibratory energy is converted to electrical energy, which is processed to create an image.

Ultrasonic waves are refracted and reflected differently by tissues based on their various densities. The speed at which these sound waves are traveling when returning to the probe is converted to an image that is color coded in grayscale. The depth of the structure is determined by the time it takes from the wave transmission until the reflected sound wave returns. Image color may be darkened or lightened using the gain function of the machine. In contrast, air does not conduct sound waves (including ultrasonic waves) well. This limits the abilities of cardiac POCUS during situations involving pneumomediastinum or pneumothorax. Additionally, lung ultrasound relies more on observing artifacts and scatter from lung structures that generate certain ultrasonographic signs indicative of normal and pathologic conditions.

Most modern machines are equipped with complex software that is designed to reduce artifacts which is of benefit when scanning solid structures (e.g., the heart and liver). However, when scanning lung tissue, this feature should be turned off as artifact is vital to image interpretation. Many machines have pre-settings in which image quality is optimized for the structure of interest.

Ultrasound machines have probes of different configurations, sizes, and with a wide range of frequencies. The frequency of the ultrasonic wave emitted is inversely proportional to the amplitude of the wave and hence the resolution. Therefore, a higher frequency probe, with a lower amplitude, is able to delineate structures more finely. On the other hand, waves with higher amplitude attenuate more slowly as they travel through tissue. Therefore, a higher frequency, lower amplitude probe is able to penetrate to a lower depth in the body, while a lower frequency probe is able to penetrate to a greater depth, e.g., in obese habitus or deeper

structures. Depending on the brand of ultrasound equipment, a range of frequencies may be available with capabilities between 3 and 8 Hz. Cardiac POCUS is typically performed using a phased array probe while lung POCUS relies on a linear array probe (Figures 17.1 and 17.2). Providers should consider the size (space between ribs) of the patients and object of interest (e.g., lung or heart) when selecting a probe.

Performing cardiac POCUS

Basic cardiac POCUS relies on four main views. These are generally performed while the patient is supine with the exception of the apical four-chamber view that benefits from left lateral decubitus positioning. Each ultrasound machine has a specific method for indicating the probe side also known as the orientation marker, which is located on the side of the probe.

Parasternal long-axis view

The parasternal long-axis (PLAX) view is obtained with the probe in the second left intercostal space with the orientation marker facing toward the patient's right shoulder (10 o'clock position). The top of the screen depicts the anterior aspect, and the right and left of the screen are directed toward the feet and head of the patient, respectively. Visualized in this view are left atrium, left and right ventricles, aortic and mitral valves, and left ventricular and a portion of the right ventricular outflow tracts (Figure 17.3).

Figure 17.1 Varying sizes of phased-array probes for use in cardiac point-of-care ultrasound. Arrows indicating the orientation marker.

Parasternal short-axis view

The parasternal short-axis (PSAX) view is obtained by rotating the probe 90° clockwise from the PLAX view, so the orientation marker points toward the patient's left shoulder (2 o'clock). This view may be optimized by moving the probe up or down one rib space. Visualized in this view are the right and left ventricles, the cardiac apex, and the mitral valve (Figure 17.4).

Apical four-chamber view

The apical four-chamber view is obtained by placing the probe in the fourth or fifth intercostal space along the anterior axillary line with the orientation marker facing toward the left (3 o'clock position). Visualized in this view are the right and left atria and ventricles and the atrioventricular valves (Figure 17.5).

Subcostal four-chamber and inferior vena cava views

The subcostal four-chamber view is obtained with the probe in the subxiphoid space, with the probe facing the patient's left axilla and orientation marker on the oriented at 2–3 o'clock position (Figure 17.6). To obtain the inferior vena cava (IVC) view, the probe is rotated counterclockwise, so that it is vertical with the orientation marker facing straight up. Visualized in the subcostal four-chamber view are the right and left atria and ventricles and the atrioventricular valves. Visualized on the IVC view is the liver, intrahepatic IVC with entrance into the right atrium as well as the hepatic veins (Figure 17.7).

Individual structure assessment using cardiac POCUS

In the following section, the common structures evaluated during cardiac POCUS are discussed. A key requirement of POCUS, and specifically cardiac and lung assessments, is for the provider to recognize normal from abnormal. This requires deliberate training and review of images, so that the sonographer is able to distinguish and identify ultrasonographic signs of pathology from normal sonoanatomy.

Assessment of the left ventricle

Systolic dysfunction—Perhaps, the most common use of POCUS in children, including those with CHD, involves the assessment of systolic function. This may be prompted by new onset hypotension in the perioperative period, presentation in shock and concern for cardiogenic etiology, or new onset ventricular arrhythmias. This assessment permits further clinical decision-making including choice of vasoactive agent, next steps of resuscitation, possible need for activation of mechanical support team, or need for further advanced investigations. All typical cardiac POCUS views can be employed to assess left ventricular systolic function, but PSAX and PLAX views are more commonly employed views to utilize eyeball or quantitative methods. It is important to note that children who have undergone ventricular septal defect repair with patch will have dyskinesis of the part of the interventricular septum that is composed of patch material. The nuances of this cannot be worked out on cardiac POCUS and would need a formal echocardiogram. Also, operators must recognize that cardiac POCUS will give information only about systolic dysfunction and is not intended for diastolic dysfunction.

Qualitative or eyeball method assessment via ultrasound is best supported for the evaluation of left ventricular size and systolic function. While the method is inherently subjective, it compares quite well with more objective parametric measures of left ventricular systolic function when employed

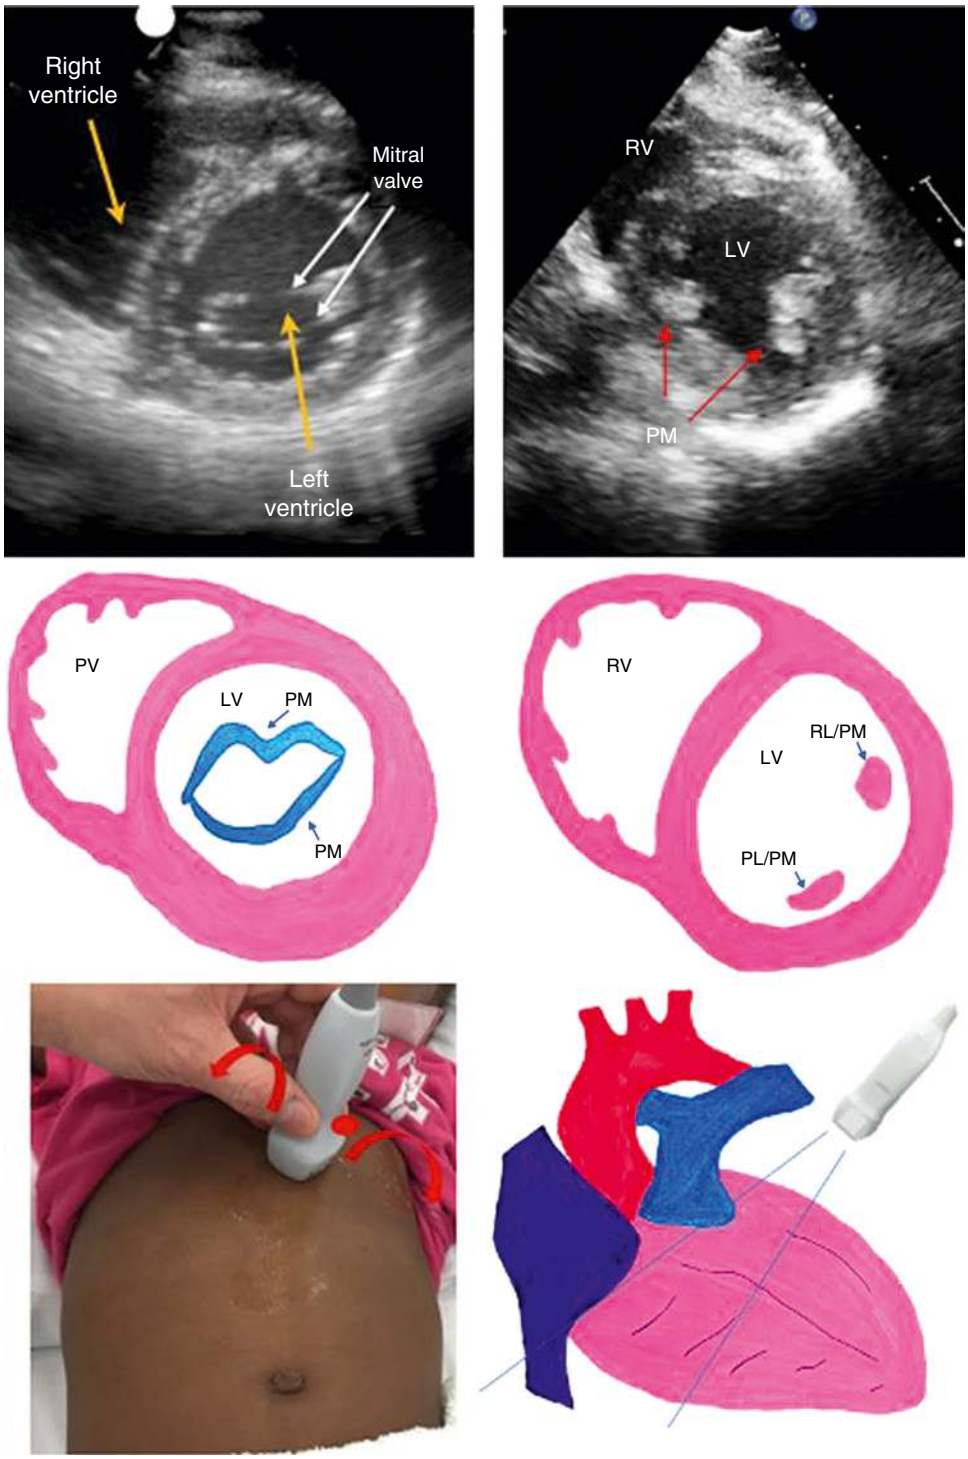

Figure 17.4 Demonstration of the parasternal short-axis view including ultrasonographic appearance at the level of the mitral valve (upper left) with accompanying diagram (middle left) and at the level of the papillary muscles (upper right) with accompanying diagram (middle right) as well as probe placement (bottom left) with orientation marker (red dot) and suggested fanning planes (red arrows) and corresponding scanning lines (bottom right). RV = right ventricle, LV = left ventricle, PM = papillary muscle, ALPM and PMPM = anterolateral and posterior medial papillary muscles respectively. Illustration by A. Adler, MD.

by experienced users [20]. For the novice user, the qualitative assessment of ventricular systolic function can be broken down into the evaluation of how well the ventricular walls are thickening and how well the ventricular walls are symmetrically moving towards the center of the cavity [21]. Precise estimation or quantification of ventricular ejection fraction is out of scope for cardiac POCUS, but novel users should know when evaluating the ventricular wall "squeeze" toward the center that the left ventricle normally ejects about 55–70% of its contents with each contraction. The decrease in

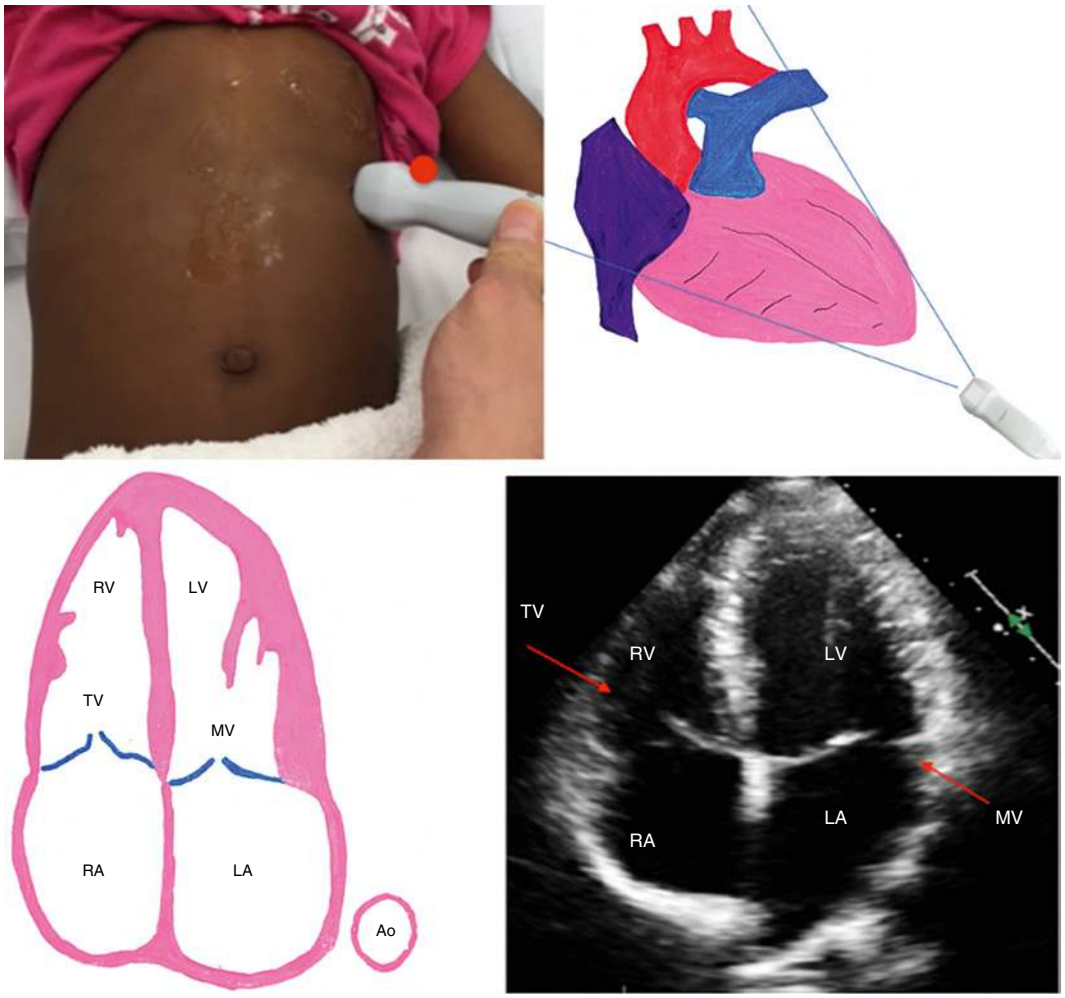

Figure 17.5 Demonstration of the apical four-chamber view including probe placement (upper left) with red dot denoting orientation marker, scanning plane (upper right) and accompanying diagram (bottom left), and ultrasonographic appearance (bottom right). RA = right atrium, RV = right ventricle, LA = left atrium, LV = left ventricle, MV = mitral valve, TV = tricuspid valve, Ao = aorta. Illustration by A. Adler, MD.

chamber size is largely created by the thickening of ventricular walls during contraction. Making sure that the ventricular walls are actually contracting is important, because there can be misleading scenarios with poor imaging windows where the heart is moving or "rocking" on the screen, but there is ineffectual ventricular wall contraction and the chamber size decrease is difficult to evaluate.

While tracking the ventricular wall motion, it can be helpful to note that the left ventricle normally employs a relatively even combination of longitudinal, circumferential, and radial wall motions, resulting in a fundamental twisting and untwisting type of ventricular wall movements [22]. Accurate tracking of the types of wall motion is out of the scope of cardiac POCUS and is used in higher order echocardiography image packages, namely, speckle tracking or strain imaging. However, the user should be generally aware of the how left ventricular walls move in this coordinated fashion during normal contractions.

POCUS assessments of left ventricular systolic function should be limited to whether systolic function is normal, abnormal, or unclear. There may be value in identifying somewhat depressed left ventricular systolic function in pediatrics, but it is not clear at this point if this is a reliable POCUS practice. Repeated exposure to variable degrees of left ventricular systolic function via image libraries can help novice users improve their proficiency diagnosing ventricular dysfunction [22]. Quantification (e.g., shortening fraction, ejection fraction, E-point separation) during POCUS is generally avoided since incorrect measurements are common in rapid image acquisition and can potentially solidify false impressions of cardiac size or performance [8].

Assessment of the right ventricle

The right ventricle's anterior position below the chest wall and its complex geometric shape with thin walls are the main challenges to interrogate it via transthoracic ultrasound [22]. Therefore, the assessment of the right ventricle in cardiac POCUS is typically more limited than other structures and, at times, is not possible.

Right ventricular enlargement often accompanies right ventricular strain or pressure or volume loading, therefore can be helpful if present to identify right heart pathology [22]. But, the absence of right ventricular dilation by cardiac

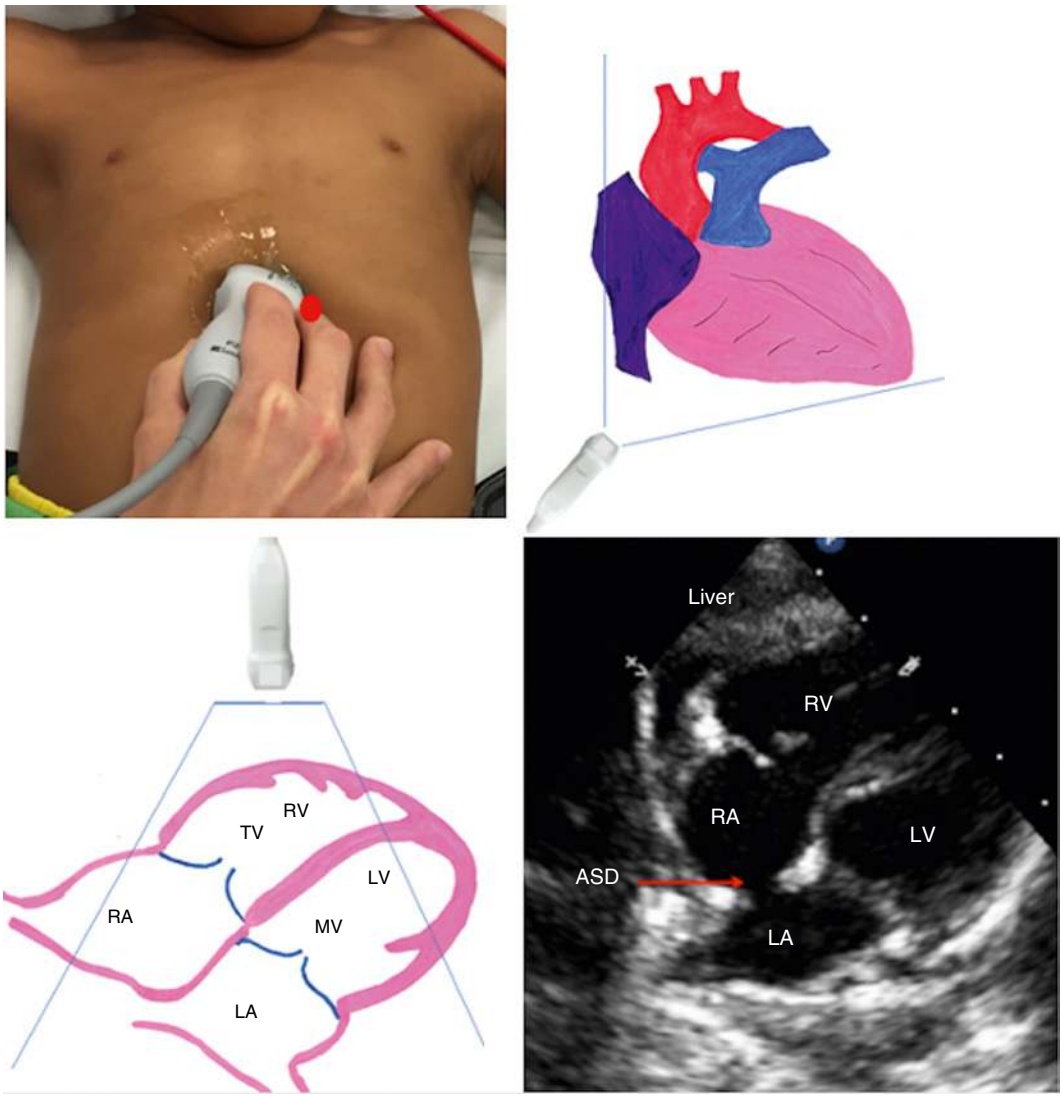

Figure 17.6 Demonstration of the subcostal four-chamber view including probe placement (upper left) with red dot denoting orientation marker, scanning plane (upper right) and accompanying diagram (bottom left), and ultrasonographic appearance (bottom right). RA = right atrium, RV = right ventricle, LA = left atrium, LV = left ventricle, MV = mitral valve, TV = tricuspid valve. Illustration by A. Adler, MD.

POCUS does not suggest the absence of right heart pathology, likely since large portions of the right ventricle may not be adequately visualized and pathologic dilation can be missed [23]. Qualitative assessment of right ventricular size is based mostly on the comparison of size to adjacent structures (assuming the absence of pathology of the adjacent structures, such as left ventricular dilation). In the PLAX views, a portion of the right ventricle body can be seen just below the transducer. As a general rule of thumb, the diameters of the right ventricular body, aortic root, and left atrium in the PLAX view should roughly be the same. In PSAX and apical four chamber views, the right ventricle should appear about ⅓ to ½ the size of the left ventricle [23].

Even with experienced echocardiographers, eyeball assessment of right ventricular systolic function by ultrasound has been shown to be less reliable as compared to the left ventricular systolic function evaluation [23]. Some limited evaluations of the right ventricular systolic function are possible employing a similar approach to evaluating the left ventricle, again, based on how well the ventricular walls are thickening and how the ventricular walls are moving toward the center of the cavity. When evaluating ventricular wall motion, it is important to note that the right ventricle systolic contractions have more longitudinal wall motion (annulus to apex) than the left ventricle [23]. This longitudinal wall motion of right ventricular contraction is typically best seen from apical four-chamber views when the tricuspid valve moves toward the apex and transducer. Additionally, parasternal and subcostal views offer limited assessment of right ventricular wall contractions. Subcostal views of the right ventricle can be valuable, if available, in critically ill patients who do not have adequate apical or parasternal views because they cannot be repositioned on their side.

Interventricular septal configuration can be evaluated by POCUS and used as a correlate of right ventricular health and pressures [14]. Interventricular septal configuration reflects the relative pressure between the two ventricles throughout

the cardiac cycle and thus provides qualitative insight to right ventricular pressure estimates. In general, when the right ventricle pressures are less than ½ of the left ventricular pressure, the interventricular septal configuration should have a rounded appearance with the convex aspect directed into the lower pressure right ventricle [23]. Flattening of the interventricular septal configuration is suggestive that the right ventricular pressures are greater than ½ of the left ventricular pressures at that moment of the cardiac cycle. Diastolic flattening of the interventricular septal configuration typically represents a right ventricular volume load or an elevated right ventricular end-diastolic pressure [23]. Systolic flattening of the interventricular septal configuration represents a right ventricular pressure load or an elevated right ventricular systolic pressure. The differential diagnoses for flattening of the interventricular septal configuration can be narrowed by timing of flattening, but it remains broad, e.g., pulmonary hypertension, CHD, and pulmonary embolism. Most POCUS exams will not utilize simultaneous ECG readings; therefore, pinpointing the timing of the septal flattening within the cardiac cycle can be difficult, particularly during live scanning in critical scenarios. Additionally, false appearance of interventricular septal flattening can be easily created during off-angle PSAX views. For these reasons, we recommend that any flattening of the interventricular septal configuration should therefore prompt referral for standard echocardiography and more in-depth cardiac evaluation.

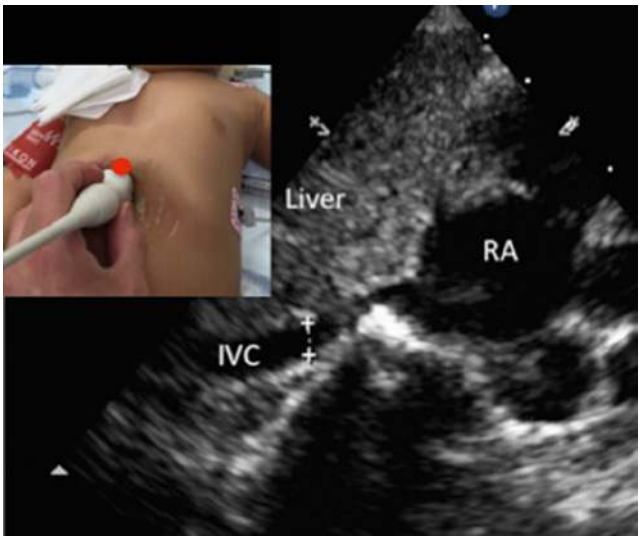

Figure 17.7 Demonstration of the inferior vena cava (IVC) view including ultrasonographic appearance and probe placement (insert) in which the IVC can be visualized entering the right atrium (RA).

Assessment of pericardial space and early tamponade physiology

The early diagnosis of pericardial effusions in children is a valuable aspect of pediatric cardiac POCUS [14]. Physical examination is insensitive to the condition and chest radiograph is unable to make the final diagnosis. A pericardial effusion resulting in tamponade physiology impervious to medical therapy should prompt referral to a skilled interventionalist [23].

The pericardium is typically visible in ultrasound evaluations of the heart, recognizable by the bright echogenic line surrounding and closely abutting the myocardium in physiologic conditions. With buildup of excessive pericardial fluid, an echo-lucent or black area can be seen via ultrasound beginning to build between the myocardium and pericardium. It is important to evaluate whether that the effusion is within the pericardial space since adjacent pleural effusions can be present or coexist (Figure 17.8). Subcostal views can help differentiate these potential spaces and identify concomitant issues such as other effusions (Figures 17.8 and 17.9). On PLAX views, evaluating the relationship of the echo-lucent fluid collection between the pericardium and the

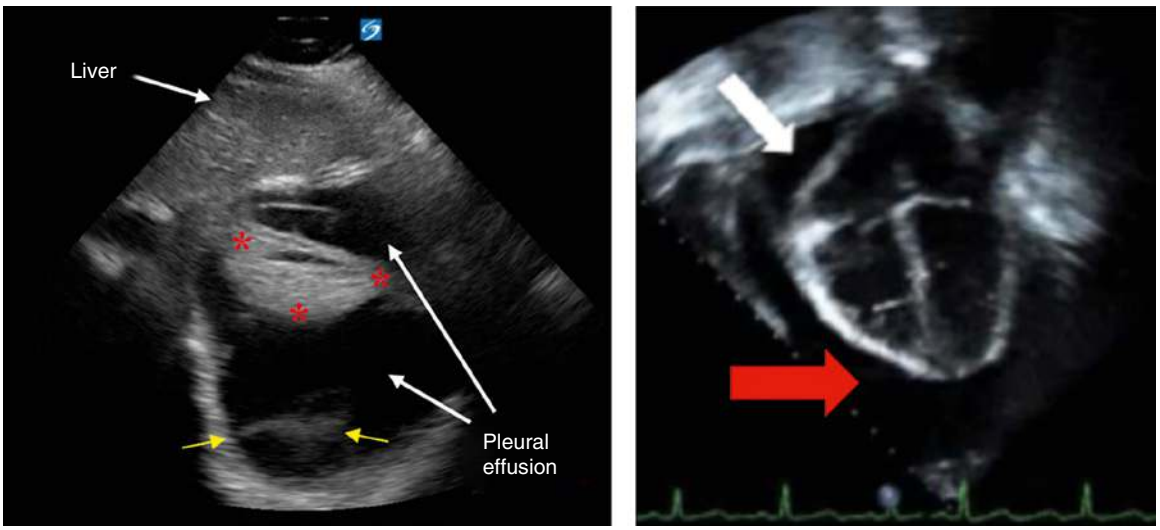

Figure 17.8 POCUS imaging demonstrating (A) large pleural effusion with lung consolidation (red stars) and fibrinous exudate (yellow arrows) and (B) apical four-chamber view with large circumferential pericardial effusion (red arrow) and right atrial collapse (white arrow). (Source: Adler et al. [32]. Reproduced with permission from Springer Nature.)

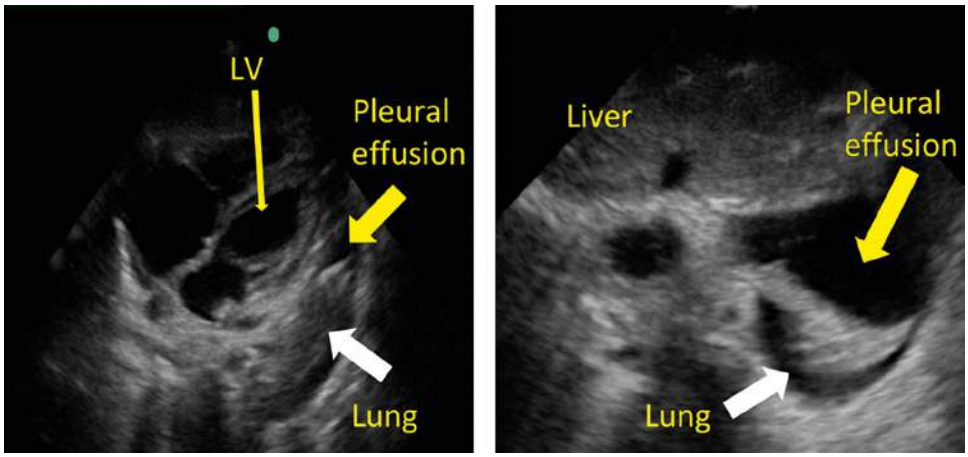

Figure 17.9 (A & B): Subcostal four-chamber view with large pleural effusion and lung consolidation, LV = left ventricle. (Source: Adler et al. [40]. Reproduced with permission from John Wiley & Sons.)

descending aorta can provide good information of the location. The descending thoracic aorta is a structure outside the pericardium; therefore, some pleural effusions can be in continuity with the descending aorta seen in its short axis behind the cardiac mass. On the other hand, no pericardial effusions will be in continuity with descending aorta [23].

The pericardium is composed of elastic fibers and collagen into visceral and parietal layers. The pericardial sac is able to slowly expand with chronic effusions, but it is inextensible beat-to-beat and during rapid accumulation of pericardial fluid. Therefore, a rapid accumulating, even relatively small, pericardial effusion is more likely to result in an inward force and eventual tamponade physiology as compared to a slowly evolving pericardial effusion seen in some medical diseases [23]. Pericardial pressure is negligible in physiologic conditions. But, as a pericardial effusion enlarges, pericardial pressure will eventually begin to elevate. As pericardial pressure rises, it can begin to overcome intracardiac pressures during certain nadirs in the chambers' cardiac cycles, resulting in partial collapse or indentation, which can be seen via cardiac POCUS. The right heart chambers that tend to have lower pressure in general, therefore, are the first chamber to demonstrate collapse with worsening pericardial effusion. The right atrium will most likely start to show collapse during ventricular systole, as this is the typical nadir of the right atrial pressure during the cardiac cycle. The right ventricle will most likely start to show collapse during ventricular diastole, as this is its nadir [23]. These early phases imply impaired cardiac filling and onset of tamponade physiology. Therefore, one of the earliest physiologic responses to a significant pericardial effusion is tachycardia due to the inadequate preload. There is the caveat of coexisting pathologic arrhythmias, such as sinus node dysfunction. True tamponade is when the pericardial pressures overcome all cardiac pressures and blood is unable to circulate through the cardiopulmonary system despite normal ventricular systolic and diastolic function. Medical therapies and chest compressions are essentially useless in this scenario, with needle compression being the definitive therapy [23]. Therefore, again, timely diagnosis prior to frank tamponade is of paramount importance and concerns for large or hemodynamically significant effusions diagnosed by cardiac POCUS should prompt urgent formal echocardiographic and/or interventionalist evaluation.

It is important to remember that not all pericardial effusions are circumferential. They can be loculated or localized in certain areas of the pericardial space, potentially impacting adjacent heart chambers. Localized, particularly rapidly accumulating pericardial effusions can be just as hemodynamically active as a larger circumferential effusion. This is can be seen in postoperative or postprocedural situations or if there are adhesions within the pericardial space. Careful assessment of the whole pericardial space via long sweeps of the heart is important in cardiac POCUS, particularly if there is clinical concern for hemodynamically significant pericardial effusion. The best long sweeps to assess for effusions in cardiac POCUS are usually obtained in subcostal views, sweeping either posterior to anterior (coronal views) or left to right (short axis).

Assessment of the atria and valves

A qualitative view of the atria should be appreciated when performing cardiac POCUS. Most notably, providers should observe that the atria do not appear large or compressed. Similar to ventricular assessment, the provider should attempt to distinguish atria as normal or abnormal. Additionally, the presence of a large thrombus can be identifiable, even to the novice sonographer. However, small thrombi that may be clinically significant can be missed.

With regard to valvular assessment, the atrioventricular and semilunar valves may be observed for obvious structural deformity, stenosis, or regurgitation. While not typically part of basic cardiac POCUS, limited assessment using color Doppler can aid an overall assessment of stenosis or regurgitation. Assessments should be limited, qualitative in nature, and should attempt to discern if a clinically significant pathology is present. Ruling out pathologic atrioventricular valve dysfunction is likely out of the scope of POCUS.

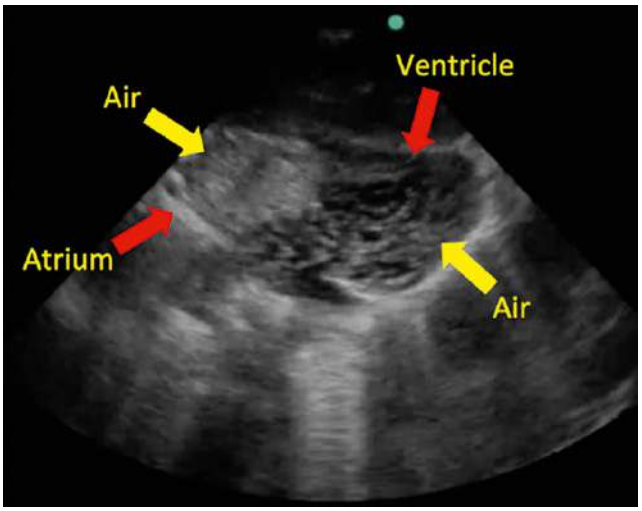

Figure 17.10 Subcostal four-chamber view showing a large volume of air microemboli after inadvertent injection of air during cardiac catheterization in a 4-month-old with hypoplastic left heart syndrome, resulting in arterial desaturation, hypotension, bradycardia, and ST-segment elevation. The patient recovered after 2 boluses of epinephrine of 1 mcg/kg and fluid bolus of 20 mL/kg. (Source: Adler [34]. Reproduced with permission from Elsevier.)

Assistance during cardiac arrest

POCUS is valuable during cardiac arrest in identifying reversible causes of cardiopulmonary collapse as well as assessing the likelihood for achieving return of spontaneous circulation (absence of intrinsic cardiac function). The subcostal four-chamber view can be performed during cardiopulmonary resuscitation at times where chest compressions are paused for pulse checks. In this view, the provider can identify intrinsic cardiac function and presence of large pericardial effusions. The chest may also be scanned to evaluate for pneumothoraces which may be under tension and the case of the cardiopulmonary arrest. In addition, intracardiac air can be easily visualized as a cause of hemodynamic instability or cardiac arrest (Figure 17.10) [24].

Assistance during central line placement

The use of modified cardiac POCUS has been described for assistance with central line placement and positioning in children. Park YH et al. described the use of POCUS to guide central line depth in infants undergoing congenital heart surgery [25]. Specifically, they describe the use of longitudinal images of the right atrium and superior vena cava in addition to obtain a pulmonary bifurcation view allowing for imaging of the right atrium [25]. Alternatively, the right ventricular inflow view can also serve to aid in the visualization of proper central line positioning. While these views do not fall within basic POCUS, this highlights the ability for deliberate expansion of this modality to aid in the care of patients.

Specific clinical situations and corresponding limitations

As described above, cardiac POCUS can yield key information in several clinical scenarios for children. While systolic dysfunction and pericardial effusion are the most common indications for performing cardiac POCUS, specific indications emerging in the pediatric heart disease and pediatric cardiac critical care settings include right ventricular failure and position evaluation for mechanical circulatory support devices. The latter are indications that would be applicable only to centers taking care of patients with advanced pulmonary hypertension or advanced heart failure and cardiogenic shock. Additionally, utilization of the cardiac POCUS is an evolving use and may be particularly helpful in elucidating shock states [26]. Figure 17.11 summarizes the approach to cardiac and lung POCUS evaluation of unexplained hemodynamic instability in the intraoperative or postoperative settings [1].

POCUS during assessment of shock

There are varying etiologies of shock (e.g., cardiogenic, hypovolemic, septic). POCUS, in addition to traditional methods for elucidating the type of shock, such as physical examination and hemodynamic parameters (e.g., cardiac output, heart rate, central venous pressure), can be tremendously helpful particularly for guiding fluid therapy and vasoactive medications. The surviving sepsis campaign international guidelines suggest the use of POCUS of advanced echocardiography in tailoring therapy for children with sepsis [27].

Hypotension or shock due to right ventricular failure

A patient with a clinical picture concerning for new pulmonary embolism – syncope, hypotension, ECG changes, and/or desaturation – may be a scenario for a cardiac POCUS while awaiting laboratory results. The presence of severely depressed right ventricular function may suggest right ventricular failure due to an embolic event. The right ventricular systolic function can be assessed in the PLAX, PSAX, and apical four-chamber views. Final diagnostic studies with echocardiogram and chest computed tomography (CT) scan are still needed; however, a cardiac POCUS performed by a credentialed team that shows these findings may be a criterion for activating surgical and/or mechanical support teams.

A patient with underlying pulmonary hypertension (idiopathic, genetic, or secondary to CHD) may present with signs and symptoms concerning for episodes of right ventricular failure, e.g., worsening hypotension, ST segment changes, and/or desaturations. An assessment of the position of the interventricular septum on cardiac POCUS can yield important clues to the best next step for management. Diagnosis of worsening pulmonary hypertension by POCUS can lead to the early initiation of additional or new pulmonary vasodilators. Additionally, a septum bowing into the left ventricle with preserved left ventricular function suggests that vasoconstrictor agents (vasopressin or norepinephrine) may be beneficial to increase the left ventricular afterload to optimize ventriculo-ventricular interactions by shifting the interventricular septum over toward the right ventricle and into a more neutral position. This can permit better left ventricular preload and function to improve cardiac output. This assessment is best performed in the PSAX view to assess the interventricular septum as well as the relative left and right ventricular sizes.

Position of cannulae or device for patients on mechanical support

An evolving use of cardiac POCUS is the assessment of position of mechanical circulatory support devices; particularly, the positioning of venous cannula in venous-arterial extracorporeal membrane oxygenation (ECMO) cannulation or the dual-lumen cannula (e.g., Avalon cannula) is utilized for venovenous ECMO cannulation [28]. At the time of initial cannulation, the positioning of the venous cannula, particularly for venovenous ECMO, is typically performed under formal echocardiogram guidance [29]. However, if there is an urgent change in oxygen saturations or concern for worsening recirculation, cardiac POCUS in the subcostal views can be utilized by credentialed operators to assess the position of the outflow and inflow ports. When a dual-lumen cannula is utilized for venovenous cannulation, the tip of the cannula is positioned in the IVC with the outflow port in the superior one-third of the right atrium with flow directed toward the tricuspid valve.

The Impella® device is increasingly used for mechanical support in pediatric patients in cardiogenic shock. The positioning of the Impella® requires device-specific distance between the aortic valve and the tip of the device as well as between the mitral valve and the device. Repositioning of the device may be needed in case of any movement or migration, as malposition can cause suction events, inadequate support, or worsening hemolysis. Although not yet well investigated in pediatrics, a cardiac POCUS may be helpful in these situations to help reposition the device with the assistance of the interventional cardiologist. The most useful views for this purpose would be a PLAX view as well as the apical four-chamber view, to evaluate the device in the long axis.

It is important to note that these device-specific uses of cardiac POCUS require technical knowledge of the technology being evaluated. This is ideally suited to institutions with formal cardiac POCUS protocols for these specific indications as well as cohorting of these technologies, patients, and their providers. This will allow the relevant operators to be familiar with the appropriate positioning of the mechanical support devices as well as allow them case volumes to maintain competence of their skills in performing these assessments.

Performing lung POCUS

Basic lung POCUS relies on scanning of two to three planes and is generally performed while the patient is supine. The chest can be divided into segments to ensure that the provider scans all portions of the chest. The provider should scan long the anterior and posterior axillary lines and along the parasternal line (Figure 17.12) [30]. Scanning of these planes ensures that all lung segments are evaluated in a brief but systematic way. Similar to all diagnostic modalities, lung ultrasound is operator dependent and requires deliberate training to ensure that the sonographer is able to recognize the ultrasonographic signs indicative of pathology.

Scanning is performed using the linear array probe with the orientation marker in the 12 o′ clock position and should proceed systematically (Figure 17.13) [31].

Structures by artifact visualization

A-lines
- Motionless artifacts that are reverberation reflections of the pleural line
- Appear at repeated and fixed intervals from the pleural line (Figure 17.14)
- Normal finding in the presence of pleural sliding (Figure 17.15)

B-lines
- Hyperechoic laser-like projections extending from the pleural line to the bottom of the screen (Figure 17.15)
- Typically obliterate A-lines
- Usually indicative of increased lung parenchymal density as seen with pulmonary edema

Figure 17.13 Probe positioning for lung ultrasound in the parasternal line (A) and posterior axillary line (B). Red dot indicates location of orientation marker. (Source: Adler et al. [1]. Reproduced with permission from Elsevier.)

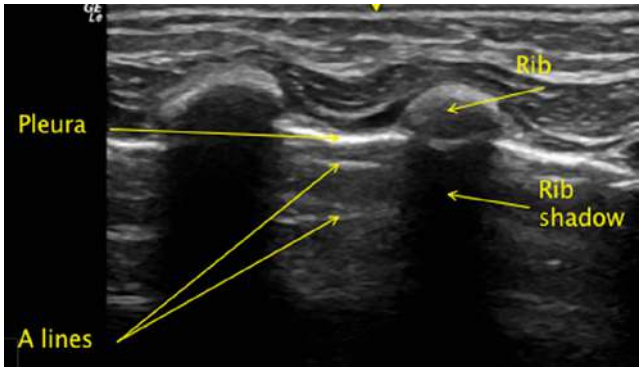

Figure 17.14 Lung ultrasound imaging demonstrating the appearance and location of the pleural line, ribs, and ensuing shadowing as well as A-line reflections of the pleural line.

Lung Sliding	• Shimmering motion artifact representing normal movement of the opposing visceral and parietal pleura during the respiratory cycle
Seashore Sign	• Granular and homogenous pattern visualized on M-mode below the pleural line (Figure 17.16) • Normal finding indicative of the interface between the chest wall and the mobile lung
Barcode Sign	• Sonographic sign of absent lung sliding using M-Mode (Figure 17.16) • Change in appearance from a Seashore to a Barcode appearance below the pleural line • Pathognomonic for pneumothorax
Spine Sign	• Visualization of the thoracic vertebral bodies • Indicative of fluid (effusion, hemothorax, and consolidation) enhancing the ultrasound waves allowing for deeper penetration to visualize the spine
Lung Point	• Distinct area of transition between normal lung sliding and absent lung sliding • Pathognomonic for pneumothorax
Lung Pulse	• intermittent pulsation of the pleural line (without lung sliding) synchronous with the heartbeat • Occur with increased lung density (atelectasis) or in the absence of ventilation (without pneumothorax) such as during contralateral one lung ventilation

Performance of lung ultrasound should occur systematically across all regions of the chest with the intent on observing specific sonographic signs above to identify normal lung from pathology [30] (Figure 17.17).

Incorporation of lung ultrasound into anesthesia practice

The majority of reports using lung ultrasound perioperatively has been limited to case reports and series [32–34]. While lung ultrasound can be useful in identifying etiologies for pulmonary-related issues, it is likely that the fully utility of this modality has yet to be realized within anesthesia practice. Lung ultrasound has been successful in guiding airway management, particularly the assessment of one lung ventilation [35, 36]. Additionally, lung ultrasound has been shown to assist ventilatory management in patients undergoing congenital heart surgery. Song et al. performed a randomized controlled study using ultrasound guided lung recruitment to rescue intra and postoperative desaturation as well as mechanically ventilatory times in children undergoing congenital heart surgery [37].

Comparative analysis conducted by Wu et al. assessed the diagnostic ability of perioperative lung ultrasound for identification of excessive pulmonary blood flow (detection of

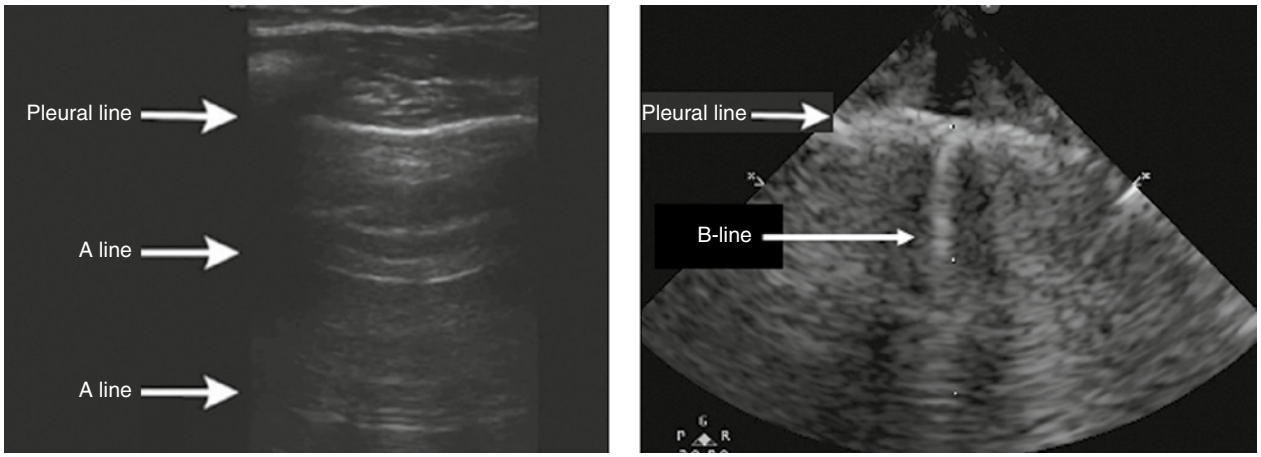

Figure 17.15 Lung point-of-care ultrasound demonstrating the presence of the pleural line and A-lines (left panel) and B-lines (right panel)

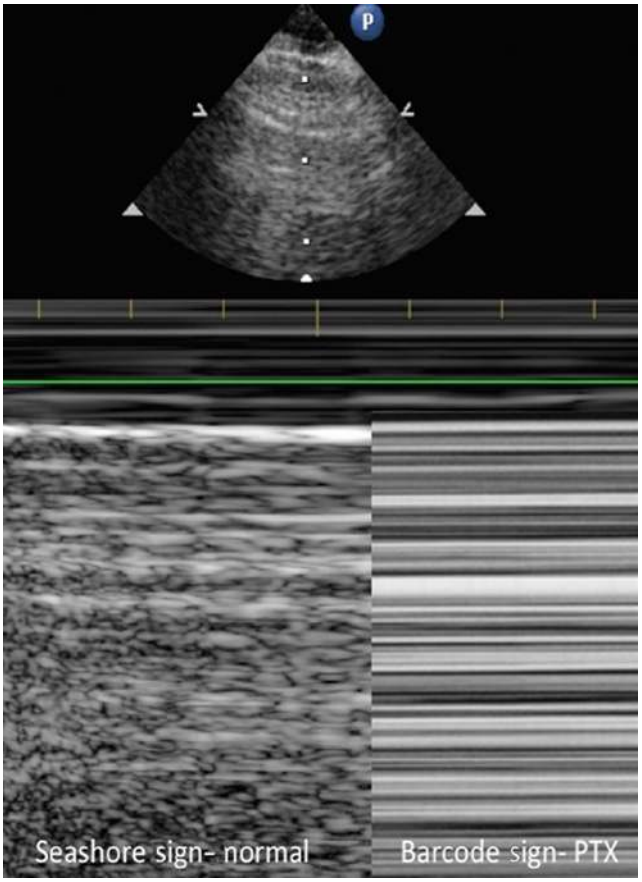

Figure 17.16 Lung point-of-care ultrasound (Motion Mode: M-Mode) demonstrating the change of appearance from normal aerated lung (left) with a seashore sign to appearance with presence of a pneumothorax (PTX-right) and a barcode sign. (Source: Adler et al. [1]. Reproduced with permission from Elsevier.)

pleural fluid and pulmonary edema as indicated by B-lines) as often seen in children with CHD [38]. Specifically, they evaluated the diagnostic abilities of lung ultrasound in comparison with preoperative chest X-ray (CXR) and CT [38]. This study demonstrated the sensitivity and specificity of lung ultrasound (96 and 95%, respectively) to be similar to chest CT and far superior to CXR (74 and 50%, respectively) for the detection of excessive pulmonary blood flow and interstitial edema [38].

POCUS training and credentialing

Again, while POCUS specific machines have fewer controls and cardiac POCUS imaging protocols are simpler than standard echocardiography, cardiac imaging remains a complex task and one should not believe that cardiac POCUS training is a simple endeavor. Short weekend or day-long POCUS crash courses or workshops may be able to provide some fundamental knowledge to begin POCUS training. However, experts consistently recommend that the best approach to teach POCUS is multifaceted, including longitudinal training programs which emphasize and demonstrate learner competency [8, 39, 40]. Published pediatric POCUS training programs tend to be multidisciplinary in nature, drawing upon expertise of subspecialists in order to cover the POCUS imaging cores [11, 23, 41]. For cardiac POCUS, collaboration with cardiology subspecialists and the institutional echocardiography laboratory provides invaluable access to expert operators and cardiac pathology exposure [23, 42].

The basic cardiac POCUS curriculum components typically include didactics, cardiac ultrasound image library, and supervised hands-on scanning; ultrasound simulators or cardiac phantoms may also be used to complement patient scanning experiences [8]. Dedicated faculty with interest in cardiac POCUS and education is needed to create the didactics and image library or to curate free online medical education materials. Faculty mentorship for learner bedside scanning supervision or remote image review is critical, but this is more time-consuming and can be challenging to maintain.

Didactics for cardiac POCUS should include fundamentals of ultrasound physics, including artifacts and the fundamentals of machine use. Typically, this also includes instruction of terminology and basic probe orientation. While there are fewer options for image optimization and probe

AL Grawany

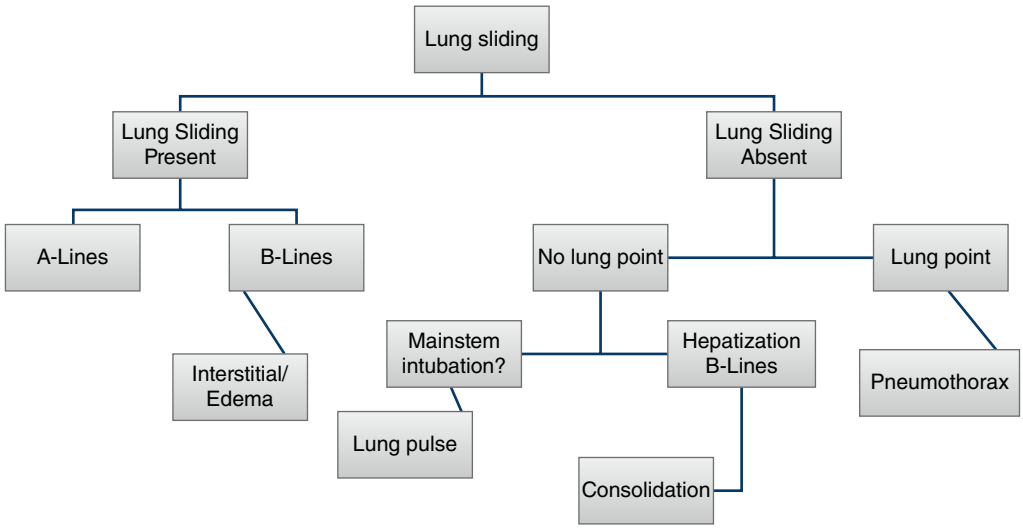

Figure 17.17 Suggested algorithm for approaching lung point of ultrasound for the anesthesia provider.

selection with POCUS machines to review, the imaging limitations of these machines compared to standard echocardiography should be emphasized. Additionally, the scope of practice of cardiac POCUS as compared to standard echocardiography should be reviewed, particularly related to the limited diagnostic targets in POCUS and the concerns regarding its use in CHD [14]. Optimal method or modality of didactics is not established, but asynchronous or online methods can be an attractive solution to teach medical personnel with busy clinical schedules. Additionally, online teaching can be viewed repeatedly by users and potentially provide the opportunity for a learning forum for discussion or interactivity with other learners and experts [43].

Development of competent cardiac POCUS psychomotor skills requires a component of hands-on training, of which at least some should be directly proctored by an expert user [8, 44]. This can be accomplished in different manners, including dedicated standardized patient workshops or in clinical scenarios with a mentor. Weekend workshops provide opportunities for scanning on multiple standardized patients with variable quality of imaging windows. If designed well, the workshop should have ample time for expert feedback on the technical aspects of imaging acquisition. However, given the nature of standardized patients or volunteers, there will likely be a paucity of pathology. Proctored scanning in clinical scenarios can provide opportunities for pathology exposure, but caution is recommended regarding clinical integration of learner scan findings. This can be ameliorated by the usage of clear terminology (POCUS vs. standard echocardiography) and proctors aware of the clinical scenario as well as the scope of practice for POCUS and standard echocardiography.

In pediatric centers, even large ones, cardiac pathology can be relatively rare and exposing a number of POCUS learners to enough pathology in clinical scenarios in a finite period of time can be difficult. POCUS image libraries can provide avenues to improve learners' competency to recognize cardiac disease, particularly recognizing the variety of ventricular systolic dysfunction [23]. Again, there are multiple free online medical education resources (mostly adult medicine centric) to draw from. These image libraries can also be created locally drawn from institutional POCUS and standard echocardiography images (http://learn.pocustraining.com). These libraries can also be used track users' progress and provide feedback (individually or via expert comments on specific POCUS images).

Teaching POCUS with a goal of competency is the optimal approach and it can provide a pathway for a local credentialing process. Assessment of cardiac POCUS competency is an evolving science but seems to be based on a combination of number of scans performed and an expert assessment of the quality of the acquired images. Conlon et al published that a minimum of 25 certified cardiac POCUS scans as the criteria for credentialing purposes in their pediatric critical care medicine division [11]. Mechanisms for expert feedback on adequacy and quality images are important for credentialing, but also for ongoing quality assurance programs. Some POCUS imaging reporting systems provide quality assurance packages. There are also available cardiac POCUS assessment tools available to provide richer feedback for both teaching and ongoing quality assurances purposes [45]. Cardiology consultation is likely helpful to build and maintain cardiac POCUS credentialing and quality assurance processes, but both the American Medical Association and American Council of Emergency Physicians recommend that credentialing processes remain internal within the subspecialty [46, 47]. This recommendation is likely due, in part, that POCUS scope of practice within a subspecialty is best ultimately determined by the subspecialists themselves.

Introduction

Congenital heart defects (CHD) are the most common of all congenital anomalies. Every day in the United States, 11,500 babies are born; of whom 450 have a congenital anomaly, of which 87 (20%) are congenital heart defects [1]. The incidence of CHD has remained consistent over the years and is similar across various geographic, racial, and ethnic groups. Although there is a suggested increase in the prevalence of specific lesions in certain regions, the incidence is mostly 7–10/1,000 live births [2, 3].

The patient with congenital heart disease

The demographics of patients with CHD are changing as screening methods evolve, diagnostic tools improve, and interventions change. Although CHD is frequently considered a disease of childhood, the population of adults with CHD is growing at the rate of 5% every year, and by the end of this decade, there will be more adults than children with CHD. The congenital cardiac anesthesiologist thus must be prepared to evaluate and care for adults as well as children with heart defects. However, there remains a significant population of neonates and infants with critical CHD who require care in their first days or months of life. In an epidemiologic study, 15% of all infants with CHD had significant physiological compromise (metabolic acidosis, seizures, cardiac arrest, or evidence of renal or hepatic injury) that required an invasive intervention in the first few weeks of life [4]. Many lesions are diagnosed prenatally, and fetal interventions to improve the outcome and progress of patients are increasingly applied [5]. The interventions are also changing rapidly, and an anesthesiologist must include in the preoperative evaluation an understanding of the planned procedure, the location, and the coordination needed between various teams. Many centers have adopted a hybrid approach to many defects, especially hypoplastic left heart syndrome [HLHS]) and multiple ventricular septal defects (VSDs). These procedures will require an up-to-date understanding and preparation for those ever-changing interventions [6, 7].

Terminology and classification

The primary step in the preoperative anesthetic evaluation of the patient with CHD is an understanding of the terminology and nomenclature used for these defects. The communication between various chambers and vessels is described in terms

Anesthesia for Congenital Heart Disease, Fourth Edition. Edited by Dean B. Andropoulos, Emad B. Mossad, and Erin A. Gottlieb.

of concordance and/or discordance. Sidedness and morphology of chambers, valves, and vessels also follow a standard description approach. To understand the nomenclature of a specific lesion, the anesthesiologist carefully considers:

- Systemic and pulmonary venous drainage
- The outlet/drainage of the atrial and ventricular chambers (e.g., a double inlet left ventricle [DILV] has both right and left atria draining into the left ventricular chamber; in a double outlet right ventricle [DORV] the right ventricle communicates directly to both the systemic and pulmonary outlets)
- Atrioventricular and ventriculoarterial communication (e.g., in congenitally corrected transposition of the great arteries [CCTGA] there is atrioventricular and ventriculoarterial discordance)
- The morphology of the atrioventricular and semilunar valves Systemic and pulmonary arterial morphology and branching.

Following an interpretation of the nomenclature and terminology, the anesthesiologist has to understand the physiologic implications of various lesions. The most practical approach is to follow a physiologic classification for all CHDs (Table 18.1). Many CHDs that present in the neonatal period requiring urgent care are ductal-dependent lesions where a patent ductus arteriosus is essential to maintain either systemic or pulmonary flow. Defects presenting later in life or requiring later care are classified according to the presence and direction of shunting, pulmonary blood flow, and obstruction. Although there are numerous CHDs, the majority will be classified into one of four categories, with the incidence of the most commonly seen defects representing one of each of those categories [8, 9]. Chapter 4 has a detailed presentation of the terminology and nomenclature of different CHDs.

Table 18.1 Classification of congenital heart defects

Category	Shunt direction	PBF	Most common examples
Ductal-dependent lesions (neonatal period)			
DDL for PBF	L-to-R	Decreased	Pulmonary atresia, tricuspid atresia, TOF with severe PS, Critical PS
DDL for SBF	R-to-L	Increased	HLHS, Preductal coarctation, IAA, Critical AS
Common CHD			
Acyanotic shunt lesions	L-to-R	Increased	**VSD** (**20%**), ASD (16%), PDA (12%), P/CAVC (4%)
Cyanotic shunt lesions	R-to-L	Decreased	**TOF** (**7%**), Ebstein anomaly, PA-VSD-MAPCA
Obstructive lesions	No shunting	Normal	**Coarctation** (**6.8%**), AS, PS, cor triatriatum, MS
Mixing lesions	L ↔ R	Variable	**d-TGA** (**3.6%**), Truncus Arteriosus, TAPVR
Regurgitant lesions	No shunting	Normal	MR, TR, AI, PI (most post-surgical repairs)
Others	Variable shunting	Variable	Vascular rings, anomalous coronary lesions (ALCAPA), tumors, cardiomyopathy (IDCM, HCM)

DDL, ductal-dependent lesion; PBF, pulmonary blood flow; L, R, left and right; TOF, tetralogy of Fallot; PS, pulmonary stenosis; SBF, systemic blood flow; HLHS, hypoplastic left heart syndrome; IAA, interrupted aortic arch; AS, aortic stenosis; VSD, ventricular septal defect; ASD, atrial septal defect; PDA, patent ductus arteriosus; P/CAVC, partial or complete atrioventricular canal defect; PA-VSD-MAPCA, pulmonary atresia with a ventricular septal defect and multiple aortopulmonary collaterals; MS, mitral stenosis; d-TGA, dextro-transposition of the great arteries; TAPVR, total anomalous pulmonary venous return; MR, mitral regurgitation; TR, tricuspid regurgitation; AI, aortic insufficiency; PI, pulmonary insufficiency; ALCAPA, Anomalous origin of the left coronary artery from the pulmonary artery; IDCM, idiopathic dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy.

Multidisciplinary approach

The preoperative period is the appropriate time to consider all the variables that can impact the preparation, planning, and conduct of the perioperative care for the child with CHD. The majority of congenital cardiac centers have a set weekly conference to discuss patients scheduled for surgical as well as catheter interventions. In that multidisciplinary conference, the history and condition of the patients are discussed, imaging studies are reviewed, and plans for any further consults or tests are investigated. The goal of the conference and the preoperative evaluation is to bring all the necessary expertise to understand the lesion, optimize the condition of the patient, and plan the best approach or intervention to the patient.

Consent

The preoperative visit is an essential phase in preparing children with CHD and their families for the upcoming intervention. Parental knowledge, whether provided verbally or in written or visual form has been shown to improve the parents' involvement and effectively reduce their anxiety [10]. The purpose of the preoperative visit and the consent process is not the delivery of information and significant potential risks, but to provide the necessary knowledge to the parents (and potentially the child) of the specifics of the anesthetic procedures, the common risks and the plans to prevent or mitigate them, and the role of the various caregivers. The consent process should bring the physicians and the family together as partners with the same purpose: the best care possible and the least risk acceptable for the care of the child. Well-informed parents are able to participate in educating their children and preparing them for the intervention through therapeutic play interventions, establishing a rapport and connection with the anesthesiologist. Children whose parents are better educated and informed, and who are involved in the preparation process are less anxious and more prepared for the interventions [11].

KEY POINTS: APPROACH IN PATIENTS WITH CHD

- CHD is the most common birth defect requiring intervention, and survivors have increasingly complex CHD.

AL Grawany

- Venous drainage, outlets of atria and ventricles, atrioventricular and ventriculoarterial communication, the morphology of the cardiac valves, and arterial branching are crucial components of classification and nomenclature of CHD.
- A multidisciplinary planning conference for surgical patients that includes surgeons, anesthesiologists, cardiologists, intensivists, and radiologists is a key component of the perioperative care of the patient with CHD.
