- The immediate clinical concern for patients with AMI is to reverse the underlying malperfusion to prevent bowel infarction.
- The etiology of AMI (i.e., embolus, in situ thrombosis, NOMI, mesenteric venous thrombosis, dissection) can usually be determined from the history and clinical setting.
- The emboli responsible for AMI usually lodge in the superior mesenteric artery and originate from the heart as a result of atrial fibrillation, an acute myocardial infarction, or a ventricular aneurysm.
- In patients with in situ thrombosis, the presentation of AMI is superimposed upon the symptoms of CMI in more than 50% of patients.
- NOMI represents an abnormal or paradoxical mesenteric vasoconstriction characterized by the loss of autoregulation.
- Mesenteric venous thrombosis is associated with a high incidence of hypercoagulable states and merits immediate and long-term anticoagulation, even in the absence of an identifiable condition.
- CT arteriography with 1- to 2-mm cuts has emerged as the diagnostic study of choice for most patients with AMI, whereas catheter-based arteriography remains the optimal imaging study for NOMI.
- Patients with AMI from an embolus or in situ thrombosis require emergent revascularization with inspection of the bowel viability.
- Operative treatment for patients with NOMI and mesenteric venous thrombosis is reserved for cases that have failed conventional therapy and when bowel infarction is suspected.
- The postprocedure course for patients undergoing treatment for AMI is oftentimes associated with the development of MODS, similar to the treatment of CMI.

Abdominal Compartment Syndrome

Zsolt J. Balogh and Frederick A. Moore

HISTORICAL PERSPECTIVE

Pediatric surgeons closing omphaloceles have long recognized the lethal combination of pulmonary compromise and impaired renal function caused by increased intraabdominal pressure (IAP). Silo closure with gradual reduction of abdominal defect was recommended to prevent fulminant organ failure.[1] Concurrent improved survival of patients with ruptured abdominal aortic aneurysms (AAAs) increased awareness of the adverse consequences of high IAP. Vascular surgeons popularized the use of high IAP as a criterion for re-exploration.[2] In fact, the term *abdominal compartment syndrome* (ACS) was coined by vascular surgeons to describe the presentation of "increased ventilator pressure, increased central venous pressure (CVP), and decreased urinary output (UO) associated with massive abdominal distension not due to bleeding" in four early survivors after ruptured AAAs.[3] However, ACS did not become widely recognized until the mid-1990s, after an epidemic of ACS emerged in high-volume trauma centers as a result of fundamental advances in trauma care.[4–6] With the development of trauma systems, severely bleeding patients were triaged into level 1 trauma centers where the principles of the new Advanced Trauma Life Support course was being ingrained.[7] Early isotonic crystalloid resuscitation to achieve normal blood pressure became standard of care. It also became apparent that exploratory laparotomy with definitive repairs of all injuries resulted in a prohibitively high on-table operating room (OR) mortality from exsanguination.[8] Stone and colleagues introduced the concept of an abbreviated surgery for these patients with the aim of acute restoration of physiology and later staged definitive surgery.[9] This practice was exemplified by the widespread adoption of nonresectional management of major liver injuries with perihepatic packing and "towel clip" midline abdominal closure to enhance tamponade.[10] Survival notably improved, and this concept was extended to include all severely bleeding trauma patients, and the term *damage control laparotomy* gained popularity.[11,12] Finally, Kern and Shoemaker promoted the presumptive placement of pulmonary artery catheters (PACs) to guide supranormal oxygen delivery resuscitation to prevent occult hypoperfusion.[13] Because of these advances, more severely bleeding patients survived the first 24 hours. However, a substantial number of survivors progressed to develop ACS with organ dysfunctions. After repeat laparotomy to open the abdomen and decreased IAP, organ dysfunctions improved dramatically, but unfortunately, many of these patients would later deteriorate into a new predominant phenotype of fulminant multiorgan failure (MOF). This was a major challenge for trauma intensivists.[14]

This epidemic spurred research in the late 1990s and early 2000s to clarify the epidemiology and pathophysiology of ACS. The World Society of the Abdominal Compartment Syndrome (WSACS) was founded, which spurred international discussions and further research.[15,16] Definitions were standardized, monitoring of IAP was optimized, and consensus treatment guidelines were developed. ACS was recognized to be largely an iatrogenic problem. The abandonment of PAC-directed supranormal ICU resuscitation substantially decreased, but did not eliminate ACS.[17] Studies showed that the pathologic trajectory of ACS could be accurately predicted in the emergency department (ED).[18] Excessive crystalloids and failure to rapidly achieve hemorrhage were identified as the major contributing factors. This prompted the widespread adoption of the focused abdominal sonography of trauma (FAST) examination in the ED to ensure rapid triage to the OR for severe abdominal bleeding where liberal use of damage control and open abdomen surgery were used.[19] Protocols were implemented to rapidly identify major pelvic fractures and ensure appropriate use of pelvic binding, pelvic packing, interventional radiology embolization, and orthopedic external fixation.[20] Massive transfusion protocols (MTPs) enriched with fresh frozen plasma (FFP) were developed to ensure that transfusions were started as soon as possible after ED arrival and to minimize crystalloid use.[21] Hypotensive resuscitation was selectively used. Trauma-induced coagulopathy was recognized to be a distinct entity, and the resulting research supported early 1:1:1 ratios of FFP/platelets/packed red blood cells in MTPs and the use of fibrinogen and tranexamic acid. With these fundamental changes in initial management, ACS has become a relatively uncommon event in trauma ICUs.[22] With this focus to understand ACS as an acute event after trauma, ACS was described in a variety of other scenarios such as extreme constipation,[23] ovarian hyperstimulation,[24] noninvasive ventilation,[25] pancreatitis,[26] and severe burns.[27] With more timely diagnosis and treatment, more than 50% of afflicted patients are now surviving.

TERMINOLOGY

IAP is the pressure in the abdominal cavity. Clinical examination for monitoring IAP can provide inaccurate results.[28,29] The intravesical technique involving the use of a standard urinary catheter is the most reliable and least invasive method for monitoring IAP.[30] The intravesical technique has been shown to correlate well with IAP measured directly using a laparoscopic insufflator.[31] The vesical route is more accurate for monitoring IAP than rectal and gastric routes.[31] Animal studies have shown that the pressure in the inferior vena cava correlates well with the vesical pressure but is more invasive.[32,33] Several proprietary devices are available to intermittently monitor urinary bladder pressure. Unfortunately, IAP measurements are rarely obtained more often than every 4 hours because of logistic problems. These shortcomings have been overcome by developing and validating a continuous IAP measurement technique.[34] The mean value of IAP in hospitalized patients is 6.5 mm Hg (range, 0.2–16.2 mm Hg).[35] In critically ill patients, IAP is typically higher (12–16 mm Hg).[18]

Intraabdominal hypertension (IAH) is defined by abnormally high IAP and graded from I to IV based on IAP (grade I: 12–15 mm Hg;

TABLE 150.1 Classification of Abdominal Compartments

SYNDROME	
Basis of Classification	**Subcategories**
Time frame	Acute
	Chronic
Relation to peritoneal cavity	Primary
	Secondary
Etiology	Trauma
	Burn
	Postoperative
	Pancreatitis
	Bowel obstruction
	Ileus
	Abdominal aortic aneurysm
	Oncologic
	Gynecologic

grade II: 16–20 mm Hg; grade III: 21–25 mm Hg; and grade IV: above 25 mm Hg).[4]

ACS is defined by the presence of sustained IAP of greater than 20 mm Hg associated with attributable organ dysfunctions (described later). ACS can be classified based on its duration, presence or absence of intraperitoneal pathology, and cause of increased IAP (Table 150.1). Most of the available information related to ACS describes an acute syndrome in critically ill patients. However, ACS can be present in certain clinical conditions with chronic IAH, such as morbid obesity, chronic constipation, and pregnancy.[36]

Primary ACS is a condition associated with injuries or diseases in the abdominopelvic region. It typically develops after a damage-control surgery with temporary abdominal closure.[15] Intraperitoneal packing to tamponade bleeding increases intraabdominal contents, and when these packs are placed to control major liver injuries, they can partially occlude the portal vein, which promotes bowel edema. As time progresses, intraabdominal bleeding and worsening gut edema with ascites (secondary to resuscitation) cause further increases in the volume of the intraabdominal contents that significantly increase IAP, thus precipitating organ dysfunctions that characterize ACS. Primary ACS can also occur in patients who fail nonoperative management of liver and spleen injuries because of bleeding.[37]

Secondary ACS occurs after injuries or conditions that do not originate in the abdominopelvic region in the setting of massive resuscitation.[18] Secondary ACS is more elusive and unexpected, which delays its diagnosis.[38] It is typically associated with large-volume isotonic crystalloid resuscitation for ongoing bleeding related to mangled extremity injuries or penetrating chest injuries[39] and for severe burns or pancreatitis.[27,40]

DAMAGE CONTROL LAPAROTOMY

Patients undergoing laparotomy for major bleeding are at risk for entering the "bloody vicious circle" physiology of progressive acidosis, hypothermia, and coagulopathy, and this results in exsanguination from diffuse bleeding.[8] Prevention of this scenario is the rationale of damage control.[41] Damage control laparotomy has two goals: (1) quick control of bleeding to prevent the lethal spiral of the "bloody vicious cycle" and (2) prevent further contamination from hollow viscous perforations. After these goals are accomplished, the abdomen is temporarily closed without midline fascial approximation, and the patient is triaged to the intensive care unit (ICU) for resuscitation and correction of abnormal "bloody vicious circle" physiology. After this is accomplished, patients are returned to the OR (usually within 24 hours) for completion of the needed surgical interventions. The common use of damage control laparotomy necessitated the development of novel techniques of managing the open abdomen.

ABDOMINAL DECOMPRESSION

Traditionally, abdominal decompression has been achieved through a full midline laparotomy. Recently, other techniques such as transverse laparotomy and minimally invasive linea alba fasciotomy have been described as potentially useful methods in selected cases. Decompressive laparotomy can be performed in ICUs in extreme cases. However, it is generally preferred to be done in the OR, especially when further intraabdominal procedures or need to control bleeding is anticipated.

PATHOPHYSIOLOGY

IAP: The volume of the abdominal cavity is limited by its least tensile component, the fascia. Increased pressure can be caused by an increase in the volume of abdominal contents or because of a decrease in the volume of the "container" (Table 150.2). After IAP increases to greater than 20 mm Hg, the abdominal cavity is on the steep portion of its pressure-volume curve, and as a result, small increases in content volume or decreases in cavity volume can cause dramatic increases in IAP. This is when close monitoring of IAP (preferably continuously) and organ dysfunction is essential for timely intervention. In the 1990s it was popular to volume-load patients with impending ACS, but the result was a rapid increase in IAP with progression into full-blown ACS.

TABLE 150.2 Causes of Intraabdominal Hypertension and Abdominal Compartment Syndrome

Increased Abdominal Contents	Decreased Abdominal Volume
Ascites	Reduction of large, long-standing hernia
Hemoperitoneum	Direct closure of large, long-standing abdominal wall defect
Visceral edema	Circumferential abdominal wall burn
Abdominal packs	Continuous positive-pressure ventilation
Peritonitis	
Retroperitoneal edema (pancreatitis)	Retroperitoneal edema (pancreatitis)
Large pelvic and retroperitoneal hematoma	Large pelvic and retroperitoneal hematoma
Intestinal obstruction	
Ileus	
Gastric distention (esophageal ventilation)	
Abdominal aortic aneurysm	
Severe constipation	
Large abdominal tumor (chronic)	
Morbid obesity (chronic)	
Pregnancy (chronic)	

CEREBRAL PERFUSION

Increased IAP forces the diaphragm cephalad, thus increasing the intrathoracic pressure, which impedes venous return from the brain. This increases intracranial pressure (ICP) and consequently decreases cerebral perfusion.[42,43]

CARDIAC FUNCTION

Increased IAP impedes venous return to the heart, thus decreasing preload. However, high IAPs elevate CVP, falsely signifying euvolemia. Simultaneously, left ventricular afterload increases because of increased systemic vascular resistance. Increased intrathoracic pressure also increases right ventricular afterload, leading to right dilation with leftward displacement of the ventricular septum and impairment of left ventricular filling.[44–47] Low cardiac index (CI) is a typical finding associated with ACS. Contrary to traditional beliefs, low CI in the setting of increased IAP (and CVPs) usually does not respond to fluid challenges; moreover, ongoing volume loading can lead to the "futile crystalloid cycle" (described later; Fig. 150.1). An increase in CI in response to decompression is a predictor of improved outcome.[18]

Respiratory function: High-risk patients may develop acute lung injury, and ongoing crystalloid resuscitation worsens pulmonary edema. Increased IAP pushes the diaphragm into the thoracic cavity, thus decreasing thoracic compliance and lung volume. Therefore increased airway pressure is required to restore the lung functional residual capacity to improve oxygenation during mechanical ventilation.[47,48] Airway pressure promptly decreases in response to abdominal decompression. However, this cannot be used to differentiate between survivors and nonsurvivors.[18] Monitoring of airway pressure is important during attempted primary fascial closure after laparotomy, when ACS is a possible complication.

RENAL FUNCTION

In the early reports, oliguria or anuria was the typical presenting diagnostic sign of ACS. Mechanisms responsible for decreased renal function include direct compression of the renal parenchyma, decreased perfusion of the kidneys, and increased water and sodium retention because of activation of the renin-angiotensin system.[48–51] As high-volume crystalloid resuscitation became standard of care, low UO became a less reliable early sign of ACS.

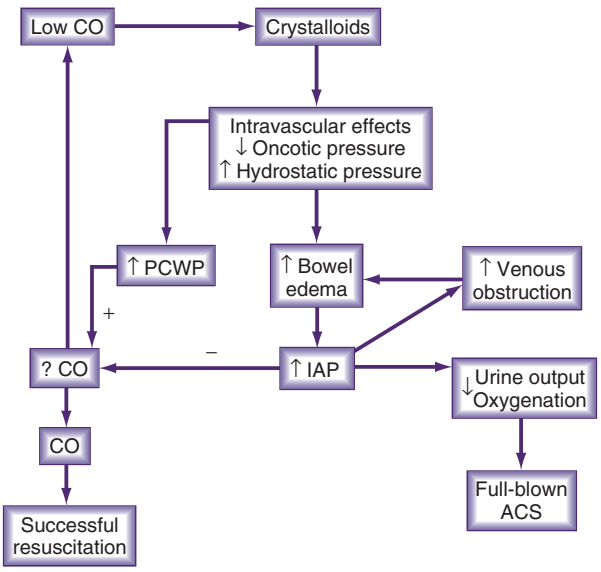

Fig. 150.1 Futile crystalloid preloading. *ACS,* Abdominal compartment syndrome; *CO,* cardiac output; *IAP,* intraabdominal pressure; *PCWP,* pulmonary capillary wedge pressure; ↑, increased; ↓, decreased; +, positive effect; −, negative effect.

GUT PERFUSION

Increased IAP impairs splanchnic perfusion by decreasing CI and by increasing splanchnic vascular resistance. Gut ischemia can occur in severe cases.[52–54] In the 1990s gastric tonometry was frequently used in the ICU, and increased gastric regional partial pressure of carbon dioxide ($PrCO_2$) or GAP_{CO_2} ($PrCO_2 - PaCO_2$) became accepted indicators of impaired intestinal perfusion. After damage control surgery to control major bleeding, $PrCO_2$ was frequently high because of ongoing hypovolemic shock. With effective resuscitation, $PrCO_2$ would decrease. However, with ongoing futile volume loading, IAP would increase because of progressive gut edema with increasing $PrCO_2$ into pathologic levels (>65 mm Hg) indicative of gut ischemia. Combined with concurrent IAP monitoring, tonometry to identify increasing $PrCO_2$ proved to be an excellent adjunct for identifying impending ACS.[16] Moreover, the physiologic response to effective decompression is a prompt decrease in $PrCO_2$, reflecting gut reperfusion.[18] Laboratory studies have shown that ACS induces gut ischemia and that decompression-induced gut reperfusion primes circulating neutrophils and releases cytokines into portal circulation. This causes acute lung injury, which is similar to that induced after hemorrhagic shock and resuscitation.[55,56] Therefore abdominal decompression in patients with very high IAPs can result in gut ischemia/reperfusion and serve as a "second hit" for early MOF.[57]

LOWER EXTREMITY PERFUSION

Increased IAP increases femoral venous pressure, increases peripheral vascular resistance, and decreases femoral artery blood flow by as much as 65%.[58] This can be an important contributing factor in the development of lower extremity compartment syndrome. ACS complicated by a lower extremity compartment syndrome is especially lethal.

PREDICTION

Potential risk factors of ACS include severe hemorrhagic shock, high-volume crystalloid resuscitation, damage-control laparotomy, high injury severity score, and markedly elevated $PrCO_2$ level.[59–61] Studies on secondary ACS have identified resuscitation fluid volume thresholds that warrant IAP monitoring. Maxwell and colleagues recommended that IAP be monitored when resuscitation volume exceeds 10 L of crystalloid fluid or 10 units of packed red blood cells.[62] Ivy and colleagues suggested that the trigger to initiate IAP monitoring should be greater than 0.25 L/kg of crystalloid resuscitation.[40,63] Biffl and colleagues reported that both these cutoffs are ineffective and recommended the following thresholds: 6 L of crystalloid fluid or ≥6 units of packed red blood cells in a 6-hour period in patients with a base deficit of greater than 10 mEq/L, especially when a vasopressor agent is required.[64]

Multiple logistic regression analysis was performed using a prospective database of patients who experienced a major torso trauma and who underwent standardized shock resuscitation.[18] An ED model (at 3 hours in patients discharged from the ED) and an ICU model (at 6 hours in patients admitted to the ICU) were developed. Table 150.3 lists independent risk factors of primary and secondary ACS that were determined using the ED and ICU models. A receiver operator characteristic curve of 0.88 was a predictor of ACS in the ED model and of 0.99 was a predictor of ACS in the ICU model.

TABLE 150.3 Independent Predictors of Postinjury Primary and Secondary Abdominal Compartment Syndrome

	ED MODEL	ICU MODEL
	Independent Predictors	Independent Predictors
Primary ACS	To OR <75 min	Temp ≤34°C
	Crystalloids ≥3 L	$GAPco_2$ ≥16
		Hb ≤8/dL
		BD ≥12 mEq/L
Secondary ACS	Crystalloids ≥3 L	$GAPco_2$ ≥16
	No urgent surgery	Crystalloids ≥.5 L
	PRBC ≥3 units	UO ≤150 mL

ACS, Abdominal compartment syndrome; *BD,* arterial base deficit; ED, emergency department; *$GAPco_2$,* carbon dioxide gap; *Hb,* hemoglobin concentration; *ICU,* intensive care unit; *OR,* operating room; *PRBC,* packed red blood cells; *Temp,* temperature; *UO,* urine output.

TREATMENT

Nonsurgical medical interventions: For patients with impending ACS, medical management should be initiated to reduce and prevent further increases in IAP.[3,65,66] These include (1) reduce abdominal distention (e.g., nasogastric or rectal tubes, reduce enteral feeding),(2) improve abdominal wall compliance (e.g., adequate pain/sedation followed by neuromuscular blockade), and (3) optimize fluid balance (e.g., minimize isotonic crystalloids, use hypertonic saline or colloids, start diuresis). Additionally, treatment of early organ dysfunction by traditional ICU interventions is often necessary; however, these interventions may aggravate the underlying pathophysiology. For example, ventilator strategies for increasing mean airway pressure to improve oxygenation directly increase IAH by pushing down the diaphragm. In addition, increased intrathoracic pressure impedes venous outflow from the abdominal cavity. This promotes gut edema with ongoing crystalloid resuscitation. Seminal studies performed in the mid-1990s advocated volume loading to improve low UO in patients with moderately high IAP. Increased IAP falsely elevates CVP, resulting in the underestimation of ventricular end-diastolic volume. Thus volume loading was recommended to increase preload for improving CI to increase renal and gut perfusion.[67] Although this makes physiologic sense, close monitoring in a standardized resuscitation protocol identified this to be ineffective in increasing CI, and if volume loading continued, it would precipitate full-blown ACS. This is referred to as the *futile crystalloid cycle* (see Fig. 150.1).[67,68]

PERCUTANEOUS METHODS

If ACS is caused by acute or chronic fluid collection, its symptoms can be relieved by initiating percutaneous drainage. Case reports have described successful drainage of abdominal fluid in burn patients with secondary ACS and drainage of blood in patients with nonoperatively managed liver injuries.[69–71]

SURGICAL DECOMPRESSION

Surgical decompression by opening the midline fascia along its full length remains the primary recommended intervention. Almost all reports have described a very good physiologic response to decompression. However, this does not necessarily translate into better outcomes. The best predictors of survival are postdecompression improvement in CI and urine output.[18,39] The decision to perform surgical decompression is a difficult one because it results in an open abdomen that is associated with numerous complications. This is especially true in patients with pancreatitis because delayed fascial closure is unlikely. These patients end up with a prolonged open abdomen and a large ventral hernia if they survive. On the other hand, case series in trauma patients have shown that early decompression is associated with better outcomes. However, patients with ACS are critically ill, and their intrahospital transfer can exert detrimental effects. Thus if no other intraabdominal surgical intervention is anticipated, bedside decompression can be performed in the ICU. More recently, alternatives to midline laparotomy, such as transverse laparotomy and linea alba fasciotomy, were described. These approaches were popularized in cases of severe acute pancreatitis.[72] The (subcutaneous) linea alba fasciotomy can prevent peritoneal contamination in selected pancreatitis cases where laparotomy is not required, only reduction of IAP.[73,74]

MANAGEMENT OF THE OPEN ABDOMEN

Decompressive laparotomy results in an open abdomen, and temporary abdominal closure is performed to keep the fascia open. Several methods (towel clips, Bogota bag, synthetic mesh, vacuum-assisted closure, Velcro patch, and zipper) are available. The key goals are to prevent evisceration, allow swelling of abdominal contents, control peritoneal fluids, prevent contamination, and preserve the fascia for a possible later closure. It is important to note that patients with open abdomens can develop recurrent ACS. This is especially true with temporary closure methods that decrease abdominal volume (e.g., vacuum-assisted closure, Velcro patch, and zipper) with the intention of promoting delayed fascia closure. Ongoing experience with a vacuum-assisted closure technique has provided very promising results. In trauma patients, rate of delayed primary fascial closure is greater than 85%. Moreover, use of the vacuum-assisted closure technique has dramatically improved the daily management of the open abdomen.[75–77]

KEY POINTS

- It is essential to distinguish between IAH and ACS through the early identification of organ dysfunction.
- IAP should be monitored during shock resuscitation requiring ongoing volume loading regardless of the cause of the shock (e.g., burn, sepsis, and trauma).
- Physical examination is unreliable at detecting ACS, and at present, the safest and most feasible method to monitor IAP is the intravesical technique.
- ACS can occur without abdominal pathology or injury (secondary ACS).
- To date, the best-characterized types of ACS are postinjury ACS, burn-associated ACS, and pancreatitis-associated ACS.
- Outcomes associated with ACS are very poor even after performing early decompression. Prevention, prediction, and surveillance are the keys to achieving successful management of ACS.
- Postinjury primary and secondary ACS can be accurately predicted 3–6 hours after hospital admission through adequate monitoring.
- Efforts to limit excessive crystalloids during shock resuscitation have decreased the incidence of ACS.
- Outcomes with open abdomen are improving with the use of vacuum-assisted closure techniques.

Extremity Compartment Syndromes

Roman Košir and Andrej Čretnik

EPIDEMIOLOGY

Extremity compartment syndrome occurs whenever the tissue pressure within a limited space of the body reaches the point where the circulation, nerve function, and muscle function of that space are compromised. For compartment syndrome to occur, the body compartment should be enveloped by fascia that prevents inner tissue expansion, and there should be at least one cause of increased tissue pressure present, either externally or internally.

The German physician Dr. Richard Von Volkmann first described the late sequelae of compartment syndrome in 1881.[1] He wrote: "The paralyses and contractures that follow tightly applied bandages, chiefly in the forearm and hand, and less often in the lower extremity, are to be viewed as ischemic. They arise from the arterial supply being interrupted for too long." Volkmann's ischemic muscle contractures of untreated forearm compartment syndrome are named after him (eFig. 151.1). Later, in 1912, Wilson first described exertional compartment syndrome,[2] and Mavor, in 1956, first reported chronic exertional compartment syndrome in a football player.[3] Since then, various cases of compartment syndrome have been reported in the literature, and the pathophysiology and treatment options have been discussed. Compartment syndrome has been reported in a wide variety of clinical conditions, including tetanus, meningococcemia, malignant hyperthermia, frostbite, horseback riding, and childbirth.[4–8] Typically, it occurs after traumatic events, most commonly those involving fractures or vascular trauma with subsequent ischemia-reperfusion injuries. The most commonly affected body compartments are lower extremity compartments. The literature describes an increasing incidence of around 2% in severely injured patients.[9–11] This occurs with developments in shock resuscitation in a population of patients with otherwise noninjured extremities. The incidence of compartment syndrome varies depending on the patient population studied and the etiology of the syndrome. In a group of patients with leg pain, according to Qvarfordt and colleagues, 14% were noted to have anterior compartment syndrome.[12] Compartment syndrome was also seen in 1%–9% of leg fractures.[13]

Common locations of compartment syndromes are in the upper and lower limbs. The most commonly affected are the four compartments of the lower extremity (anterior, lateral, superficial posterior, and deep posterior), followed by two compartments of the forearm (volar and dorsal). Other compartments that may be affected are the deltoid and biceps compartments of the arm; interosseous compartments of the hand; gluteal compartment of the buttock; quadriceps compartment of the thigh; and interosseous, medial, central, and lateral compartments of the foot.[14–17]

The etiology of compartment syndrome varies and can be divided into three major groups: decreased compartmental volume, increased compartmental content and therefore pressure, and externally applied pressure. There are probably more than 40 causes that fit into one of these groups. Common causes in critical care surgical cases are presented in Table 151.1.[18]

The most common causes of extremity compartment syndrome are categorized based on increased compartmental content. The pathophysiologic mechanism of bleeding is easy to understand. Most commonly, bleeding is caused by trauma, but recently, more reports of atraumatic bleeding caused by wide use of warfarin, low-molecular-weight heparins, or recombinant tissue plasminogen activator (rtPA) have been reported.[19–21]

Increasing volume of blood in a space limited by noncompliant fascia results in an exponential rise in intracompartmental pressure. Postischemic swelling or reperfusion injury is more complex because it causes the so-called *double ischemic insult.* Initial ischemic insult from any cause leads to abnormal function of all tissues, including nerves, muscles, and capillaries. This results in abnormalities of neuromuscular function; this is the *first insult.* Increased permeability after the relief of initial ischemia leads to postischemic swelling and subsequently increased compartmental volume and pressure. This leads to the development of compartment syndrome, which causes additional injury to neuromuscular function; this is the *second insult.* This process has clinical consequences. The classic physical examination in patients with reperfusion injury can be unreliable because of loss of motor and nerve function.[18,22,23]

CLINICAL PRESENTATION

Most extremity compartment syndromes in patients who are able to cooperate can be diagnosed by a clinical examination. The most common clinical signs found in the literature are the classic 5 Ps: pain (out of proportion), pulselessness (or weak pulse), pallor, paralysis (numbness and loss of motor function), and pressure (swelling and tenseness of compartment). Occasionally, poikilothermy (cold extremity) is also included (Fig. 151.1A). These signs are a consequence of increased intracompartmental pressure and loss of various tissue functions. Other signs include skin edema and blisters, swelling, and subcutaneous blood suffusions (see Fig. 151.1B).

To make the diagnosis, there must first be evidence of increased intracompartmental pressure. If so, these signs do not occur simultaneously but develop with time. One of the first signs is a swollen or tight compartment in combination with severe pain that is out of proportion to the injury and is not relieved by typical analgesia. Other signs present late and often, when present, represent irreversible damage to soft tissues. Numerous other pathophysiologic events can cause a similar clinical picture. In fact, a large meta-analysis of studies comparing clinical signs with the development of acute lower extremity compartment syndrome showed a sensitivity of

eFig. 151.1 Dr. Richard Volkmann. (Courtesy of the United States National Library of Medicine, Portrait no. 6859.)

TABLE 151.1 Most Common Etiology of Increased Compartment Pressure in Critical Care Surgery

Decreased compartmental volume	Application of excessive traction because of fracture immobilization Closure of fascial defects after trauma
Increased compartmental content	Intracompartmental bleeding caused by fractures, vascular injury, or bleeding disorders Increased capillary filtration in reperfusion after ischemia, embolectomy, soft tissue trauma, burns, fracture fixation
Externally applied pressure	Tight immobilization of fractures Lying on limb

Adapted from Matsen FA. *Compartmental Syndromes.* New York, NY: Grune & Stratton; 1980.

Fig. 151.1 A, A patient with right lower extremity compartment syndrome caused by isolated tibial fracture. On clinical presentation, pain, swelling, and inability of dorsal flexion of the toe were noted. **B,** Another patient with left lower extremity compartment syndrome after popliteal artery tear and revascularization in combination with proximal tibial fracture was treated with external fixation. A few hours later after initial treatment, there are obvious signs of developing compartment syndrome with swelling, skin discoloration, function loss, and fracture blisters.

13%–19%, specificity of 97%, positive predictive value of 11%–15%, and negative predictive value of 98%.[24] Thus the absence of this sign rules out compartment syndrome, but the presence rarely confirms the correct diagnosis.

Nevertheless, clinical observation of the suspected compartment is what is recommended because the progress of the symptoms over hours is what should be noted first before making a definitive diagnosis and initiating definitive treatment. In traumatic cases, careful observation is required in open fractures as well. Although early surgery is usually indicated in this group of patients, they can still present with compartment syndrome. One animal study has confirmed the necessity of careful monitoring of both open and closed tibial fractures.[25] A useful tool for such monitoring could be a simple sheet with notes about date, time, location, pain level, and motor and sensory testing. To do this, one must know the anatomic position of various compartments and their vascular and nerve content. A simple screening form of the most commonly observed acute lower extremity compartments is a useful tool for monitoring of the patient (eFig. 151.2).[26] To focus on this relatively rare syndrome and prevent missed diagnoses, more complex systems for monitoring and recognition have been developed in some institutions, with better recognition and outcomes.[27] In literature, special groups of patients with various etiology are described, where this condition occurs more often. Screening in these patients is highly recommended. In a large review study, stepwise logistic regression identified the presence of vascular injury, need for packed red blood cell (PRBC) transfusion, male gender, open fracture, elbow or knee dislocation, Gunshot Wounds (GSW), Injury Severity Score (ISS) greater than or equal to 16, and age less than 55 years as independent predictors for the need for extremity fasciotomy.[28] Several statistically significant predictors of relevant compartment syndromes after surgical reperfusion were found, including lactate, uric acid, transcutaneous oxygen pressure, bilirubin, intrafascial pressure, and serum myoglobin.[29]

DIAGNOSIS

To make a diagnosis of compartment syndrome, there must be evidence of increased tissue pressure, inadequate tissue perfusion, and loss of tissue function. When all three factors are present, the diagnosis may be made with assurance; when one or more of these factors are absent, the diagnosis is less accurate. Evidence of increased tissue pressure may include patient complaints of tightness or pressure in the involved area. By palpation, a physician may perceive tenseness of the compartmental envelope.[30]

Evidence of inadequate perfusion of local tissue pressure may include the symptom of pain out of proportion to what would be anticipated from the clinical situation. Increasing analgesia requirements in a properly immobilized leg should raise suspicion. Pain on a passive stretch of the intracompartmental muscles is another useful indication of increased pressure, especially if the muscles have not been injured. Reduced peripheral pulses are very late signs of compartment syndrome; in fact, studies have shown normal pulses with Doppler signals in otherwise severely elevated intracompartmental pressures. Arterial flow is rarely compromised in elevated tissue compartment pressures. On the other hand, diminished pulses could be a result of other causes (e.g., vascular lesions) and, in combination with reperfusion injury, could also lead to the development of compartment syndrome.[30]

Evidence of abnormal tissue function includes weakness of the intracompartmental muscles and nerves, including sensory branches, leading to hypoesthesia. Both nerve and muscle function may be altered by direct injury; therefore evidence of progressive loss of function over time may be a more reliable sign.[30]

Acute Lower Extremity Compartment Syndrome
Screening Form

Start Date: ___/___/___

Start Time: _____

CLINICAL DIAGNOSES

Increased tissue pressure / swelling — ***YES / NO***

Pain — *Assess according to scale from 1 to 10*

Calf Pain - Calf pain at rest

PPSF - Pain with passive stretch, foot in plantarflexion

PPSE - Pain with passive stretch, foot in extension/dorsiflexion

Vascular Exam	*Pulse*	*Scale*
DPA – Dorsal Pedal Artery	Palpable	4
	Diminished	3
PTA – Posterior Tibial Artery	Non-palpable, Doppler positive	2
	Non-palpable, Doppler negative	1

Neurologic Exam - Motor	*Strength*	*Scale*
DPN - Deep Peroneal Nerve **DPN-M** Foot dorsiflexion	Movement against gravity with full resistance	6
	Movement against gravity with some resistance	5
	Movement against gravity only	4

Acute Lower Extremity Compartment Syndrome Screening

Patient Sticker

eFig. 151.2 An example of a screening form for acute lower extremity compartment syndrome observation. (From Kosir R, Morre FA, Selby LH, et al. Acute lower extremity compartment syndrome (ALECS) screening protocol in critically ill trauma patients. *J Trauma*. 2007;63:268–275.)

To summarize, in awake and cooperative patients who can be reexamined frequently, the diagnosis of compartment syndrome is associated with the following findings:

- Pain out of proportion to what is anticipated from the clinical situation
- Weakness of the muscles in the compartment
- Pain on a passive stretch of the muscles in the compartment
- Hypoesthesia in the distribution of the nerves coursing through the compartment
- Tenseness of the compartmental envelope

Because some clinical signs progress over time, the clinical decision making can be challenging.[14,31–34] In addition, clinical symptoms and signs have well-documented poor sensitivity.[24,35] Especially in critically ill patients who are unable to cooperate because of head trauma, sedation, or even neuromuscular-blocking drugs, the diagnosis cannot be made based on the clinical examination alone.[26] In the pediatric population, compartment syndrome does not always present classically, making clinical diagnosis uniquely challenging.[33]

Although the clinical examination should be a cornerstone of the diagnosis of compartment syndrome, it has the disadvantage of being subjective and requiring patient cooperation.[14,24,34] Therefore tissue pressure measurement should be performed to assist in establishing a diagnosis so that immediate treatment can be initiated. The normal compartmental interstitial tissue pressure is around 5 mm Hg. Capillary blood flow becomes compromised at 20 mm Hg, and pain develops at pressures between 20 and 30 mm Hg. A tissue pressure of more than 45 mm Hg has been reported to be usually associated with compartment syndrome, and a pressure of more than 60 mm Hg can confirm the diagnosis.[36–38] However, the tolerance of tissues for increased pressure may be reduced by other factors, such as arterial occlusion, limb elevation, and shock.[37,39] In these conditions, compartment syndrome may occur at significantly lower interstitial pressures. According to the arteriovenous gradient theory, the local blood flow (LBF) depends on the pressure gradient between arteries (Pa) and veins (Pv) and local vascular resistance to flow (R). This is described by the following formula[40]:

$$LBF = (Pa - Pv)/R$$

LBF should be maintained to deliver enough oxygen to the tissues. According to the previous relationship, increased resistance that correlates with interstitial pressure is not the only factor that reduces LBF. The arterial pressure is also important, whereas venous pressure is somehow related to interstitial pressure. Increasing interstitial pressure also increases venous pressure and furthermore decreases blood flow.

Because tolerance of tissues to increased intracompartmental pressure varies among different individuals, and as there are more factors that influence LBF, only one isolated measurement of interstitial pressure may not be enough to diagnose compartment syndrome.[41] For example, higher compartment pressures may be necessary before injury occurs to peripheral nerves in patients with systemic hypertension,[37] whereas compartment syndrome may develop at lower pressures in those with hypotension and/or peripheral vascular disease.[39,42] It has been proposed that the difference between diastolic pressure and intracompartmental pressure is a better marker for compartment syndrome. ΔP is calculated as follows: ΔP = DBP (diastolic blood pressure) − IP (interstitial pressure), and values greater than 30–35 mm Hg suggest compartment syndrome, but a specific threshold does not exist.[43–46]

There are numerous methods of tissue pressure measurement.[47–50] The most commonly used are commercial handheld pressure monitors (e.g., the Stryker device); a simple needle manometer system (Whitesides technique); and the needle, wick, or slit catheter techniques. The question is accuracy because there are reports that an arterial line manometer is the most accurate device.[51] The slit catheter, side-ported bevel-tipped needle, or an 18-gauge needle, when appropriately used with current electronic transducer monitoring, may be used clinically with confidence.[52] The arterial line manometer device has an additional advantage of being able to monitor pressure continuously. This is reported to be useful in tibial diaphyseal fractures, where the estimated sensitivity and specificity of continuous pressure monitoring are high and continuous monitoring should be considered.[35,53] Independent of the method used to measure compartment pressures, accuracy depends on proper calibration of the measuring device and placement of the needle or pressure sensor at the level of the injured compartment. The principle of tissue pressure measurement in the case of acute lower extremity compartment syndrome is shown in Fig. 151.2.

Reported diagnostic performance characteristics of clinical symptoms and signs of acute compartment syndrome (ACS) and intracompartmental pressure monitoring are shown in Table 151.2.

Use of near-infrared spectroscopy (NIRS) for detection of low tissue oxygenation, and therefore the development of compartment syndrome, is controversial. It has been reported as a useful noninvasive tool in diagnosing compartment syndrome after surgical revascularization of lower limb ischemia and in traumatically injured patients. But some subsequent studies did not prove its utility in injuries because of severe edema of the soft tissues, and it cannot measure tissue hemoglobin oxygen saturation (StO_2) inside the muscle compartment.[31,45,54–61]

In a large review of studies, several noninvasive diagnostics for extremity compartment syndrome after traumatic injury have been analyzed, including tissue hardness, ultrasound for fascial displacement, magnetic resonance imaging (MRI) and microwave tomography for tissue imaging, B-mode ultrasound for displacement, pulse oximetry for peripheral SpO_2, infrared imaging for surface temperature, contrast-enhanced ultrasound for perfusion, Doppler ultrasound in

brachial arterial flow, and NIRS for StO_2 detection. Although NIRS has shown the most promise, whether such technologies will be of diagnostic benefit await the completion of ongoing clinical trials.[62]

In animal research, the role of intramuscular glucose and partial pressure of oxygen for detecting compartment syndrome has been evaluated. Intramuscular glucose concentration and partial pressure of oxygen measured with commercially available probes rapidly identified muscle ischemia with a high sensitivity and specificity after an experimentally induced compartment syndrome in an animal model.[63]

Ultrasound shear wave elastography for measuring intracompartmental pressure of compartment syndrome has been used in another recent animal study, and this noninvasive technology can potentially help surgeons with early detection, monitoring, and prognosis of intracompartmental pressure.[64]

Another recent study described a noninvasive ultrasound compartment fascia flattening pressure measurement method in a cadaver model of anterior lower leg compartment syndrome. In this study ultrasound is coupled with pressure transducer and fascia flattening is visualized and pressure is recorded. This method is reported to be as an adjunct to clinical examination and includes evaluating injured and noninjured extremities, is noninvasive, is easily reproducible, and can be performed quickly without patient discomfort.[65]

In establishing a diagnosis of compartment syndrome, other causes of pain-producing symptoms have to be ruled out or confirmed or a cause of elevated intracompartmental pressure should be determined. When facing traumatic injuries, a workup for rhabdomyolysis (creatinine phosphokinase [CPK], renal function, urinalysis, and urine myoglobin) should be considered. In a group of patients with tibial fractures with or without compartment syndrome, a model combining maximal CPK level greater than 4000 U/L, maximal chloride level greater than 104 mg/dL, and minimal blood urea nitrogen (BUN) level less than 10 mg/dL had a 100% association with compartment syndrome.[66]

Moderate evidence supports that in patients with acute vascular ischemia, femoral vein lactate concentration samples during surgical embolectomy may assist in the diagnosis of ACS. On the other hand, there is little evidence supporting that serum troponin may assist in diagnosing ACS in patients with traumatic lower extremity injury.[67]

Extremity x-ray or computed tomography (CT) scans can confirm the presence of a fracture. MRI features of ACS include increased fascial and intramuscular T2 signal reflective of edema, and bulging of the fascia may also be present postcontrast, and fat-suppressed T1-weighted images demonstrate diffuse enhancement corresponding to the edema identified on the T2 sequences.[68] Ultrasonography can show muscle or any other tissue tears. Doppler ultrasonography or arteriography can detect vascular abnormalities.

MANAGEMENT

The objective of treatment of compartment syndrome is to minimize deficits in muscular and neurologic function by promptly restoring LBF. Certain nonoperative measures may be effective, such as eliminating external pressure and maintaining local arterial pressure. When there is external pressure that causes compartment syndrome, such as tight casts, it is essential to release the envelope immediately (remove and exchange for a noncircular splint) when only one symptom or sign is present. Usually, this is pain and is most often observed in patients with fracture splints several hours after treatment. Restoration of normal limb perfusion has priority over closed fracture treatment, and this can be postponed until perfusion returns to normal. Before resorting to operative methods for reducing tissue pressure, it is important to consider improvement of LBF if it has been reduced by shock, peripheral vascular disease, or elevation of the limb above the heart. All causes of systemic hypotension should be treated. Limb elevation should be avoided because it lowers local arterial pressure and does not help in reducing swelling.[69] Use of vasodilating drugs or sympathetic blockade appears to be ineffective because, in this condition, local maximal vasodilatation is already present. The use of phosphodiesterase inhibitors in experimental animal models caused modulation of compartmental pressures.[70] In a large study on trauma patients with isolated arterial injury, early anticoagulation with heparin was found to reduce the incidence of compartment syndrome without significant bleeding as a consequence.[71] Carbon monoxide–releasing molecule-3 displays a potent protective/antiinflammatory action in an experimental model of compartment syndrome, suggesting a potential therapeutic application for patients at risk of developing compartment syndrome.[72]

The primary goal of treating compartment syndrome is to decrease intracompartmental pressures. Surgical decompression of all limiting envelopes is the gold standard of treatment, indicated in the presence of a characteristic clinical picture of compartment syndrome in a cooperative patient. When the clinical examination is unreliable or difficult to obtain, pressure measurement should be obtained, where either pressure should not exceed 45 mm Hg or ΔP should not be below 30 mm Hg.

Standard treatment involves a long skin incision and fasciotomy of all involved compartments and debridement of obvious nonviable tissue. Usually, this procedure is performed under general or spinal anesthesia. Bedside fasciotomy under local anesthesia has been described in select cases to be feasible and reliable.[73] Fasciotomy should be performed without a tourniquet to avoid prolonging ischemia and to permit the surgeon to assess the degree of viability and restoration of blood flow. The skin is incised through the entire length of the involved compartment. Obvious muscle bulging is observed in true

compartment syndrome (Fig. 151.3). Only obvious necrotic muscle should be removed because the tissue may have the potential for reperfusion and recovery. The sign of contractility with electrostimulation should not be used initially. After fascial release, postischemic swelling should be anticipated; therefore the skin should be left open and the wound temporarily closed with a patch of compliant artificial temporary skin closures. If release of the compartment is not complete, "rebound" compartment syndrome may occur.

After surgical decompression and temporary skin closure, sterile dressings are applied and the extremity is usually splinted in a functional position. In the presence of fractures, one should consider fixation with external fixators, rarely with plates or intramedullary nails. This stabilization is performed immediately after fascial decompression and greatly facilitates later care of the wound, limb, and fracture. Passive stretching exercises are performed to maintain range of joint motion. Skin closure may usually be performed 3–5 days after surgical decompression, usually by a mesh graft and rarely by direct suturing (Fig. 151.4). At that time, additional debridement of nonviable tissue can be performed. Fascial closure is not recommended because this requires closure under tension and can lead to redevelopment of compartment syndrome. Muscle hernia is left behind and should be large enough to not cause additional late problems. When an optimal cosmetic result is desired, one may progressively approximate the wound edges over 7–14 days with sutures or commercial devices to achieve direct skin closure.

Fig. 151.3 The patient in Fig. 151.1A after fasciotomy of the anterior and peroneal compartment and external fixation of the tibial fracture. Note obvious muscle bulging after release of fascial compartments. Direct skin closure was not possible.

Fig. 151.4 Cosmetic result of the lower extremity compartment syndrome after mesh grafting of the lateral compartment.

Negative-pressure wound care closure devices can be useful in the management of fasciotomy wounds. Negative pressure decreases wound edema, facilitates approximation of the skin edges, enhances LBF, promotes granulation tissue, and decreases bacterial colonization. Conversely, in one animal study, negative pressure may be harmful to skeletal muscle after compartment syndrome.[74] One randomized study compared vacuum-assisted closure (VAC) with the shoelace technique. Both techniques were safe, reliable, and effective methods for closure of leg fasciotomy wounds. VAC required a longer time for definite wound closure and was reported to be far more expensive than the shoelace technique, especially when additional skin grafting was required.[75] In retrospective analyses, negative pressure led to significantly higher rates of complete skin closure and decreased time to skin closure.[76,77] In a recent large meta-analysis the highest success rate for closure of the wounds without skin grafting was observed with dynamic dermatotraction and gradual suture approximation, whereas VAC had the lowest complication rate.[78] Hyperbaric oxygen as an adjunct to management after fasciotomy is reported in some case reports and animal studies, but there is a lack of evidence suggesting that this is advantageous over current practices.[79–83]

FASCIOTOMY

Fasciotomy depends on the underlying condition or mechanism that caused compartment syndrome. The length of the lower extremity skin incisions has been debated for a long time. Minimal skin incisions with more extensive fascial incisions could place the patient at risk of recurrent compartment syndrome.[84–86] The degree of muscle swelling after reperfusion cannot be predicted, and peak edema occurs several hours after surgery.

An example of a treatment algorithm that includes both conscious and unconscious groups of patients helping in making a decision when to perform emergency fascia release is shown in Fig. 151.5.

FASCIOTOMY OF THE UPPER EXTREMITY

The upper extremity is anatomically divided into the brachium, antebrachium, and hand. Each of the anatomic segments has a different number of compartments with various muscle functions. Techniques for release of these compartments have to be discussed separately, and combined fasciotomy is shown in Fig. 151.6.

Fasciotomy of the Brachium

The arm has two compartments: anterior, which includes the biceps and brachioradialis muscles, and posterior with the triceps muscle. Fasciotomy includes a lateral skin incision from the deltoid insertion to the lateral epicondyle. Care must be taken to avoid damage to the larger cutaneous nerves. At the fascial level, the intermuscular septum between the anterior and posterior compartments is identified, and fascia overlying each compartment is released with longitudinal incisions. The radial nerve should be protected as it passes through the intermuscular septum from the posterior compartment to the anterior compartment just below the fascia (see Fig. 151.6).

Fasciotomy of the Antebrachium

The antebrachium has three muscular compartments: mobile wad proximally, volar compartment, and dorsal compartment. Fasciotomy consists of a longitudinal, centrally placed incision over the extensor compartment and a curvilinear incision on the flexor aspect beginning at the antecubital fossa (Fig. 151.7). A palmar incision is made between

the thenar and hypothenar muscles in the palm, where the carpal tunnel can be released if needed. The incision is extended transversely across the wrist flexion crease to the ulnar side of the wrist and then arched across the volar forearm back to the ulnar side at the elbow. At the elbow, the incision is curved just radially to the medial epicondyle across the elbow flexion crease, and the deep fascia is released. At the antecubital fossa, a fibrous band overlying the brachial artery and median nerve is carefully released. This incision allows for soft tissue coverage of underlying neurovascular structures at the wrist and elbow and prevents soft tissue contractures from developing at flexion creases. A second straight dorsal incision can be made to release the mobile wad if necessary.

Fasciotomy of the Hand

The hand has a unique anatomy with 10 separate fascial compartments: 4 dorsal and 3 volar interossei, thenar muscles, hypothenar muscles, and the adductor pollicis muscle. Fasciotomy consists of four incisions (Fig. 151.8). One incision on the radial side of the thumb metacarpal releases the thenar compartment. A dorsal incision over the index finger metacarpal is used to release the first and second dorsal interossei, to reach the ulnar-to-index finger metacarpal, and to release the volar interossei and adductor pollicis muscle. A dorsal incision over the ring finger metacarpal is used to release the third and fourth dorsal interossei and to reach down along the radial aspect of the ring finger and small finger metatarsal to release volar interossei. An incision placed at the ulnar aspect of the small finger is used to release the hypothenar muscles.

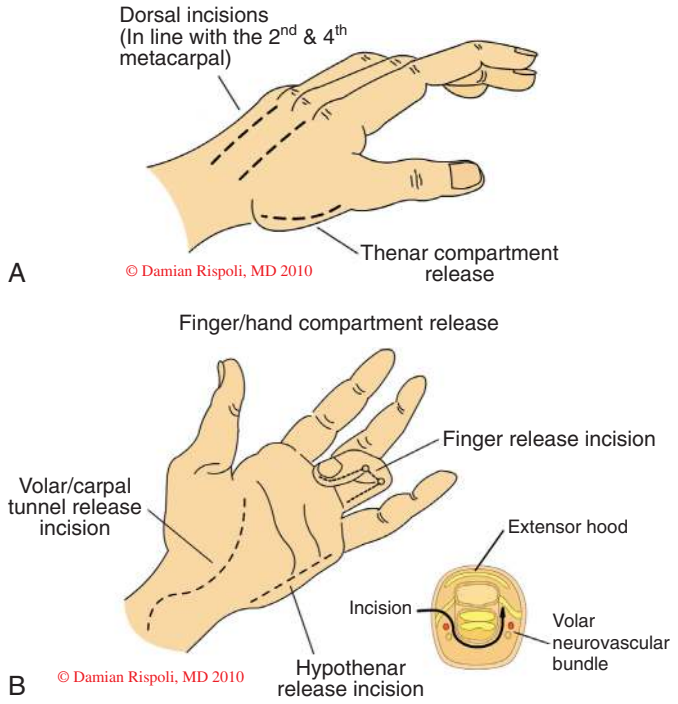

Fig. 151.8 Fasciotomy of the hand. Dorsal (**A**) and volar (**B**) aspects. (From Wheeless CR. *Wheeless' Textbook of Orthopaedics.* Towson, MD: Data Trace; 2014. © 2010, Damian Rispoli, MD.)

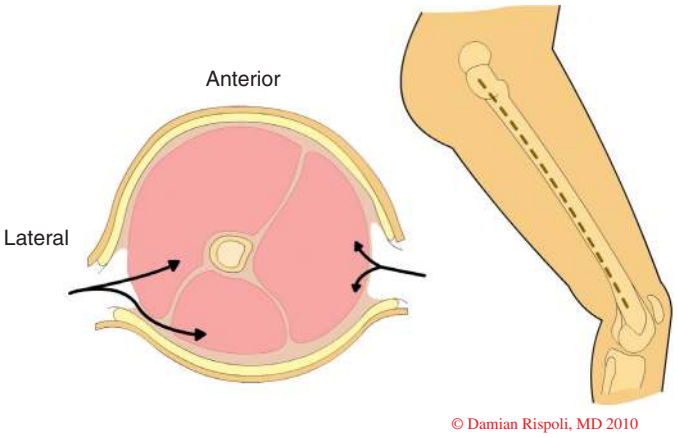

Fig. 151.9 Schematic presentation of fasciotomy of the thigh. (From Wheeless CR. Wheeless' Textbook of Orthopaedics. Towson, MD: Data Trace, 2014. © 2010, Damian Rispoli, MD.)

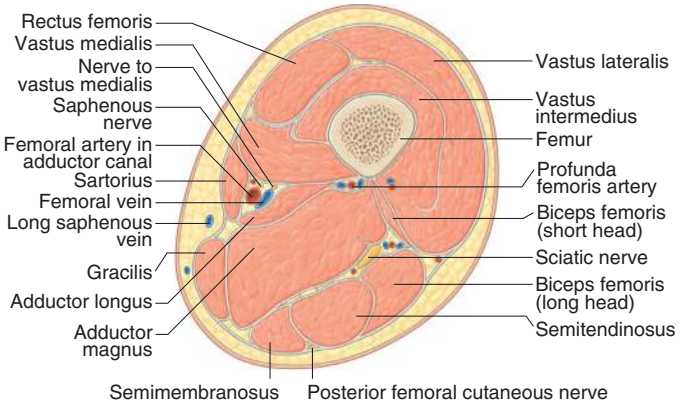
FASCIOTOMY OF THE LOWER EXTREMITY

The lower extremity is anatomically divided into three parts: thigh, lower leg, and foot. As in the upper extremity, each anatomic segment has a different number of compartments with various muscle functions. Techniques for release of these compartments are discussed separately as well.

Fasciotomy of the Thigh

The thigh has three compartments: anterior (quadriceps), medial (adductors), and posterior (hamstrings) (eFig. 151.3). Because of the large potential volume, compartment syndrome and blending of fascial compartments with the hip (allows extravasation of blood outside compartments) in the thigh are less likely to occur but can be seen especially in patients with high-energy femoral fractures or hip fractures. Fasciotomy consists of lateral incisions made from the greater trochanter to the lateral condyle of the femur. The iliotibial band is incised, and the vastus lateralis is reflected off the intermuscular septum bluntly, thereby releasing the anterior compartment. The intermuscular septum is then incised over the length of the incision, releasing the posterior compartment. This release should not be done close to the femur because a series of perforating vessels pass through the septum posteriorly to anteriorly near the bone. The medial compartment is released through separate anteromedial incisions (Fig. 151.9).



eFig. 151.3 Anatomy of the compartments of the thigh. (From Standring S, Borley NR, Gray H. *Gray's Anatomy,* 40th ed. Edinburgh, Scotland: Churchill Livingstone; 2008.)

Fasciotomy of the Lower Leg

Lower extremity compartment syndrome is the most common because of the unique anatomy of compartments. Most of the studies on compartment syndrome have been conducted on this part of the body, and most of the current knowledge about epidemiology and treatment is based on lower extremity compartment syndrome studies. Reported predictors for developing ACS of the lower leg are plateau fractures type Schatzker VI, especially when combined with shaft or fibular fractures, high energy mechanism, and fracture length.[87] The lower leg has four compartments: lateral (peroneal brevis and longus), anterior (extensor hallucis longus muscle, extensor digitorum longus muscle, tibialis anterior muscle, and peroneus tertius), superficial posterior (gastrocnemius and soleus), and deep posterior (flexor hallucis longus muscle, flexor digitorum longus muscle, and tibialis posterior muscle) (eFig. 151.4). The anterior compartment is the most commonly involved, followed by the deep posterior compartment. In the case of compartment syndrome of any of the compartments, release of all four is generally recommended. Some authors recommend selective fasciotomy of only the affected compartment as a less invasive and feasible treatment option, but recommend further comparative studies.[88]

There are two surgical techniques for release of all four compartments in the lower leg: the one-incision technique (Figs. 151.10 and 151.11) and two-incision technique (Fig. 151.12). There is no strong evidence on which technique has an advantage over the other. The only retrospective study in the setting of tibial fractures comparing the two methods found similar infection and nonunion rates.[89] The one-incision technique resulted in only one surgical wound and fewer related complications in one study.[90] It seems that the choice for fasciotomy can be based on surgeon experience, and, because of simplicity, the two-incision technique is more often used.

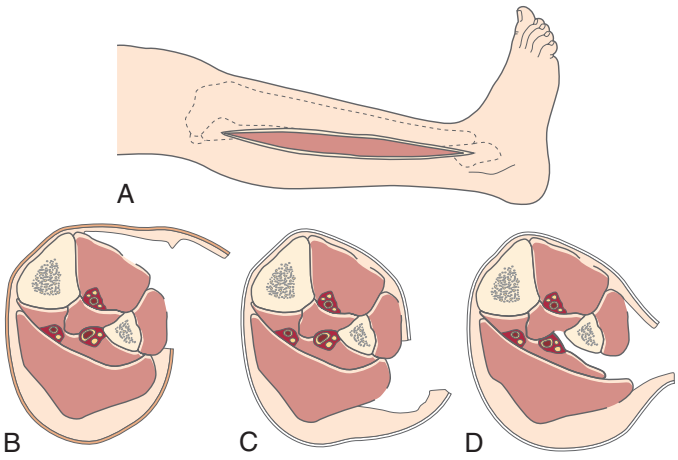


Fig. 151.10 Single-incision fasciotomy of the lower leg. **A,** Lateral skin incision from the fibular neck to 3–4 cm proximal to the lateral malleolus. **B,** The skin is undermined anteriorly, and a fasciotomy of the anterior and lateral compartments is performed. **C,** The skin is undermined posteriorly, and a fasciotomy of the superficial posterior compartment is performed. **D,** An interval between the superficial posterior and lateral compartments is developed. The flexor hallucis longus muscle is dissected subperiosteally off the fibula and retracted posteromedially. The fascial attachment of the posterior tibial muscle to the fibula is incised to decompress the muscle. (From Davey JR, Rorabeck CH, Fowler PJ. The tibialis posterior muscle compartment: An unrecognized cause of exertional compartment syndrome. *Am J Sports Med.* 1984;12:391–397.)

One-Incision Technique

The one-incision technique is technically more difficult, as it is difficult to visualize the deep posterior compartment, and therefore there is an increased risk of injury to the peroneal artery and nerve. The technique starts with a skin incision 1–2 cm anterior and parallel to the fibula, just inferior to the fibular head, and 3–4 cm proximal to the lateral malleolus. An anterior flap enables exposure of the anterior and lateral compartments. Longitudinal incisions are made in the fascia, and care must be taken to avoid damage to the common, superficial, and deep peroneal nerves at the fibular head. A lateral flap is exposed more posteriorly to visualize the superficial posterior compartment. The gastrocnemius muscle should be identified, and the fascia is incised longitudinally. The deep posterior compartment is identified later, after exposure of the posterior side of the fibula with dissection of the soleus muscle. Fasciotomy of the deep posterior compartment is performed at the medial border of the fibula. Here, peroneal vessels should be retracted and protected posteriorly to avoid injury (see Fig. 151.10).

A recently described variant of the one-incision technique uses a paratibial route to release the deep posterior compartment rather than a transfibular or parafibular route (see Fig 151.11). This affords a faster fasciotomy with a smaller flap and avoids potential damage to the neurovascular bundle and lessens the risk of injury to the peroneal nerves, which could occur with dissection of the posterior aspect of the fibula.[91]

Two-Incision Technique

This technique uses medial and lateral longitudinal incisions that should be long enough to completely release all four compartments. In adults, incisions can be up to 30 cm long. The lateral incision starts about 5 cm lateral to the anterior border of the tibia. Underlying the incision are the fascial tissues of the anterior and peroneal compartments; these are identified and released. The intermuscular septum should be identified to ensure that both compartments are released. Care must be taken to not damage the common peroneal nerve proximally as it passes around the fibular head; therefore skin incisions should not reach the fibular head level. Distally, the skin incision ends about 5 cm above the lateral malleolus. The medial incision of the two-incision technique starts 2 cm medial to the tibial margin. It is used to release both posterior compartments. Care must be taken to avoid saphenous nerve and vein damage, and these structures should be identified before fasciotomy of these compartments. The superficial posterior compartment is decompressed by incising the gastrocnemius fascia in a longitudinal direction proximally to distally. The posterior compartment is decompressed by dividing the attachments of the soleus muscle to the tibia (see Fig. 151.12).

Fasciotomy of the Foot

Acute compartment syndrome of the foot most commonly occurs because of crush injury, and fasciotomy is rarely needed. There are four major compartments of the foot: intraosseus, lateral, central (calcaneal), and medial (eFig. 151.5). They are further divided into smaller muscle groups, so there are nine compartments in the foot, but this number is controversial (eFig. 151.5). Common needle insertion sites to measure the intracompartmental pressures of the foot are shown in Fig. 151.13. Whereas each of the compartments should generally be released, some debate exists whether the superficial compartment of the dorsal central compartment, which contains the flexor digitorum brevis muscle, should be included. A dorsal approach is most commonly used and requires less dissection than the other two. It begins with dual dorsal longitudinal incisions over the medial side of the second metatarsal bone and the lateral side of the fourth metatarsal bone. Each of the four interosseous compartments is released first between the metatarsal bones. The medial

(From Lutter C, Schöffl V, Hotfiel T, et al. Compartment syndrome of the foot: An evidence-based review. *J Foot Ankle Surg.* 2019;58[4]:632–640.)

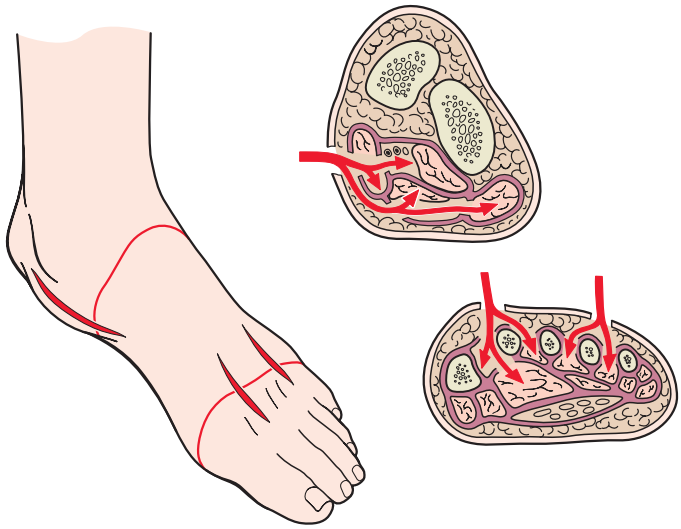

Fig. 151.14 **Fasciotomy of the foot. Medial and dorsal approaches.** (From Banerjee R, Nickisch F, Easley ME, et al. Foot injuries. In Browner BD, Jupiter JB, Levine AM, et al, eds. *Skeletal Trauma,* 4th ed. Philadelphia, PA: Saunders; 2009.)

compartment may be released by accessing a space medial to the second metatarsal; the lateral compartment is released by accessing a space lateral to the fourth metatarsal bone. The calcaneal compartment lies underneath the second interosseous space and can be released through a medial incision. The superficial compartment is accessed through the calcaneal compartment by blunt dissection of the adductor hallucis muscle. Sometimes release of this compartment is not required, because it contains predominantly tendons of the finger flexors and is not a "true" muscular compartment. Fasciotomy approaches to the foot compartments are shown in Fig. 151.14.

POTENTIAL COMPLICATIONS

Delay of treatment of compartment syndrome can lead to irreversible complications and, left untreated, can lead to death. The initial management should be focused not only on preservation of tissue viability in the compartment but also on the initial management of systemic complications of reperfusion injury. This requires restoration of intravascular volume, prevention of hyperkalemia, and treatment of metabolic acidosis and myoglobinuria, which may lead to acute kidney injury. Complications may also occur as a sequela of surgical procedures performed and wound management. Late sequelae of compartment syndrome include persistent hypoesthesia, dysesthesia, persistent motor weakness, infection, myoglobinuric renal failure, contractures, amputation, and death. In one study, persistent sequelae were reported to be associated with a higher number of operations, postfasciotomy complications, closures with skin grafting, and increased time to closure.[92]

Technical complications of fasciotomy are preventable when considering the anatomy of important structures. Persistent or recurrent compartment syndrome can occur if fascial incisions are not adequate to permit complete decompression of the compartment or if selective fasciotomy has been performed.[84]

Persistent neurologic deficits after fasciotomy are common. Nerve injury can occur because of the initial traumatic event, prolonged

ischemia, or as a consequence of fasciotomy dissection and tissue débridement. The most common neuropathic syndrome is altered sensation at the margins of the incision; chronic pain syndromes are also described.[93] Impaired neurologic function after lower extremity fasciotomy is described in 7%–36% of injured limbs.[94–96]

Wound complications after fasciotomy may occur immediately or be delayed for months to years. Early wound complications occur in up to 40% of patients after lower extremity fasciotomy.[94,97,98] Risk factors are related to the presence of vascular injury, lower extremity site, and premature or delayed closure of the wound.[98] Wound infection occurs in 4%–7% of extremity fasciotomies.[94,97] Prophylactic antibiotics should be given at the time of fasciotomy and discontinued after 24 hours. Repeated débridement of devitalized tissue may protect from severe wound infections and sepsis. Late wound complications are reported in 4%–38% of limbs.[93,94,97,98] Delayed wound complications include tethered scars and tendons, muscle hernias, and poor healing and ulceration, especially in patients with underlying vascular diseases. Venous insufficiency can predispose patients to chronic venous disease after fasciotomy. Tibial diaphyseal fracture healing in patients with compartment syndrome has been found to be delayed, and the rates of nonunion are reported to be higher compared with patients without compartment syndrome.[99]

Acute extremity compartment syndrome is associated with significant risk of limb loss.[100] Major amputation will be required in 5%–21% of limbs treated with fasciotomy.[94,95,97,98,100] Combined orthopedic and vascular injury, other severe injuries, and systemic factors may contribute to the need for amputation in severely injured patients. The highest amputation rate occurs in patients with severe vascular injuries with occlusion.[94] A large review of the National Trauma Data Bank for lower extremity vascular injury comparing early versus late fasciotomy findings suggests that appropriate implementation of early fasciotomy may reduce amputation rates.[101] Amputation of the upper extremity after fasciotomy is rare.

The most severe cases of compartment syndrome left untreated may cause death. Reported mortality ranges from 11% to 25% and depends on the epidemiology of the compartment syndrome.[84,95,97,102] Mortality is most often the result of massive trauma, severe hypovolemic shock, and multisystem organ failure and cannot be attributed only to the need for fasciotomy. This is especially true in severely injured patients with massive shock resuscitation where the mortality after fasciotomy in one study reached 67%.[26]

CONCLUSION

The patient who undergoes fasciotomy requires a physical therapy program to regain function. Postoperative care and rehabilitation are just as important as the procedure itself. During the immediate postoperative period, weight bearing is limited, and assistive devices (e.g., crutches) are needed. Within a few days, and with adequate pain control, the use of crutches can be discontinued. The rehabilitation program then involves range of motion (ROM) and flexibility exercises involving the muscles of the affected compartment. Adjacent joints need to be exercised to maintain their normal ROM.

Once the patient is able to ambulate with a normalized gait pattern, a program of graduated resistive exercises (depending on the patient's regular activities or work) is initiated. In the case of athletes, sports-specific exercises are started with the intention of returning to a regular athletic schedule. Cross training is also beneficial for these athletes. Activities such as swimming, pedal exercises, water jogging, or running help athletes regain muscle strength and flexibility without loading the affected compartment.

With surgical intervention for decompression, occupational therapy consultation should be considered early in the postoperative period. Appropriate treatment and assessment of the patient's deficits with regard to activities of daily living and for instruction in the use of any necessary assistive devices should be assessed.

KEY POINTS

- Compartment syndrome is a life-threatening condition and should be treated as soon as it is diagnosed.
- One of the first signs of compartment syndrome is a swollen extremity with pain out of proportion and increasing requirements for analgesia.
- Unfortunately, clinical signs alone are inadequate in the diagnosis of ACS because of well-documented poor sensivity.
- Critically ill patients, especially after severe trauma with massive fluid resuscitation, and youth patients with high energy mechanism and an associated underlying fracture, require special attention and frequent evaluation.
- Diagnosis of compartment syndrome is very likely when intracompartmental pressure reaches 45 mm Hg or the difference between diastolic blood pressure and intracompartmental pressure is less than 30 mm Hg for more than 2 hours.
- Treatment of compartment syndrome is primarily surgical with prompt release of all affected muscle compartments by fasciotomy.

ANNOTATED REFERENCES

Duckworth AD, McQueen MM. The diagnosis of acute compartment syndrome. A critical analysis review. *JBJS Rev.* 2017;5(12):e1. doi:10.2106/JBJS.RVW.17.00016.
Although pain is characteristically the index sign associated with the development of acute compartment syndrome, clinical findings in isolation have been proven to have inadequate diagnostic performance characteristics, with sensitivity ranging from 13% to 54%.

Ebraheim NA, Abdelgawad AA, Ebraheim MA, et al. Bedside fasciotomy under local anesthesia for acute compartment syndrome: A feasible and reliable procedure in selected cases. *J Orthop Trauma.* 2012;13:153–157.
Standard compartment syndrome treatment involves a long skin incision and fasciotomy of all involved compartments and débridement of obvious nonviable tissue. Usually, this procedure is performed under general or spinal anesthesia. Various reasons can cause delay in performing the surgery. The authors of this study conclude that bedside fasciotomy under local anesthesia can be done safely and effectively to avoid delay in compartment release.

Hammerberg EM, Whitesides Jr. TE, Seiler III JG. The reliability of measurement of tissue pressure in compartment syndrome. *J Orthop Trauma.* 2012;26:24–31, discussion 32.
There are numerous commercially available methods of tissue pressure measurement (e.g., the Stryker device). To achieve adequate accuracy when measuring intracompartmental pressure without these devices, authors of this study concluded that the slit catheter, side-ported bevel-tipped needle, or an 18-gauge needle, when appropriately used with current electronic transducer monitoring, may be used clinically with confidence.

Jauregui JJ, Yarmis SJ, Tsai J, et al. Fasciotomy closure techniques: A meta-analysis. *J Orthop Surg.* 2017;25(1):2309499016684724.
The authors evaluated the risks and success rates of the three major techniques for compartment syndrome fasciotomy closure by reviewing all literature published to date. Success was defined as all wounds that could be closed without skin grafting, amputation, or death. The highest success rate was observed for dynamic dermatotraction and gradual suture approximation, whereas vacuum-assisted closure had the lowest complication rate.

Kosir R, Moore FA, Selby LH, et al. Acute lower extremity compartment syndrome (ALECS) screening protocol in critically ill trauma patients. *J Trauma.* 2007; 63:268–275.
In this study during a 6-month period, the incidence of acute lower extremity compartment syndrome (ALECS) in screened patients was surprisingly high

at 20% (nine patients). These were patients with severe injuries with an Injury Severity Score of 32.0 ± 12.5 who exhibited significant volume depletion, with a base deficit of 12.9 ± 5.9 mEq/L and a lactate level of 13.0 ± 5.2 mmol/L, requiring large-volume resuscitation. Acute lower extremity compartment syndrome was associated with an exceedingly high mortality rate at 67%. Mortality in severely injured patients is most often the result of massive trauma, severe hypovolemic shock, and multiple organ failure and cannot be attributed only to the need for fasciotomy.

Marchand LS, Working ZM, Rane AA, et al. Compartment syndrome in tibial plateau fractures: Do previously established predictors have external validity? *J Orthop Trauma*. 2020;34(5):238–243.

Injuries of the lower extremity are the most common cause of extremity compartment syndrome. In this retrospective review 513 patients with tibial plateau fractures treated operatively over a 10-year period (OTA/AO 41B1-3 & 41C1-3; Schatzker I-VI) were analyzed. This study confirms that several factors are associated with the development of ACS. Reported predictors for developing ACS of the lower leg are plateau fractures type Schatzker VI, especially when combined with shaft or fibular fractures, high energy mechanism, and fracture length. The presence of each independent predictor had a cumulative effect such that when more than one variable is present, the chance of ACS increases.

McQueen MM, Court-Brown CM. Compartment monitoring in tibial fractures. The pressure threshold for decompression. *J Bone Joint Surg Br.* 1996;78:99–104.

In this early prospective study of 116 patients with tibial diaphyseal fractures, continuous monitoring of anterior compartment pressure for 24 hours was studied. Three patients developed acute compartment syndrome (2.6%). In their series, the use of a differential pressure (ΔP) of 30 mm Hg as a threshold for fasciotomy led to no missed cases of acute compartment syndrome. The authors recommend that decompression be performed if the the differential pressure level drops to under 30 mm Hg.

Thromboembolization and Thrombolytic Therapy

Anthony J. Lewis and Edith Tzeng

INTRODUCTION

Thrombolytic agents comprise a diverse group of compounds that indirectly initiate the lysis of a thrombus. After the initiation of the coagulation cascade, fibrinolytic mechanisms are concomitantly activated to prevent unconstrained thrombosis. Fibrinolysis begins with the cleavage of proenzyme plasminogen to plasmin, which hydrolyzes key bonds within a fibrin clot matrix, resulting in clot lysis (Fig. 152.1). Thrombolytic agents function by converting plasminogen to plasmin. Different thrombolytic agents vary in their specificity for plasminogen, metabolic half-life, and antigenicity (Table 152.1).

DRUGS

Streptokinase

Streptokinase, a protein produced by beta-hemolytic streptococci, was identified as having fibrinolytic properties in the 1930s and was the first compound to be used clinically as a thrombolytic drug.[1,2] Streptokinase complexes with plasminogen and converts it to plasmin. However, one of the major drawbacks of using streptokinase is its antigenicity, as streptococcal infection may induce antibody formation. Mild allergic reactions occur in 2%–5% patients; however, severe anaphylactic reactions may also occur.[3]

Urokinase

Urokinase is a thrombolytic protein that was initially isolated from human urine and has been used clinically for over 30 years. At present, it is isolated from human fetal renal tissue cultures. Unlike streptokinase, urokinase enzymatically cleaves plasminogen. In 1999 urokinase was removed from the U.S. market after concerns raised by the Food and Drug Administration (FDA) regarding its safety.[4] It was reintroduced in the United States in 2002 after rigorous testing showed that urokinase preparations were free of human pathogens. However, at present, it is only approved for treating pulmonary embolism (PE). Pro-urokinase, also known as single-chain urokinase-type plasminogen activator, is a single-chain precursor of urokinase that is converted into two-chain urokinase by hydrolysis.

Tissue Plasminogen Activator

Tissue plasminogen activator (tPA), which was first isolated in 1981, is a naturally occurring protein synthesized by human vascular endothelial cells.[5] Several recombinant variants of tPA are available, including alteplase (rtPA, approved by the FDA in 1987) and duteplase. Other forms of tissue-type tPAs include reteplase (rPA), tenecteplase (TNK-tPA), and lanoteplase (nPA). Recombinant tPAs are nonantigenic and show specificity for fibrin-bound plasminogen. They also avoid the infectious risks associated with products isolated from cultured human tissues. Newer recombinant tPAs have improved pharmacokinetics that enable their convenient administration, such as bolus dosage.

Other Agents

Other compounds that have been developed and investigated include vampire bat plasminogen activator (isolated from the saliva of vampire bat), fibrolase (isolated from the venom of southern copperhead snake), and staphylokinase (isolated from *Staphylococcus aureus*). However, data on these compounds are relatively limited; hence, they are rarely used clinically.

CLINICAL INDICATIONS

Myocardial Infarction

Acute myocardial infarction (AMI) is associated with a significant healthcare burden in industrialized countries. Modern management of AMI focuses on rapidly restoring perfusion to optimize myocardial salvage. Primary percutaneous coronary interventions are superior to thrombolytic therapy when employed as an early reperfusion strategy after AMI and are the first-line therapy.[6] However, logistic barriers hinder the access of patients with AMI who require interventional cardiology services to perform early percutaneous coronary intervention (PCI). On the other hand, fibrinolytics are administered in almost all hospitals.

Lytic therapy was first used for treating AMI in the 1950s.[7] The Fibrinolytic Therapy Trialists' Collaborative Group performed a meta-analysis by using results obtained from over 58,000 patients treated with thrombolytics.[8] This meta-analysis showed that treatment with thrombolytics resulted in approximately 25% reduction in mortality in patients with ST-segment elevation or bundle branch block. Since then, numerous studies have evaluated the efficacies, dosage strategies, administration routes, and adjunctive therapies with these agents for rapidly restoring blood flow in thrombosed coronary arteries.

Early studies such as ISIS-2 and GISSI focused on the use of streptokinase and showed 18% and 25% reduction in mortality after 3 and 5 weeks, respectively.[3,9] Similar results were obtained after 1- to 10-year follow-up.[10] The efficacy of tPA was studied in the GUSTO-1 trial, which examined four dosing regimens for the treatment of MI in 41,021 patients.[11] This study used "accelerated" tPA dosage in which two-thirds of the total dose were administered in the first 30 minutes rather than over a 3-hour period. This dosage regimen resulted in a modest but significant reduction in 30-day mortality (6.3%) compared with streptokinase (7.4%) or a combination of tPA and streptokinase (7.0%). The GUSTO angiographic substudy showed that differing patency rates among patients treated with either agent accounted for this difference in clinical efficacy. However, a subsequent meta-analysis of this approach failed to validate the survival advantage.[12]

TABLE 152.1 Properties of Commonly Used Thrombolytics

	Streptokinase	Urokinase	Tissue Plasminogen Activator (tPA)
Source	Group C *Streptococcus*	Human fetal kidney	Recombinant
Lytic	First	First (prourokinase: second)	Second (non-alteplase tPAs: third)
Generation	Anistreplase		
Available compounds	APSAC (half-life, 70–120 min)	Prourokinase	Alteplase, duteplase, reteplase (rPA), tenecteplase (TNK-tPA), and lanoteplase (nPA)
Molecular weight (kD)	47	35–55	63–70
Half-life (min)	18–23	14–20	3–4
Metabolism	Hepatic	Hepatic	Hepatic
Antigenicity	Yes	No	No
Fibrin specificity	Minimal	Moderate	Moderate
Plasminogen binding	Indirect	Direct	Direct

APSAC, Anisoylated plasminogen streptokinase activator complex.

Newer-generation tPAs such as r-PA and TNK-tPA can be used to administer a bolus dosage. The GUSTO III trial compared reteplase, the recombinant deletion mutant of tPA, with accelerated tPA in 15,059 patients. This trial did not detect any survival advantage with r-PA and showed that rates of intracranial hemorrhage (ICH) were similar after treatment with r-PA and tPA (0.91% and 0.87%, respectively).[13] The ASSENT-2 trial showed that 30-day mortality and ICH rates were identical in patients treated with TNK-tPA and those treated with accelerated tPA.[14] Although r-PA and TNK-tPA are not superior to tPA in terms of safety and efficacy, their pharmacokinetics allow simplified administration compared with that of accelerated tPA.

Adjunctive therapies such as aspirin, clopidogrel, and antithrombin agents improve the results of lytic therapy. Fibrinolysis strips fibrin from an occluding thrombus; the exposed thrombin then initiates platelet aggregation and subsequent rethrombosis.[15] Antiplatelet agents are essential to reducing this process. Heparin is typically used to maintain activated partial thromboplastin time (aPTT) between 50 and 70 seconds. If heparin-induced thrombocytopenia is suspected, direct thrombin inhibitors such as hirudin or bivalirudin are viable options.[16] Another development is the introduction of glycoprotein IIb/IIIa receptor blockers such as abciximab (ReoPro), eptifibatide (Integrilin), and tirofiban (Aggrastat).[17–19] Despite some promising early results, no randomized trial has yet to show a benefit of these agents on mortality.[20–23] A meta-analysis of 11 randomized trials assessing thrombolytic treatment with and without abciximab suggested a significantly increased risk of major bleeding events (5.2% vs. 3.1%, $P < 0.001$) with abciximab.[24]

The timing of diagnosis and institution of thrombolytic therapy is critical.[25,26] Patients with AMI who are treated with thrombolytic agents at more than 4 hours after symptom onset have twofold to threefold higher 30-day and 6-month mortality rates than patients treated within 2 hours of symptom onset.[27] The Late Assessment of Thrombolytic Efficacy study reported 1-year mortality rates of 17.6% and 15.8% in patients treated with rtPA at greater than 3 hours and less than 3 hours, respectively, after symptom onset.[28] Therefore prehospital administration of thrombolytics is recommended in select patients showing ST-segment elevation on electrocardiogram.[29,30]

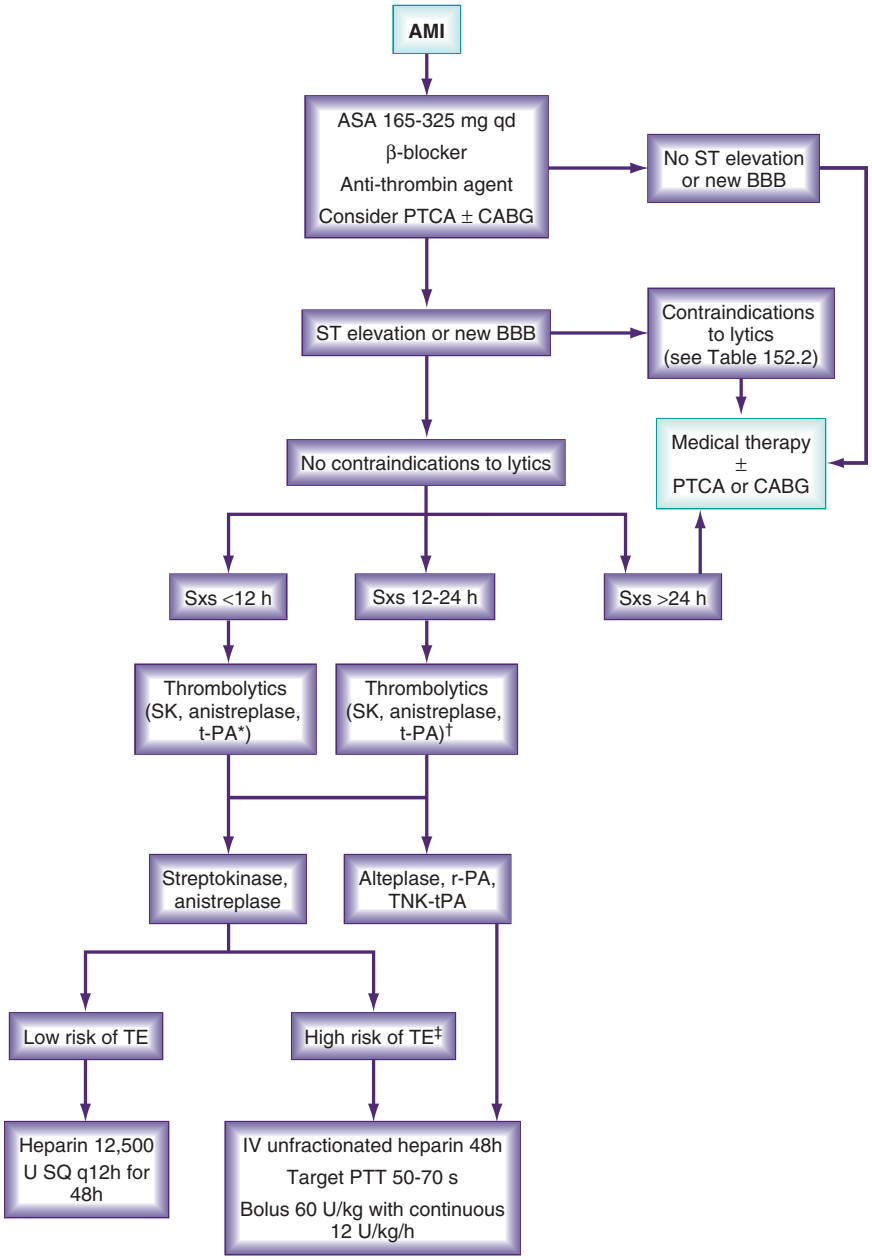

Fig. 152.2 Algorithm for treating acute myocardial infarction.*Preferred for symptom duration of <6 hours; †grade 2b data; ‡anterior myocardial infarction, existing heart failure, previous embolus, atrial fibrillation, and left ventricular thrombus. *AMI,* Acute myocardial infarction; *BBB,* bundle branch block; *CABG,* coronary artery bypass grafting; *PTCA,* percutaneous transluminal coronary angioplasty; *PTT,* partial thromboplastin time; *SK,* streptokinase; *SQ,* subcutaneous; *Sxs,* signs and symptoms; *TE,* thromboembolism. (Data from 1999/2002 ACC/AHA Guideline Update and 2001 ACCP Consensus Conference.)

The currently accepted guidelines for lytic therapy of AMI are outlined by the American College of Chest Physicians in the eighth edition (2008) of *Evidence-Based Clinical Practice Guidelines* and by the American College of Cardiology/American Heart Association in their 2013 guidelines.[31,32] A treatment algorithm for AMI is shown in Fig. 152.2. The established guidelines indicate that patients who are most likely to benefit from fibrinolytic therapy are those with ST-segment elevation, symptoms that began within 3 hours, anticipated delay in reaching a PCI facility, and low bleeding risk. However, the value of thrombolytic agents in the management of unstable angina remains unproven thus far. At present, lytic therapy is not used for treating acute coronary syndrome without ST-segment elevation in two or more contiguous leads or without new-onset bundle branch block. Contraindications to lytic therapy in the setting of AMI are summarized in Table 152.2.

Since the development of thrombolytics, coronary angioplasty has become the gold standard for treating myocardial infarction (MI) with ST-segment elevation. A large meta-analysis of 7739 patients with ST-segment elevation who were randomized to receive thrombolytic therapy (76% receiving fibrin-specific lytics) or primary percutaneous transluminal coronary angioplasty (PTCA) showed that short-term (4- to 6-week) mortality in patients in the PTCA group

TABLE 152.2 Contraindications to Thrombolytic Therapy in the Setting of Acute Myocardial Infarction (With ST-Segment Elevation and/or New Bundle Branch Block)

Absolute Contraindications	Relative Contraindications
>24 hours since symptom onset	12–24 hours since symptom onset
Prior intracranial hemorrhage	Age >75 years
Stroke within the past year	Systolic blood pressure of >180 mm Hg or diastolic blood pressure of >110 mm Hg
Intracranial neoplasm	Bleeding disorder
Active bleeding/bleeding diathesis	Prior allergic reaction to thrombolytics
Suspected aortic dissection	Pregnant or lactating
Significant closed-head or facial trauma within 3 months	Prolonged cardiopulmonary resuscitation (>10 min)
	Recent internal bleeding (less than 2–4 weeks)
	Active peptic ulcer

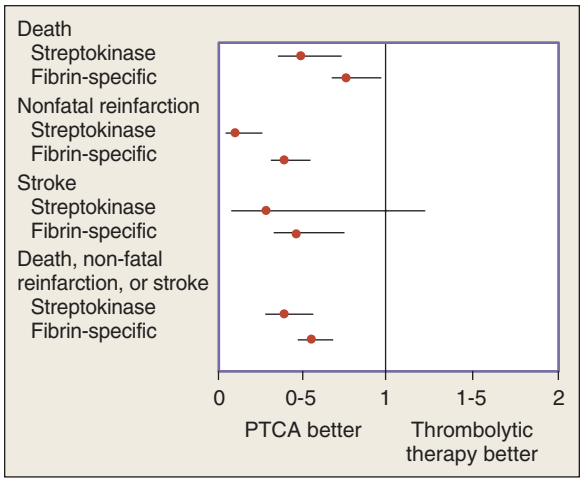

Fig. 152.3 Short-term clinical outcomes in patients treated with percutaneous transluminal coronary angioplasty and those treated with thrombolytic therapy. Odds ratios with 95% confidence intervals. (Reprinted with permission from Keeley EC, Boura JA, Grines CL. Primary angioplasty versus intravenous thrombolytic therapy for acute myocardial infarction: A quantitative review of 23 randomised trials. *Lancet*. 2003;361:13–20.)

was 7% compared with 9% in patients in the lytic therapy group ($P = 0.0003$).[6] Patients treated with primary PTCA showed lower rates of nonfatal reinfarction (3% vs. 7%) and stroke (1% vs. 2%) during follow-up in a smaller study.[33] Short-term results of this meta-analysis are summarized in Fig. 152.3.

Potential advantages of angioplasty over thrombolysis as the primary therapy for AMI are tempered by the recognition that results of angioplasty are highly dependent on the volume of cases at a given treatment center.[34–37] Moreover, many patients initially present to facilities where interventional cardiology services are not available for performing PCI, resulting in the use of thrombolytics before performing PCI. The Strategic Reperfusion Early After Myocardial infarction (STREAM) trial showed that fibrinolytic therapy, clopidogrel, and enoxaparin followed by PCI had improved outcomes as compared with primary PCI in patients with MI associated with ST-segment elevation who were unable to undergo PCI within 1 hour.[38] Moreover, the Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction (TRANSFER-AMI) trial showed a reduction in the composite endpoint of death, reinfarction, recurrent ischemia, new or worsened congestive heart failure, or cardiogenic shock within 30 days (11.0% vs. 17.2%; odds ratio [OR], 0.64; 95% confidence interval [CI], 0.47–0.87) in patients treated with early (<6 hours) PCI after thrombolytic therapy compared with those treated with standard therapy.[39] The ideal treatment for some patients may involve a combination of thrombolytic therapy, antithrombotic agents, antiplatelet agents, and PCI.

Stroke

Stroke is the third leading cause of death in the United States, affecting over 700,000 people per year. The majority of strokes are ischemic and result from sudden occlusion of the arteries that deliver blood to the brain. Traditional therapy for ischemic stroke includes anticoagulant and antiplatelet agents for medical support, followed by rehabilitation after the acute event. More recently, thrombolysis has emerged as a treatment for ischemic stroke. Similar to that for AMI, the efficacy of thrombolysis in the setting of stroke is highly time dependent because of the characteristics of the ischemic penumbra and is the highest when lytic treatment is initiated within 90 minutes after symptom onset.[40,41]

Use of thrombolytic therapies for ischemic stroke dates back to 1995 when the National Institute of Neurological Disorders and Stroke (NINDS) published a study on rtPA for treating acute ischemic stroke.[42] The trial examined the clinical efficacy of intravenous (IV) tPA administered within 3 hours of symptom onset. Administration of tPA did not improve neurologic function at 24 hours compared with administration of placebo. However, in the long term, patients who received tPA were 30% more likely to have minimal residual disability or were more likely to return to baseline functional status after 3, 6, and 12 months.[43] However, patients treated with tPA showed a higher incidence of intracerebral hemorrhage (6.4% vs. 0.6%, $P < 0.001$) at 36 hours. Nevertheless, mortality at 3 months was not significantly different (17% vs. 21%, $P = 0.30$). The results of this study led to FDA approval of IV tPA for the treatment of acute ischemic stroke when diagnosed within 3 hours of symptom onset.

Other early randomized trials on IV tPA for treating acute stroke were the European Cooperative Acute Stroke Study (ECASS-I), ECASS-II, and ATLANTIS trials.[40,44–46] Although these trials did not reach significance for their primary outcome measure, they did show a significant benefit of using tPA within 6 hours of symptom onset for improving alternative outcome measures, thus supporting its clinical use. More recently, the ECASS-III trial showed a significant but modest benefit of tPA compared with that of placebo when administered within 3–4.5 hours of symptom onset with no difference in mortality.[47] Based on the results of this trial, Lansberg and colleagues calculated the number of patients deriving benefit per 100 treated as 28, 23, and 17 for the 0- to 1.5-, 1.5- to 3-, and 3- to 4.5-hour windows, respectively.[48] As a result of the ECASS III trial, IV tPA for the treatment of stroke within 3–4.5 hours has been supported by the Scientific Advisory Committee from the American Heart Association Stroke Council. The European Medicines Agency has approved the use of IV tPA within 4.5 hours of symptom onset even though the FDA has not approved tPA use at this time interval.[49] The third International Stroke Trial evaluated whether tPA had beneficial effects in patients treated within 6 hours of symptom onset and in patients older than 80 years. The 18-month follow-up showed no improvement in mortality in those treated with alteplase versus standard care alone (34.9% vs.

35.1%, $P = 0.85$), but a modest statistically significant improvement was observed in patients with a low (0–2) Oxford handicap scale score (35.0% vs. 31.4%; OR, 1.28; 95% CI, 1.03–1.57; $P = 0.024$).[50]

At present, IV tPA is the only drug and route of administration approved by the FDA for treating ischemic stroke. However, intraarterial (IA) administration of thrombolytics has also been investigated. This method requires a neurointerventionalist to place a catheter into the thrombosed vessel to directly infuse a thrombolytic. The Prolyse in Acute Cerebral Thromboembolism (PROACT II) study[51] randomized 180 patients with middle cerebral artery occlusion to receive IA prourokinase plus heparin versus heparin alone. This study showed that over 40% of patients receiving IA prourokinase plus heparin had improved modified Rankin score of ≤2 compared with only 25% of the patients receiving heparin alone. The Japanese MELT trial on IA urokinase was halted early by the trial's independent monitoring committee after the approval of IV tPA for stroke in Japan, and thus did not reach significance for its primary endpoint.[52] Nevertheless, secondary analysis of this study and combined analyses with PROACT trials suggested a benefit of IA urokinase.[53]

Interventional Management of Stroke trialists conducted a phase III trial to compare a standard dose of IV tPA with that of an IV tPA bridge for endovascular treatment.[54] The trial was stopped early because of futility. Patients treated with tPA and endovascular therapy did not show significant differences in 90-day mortality (19.1% vs. 21.6%, $P = 0.52$) or modified Rankin score of ≤2 (40.8% vs. 38.7%, absolute adjusted difference, 1.5 percentage points; 95% CI, −6.1 to 9.1) when compared with patients treated with tPA alone. More recent data have demonstrated a benefit for endovascular therapy in anterior circulation ischemic stroke. A meta-analysis pooling patient-level data from five randomized controlled trials showed the benefit of mechanical thrombectomy in this population when performed within 6 hours of symptom onset.[55] Patients undergoing mechanical thrombectomy were more than twice as likely to have a modified Rankin score ≤2 at 90 days (OR 2.35; 95% CI, 1.85–2.98; $P < 0.0001$). There was no difference in patient mortality. The 2019 American Stroke Association guidelines recommend that patients eligible for IV tPA treatment receive the treatment even if endovascular therapy is being considered.[56] At centers without neurointerventionalist availability, IV tPA administration can be initiated before transfer to centers with endovascular capability. Standard contraindications for IV thrombolytic therapy in patients with acute ischemic stroke were included in the exclusion criteria used in the NINDS study (Table 152.3).

TABLE 152.3 Contraindications for Thrombolytic Therapy in Ischemic Stroke

Contraindications	Relative Contraindications
Symptom duration of >6 hours	Symptom duration of 3–6 hours
History of intracranial hemorrhage	Witnessed seizure
Evidence of active bleeding	Gastrointestinal or urinary
Platelet count of <100,000/mm^3	Hemorrhage within 3 weeks
	Recent lumbar puncture, noncompressible arterial puncture site
Prior stroke, head trauma, or intracranial surgery within 3 months	Systolic blood pressure of >185 mm Hg or diastolic blood pressure of >110 mm Hg
Rapidly improving or only minor symptoms Major surgery within 14 days	Mass effect or hypodensity of more than one-third of middle cerebral artery distribution on head computed tomography
Known arteriovenous malformation or intracranial aneurysm	Glucose level of <50 or >400 mg/dL Elevated partial thromboplastin time or international normalized ratio (>1.7)

Pulmonary Embolism

PE is a major source of morbidity and mortality in hospitalized patients, accounting for up to 15% of in-hospital deaths.[57] Anticoagulation has been the mainstay of treatment for PE since it was first shown to be beneficial in 1960.[58] This has been historically achieved with IV unfractionated heparin (UFH), although subcutaneous (SC) low-molecular-weight heparin (LMWH), SC fondaparinux, and monitored or fixed-dose SC UFH may also be used.[59] Despite the proven efficacy of anticoagulation for treating acute PE, a significant proportion of patients show incomplete resolution of their occlusion, with subsequent organization of the thrombus and obstruction of the involved pulmonary artery.[60–62] Therefore thrombolysis as a treatment for PE to initiate rapid and complete resolution of thrombus became a therapeutic approach.

The Urokinase Pulmonary Embolism Trial (UPET) was one of the initial studies to evaluate thrombolytic therapy for treating PE.[60] This prospective study did not show any improvement in mortality or perfusion rate after 5 days of lytic therapy. However, the UPET and the Urokinase-Streptokinase Embolism Trial showed improvements in small-vessel patency at 2 weeks and 1 year after thrombolytic therapy as compared with anticoagulation therapy alone.[63,64] A 7-year follow-up of this cohort of patients suggested that the risk of pulmonary hypertension decreased after thrombolytic therapy, presumably through clot dissolution.[65]

Current CHEST guidelines recommend thrombolytic therapy for the treatment of patients with massive PE with hemodynamic instability.[66] In addition, patients with right ventricular dysfunction or refractory hypoxemia in the setting of preserved systemic arterial blood pressure may benefit from thrombolytic therapy. Right heart strain is correlated with an intermediate risk of death.[67] Patients with submassive PE showed an improved clinical course after treatment with systemic IV thrombolytic therapy compared with anticoagulation alone; however, systemic thrombolysis did not improve long-term mortality.[68] Pulmonary Embolism Thrombolysis (PEITHO) investigators conducted a randomized trial involving 1006 patients with PE, right ventricular dysfunction, and cardiac enzyme elevation to compare TNK-tPA and heparin with placebo and heparin. The primary outcome of death or hemodynamic compromise within 7 days was reduced in patients treated with TNK-tPA as compared with anticoagulation alone (2.6% vs. 5.6%; OR, 0.44, 95% CI, 0.23–0.87; P = 0.02), although not without complications—patients receiving thrombolytic therapy had higher rates of stroke (2.4% vs. 0.2%, $P = 0.003$) and major bleeding (6.3% vs. 1.2%, $P < 0.001$). However, 30-day mortality was similar between the treatment arms (2.4% vs. 3.2%, $P = 0.42$).[69]

Although no significant differences exist among different thrombolytic regimens, IV tPA is preferred because of its short infusion time.[70,71] FDA-approved regimens for treating acute PE are listed in Table 152.4. Major hemorrhagic complications occur in approximately 12% of patients irrespective of the lytic agent used.[72] Fear of bleeding after thrombolytic administration has led some centers to investigate the use of "half-dose" thrombolysis, which has a low bleeding rate, although published series are small.[73] Propensity-matched comparison of 548 pairs of patients with PE undergoing half-dose versus standard-dose systemic thrombolysis revealed similar overall in-hospital mortality (13.0 vs. 15.1%, half-dose vs. full-dose, $P = 0.30$), but a higher percentage of patients receiving half-dose therapy required escalation

TABLE 152.4 Food and Drug Administration–Approved Regimens for Treating Pulmonary Embolism

Drug	Systemic Administration
Streptokinase	250,000 U over 30 minutes, followed by 100,000 U/hr for 24 hours
Urokinase	4400 U/kg over 10 minutes, followed by 4400 U/kg/hr for 12–24 hours
tPA (alteplase)	100 mg over 2 hours

of treatment in the form of secondary thrombolysis or catheter-based thrombectomy.[74] Costs were higher in the half-dose group as a result. Further, the theoretical benefit of lower intracranial bleeding risk was not realized in this series (0.5 vs. 0.4%, $P = 0.67$).

Verstraete and colleagues performed the first trial to compare direct pulmonary artery thrombolytic infusion with IV infusion.[75] However, this trial failed to show a benefit of pulmonary artery infusion. Other adjunctive techniques include use of ultrasound-producing catheters that may increase the permeability of tPA within a clot. A prospective randomized trial comparing the efficacy of ultrasound-assisted catheter-directed thrombolysis (USAT) with that of anticoagulation alone in patients with right heart strain showed the superiority of USAT in reversing heart strain within the first 24 hours.[76] Current guidelines do not support the use of catheter-directed thrombolysis (CDT) as a first-line therapy for PE because of the paucity of published trials addressing this question. The CHEST guidelines recommend catheter-directed therapies in patients who are at high risk for bleeding with systemic thrombolysis, patients who have failed systemic thrombolysis, and patients with impending cardiovascular collapse who may die before systemic thrombolytics can take effect.[66] Interest in catheter-directed therapy continues to rise. Catheter-based delivery of thrombolytics offers the potential to reduce hemorrhagic complications by dramatically reducing the total dose of tPA required—often 20% of systemic dosing.[77] Reported major hemorrhage rates were 1% or less.[77] A propensity-matched comparison of data from the National Inpatient Sample found an equivalent mortality rate between systemic and CDT among 1430 matched pairs, with a significantly reduced rate of intracranial hemorrhage in the catheter-directed lysis cohort (OR 0.47; 95% CI, 0.27–0.82; $P = 0.01$).[78] Randomized trials are necessary to compare systemic thrombolysis with catheter-directed therapy in a prospective fashion.

Deep Venous Thrombosis

The formation of deep venous thrombosis (DVT) is common in acutely ill patients, occurring in as many as 30% of intensive care unit patients despite prophylaxis.[79] Acute occlusion of the deep venous system leads to severe sequelae, such as venous gangrene (phlegmasia cerulea dolens), and long-term sequelae, including recurrent DVT and postthrombotic syndrome (PTS).[80–83] PTS is characterized by persistent pain, edema, discoloration, and ulceration. Patients with iliofemoral DVT experience a higher incidence and severity of postthrombotic morbidity than those with infrainguinal DVT. The standard therapy for DVT focuses on the prevention of thrombus propagation, stabilization of thrombus, and prevention of PE. This is achieved with anticoagulation. However, anticoagulation alone has limited efficacy in restoring venous patency and function. Thrombolytic therapy of DVT focuses on the dissolution of the clot to prevent PTS. The 2016 Cochrane review, which grouped both systemic and regional thrombolysis with anticoagulation versus anticoagulation alone, found that patients receiving lytic therapy showed more complete clot resolution (risk ratio [RR], 4.91; 95% CI, 1.66–14.53; $P = 0.004$) and lower incidence of PTS (RR, 0.66; 95% CI, 0.53–0.81; $P < 0.0001$). Thrombolysis carried a higher risk of bleeding complications (RR, 2.23; 95% CI, 1.41–3.52; $P = 0.0006$), but there was no significant difference in mortality.[84]

More recently, CDT and pharmacomechanical thrombolysis (PMT) have evolved as the first-line lytic therapies for DVT because they are theoretically associated with a reduced risk of bleeding complications. CDT involves catheter-directed infusion of thrombolytic agents into the affected venous bed and reduces the total dose of thrombolytic agent, which in turn decreases systemic side effects. The CaVenT study, a randomized controlled trial involving 209 patients, showed that patients with first-time iliofemoral DVT who were treated with CDT within 21 days of symptom onset showed improved iliofemoral patency at 6 months (65.9% vs. 47.4%, $P = 0.012$) and reduction in PTS at 2 years (41.1% vs. 55.6%, $P = 0.047$) compared with patients treated with anticoagulation alone. However, patients receiving thrombolytics also experienced 20 bleeding complications.[85] The ATTRACT multicenter randomized trial investigated the effect of PMT plus anticoagulation versus anticoagulation alone in patients with proximal DVT involving the femoral vein, common femoral vein, and/or iliac veins.[86] There was no significant difference in the development of PTS at 24 months of follow-up (47% PMT vs. 48% control, $P = 0.56$). Although representing the largest trial on CDT for DVT to date, this study has been criticized for grouping together patients with iliofemoral DVT and femoropopliteal DVT, the former of which are much more likely to develop PTS. This may have led to underestimation of the treatment effect of PMT on development of PTS in patients with iliofemoral DVT. Subsequent subgroup analysis of iliofemoral DVT patients in the ATTRACT trial did demonstrate a reduction in moderate-or-severe PTS in patients undergoing PMT (Villalta scale ≥10 or ulcer: 18% vs. 28%; RR, 0.65; 95% CI, 0.45–0.94; $P = 0.021$).[87]

The current guidelines put forth by the Society for Vascular Surgery and the American Venous Forum recommend CDT or PMT for treating patients with iliofemoral DVT diagnosed within 14 days of symptom onset, good functional capacity, acceptable life expectancy, and low bleeding risk.[88] The American College of Chest Physicians also recommended similar guidelines and reported that CDT was a more preferable approach than systemic thrombolysis.[66] CDT and/or PMT are also recommended for patients with phlegmasia cerulea dolens. In addition to treating patients with lower extremity disease, CDT has been used for treating young patients with primary upper extremity DVT resulting from effort thrombosis (Paget-Schroetter syndrome) or idiopathic factors.[89]

Acute Peripheral Arterial Occlusion

Acute peripheral arterial occlusion (APAO) is a potentially fatal condition that can lead to amputation in 10%–30% of cases and is associated with a mortality rate of 15% at 30 days.[90] Arterial occlusions arise from dissection, trauma, local thrombosis, or emboli. Various noninvasive methods have been developed for treating thromboembolic diseases.

Thrombolysis has become a popular means of treating acute arterial occlusion in certain settings, such as for those without an immediately threatened limb. This approach has been performed since the 1950s.[2] Initial attempts involved systemic delivery but were associated with high bleeding risks and poor clinical outcomes. Since the early 1970s, catheter-directed infusion has become the standard of care, which allows higher local thrombolytic concentrations while decreasing the systemic exposure to the medications.[91] Various infusion methods have been developed, including low-dose infusion regimens, high-dose infusion regimens, and high-pressure infusion (pulse spray).

However, none of these methods have shown genuine benefit in terms of clinical outcomes.[92,93]

Although streptokinase was the first agent used for treating APAO, multiple studies have indicated that urokinase and tPA are more effective for treating APAO than streptokinase with fewer bleeding complications.[94–96] Recently, tPA and its derivatives have supplanted urokinase as the agents of choice for treating APAO. The safety and efficacy profiles of low-dose (<2 mg/hr, usually beginning at 0.5 mg/hr) tPA regimens are similar to those of urokinase, with adjunctive heparin infusion to maintain the aPTT at 1.5 times of that at baseline. With this regimen, over 60% of patients have shown complete resolution and 30% of patients have shown partial resolution of thrombus within 24 hours of treatment initiation.[97] An advisory panel on CDT recommended weight-based dosing (0.001–0.02 mg/kg/hr) or non–weight-based dosing (0.12–2.0 mg/hr), with total doses not exceeding 40 mg.[98]

Use of thrombolytics for treating APAO is part of a multifaceted approach that often involves additional endovascular techniques and/or surgical interventions. The Rochester Trial compared initial surgery with urokinase treatment in 114 patients with severely threatened limbs.[99] Limb salvage rates in the two groups were identical (82%) at 12 months; however, mortality was significantly lower in patients treated with urokinase (16% vs. 42%). The Surgery or Thrombolysis for the Ischemic Lower Extremity (STILE) trial examined 393 patients randomized to surgery or one of two lytic therapies (rtPA or urokinase).[100] At 30 days, limb loss rates (5% with lysis vs. 6% with surgery) and mortality rates (4% vs. 5%, respectively) were similar between the two groups. Subgroup analyses performed in this study showed a higher benefit of thrombolytic therapy in patients with graft occlusion than in those with native vessel occlusion and acute ischemia of less than 2 weeks.[101,102] The TOPAS Trial compared recombinant urokinase therapy with surgery in 544 patients.[103,104] Although it failed to demonstrate an amputation-free survival benefit at 1 year (68% for urokinase, 69% for surgery), it did show that over 30% of the patients treated with urokinase were not only alive without amputation but also had nothing more than a percutaneous procedure at 6 months. Thus a significant number of patients presenting with APAO and treated with thrombolysis can avoid surgery. A contemporary series by Taha and colleagues comparing the effectiveness of endovascular (154 limbs) with surgical (326 limbs) revascularization for acute limb ischemia also showed similar amputation rates at 1 year (13.0% vs. 19.6%, $P = 0.074$). In this study, 1-year mortality was significantly lower in patients in the endovascular group (12.9% vs. 33.8%, $P < 0.001$).[105]

A 2018 Cochrane review identified five prospective, randomized trials from the 1990s that compared surgery with thrombolytic therapy for the management of acute limb ischemia. The review did not show any overall difference in limb salvage or mortality at 1 year. As expected, patients treated with thrombolysis showed a higher rate of major hemorrhage (OR 3.22, 95% CI 1.79–5.78; $P < 0.0001$) and stroke (OR 5.33, 95% CI 0.95–30.11; $P = 0.06$).[106] Therefore thrombolytic therapy is still not considered the standard of care for treating APAO. However, it is useful for treating patients who are poor candidates for surgery and may be best regarded as an adjunct to surgical therapy rather than a competing modality. In some cases, thrombolysis can aid in recanalization of distal vessels that are not patent at treatment initiation, thus permitting subsequent revascularization through bypass surgery. Moreover, it may be the best approach for treating patients with occluded bypass grafts (Fig. 152.4).[100,101] A recent review of available published data affirm the high rate of technical success for CDT in APAO, approaching 80%, and a pooled 30-day amputation-free survival of 88.5%.[107] Use of thrombolysis is contraindicated in patients with early postoperative thrombosis, thrombosis after penetrating or multiple trauma, or irreversible ischemia in the limbs.

Other Applications

In addition to the previously listed indications for thrombolytic therapy, another common application is the treatment of thrombosed dialysis grafts or central venous catheters. Although the ultimate goal is to recognize and treat a graft before it fails, thrombolytic treatment can play an important role once the graft is occluded. Several techniques have been used for treating acutely thrombosed grafts, including mechanical thrombectomy, surgical revision, and pharmacologic thrombolysis. A meta-analysis indicated that surgical thrombectomy remains the standard of care and is associated with superior patency, presumably because of anastomotic revision, which is performed concurrently.[108] In patients with occluded central venous catheters, the instillation of 2-mg (1 mg/mL) aliquot of alteplase into each lumen for 2 hours may be used to restore patency of the catheters.[109] Multiple studies have shown this regimen to be both safe (≤1% bleeding risk) and efficacious (<90% patency after two treatments).[109,110]

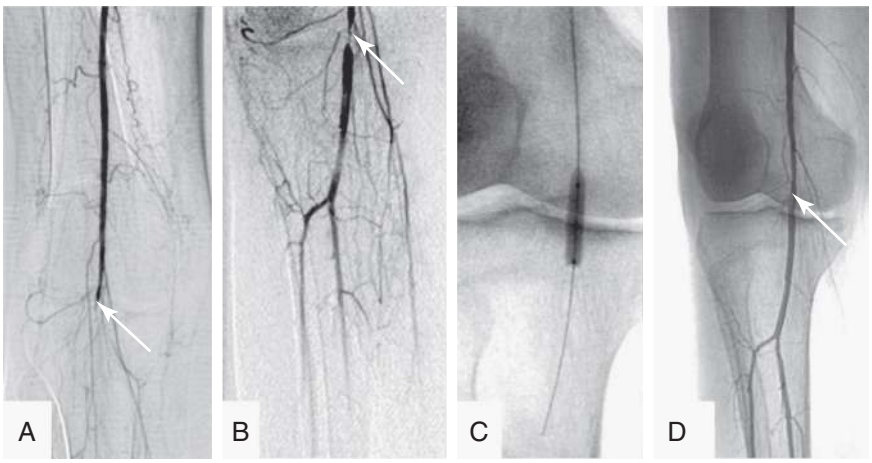

Fig. 152.4 Successive angiograms showing occluded popliteal artery (*arrow*, **A**) treated with thrombolytics. After thrombolysis, a focal popliteal artery stenosis is observed (*arrow*, **B**) along with patent distal vessels. This area was subsequently treated by performing balloon angioplasty **(C)**. Thrombolysis and angioplasty resulted in a patent popliteal artery (*arrow*, **D**), with good distal arterial flow.

MANAGEMENT/LABORATORY VALUES

Administration of thrombolytic agents decreases the circulating levels of plasminogen and fibrinogen. Fibrinogen is degraded during fibrinolysis, reaching nadir values between 5 and 7 hours after the initiation of therapy.[111] In most patients, these values return to baseline within 48 hours after lysis. Fibrin degradation products are a reliable indicator of fibrinolytic activity because degradation of fibrinogen or fibrin by plasmin is the only source of these products in humans.

Monitoring of fibrinogen levels every 6–8 hours is recommended during lytic therapy, with a decrease in dose or discontinuation of infusion if levels decrease to below 100 mg/dL. In addition, platelet counts should be monitored daily. Thrombocytopenia occurs in as many as 10% of patients receiving rtPA compared with less than 1% patients receiving streptokinase.[112–114] If bleeding occurs, thrombolysis should be discontinued and blood products—namely, fresh frozen plasma or cryoprecipitate—should be administered to correct the patient's coagulopathic state.

CONCLUSION

Although evidence strongly supports the use of thrombolytic agents for the treatment of various occlusive vascular disorders, this therapy is administered in relatively few patients. Increasing data support the safety and efficacy of thrombolytic therapy for a variety of disorders, which has substantially increased its use over the past two decades. One of the challenges in the coming years will be to more clearly define the patients who will benefit the most in terms of improved outcomes of the underlying disorder, decreased mortality, and prevention of hemorrhagic complications. Evolution of technology, including diagnostic modalities, mechanical thrombectomy devices, and adjunctive therapies, will continue to expand the indications for thrombolytic therapy.

ACKNOWLEDGMENT

The authors would like to thank Dr. Michael C. Madigan for his contributions to a previous version of this chapter.

KEY POINTS

- Thrombolytics comprise a diverse group of compounds that convert plasminogen to plasmin.
- Thrombolytic therapy is indicated within 6 hours of the onset of AMI, especially in patients who are not eligible for primary angioplasty.
- Patients with acute ischemic stroke receive the greatest long-term benefit from thrombolytic therapy when performed within 4.5 hours of symptom onset, and thrombolytic therapy may serve as a pharmacologic bridge to CDT in appropriate patients.
- The role of thrombolytic therapy in PE is primarily limited to patients with hemodynamic instability based on currently available data. The choice of systemic versus catheter-directed therapy must be made based on patient bleeding risk, previous lysis attempts, hemodynamic status, and available local expertise.
- Thrombolysis in deep venous thrombosis is controversial outside of cases of phlegmasia. Proponents of catheter-directed techniques cite lower rates of post-thrombotic syndrome morbidity.
- Urokinase and tissue plasminogen activator are commonly used for managing acute peripheral arterial occlusion. Highest benefit is observed in patients with occlusions for less than 14 days duration and in those with previous extremity bypasses.
- Thrombolytic therapy requires intensive monitoring and follow-up radiography. Fibrinogen levels should be monitored every 6 to 8 hours, and patients should be closely monitored for signs of major hemorrhage.

Atheroembolization

Cristian Baeza and Yasir Abu-Omar

Atherosclerosis and its thromboembolic complications are leading causes of mortality and morbidity. This progressive disorder usually remains clinically silent until it causes end-organ damage resulting in stroke, ischemic heart disease, and/or peripheral vascular insufficiency. Atherosclerosis characteristically affects the aorta, with the abdominal aorta more widely involved than the thoracic aorta. Lower limb vessels are more frequently affected than upper limb vessels, whereas renal, pulmonary, and mesenteric vessels are the least susceptible.

Nearly half of all strokes were thought to result from cerebral vasospasm until the 1950s, when Fisher stressed the etiologic importance of emboli from carotid artery atherosclerotic plaques.[1] Although embolization from the heart and major vessels accounts for a large number of ischemic cerebrovascular accidents, the cause of a significant proportion (40%) remains undetermined; nevertheless, after appropriate imaging studies, about 20% of them could be reclassified as embolic in origin.[2] The following account will focus on the pathophysiology, clinical consequences, detection, prevention, and management of atheromatous embolization.

PATHOPHYSIOLOGY

Atherosclerosis

The process of atherosclerosis may begin as early as childhood, developing slowly with effects rarely manifesting before the fourth or fifth decades of life. Traditional risk factors include hypertension, diabetes, smoking, and hypercholesterolemia.

Atherosclerosis can affect any artery, but the most frequently affected are the large and medium-sized arteries. Intravascular sites of blood turbulence, such as bifurcations, favor the development of atherosclerotic lesions. Initial changes in arterial wall morphology result in the formation of fatty streaks that consist of lipid-engorged macrophages in the arterial intima. Progression of such precursor lesions occurs secondary to an inflammatory process initiated by endothelial injury and dysfunction.[3] Insufficient nitric oxide production results in increased adhesion and aggregation of platelets. Up-regulation of the expression of endothelial adhesion molecules and selectins leads to the accumulation of monocytes and T lymphocytes. These cells become activated and produce growth factors, cytokines, and chemokines. Smooth muscle cells migrate from the media into the intima and proliferate. In time, these lesions develop into raised, fibrous plaques consisting of a fibrous cap covering a core containing necrotic material, lipids, and cholesteryl esters. This advanced plaque forms the base onto which the complex plaque develops, consisting of fissures, erosions, or ulceration. Interest has increased in the role of monocytes and macrophages in the pathogenesis of plaque progression and rupture,[4] processes that are related to thrombosis, embolism, and clinical manifestations.

Atheromatous Embolization

Atheromatous embolization is a descriptive term for embolization of any atheromatous material. *Atheroembolization* refers to the dislodgment of vascular plaque material that contains cholesterol crystals, red blood cells, and fibrin.[5] This "cholesterol emboli" syndrome comprises renal failure, skin lesions, blue toes, and neurologic manifestations. It can develop spontaneously (because of plaque rupture) or after the use of thrombolytics or anticoagulants,[6] or result from arterial manipulation (during surgical procedures, cardiac catheterization, insertion of an intraaortic balloon pump [IABP], percutaneous aortic valve replacements [transcatheter aortic valve implantation (TAVI)], and aortic endo-stent placements [thoracic endovascular aortic repair/endovascular aortic repair (TEVAR/EVAR)]).[7] Disruption of a vascular plaque results in the release of cholesterol crystals with subsequent downstream vascular obstruction and initiation of an inflammatory process with lymphocytic and mononuclear cell infiltration. Biopsy specimens of affected organs such as skin or kidneys are usually diagnostic.

Plaque Morphology and Embolic Risk

Severe atherosclerosis of the ascending aorta appears to be the most important morphologic indicator of an increased risk of atheromatous embolization. The French Aortic Plaque in Stroke group identified a plaque thickness of 4 mm or greater on transesophageal echocardiogram (TEE) as an independent predictor of recurrent embolization.[8,9] Plaque ulceration and morphology may contribute to an increased risk of embolic events, with evidence of pedunculated, mobile plaques and the absence of calcium conferring a higher risk.[10,11] The cerebral embolic risk is also influenced by plaque location; as complex plaques are more frequent distal to the ascending aorta, there is increased risk to the left cerebral hemisphere and the peripheral circulation.[10]

Macroembolization and Microembolization

Emboli can be divided into macroemboli and microemboli, also described as *thromboembolism* and *atheroembolism.* Despite sharing the same underlying pathophysiology, clinical manifestations differ. Thromboemboli affect arteries larger than 200 μm in diameter, whereas atheroemboli affect smaller arteries, arterioles, and capillaries.[12] Macroemboli may cause overt clinical presentations (e.g., stroke or peripheral ischemia), whereas microemboli tend to be more occult in their manifestations of end-organ injury or dysfunction (e.g., renal injury, neuropsychological impairment). Embolization may arise spontaneously or be related to vascular interventions and cardiovascular surgery. The complex aortic plaque–related 3-year mortality is reported to be as high as 20%.[13]

CLINICAL CONSEQUENCES OF ATHEROMATOUS EMBOLIZATION

Cerebral

As the prevalence of aortic atherosclerotic disease increases with age, so does the rate of atheromatous embolization. Postmortem studies indicate that it affects 20% of patients in their fifth decade, increasing to 80% in those in their eighth decade.[14] Emboli from the atherosclerotic thoracic aorta commonly result in stroke (50%) and transient ischemic attack (35%),[13] with the middle cerebral artery being the most frequent site of arterial embolism. Stroke has profound effects; outcomes from acute stroke are measured in terms of survival, functional independence, and financial cost. Survival after stroke is significantly poorer than after myocardial infarction (MI) or most cancers and is the leading cause of disability in developed countries.[15]

Cholesterol emboli (atheroembolization) are an important and frequently unrecognized cause of stroke.[16] Microembolization is a recognized cause of more subtle, sometimes subclinical neurologic injury.[17,18] This injury is manifested by subtle changes in cognitive function that may only be evident on detailed neuropsychological testing[19,20] and include amaurosis fugax, transient ischemic attack, and confusional state. Rarely, embolization to the spinal cord can lead to lower extremity paralysis. The importance of microembolization has increased over recent years, particularly in patients undergoing coronary artery bypass surgery (CABG); nevertheless, the evidence suggests that the late cognitive decline between 1 and 5 years after surgery may be secondary to high rates of cerebrovascular disease among patients who need CABG. A history of hypertension and other cardiovascular risk factors are known to be associated with increased risk for long-term cognitive decline.[21]

Cardiac

Atherosclerotic disease is the leading cause of death in developed countries. Every year it results in over 19 million deaths worldwide, and coronary heart disease accounts for the majority of those.[22] Most acute coronary syndromes are caused by plaque rupture. Distal embolization of cholesterol and atheromatous material may be important in the pathogenesis of some acute coronary syndromes.[23] The occurrence of distal coronary embolization in the setting of acute coronary syndromes has been followed using serum levels of cardiac troponins to detect small degrees of myocardial necrosis. Embolization after percutaneous coronary interventions is well recognized, and elevated troponins are seen in up to 44% of patients.[24,25]

Peripheral

Peripheral emboli most frequently lodge in the lower extremities. Cholesterol atheroembolization may be subclinical or result in systemic effects. Although renal, neurologic, and cutaneous manifestations tend to dominate the clinical picture, involvement of most organs has been reported.

Cholesterol embolization frequently manifests as acute kidney injury[26,27] and can even lead to renal failure.[26,27] In those cases, renal biopsy is diagnostic.[28] Cutaneous manifestations, including livedo reticularis and "blue-toe" syndrome, are the most common signs of atheroembolism, occurring in up to 34% of cases.[29] Atheroemboli from the carotid vessels give rise to retinal emboli,[30] resulting in visual symptoms. The mesenteric circulation may also be affected, resulting in small bowel bleeding[31] and intestinal infarction. The pancreas, spleen, liver, and gallbladder may also be involved.[32] More rarely, involvement of transplanted viscera such as the kidney may result in renal failure.[33]

DIAGNOSIS AND SCREENING

Full clinical assessment and screening of patients presenting with embolic complications are essential in guiding management and prevention strategies. Diagnosis of cholesterol embolization syndrome relies on clinical findings in patients with atherosclerotic disease and a history of recent vascular intervention. As different organs can be involved, a high index of clinical suspicion is vital. It is important to differentiate between atheroembolism and thromboembolism, as the treatment may be guided accordingly.

Many imaging modalities have been used to visualize atherosclerotic plaques—some in routine clinical practice and others reserved for research. Technologic advances in imaging have provided tools that allow primary prevention by identifying those at highest risk, enabling appropriate disease-modifying treatment to be initiated.

X-ray Angiography

X-ray angiography is an invasive procedure that allows assessment of the vascular lumen. However, it is not as sensitive in plaque detection as other imaging modalities and also confers an additional risk of plaque disruption secondary to instrumentation. Despite these limitations, angiography is still regarded as the gold standard for imaging coronary, carotid, and peripheral arterial disease.[34]

Surface and Transesophageal Ultrasonography

Measurement of carotid and aortic wall thickness in addition to qualitative and quantitative assessment of atherosclerotic plaques can be determined using ultrasonography. The North American Symptomatic Carotid Endarterectomy Trial and the Asymptomatic Carotid Artery Stenosis Study have shown that the degree of stenosis and its hemodynamic consequences are important in the development of stroke.[35,36] High-resolution, real-time B-mode ultrasound with Doppler flow imaging is currently considered the modality of choice in imaging the carotid arteries.[37]

With respect to screening, carotid intima-medial thickness (CIMT) measured by B-mode ultrasound is assessed as a risk factor and a marker for vascular disease risk. This marker most accurately represents subclinical vascular disease, but not plaque formation or atherosclerosis per se. Epidemiologic and clinical trial evidence, digitization, and standardization have made CIMT a validated and accepted marker for generalized atherosclerosis burden and vascular disease risk.[38] CIMT is a predictor of coronary events and stroke, in addition to all-cause mortality.[39,40] The American Society of Echocardiography Carotid Intima-Media Thickness Task Force recommends the use of CIMT measurement by ultrasound in intermediate-risk asymptomatic patients, with a goal of predicting future coronary heart disease events.[41]

TEE is a quick and safe procedure with widespread use ranging from the operating theater to the bedside.[42] TEE is the procedure of choice for the detection, assessment, and characterization of thoracic aortic atherosclerosis. TEE can reliably detect intimal thickening, ulceration, calcification, and the presence of mobile components within the aortic plaque (Fig. 153.1). The French Aortic Plaque in Stroke investigators used TEE to assess aortic plaque thickness in patients with stroke, reporting that increased plaque thickness imparted a significant increase in stroke risk.[8,9] Katz and colleagues used the following five-grade ranking system to indicate the severity of aortic atherosclerosis as assessed using TEE in 130 patients undergoing cardiac surgery with cardiopulmonary bypass: grade 1, normal aorta; grade 2, flat intimal thickening; grade 3, protruding atheroma in the aortic lumen (<5 mm); grade 4, protruding atheroma (>5 mm); and grade 5, atheroma with a mobile thrombus.[43] Patients with grade 5 lesions were at highest risk of stroke. Logistic regression identified aortic arch atheroma

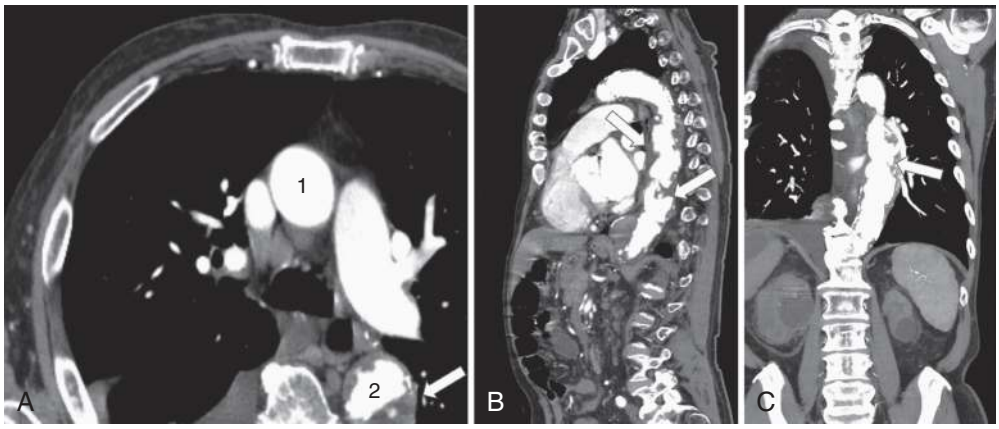

Fig. 153.1 CT angiography demonstrating heavily diseased thoracic aorta ("shaggy aorta"). The arrows show atherosclerotic plaques. The difference between a normal vessel and a severely atherosclerotic one can be appreciated here in ***A,*** between the ascending aorta (1) and the descending aorta (2). ***A,*** Transversal view; ***B,*** sagittal view; ***C,*** coronal view.

as the only variable that was predictive of stroke, with an odds ratio of 5.8. Another study of 315 CABG patients undergoing intraoperative TEE also reported a significant increase in the risk of stroke in patients with aortic arch intimal thickening of greater than 5 mm.[44]

It is no surprise that patients with the highest-risk carotid lesions also have high-risk aortic plaques. Assessment of the carotid arteries and the aorta is prudent in the investigation of atherosclerotic patients who have suffered embolic events.

Intraoperative Epiaortic Ultrasound

Epiaortic ultrasonography involves intraoperative imaging of the ascending aorta using a sterile-sheathed transducer. This technique is noninvasive and has been used in the context of cardiac surgery to detect areas of ascending aortic atherosclerosis,[45] thus allowing modification of the surgical technique in an attempt to reduce potential embolic complications.[46] The main disadvantage of this technique is suboptimal imaging of the aortic arch. Intraoperative epiaortic ultrasound can therefore be used to complement the information on the aortic arch obtained by TEE.

Transcranial Doppler

Transcranial Doppler (TCD) ultrasonography can be used to detect and quantify cerebral microemboli. Ultrasound probes are placed bilaterally on the temple, overlying the middle cerebral vessels. Emboli cause an increase in the reflected ultrasound, causing high-intensity transient signals (HITS). These HITS are the footprints of microemboli, which may consist of air, fat, atheromatous material, or platelet-fibrin emboli. In addition to detecting cerebral microemboli, TCD can be reliably used to assess cerebral vasomotor reactivity and autoregulation; to document the circle of Willis functional status; and to identify cerebral hypoperfusion and hyperperfusion, recanalization, and reocclusion.[47]

TCD can reliably detect HITS intraoperatively and has been used extensively in the context of cardiac and carotid surgery. During cardiac surgery, microemboli can be detected after intraoperative aortic manipulation (aortic cannulation and application and removal of aortic cross-clamp) and during cardiopulmonary bypass; nevertheless, this study and others showed that advanced age is still the strongest predictor of postoperative neurocognitive impairment after surgery.[48] HITS have also been identified in patients with symptomatic carotid artery stenosis,[49] patients with prosthetic heart valves,[50] and those with aortic atherosclerosis.[51] Their presence is a significant independent predictor of early recurrence of stroke.[52]

A major limitation is an inadequate acoustic window in 5%–20% of individuals.[53] With multirange, multifrequency Doppler systems, automatic artifact rejection and differentiation between solid and gaseous microemboli have become possible with high sensitivity and specificity.[54,55] A significant reduction in intraoperative cerebral microembolism and a reduction in the proportion of solid microemboli have been reported with TCD, with avoidance of cardiopulmonary bypass and minimizing manipulation of the ascending aorta during cardiac surgery.[48,56]

An exciting recent development with TCD ultrasonography is its therapeutic use in the treatment of stroke. This procedure involves the use of TCD ultrasound to augment the effect of fibrinolysis and has been shown to at least double the chance of early complete arterial recanalization.[57]

Computed Tomography

Computed tomography (CT) can be used for imaging the aorta and quantifying aortic wall calcification. Contrast-enhanced CT has been proposed as a valuable method for following the progression and regression of atherosclerotic disease.[58] The main advantage over TEE is the ability to completely image the thoracic and abdominal aorta. Disadvantages include radiation and contrast exposure with potential for renal damage, limiting its use in asymptomatic populations.

Coronary multidetector CT angiography (MDCTA) can be used in identifying patients at a particularly high risk of dying suddenly or suffering a nonfatal MI. It provides information on coronary artery stenosis and an estimate of calcification: coronary artery calcium (CAC). The latter is related to multiple risk factors of coronary artery disease. The importance of CAC screening lies in its potential to increase the predictive power of testing for future events.[40,59]

Magnetic Resonance Imaging Techniques

Magnetic resonance imaging (MRI) has emerged as a leading noninvasive imaging modality for atherosclerotic disease. MRI can be used to image atherosclerotic plaques in aortic, carotid, peripheral, and coronary arterial disease.[60,61] Its major strengths rest in its ability to determine plaque morphology. Using a range of techniques, MRI can provide valuable information on the composition of the atherosclerotic plaque by identifying the three main factors that determine plaque stability: (1) presence of a lipid core, (2) thickness of the fibrous cap, and (3) inflammation within the cap. MRI allows identification of

high-risk unstable plaques and thus guides intervention and therapy[62] in addition to monitoring response to therapy with statins.[63] Magnetic resonance angiography has a high sensitivity and specificity and can be used to image the aorta, carotid, renal, and other peripheral vessels. Evolving magnetic resonance techniques include intravascular[64] and transesophageal[65] MRI.

Tissue Diagnosis

Cholesterol embolization can only be confirmed with biopsy, as the clinical manifestations are often subtle and nonspecific compared with those of thromboembolism. Cholesterol clefts in arterioles are evidence of cholesterol crystal emboli that have dissolved during the process of fixation of the specimen. Intimal proliferation of the arterial vascular bed after cholesterol crystal embolization may be responsible for the end-organ malperfusion.[66]

VASCULAR MANIPULATION AND EMBOLIC EVENTS

Cardiac Surgery

Stroke, transient ischemic attack, and peripheral embolization are potential complications after cardiac surgery. Atheroembolism results in a variety of clinical manifestations and can be fatal in about 20% of patients.[67] Stroke affects less than 2% of CABG patients and is higher in those undergoing open heart procedures.[68] The risk of perioperative stroke increases with advancing age, and those with concomitant cardiovascular risk factors are at highest risk.[69] Additionally, female sex is independently associated with a significantly higher risk of perioperative stroke.[70] Embolization from the atheromatous aorta is the single most important etiologic factor for stroke. This risk arises during intraoperative manipulation of the aorta, including cannulation for cardiopulmonary bypass, application and removal of an aortic cross-clamp for administration of cardioplegia, and the use of side-clamps for anastomosis of the proximal end of the graft to the aorta. Special approaches such as single-clamp or touchless aortic techniques significantly reduce this risk.[71] Patients undergoing cardiac surgery with aortic plaque greater than or equal to 5 mm had a higher incidence of stroke.[72] As previously mentioned, mobile plaques confer a greater risk of stroke. This effect was seen in an analysis of 130 patients undergoing CABG, with a higher incidence of stroke in the cohort in whom mobile plaques were identified.[73] Roach and colleagues showed that atherosclerosis of the ascending aorta is the strongest independent predictor of perioperative stroke, with an odds ratio of 4.5.[74]

Cardiac Catheterization and Peripheral Vascular Intervention

Aortic manipulation during cardiac catheterization procedures or IABP insertion may cause embolization from aortic atheroma. In a report comparing 59 patients with atherosclerotic aortic debris undergoing transfemoral cardiac catheterization, an embolic event occurred in 17% of the patients with atherosclerotic aortas compared with 3% of controls.[75] In the proportion of patients requiring IABP, 5 out of 10 patients with atherosclerotic aortas had an embolic event compared with none of the 12 patients with IABP in the control group. When a transbrachial approach was used in patients with atherosclerotic aortas, none of the 11 patients suffered an embolic event. Patients with mobile aortic atheromas on TEE are at the highest risk of catheter-related embolization.[75] A recent study reported the rate of clinically significant distal embolization in 2.4% of patients undergoing peripheral arterial intervention.[76]

Cholesterol embolization can complicate cardiac catheterization. Because it is commonly asymptomatic, the exact incidence is uncertain and mainly depends on the detection criteria used (clinical or pathologic). Cholesterol can be identified in the lumen of affected arterioles in up to 12% of patients after cardiac catheterization.[77] A prospective multicenter study reported cholesterol embolization in 1.4% of patients after cardiac catheterization based on evidence of peripheral cutaneous involvement or renal dysfunction.[78] The syndrome occurred more frequently in patients with generalized atherosclerosis.

PREVENTION AND MANAGEMENT

Treatment of atheromatous embolization depends on the clinical manifestation. However, evidence of atherosclerotic disease with plaque should be considered a cardiovascular risk factor, and preventive measures should be taken despite the symptomatic status of the individual. General measures include identification and modification of risk factors. Patients with the clinical syndrome of cholesterol embolization have a generally poor prognosis, particularly when there is evidence of visceral and renal involvement. Supportive management with blood pressure control and, if necessary, renal replacement therapy is indicated. Strategies for the general prevention and management of atheromatous embolization are discussed here.

Antiplatelet Agents and Anticoagulants

As thrombi can develop on and embolize from atherosclerotic plaques, it seems logical to use antiplatelet agents or anticoagulants to prevent these thromboembolic complications. Three studies have reported a reduction in the risk of stroke with anticoagulation.[79–81] These studies, however, were not randomized and did not include long-term follow-up. A randomized trial reported that in patients with stroke, large aortic plaques remain associated with an increased risk of recurrent stroke and death at 2 years despite treatment with warfarin or aspirin.[82]

The Aortic Arch Related Cerebral Hazard (ARCH) trial was an open-label trial where patients with aortic arch atheroma (4 mm or greater) and nondisabling stroke were assigned to warfarin (target international normalized ratio [INR], 2.0–3.0) versus aspirin (75 mg/d) plus clopidogrel (75 mg/d) and followed longitudinally to determine which treatment was superior for secondary stroke prevention. Unfortunately, the trial was stopped prematurely and was underpowered to determine a difference in the primary endpoints of cerebral infarction, MI, peripheral embolism, and intracranial hemorrhage, although vascular death was significantly lower in the dual-antiplatelet cohort.[83] The main concern with anticoagulation is the risk of plaque hemorrhage and atheroembolization.[84] However, the risk of clinical atheroemboli syndrome during warfarin therapy in such patients appears to be low (only 1 episode in 134 patients according to the Stroke Prevention in Atrial Fibrillation trial).[79]

In patients with atherosclerosis, acute ischemic events are usually precipitated by thrombosis, and antiplatelet agents play a fundamental role in thrombosis prevention. Routine use of aspirin in high-risk patients is universally recommended.[85] The Antithrombotic Trialists' Collaboration published a major meta-analysis with over 200,000 patients assessing the effect of antiplatelet therapy in patients with various manifestations of atherosclerosis. This study reported a significant reduction in the rate of stroke, MI, or vascular death in those on antiplatelet therapy.[86]

Aspirin is the most commonly used antiplatelet agent. It inhibits thromboxane-dependent platelet aggregation. Thienopyridines, including clopidogrel and ticlopidine, act by blocking adenosine diphosphate (ADP)–dependent activation of platelets. There is evidence that thienopyridine derivatives are modestly but significantly more effective than aspirin in preventing serious vascular events in patients at high risk, but there is uncertainty about the size of the additional benefit.[86] The thienopyridines are also associated with less gastrointestinal

hemorrhage and upper gastrointestinal upset compared with aspirin but with an excess of rash and diarrhea.[87] In the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial, a long-term benefit was observed with the use of clopidogrel in addition to aspirin in high-risk patients (unstable angina and non–Q-wave MI).[88]

Platelet activation leads to a conformational change in glycoprotein IIb/IIIa, the major fibrinogen receptor on platelets. Intravenous glycoprotein IIb/IIIa inhibitors (e.g., abciximab) are generally reserved for the high-risk setting of percutaneous coronary intervention.

Dextran has antiplatelet and intravascular volume expansion effects. Postoperative or perioperative administration of 10% dextran 40 reduces the rate of TCD-detected microembolic signals after carotid endarterectomy.[89,90] Dextran, however, may interfere with crossmatching blood and cause bleeding, renal failure, or (occasionally) acute allergic reactions.

The *Guidelines for the Diagnosis and Management of Patients with Thoracic Aortic Disease* have been published by the American College of Cardiology Foundation/American Heart Association (ACCF/AHA). Oral anticoagulation therapy with warfarin (INR, 2.0–3.0) or antiplatelet therapy in stroke patients with aortic arch atheroma 4.0 mm or greater to prevent recurrent stroke was a class IIb recommendation (level of evidence, C).[91] However, American College of Clinical Pharmacy (ACCP) guidelines from 2012 recommend that patients with aortic disease with no previous neurologic event have no indication for anticoagulation.[92]

Statins

There is a clear association between elevated levels of plasma cholesterol and atherosclerotic disease. Statins or 3-hydroxy-3-methylglutaryl coenzyme-A (HMG Co-A) reductase inhibitors reduce the hepatocyte cholesterol content and increase expression of low-density lipoprotein (LDL) cholesterol receptors, resulting in a drop in serum LDL cholesterol. In addition, it has become evident in recent years that statins possess cholesterol-independent or pleiotropic effects. These include improvement of endothelial function by improving the bioavailability of nitric oxide, decreasing vascular inflammation, and stabilizing plaques.[93] Statins are widely used in primary and secondary prevention of ischemic heart disease. A meta-analysis of randomized placebo-controlled double-blind trials with statins reported a 30% reduction in stroke risk with statin therapy.[94] Another meta-analysis of data pooled from over 49,000 patients treated with statins in 28 trials reported a relative risk of stroke of 0.76 in statin-treated patients.[95] Tunick and colleagues showed that statin therapy was independently and significantly protective against the occurrence of embolic events (risk ratio, 0.39) in patients with severe thoracic aortic plaque.[13]

Plaque size reduction, stabilization, and prevention of plaque thrombosis may be the mechanisms leading to a reduction in atheromatous embolization. Two randomized studies of low-dose and higher-dose statins in patients with aortic and/or carotid plaques showed significant regression in plaques seen on MRI.[96,97]

Minimal Aortic Manipulation

The use of smaller arterial catheters during cardiac catheterization may help reduce the risk of embolization.[98] Reduction of embolization during cardiac surgery is possible with modifications to the operative technique. Avoidance of aortic manipulation intraoperatively is most important.[71] This can be achieved in patients undergoing CABG by avoidance of cardiopulmonary bypass, which obviates the need for aortic cannulation and cross-clamping.[99,100] For those patients where cardiopulmonary bypass and aortic cross-clamp cannot be avoided, there are some options using arterial cannulas with incorporated filter devices—the results using these kinds of devices have been promising in highly selected patients with preoperatively determined high risk for embolization.[101] The use of composite arterial grafts (bilateral internal thoracic artery grafts with the radial artery anastomosed to the internal thoracic artery) avoids the need for proximal aortic anastomosis requiring a side-clamp.[102] Off-pump surgery has been shown to offer a reduction in the risk of stroke in patients with atheromatous aortas.[103] We have reported a significant reduction in cerebral microembolization by avoiding cardiopulmonary bypass and aortic manipulation.[48,56] A strategy for potential prevention of embolization in cardiac surgery is summarized in Box 153.1.

BOX 153.1 Prevention of Embolization During Cardiac Surgery in Patients With Atherosclerosis

- Establish the patient's preoperative risk factors.
- Image the ascending aorta and arch preoperatively.
- Assess the carotid arteries.
- Assess the ascending aorta using intraoperative epiaortic ultrasound.
- Use evidence-based decisions to reflect the operative technique.
- Decide the site and risk of cannulation.
- Avoid repeated aortic clamping.
- Consider no-touch aortic techniques.
- Perform off-pump surgery with composite arterial grafting where possible.

Surgical Treatment

Treatment of patients with symptomatic carotid atherosclerosis is well established. The European Carotid Surgery Trial (ECST) and North American Symptomatic Carotid Endarterectomy Trial (NASCET) investigators reported a clear benefit of carotid endarterectomy in the prevention of stroke in patients with high-grade, recently symptomatic carotid stenosis.[35,104] This benefit is offset by the surgical risk of the procedure. The perioperative stroke and death rate for patients with high-grade stenosis was 8% at 30 days in ECST and 6% in NASCET. These rates are acceptable, given the absolute risk reduction by surgery of 10% and 17%, respectively. However, for patients with asymptomatic carotid disease, the risk-to-benefit ratio is narrower, and carotid endarterectomy is currently only recommended for high-grade carotid stenosis (70%–99%).

The International Carotid Stenting Study looked at angioplasty and stenting of the carotid vessels as an alternative to endarterectomy. However, they reported higher rates of stroke and mortality with carotid stenting compared with endarterectomy and therefore recommended that carotid endarterectomy should remain the treatment of choice.[105]

Management of patients with recurrent embolic events caused by aortic atherosclerotic disease can be problematic. Aortic arch endarterectomy in patients with severe aortic atherosclerosis has been reported.[106–108] This procedure is performed using deep hypothermic circulatory arrest and is associated with significant perioperative morbidity and mortality. When performed during cardiac surgical procedures using cardiopulmonary bypass, it resulted in a significantly higher rate of stroke and mortality. Therefore there is insufficient evidence to recommend this mode of treatment for stroke prevention. In the context of cardiac surgery, replacement of the ascending aorta can be performed with acceptable mortality and morbidity,[109] particularly in the intraoperative management of patients with so-called *porcelain aorta*[110] (severe diffuse atherosclerosis and calcification of the ascending aorta that causes an eggshell appearance on x-ray or CT). Systematic use of preoperative noncontrast CT of the chest in all patients

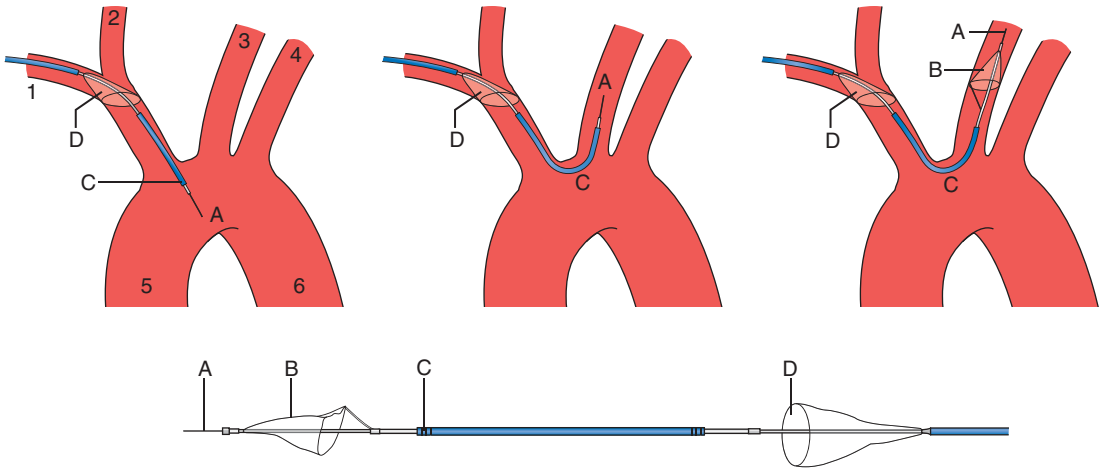

Fig. 153.2 Percutaneous antegrade cerebral filter protection device. The system is delivered through right radial artery percutaneous access and floated, under fluoroscopy guidance, to the desired position: with the proximal filter (D) deployed at the innominate trunk entrance and the distal filter (B), through a connecting sheath (C) into the proximal left common carotid artery. *1,* Right subclavian artery; *2,* right common carotid artery; *3,* left common carotid artery; *4,* left subclavian artery; *5,* ascending aorta; *6,* descending aorta; *A,* guidewire; *B,* distal filter; *C,* articulating sheath; *D,* proximal filter.

70 years of age and older who undergo open heart surgery increases the chance of identifying aortic disease and accordingly allows for planning of operative strategies and risk stratification related to perioperative stroke.[111]

With increasing interest, dedicated endovascular procedures to treat atherosclerotic aortas with stents as a means of preventing subsequent embolization from aortic plaque have been explored with some success. This involves the use of covered stents to exclude the plaque disease. This minimally invasive approach may offer a treatment strategy for patients who are unfit for conventional surgery despite its inherent risk of embolization secondary to instrumentation.[112,113]

Endovascular procedures to treat cardiac valve pathology, aortic aneurysms, dissection, hematomas, and so on have gained a leading role within the therapeutic armamentarium and open a whole new area of potential thromboembolic complications.

The presence of aortic wall thrombus (AWT) or its most aggressive entity better known as *shaggy aorta syndrome* can affect suitability to endovascular repair. A qualitative score classification system (0–10 AWT) has been used.[114] With aortic CT angiographic assessment, the number of affected aortic segments, thrombus type, thickness, area, and circumference can be identified and have a better quantification of the atherothrombotic burden (see Fig. 153.1). Modification of the surgical technique and use of filter devices can help to minimize potentially devastating complications.[114]

Transcatheter Aortic Valve Replacement

Transcatheter aortic valve replacement (TAVR) has become the leading therapeutic strategy for the treatment of patients with aortic valve disease. Since the PARTNER trial results, TAVR became the procedure of choice not just for high-risk and intermediate-risk patients but also for low-risk patients with severe aortic stenosis. Stroke remains a concerning complication and is associated with increased mortality and morbidity.[115–123] Data from MRI post-TAVR has showed the presence of clinically "silent" brain embolic lesions that could be associated with neurocognitive disorders after the procedure.[124–126] These perfusion defects can occur in up to 80% of patients after TAVR.[127–130] It is a multifactorial problem; nevertheless, the presence of perfusion defect on MRI is proof of embolization of debris from the aorta or the aortic valve during the procedure.[131–132] Previous exploratory studies attempted to minimize procedural embolization by using either transcatheter filters or deflection devices.[133–140] A randomized trial was designed to assess the safety of transcatheter cerebral embolic protection (TCEP) during TAVR and the efficacy of TCEP in reducing the effects of cerebral embolization (Fig. 153.2). As we continue to operate on patients who are increasingly older and sicker and increase application of percutaneous techniques in the treatment of vascular diseases, the continued development of strategies to minimize atheroembolization continues to be of huge importance.

KEY POINTS

- Atherosclerosis and its thromboembolic complications are a leading cause of death in the Western world.
- The risk of atheromatous embolization increases significantly with increasing plaque thickness (>4 mm) and the presence of ulceration.
- Ultrasonography (transesophageal and surface) is one of the most frequently used investigative techniques. CT provides information on coronary artery atherosclerosis and the degree of calcification. MRI provides very high resolution in imaging plaque morphology.
- The risk of embolization increases significantly during cardiac surgery and vascular interventions.
- The use of antiplatelet agents and statins is recommended in all patients with significant atherosclerotic disease.
- Perioperative aortic screening allied with minimal aortic manipulation during cardiac surgery in high-risk patients may be associated with a significant reduction in the rate of atheromatous embolization.
- The role of novel protective devices continues to evolve. Their benefits have been demonstrated in a selected group of high-risk patients

ANNOTATED REFERENCES

Antithrombotic Trialists' Collaboration. Collaborative meta-analysis of randomized trials of antiplatelet therapy for prevention of death, myocardial infarction, and stroke in high risk patients. *BMJ*. 2002;324:71–86.
This large meta-analysis with more than 200,000 patients reported that aspirin is protective in most patients at increased risk of occlusive vascular events, including those with an acute MI or ischemic stroke; unstable or stable angina; previous MI, stroke, or cerebral ischemia; peripheral arterial disease; or atrial fibrillation.

Cohen A, Tzourio C, Bertrand B, et al. Aortic plaque morphology and vascular events: A follow-up study in patients with ischemic stroke. FAPS Investigators. French Study of Aortic Plaques in Stroke. *Circulation*. 1997;96(11):3838–3841.
This study of 334 patients aged 60 years and above reported that in patients with brain infarction, the risk associated with aortic plaque thickness (≥4 mm) is markedly increased by the absence of plaque calcifications.

Evered LA, Silbert BS, Scott DA. Postoperative cognitive dysfunction and aortic atheroma. *Ann Thorac Surg.* 2010;89(4):1091–1097.
In over 300 patients undergoing cardiac surgery, the incidence of early postoperative cognitive decline was directly related to aortic atheroma burden (imaged using TEE and epiaortic ultrasound).

Haensig M, Kuntze T, Gonzalez-Lopez D, et al. Thromboembolic complications in transfemoral aortic valve implantation due to aortic wall thrombus and shaggy aorta syndrome. *Eur J Cardiothorac Surg*. 2021;60:253–260.
In a retrospective, single-center analysis,604 patients were used for a qualitative 0–10 Aortic Wall Thrombus (AWT) score classification system. Severe and irregular thrombus of the descending thoracic and abdominal aorta has been strongly associated with acute respiratory failure and peri-interventional stroke in transfemoral aortic valve implantation.

Kapadia SR, Kodali S, Makkar R, et al. Protection against cerebral embolism during transcatheter aortic valve replacement. *J Am Coll Cardiol.* 2017;69:367–377.
A novel device: transcatheter cerebral embolic protection (TCEP). *Nineteen centers randomized 363 patients undergoing TAVR to a safety arm (n = 123), device imaging (n = 121), and control imaging (n = 119). TCEP was safe, captured embolic debris in 99% of patients, and did not change neurocognitive function.*

Pressure Ulcers

Laura J. Moore

EPIDEMIOLOGY

A *pressure ulcer* is any wound that develops in the upper, outer layers of the skin as a result of sustained, external pressure.[1] Pressure ulcers are serious complications among hospitalized patients. They increase healthcare costs, decrease patient quality of life, and often result in prolonged hospital stays. Hospital-acquired pressure ulcers are generally considered to be preventable, and if allowed to progress to full-thickness skin loss must be reported as "never events" to the Centers for Medicare & Medicaid Services. Current estimates of the prevalence of pressure ulcers among hospital patients are highly variable but have been decreasing across the United States.[2] In the largest investigation to date, the incidence of hospital-acquired pressure ulcers is 4.5% and the prevalence of pressure ulcers on admission is 5.8%. More significantly, in those admitted with a previously acquired pressure ulcer, almost one in five patients developed an additional pressure ulcer at a different site during their hospital stay.[3,4] The prevalence of pressure ulcers is even higher among residents of long-term geriatric facilities, occurring in up to 30% of patients. Whereas the majority of the ulcers (50%) in hospitalized patients are stage I, the prevalence of stage III and IV ulcers is estimated to be as high as 4% in patients who reside in long-term care facilities.

Pressure ulcers result in a substantial financial burden, with an estimated cost ranging from $3.3 billion to $11 billion per year.[5,6] The Centers for Medicare & Medicaid Services has reduced the reimbursement for hospital-acquired pressure ulcers, with a single episode costing hospitals $500 up to $70,000.[7]

RISK FACTORS

There are multiple risk factors for the development of pressure ulcers; they can be categorized as intrinsic and extrinsic. Intrinsic risk factors are those related to the patient's preexisting medical condition. Extrinsic factors are those related to the patient's environment. Intrinsic risk factors include neurologic disease, motor impairment, cognitive impairment, sensory deficits, malnutrition, and hypoperfusion caused by peripheral vascular disease or congestive heart failure. Extrinsic risk factors include inadequate mobilization by care providers, trauma, sedation, application of physical restraints, improper positioning (especially among patients under general anesthesia), moisture, and shearing forces. Among these risk factors, failure to frequently change position is thought to be the biggest contributor to pressure ulcer formation. The combination of improper positioning and moisture at the skin surface is a frequent cause of pressure ulcer formation in critically ill patients.

Because of the underlying pathophysiology of pressure ulcer formation, there are several high-risk areas for the development of pressure ulcers. Pressure ulcers are more prone to develop in bony or cartilaginous areas. These include any area of the body that has limited soft tissue coverage such as the coccyx, spinous processes, heels, elbows, and ankles. In patients who are frequently positioned on their side, the iliac crest and trochanters are considered high-risk areas. Additionally, patients with malnutrition and subsequent cachexia have significant loss of soft tissue and are more prone to the development of pressure ulcers at any location. Medical devices can also be associated with the development of pressure ulcers. Examples include masks for noninvasive positive-pressure ventilation, cervical collars, endotracheal tubes, nasogastric tubes, and nasal cannula tubing.

PATHOPHYSIOLOGY

Pressure ulcers form as a result of hypoperfusion to an area. The basic principle of pressure ulcer development is simple. When externally applied pressure exceeds the capillary perfusion pressure, flow becomes impaired and tissue ischemia occurs. If the hypoperfusion and ischemia are not reversed, necrosis of the involved tissue layers will occur. Ischemia to the area will initially present with erythema and induration. If this progresses to necrosis, tissue loss will occur. The critical duration of ischemia varies from patient to patient. However, it is generally accepted that pressure injury typically occurs between 30 and 240 minutes of hypoperfusion. In patients with preexisting peripheral vascular disease, the time to critical ischemia is shorter. Because of impaired arterial inflow, these patients experience significant delays in restoration of perfusion and reversal of tissue hypoxia after the external pressure has been removed. In addition, because of poor underlying tissue perfusion, these patients will experience longer healing times once pressure ulcers develop.

CLASSIFICATION

All pressure ulcers begin in the outer layers of the skin. With ongoing pressure, the ischemia progressively extends to deeper layers of the skin. Therefore the classification of pressure ulcers is based on the depth of skin involvement. Pressure ulcers are classified as stage I through IV, with stage I being the most superficial and stage IV being the deepest. The classification of pressure ulcers is listed in Table 154.1. Having a uniform, well-defined classification system for pressure ulcers is critical. It not only allows for standardization of wounds for research purposes but also allows for accurate communication of wound staging among healthcare providers. Once a pressure ulcer develops, it is important to classify the wound and monitor the progress of the wound bed. Having a standard grading system allows for continuity of care and objective monitoring of the progression of the wound.

PREVENTION

Prevention of pressure ulcer formation should be standard practice. This is of particular importance when caring for critically ill patients, because they often possess multiple risk factors for pressure ulcer formation.

TABLE 154.1 Pressure Ulcer Staging

National Pressure Ulcer Staging System	
Stage I	Nonblanching erythema of intact skin.
Stage II	Partial-thickness skin loss involving the epidermis and/or dermis. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater.
Stage III	Full-thickness skin loss with damage and/or necrosis of the subcutaneous tissue. The wound extends down to, but not through, the underlying fascia.
Stage IV	Full-thickness skin loss with extensive destruction and necrosis of overlying structures, including muscles, bone, or tendon

Risk Assessment

Prevention programs should include an initial risk assessment of the individual patient. This assessment should include questioning about previous or preexisting pressure ulcers; a thorough skin inspection; evaluating the patient's mobility/activity level, continence, and nutritional status; and a review of comorbid conditions that may contribute to the development of pressure ulcers. Assessment of these risk factors should be standardized and documented on all patients. Several tools have been developed for pressure ulcer risk assessment. The Braden Scale (Fig. 154.1) assesses external pressure forces and skin-related factors in a standardized fashion.[8] The scores on the Braden Scale range from 6 to 23, with a score of 15–18 indicating mild risk, a score of 13–14 indicating moderate risk, a score of 10–12 indicating high risk, and a score ≤9 indicating very high risk. The Norton Scale assesses patient-specific risk factors (age, cognitive impairment, mobility, incontinence) for pressure ulcer development.[9] The Waterlow Scale assesses both intrinsic and extrinsic risk factors and was initially developed for use in the pediatric population.[10] However, studies to date have shown little efficacy in reducing the incidence of pressure ulcers with these tools compared with nonstructured risk assessment.[11]

Prevention Plan

Once the individual patient risk assessment has been addressed, a plan for pressure ulcer prevention should be implemented. Regardless of the plan used, a frequent assessment of its efficacy must be performed and any necessary adjustments made. The key elements of prevention include patient mobilization, patient positioning to prevent/remove pressure, and the use of positioning aids to redistribute pressure. Among critically ill patients, this requires vigilance and team effort, particularly among those patients who are sedated for prolonged periods. Prevention also includes avoidance of skin damage by shearing forces and avoidance of maceration of the skin as a result of moisture from incontinence and heat accumulation. A variety of support services are available to help decrease the risk of pressure ulcer formation. These pressure-reducing surfaces include static support surfaces (mattresses, mattress overlays) and dynamic support surfaces that mechanically alter the amount of pressure applied to the patient's skin. Examples of dynamic support surfaces include low-air-loss beds, air-fluidized mattresses, and alternating pressure mattresses. The use of foam mattress overlays can reduce the risk of pressure ulcer development in high-risk populations.[12] Although associated with higher costs, dynamic mattresses have not consistently been shown to be superior to static support surfaces. However, dynamic mattresses are better than standard hospital mattresses in preventing pressure ulcer formation.

TREATMENT

A variety of treatment options and products are available for the management of pressure ulcers. Very few of the currently available treatment options have been rigorously evaluated in randomized controlled trials.[13,14] An in-depth discussion of all the currently available products is beyond the scope of this text, so general classes of treatment options are discussed rather than specific products.

Wound Débridement

Débridement of the wound bed is a critical step in the healing process of pressure ulcers. The purpose of débridement is to remove foreign material and devitalized tissue from the wound. After débridement, a wound bed of healthy tissue should be visible. Débridement of the wound bed reduces the production of inflammatory mediators that inhibit wound healing. A variety of techniques are used for wound débridement. These include surgical débridement, hydrotherapy, larval therapy, and application of topical enzymatic débridement solutions. The choice of débridement techniques used depends on multiple factors, including the size of the wound, comorbid conditions, and the presence of infection. Surgical débridement is most often required in large-volume wounds when extensive tissue débridement is needed. However, surgical débridement requires the patient be a suitable candidate for general anesthesia. The risk of subjecting a critically ill patient to general anesthesia and a trip to the operating room must be weighed against the benefits of sharp surgical débridement of a pressure ulcer. Hydrotherapy, although commonly practiced, has not been rigorously evaluated in the setting of a large randomized controlled trial. However, some small studies of patients with stage III or IV pressure ulcers have demonstrated faster wound healing among patients receiving hydrotherapy as compared with those who did not receive hydrotherapy.[15,16]

Larval therapy, also referred to as *biosurgery,* has been used for débridement of pressure ulcers. The basic concept is that application of larvae to wounds results in rapid débridement of necrotic tissues, with avoidance of the potential complications of surgical débridement such as pain and bleeding. Currently, there is evidence that compared with topical enzymatics, larval therapy significantly reduces the time to débridement of necrotic tissue. However, the use of larval therapy did not appear to have any effect on time to wound healing.[17]

A variety of topical enzymatic débridement products are commercially available. These can be used alone or in conjunction with other débridement techniques. These agents are applied directly to the wound bed once or twice a day. Multiple randomized controlled trials have validated the efficacy of topical enzymatic débridement products for the removal of necrotic tissue from the wound bed.[18] Before applying these agents, the wound bed should be cleansed with normal saline. The presence of any topical wound products containing metal will diminish the efficacy of topical enzymatics, and removing these agents from the wound bed is critical for the success of the enzymatics. In the event an eschar is overlying the wound bed, it is recommended that the eschar be cross-hatched with a surgical blade to allow for penetration of the topical enzymatic agent. Once applied, the wound bed should be covered with gauze. These agents are a viable and valuable therapy, particularly in those patients who are not candidates for alternative débridement methods.

Hydrocolloids

Hydrocolloid dressings are widely used in the management of pressure ulcers; their purpose is to absorb wound exudates. Typical hydrocolloid dressings contain some type of gel-forming agent placed in contact with the wound bed, and this is covered with a membrane that

BRADEN SCALE FOR PREDICTING PRESSURE SORE RISK

Patient's Name _____ Evaluator's Name _____ Date of Assessment

SENSORY PERCEPTION Ability to respond meaningfully to pressure-related discomfort	**1. Completely Limited** Unresponsive (does not moan, flinch, or grasp) to painful stimuli, due to diminished level of consciousness or sedation OR limited ability to feel pain over most of body.	**2. Very Limited** Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness OR has a sensory impairment which limits the ability to feel pain or discomfort over ½ of body.	**3. Slightly Limited** Responds to verbal commands, but cannot always communicate discomfort or the need to be turned OR has some sensory impairment which limits ability to feel pain or discomfort in 1 or 2 extremities.	**4. No Impairment** Responds to verbal commands. Has no sensory deficit which would limit ability to feel or voice pain or discomfort.				
MOISTURE Degree to which skin is exposed to moisture	**1. Constantly Moist** Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is detected every time patient is moved or turned.	**2. Very Moist** Skin is often, but not always moist. Linen must be changed at least once a shift.	**3. Occasionally Moist** Skin is occasionally moist, requiring an extra linen change approximately once a day.	**4. Rarely Moist** Skin is usually dry, linen only requires changing at routine intervals.				
ACTIVITY Degree of physical activity	**1. Bedfast** Confined to bed.	**2. Chairfast** Ability to walk severely limited or non-existent. Cannot bear own weight and/or must be assisted into chair or wheelchair.	**3. Walks Occasionally** Walks occasionally during day, but for very short distances, with or without assistance. Spends majority of each shift in bed or chair.	**4. Walks Frequently** Walks outside room at least twice a day and inside room at least once every two hours during waking hours.				
MOBILITY Ability to change and control body position	**1. Completely Immobile** Does not make even slight changes in body or extremity position without assistance.	**2. Very Limited** Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently.	**3. Slightly Limited** Makes frequent though slight changes in body or extremity position independently.	**4. No Limitation** Makes major and frequent changes in position without assistance.				
NUTRITION Usual food intake pattern	**1. Very Poor** Never eats a complete meal. Rarely eats more than ½ of any food offered. Eats 2 servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement OR is NPO and/or maintained on clear liquids or IVs for more than 5 days.	**2. Probably Inadequate** Rarely eats a complete meal and generally eats only about ½ of any food offered. Protein intake includes only 3 servings of meat or dairy products per day. Occasionally will take a dietary supplement OR receives less than optimum amount of liquid diet or tube feeding.	**3. Adequate** Eats over half of most meals. Eats a total of 4 servings of protein (meat, dairy products) per day. Occasionally will refuse a meal, but will usually take a supplement when offered OR is on a tube feeding or TPN regimen which probably meets most of nutritional needs.	**4. Excellent** Eats most of every meal. Never refuses a meal. Usually eats a total of 4 or more servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation.				
FRICTION & SHEAR	**1. Problem** Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures or agitation leads to almost constant friction.	**2. Potential Problem** Moves feebly or requires minimum assistance. During a move skin probably slides to some extent against sheets, chair, restraints or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down.	**3. No Apparent Problem** Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair.					
				Total Score

protects the wound against external contamination but allows for water evaporation.[18] Hydrocolloid dressings are typically applied every 3–5 days, depending on the amount of exudates being produced by the wound. When compared with standard gauze dressings, hydrocolloids have been shown to be more absorptive and less painful.[18]

Negative-Pressure Therapy

The use of negative-pressure therapy for wound healing has become increasingly common in the past decade. The basic concept behind this therapy is that applying negative pressure to the wound bed both removes edema fluid and increases blood flow to the area. Increased blood flow results in delivery of oxygen and nutrients, which promote wound healing. In addition, the application of negative pressure to the wound results in wound contracture. Compared with standard wet-to-dry dressings, another benefit to patients of negative-pressure therapy is decreased frequency of dressing changes. The use of negative-pressure therapy for pressure ulcers has been associated with improved wound healing and decreased length of hospital stay.[19] Traditionally, negative-pressure therapy has been applied to clean wounds that had very little slough or necrotic tissue. However, there is some evidence that the application of negative-pressure therapy to wounds that are covered with soft necrotic tissue is a viable option.[20]

Nutritional Support

The presence of malnutrition has a significant impact on wound healing. In fact, its mere presence results in weakening of the skin and increases the risk of pressure ulcer development. Unfortunately, nutritional assessment is often neglected, particularly in chronically institutionalized patients. Establishing nutritional assessment protocols and treating malnutrition are essential in preventing and healing pressure ulcers. This is best accomplished by a multidisciplinary team that includes physicians, dieticians, and nursing staff.[21]

An initial nutritional assessment should be performed. Any recent weight loss, the current weight, and the patient's dietary intake should all be evaluated. After the initial assessment is completed, a nutrition plan should be created and implemented to address any issues identified. Weekly monitoring of the patient's nutritional status should occur to determine if the nutritional intervention is having the desired effect. Monitoring should include the patient's weight and assessment of functional status. The use of biochemical tests, including serum prealbumin, transferrin, and nitrogen balance, is also helpful.

CONCLUSION

Pressure ulcers continue to be a common problem among critically ill patients. Constant vigilance and education of care providers are essential components of pressure ulcer prevention. When pressure ulcers do occur, a multidisciplinary approach is needed to manage these debilitating wounds. Management should include objective assessment of the scope of the wound, a multimodality treatment program specifically adapted to the patient's needs, and optimization of nutritional status to promote wound healing.

KEY POINTS

- Prevention is critical. The key elements of prevention include patient mobilization, patient positioning to prevent/remove pressure, and the use of positioning aids to redistribute pressure. Among critically ill patients, this requires vigilance and team effort, particularly among those patients who are sedated for prolonged periods. Avoidance of skin damage by shearing forces and avoidance of maceration of the skin because of moisture from incontinence and heat accumulation are also essential.
- Perform a structured risk assessment to identify high-risk individuals upon admission. High-risk factors include difficulty with mobilization, improper positioning, moisture, and hypoperfusion. Repeat risk assessment at regular intervals.
- Develop a plan for prevention and care. This should include regular repositioning and use of dynamic support surfaces to relieve skin pressure.

ANNOTATED REFERENCES

Anders J, Heinemann A, Leffmann C, et al. Decubitus ulcers: Pathophysiology and primary prevention. *Dtsch Arztbl Int.* 2010;107(21):371–382.
In this article the authors performed a systematic review of the literature related to the pathophysiology and prevention of pressure ulcers. They identified age, presence of comorbid conditions, and immobility to be the highest risk factors for development of pressure ulcers. They found that the most useful means for prevention and treatment of pressure ulcers is avoidance of excessive pressure by encouraging mobility. In addition malnutrition, tissue hypoperfusion, and impaired mobility must be recognized and addressed as part of a comprehensive strategy to prevent pressure ulcer development.

Baharestani MM, Houliston-Otto DB, Barnes S. Early versus late initiation of negative pressure wound therapy: Examining the impact on home care length of stay. *Ostomy Wound Manage.* 2008;54(11):48–53.
In this retrospective analysis of over 500 patients the authors evaluated the impact of early vs. late application of negative-pressure wound therapy to stage III and stage IV pressure ulcers. They found that earlier application of negative-pressure wound therapy was associated with shorter lengths of stay. In addition, for each day in delaying the application of negative-pressure wound therapy, almost 1 day was added to the total length of stay.

Barrett R, Tuttle V, Whalen E, et al. Pressure ulcers and nutritional support: A partnership to improve patient outcomes. *J Nurs Care Qual.* 2010;25(2):145–150.
This article describes the implementation of a targeted strategy to improve the provision of nutritional support for patients at risk of developing pressure ulcers. They identified three key lessons. First, pressure ulcer risk assessments can be used as an opportunity to trigger evaluation by a dietician for recommendations to optimize nutritional status. Second, visual triggers and educational initiatives to increase staff awareness about the importance of nutrition and pressure ulcer assessment contribute to quality patient care. Third, interdisciplinary partnerships are an effective way to implement evidence-based care.

Reddy M, Gill SS, Rochon PA. Preventing pressure ulcers: A systematic review. *JAMA.* 2006;296(8):974–984.
This systematic review discusses interventions for pressure ulcer prevention. A total of 59 randomized control trials were included. Studies were grouped into three categories: mobility, nutrition, and skin health. The strategies found to be most useful for impaired mobility included use of support surfaces, mattress overlays on operating room tables, and specialized foam or sheepskin overlays. For nutritional deficiency, dietary supplements were found to be beneficial. Finally, no clear benefit could be found for any specific topical agent for skin health.

Rondinelli J, Zuniga S, Kipnis P, et al. Hospital-acquired pressure injury. *Nurs Res.* 2018;67(1):16–25.
In this article the authors describe the incidence, risk factors, and risk-adjusted variation in hospital-acquired pressure ulcers within Kaiser Permanente, an integrated healthcare delivery system in California. They analyzed over 1600 inpatients with hospital-acquired pressure ulcers and determined that age, severity of illness, comorbid conditions, and Braden Scale scores were all important predictors for pressure ulcer risk. They also demonstrated that female gender appeared to be protective against the development of pressure ulcers.

Burns, Including Inhalation Injury

Ian R. Driscoll and Julie A. Rizzo

INTRODUCTION

Patients with severe burns today are more likely to survive compared with those injured decades ago. Advances in early source control of deep burns, antimicrobial strategies, and critical care medicine are largely responsible, buoyed by translational research in burn-induced inflammation, hypermetabolism, and the wound environment. As survival rates improve, burn clinicians are challenged to address the sequelae of critical illness after recovery.

Designated burn centers and units are resource-intensive initiatives that thrive in a collaborative model of care. A wide variety of personnel provide specific expertise to ensure the survival and functional recovery of injured patients. The burn team consists of surgeons, intensivists, anesthesiologists, nurses, physical and occupational therapists, respiratory therapists, nutritionists, psychiatrists and psychologists, chaplains, and child-life therapists, among others.[1]

Disasters, both natural and those caused by humans, repeatedly highlight the need for nonburn and nontrauma centers to develop plans for managing large numbers of casualties. In this setting, intensivists and surgeons must have some familiarity with the acute resuscitation and stabilization of burn patients until safe transfer can occur.

INITIAL CARE OF THE BURN PATIENT

Although most burn patients encountered in the intensive care unit (ICU) arrive having been screened by a trauma team, simultaneous transfer of multiple casualties and other factors may curtail the attention these patients receive. Burn patients may have other injuries, and it is important for critical care clinicians to not be distracted by the visual appearance of the skin. Injuries noted on primary and secondary surveys causing hemorrhage, airway compromise, or other threats to life should be addressed before beginning burn-specific resuscitation. Removal of contaminants, including fuel, should occur before transfer. Patients must be protected from hypothermia.

Early and serial assessments of the airway are critical. Smoke inhalation injury is familiar as a risk for airway compromise. However, mucosal and soft tissue edema from burns to the face or over large surface areas alone may cause progressive airway narrowing, when volume resuscitation is superimposed.[2] Patients likely to require endotracheal intubation include those with symptomatic smoke inhalation injury, deep facial burns, or second- and third-degree injuries greater than 40% total body surface area (TBSA) (Box 155.1). Supraglottic devices fail in the setting of oral and laryngeal edema. Using as large an endotracheal tube as practical facilitates pulmonary toilet. Endotracheal tubes should be secured with cotton twill ties, which are adjusted as edema progresses during resuscitation; many standard airway device holders do not adhere to burned skin (Fig. 155.1). Frequently reassess the depth of the tube during the acute resuscitation period. Urgent tracheotomy is not indicated.

Volume resuscitation can be reliably conducted via peripheral intravenous (IV) or intraosseous (IO) catheters, but soft tissue edema often leads to early failure of such devices. Consider transitioning to central venous access in burns >40% TBSA. Likewise, deep burn eschar and soft tissue edema make noninvasive blood pressure measurements less reliable. For large burns, invasive arterial blood pressure measurement is recommended.

It is difficult to provide an early definitive visual diagnosis of burn depth. Soot and other debris may mask important visual cues, and progression of edema and cell death continue for hours.[3] Clinicians should make their best estimate of burn depth upon initial survey and reassess periodically. Superficial burns (first degree) do not form blisters and appear red and blanchable. Partial-thickness burns (second degree) form blisters and remain moist and sensate and are often quite painful. Not all second-degree injuries are created equal, however. Slow capillary refill in second-degree injuries may indicate deeper dermal damage. These deeper partial-thickness injuries often act more like full-thickness injuries in their healing trajectory and contribution to inflammation.[4] Full-thickness burns (third degree) are insensate and form leathery eschar and thrombosed vessels.

Make an initial estimate using the rule of nines or Lund-Browder Burn Estimate and Diagram by adding the areas of all second- and third-degree burns (Fig. 155.2). Thus the percentage of TBSA reflects only second-degree and third-degree areas. For irregularly shaped areas, the patient's hand (palm and fingers included) roughly estimates 1% TBSA. Once wounds are cleansed, recalculate the injury size.

Antihypothermia measures such as a warm room, warm fluid infusions, and convective forced-air blankets should take priority over antimicrobial dressings initially. Extremity escharotomy for circumferential burns, discussed later, is ideally completed by the most experienced clinician in the warmest, best-equipped, and best-lit location, often the operating room (OR) or dedicated burn ICU. This procedure may be deferred in patients with evidence of intact distal extremity perfusion until trauma surveys are completed. Thoracic escharotomy, however, can be a lifesaving procedure in a patient with deep circumferential torso burns who cannot be ventilated.

ACUTE BURN RESUSCITATION

Fluid resuscitation after acute burn injury remains challenging. At TBSA ≥20%, the intense inflammatory response at the injury sites becomes a global cytokine storm, resulting in profound capillary leak and severe hypovolemia. Burn shock is caused by hypovolemia coupled with depression in cardiac function and low systemic vascular resistance.[5] Resuscitation strategies during burn shock must restore intravascular preload with only as much fluid as is needed to reduce the risk of edema formation and resuscitation morbidity from capillary leak. The pathophysiology of edema involves disruption of the

BOX 155.1 Endotracheal Intubation and Inhalation Injury Signs

Indications for Endotracheal Intubation
Symptomatic smoke inhalation injury
Deep facial burns
>40% TBSA

Inhalation Injury Signs
Deep facial burns
Stridor
Soot in nares and mouth
Carbonaceous sputum
Patient rescued from enclosed space

TBSA, Total body surface area.

Fig. 155.1 Cotton twill-tie endotracheal tube. A twill-tie harness is a reliable way of securing the endotracheal tube. Protective pads may reduce injury to oral commissures. Tube security should be regularly assessed because reintubation can be very difficult in this setting.

interstitial scaffold and loss of the oncotic gradient.[6] The amount and type of fluid given during burn resuscitation continue to be debated.[7]

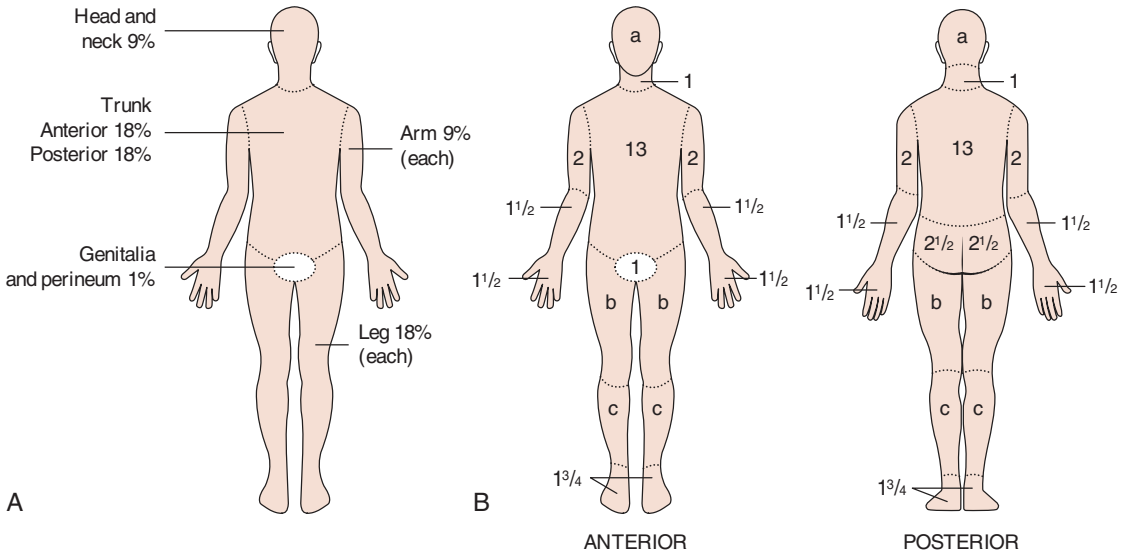
Many developments in burn resuscitation occurred in the 20th century after large urban fires resulted in mass burn casualties. After the 1921 Rialto Theatre fire in New Haven, Connecticut, Underhill noted the composition of burn blister fluid was similar to plasma, suggesting fluid losses be replaced with infusions containing protein.[8] Fluid replacement strategies based on percentage TBSA were introduced after the 1942 Cocoanut Grove nightclub fire. Refined by Evans in 1952, early strategies included both colloids (plasma) and crystalloids as resuscitation fluids in addition to dextrose-containing crystalloids as maintenance fluids.[9] A modification decreasing the amount of colloid fluid required became known as the *Brooke formula*.[10] In the 1960s Baxter and Shires used both human and canine data to generate an estimated fluid requirement of 3.5–4.5 mL per percentage TBSA per kilogram in the first 24 hours after injury, which became known as the *Parkland formula*.[11] The Parkland formula and Modified Brooke formula, two of the most widely cited strategies, provide lactated Ringer's solution (LR) as the resuscitation crystalloid, use no colloid in the first 24 hours after injury, and do not provide additional maintenance fluid.[12] The previously discussed burn formulae rely on intravenously administered fluid. However, the enteral route may allow early initiation of resuscitation fluids, especially in resource-constrained environments, and warrants further study.[13]

All resuscitation formulae require an accurate estimation of second- and third-degree burn size. Resuscitations of patients with ≥20% TBSA should be guided by one of the formulae, but clinicians must recognize that these formulae are initial estimates only.[14] Typically, isotonic crystalloid fluid rates are increased or decreased each hour in response to urine output without boluses. The fluid volume a burn patient actually requires will vary widely based on many factors, including time from injury, the ratio of second-degree to third-degree burns, age, medical comorbidities, and presence of inhalation injury, among others.[15,16] Administered fluid significantly outpaced recommended estimates in burned casualties during the wars in Afghanistan and Iraq.[17] The rule of 10 was developed in order to simplify the initial fluid rate calculation.[18] The percentage TBSA is multiplied by 10, and the result is the initial crystalloid fluid rate in mL/h. For example, a patient with 40% TBSA would be initially given isotonic crystalloid at $40 \times 10 = 400$ mL/h. The rule of 10 applies to patients between 40 and 80 kg. For patients greater than 80 kg, 10 mL/h is added to the initial calculation for every 1 kg over 80 kg. The fluid rate is adjusted up or down by 20%–25% each hour to maintain normal urine output (0.5 mL/kg/h for adults). The rule of 10 does not give a 24-hour fluid estimate, but rather forces the clinician to monitor and adjust the resuscitation for the individual patient. A suggested algorithm for burn resuscitation is given in Fig. 155.3. Other endpoints of resuscitation are discussed later, although urine remains the standard method of titrating resuscitative fluids in burn patients (Table 155.1).

Balanced crystalloid solutions such as LR continue to be recommended.[19,20] The introduction of colloid should reduce the crystalloid fluid totals and subsequent tissue water deposition. The use, timing, and duration of the colloid fluid adjunct continue to be debated, and prospective observational trials are currently underway.[21] Patients who would benefit from early colloid use are those at risk of overresuscitation morbidities—historically burn size ≥30% TBSA. Common colloids include 5% or 25% human albumin solutions and fresh frozen plasma (FFP), with each choice reducing fluid totals, although conclusions on mortality require further study.[22–25]

Vitamin C (ascorbic acid) is a pharmacologic adjunct thought to reduce resuscitation-related complications. As an antioxidant, it regenerates vitamin E, which scavenges reactive oxygen species (ROS) in the cell membrane. ROS are plentiful during burn shock and contribute to endothelial injury.[26] Preclinical studies and limited clinical data have shown that a high-dose vitamin C infusion during the early hours of burn resuscitation reduces the isotonic crystalloid requirement, decreases tissue water deposition, and improves respiratory function. The vitamin C dose (66 mg/kg/h) is infused in an LR solution and its rate calculated as part of the total LR resuscitation volume. This adjunct performs best when started early (within 6 hours of injury) for burns >30% TBSA. Counterintuitively, increases in IV fluid rate may be required for a portion of the first 24 hours because of the diuretic effect of high-dose vitamin C. Savings in tissue water deposition result from the *net* 24-hour volume and reduction in oxidative stress.[27,28]

Other adjuncts to resuscitation include vasoactive medications, renal replacement therapy (RRT), and total plasma exchange (TPE). Vasoactive medications lack a clearly defined role, as the primary mechanism behind shock in these patients is hypovolemia. However, vasopressin (at 0.04 unit/min) and other vasoactive medications are useful for maintaining mean arterial pressure (MAP) >65 mm Hg in patients who appear to be receiving adequate volume.[29] Vasopressors allow focused treatment of the vasodilatory component of burn shock. Crystalloid boluses in this setting contribute to overresuscitation morbidity. Patients who demonstrate persistently decreased cardiac function also may benefit from cardiac inotropic support during



Relative percentage of body surface areas (% BSA) affected by growth

	0 yr	*1 yr*	*5 yr*	*10 yr*	*15 yr*
a–½ of head	9½	8½	6½	5½	4½

Fig. 155.2 Burn area diagrams. The rule of nines (A) and Lund-Browder Burn Estimate and Diagram (B) graphically display second- and third-degree burn burden and allow burn formula calculations. (From Artz CP, Moncrief JA. *The Treatment of Burns,* 2nd ed. Philadelphia, PA: Saunders; 1969.)

RESUSCITATION OF MAJOR BURNS

PATIENT ARRIVAL

- Establish vascular access
- Establish definitive endotracheal airway if needed
- Prevent hypothermia
- Place urinary catheter
- Estimate patient weight (kg)
- Estimate % TBSA (2nd- and 3rd-degree burns)
- Screen for other injuries

INITIAL FLUID RESUSCITATION RATE CALCULATION (Lactated Ringer's Solution, LR)

For **ADULT** burns>20% TBSA
Calculate initial fluid resuscitation rate (mL/h) using the Rule of 10:
(10 x %TBSA for 40–80 kg) + (10 x kg for>80 kg)
Increase or decrease fluid rate each hour by 20%–25% to maintain urine output 0.5 mL/kg/hr

For **PEDIATRIC** burns>15% TBSA
Calculate initial fluid resuscitation rate using Modified Brooke Formula:
3 mL/kg/24 h estimate ½ in first 8 hours and ½ in second 16 hours
Increase or decrease fluid rate each hour by 20%–25% to maintain urine output 0.5–1 mL/kg/h
Add maintenance fluid containing dextrose according to the 4:2:1 rule
(1–10 kg x 4) + (11–20 kg x 2) + (>20 kg x 1) mL/h

COMPLICATED BURN RESUSCITATION

Do not bolus IV fluids
At 12 hours post-injury, estimate 24-hour fluid total assuming stable fluid rate
Warning signs: >250 mL/kg over 24 hours
Persistent oliguria
Hypotension (MAP<65 mmHg) refractory to fluid titration
Evaluate intravascular volume status
Begin vasopressin 0.04 unit/min, then norepinephrine 2–20 µg/min (goal MAP>65 mmHg)
For **adults**, begin colloid fluid (5% albumin or fresh frozen plasma) at the following rates:

% TBSA burn	30%–49% TBSA	50%–69% TBSA	>70% TBSA
Colloid infusion rate (mL/h)	50	100	150

SHOCK REFRACTORY TO FLUID TITRATION OR ADJUNCTS

Evaluate for missed injury
Treat acidemia (ventilation, bicarbonate, RRT)
Replace calcium
Treat adrenal insufficiency with hydrocortisone

Fig. 155.3 Burn resuscitation algorithm. A sample algorithm is provided to guide initial resuscitation fluid titration and the use of adjuncts in difficult cases. *IV,* Intravenous; *MAP,* mean arterial pressure; *RRT,* renal replacement therapy; *TBSA,* total body surface area.

TABLE 155.1 Burn Resuscitation Endpoints

Endpoint	Target Range
Urine output	Adults: 0.5 mL/kg/h Children: 0.5–1 mL/kg/h Infants: 1 mL/kg/h
Mental status	Follows commands, purposeful age-appropriate activity
Heart rate	Adults: <130 bpm Children: <140 bpm Infants: <160 bpm
Systolic blood pressure	Adults: >90 mm Hg Children: 70–90 + (twice age in years) mm Hg Infants: 60–70 mm Hg
Central venous pressure	6–10 mm Hg
Stroke volume variation	<13%
Lactate	<2
Base deficit	Trend toward zero
Hematocrit	Gradual dilution

resuscitation. The use of vasoactive medications and inotropes must be guided by both invasive hemodynamic and laboratory monitoring. Failure to correct hypovolemia before using these agents often leads to worsening of the shock state. RRT and TPE have both been used during burn resuscitation. They are believed to facilitate resuscitation by cytokine removal, thus blunting the proinflammatory "cytokine storm" of early burn shock.[30,31]

Monitoring a burn resuscitation requires serially evaluating a constellation of physical examination findings, vital signs, laboratory data, and invasive monitors. Urine output remains the primary monitor, with a goal of 0.5 mL/kg/h (30–50 mL/h for most adults).[32] However, confounding factors such as early oliguric acute kidney injury, prior dehydration, alcohol intoxication, use of diuretics, and glycosuria can make urine output an unreliable indicator of resuscitation progress. The vital sign derangements typically encountered in burn shock are caused by a massive release of catecholamines, which increase the heart rate to 130 bpm or greater. This effect can persist for months without intervention (see Table 155.1).[33] Controversy remains over the most useful laboratory values during burn resuscitation. Serum lactate and base deficit have correlated with mortality and morbidity.[34,35] Central venous oxygen saturation has crossed over from sepsis resuscitation into burn shock management.[36] Hemoconcentration is observed early after burn injury and is late to correct. Titrating crystalloid fluid resuscitation to endpoints other than urine output is quite difficult, and no one endpoint should take precedence. Instead, the trends of as much data as possible should be examined to determine if volume resuscitation should be augmented versus other interventions such as vasopressors to address vasodilation.

Examining the impact of burn resuscitation on cardiac function requires advanced monitoring. Although the pulmonary artery (PA) catheter has largely been replaced by other technologies such as echocardiography and arterial waveform monitoring (stroke volume variation [SVV]), it may be required in patients with a history of heart failure or who require inotrope use.[37] The hyperdynamic response to burn injury and poor correlation of preload and cardiac output estimations with ultimate fluid requirements have challenged the universal adoption of these technologies in the burn ICU.[38] Clinicians must take as many variables into consideration as possible when determining the adequacy of resuscitation.

The judicial use of fluid and accurate monitoring is essential to avoid overresuscitation morbidities, including extremity compartment syndrome, acute respiratory distress syndrome (ARDS), abdominal compartment syndrome (ACS), orbital compartment syndrome, and cerebral edema. These complications are associated with severe morbidity or mortality. Patients at risk of receiving large resuscitation fluid volumes should be identified. One assessment is the "Ivy Index," which associates patients who receive >250 mL/kg in the first 24 hours postburn with increased risk of ACS.[39] Recognizing this trajectory allows initiation of fluid-sparing adjuncts, including colloids, vasopressin, RRT, or surgical intervention such as decompressive laparotomy.

INHALATION INJURY

Clinical evidence of inhalation injury includes deep facial burns, stridor, soot about the nares and mouth, or carbonaceous sputum. Patients evacuated from enclosed spaces (vehicles and buildings) are most at risk. Fiberoptic bronchoscopy in the intubated patient may confirm subglottic inhalation injury, although the visual grade of inhalation injury does not necessarily correlate with common sequelae, including increased resuscitative fluid requirements, airway obstruction, bronchospasm, pneumonia, and ARDS.[40] The burden of carbonaceous debris and epithelial sloughing are managed with aggressive pulmonary toilet. Nebulized adjuncts include unfractionated heparin (antiinflammatory and anticoagulant), N-acetylcysteine (antioxidant), and beta-adrenergic agonists (antiinflammatory and treats bronchospasm).[41,42] Prophylactic antibiotics are not recommended, but as pneumonia is common, clinicians should have a low threshold for obtaining cultures, including bronchoalveolar lavage samples, and starting antibiotic therapy in patients with new-onset fever and worsening respiratory function in the days after injury.

Adherence to lung-protective ventilation strategies is standard in most ICUs and should be extrapolated to most patients with burns and inhalation injury.[43] However, hypercatabolism or inhalation injury may cause severe gas exchange derangements, necessitating higher-than-expected mean airway pressures. Inverse ratio modes may not allow adequate expiratory time in the setting of hypercarbia. Specialized strategies, including high-frequency percussive ventilation (HFPV), have been used to obtain early bronchial clearance of debris, lower mean airway pressures, and provide tidal breaths and have found a niche in the burn population.[44] Timing of tracheotomy in burn patients unable to liberate from mechanical ventilation varies among centers.[45] Injury location, respiratory dysfunction, metabolic demands of large injuries, and refractory delirium all play a role in the decision and should become clear within 2 weeks of injury.

Patients with severe ARDS after inhalation injury are typically supported by lung-protective ventilation and adjuncts including reduction of excess fluids, early use of diuretics, neuromuscular blockade, prone positioning, and use of pulmonary vasodilators. Extracorporeal membrane oxygenation (ECMO), long avoided in adult burn patients, is now applied more regularly. ECMO strategies without systemic anticoagulation have seen successful use in burn patients requiring excision and grafting. Mortality in burn patients requiring ECMO is similar to nonburn patients.[46]

All patients with suspected inhalation injury should also be suspected to have carbon monoxide (CO) exposure. Co-oximetry via arterial blood gas is used to measure CO-hemoglobin levels. Symptoms of CO toxicity include confusion, stupor, coma, seizures, and cardiac ischemia. Administer 100% oxygen. Hyperbaric oxygen therapy may reduce the CO-hemoglobin half-life, but this therapy is cumbersome, particularly in the critically ill patient.[47]

Cyanide (CN) toxicity after smoke inhalation causes failure of oxygen utilization. Severe lactic acidosis is noted, although underresuscitated

burn patients present in similar fashion.[48] In addition to 100% oxygen, the antidote hydroxocobalamin should be administered.[49] Sodium thiosulfate may be given via the intramuscular injection route.[50]

CIRCUMFERENTIAL EXTREMITY BURNS

Escharotomy may be required for circumferential full-thickness burns to extremities with evidence of distal ischemia. If the burn is partial thickness or not circumferential, first rule out hypovolemic or hemorrhagic shock. Burned extremities should be elevated 30–45 degrees to decrease edema. Repeat the vascular examination at least every hour. The requirement for escharotomy usually presents in the first 24 hours. If available, use a handheld Doppler probe to assess the palmar arch, dorsalis pedis, and posterior tibialis for a normal triphasic signal. Consider performing escharotomy early, based on the vascular examination.

Escharotomy is performed by incising full-thickness burns just into the subcutaneous fat to allow the incision to visibly spring open. Patients will require analgesia, sedation, and usually intubation. Even though the eschar is insensate, deeper structures are not. Electrocautery is recommended because blood loss can be significant. Although this procedure can be performed in the ICU or emergency department, the OR, with its lighting and equipment, may be the better option. Extend escharotomy incisions the entire length of the circumferential portion of full-thickness burn, crossing all affected joints (Fig. 155.4). Reassess circulation after performing each incision. Once perfusion is restored, control bleeding, perform dressing care, and elevate the extremity once again. Continue regular vascular assessments. Be prepared for late bleeding as the tourniquet effect of circumferential burns is released. Fasciotomies on burned extremities are rarely required. Patients at risk for requiring a fasciotomy often have associated vessel injury with delayed revascularization, massive transfusion, or crush injury.[51]

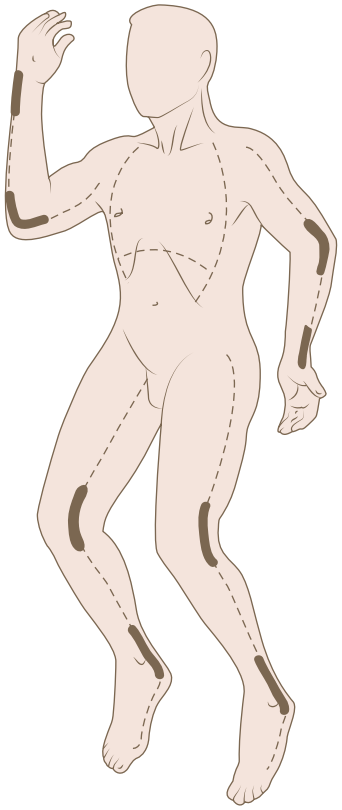

Fig. 155.4 Escharotomy. Properly performed escharotomy will result in immediate improvement in extremity blood flow. (From Steurer M, Chang T, Lancman B. Anesthesia for trauma. In Pardo MC, Miller RD, eds. *Basics of Anesthesia,* 7th ed. Philadelphia, PA: Elsevier; 2018:715–723.e2, Fig. 56.7.)

PERIOPERATIVE MANAGEMENT OF THE BURN PATIENT

Burn wound management is central to burn patient care, and the OR should be considered an extension of the ICU. A formal communication process between intensivists, surgeons, anesthesiologists, nurses, and OR staff is required. Continuation of ICU mechanical ventilators and continuous RRT should be strongly considered in the most critically ill patients to allow adequate surgical source control without interrupting needed therapy.

Hypothermia and intravascular volume depletion can occur rapidly via exposed surfaces. In addition to warming the OR air, convective warming blankets, IV fluid warmers, and esophageal warming devices should be used liberally.[52,53] IV fluid replacement should be guided by hemodynamic monitoring, urine output, and serial laboratory data.

Blood loss during tangential excision of large burn surface areas can be enormous. Adequate crossmatched blood products should be available before the start of the case. Replacement of large volume losses should approximate a 1:1:1 ratio of packed red blood cells, FFP, and platelets. Burn patients should be monitored intraoperatively for coagulopathy by standard assays and thromboelastography (TEG) if available.[54]

WOUND COVERAGE

Early excision, within 1 week of injury, is fairly standard for deep burns today.[55] Although wound care protocols vary widely, antimicrobials and grafts delay microbial recolonization while wounds close. An autograft (split-thickness skin graft) is used for definitive closure of deep burns. It survives via diffused oxygen and nutrients from wound fluid. The autograft is usually meshed to expand the area each graft covers and to allow evacuation of fluid. Mesh ratios >2:1 require a second skin substitute layer to protect the autograft while its interstices (spaces in the mesh) close. Silver-impregnated dressings are gaining in popularity, allowing for less frequent manipulation. The wound is considered "closed" once interstices are filled with a layer of epidermal cells. Although a grafted wound may close within a week, appearance and functionality continue to evolve over many months.

Much research effort is devoted to wound coverage, including spray-on autologous epithelial cells, laboratory-grown keratinocytes, and artificial skin substitutes.[56–58] Common skin substitutes remain biologic ones. An allograft (split-thickness deceased donor skin) is used if the wound bed is not conducive to autograft survival. Although eventually rejected by the host, it buys precious time during periods of instability or while awaiting healing of donor sites.

ANALGESIA AND SEDATION

Pain, anxiety, and sedation are discussed daily. The largest burn injuries lead to lengthy hospital stays and medication tolerance. Patients should be normalized as much as possible while providing adequate analgesia to accomplish procedures, therapy, and sleep. Continuous titratable analgesic and sedative infusions are used during periods of resuscitation and organ dysfunction. The use of ketamine as both procedural and maintenance sedation in adults has increased in recent years and is recommended during the hemodynamic instability of

acute postburn resuscitation.[59] De-escalation to intermittent dosing and the addition of oral analgesic formulations and multimodal strategies are used as patients become less critically ill and wound coverage progresses.[60] Management of behavioral health (e.g., depression, anxiety, and psychoses) is linked to adequate pain control. Have a low threshold to consult specialists in psychiatry and psychology, especially in the setting of preexisting disorders.

INFECTION IN THE BURN PATIENT

Prophylactic systemic antibiotics are not indicated for cutaneous burns alone. Early excision of deep burns and topical antimicrobials are the mainstays of infection prevention. However, associated traumatic injuries such as penetrating wounds, soiled lacerations, or open fractures do warrant systemic antibiotics. The choice and duration of this therapy should be selected according to institutional guidelines. Tetanus prophylaxis is given to all burn patients.

Deep, unexcised burn wounds are particularly susceptible to gram-negative colonization and wound sepsis. A wide variety of topical antimicrobials exist to cleanse wounds and act as barriers to colonization (Table 155.2). These agents, however, do not replace prompt surgical excision of deep wounds followed by immediate coverage with autologous skin or temporary skin substitutes. All topical agents have advantages and disadvantages. Although several topical agents allow for continuous use over many days, new-onset fever or organ dysfunction should prompt dressing removal and a complete wound examination.

The expected hyperdynamic response to major burns can be prolonged even months after injury, causing elevated thresholds for hyperthermia, tachycardia, and tachypnea.[61] Suspected systemic infection should trigger a complete physical examination, including of all wounds and grafts. Antibiotics should be started while awaiting culture data if new organ dysfunction occurs.

Burn wound infection is a clinical diagnosis. Signs include cellulitis (expanding induration and tenderness), foul odor, purulent drainage, graft necrosis, and previously healing partial-thickness injuries that now appear full thickness. Diagnosis may be augmented by quantitative cultures or wound histology showing invasion of organisms into viable tissue.[62] These efforts are merely adjuncts, however, and wound biopsy is less frequently employed today. Swab cultures of wound sites are of little benefit, as they cannot differentiate between infection and colonization.

Once a wound infection is diagnosed, empiric systemic antibiotic therapy and topical antimicrobials should be directed against both gram-positive and gram-negative bacteria using known institutional susceptibilities. *Pseudomonas* species, including resistant strains, are common. The best prevention of burn wound sepsis is early excision of deep burns and autologous tissue coverage. If wound infection is diagnosed in previously excised wound beds, re-excision may be required. With hyperdynamic physiology and increasing use of extracorporeal organ support, serum levels of systemic antibiotics should be monitored closely to ensure adequate therapeutic ranges.

The inflammatory response after burn injury alters electrolyte homeostasis. Hypocalcemia, hypomagnesemia, and hypophosphatemia are frequently encountered and are often severe. Tissue water deposition and insensible losses contribute to hypernatremia early after the acute resuscitation period, and liberal free water replacement is required. Later in the course of the hospitalization, hyponatremia is routinely noted.[63]

TABLE 155.2 Topical Antimicrobials

Agent	Characteristics
Antibiotic ointments	Oily preparations for partial-thickness burns, limited antibacterial activity, Bactroban (mupirocin) active against MRSA
Ionic silver dressings	May be left for several days, broad-spectrum antibacterial
Dakin solution	Dilute sodium hypochlorite, used in soiled wounds, broad spectrum, toxic to keratinocytes at strengths >0.0025%
Silver sulfadiazine	Well tolerated and widely available, does not penetrate eschar
0.5% Silver nitrate	Often used for SJS/TEN, stains black, causes hyponatremia
Mafenide acetate	Used as a cream or dilute solution, penetrates eschar, can be painful, causes metabolic acidosis

MRSA, Methicillin-resistant *Staphylococcus aureus; SJS,* Stevens-Johnson syndrome; *TEN,* toxic epidermal necrolysis.

GASTROINTESTINAL STRESS ULCERATION

Historically, gastric acid–reducing medications have been associated with decreased incidence of Curling ulcer (burn-specific stress ulceration) and mortality from gastrointestinal bleeding in patients with large burns.[64] Hemodynamic support, nutrition interventions, and wound sepsis prevention have also likely contributed to the low modern incidence of significant gastrointestinal hemorrhage. Patients with injuries ≥20% TBSA should receive stress ulceration prophylaxis with a proton pump inhibitor or other gastric-reducing agent.[65] Advancing enteral nutrition as soon as practicable is recommended.

NUTRITION

It is challenging to provide adequate nutrition during the hypercatabolic response to large surface area burns. Early (even during resuscitation) enteral feeding has become standard in many centers. Calculated calorie and macronutrient goals vary in the literature. Adult burn patient consensus guidelines suggest approximately 1.5–2 g/kg/day of protein, which many American Burn Association (ABA)–verified burn centers consider inadequate to meet the nutritional needs of the hypermetabolic burn patient. Nonprotein caloric load goals are no longer recommended.[66] Indirect calorimetry repeated at intervals can provide metabolic data to assist with nutritional interventions. Ultimately, the quality and rate of wound closure reflect the adequacy of nutrition. Admission screening of weight, HbA_{1c}, vitamin D, calcium, and albumin levels provide important information about preinjury nutrition status. Micronutrients such as vitamin C, zinc, copper, and selenium play important roles in wound healing in the largest burns.[67] Anabolic steroids and beta-adrenergic blockade are routinely used to reduce the effect of hypercatabolism.[68,69]

Patients able to swallow effectively should receive a high-protein, high-calorie diet. Patients with ≥30% TBSA burns are often unable to attain adequate nutrition via oral intake alone. These and patients with dysphagia should have nasoenteric access. Percutaneous placement of gastric tubes (PEG tubes) must be weighed against the risks of site complications, particularly if torso burns are present.[70] Enteral feeding should be continued in patients who are not exhibiting worsening shock. Meeting nutritional goals can be challenging when enteral infusions are interrupted for frequent procedures. Postpyloric access is not necessary but may decrease perioperative interruptions in formula infusion. An increasing number of centers continue uninterrupted

TABLE 155.3 Splinting Recommendations

Location	Positioning	Splinting
Neck/face	Anterior neck burns: extension Posterior neck burns: neutral Ear burns: no pillows	Soft neck collar
Shoulder/axilla	Keep arm elevated	Abduction wedge
Chest	Shoulder abduction, arms elevated	Abduction wedge or pillows
Elbows	Elevate arms above heart	Extension splint
Hands	Elevate hands and arms above heart	Intrinsic plus splints: MCP joint flexion and PIP/DIP joint extension Splints are worn at all times when not performing therapy
Hips	Hips are extended and abducted; avoid hip flexion	
Legs	Elevate legs above heart level Check for Achilles and heel wound breakdown Avoid pillows behind knees	Elevate legs above level of heart Ankle dorsiflexion splint Knee extension splints (knee immobilizer)

DIP, Distal interphalangeal; *MCP,* metacarpophalangeal; *PIP,* proximal interphalangeal.

enteral feeding during operative cases.[71] The enteral route is preferred for provision of nutrition, but supplemental parenteral nutrition should be considered in patients who are unable to reach a significant proportion of their estimated needs after 1 week.[72,73]

REHABILITATION IN THE BURN ICU

Physical and occupational therapists are essential members of the multidisciplinary team and inform daily ICU goals. Generally, injured extremities are elevated above the level of the heart to reduce edema. Check for skin and wound breakdown caused by pressure (e.g., sacrum, heels, elbows, and occiput). Splints are used to prevent flexion contractures (Table 155.3). Extremities with unexcised burns or those covered with temporary skin substitutes should be allowed full active and passive range of motion. Extremities receiving a split-thickness autograft, particularly over joints, may receive range-of-motion limitations for several days, but these restrictions are increasingly being liberalized at many centers.[74] Patients should be given liberal access to sunlight, outdoor spaces, and even the gym.

PEDIATRIC PATIENTS

Although pediatric burn injuries are most associated with the need to screen for abuse or neglect, clinicians are reminded that *all* burn-injured patients are potentially victims and should be alert to other traumatic injuries and evidence of malnutrition.

The smaller airways of pediatric patients are at risk for faster compromise.[75] As with adults, IV and IO access can be used for resuscitation, but central venous catheters are generally required for the largest burns. The relative surface areas of extremities, trunk, and head vary with age. Percentage TBSA may be estimated using the Pediatric Lund-Browder Burn Estimate and Diagram (see Fig. 155.2), which has both infant and child estimates.

For burn sizes ≤15% TBSA, children may be given 1.5 times their expected maintenance rate while monitoring urine output and vital signs. Maintenance fluid needs may be estimated with the "4:2:1 rule." For each kilogram in the range of 1–10 kg, provide 4 mL/h; for each kilogram in the range of 11–20 kg, provide 2 mL/h; and for each kilogram >20 kg, provide 1 mL/h.[76] The enteral route should be used for at least some hydration if possible. Infants may be given breast milk or bottle feeds, and older children may be given nasoenteric infusions of oral rehydration formulas, such as the World Health Organization (WHO) Oral Rehydration Solution (ORS).[77]

For burn sizes >15% TBSA, place an appropriately sized urinary catheter. Anticipate volume requirements with the Pediatric Modified Brooke formula (3 mL/kg/%TBSA LR or other isotonic fluid divided over 24 hours, with one-half given during the first 8 hours). As with adults, the formula only provides a resuscitation starting point. Increase or decrease the IV isotonic fluid infusion rate by 20%–25% each hour to attain goal urine output: 0.5–1 mL/kg/h for children. Young children <20 kg with large burns will require additional dextrose-containing maintenance fluid (LR containing 5% dextrose) according to the 4:2:1 rule to compensate for inadequate glycogen stores. Unlike the isotonic fluid given for resuscitation, this maintenance infusion is not titrated.

To reduce the risk of overresuscitation, colloid fluid in the form of 5% albumin should be added for children with burns >30% TBSA. Starting at 12 hours postinjury, give 5% albumin at the calculated maintenance rate using the 4:2:1 rule. Subtract this volume from the hourly isotonic fluid rate. This albumin infusion is not titrated. Continue the albumin infusion until 48 hours postinjury. Pediatric burn resuscitations are monitored using urine output, vital signs, and laboratory data, which must be compared with age-related norms.

High-quality burn care in the pediatric population is particularly resource-intensive. Access to experienced consultants in addition to pediatric psychosocial support and physical and occupational therapists is critical. Malnutrition is poorly tolerated in children, and enteral feeding with a pediatric formula should be given to all hemodynamically stable patients.[78] Tolerance to sedative and analgesic medications is common and monitored procedural sedation is standard for dressing care and other manipulations that cause pain and anxiety.[79]

OPHTHALMIC INJURY

Patients with facial burns or exposure to blasts, flash fires, or chemicals may also have ophthalmic injuries. Eye examinations should be completed before significant facial edema occurs. Examination with the Wood's lamp screens for corneal injury, which should prompt early ophthalmology specialist consultation. At a minimum, if no eye injuries are identified, intubated patients should receive frequent lubricating eye drops. Lateral canthotomy should be considered in those patients demonstrating intraocular hypertension during resuscitation.

CHEMICAL BURNS

Patients with known or suspected chemical exposure should be cleansed with low-pressure water for at least 30 minutes. Litmus paper may be applied to affected areas to track the progress of decontamination. Obtain as much information about the exposure as possible to anticipate potential systemic effects. Fluid resuscitation of chemical burn casualties proceeds as for a similar area of flame burns. Visual declaration of wound depth may be delayed. Cement causes alkali contact burns after extended exposure, and patients often present in delayed fashion.[80] Hydrofluoric acid exposure may result in severe systemic hypocalcemia and require subeschar injection of 10%

calcium gluconate as a bridge to urgent excision.[81] Tar used for paving and other applications causes very high-temperature contact burns, and the material quickly solidifies. Cool water irrigation is followed by lipophilic solvent application and then operative excision.[82]

Chemicals and certain munitions may be encountered during periods of armed conflict or acts of terrorism. Medical providers must protect themselves from exposure to the very agents they are treating. Institutional protocols for decontamination of chemical exposure casualties should be developed and practiced. White phosphorus is an incendiary and antipersonnel compound that ignites in the presence of oxygen. Wounds should be covered with soaking wet cloth to prevent reignition of retained fragments. Urgent operative exploration addresses particles buried deeply in soft tissues, and copper sulfate may aid in their identification.[83] Vesicant compounds such as sulfur mustard, phosgene, and lewisite are used as chemical weapons and cause contact injuries to skin and epithelial surfaces.[84] Respiratory compromise may occur early, but skin lesions may take days to fully develop, depending on the agent. Patients are prone to ARDS, early pulmonary infection, wound sepsis, and pancytopenia. Fluid resuscitation needs are often less than those predicted by burn formulae.

ELECTRICAL INJURY

Electrical injuries are defined as "low-voltage" (110–220 volts) and "high-voltage" (>1000 volts) exposures. The distinction can be misleading, however. Even low-voltage exposures may result in dysrhythmias, wound complications, and neurologic sequelae.[85] In addition to these problems, high-voltage exposures have the potential to cause even more widespread tissue injury and secondary effects such as rhabdomyolysis, flame burns, corneal injury, and blunt trauma. Patients presenting after significant electrical contact should have a full trauma evaluation.

Admission criteria after electrical exposure are not universal, but it is reasonable to observe patients with high-voltage exposures and no obvious injuries for 24 hours. A 12-lead electrocardiogram should be obtained to screen for cardiac dysrhythmias, even after low-voltage contact. Admitted patients will typically have evidence of cutaneous burns or other injury. Fluid resuscitation should proceed as for thermal burns, but be prepared to increase the rate of isotonic crystalloid fluid in response to urine output and other indicators of perfusion. Urine output should be examined for gross pigmenturia (the color of red wine). If this is present, the crystalloid rate should be increased to target a urine output of 1 mL/kg/h. Acute kidney injury is common in this setting, and continuous RRT is an important adjunct to management.[86] Rhabdomyolysis usually indicates deep tissue injury. Suspected compartment syndrome in affected extremities should prompt urgent fasciotomy and excision of burns. In this setting, definitive coverage is best deferred until tissue necrosis is absent after several OR trips.

COLD INJURY

Cold injuries, often referred to burn centers, are classified as freezing or nonfreezing. Freezing injury, including frostbite, occurs in tissues exposed to below-freezing temperatures (≤0°C). Nonfreezing injury, such as trench foot, results from prolonged exposure to wet and cold conditions (>0°C).[87] Patients with comorbid conditions such as advanced age, dehydration, peripheral vascular disease, diabetes, and a history of alcohol overuse or nicotine dependence are at increased risk of cold injury. Hypothermia is managed by providing a warm environment, convective heating, and warm fluid infusions. Avoid lactated and potassium-containing fluids. Cardiac arrest in the hypothermic patient should be treated by external cardiac massage, warm fluid infusion (including lavage through gastric and rectal tubes), and correction of acidosis and hyperkalemia. As core temperature rises, defibrillation may be attempted.[88]

Frostbite occurs when tissue water crystallizes. Areas affected by frostbite may be warmed in a water bath of 40°C. Hemorrhagic bullae should be left intact.[89] It is difficult to predict the extent of tissue loss; thus early débridement or amputation is discouraged until full demarcation of necrosis occurs, often over weeks to months. Multimodal analgesia is recommended. Given the high levels of prostaglandin $F_{2\alpha}$ and thromboxane A_2 in blister fluid, nonsteroidal antiinflammatory drugs (NSAIDs) are used routinely.[90] Other adjuncts such as thrombolytic therapy may be considered on an individual basis.[91] Wounds are covered with loose antimicrobial dressings. Early physical and occupational therapy is required.

RADIATION INJURY

Exposure to ionizing radiation can occur during industrial accidents and armed conflict. Localized radiation injury from high-dose exposure > 8–10 Gy causes burns with similar visual appearance to thermal burns. Erythema appears quickly and usually subsides only to reappear weeks later. This may be accompanied by hair loss and blistering. Skin necrosis may be significantly delayed from the index injury.[92] Treatment of partial-thickness burns is conservative and relies on moist antimicrobial dressings and skin substitutes until epidermal healing occurs. Full-thickness injuries are excised, followed by skin grafting only when granulation tissue appears adequate.

Whole-body radiation exposure results in critical illness after prodromal and latent phases. The higher the cumulative radiation dose, the faster the onset of pancytopenia, gastrointestinal mucosal sloughing, neurologic deterioration, and cardiovascular collapse.[93] Decontamination protocols are necessary to protect clinicians from secondary exposure. The need for prolonged supportive care should be factored into triage decisions.[94]

DESQUAMATIVE DISORDERS

Burn centers are often asked to evaluate patients with desquamative disorders (severe cutaneous adverse reactions [SCARs]). Stewardship of limited burn beds mandates accurate diagnosis. The Stevens-Johnson syndrome/toxic epidermal necrolysis (SJS/TEN) continuum are T-cell immune reactions classified by extent of epidermal detachment. Many triggers have been reported, including anticonvulsant medications, antibiotics, and viral illnesses, among others. Often, a prodromal phase of fever, lethargy, and dysphagia is followed by sloughing of the epidermis, tracheobronchial tree, gastrointestinal tract, vaginal mucosa, cornea, and oropharynx. Clinical suspicion should be corroborated by cutaneous punch biopsies.[95,96]

Stop all potential offending agents. Although the capillary leak is not as severe as for thermal burns, patients' fluid status must be closely monitored. Comorbid organ dysfunction often worsens in the setting of the inflammatory response to SJS/TEN. Blisters may be left in place. Exfoliated areas may be covered with silver-based dressings while awaiting re-epithelialization, which should occur within 2–3 weeks. Specialist consultation in ophthalmology, dermatology, and gynecology is recommended for affected structures. Early administration of immune adjuncts may benefit select patients and should be guided by experienced clinicians. This includes the use of intravenous immunoglobulin (IVIg), corticosteroids, cyclosporin A, and granulocyte colony-stimulating factor (G-CSF).[97,98]

CONCLUSION

Patients with major burn injuries rely on aggressive management of their wounds combined with multidisciplinary critical care to increase their odds of a good outcome. Although resource-intensive, quality burn care is an investment that returns precious time to patients in their most productive years.

KEY POINTS

- Do not become distracted by the cutaneous injuries of burn patients; screen for other traumatic injuries per advanced trauma life support (ATLS) guidelines.
- Fluid resuscitation and hypothermia prevention are early priorities after burn patient arrival.
- Establish a definitive endotracheal airway in patients with symptomatic smoke inhalation injury, deep facial burns, and burns >40% TBSA; secure with cotton twill ties.
- Suture all IV and central venous and arterial catheters in place.
- Perform frequent neurovascular assessments of deep circumferential extremity burns and perform escharotomy early if required.
- All burn formulae provide starting points only; titrate isotonic crystalloid rates hourly to attain urine output and other resuscitation endpoints.
- Increased urine output should be targeted in the setting of electrical injury with gross pigmenturia.
- The hypercatabolic state after burn injury may last months.
- Early nutrition without frequent interruptions is required to heal large burns.
- Physical and occupational therapy must begin early in the hospital course.

Thoracic Trauma

Frank Z. Zhao and Walter L. Biffl

Thoracic trauma is responsible for approximately 20% of all trauma-related deaths and is second only to central nervous system injury as the primary cause of death at the scene. For patients arriving at the emergency department (ED) alive, rapid diagnosis and treatment of potentially life-threatening injuries are required to prevent death during the "golden hour" of initial resuscitation. However, many thoracic injuries that are not immediately life-threatening still have the potential for significant morbidity and mortality. The following is an overview of the diagnosis and management of thoracic trauma.

INITIAL ASSESSMENT

Primary Survey

The Advanced Trauma Life Support (ATLS) course of the American College of Surgeons Committee on Trauma[1] provides basic tenets for the management of injured patients. The process begins with the primary survey, a stepwise evaluation of the "ABCs": airway, breathing, and circulation.

Airway patency may be compromised by neurologic injury, facial injury, or obstruction (e.g., by the tongue, blood, vomitus, or tooth or bone fragments). Trauma to the larynx, trachea, or bronchus may also complicate or preclude airway control. Thoracic trauma may also cause life-threatening breathing (e.g., pneumothorax [PTX], pulmonary contusion) and circulation (e.g., tension PTX, pericardial tamponade, massive hemothorax) problems. These must be identified and treated rapidly.

Resuscitative Thoracotomy

Resuscitative thoracotomy (RT) is indicated for traumatic cardiac arrest or persistent severe hypotension (e.g., systolic blood pressure [SBP] <60 mm Hg). The primary objectives of RT are to (1) release pericardial tamponade and repair cardiac injuries, (2) control intrathoracic hemorrhage, (3) control bronchovenous air embolism or bronchial injury, (4) perform open cardiac massage, and (5) attenuate subdiaphragmatic hemorrhage and redistribute blood flow to the brain and myocardium.[2] The critical determinants of survival after this procedure are the mechanism of injury and the patient's condition. The best outcomes are seen in adult patients with isolated penetrating cardiac injuries who present with detectable SBP; survival averages 35% in one large series. In contrast, RT is least beneficial in the treatment of blunt injury without signs of life, with only 0.7% of patients surviving.[3]

An algorithm for resuscitation of moribund trauma patients is presented in Fig. 156.1.[2] Patients arriving in extremis after blunt injury undergo thoracotomy if they have had less than 10 minutes of cardiopulmonary resuscitation (CPR). Penetrating trauma victims undergo thoracotomy if they have had less than 15 minutes (for torso injuries) or 5 minutes (nontorso injuries) of CPR. The pericardium is opened; if there is no organized cardiac activity and no blood in the pericardium, the patient is pronounced dead. Otherwise, the descending thoracic aorta is occluded to limit subdiaphragmatic hemorrhage and redistribute perfusion to the myocardium and brain. Patients who do not respond with SBP >70 mm Hg are pronounced dead on the basis of futility. The value of thoracotomy in the resuscitation of a patient in profound shock is unquestioned. Its indiscriminate use, however, is not appropriate. Although the performance of RT only "costs" the price of a scalpel and sterilization of the instrument tray, it is critical to recognize futility and avoid initiating massive transfusion or transferring the patient to the operating room (OR). These costly resources should be reserved for potential survivors. Furthermore, although no cases have been specifically reported, there is a potential risk of transmission of bloodborne disease to the healthcare team. An alternative approach to selective RT involves the use of focused ultrasonography to evaluate for meaningful cardiac activity. Inaba and colleagues showed in a prospective study of 187 patients that cardiac motion seen on focused assessment with sonography in trauma (FAST) examination was 100% sensitive for identification of survivors and organ donors. Thus the performance of RT was deemed futile to both overall survival and survival to organ donation in patients without cardiac motion.[4]

Recently, the use of resuscitative endovascular balloon occlusion of the aorta (REBOA) has been proposed for traumatic cardiac arrest.[5] This has not been studied in adequately controlled prospective trials—it takes precious time to deploy, and major thoracic hemorrhage is considered an absolute contraindication to its use.[6] The patient presenting in extremis secondary to subdiaphragmatic hemorrhage is most likely to benefit from REBOA if it can be deployed rapidly.[5] For the patient presenting in cardiac arrest resulting from exsanguination or pericardial tamponade, open-chest CPR has proven superior to closed-chest CPR, and thus RT remains our recommendation in this setting.[7]

PLEURAL SPACE

Pneumothorax

PTX is common in thoracic trauma. Clinical diagnosis based on decreased breath sounds and hyperresonance to percussion is not accurate, especially in the noisy trauma resuscitation bay. Chest x-ray (CXR) has long been considered the diagnostic standard, but ultrasonography performed as part of the extended focused assessment with sonography for trauma (E-FAST) has potentially greater sensitivity for a small PTX in the supine patient.[8] An untreated PTX may progress to tension PTX, especially if the patient is receiving positive-pressure ventilation. In this setting, the mediastinal structures are shifted away from the affected side. Once venous return to the heart is impaired, cardiovascular collapse ensues. Immediate decompression of tension

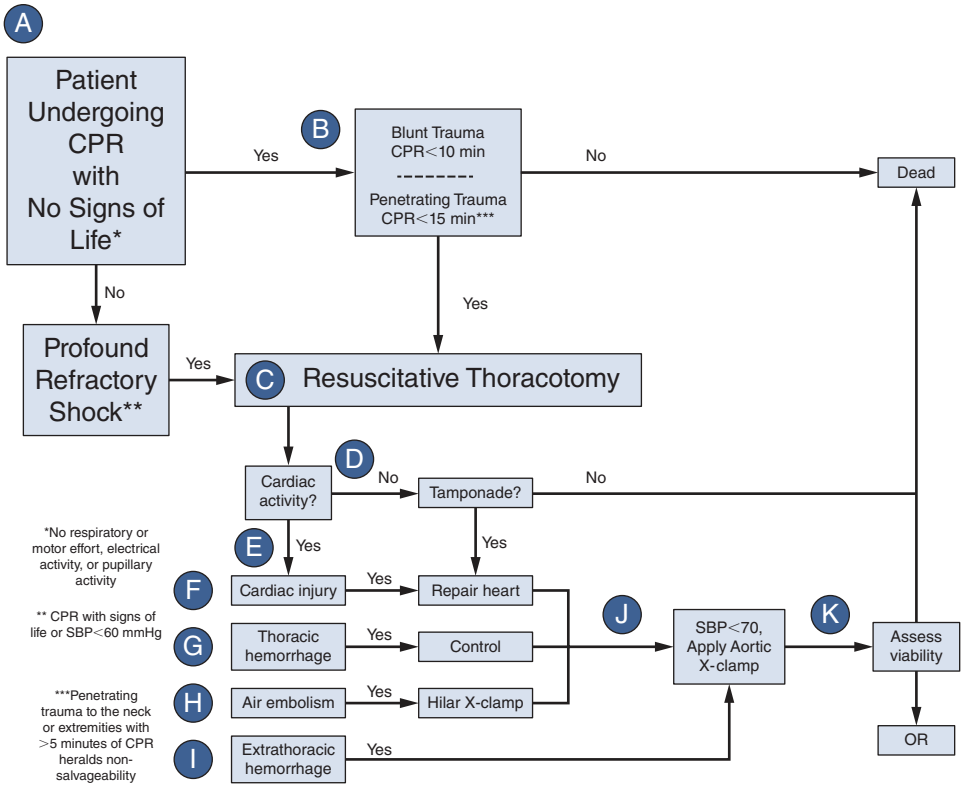

Fig. 156.1 Algorithm for resuscitative thoracotomy. *CPR*, Cardiopulmonary resuscitation; *OR*, operating room; *SBP*, systolic blood pressure. (From Burlew CC, Moore EE, Moore FA, et al. Western Trauma Association critical decisions in trauma: Tesuscitative thoracotomy. *J Trauma Acute Care Surg.* 2012;73[6]:1359–1363.)

PTX is imperative. If a patient arrives in extremis and has evidence of chest trauma (e.g., penetrating wound, subcutaneous crepitance, tenderness consistent with rib fractures), empiric tube thoracostomy for presumed hemopneumothorax is recommended.

An open PTX (aka "sucking chest wound") results from a full-thickness chest wall wound. If the wound diameter exceeds two-thirds of the tracheal diameter, negative intrapleural pressure associated with inspiratory effort results in air entering the pleural space preferentially through the wound. Because of the large hole, there is little chance of tension. However, this can be life-threatening because it prevents pulmonary gas exchange. It is managed by an occlusive dressing secured on three sides to prevent sucking of more air but allowing decompression of the PTX until definitive wound closure, and tube thoracostomy should be performed.

With the growing use of thoracic computed tomography (CT), small PTXs are often discovered that are not seen on CXR. These "occult PTXs" generally do not require treatment but should be monitored for progression. A prospective multicenter study of the American Association for the Surgery of Trauma (AAST) found that only 6% of patients with occult PTX ultimately required a chest tube. Moreover, consistent with earlier studies, fewer than 20% receiving positive-pressure ventilation required chest tubes, and none of them had tension.[9] Another recent study of small traumatic PTXs from both blunt and penetrating injuries found that a distance of ≤35 mm between the visceral and parietal pleura was a safe cutoff for observation.[10]

Tube Thoracostomy

Tube thoracostomy is the definitive treatment for PTX and hemothorax. The procedure is not difficult and can be performed rapidly, but care must be taken to avoid malpositioning. The optimal position is posterior to facilitate dependent drainage of blood and is directed to the apex of the pleural cavity. The current trend is to place smaller-diameter tubes (28–32F), as they cause less discomfort for the patient and are adequate to drain most nonclotted hemothoraces.[11]

In the setting of tension PTX, if tube thoracostomy is not immediately available, the chest can be quickly decompressed with finger thoracostomy or needle decompression. Although many authors previously promoted needle thoracostomy via the second intercostal space in the midclavicular line, it has been recognized repeatedly that catheters may be kinked in the pectoralis major muscle or breast tissue, rendering them ineffective—often unbeknownst to the clinician. Recent literature has documented that the chest wall is, on average, 10–12 mm thinner in the anterior axillary line at the fifth intercostal space. This site allows rapid, reliable, safe entry into the pleural space and is currently promoted by ATLS.[12]

A recent meta-analysis of 12 randomized trials concluded that prophylactic administration of antibiotics was associated with significantly less risk of empyema and pneumonia. We thus recommend preprocedural administration of a first-generation cephalosporin with duration no longer than 24 hours.[13]

Pneumothoraces and air leaks should be resolved before removal of the tube, and ideally, drainage should be less than 2–3 mL/kg/day. After 12–24 hours without an air leak, the tube may be removed while on suction. However, a 6- to 12-hour trial of water seal drainage is generally warranted to observe for an occult air leak.[14] It has been recommended that tubes be removed at maximal deep inspiration with a Valsalva maneuver, but recurrent PTX may occur in 6%–8% of patients regardless of respiratory phase. More than 20% of patients require longer than 3 days to resolve an air leak, in which case their hospital course may be expedited by the use of thoracoscopy.[15]

Hemothorax

Blunting of the costophrenic angle on upright CXR requires 200–250 mL of blood, and in a supine patient, there may be only subtle haziness of the affected hemithorax. Whereas small, asymptomatic hemothoraces may be managed expectantly, it is currently recommended that hemothoraces greater than 300 mL be drained by tube thoracostomy.[16] A massive hemothorax is usually the result of a major vascular injury and is life-threatening. Indications for thoracotomy include the immediate return of 1500 mL of blood via tube thoracostomy or continued output of more than 200 mL/h for 2–3 consecutive hours. The clinician should be wary of an initial high-volume chest tube output (>10 mL/kg) that is followed by an abrupt decrease in volume. If there is clinical suspicion of ongoing bleeding, a repeat CXR should be obtained to rule out a retained hemothorax. This can occur because of a malpositioned, kinked, or clotted chest tube and should prompt a second chest tube. If the hemothorax remains significant, thoracoscopy or thoracotomy is indicated.[17] Occasionally, in penetrating trauma there will be a "caked hemothorax" where the original chest tube is well positioned, but there is ongoing arterial bleeding that is too rapid to be evacuated. The result is retained "tension" hemothorax with a mediastinal shift and mandates immediate thoracotomy. Additionally, hemothoraces associated with massive blunt chest wall trauma can pose special challenges. Ongoing bleeding suggests the need for thoracotomy, but a large incision may compound the bleeding, and diffuse bleeding from bone and soft tissue disruption may prove difficult to control. In this setting, angioembolization of the intercostal vessels can be considered in the hemodynamically stable patient.

Rib Fractures

Rib fractures are present in 10% of trauma patients admitted to the hospital. Elderly patients are especially susceptible to diminished pulmonary function and complications. Patients over the age of 65 have twofold to fivefold increases in morbidity and mortality compared with younger patients with similar injuries.[18] In addition, it is important to identify patients who are at risk for respiratory decompensation and admit them to units with closer monitoring. Fig. 156.2 shows our institutional algorithm for initial triage and management of rib fracture patients.

Another key factor in the management of these patients is protocolized multimodal pain management. This allows facilitation of pulmonary physiotherapy to avoid atelectasis and improve clearance of secretions. Epidural catheters have proved to be efficacious and superior to patient-controlled analgesia in this regard and may also modify the immune response.[18] Often the polytrauma patient has contraindications to epidural catheters, such as spinal fractures and coagulopathy.[19] In these patients, intercostal nerve/rib blocks may provide immediate relief in the ED or intensive care unit (ICU) while awaiting further therapy. Alternatively, paravertebral catheter infusion of bupivacaine can provide significant relief of rib fracture pain and may be equivalent to epidural catheters in terms of efficacy. These catheters can also be used in patients who have contraindications to epidural catheters.[20,21]

Although pain and morbidity from rib fractures are often emphasized for hospitalized patients, there is a growing body of literature detailing the presence of prolonged pain and physical incapacity 2–12 months after hospital discharge.[22,23] Recently, the technique of

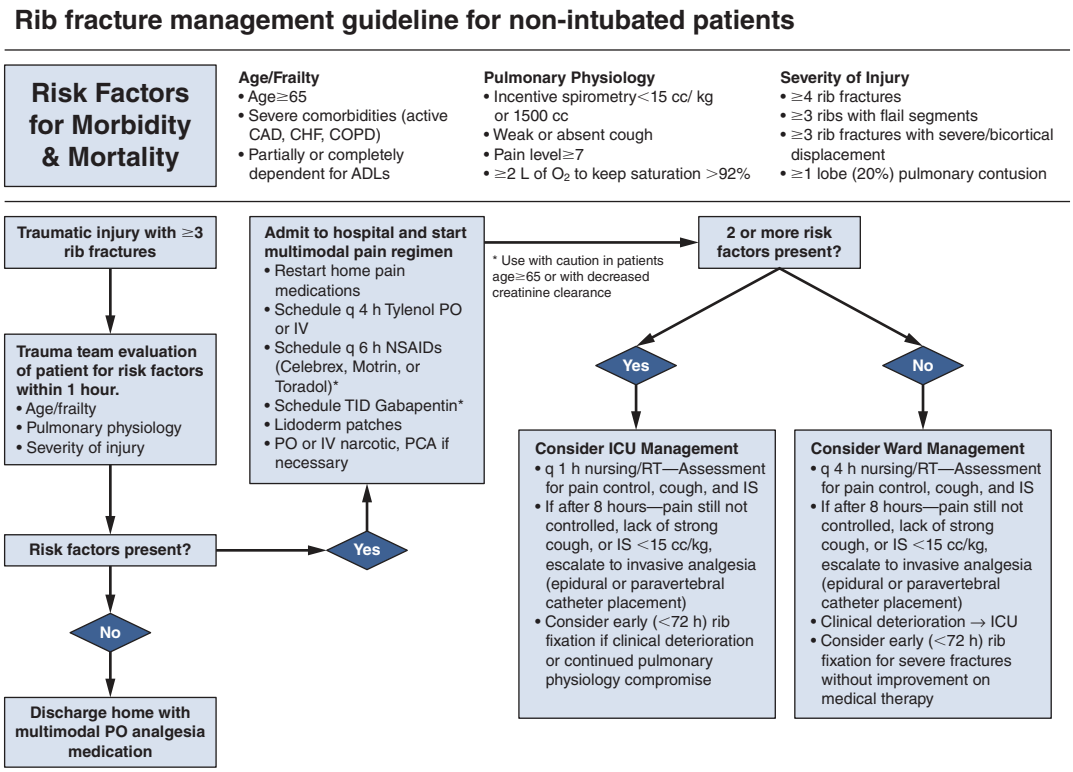

Fig. 156.2 Institutional rib fracture triage and management guideline. (Data from Witt CE, Bulger EM. Comprehensive approach to the management of the patient with multiple rib fractures: A review and introduction of a bundled rib fracture management protocol. *Trauma Surg Acute Care Open*. 2017;2[1]:e000064; and Brasel KJ, Moore EE, Albrecht RA, et al. Western Trauma Association Critical Decisions in Trauma: Management of rib fractures. *J Trauma Acute Care Surg*. 2017;82[1]:200–203.)

intercostal nerve cryoablation has become a topic of interest for pain management secondary to severe rib fractures, given its ability to provide longer-lasting (8–12 weeks) analgesia. The technique causes axonotmesis but leaves the perineural structures intact. In this manner the nerve regenerates and provides reinnervation over time in anatomic fashion. Preliminary studies in trauma patients have shown a significant decrease in postoperative numerical pain levels.[24] In addition, pediatric surgeons performing chest wall reconstruction have been able to show decreases in opioid use, pain levels, and hospital length of stay using this technique.[25]

Flail Chest

Three or more ribs fractured in two or more places produce a flail segment of the chest wall. In the nonventilated patient, this segment may move paradoxically—inward during inspiration, outward during expiration—and consequently impair ventilation. Additionally, flail chest is often accompanied by pulmonary contusion, which compounds the degree of pathophysiology, as contused lung tissue cannot function in oxygenation. Treatment for pulmonary contusions is supportive, including supplemental oxygen, analgesia, and pulmonary toilet. See further details in this chapter.

Surgical Stabilization of Rib Fractures

Although surgical stabilization of rib fractures (SSRF) has been undertaken since the early 20th century, the wider adoption of the technique has only occurred in the past 20 years. As technology has improved with chest wall–specific tools and systems, muscle sparing and minimally invasive techniques have replaced older thoracotomy incisions and associated morbidities. Although not definitive, the physiologic and functional benefits of SSRF have gained more acceptance in the past 10 years. A systematic review was performed by the Eastern Association for the Surgery of Trauma (EAST) showing decreased ICU length of stay, time on ventilator, pneumonia rates, tracheostomy rates, and mortality for patients with flail chest.[26] For patients who have severely displaced rib fractures without flail chest, a recent multicenter prospective randomized trial of the Chest Wall Injury Society (CWIS) demonstrated decreased numeric pain scores, pleural space complications, and narcotic consumption and improved quality of life.[27] Overall indications for SSRF have been codified in recent CWIS consensus guidelines[28] and can be summarized as a patient with either flail chest or severely displaced rib fractures, especially one who is concurrently experiencing physiologic deficits.

Sternal Fracture

An early series of sternal fractures described the "steering wheel syndrome" (rapid deceleration, with impact of the sternum on the steering wheel) as the most common cause of sternal fractures. Associated blunt cardiac injury was common, so sternal fractures were thought to be harbingers of significant thoracic injury. More recently, however, sternal fractures have been reported more commonly with the "seat belt syndrome" (in conjunction with three-point or bandolier seat belts). Associated injuries are less frequent, so stable patients without electrocardiogram (ECG) abnormalities can be safely discharged from the ED. For hospitalized patients with severely displaced sternal fractures, surgical fixation can be a consideration; however, the body of scientific literature remains weak and requires more robust studies in the future.[29]

BLUNT LUNG INJURY

The spectrum of lung parenchymal injury after blunt chest trauma ranges from simple contusions to frank lacerations. Pulmonary contusion is by far the most common and is merely a bruise of the lung. The pathophysiologic changes fundamentally include alveolar hemorrhage with surrounding edema, with a broad range of severity. The clinical result is hypoxia and increased work of breathing because of ventilation/perfusion mismatching and decreased pulmonary compliance. Pulmonary contusions may not appear on initial chest radiographs, although they are usually seen by 6 hours after the injury; chest CT is more sensitive at diagnosing early pulmonary contusions. Treatment is supportive, including supplemental oxygen, pain control, pulmonary toilet, and judicious fluid management. There is no role for either routine antibiotics or steroid therapy.[30] Intubation and mechanical ventilation are employed only as necessary. The degree of pulmonary dysfunction can peak at 72 hours and generally resolves in the absence of associated nosocomial pneumonia.

Posttraumatic pulmonary pseudocysts (PPPs) are cavitary lesions that occur in approximately 3% of lung parenchymal injuries after blunt trauma.[31] They are seen more often in children as an incident CXR finding after relatively minor trauma (e.g., fall from bicycle) and are more likely to occur because of their more compliant chest walls. The clinical course is benign (with occasional minimal hemoptysis and fever). In adults, however, PPPs occur after more severe blunt mechanisms, appear as a dense pulmonary contusion on CXR, and most resolve spontaneously as a nonspecific infiltrate. However, occasionally, they will become infected, leading to an abscess that will be resistant to antibiotic therapy and require interventional radiologic drainage or surgical resection.[32] In patients with previous severe chest trauma who develop delayed nonresolving sepsis, a CT scan of the chest should be obtained to rule out an infected PPP. A blunt pulmonary laceration is rare and typically presents as a major hemopneumothorax. The initial tube thoracostomy reveals severe bleeding with a significant air leak, and this often requires an emergency thoracotomy.

PENETRATING LUNG INJURY

After penetrating trauma, a laceration likewise presents as a hemopneumothorax but with less severe bleeding that is usually self-limited. The vast majority are definitively managed by tube thoracostomy alone. Of the 10% of patients requiring thoracotomy, approximately 20% need lung resection. Historically, anatomic resection patients experienced high morbidity and mortality, with mortality after pneumonectomy approaching 100%. In 1998, Wall and colleagues introduced the concept of pulmonary tractotomy as a nonresectional means of managing penetrating lung injuries.[33] It is indicated for deep through-and-through injuries that do not involve central hilar vessels or airways. The wound tract is exposed by passing clamps (as originally described) or a stapling device (our preference) through the wound and dividing the bridge of lung tissue. Air leaks and bleeding points are sutured, and the wound tract is left open. Morbidity and mortality compare favorably with anatomic resections.[34]

In patients with multiple anatomic sites with active hemorrhage, including the thorax, the concept of damage control thoracotomy (DCT) has been described.[35] Although this pertains to the minority of patients requiring thoracotomies (4%), the idea of lung clamping, tractotomy, and/or thoracic packing with temporary skin closure followed by a second-look thoracotomy is a reasonable course of treatment rather than immediate pulmonary resection.

MEDIASTINAL INJURIES

Pneumomediastinum

Pneumomediastinum has classically been considered a sign of aerodigestive injury, particularly when seen on CXR; however, with expanding use of chest CT, pneumomediastinum is seen with increasing

frequency. Recent analyses have found that pneumomediastinum is present on approximately 5% of chest CT scans after trauma but that only 10% of these patients actually have aerodigestive injuries.[36,37] In the absence of signs or symptoms or additional suspicious findings on CT scan, further investigation is not necessary.

TRACHEOBRONCHIAL INJURY

Tracheobronchial injuries are uncommon but should be excluded in the presence of cervical subcutaneous emphysema, pneumomediastinum, or PTX with a persistent air leak. The definitive diagnostic test is bronchoscopy. Cervical injuries are approached via cervical incisions, with partial or complete sternotomy as needed. Blunt injuries often occur in the distal trachea or right mainstem bronchus and are approached via right thoracotomy. Tracheal injuries can usually be repaired primarily or by resection and reanastomosis without tracheostomy; late stenosis is uncommon. On the other hand, laryngotracheal injuries often require tracheostomy as an adjunct to repair, and tracheal stenosis is a common late complication. Absorbable monofilament sutures are preferred. Bronchial injuries may be repaired, but severe disruptions or associated vascular injuries may necessitate pneumonectomy or lobectomy. Positive end-expiratory pressure is avoided postoperatively.[38]

ESOPHAGEAL INJURY

Esophageal perforation from blunt force trauma is a rare event caused by a sudden rise in intraluminal pressure or by the upper esophagus being crushed between the trachea and a vertebral body. More commonly, esophageal injury is the result of penetrating trauma. Early signs and symptoms of injury can be subtle. Pneumomediastinum should prompt consideration of this injury. Barium esophagography is considered the diagnostic study of choice and can be readily obtained in a stable, awake patient. However, video endoscopy can be done at the bedside virtually anywhere in the hospital and has excellent accuracy. Thus it is preferred in critically ill or unstable patients in the ICU or operating room.[39]

If the injury is identified within 24 hours, it can usually be treated with debridement, primary repair, and drainage. If a tension-free repair is not possible, it is best managed with débridement and drainage, cervical esophagostomy, and feeding tube placement.[39]

CARDIAC INJURY

Blunt Cardiac Injury

Blunt cardiac injury (BCI) represents a wide spectrum of cardiac injuries, ranging from occult and inconsequential to lethal dysrhythmias, pump failure, or cardiac rupture. It can occur after virtually any trauma to the chest.

The diagnostic criteria for BCI are not standardized; no test is 100% predictive of the uncommon but life-threatening complications of ventricular dysrhythmias and cardiac pump failure—the so-called "*significant BCI*." The pivotal issue is to identify patients at risk and have them in a setting where the complication can be identified and treated promptly.

The initial evaluation for BCI screening should include 12-lead ECG. The utility of routine cardiac enzyme testing has been an area of debate.[36] Although a 2012 EAST practice management guideline[40] made a level 3 recommendation for routine troponin as a screening test, troponin levels have not been demonstrated to independently predict significant BCI. Their primary value is in identifying a patient with potential BCI who has a normal ECG, prompting a period of monitoring. We do not recommend serial troponin testing or routine echocardiography in the patient with suspected BCI. Patients with shock, ischemic changes on the ECG, or significant dysrhythmias are admitted to the ICU. If angina or ischemic ECG changes are noted, the diagnosis of acute coronary syndrome should be pursued. Patients with significant blunt chest trauma and nonspecific ECG findings (e.g., sinus tachycardia) who are being admitted for associated injuries should have cardiac monitoring for 24 hours.[41] A subset of patients may not require admission for other injuries. These patients can be safely discharged from the ED if ECG normalizes and if a troponin-I level at 8 hours is less than 1.5 ng/mL.[42]

Dysrhythmias are treated by pharmacologic suppression. The management of cardiogenic shock from cardiac pump failure may include early placement of a pulmonary artery catheter to optimize fluid administration and inotropic support. An echocardiogram may be indicated to exclude septal or free wall rupture, valvular disruption, or pericardial tamponade. Patients with refractory cardiogenic shock may require placement of an intraaortic balloon pump to decrease myocardial work and enhance coronary perfusion.

Commotio cordis is a rare but well-described cause of sudden cardiac death in young patients with sudden traumatic impact to the chest. This impact profoundly alters the electrical stability of the myocardium, resulting in ventricular fibrillation.[43] In a series of 70 cases, Maron and colleagues reported a 90% mortality rate in a young (mean age 12 years) population of patients.[44] An experimental model demonstrated that ventricular fibrillation is reproducibly triggered by a precisely timed blow during a narrow window within the repolarization phase of the cardiac cycle (15–30 ms before the peak of the T wave). The management of this pathology is primarily prevention, centered around adequate protective equipment and prompt defibrillation using readily available automated external defibrillators (AEDs).[43]

Pericardial Injury

Pericardial tears may result from direct thoracic impact or from an acute increase in intraabdominal pressure. Herniation of the heart through a large tear may be associated with significant cardiac dysfunction. A pericardial rub may be detected on physical examination. The CXR may demonstrate pneumopericardium, displacement of the heart, or bowel gas in the chest. Echocardiography or CT may be required to confirm the injury. In a stable patient, a subxiphoid pericardial window should be performed, followed by sternotomy in the presence of large hemopericardium or a visible pericardial tear. An unstable patient may require RT. Pericardial lacerations should be repaired, but large holes that cannot be closed primarily should be left widely open to prevent future cardiac herniation. A late complication is the post-pericardiotomy syndrome, manifested by fever, chest pain, pericardial effusion, a pericardial rub, and ECG abnormalities; this is adequately treated with antiinflammatory agents.

Valvular Injury

Valve injuries are rare. Even in lethal cardiac trauma, the valves are injured in approximately 5% of patients. The most commonly injured valve is the aortic, followed by the mitral, tricuspid, and pulmonary. Aortic valve disruption may result in acute severe cardiac failure, but a mild injury may present with syncope or anginal symptoms. Mitral valve leaflet tears, or more commonly, rupture of papillary muscles or chordae tendineae, may also result in acute heart failure. A heart murmur will generally be present, and echocardiography and/or cardiac catheterization are used to confirm the diagnosis. Most valve injuries are amenable to supportive care until other injuries have been stabilized. Valve repair is generally preferred over valve replacement when feasible.[45]

Septal Injury

Septal injuries are found in 5%–7% of patients dying from blunt trauma. Ventricular septal ruptures are much more common than atrial septal injuries; they usually occur in the muscular portion near the apex. Characteristic physical findings include a systolic thrill and a harsh holosystolic murmur heard best at the left sternal edge and radiating to the right, but the symptoms may be delayed for hours or days as the defect enlarges. Atrioventricular conduction abnormalities may also be present, simulating myocardial ischemia, and severe hypoxemia may result from an acute left-to-right shunt. Prompt echocardiography is indicated to establish the diagnosis; cardiac catheterization may be needed.

Small septal defects may heal primarily, allowing expectant management with periodic follow-up. Surgical repair—either primary or with a patch graft—is indicated if the patient is hemodynamically compromised or has a left-to-right shunt with a shunt ratio of 2:1 or greater. Repair of the defect is delayed for several weeks if possible.[46]

Coronary Artery Injury

Direct injuries to coronary arteries are rare. The left anterior descending artery is the most susceptible (76% of cases), followed by the right coronary artery (12%) and the circumflex coronary artery (6%). Surgical revascularization or repair of delayed complications related to infarction, such as ventricular pseudoaneurysms, may be indicated.

Penetrating Cardiac Injury

Cardiac penetration is rapidly lethal in 90% of gunshot wounds and up to 50% of stab wounds. All patients in shock with penetrating chest injuries between the right midclavicular line and left anterior axillary line, in addition to the posterior left chest, should be considered to have a cardiac injury until proven otherwise.[47] The right ventricle, with its maximal anterior exposure, is at greatest risk, followed by the left ventricle, right atrium, and left atrium. Multiple cardiac structures are involved in a third of patients. Stab wounds are more commonly associated with tamponade, whereas gunshot wounds often result in exsanguination through a large pericardial defect.

Repair of cardiac injuries can be accomplished through either a median sternotomy or anterolateral thoracotomy incision. In a hemodynamically compromised patient, left anterior thoracotomy with transsternal extension is used for definitive repair. In a hemodynamically stable patient, sternotomy is generally preferred. A limitation of sternotomy is access to posterior mediastinal injuries. Satinsky clamps are useful in isolating atrial or caval injuries, whereas small ventricular lacerations are controlled digitally. Larger wounds may be stapled. Wounds that are very large are occasionally reparable using temporary caval inflow occlusion.[48]

Pericardial Tamponade

Potential pericardial tamponade should be suspected in all patients sustaining penetrating injuries to the anterior chest wall. Pericardial tamponade can be a two-edged sword: although it may limit initial blood loss, it can prove fatal by restricting diastolic filling of the heart.[49] Because the pericardium is not acutely distensible, as blood accumulates, the pressure in the pericardial sac rises to match that of the injured chamber. When the pressure approaches that of the right atrium, right atrial filling is impaired and right ventricular preload is reduced; ultimately, this leads to decreased right ventricular output. Increased intrapericardial pressure also impedes myocardial blood flow, which leads to subendocardial and later subepicardial ischemia, with a further reduction of cardiac output. This vicious cycle may progress insidiously with injury to low-pressure conduits, or it may occur precipitously with a ventricular wound. Acute tamponade of as little as 100 mL of blood within the pericardial sac can produce life-threatening hemodynamic compromise.

Early diagnosis is key, as the ultimate cardiovascular collapse can be abrupt. Compensatory responses, including tachycardia and vasoconstriction, can transiently stabilize the hemodynamic status of the patient. Similarly, vigorous fluid administration may improve the patient's vital signs. The classic findings of the Beck triad (hypotension, distended neck veins, and muffled heart sounds) are present in less than 10% of patients; furthermore, Kussmaul sign (neck vein swelling with inspiration) and pulsus paradoxus (SBP drop with inspiration) are not reliable indicators of acute tamponade. In fact, neck veins may not become distended until hypovolemia is corrected.

In the setting of suspected pericardial tamponade, ultrasonography using subxiphoid and parasternal views (or formal echocardiography if immediately available) is extremely helpful if the findings are positive, although a negative ultrasonographic examination may be misleading if there is a pericardial laceration.[50] If pericardial fluid is demonstrated, the patient should be transported immediately to the OR for exploration. However, if ultrasonography is equivocal, a central venous pressure line should be inserted promptly. Persistently elevated central venous pressure in a patient with thoracic trauma should prompt consideration of a subxiphoid pericardial window. If the pericardial ultrasonography is positive and there will be any delay in getting to the OR, pericardiocentesis should be done if there is any suggestion of cardiac compromise, because subclinical endocardial ischemia can lead to recalcitrant lethal dysrhythmias. The pericardial tap should be performed with a pigtail catheter to allow repeated aspiration during preparation for thoracotomy. In the setting of shock, evacuation of as little as 15 mL of blood may dramatically improve the patient's hemodynamic profile. Pericardiocentesis is successful in decompressing tamponade in approximately 80% of cases; most failures are caused by clotted blood within the pericardium. If pericardiocentesis is unsuccessful and the patient remains severely hypotensive (SBP $<$70 mm Hg), RT should be performed. Recently, several studies have questioned the mandate for a sternotomy in patients who are hemodynamically stable. If, after irrigating the pericardium, there is no reaccumulation of blood and the patient remains stable, it appears reasonable and safe to forego the sternotomy. A drain should be placed, and the patient should have intensive postoperative monitoring. One potential pitfall is the presence of a posterior pericardial wound, so accumulation of blood in the plural space should be assessed. The pericardial drain is removed once output is minimal and clear.[51,52]

TRANSMEDIASTINAL PENETRATING TRAUMA

Transmediastinal trajectory of a bullet should be considered in the setting of (1) entry and exit wounds on opposite sides of the thorax, (2) a single entry wound with the bullet ending up on the opposite side of the thoracic cavity or in close proximity to the mediastinum, or (3) multiple gunshot wounds to the thorax. Significant injury, especially to the heart or great vessels, often results in prehospital death or hemodynamic instability. There is little controversy regarding the management of unstable patients: they should have emergent thoracotomy. However, stable patients may harbor occult injuries to critical mediastinal structures (heart, great vessels, trachea, or esophagus). Helical CT angiography (CTA) of the chest has proved useful in demonstrating the trajectory of missiles in the thorax.[53] In the setting of a potential transmediastinal gunshot wound, a CT scan may confirm a trajectory remote from the mediastinum, obviating further testing. A proven transmediastinal trajectory mandates further evaluation, tailored to the specific structures at risk. Our current approach to evaluating these patients is outlined in Fig. 156.3.

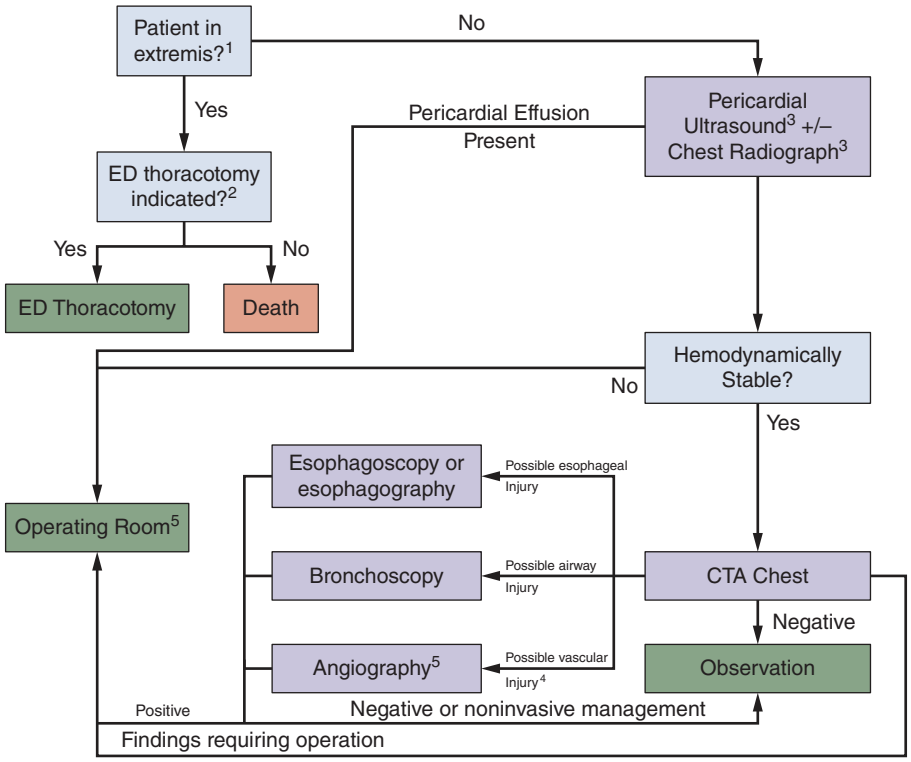

Fig. 156.3 Evaluation of suspected transmediastinal gunshot wounds (TMGSWs).[54] Transmediastinal injuries should be suspected in the presence of entry and exit wounds on opposite sides of the thorax, a single entry wound with the bullet located in the contralateral hemithorax or adjacent to the mediastinum, or multiple gunshot wounds to the thorax. *CTA*, Computed tomography angiography; *ED*, emergency department. (From Gunn ML, Clark RT, Sadro CT, et al. Current concepts in imaging evaluation of penetrating transmediastinal injury. *Radiographics*. 2014;34[7]:1824–1841.)

THORACIC GREAT VESSEL INJURY

Patients with penetrating injuries to extrapericardial thoracic great vessels often succumb in the field; however, patients can arrive with a contained hematoma. Early CXR is critical to identify hemothorax, in addition to a widened mediastinum or apical capping. Patients who are hemodynamically unstable should be taken directly to the OR; those in extremis should undergo RT. A reasonable approach can be inferred from the CXR and the location of the wounds. If the patient has a left hemothorax, a left anterolateral thoracotomy in the third or fourth intercostal space should be performed. Patients with a right hemothorax should likewise be approached via a right anterolateral thoracotomy. Unstable patients with injuries near the sternal notch may have large mediastinal hematomas or may have lost blood externally. These patients should be explored via a median sternotomy with cervical extension. Hemorrhage should be controlled digitally until the vascular injury is delineated. In a hemodynamically stable patient, CTA can facilitate a more directed approach. In the setting of pericla-vicular trajectory, it must be remembered that collateral flow around the shoulder girdle can result in palpable pulses, even in the presence of a significant subclavian artery injury.

A median sternotomy, with appropriate extension, is used for exposure of the aortic arch branch vessels. In patients who have undergone RT, the left anterolateral thoracotomy incision may have to be extended to a bilateral anterolateral thoracotomy ("clamshell"). In exposing the proximal left subclavian artery, it may be necessary to create a full-thickness flap of the upper chest wall. This is accomplished with a partial sternotomy and supraclavicular extension. If necessary, the ribs can be transected laterally, allowing the flap to be folded laterally, but this is rarely required. This incision has been referred to as an *open-book* or *trapdoor thoracotomy*. The midportion of the subclavian artery is accessible via a supraclavicular skin incision.

The great vessels are rather fragile and can be easily torn during dissection or crushed with a clamp. For this reason, injuries adjacent to the aortic arch are oversewn, and a graft is inserted onto a new location on the arch. The graft is then sewn (without tension) to the distal artery. Nonoperative management of nonocclusive peripheral arterial injuries has proved successful, and there are limited data supporting similar management within the thorax for certain patients. Similarly, lesions associated with severe neurologic injuries are usually managed nonoperatively. Experience with endovascular stenting is growing, although long-term outcomes have not been reported.[55] Clearly unstable patients require operative control and repair; however, it appears that stent graft treatment of subclavian artery injuries is preferred in stable patients and results in fewer morbidities.[56]

BLUNT THORACIC AORTIC INJURY

Blunt thoracic aortic injury (BTAI) typically results from sudden deceleration and shearing force resulting in varying degrees of aortic disruption. The injury usually occurs just distal to the left subclavian artery where the aorta is tethered by the ligamentum arteriosum. In 5% of cases, the tear occurs in the ascending aorta, in the transverse arch, or at the diaphragm. An estimated 85% of thoracic aortic injuries are fatal at the injury scene.

CXR is considered the initial screening tool of choice for determining whether further investigation is needed for BTAI. Commonly associated radiographic findings include mediastinal widening, obscured

aortic knob, deviation of the left mainstem bronchus (downward) or nasogastric tube (rightward), and opacification of the aortopulmonary window. In a AAST multicenter study, widening of the mediastinum on the anteroposterior chest radiograph was present in 85% of cases. However, 7% of patients with aortic tears had normal chest radiographs.[57] Thus additional investigations are warranted in the setting of significant energy transfer. CTA of the chest has supplanted thoracic angiography as the primary diagnostic test. When hematoma adjacent to the thoracic aorta is considered a positive finding, the sensitivity of CT for aortic injury is 100%.

Over the past decade, the surgical treatment and medical management of BTAIs have become more uniform and clearer. The Society of Vascular Surgery has classified BTAIs into four grades in increasing severity: I, minimal intimal injury; II, intramural hematoma; III, pseudoaneurysm; and IV, aortic rupture.[58] A suggested treatment algorithm based on grade is shown in Fig. 156.4. For grade I and II injuries, the mainstay of therapy is blood pressure control (<120 mm Hg), heart rate control (<90 bpm), antiplatelet therapy, and follow-up surveillance imaging to assess for either resolution or progression. Grade IV injuries should undergo surgical repair, with endovascular technique preferred over traditional open thoracotomy. Grade III injuries represent a gray area that could be managed based on the risk of rupture. Smaller pseudoaneurysms in patients who are high-risk surgical candidates may be managed medically, whereas larger pseudoaneurysms with increased risk for rupture should undergo endovascular repair. In addition, patients who are contraindicated for blood pressure control (i.e., traumatic brain injuries with intracranial hypertension) should undergo surgical repair.[59] Despite the lack of level 1 evidence, the choice of endovascular repair over open repair is now well accepted. Systematic reviews of 37 comparative studies favor endovascular repair with lower mortality (8% vs. 19%) and paraplegia rates (0.5% vs. 3%). The endovascular group did have a higher stroke rate (2.5% vs. 1%).[60]

Some debate remains regarding immediate versus delayed repair of BTAIs. Until the 1990s, BTAI was thought to require urgent repair to avoid early rupture. Recognizing significant morbidity and mortality in patients with severe associated injuries and comorbid medical conditions, the concept of immediate repair was challenged. In fact, an AAST prospective multicenter trial found that delayed repair is associated with significant survival benefit.[61] Although patients with major associated injuries are most likely to benefit, the study supported delayed repair in all patients, irrespective of risk factors. A current practice guideline by the EAST recommends delayed repair to reduce mortality and paraplegia.[60]

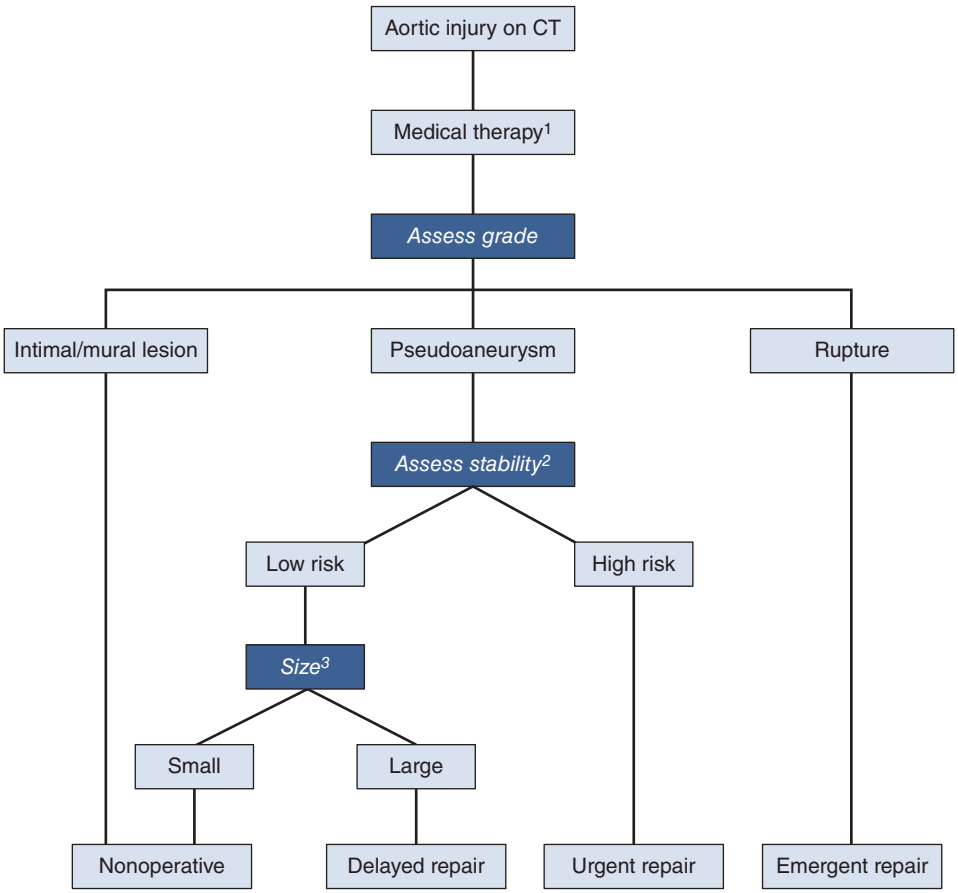

Fig. 156.4 Lesion-Specific Management for Blunt Thoracic Aortic Injury. [1]Antiplatelet therapy and beta-blockade targeting a systolic blood pressure of 100–120 mm Hg and heart rate of 60–90 bpm with additional antihypertensive agents as required for blood pressure control; repeated computed tomography (*CT*) within 48–72 hours for patients managed nonoperatively or by delayed repair to assess stability. [2]High-risk factors include two or more of the following: signs of hypotension, large pseudoaneurysm, and extensive mediastinal hematoma (refer to Table II). [3]Small defined as <50% aortic circumference or <1 cm in maximal dimension.[58] (From Harris DG, Rabin J, Starnes BW, et al. Evolution of lesion-specific management of blunt thoracic aortic injury. *J Vasc Surg.* 2016;64[2]:500–505.)

KEY POINTS

- Resuscitative thoracotomy will not yield productive survival when patients (1) sustain blunt trauma and require more than 10 minutes of prehospital CPR without response, (2) have penetrating wounds and undergo more than 15 minutes of prehospital CPR without response, or (3) manifest asystole without pericardial tamponade.
- Management of rib fractures include early triage based on risk factors for respiratory decompensation. Higher-risk patients should be initially observed in the ICU setting.
- Surgical stabilization of rib fractures can reduce patient morbidity and mortality and should be considered in patients with flail chest and severely displaced rib fractures with physiologic deficits.
- In patients with a penetrating pulmonary laceration, pulmonary tractotomy results in favorable morbidity and mortality rates compared with lung resection for trauma. Damage control thoracotomy can be considered in patients with multicompartmental hemorrhage.
- Bronchoscopy should be performed for cervical subcutaneous emphysema, pneumomediastinum, or pneumothorax with a persistent air leak to rule out tracheobronchial injuries. For esophageal injuries, contrast esophagography is the preferred diagnostic study, but video endoscopy can also be performed at the bedside in intubated patients and is superior in the pharyngeal area.
- Echocardiography is most useful in identifying pericardial tamponade or intracardiac injuries. Ultrasonography and central venous pressure monitoring are critical adjuncts in diagnosing pericardial tamponade, as the classic findings of Beck triad are present in very few patients.
- Helical CT scanning is useful in delineating the trajectory of potential transmediastinal gunshot wounds, allowing a truncated and cost-effective workup in stable, asymptomatic patients.
- In blunt thoracic aortic injury, helical CT is an excellent screening test and should be considered even in the face of a normal chest radiograph if there is severe energy transfer.
- Medical versus surgical treatment of BTAI is based on grade of severity. Medical management consists of SBP and heart rate control with a rapidly reversible beta-blocking agent. Surgical treatment should be performed endovascularly in a delayed fashion for optimum results.

Abdominal Trauma

Nicole C. Toscano and Andrew B. Peitzman

INTRODUCTION

Trauma is the leading cause of death in patients between 1 and 44 years of age.[1] The trauma patient requires rapid and systematic evaluation by a multidisciplinary team using principles defined by Advanced Trauma Life Support (ATLS).[2] These principles allow the effective transition of care from the prehospital to hospital environment. External signs of abdominal injury can be absent; effective diagnosis relies heavily on recognizing patterns of injury and maintaining a high suspicion of injury to minimize the risk of morbidity and mortality. This chapter focuses on the evaluation, diagnosis, management, and complications associated with abdominal injuries. Patients with abdominal injury will be admitted to the intensive care unit (ICU) for management of concomitant brain or spine injury, chest wall injury/pulmonary contusion, extremes of age, and nonoperative management of high-grade solid organ injury or after damage-control laparotomy.

ETIOLOGY OF INJURY

Abdominal trauma can be broadly categorized into blunt force or penetrating mechanism of injury. Each mechanism produces different injury patterns. A thorough understanding and early recognition of these patterns aid in rapid diagnosis and treatment, minimizing risk of morbidity and mortality from abdominal injury. It is important to understand that the early critical decision in management is recognizing that the trauma patient requires emergent laparotomy. Time spent on diagnostic evaluation, most often computed tomography (CT), or failure to recognize signs of abdominal injury delays definitive treatment, increasing morbidity and mortality. The priority is to detect and correct abnormal physiology, not to define the specific anatomic injuries.

Blunt Abdominal Injury

Blunt abdominal trauma accounts for 80% of abdominal injuries. These injuries result from an external force that causes direct compression, shearing, rapid change in intraluminal pressure, or deceleration forces. These forces can cause injury to solid organs, hollow organs, or vascular injury within the abdominal cavity. Blunt trauma can be associated with single-organ injury or multisystem trauma, significantly increasing patient risk of morbidity and mortality. Common mechanisms of injury include motor vehicle crash, motorcycle crash, bicycle crash, fall, pedestrian-automobile impact, abuse, and assault.

Evaluation

Clinical Evaluation. The initial resuscitation of an injured trauma patient begins with identification of the mechanism of injury and establishing patient stability. A proper handoff from emergency medical services quickly provides information regarding the mechanism of injury to guide assessment. Patients are further classified based on stability, with unstable patients exhibiting hypotension or tachycardia. Initial assessment of all patients, as defined by ATLS, begins with the primary survey to ensure a patent airway, breathing, and circulation (perfusion). The secondary survey is a head-to-toe examination, with special care taken to evaluate the abdomen. Although physical examination is often unreliable to identify abdominal injury, certain findings raise the suspicion for injury. Abdominal distention suggests massive hemoperitoneum from solid organ or vascular injury. Peritonitis is not typically associated with hemoperitoneum, but can be present with hollow viscus organ injury. Bruising across the lower abdomen or chest (seatbelt sign) suggests the presence of a hollow viscus injury or lumbar vertebral body spine (Chance) fracture. Physical examination is unreliable in the diagnosis of blunt abdominal trauma because of altered mental status or distracting injury. However, repeated abdominal examination helps identify missed injuries. The liver or spleen is the most common solid organ injured after blunt injury. As 85% of splenic and hepatic injuries are grades I to III, the vast majority of these patients are hemodynamically stable and managed nonoperatively. On the other hand, high-grade injury to the spleen or liver often produces active bleeding and a hemodynamically unstable patient. More details on specific organ injuries are discussed later in the chapter.

Diagnostic Tests. Limitations of the physical examination require appropriate use of adjunct testing for rapid diagnosis. These diagnostic tests include focused abdominal sonography for trauma (FAST), diagnostic peritoneal lavage/aspiration (DPL/DPA), plain radiography, and CT. Use of these modalities is ultimately dependent on patient stability.

Focused Abdominal Sonography for Trauma. FAST should be used in the assessment of all patients with blunt abdominal trauma. FAST both has bedside availability and is noninvasive, allowing detection of hemoperitoneum within minutes.[3–7] However, FAST has a false-negative rate as high as 40%, often missing injury to the diaphragm, hollow viscus, or retroperitoneum.[7] A positive FAST in a hemodynamically unstable patient has the highest utility to allow prompt transfer to the operating room for definitive care. However, a negative FAST does not exclude abdominal injury and often requires further assessment with CT or DPL/DPA.

Diagnostic Peritoneal Lavage or Aspiration. Patients with a negative FAST, hemodynamic instability, and ongoing suspicion for intraabdominal hemorrhage are assessed with DPL/DPA. Of note, FAST and DPA have largely replaced DPL. Similar to FAST examination, DPL/DPA is limited in its ability to assess retroperitoneal or diaphragm injury. Although this procedure is invasive, risks of complications are low in experienced hands. A positive DPA is defined by return of blood on aspiration. A positive DPL is defined by the presence of 10 cc gross blood on aspiration, >100,000 red blood cells/mm^3, >500 white blood cells/mm^3, bile, or food particles. A positive DPL/DPA in the unstable patient requires immediate laparotomy.

Computed Tomography. CT should be performed in the hemodynamically stable patient who has sustained significant blunt abdominal trauma. Modern helical CT scanners have significantly reduced imaging time and improved imaging quality. CT identifies and grades solid organ injuries and the presence of retroperitoneal injuries. However, CT is less reliable in the identification of hollow viscus, diaphragm, or pancreatic injury. Perform CT with intravenous contrast, with both arterial and portal venous phase images. Special care should be taken in the patient with known contrast dye allergy or chronic kidney disease. Patients with contrast dye allergy will require premedication to minimize the risk of allergic reaction or noncontrast studies. Oral contrast is not routinely used, as it may cause delay or place patients at risk for aspiration.

Laboratory Testing. Laboratory testing is routinely obtained on initial presentation to the trauma bay. The acutely hemorrhaging patient will rarely demonstrate anemia, as whole blood has been lost. A global assessment of perfusion is important, as patients in hemorrhagic shock may demonstrate a metabolic acidosis with an elevated base deficit or lactate level. Urinalysis with the presence of red blood cells suggests urologic injury. Although initial laboratory testing is unreliable for diagnosis, trending values can aid in resuscitation or identification of missed injury. Patients with pancreatic or hollow viscus injury may initially have normal serum amylase levels, which later become elevated. Thromboelastogram (TEG) assesses hemostasis and whole blood coagulation. It has been more routinely used in identifying trauma-induced coagulopathy and guiding resuscitation.

Penetrating Abdominal Injury

A penetrating abdominal injury (PAI) is defined as a perforating injury that violates the abdominal cavity. Anatomically, injury from the nipple line to the groins anteriorly or scapula tip posteriorly to the buttocks posteriorly should raise suspicion for possible thoracic and abdominal injury. These injuries result from high-velocity projectiles such as firearms or other mechanisms such as stabbings or impalement. A thorough understanding of missile or wound trajectory is imperative in diagnosis and management. Penetrating trauma from high-velocity weapons with significant kinetic energy produces extensive injury and tissue damage, some of which may progress over the first 24–48 hours postinjury.

Evaluation

Clinical Evaluation. Similar to the evaluation of patients sustaining blunt abdominal trauma, patients with PAI require rapid evaluation and assessment following the principles of ATLS. Initial identification of the mechanism of injury and patient stability further defines the diagnostic algorithm. Upon ensuring an intact primary survey, a patient should be examined head to toe to identify all injuries to help approximate missile trajectory. Take special care to examine the axilla, perineum, gluteal folds, rectum, and body creases to ensure no injuries are missed. Wounds should be counted, and an odd number of wounds suggests a retained foreign body (generally a bullet). Wounds are marked with radiographic markers or paperclips secured with tape. Plain radiographs of the chest, abdomen, and pelvis and cross-table lateral abdominal films then aid in determining the trajectory of missiles. Physical examination should also assess for abdominal distention and the presence of peritonitis. Identification of visceral or omental evisceration, peritonitis, or hypotension is an indication for immediate exploratory laparotomy. Stable patients selected for nonoperative management (NOM) who can provide a reliable examination should undergo serial examination for a minimum of 24 hours. Those patients who develop a change in vital signs (fever or tachycardia), peritonitis, or leukocytosis should undergo surgical exploration.

Diagnostic Tests.

FAST. FAST should be used in both stable and unstable patients who have sustained PAI. FAST may identify hemoperitoneum in PAI and, more importantly, hemopericardium in patients where the trajectory puts the heart at risk. FAST remains unreliable in the diagnosis of hollow viscus injury, which is common with penetrating injury.

Computed Tomography. Patients who remain hemodynamically stable can be assessed by CT with intravenous and oral contrast. Rectal contrast is generally not recommended currently. Cross-sectional imaging can define the trajectory of injury and violation of the peritoneal cavity. However, evaluation of violation of the peritoneal cavity with CT is limited in patients who are thin.

SURGICAL EXPLORATION

Surgical exploration can be achieved by exploratory laparotomy or diagnostic laparoscopy (in selected patients). The hemodynamically unstable patient with concerning trajectory should undergo immediate exploratory laparotomy after assessment for hemopericardium via FAST. The exploratory laparotomy in the trauma patient is a systematic evaluation of abdominal injuries. The primary goals of the trauma laparotomy are to (1) control hemorrhage, (2) stop gastrointestinal contamination, (3) define all injuries, and (4) resect/repair injuries with consideration for damage control (discussed later). Diagnostic laparoscopy should only be considered in the hemodynamically stable patient and has largely replaced DPL to exclude intraabdominal injury. It can be helpful in the assessment of diaphragmatic injuries and violation of the peritoneal cavity, especially with PAI. However, its utility to detect retroperitoneal or hollow viscus injury is limited by surgeon experience.

ORGAN-SPECIFIC INJURY

General Principles

As mentioned earlier, the essential decision in the management of abdominal injury is recognizing the need for emergent laparotomy. The initial management of patients with suspected abdominal injury begins with appropriate triage and resuscitation. Ultimately, evaluation depends on the mechanism of injury and hemodynamic stability of the patient. In the hemodynamically stable blunt trauma patient, CT with intravenous contrast is the diagnostic test of choice to determine the extent of injury (grade), presence of associated intraabdominal injuries and hemoperitoneum, and active extravasation. The majority of patients with blunt injury to the liver, spleen, or kidney are hemodynamically normal, and appropriate management will be observation.

Hemodynamically unstable patients or those with evidence of peritonitis on examination require immediate laparotomy. FAST and plain radiography of the chest and pelvis are used in the unstable patient to detect hemoperitoneum and assess the chest as a site of blood loss.

Successful NOM requires appropriate patient selection; high-quality CT; and the availability of an effective multidisciplinary team of intensive care physicians, experienced surgeons, and interventional radiologists. Institutions should have well-established protocols and consistent practice patterns to minimize risk of failure of NOM. Frequent evaluation upon admission to the ICU is necessary to monitor for complications, including bleeding, abscess, or bile peritonitis.

Hepatic Injury

With its anatomic position anteriorly in the right upper quadrant, the liver is the largest and one of the most commonly injured intraabdominal organs.[8] The highest incidence of these injuries is secondary to blunt abdominal trauma from motor vehicle crashes.[9] More than

85% of blunt hepatic injuries are low-grade injuries (American Association for the Surgery of Trauma [AAST] grade I–III) and 15% represent high-grade injuries (AAST grade IV–V). Mortality in patients with hepatic injury is dependent on the grade of injury and ranges from 10% in the low-grade injuries (AAST grade I–II) to greater than 50% in high-grade injuries.[10] Patients who present with hepatic injury are at high risk for concomitant injuries of the spleen (21%), kidney (9%), and bowel (4%).[11]

Measure serum transaminases, lactate dehydrogenase, and gamma-glutamyl transferase (GGT) on admission and trend throughout the patient's hospitalization. Abnormalities of these values have been associated with grade of hepatic injury and can serve as screening tests.[12–14]

NOM of hepatic injury in hemodynamically stable patients without peritonitis is now routine.[15,16] With appropriate patient selection, more than 85% of patients with liver injury can be managed successfully with NOM. Patients requiring immediate laparotomy for hemodynamic instability typically have AAST grade IV or V injury. Hemodynamic status remains the most important factor in predicting success of NOM. Other predictors of failed NOM in high-grade liver injuries include age, male gender, higher Injury Severity Scale (ISS), lower Glasgow Coma Scale, hypotension, and the presence of associated intraabdominal injuries.[17,18]

Frequent evaluation upon admission to the ICU is necessary to monitor for complications including bleeding, abscess, or bile peritonitis. Observation should include frequent physical examination, hemodynamic monitoring, and serial hemoglobin levels. It is of the utmost importance to prevent hypothermia and reverse coagulopathy in these patients.

Although NOM of hepatic injury has resulted in lower mortality rates, reduced transfusion requirements, and reduced length of stay, 12%–24% will develop complications. These include early (<24 hour) and late (>24 hour) bleeding, bile leak, hepatic necrosis, gallbladder necrosis, abscess, biliary-venous fistula, hemobilia, and thrombosis or pseudoaneurysm of the hepatic vasculature. Increasing liver grade is associated with a higher complication rate. Complications can be recognized by the development of a variety of symptoms, including increasing abdominal pain, change in vital signs, leukocytosis, or abnormalities of liver function tests. Patients with these symptoms and laboratory abnormalities require definitive imaging to establish the appropriate diagnosis and treatment modality. CT with intravenous contrast is effective to assess for hepatic or gallbladder necrosis, abscess, and pseudoaneurysm formation. Suspicion for bile leak can be confirmed with hepatobiliary iminodiacetic acid (HIDA) scan. Patients with hematemesis, melena, or jaundice should undergo angiography for suspicion of hemobilia.

Management of complications associated with NOM of liver injury varies and can range from observation to surgical intervention. Only 15% of complications will require operation. Small bilomas can typically be managed with observation. Bile leaks require endoscopic retrograde cholangiography and stenting. Large bilomas and abscesses can be managed with percutaneous drainage. Approximately 2%–7% of patients will develop recurrent/late bleeding or ongoing transfusion requirements, typically managed with angiography and embolization. Angiography/embolization enhances the success of NOM but should only be used in patients who are hemodynamically stable without other indications for operative intervention. Complications associated with angioembolization include hepatic necrosis, gallbladder necrosis, bile leak, and abscess formation with rates ranging anywhere from 29% to 80% (Fig. 157.1). Patients with active extravasation on CT are more likely to fail NOM and should undergo early angioembolization. Operative intervention is reserved for resection of devitalized or necrotic liver, control of large bile leaks in the setting of biliary peritonitis, and drainage.

Splenic Injury

The spleen is the intraabdominal organ secondary to blunt abdominal trauma most likely to require operation. Patients may report left upper quadrant fullness or pain and left shoulder pain (Kehr sign). Left lower rib fractures have been associated with splenic injury in 25%. However, physical examination is largely unreliable for the diagnosis of splenic injury.

Ultimate management of splenic trauma depends on the hemodynamic status of the patient. NOM of splenic trauma has become routine in the hemodynamically stable patient.[19,20] Immediate laparotomy should be undertaken in hemodynamically unstable patients or those with evidence of peritonitis.[21,22]

Patients managed nonoperatively require close observation in hospital or the ICU for high-grade injuries (AAST grade >III) with frequent physical examination, serial hemoglobin measurements, and a

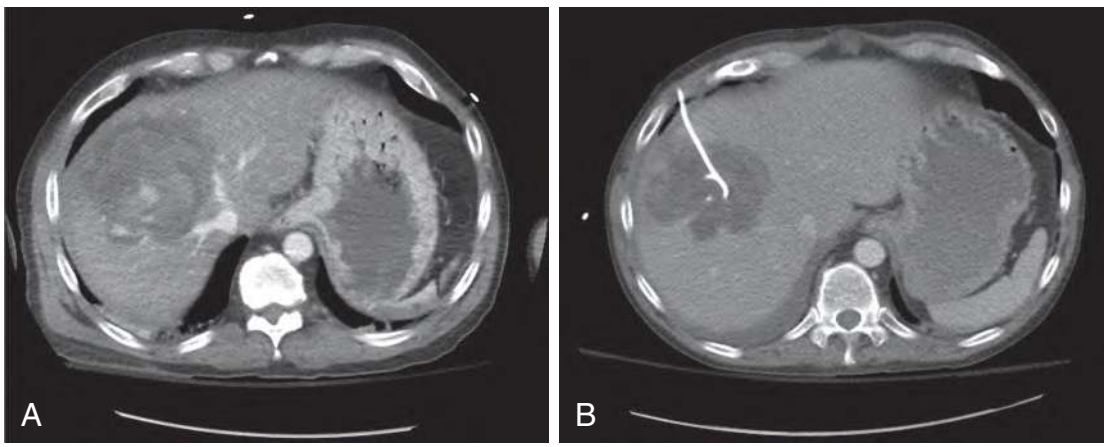

Fig. 157.1 A 52-year-old-male, motor vehicle crash, hemodynamically normal. **A,** C with contrast shows large active extravasation and clot in the right lobe of the liver. The right hepatic artery was embolized. The patient was managed nonoperatively and discharged from the hospital. **B,** The patient re-presented 2 weeks later with an elevated white blood cell count. A liver abscess was drained percutaneously.

period of immobility. Failure of NOM of splenic injuries in patients with blunt splenic trauma ranges from 3% to 38%, but generally under 10%.[23–32] Patients with high-grade injuries (AAST grade IV–V), high ISS, presence of pseudoaneurysm, arteriovenous fistula, active extravasation, moderate to large amounts of hemoperitoneum, or subcapsular hematoma are at highest risk for failure of NOM.[26,27] Ninety percent of patients who fail NOM will do so in the first 3 days after injury and 60% in the first 24 hours. Patients who undergo successful NOM with high-grade injuries should undergo interval CT (generally 48 hours post initial CT) with intravenous contrast to evaluate for the development of pseudoaneurysm, which will require angioembolization. Chemical deep vein thrombosis (DVT) prophylaxis is initiated within 48 hours and has not been shown to increase the risk of failure of NOM.[33,34]

Angiographic embolization is an adjunct in the management of splenic injuries and can enhance the salvage rate of NOM. However, this should only be considered in the hemodynamically stable patient. Patients with contrast extravasation on CT, high-grade injury (grades IV and V) even without active extravasation, moderate hemoperitoneum, or concern for ongoing bleeding should be considered for proximal or selective angioembolization.[25,29–31] Complications of angioembolization include femoral access issues, pleural effusions, contrast-induced acute kidney injury, splenic infarction, splenic rebleeding requiring splenectomy, and splenic abscesses or cysts[32] (Fig. 157.2).

After splenectomy, patients are at risk for overwhelming postsplenectomy infection (OPSI) secondary to encapsulated organisms, including meningococcus, *Haemophilus influenza, Streptococcus pneumoniae, Staphylococcus aureus,* and *Escherichia coli.* This risk is highest in the pediatric population. However, both adult and pediatric patients require immunization within 2 weeks of splenectomy or before discharge with Pneumovax, *H. influenza,* and meningococcal vaccines. Patients should be educated regarding revaccination schedules to ensure proper follow-up. Immune function in patients with high-grade injuries or after splenic artery embolization seems to be preserved. The need for vaccination after angioembolization remains controversial.

Pancreatic Injury

The retroperitoneal location of the pancreas makes injury uncommon, ranging in frequency from 0.2% to 12% in patients with abdominal trauma.[35–38] These injuries typically occur from a crushing force to the abdomen that compresses the pancreas against the vertebral column or a gunshot wound. When pancreatic injury occurs, there is a high rate of associated intraabdominal injuries of solid organs, hollow organs, and vascular structures.

Early identification of pancreatic injury remains a diagnostic challenge, especially in the injured patient who does not require immediate laparotomy. Given the retroperitoneal location of the pancreas, FAST and DPL are unreliable in the detection of injury.[39] Physical examination may reveal abdominal tenderness, ecchymosis, or no signs or symptoms and remains insensitive for the diagnosis of pancreatic injury. Laboratory studies may reveal elevated serum amylase or lipase on admission. However, this is neither sensitive nor specific for the presence of a pancreatic injury.

Operative exploration of the pancreas with visual inspection and bimanual palpation is the most sensitive method to diagnose injury. CT remains the imaging modality of choice in the hemodynamically stable patient. However, the sensitivity of CT in identification of injury remains variable, ranging from 47% to 79%.[40,41] Patients with normal pancreas architecture and without peripancreatic edema on CT should be closely observed with serial physical examination. Development of abdominal pain, leukocytosis, or change in vital signs should prompt immediate evaluation with repeat CT using a pancreatic protocol or laparotomy.

Endoscopic retrograde cholangiography (ERCP) may be used to diagnose and, at times, treat pancreatic ductal injury in the stable trauma patient with suspicion of pancreatic injury. Magnetic resonance cholangiography (MRCP) may also be used for diagnosis, but does not offer the therapeutic advantages available during ERCP. Performing an ERCP on the acutely injured patient can be challenging and can exacerbate inflammation of the pancreas.[42]

The status of the pancreatic duct, the location of injury (proximal versus distal), and the overall status of the patient determine the most appropriate management. Given the high incidence of concomitant injuries, patients with pancreatic injury generally require laparotomy. Pancreatic injury without evidence of ductal injury (AAST grade I and II) is managed with débridement and external drainage alone. Distal pancreatic injury (AAST grade III) is managed with distal pancreatectomy and drainage. Proximal pancreatic ductal injuries and disruption of the pancreatic head (AAST grade IV and V) are difficult to manage.

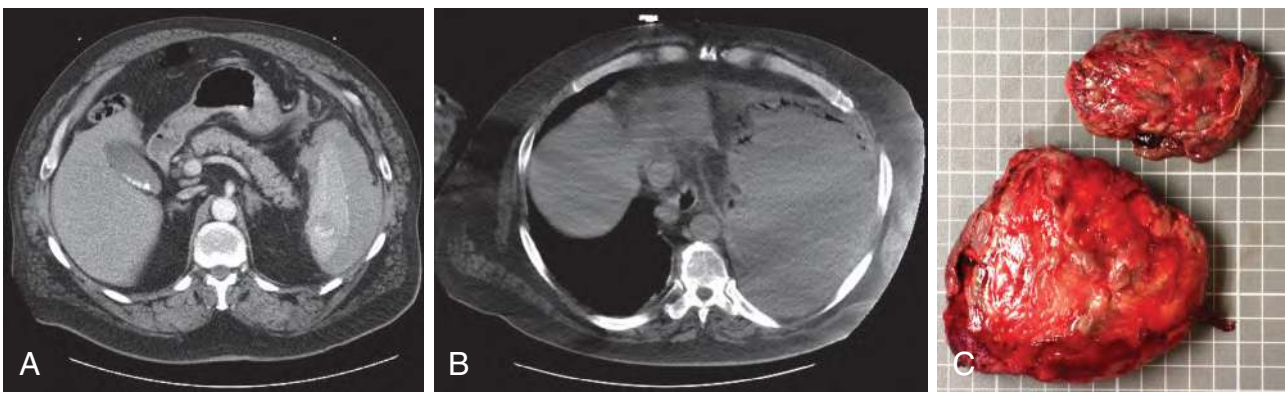

Fig. 157.2 A 54-year-old male presented 2 days after falling with abdominal pain and hemodynamically normal and benign examination. **A,** His computed tomography (CT) shows a splenic laceration with active bleeding. The splenic artery was embolized and the patient discharged from the hospital a week later. **B,** The patient re-presented 1 month later with fever, malaise, and mental status changes. White blood cell (WBC) was 35,000/mm^3. CT showed extensive splenic infection. **C,** The patient was promptly taken for splenectomy. Gross pathology of the spleen. Microscopy revealed diffuse and chronic inflammation. Cultures grew heavy *Propionibacterium granulosum* and moderate *Peptostreptococcus* species. He did well postoperatively.

Recommendations range from simple drainage to complex procedures, including pancreaticoduodenectomy or on-lay pancreaticojejunostomy. Pancreaticoduodenectomy is rarely required.[43,44]

Mortality from pancreatic injury ranges from 9% to 24%.[43] Early mortality after pancreatic trauma is primarily associated with vascular injuries. Sepsis, multiple-organ failure, respiratory failure, and delay in the diagnosis of pancreatic injury account for late mortality.[44] Complications related to pancreatic injury are dependent on the presence of ductal injury and the grade of injury or concomitant duodenal injury. Patients are at risk for developing pancreatic fistula, abscess, posttraumatic pancreatitis, pseudocysts, and hemorrhage of adjacent retroperitoneal vessels. Postoperative hemorrhage can be appropriately managed with angioembolization or laparotomy in the unstable patient. Pancreatic fistulae are typically managed conservatively and resolve spontaneously. Evidence regarding the use of somatostatin analogues for fistula prevention and management is variable. Abscesses are managed with percutaneous drainage and intravenous antibiotics. These rarely require surgical intervention. Patients with traumatic pancreatitis will need enteral nutritional support with nasojejunal feeding access or parenteral nutrition if this is unable to be obtained.

Hollow Viscus Injury

Hollow viscus injuries, including stomach, small bowel, duodenum, colon, and rectum, are most commonly secondary to penetrating trauma. Small bowel followed by the stomach have the highest incidence of injury secondary to penetrating trauma. High-velocity penetrating injury can cause a significant degree of tissue destruction, making management of these injuries challenging. Blunt trauma accounts for only a fraction of hollow viscus injury and usually results from a sudden increase in intraluminal pressure and distention or deceleration forces that cause contusion, serosal injury, or hematoma.

Patients who have sustained penetrating trauma often require surgical exploration via diagnostic laparoscopic or laparotomy to exclude hollow viscus injury. Blunt trauma poses a more difficult diagnostic challenge when assessing for hollow viscus injury. These challenges can result in a delay in diagnosis and significantly increase morbidity and mortality. Physical examination may reveal tenderness, seatbelt sign, or peritoneal signs. However, this is unreliable in the early diagnosis of injury, as definitive signs and symptoms of injury may not be present until later. Digital rectal examination should be performed if there is a high suspicion for rectal injury. The presence of blood on digital rectal examination is concerning for the presence of a rectal injury and should be interrogated in the operating room with proctosigmoidoscopy at a minimum. However, the absence of blood does not exclude injury. Plain radiography of the chest or abdomen may reveal free air, which should prompt immediate exploration. However, the absence of free air on plain radiography does not exclude injury.[45,46]

The presence of free air and oral contrast extravasation on CT is highly suggestive of injury and requires surgical exploration. CT findings of free fluid without evidence of solid organ injury, mesenteric hematoma or stranding, mesenteric blush, bowel wall thickening, or edema suggest injury. Intestinal injury may be present despite normal findings by CT. Should a high suspicion for hollow viscus injury remain, diagnostic laparoscopy can be used as an adjunct to CT. The sensitivity of diagnostic laparoscopy depends on surgeon skill, and injuries can be missed. Some authors suggest repeat abdominal CT scan with oral contrast in this setting.

Hollow viscus injury is managed with surgical exploration. Management strategies depend on the degree of destruction and range from primary repair, resection with primary anastomosis or proximal diversion, and wide drainage for rectal injuries. Antibiotics are administered in the perioperative period.

Postoperative complications after the management of hollow viscus injury include leak, abscess formation, and wound infection. Patients who develop increasing abdominal pain, tachycardia, or leukocytosis warrant evaluation with CT with oral and intravenous contrast to detect leak or abscess formation. Tachycardia and abdominal pain in the early postoperative period are suggestive of leak.

Diaphragmatic Injury

Traumatic diaphragm injuries have an incidence of less than 1% with more than two-thirds of these injuries secondary to penetrating trauma.[47] Blunt diaphragm injuries are more common on the left, as the liver offers a protective advantage on the right.

Diagnosis of diaphragm injuries is challenging. Chest radiograph is normal in 25% of all patients with a diaphragm injury.[48] Occasionally, chest radiography may demonstrate a hollow viscus or a coiled nasogastric tube in the left hemithorax, which is diagnostic for a diaphragm injury and requires surgical exploration. CT similarly is insensitive in the diagnosis of diaphragm injuries. Surgical exploration via diagnostic laparoscopy or laparotomy remains the most sensitive method for evaluation. Patients who have sustained a penetrating thoracoabdominal injury are at high risk for diaphragm injury and should undergo surgical exploration, generally laparoscopy in the stable patient. Diaphragm injuries can be missed at a patient's initial presentation and may present years later with herniation of and entrapment of intraabdominal organs. Posterior diaphragm injuries can be particularly challenging to diagnose and can be missed even during surgical exploration.

Management of diaphragm injuries requires surgical repair either through the chest or abdomen. In the acute setting, repair is performed through the abdomen, as there is a high risk of associated injuries to the spleen, stomach, small intestine, and colon. Injuries are repaired primarily with nonabsorbable sutures. Uncommonly, synthetic, nonabsorbable mesh or biologic grafts are required for large defects. Patients with concomitant hollow viscus injury and gross contamination of the abdominal and thoracic cavity are at risk for abscess formation. Development of fevers and leukocytosis postoperatively warrants imaging with CT with intravenous contrast to evaluate for abscess formation.

Genitourinary Injury

Genitourinary trauma occurs in 10% of all injured patients, with the kidney representing the majority of these injuries. More than 80% of renal injuries are secondary to blunt trauma.

Hematuria is the hallmark sign of injury to the genitourinary system and can be classified as macroscopic or microscopic. Gross hematuria is highly suspicious for genitourinary tract injury and warrants evaluation of the upper and lower urinary tract. Patients with microscopic hematuria warrant further evaluation in the setting of blunt trauma, hypotension, lower rib fractures, flank tenderness or ecchymosis, spine fractures, or high ISS.[49,50] Patients with pelvic fractures, difficulty voiding, perineal hematoma, high-riding prostate, or blood at the urinary meatus should be evaluated for the presence of urethral injury.

Selection of the appropriate imaging modality depends on the area of the genitourinary tract injured. Male patients with suspected urethral injury should undergo retrograde urethrogram (RUG) before Foley catheter placement. Upper genitourinary tract injuries, including the kidney and ureters, are most effectively evaluated with CT of the abdomen/pelvis with excretory imaging. CT allows staging of renal injuries, evaluation of the collecting system, presence of contrast extravasation, and confirmation of a normal contralateral kidney. One-shot intravenous pyelography can be performed intraoperatively in the patient who requires emergent laparotomy for evaluation of renal or ureteral injury. Retrograde cystography or CT cystogram are the diagnostic modalities to evaluate intraperitoneal and extraperitoneal bladder injuries.

Renal preservation is the goal when managing genitourinary trauma. NOM has become routine in hemodynamically stable patients with blunt renal trauma regardless of injury grade. Angioembolization can be used as an adjunct to NOM in select cases. Patients with renal trauma who undergo NOM successfully should undergo interval CT imaging at 48–96 hours to evaluate for urinoma or pseudoaneurysm. When operative exploration is required, renal salvage is attempted with renal reconstruction and renorrhaphy. However, hemodynamically unstable patients with high-grade injuries not amendable to repair will require nephrectomy. After renal trauma, patients are at risk for development of urinomas and perinephric abscesses, especially in high-grade injuries. Persistent urine leaks from collecting systems can be managed with stenting or percutaneous nephrostomy tube placement. Abscesses are best managed with percutaneous drainage. Postinjury hypertension can develop months after injury and often requires antihypertensive therapy. In rare instances, refractory cases of hypertension require nephrectomy.

Definitive management of bladder injuries depends on the location of the injury. Extraperitoneal bladder injuries are managed with bladder decompression with Foley catheter placement for a minimum of 7–10 days. Intraperitoneal bladder injuries require surgical repair. These injuries are frequently associated with hollow viscus injury and have a higher degree of morbidity and mortality. A follow-up cystogram is performed for both intraperitoneal and extraperitoneal bladder rupture before Foley catheter removal. Complications related to bladder injury include persistent bladder leak resulting in urinoma, abscess, and osteomyelitis. Furthermore, patients are at risk for incontinence and urinary retention.

Ureteral injuries are rare, with the majority secondary to penetrating trauma. Ureteral injuries require surgical repair if patient stability allows. Postoperatively patients can develop persistent urine leak, stricture, and fistula formation. Urethral injury is more common in men in the setting of pelvic fracture or direct crushing of the urethra from a straddle injury. Urethral injury requires surgical repair in a delayed fashion with bladder decompression via suprapubic tube. Patients who undergo early surgical repair are at high risk for incontinence, impotence, and stricture formation.

Abdominal Vascular Injury

Major abdominal vascular injury typically occurs secondary to penetrating trauma. However, blunt trauma can produce avulsion or thrombotic injury to vasculature. Patients require prompt recognition of injuries and urgent intervention to minimize the morbidity and mortality associated with these injuries. Patients with penetrating major abdominal vascular injury are generally unstable on presentation. On occasion, hemodynamically stable patients can be evaluated with CT with intravenous contrast.

Intraoperatively, patients may undergo aortic cross-clamping or ligation of major venous structures. Operative time is kept to a minimum, and damage control laparotomy performed. Recognition of these intraoperative proceedings significantly affects patients postoperatively. Patients with prolonged aortic cross-clamping are at high risk for end-organ dysfunction, particularly acute kidney injury. These patients may require early initiation of continuous renal replacement therapy. Similarly, combined arterial and venous injuries affecting perfusion to the lower extremities can result in extremity compartment syndrome. Frequent compartment checks and trending creatine phosphokinase can ensure early recognition of extremity compartment syndrome and need for lower extremity fasciotomies. These patients often develop profound trauma-induced coagulopathy and should be kept warm with correction of coagulopathy.

Damage Control

Damage control refers to a truncated surgical operation to control immediate life-threatening problems, including hemorrhage and gastrointestinal contamination.[51] Prolonged efforts in the operating room for definitive repair of injuries subjects patients to a lethal triad of acidosis, hypothermia, and coagulopathy.[51–53]

Damage control laparotomy involves a truncated operation with placement of temporary abdominal closure, often performed in 1 hour or less, with coordinated resuscitative efforts by a multidisciplinary team before return to the operating room. The patient is subsequently scheduled to return to the operating room within 24–48 hours, unless the patient requires intervention more urgently. Reoperation involves removal of packs, resection of devitalized tissue, and definitive repair of injuries.

The postoperative management of a patient after damage control requires coordinated efforts between the intensivists and surgical team. The goal of this resuscitative period is to prevent the lethal triad by rewarming, reversing coagulopathy, and restoring adequate tissue perfusion. These patients are at high risk for missed injury. Thorough initial assessment upon arrival to the ICU includes a thorough physical examination and full laboratory studies to assess acid-base status, oxygenation, hemoglobin, and coagulation profile. Bedside radiographs should be used to assess line and tube positions that may have been placed under emergent conditions. If patient stability allows, central lines placed emergently under potentially unsterile conditions should be replaced. These patients often have not undergone complete radiographic imaging to determine the extent of their injuries. Extremity injuries can be assessed with bedside radiographs. Patients should be kept in strict spine precautions and a cervical collar maintained. These patients are often too unstable for transport, and trips outside of the ICU should be minimized at all costs. These patients often require massive transfusion and ongoing resuscitation that places them at high risk for acute lung injury and acute respiratory distress syndrome. As a result, lung-protective ventilation strategies should be employed. Attempt to minimize crystalloid infusion. Use whole blood or 1:1:1 transfusion of blood products. Patients should undergo frequent reassessment. Failure to correct persistent acidosis, increasing vasopressor requirements, ongoing laboratory derangements, persistent transfusion requirements, and changes in drain output should be immediately communicated to the surgical team. These changes may indicate the need for immediate return to the operating room. After damage control surgery, patients are at risk for abdominal compartment syndrome, even when the abdomen is managed with a temporary abdominal closure. The bladder pressure should be measured at least every 4–6 hours. A tertiary survey, involving a head-to-toe examination, should be performed, again looking for missed injuries. This examination should be repeated once the patient can participate in the examination without distracting injuries.

Patients who have undergone damage control present to the ICU with an open abdomen with placement of a temporary abdominal closure device. The abdominal wall fascia is left unapproximated to allow swelling and edema of the abdominal viscera and to minimize risk of development of abdominal compartment syndrome. These temporary closure devices are negative-pressure vacuum seal dressings that create a protective layer over the bowel and minimize fascial retraction (Fig. 157.3). Although this technique minimizes operative time and simplifies re-exploration, ultimate closure can prove to be challenging. Patients with an open abdomen are at risk for development of enterocutaneous fistula, enteroatmospheric fistula, and ventral hernia. Attempts should be made at abdominal closure as soon as patient condition allows. Often closure is complicated by massive resuscitation and

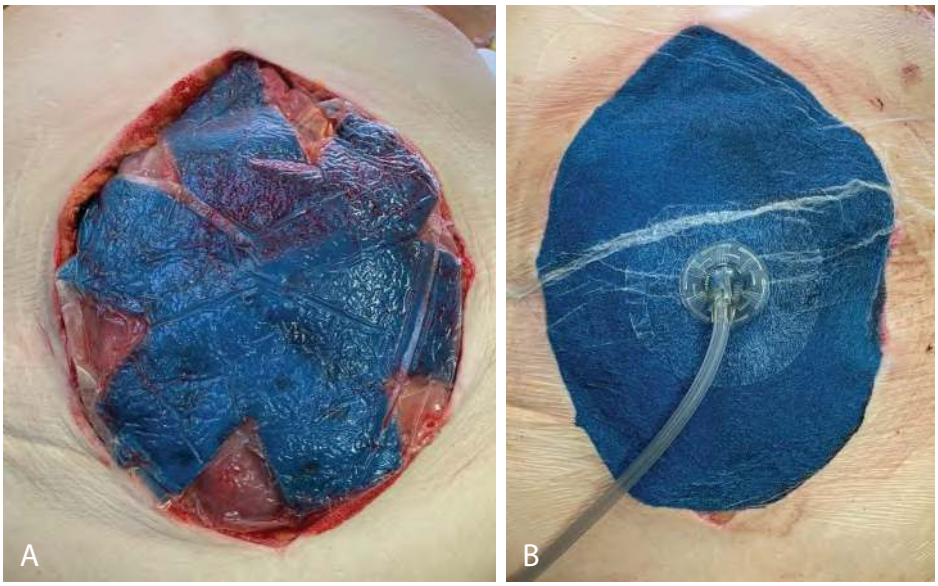

Fig. 157.3 **A,** This picture shows the inner visceral protective layer of the ABThera open abdomen negative-pressure system (KCI, San Antonio, TX). **B,** Completed VAC dressing with the outer sponge seen and external suction system.

shock state, which results in abdominal wall and visceral edema. Diuresis when patient hemodynamics allow may improve attempts at fascial closure. Patients may require staged abdominal closure with multiple trips to the operating room, placement of mesh, and even complex abdominal reconstruction.[53]

KEY POINTS

- Abdominal injury can result in significant morbidity and mortality. These patients remain susceptible to delay in diagnosis and missed injury.
- Prompt evaluation, resuscitation, and recognition of injuries help minimize the risk of avoidable morbidity and mortality.
- Coordinated efforts with clear lines of communication between a multidisciplinary team of intensivists and surgeons ensure patient safety and improve outcomes.
- Eighty percent of abdominal injuries are produced by a blunt mechanism of injury. The most common penetrating mechanisms are gunshot wounds and stab wounds.
- Trauma patients with abdominal injury will be admitted to the ICU for management of chest wall injury/pulmonary contusion, extremes of age, nonoperative management of high-grade organ injury, after damage control laparotomy, or management of concomitant brain or spine injury.

Pelvic Fractures and Long Bone Fractures

Sumeet V. Jain and Nicholas Namias

INTRODUCTION

Pelvic and long bone fractures are found frequently in trauma patients, especially in blunt polytrauma patients with significant injury burden. Initial intensive care management of severe pelvic fractures or long bone injury is similar: damage control resuscitation, hemorrhage control, antibiotic prophylaxis for open fractures, identification and treatment of concomitant injuries, early nutrition, and supportive care for known complications like pulmonary embolism and fat embolism syndrome. In this chapter, we will examine overall management and specific considerations for pelvic and long bone fractures.

INITIAL MANAGEMENT

Damage Control Resuscitation

The most common manifestation of pelvic and long bone fracture in the intensive care unit (ICU) is hemorrhage. It is well established that severely injured trauma patients arrive at the hospital with coagulopathy already present, and this is an independent predictor of mortality.[1,2] The development of coagulopathy is a multifactorial process, theorized to stem from humoral activation of the coagulation cascade with consumption, systemic inflammation, and fibrinolysis. Acquired traumatic coagulopathy develops independent of resuscitation strategy, but it is believed that subsequent resuscitation with crystalloid or packed red cells alone further exacerbates coagulopathy. Therefore management of hemorrhagic shock from trauma has shifted from liberal administration of early crystalloid and red blood cells (RBCs) to the concept of "damage control resuscitation," or balanced resuscitation with more plasma and platelet administration.[3]

Early data from military and civilian trauma centers demonstrates that increased plasma:RBC ratios are associated with survival to hospital discharge.[4,5] Subsequent clinical trials have validated the use of balanced resuscitation strategies on mortality and hemostasis in multitrauma patients. The Prospective, Observational, Multicenter, Major Trauma Transfusion study (PROMMTT) is a landmark study that demonstrated reduced mortality with early administration of plasma and platelets and higher plasma:platelet:RBC ratios in the early resuscitation period.[6] Further, the Pragmatic, Randomized Optimal Platelet and Plasma Ratios trial (PROPPR) assessed the efficacy of a 1:1:1 ratio of blood product administration vs. a 1:1:2 ratio; the trial found no difference in mortality between these two groups at 24 hours or 30 days, but did find increased hemostasis and less death because of hemorrhage.[7] Importantly, there was also no difference in rates of acute respiratory distress syndrome, multiple organ failure, venous thromboembolism, sepsis, or transfusion-associated complications. Overall, damage control resuscitation with a 1:1:1 ratio of platelets:plasma:RBC administration in patients suffering hemorrhagic shock decreased mortality and overall volume of resuscitation and has become the accepted standard for the resuscitation of trauma patients.[5] Further resuscitation in the ICU consists of correction of coagulopathy as needed, with the aid of coagulation studies or viscoelastic testing if available.[8]

Another factor to consider during damage control resuscitation is the presence of hyperfibrinolysis. Initially, there was much excitement over the use of tranexamic acid (TXA)—an antifibrinolytic agent—because of the Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage 2 (CRASH-2) study. This study examined adult trauma patients with hemorrhagic shock and found reduced mortality with administration of TXA within 3 hours.[9,10] A subgroup analysis of the PROPPR trial also showed improved 6-hour mortality in patients with hyperfibrinolysis on admission who were given TXA without an increase in venous thromboembolism.[11] However, there have been conflicting data regarding dosing TXA universally in trauma patients with hemorrhagic shock, with evidence that there may be an increase in mortality and venous thromboembolic phenomenon in a subset of patients who required operative intervention and presented early to a level 1 trauma center.[12,13] It also appears late administration of TXA offers no mortality benefit compared with administration within 3 hours of injury.[10] Viscoelastic testing, such as thromboelastography if available, may help stratify hemorrhaging patients into those that do and do not have hyperfibrinolysis based on the LY30 value. LY30 greater than 3% identifies hyperfibrinolysis, and this patient population appears to benefit from TXA administration.[14,15] The use of TXA and thromboelastography in trauma, however, is controversial; at present both are tools available to the ICU physician and must be used based on clinical judgment while more research is performed.

Open Fractures

Whether a fracture is open or closed is an important distinction and should be a component of the initial assessment of any fracture. There are significant implications on the risk of wound infections, osteomyelitis, fracture nonunion, morbidity, and mortality depending on the presence of an open fracture and the degree of contamination.[16–18] An open fracture is defined as any fracture with an overlying soft tissue defect that tracks to the fracture site. Open fractures can be further subclassified into grades, with higher grades associated with increased infectious complications and mortality. Broadly, grade I and II involve simple, clean lacerations without a crushing component or degloving injury, whereas grade III fractures involve much more complex and contaminated wounds and special cases such as farming accidents or arterial injury requiring surgical intervention.[19] Infections typically involve gram-negative rods and gram-positive cocci.[20] Though multidrug-resistant organisms have been implicated in some outbreaks of open fracture infections in the hospital, this is relatively uncommon

and not prevented by broader prophylactic antibiotic coverage. Antibiotics should be started within 3 hours of presentation. The use of a first-generation cephalosporin (e.g., cefazolin—or clindamycin if anaphylactic to penicillin) for 48–72 hours is adequate antibiotic prophylaxis for grade I–II fractures, and an aminoglycoside should be added for grade III fractures.[21] In farm-related accidents, penicillin G or clindamycin should be added to the antibiotic regimen because of the higher risk of infection by *Clostridium* species. In addition to antibiotics, open fractures require early operative exploration to wash out the tissues, stabilize the fracture, and cover the fracture with soft tissue to reduce the risk of infection.

Nutrition

After severe injury, patients frequently enter a state of hypermetabolism that progresses to catabolism that progresses rapidly to malnutrition. When evaluating all geriatric patients with hip fractures, an increasingly common patient population both in and out of the ICU, there is a significant practice pattern variation with regard to nutritional supplementation. Specifically, there is a tendency to underfeed this population.[22] Underfeeding occurs despite evidence that in that patient population, malnutrition increases mortality, whereas adequate nutrition supplementation leads to greater functional recovery.[23] When evaluating the subset of critically ill trauma patients, inadequate nutrition has been shown to increase morbidity and mortality.[24] Early enteral nutrition has been shown to have numerous benefits in the ICU setting. It promotes gut mucosal integrity, motility, and immunity and reduces nosocomial infections.[25] Furthermore, in trauma patients specifically, early enteral nutrition has clearly been shown to decrease mortality.[26] If enteral nutrition cannot be administered, parenteral nutrition should be considered. A recent meta-analysis by the Cochrane Collaboration demonstrated no difference between enteral and parenteral routes with regard to mortality, aspiration, and pneumonia, although the enteral route may be associated with decreased incidence of sepsis.[27,28]

The 2016 American Society for Parenteral and Enteral Nutrition Guidelines (ASPEN) and the 2019 European Society guidelines recommend early initiation of enteral feeding (i.e., within 24–48 hours), provided the patient does not have any known bowel injury and is hemodynamically stable.[29,30] The ASPEN guidelines recommend administration of immune-modulating formulas containing arginine and glutamine in the trauma population because of decreased infection rates. These enteral formulas can be used in patients with open abdomens as well, provided they have intestinal continuity. Protein delivery is an especially important element of nutrition supplementation in this population; multitrauma patients will be on the upper end of the 1.2–2 g/kg/day protein that is recommended in the ICU. If enteral nutrition cannot be safely provided, or if it will not be able to meet the caloric needs of the patient, then parenteral nutrition should be initiated early in this high-risk population. Current guidelines recommend hypocaloric parenteral feeding initially at 80% basal energy expenditure, or <20 kcal/kg/day, while still maintaining adequate protein feeding at 1.2–2 g/kg/day, increasing gradually to cover full basal energy expenditure with frequent clinical reassessment. A full discussion regarding nutrition for ICU and trauma patients is outside of the scope of this chapter.

COMPLICATIONS OF PELVIC AND LONG BONE FRACTURES

Pulmonary Embolism

Trauma patients are known to be at increased risk of deep venous thrombosis (DVT) and pulmonary embolism (PE) because of intrinsic hypercoagulability, with an incidence of approximately 12% and 1.5%, respectively, and higher in patients who do not receive prophylaxis.[31] PE in particular has a high associated mortality rate at 17%–26%.[32] Pelvic and long bone fractures are independent risk factors for increased risk of venous thromboembolism (VTE) because of associated trauma-induced hypercoagulability, immobility, venous stasis, and the need for major surgical procedures; these events often occur early in the hospital course, within 72 hours.[32–35] Interestingly, it is unclear if VTE is the only cause for PE in trauma patients. For one, Allen and colleagues demonstrated that DVT surveillance in high-risk trauma patients—with either therapeutic anticoagulation or inferior vena cava (IVC) filter if DVT was present—decreased the rate of VTE.[36] At the same time, studies examining DVT surveillance after diagnosis of PE demonstrated that >20% of patients did not have concomitant lower extremity or pelvic DVT.[37,38] It is unknown why, with the theory being either complete VTE without residual clot or de novo formation of pulmonary artery thrombus instead of VTE. Regardless of the method, balancing the need for blood products in the hemorrhaging fractured trauma patient and the bleeding risk with VTE pharmacologic prophylaxis versus the high risk of VTE or de novo PE in a patient with a known hypercoagulable state represents a significant management challenge for the ICU physician.

The preferred method of VTE prophylaxis is pharmacologic with subcutaneous heparinoids. The current body of evidence, including a Cochrane review by Barrera and colleagues, has demonstrated that subcutaneous low-molecular-weight heparin specifically is better at reducing VTE than subcutaneous heparin and mechanical prophylaxis.[39,40] In a trauma patient without significant bleeding risk or renal dysfunction, the most effective dosing for DVT prophylaxis is enoxaparin 30 mg twice daily. Unlike standard 40 mg once-daily dosing used in other settings, in a trauma patient without significant bleeding risk or renal dysfunction enoxaparin 30 mg twice daily is used, though there is evolving evidence that suggests a benefit from higher doses. Subcutaneous heparin can be used in the presence of renal dysfunction. In a patient who develops VTE, therapeutic anticoagulation should be initiated if there is no contraindication. Our preference is to start with a heparin drip, as this is easily reversed with protamine if the patient does develop a bleeding complication, unlike therapeutic Lovenox or direct oral anticoagulants (DOACs). If the patient tolerates a heparin drip without bleeding, they can be bridged with a heparin drip or therapeutic Lovenox to destination oral anticoagulation with warfarin or a DOAC such as apixaban.

What remains more controversial is the role of prophylactic IVC filters in a trauma patient with a high bleeding risk. It is established that placing IVC filters in all hospital patients who are on anticoagulation does not reduce mortality.[41,42] Further, in the trauma population there is no high-quality evidence that shows a benefit to IVC filters, and more recent evidence has shown no decrease in mortality when using prophylactic IVC filters.[43–47] Despite the fact that modern IVC filters are retrievable, the fact remains that the majority of filters are not retrieved, and there is associated morbidity with the long-term placement of IVC filters, including erosion and DVT. Currently, there is no strong recommendation for prophylactic IVC filter placement because of the lack of benefit and increased morbidity. Current American College of Chest Physicians guidelines recommend against IVC filters in patients on anticoagulation, but recommend IVC filter placement in patients with an established diagnosis of DVT or PE with contraindications to anticoagulation.[41,48] Once a patient is able to receive therapeutic anticoagulation, however, it should be initiated even with an IVC filter in place. Ideally, an IVC filter should also be retrieved at a later point when it is no longer needed.

The latest technology for the prevention of VTE is the Angel catheter. The Angel catheter is a vena cava filter permanently attached to a central venous line. Its intended use is for short-term (<30 days) VTE prophylaxis in high-risk patients. The thought is that the catheter can

Fig. 158.1 Angel catheter. (Courtesy Mermaid Medical, Stenløse, Denmark.)

be placed quickly via femoral access without fluoroscopy, and once the central line is removed, the vena cava filter is removed with it. Currently it is indicated for patients with PE with contraindications to anticoagulation or critically ill patients at high risk for VTE with increased bleeding risk. The catheter has been primarily tested in all critically ill patients, though there are case reports in trauma patients.[49] Efficacy has been inferred from studies showing reduced in-hospital mortality in noncancer patients with acute PE and contraindication to anticoagulation.[50,51] Feasibility studies have shown no increase in adverse events with the use of the Angel catheter (Figure 158.1); however, at this stage more evidence is needed to support whether early use of the Angel catheter decreases mortality and VTE in high-risk patients with contraindications to anticoagulation.[52–54]

Fat Embolism Syndrome

Fat embolism after trauma was well described by Dr. Zenker in 1862.[55] It has been a relatively common finding at autopsy of posttraumatic patients, especially those with pelvic or lower extremity long bone fractures. The presence of fat embolism should not be confused with fat embolism syndrome (FES); pulmonary fat embolism occurs regularly in patients with fractures—as high as 90%–100% on autopsy studies—but FES is relatively rare, with an incidence of less than 2%.[56,57] Diagnosis is based primarily on clinical examination, and it remains a diagnosis of exclusion. Signs and symptoms typically occur 24–72 hours after injury. The classic triad for FES is petechial rash of the mucous membranes, conjunctiva, anterior neck, and/or thorax; hypoxemia with pulmonary edema; and mental status changes unrelated to head injury. However, petechial rash occurs in less than 50% of FES patients, and so it is not a reliable physical examination finding. Other associated findings include tachycardia greater than 110 beats per minute, fever greater than 38.5°C, retinal emboli, lipuria, or an unexplained drop in hemoglobin.[58,59] Originally, it was suggested that patients with FES manifest with petechial rash and neurologic signs because of a patent foramen ovale leading to fat embolization into the systemic circulation.[60,61] More recent evidence suggests, however, that these findings occur even in patients with a sealed foramen ovale, suggesting either a biochemical explanation for fat embolism or microembolization of fat particles through the capillary network into the systemic circulation.[62]

If there is suspicion for FES, initial testing involves exclusion of other causes. Patients with hypoxia will invariably get chest imaging, whether computed tomography (CT) or plain films, to evaluate for consolidation, effusion, or pneumothorax. Because of the neurologic symptoms, a CT brain is often done to rule out a missed head injury or stroke. CT angiography of the chest is not needed to diagnose FES but may help exclude thrombotic PE. Other invasive testing is not routinely indicated—such as bronchoscopy, transesophageal echocardiogram, or pulmonary artery catheter—unless being done to exclude another diagnosis. Treatment consists of supportive care, primarily with fluid resuscitation, circulatory support, oxygenation, and mechanical ventilation if needed. Early femur fracture fixation has also been shown in multiple studies to decrease the rate of pulmonary complications, including FES.[63,64] If the patient has profound hypoxia despite maximal ventilatory support, venovenous extracorporeal membrane oxygenation has also been described and should be considered.[65] There is evidence that corticosteroids may improve symptoms from FES, and possibly even prevent it; unfortunately, no reduction in mortality has been demonstrated, and the dosing required is unclear, varying from 6 to 90 mg/kg of methylprednisolone over 48 hours.[66–68] Furthermore, there are known risks of even short-term steroid use, including immune suppression leading to increased risk of sepsis, VTE, and impaired wound healing.[69] With current evidence, we cannot recommend routine steroids in patients with multiple long bone or pelvic fractures for prevention of FES.

PELVIC FRACTURE

In blunt trauma, pelvic fractures have an estimated incidence of 9%, with another 10% of those being classified as severe.[70] Mortality in patients with pelvic fracture early on stems from hemorrhage, often from several sources and not just the pelvis. Deaths outside of 6 hours typically occur from other causes, such as head injury and multiple organ failure.[71,72] The force required to fracture the pelvis has a high chance of causing other injuries that contribute to the morbidity and mortality of patients. Concomitant intraabdominal or urogenital injury occurs in 11%–20% of patients with pelvic fractures, with a higher incidence in patients with more severe injury. Blunt trauma leading to combined pelvic fracture and thoracic trauma or head injury is also common.[73] Specific considerations for management of pelvic fractures in the ICU are control of pelvic hemorrhage and the diagnosis and management of associated intrapelvic injuries. The management of thoracic, abdominal, and head trauma must also be carefully considered, but is outside the scope of this chapter.

Pelvic Hemorrhage Control

Pelvic ring disruptions, the so-called *"open book" pelvic fracture,* can cause significant venous plexus bleeding or internal iliac branch arterial bleeding. Although a minority of pelvic fractures involve unstable ring disruptions, patients with this injury pattern have an estimated mortality of 34%–50%.[74,75] The majority of mortalities from pelvic fractures is related to early hemorrhage, from both pelvic and extrapelvic sources, and this has been the case for decades.[71,72,76,77] Damage control resuscitation, as described earlier, and control of pelvic bleeding points are critical in reducing morbidity and mortality in this population. One reason for profound hemorrhage in severe pelvic fracture is that the extraperitoneal pelvic space expands in size dramatically with pelvic ring disruption. A 5-cm diastasis, for example, increases the pelvic space by more than 20%, allowing a significant volume of blood to extravasate into the pelvic space without tamponade.[78] Initial maneuvers for pelvic hemorrhage control involve reducing the size of the potential retroperitoneal space to tamponade the bleeding via pelvic binding, extraperitoneal pelvic packing, or external fixation. This section will discuss these techniques and two additional supplementary techniques: resuscitative endovascular balloon occlusion of the aorta (REBOA) and pelvic angiography.

The easiest early maneuver is placement of a pelvic binder or tying a sheet around the pelvis to externally close the pelvic space.[79,80] It is important to place the binder in the proper position at the level of the acetabulum; the goal is to reduce the pubic symphysis and close the pelvic ring. Placing the binder higher on the pelvis, such as at the anterior superior iliac spine, will not reduce the fracture, and may even

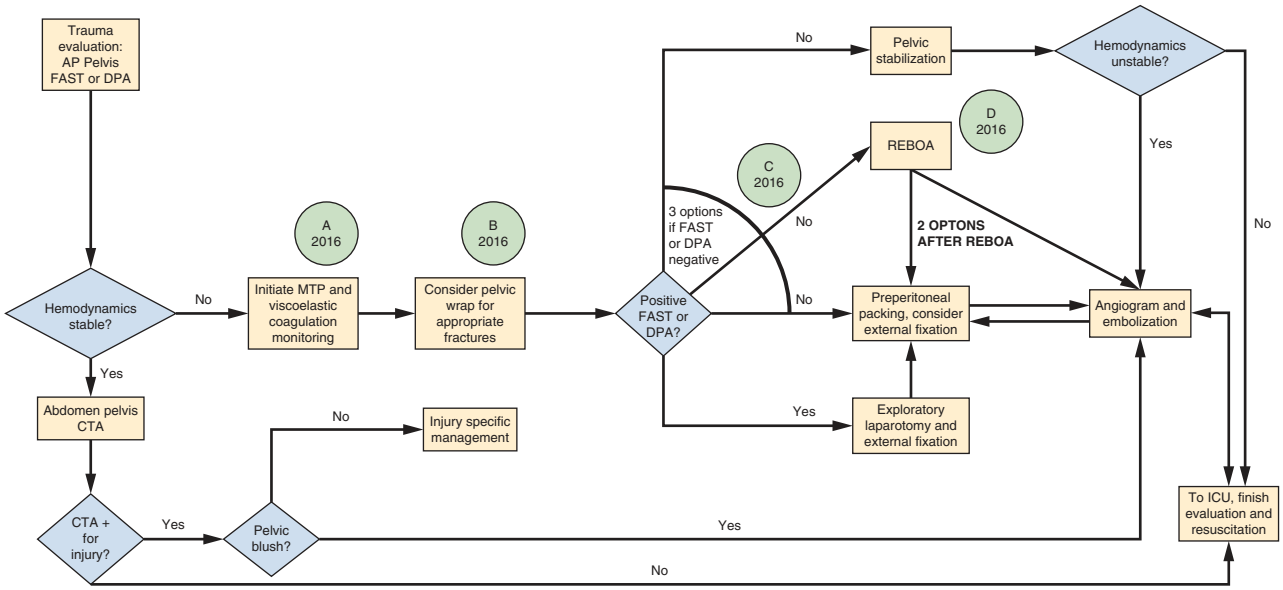

Fig. 158.2 Pelvic hemorrhage control algorithm.

worsen the fracture and associated hemorrhage. Correct binder placement may be enough to tamponade pelvic venous bleeding and allow time for adequate resuscitation. If the patient continues to have signs of hemorrhagic shock despite this maneuver, more invasive means of hemorrhage control may be necessary. Early evaluation by a multidisciplinary team consisting of trauma and orthopedic surgeons is critical to quickly and decisively intervene in the hemorrhaging patient with an unstable pelvic fracture. The Western Trauma Association also has a published algorithm for hemodynamically unstable pelvic trauma that serves as a useful guide in this case.[81] After pelvic binder placement or sheet stabilization, a focused abdominal ultrasound or direct peritoneal aspiration is performed to rule out abdominal trauma. If this is positive, the patient must go for laparotomy to control intraabdominal sources of hemorrhage. Alternatively, if there is no evidence of intraabdominal hemorrhage, then three options may be considered: preperitoneal pelvic packing in the operating room, external fixation, and REBOA, all of which can be done in conjunction with angiographic embolization.

Extraperitoneal packing is an operative technique that involves direct surgical packing of the pelvis to exert pressure and limit the size of the retroperitoneal space.[82] It has been shown to be expeditious and efficacious in limiting hemorrhage when used by an experienced team as part of a pelvic hemorrhage algorithm.[83,84] Another advantage is the ability to use this technique as a bridge to other adjuncts, namely external fixation and pelvic angiography. This is important because unstable pelvic fractures have a significant risk of arterial hemorrhage for which extraperitoneal pelvic packing alone is insufficient.[85,86] The pelvic packs should be removed within 48 hours when the patient is stabilized; otherwise, there is a risk of infectious complications.

One newer technique for pelvic hemorrhage management is REBOA. Originally described for noncompressible intraabdominal hemorrhage, REBOA is a technique that shows promise as a bridge to angioembolization in the hemorrhaging pelvic fracture patient with arterial bleeding.[81] To perform REBOA, arterial access is obtained in the common femoral artery with ultrasound guidance. The catheter is then guided into the infrarenal aorta and the balloon inflated. This raises the systolic blood pressure and diminishes flow to the pelvic arteries in addition to the bilateral lower extremities. Because of the ischemia caused

Fig. 158.3 REBOA catheter. (Courtesy Prytime Medical, Boerne, Texas.)

by REBOA, it is paramount that the patient be taken for further intervention as soon as possible, with the goal of removing the REBOA as soon as a more definitive method of repair is performed, whether that is angioembolization or packing and fixation.[87] Whether REBOA truly reduces mortality and morbidity requires further inquiry.

The goal of external fixation is fracture reduction to reduce the potential pelvic space and allow for bony alignment on a temporary or definitive basis to reduce bleeding from the cancellous bone.[88] The benefit to external fixation, whether posterior fixation with a C-clamp or an anterior fixation device, is that it is more quickly applied than definitive internal fixation and has greater pelvic stability than a pelvic binder or preperitoneal packing because of the immobility of the device.[89] Further, it decreases pain levels, reduces deformity, and improves functional outcome in the long term.[90] However, it is more time consuming than either pelvic binder placement or extraperitoneal

packing; the decision of when and how to proceed with external fixation depends entirely on the patient's condition. Again, using a binder or extraperitoneal pelvic packing may serve as a bridge to external fixation. In the hypotensive, bleeding unstable pelvic fracture patient, it is prudent to proceed with extraperitoneal pelvic packing, REBOA, and angiography before external fixation.

Pelvic angiography is the most effective way to manage arterial bleeding. Most pelvic arterial bleeding comes from branches of the internal iliac arteries, branches which are difficult to find and ligate surgically. Angiography allows for control of these vessels to staunch bleeding in patients in hemorrhagic shock, often after the adjuncts mentioned. If there is no intrabdominal bleeding suspected based on ultrasound or direct peritoneal aspiration, then angiography is indicated and should be performed after one of the adjuncts.[76,81,91] Furthermore, if the patient is stable enough for a CT scan and is found to have intravenous (IV) contrast extravasation in the pelvis, this is another indication for angioembolization regardless of hemodynamic stability, as this patient population has a high chance of continued bleeding.[92] Angioembolization is effective between 85% and 99% of the time; if a patient continues to show signs of hemorrhage after embolization and nonpelvic sources have been ruled out, repeat angioembolization should be performed.[93]

Treatment of unstable pelvic fracture hemorrhage requires a multidisciplinary algorithm because of the numerous options available. Damage control resuscitation and early intervention to control hemorrhage are critical to mortality reduction. Often, patients will come into the ICU after many of these interventions have taken place, such as pelvic packing and angiographic embolization. It is at this point that continued reassessment and awareness of management strategies is important to ensure hemodynamic stability to move onto further management.

Urinary Tract and Rectal Injuries

Pelvic fracture patterns can be associated with specific injuries to organs in the general vicinity, namely the lower urinary tract and rectum. Lower urinary tract injury is relatively rare—approximately 3%–6% of patients with pelvic fractures—and more commonly occurs in severe anterior pelvic ring disruptions.[94,95] Rectal injuries are even more rare and are more likely to occur with penetrating pelvic trauma than blunt trauma.[96] Neither of these injuries are immediately life threatening, so the management priorities still focus on pelvic stabilization and hemorrhage control first. However, after stabilization, identification can allow for early intervention by the appropriate surgical team and limit morbidity.

The lower urinary tract consists of the bladder and urethra, and each has a different series of findings on physical examination and imaging. Bladder injuries are commonly identified on CT imaging, especially on a delayed phase when IV contrast enters the urinary collecting system and can be seen in the bladder. On physical examination, hematuria is also suggestive of injury to either the bladder or kidneys. If there is any concern for bladder rupture, then CT cystography should be performed.[97] Bladder ruptures may occur in the extraperitoneal or intraperitoneal space. Intraperitoneal bladder ruptures require repair in the operating room. Extraperitoneal bladder ruptures often can be treated with Foley decompression, with the rupture site healing on its own with time. However, in an unstable pelvis where definitive repair will involve hardware insertion, there is some evidence that operative repair may reduce the risk of morbidity, such as hardware infection.[98,99] Urethral injuries are much more common in men than in women, and classic signs are perineal bruising or hematoma, displaced pubic ramus fracture, blood at the urethral meatus, and a high riding or impalpable prostate.[100] If perineal bruising or blood at the urethral meatus is found, Foley should not be attempted and instead a retrograde urethrogram should be performed.[101] If this is positive, a Foley catheter should not be placed and a urologist called to evaluate the patient. Depending on the degree and type of urethral injury found, treatment can range from catheterization and time to complex surgical approaches.[102]

Rectal injuries are more common in penetrating trauma, which accounts for greater than 70% of all rectal injuries. The remainder are associated with less than 5% of pelvic fracture patients.[96] On physical examination, typically rectal injuries are found by the presence of rectal bleeding and a high index of suspicion. If one is found, regardless of whether it is intraperitoneal or extraperitoneal, surgical consultation is indicated for diverting colostomy and rectal repair; missed rectal injuries in this setting can lead to disastrous pelvic sepsis, including abscess formation and osteomyelitis.

LONG BONE FRACTURE

Initial priorities in the management of long bone fractures are like pelvic fractures: hemorrhage control and identification of associated injuries. Extremity fractures can lead to significant hematoma and hemorrhage from the bone itself in addition to concomitant vascular injury, which may require damage control resuscitation as mentioned earlier. In addition, limb viability must be assessed continuously because of complications related to vascular injury and compartment syndrome. Patients with long bone fractures are also at risk for rhabdomyolysis, particularly if they suffer a crush injury or reperfusion injury.

Hemorrhage Control Adjuncts, Vascular Injury, and Limb Viability

Hemorrhage control for long bone fractures ultimately depends on the source. The bony break itself and associated soft tissue damage are the most common sources and can lead to a surprising amount of bleeding. Femoral fractures, for example, can have a significant amount of bleeding into the soft tissue space. In addition, long bone fractures can lacerate or crush major arteries and veins that travel alongside them. Key steps first involve assessment for external compressible hemorrhage, for which control often can be obtained by applying direct pressure above the bleeding point.[103] If this maneuver fails, hemostatic agents and/or a tourniquet can be safely applied in the prehospital setting to increase limb salvage and reduce mortality.[104–106] This could theoretically be extended to the ICU in an emergency with the understanding that quick action must be taken afterwards to definitively control bleeding; tourniquets cannot be left on indefinitely without consequence, and early surgical involvement is paramount to assess limb viability and reduce morbidity. Improperly placed tourniquets can cause major harm: placement for longer than 6 hours leads to profound ischemia and reperfusion injury, and a venous tourniquet, with intact arterial flow, promotes compartment syndrome and amputation. It cannot be overemphasized that tourniquet placement is a bridge to operative interventions that are primarily helpful in the prehospital setting and should be removed as soon as possible; tourniquets should not be used for long-term hemorrhage control.

Assessment of limb viability starts with looking for "hard signs" of vascular injury and performing a complete pulse examination. If a tourniquet is present, this should be loosened for evaluation and tightened again if the patient begins to hemorrhage. "Hard signs" of vascular injury include a rapidly expanding hematoma, obvious arterial bleeding, thrill from a traumatic arteriovenous fistula, or a pulseless extremity. The presence of any of these signs warrants operative exploration without any imaging required.[107] If these signs are not present, the patient should be evaluated for "soft signs" of vascular injury. "Soft signs"

include neurologic deficit, a nonexpanding hematoma, and wound proximity to an artery.[108] If "soft signs" are present or pulses feel diminished, noninvasive vascular testing should be performed (i.e., ankle-brachial index or brachial-brachial index). An ankle-brachial index or brachial-brachial index <0.9 is an excellent noninvasive test that has a sensitivity and specificity of more than 95% for major arterial injury.[109] If the patient is hemodynamically normal and the patient's noninvasive testing is consistent with vascular injury without "hard signs," CT angiogram of the affected extremity should be done as part of the workup. Blunt trauma patients are less likely to have vascular injury, but when present, they often are seen with crush or stretch injury, dissection, or even arterial compression from fracture fragments.[110–112] In these cases, fracture reduction and splinting may allow return of flow, and perfusion should be reassessed afterwards. In penetrating trauma, the likelihood of a direct arterial injury is higher, but in select cases minimally invasive methods may be more appropriate. Additionally, CT angiogram is less invasive than traditional angiography, with sensitivity and specificity approaching 100%. In the setting of combined fracture and vascular injury, management can prove particularly challenging because patients need urgent fracture fixation and vascular repair. This often will involve temporary vascular shunting and external fixation, with subsequent definitive vascular repair.[113,114] Postoperatively after vascular repair for trauma, we do not recommend routine heparinization for these patients, as the risk of bleeding must be carefully weighed against the risk of graft thrombosis.

After assessing for vascular injury, fracture stabilization should be performed. Plain films should be performed of the suspected fracture site in addition to a joint above and below the injury to assess for occult fractures. If significantly displaced, reduction should be attempted by an experienced practitioner, with subsequent splinting. This may require sedation, but reduction can help reduce hemorrhage in addition to pain. Depending on the extremity, other techniques may be indicated, such as traction in femur fractures. Traction has previously been used extensively throughout history to reduce fractures, with the thought that it can reduce pain and bleeding from fracture sites. Displaced femur fractures, in particular, can bleed substantially into the thigh compartment. There have not been sufficient clinical data in favor of or against traction, and so it should be performed on a case-by-case basis in the hands of an experienced practitioner. Early fixation of long bone fractures, especially femur fractures in the elderly, is particularly important, as there is reduced morbidity compared with delayed repair.[63,115–117]

Acute Compartment Syndrome and Rhabdomyolysis

All extremity fractures need to be continuously assessed for limb viability and compartment syndrome, whether in a preoperative splint or after temporary or definitive fixation postoperatively. The most common site is the lower leg, though thigh and arm compartment syndromes can occur. Acute compartment syndrome of the extremity requires a high index of suspicion and frequent evaluation to detect.[118] Crush injury, limb ischemia, vascular reperfusion, open fractures, and even overly tight dressings are at particular risk for progressive edema of the leg. This increases compartment pressures and reduces perfusion leading to tissue hypoxia and, ultimately, myonecrosis and rhabdomyolysis.[119] Acute compartment syndrome is notoriously difficult to diagnose. The classic symptoms are the "five Ps": pain, pallor, paresthesia, pulselessness, and poikilothermia, with pain often described as occurring with passive stretch. Unfortunately, although these signs may be specific, they are not particularly sensitive for the diagnosis.[120] In an obtunded ICU patient, compartment syndrome can be particularly difficult to diagnose, as these clinical signs cannot be assessed easily, and pulselessness is known to be a very late sign of compartment syndrome. There also are no specific biomarkers that can be checked for compartment syndrome. In this situation, compartment pressure measurements may be indicated with appropriate clinical suspicion. Unfortunately, an "elevated" compartment pressure is ill defined, though accepted values are an absolute pressure >30 mm Hg or a perfusion pressure (i.e., diastolic blood pressure minus compartment pressure) <20 mm Hg. Compartment syndrome is a surgical emergency requiring fasciotomy, and the more delay there is in recognition, the higher the morbidity and rate of limb loss, highlighting the need for continuous limb assessment in this patient population.

Rhabdomyolysis is related to myonecrosis resulting in the release of myoglobin in the blood. It is often associated with compartment syndrome, though it may also occur in ischemia-reperfusion from vascular injury and from severe crush or burn injuries. It is thought that rhabdomyolysis is primarily propagated by oxygen-free radicals with subsequent release of myoglobin.[121] The circulating myoglobin then causes renal toxicity by tubular obstruction, vasoconstriction, or direct toxic effects.[122] This may be exacerbated by prerenal azotemia secondary to hypovolemia in the bleeding or severely injured trauma patient. Numerous therapies have been suggested: mannitol for oxygen free radical scavenging and osmotic effects, loop diuretics to dilute the urine, and sodium bicarbonate to alkalinize the urine with the hope of preventing tubular obstruction. However, to date the only therapy that appears to reduce the incidence of kidney injury from myoglobinuria is early and aggressive fluid resuscitation with isotonic fluid.[123] Patients with rhabdomyolysis will also have hyperkalemia because of the release of intracellular potassium with myonecrosis. Hyperkalemia combined with associated kidney injury may necessitate the use of renal replacement therapy. Continuous renal replacement therapy does not offer any advantage over intermittent hemodialysis but may be more appropriate in the hypotensive severely injured trauma patient, depending on the clinical picture.[124]

CONCLUSION

Pelvic and long bone fractures are common injuries in the trauma population, particularly in the blunt polytrauma patient. The first management consideration is evaluation for shock and the necessity for damage control resuscitation and hemorrhage control. Hemorrhage control may require numerous adjunctive therapies, such as a binder for pelvic fractures or a tourniquet for lower extremity fractures, and even interventional or operative intervention. Additionally, these fracture patterns can have numerous associated injuries that must be diagnosed and addressed once the patient is stabilized. Finally, there are several complications that one must be vigilant in diagnosing: PE, FES, and acute extremity compartment syndrome.

KEY POINTS

- "Damage control resuscitation" using a 1:1:1 ratio of plasma:platelets:packed red blood cells should be initiated for hemorrhage related to pelvic or long bone fractures. Early blood product use is favored over crystalloid administration.
- Fractures should be assessed for overlying soft tissue defects and contamination. Open fractures should be treated with prophylactic antibiotics for 48–72 hours.
- When possible, early enteral nutrition should be initiated to reduce the risk of nosocomial infections, promote intestinal mucosal integrity and immunity, and prevent catabolism.
- Major trauma patients, especially those with pelvic and/or long bone fractures, are at high risk for VTE and should be started on chemical prophylaxis as soon as it is possible and safe.
- FES is a rare but potentially deadly complication of major orthopedic trauma that presents with tachycardia, hypoxia, and altered mental status. Treatment is supportive care.
- Pelvic fracture hemorrhage requires multidisciplinary management. Adjuncts to controlling hemorrhage include short-term binder or sheet stabilization, preperitoneal pelvic packing, angioembolization, REBOA, and external fixation.
- Pelvic fracture patients should be assessed for associated injuries, including the lower urinary tract and rectum.
- Assessment of major long bone fractures starts with assessment of vascular injury and limb viability first, followed by early fracture stabilization.
- Clinicians should assess patients with extremity fractures for compartment syndrome and rhabdomyolysis to prevent morbidity.

Landmark observational study in which the authors demonstrated reduced mortality with early administration of plasma and platelets and higher plasma:platelet:RBC ratios in the early resuscitation period. This study led to further investigation into RBC/plasma ratios and popularized damage control resuscitation.

Johansen K, Lynch K, Paun M, et al. Non-invasive vascular tests reliably exclude occult arterial trauma in injured extremities. *J Trauma*. 1991;31(4):515–519; discussion 519–522.
A landmark study from Harborview Medical Center in Seattle, Washington, this study demonstrates that the measurement of ankle-brachial index can reliably exclude major occult arterial injury in extremity injuries. This study was performed before widespread use of CT arteriogram, when formal angiography had to be performed to evaluate for arterial injuries; however, noninvasive vascular tests are still an excellent initial assessment to decide if further workup is needed.

Tran TL, Brasel KJ, Karmy-Jones R, et al. Western Trauma Association Critical Decisions in Trauma: Management of pelvic fracture with hemodynamic instability – 2016 updates. *J Trauma Acute Care Surg*. 2016;81(6):1171-1174.
This article by the Western Trauma Association enumerates an algorithm for the management of hemodynamically unstable pelvic fracture. It is based on the most up-to-date literature at the time of publication and expert consensus. The algorithm includes the use of damage control resuscitation and organizes the numerous adjuncts for pelvic hemorrhage control in a logical manner.

Determination of Brain Death and Management of the Brain-Dead Organ Donor

Helen I. Opdam, Rohit L. D'Costa, Dale Gardiner, and Sam D. Shemie

INTRODUCTION

The diagnosis of death using neurologic criteria is recognized as the complete and irreversible loss of capacity for consciousness and all brain function as a consequence of catastrophic brain injury.[1]

Historically and in many countries, this diagnosis is called "brain death." Some countries and academic papers have moved away from this term, which can be a source of confusion, especially in the media.[2–4] Although supportive of this move, for the purposes of this chapter, the historic and shorthand "brain death" is used.

The pathophysiologic sequelae of brain death include hemodynamic changes, activation of inflammatory and coagulation pathways, metabolic and endocrine effects, and loss of autoregulatory brain functions, all of which can affect multiple organ systems.

The physiologic care and management of the patient with brain death are important for optimizing donation and transplantation outcomes. Approximately 80% of worldwide organ donation after death occurs in individuals determined deceased using neurologic criteria.[5]

DETERMINATION OF BRAIN DEATH

The Concept and Definition of Brain Death

Brain death is accepted as death throughout most of the world, although there exists international variability in both the definition and process of determining brain death.[6] There is general consensus regarding brain death as the complete and irreversible loss of brain function resulting from a devastating brain injury with the features of unresponsive coma, brainstem areflexia, and apnea.[4]

Before the 1950s, catastrophic brain injury would inevitably lead to inadequate spontaneous respiration and rapid cardiorespiratory arrest. The advent of mechanical ventilation and cardiopulmonary resuscitation disrupted the interdependent linkage between these three functions. Complete cessation of brain function could occur and yet by intensive care support, respiration and circulation could be maintained.

Published case series from France in the 1950s first described ventilator-dependent patients in an irreversible state of apneic coma with absent brainstem reflexes and absence of electroencephalographic (EEG) activity, and the term "le coma dépassé" (a state beyond coma) was used.[7,8] In 1968 a committee of Harvard University faculty proposed criteria to diagnose this state, which they called "irreversible coma," and asserted that despite the presence of mechanically supported respiration, and consequent circulation and organ function, people with permanent loss of all functions of the entire brain were dead.[9] The Harvard report heralded the successive worldwide acceptance of brain death and the clinical approach to its determination.

The Harvard report described the requirement for "whole brain death," inclusive of the cerebral hemispheres, cerebellum, and brainstem, and this approach was accepted within the United States and most other countries. At a similar time in the United Kingdom (UK) the "brainstem death" concept was evolving, with a focus on the vital role of the brainstem in consciousness and respiration.[10] This became the legally accepted standard in the UK and in some other countries with historical colonial links.[11] Despite these differences, in practice, the occurrence and process for determining death are very similar in both circumstances.[4,12]

Recent publications have sought to move from an historical and anatomic focused view of brain death to definitions that attempt to unify all diagnoses of human death (both neurologic and circulatory) around a concept of the permanent loss of brain function.[1,13,14]

The vast majority of brain death arises from severe cerebral injury culminating in increased intracranial pressure (ICP), rostral-caudal herniation, reduced cerebral perfusion pressure, and finally the absence of brain blood flow. The loss of brainstem function is caused by ischemia and compression through uncal herniation.

The most common etiologies are hemorrhage (e.g., subarachnoid or intracerebral hemorrhage), ischemic stroke, traumatic brain injury, and hypoxic-ischemic brain injury after a resuscitated cardiac arrest. Other causes include central nervous system infection (e.g., bacterial meningitis, viral encephalitis, brain abscesses); neoplasms (primary brain tumors or metastases); obstructive hydrocephalus; and cerebral edema from hyponatremia, liver failure, or other metabolic conditions. The pathophysiology of raised ICP with loss of brain blood flow and perfusion is facilitated by the rigid nonexpanding nature of the skull and thus can be less likely or slower in onset in patients post-craniectomy and children younger than 2 years with nonfused skull sutures.

In the uncommon circumstance of an isolated brainstem or cerebellar injury, jurisdictions that require whole brain death need to ensure loss of supratentorial blood flow, as it cannot be presumed that "whole brain" death criteria have been met through clinical examination alone. Of note the majority of patients with posterior fossa lesions will with time go on to lose cerebral blood flow through the development of hydrocephalus or by other mechanisms.[15]

Given the linkage between brain and cardiorespiratory function, with cessation of the latter in the setting of devastating brain injury, the development of brain death requires, at a minimum, the provision of mechanical ventilatory support. The setting for brain death is therefore almost exclusively in-hospital and usually within intensive care units.

The fundamentals of the clinical examination for brain death are relatively consistent throughout the world. Most variability in the process of brain death determination relates to aspects such as the qualifications of the examiners and number of examinations; time intervals

between examinations; and the prerequisites for blood pressure, temperature, and drug levels, in addition to the indications and recommended techniques for ancillary testing. Healthcare providers should be knowledgeable about jurisdictional laws and guidelines and ensure their practice is consistent with local requirements.

Making a diagnosis of brain death has benefits irrespective of the potential for organ donation, as it establishes whether a patient is alive or dead. This can eradicate doubt for the family and hospital staff and allow futile and/or inappropriate treatment to cease.[16] Brain death should therefore be determined whenever it has occurred and regardless of whether donation is being considered.

Process for Determining Brain Death

Although individual jurisdictional requirements may vary, the general principles outlined here do not.

The consideration of brain death requires there to be definite clinical and neuroimaging evidence of acute brain pathology sufficient to result in the complete and irreversible loss of brain function. In countries that require "whole brain death," evidence of sufficient cerebral pathology to cause loss of *all* brain function must be present.

The patient must have observed unresponsive coma, brainstem areflexia, and lack of spontaneous breathing effort in the absence of reversible conditions. Some conditions other than a devastating brain injury may result in reversible loss of brain function mimicking brain death, such as severe Guillain-Barré syndrome, snake bite, and botulism. The diagnosis of brain death must not be entertained in such situations.

Even in jurisdictions that require ancillary investigations, the diagnosis of brain death requires a clinical examination to demonstrate the absence of brainstem function.

Preconditions to Clinical Examination

The absence of confounders is important to ensure that the clinical examination accurately reflects the absence or presence of brainstem function. If confounding factors are present (e.g., inability to exclude sedative effects), or if a portion of the examination cannot be adequately undertaken (e.g., inability to adequately examine all brainstem reflexes or perform apnea testing), a clinical examination that is as complete as possible should be conducted, as evidence of residual brain function will exclude the presence of brain death. Where confounders exist, ancillary testing will be necessary in addition to the clinical examination to determine brain death (see later).

The following preconditions should be met before and throughout the clinical examination:

- Exclusion of hypothermia (e.g., temperature ≥35°C).
- Exclusion of hypotension (e.g., mean arterial pressure [MAP] 70–100 mm Hg in an adult and age-appropriate blood pressure in children).
- Exclusion of effects of sedative medications (self-administered or otherwise). The time taken for plasma concentrations of sedative medications to fall below levels with clinically significant effects depends on the dose and pharmacokinetics of medications used and on hepatic and renal function, especially in the case of barbiturates, which take many days to metabolize. Measurement of blood levels to ensure they are below that of clinically significant effects may be necessary. Particular care should be taken to ensure the absence of continued sedative medication effect in patients who have been hypothermic (e.g., therapeutic hypothermia post cardiac arrest). If there is any doubt about the persisting effects of opioids or benzodiazepines, an appropriate medication antagonist should be administered at the time of examination, or ancillary investigations must be carried out.
- Absence of severe electrolyte, metabolic, or endocrine disturbances. These include marked derangements in plasma concentrations of glucose, sodium, phosphate, magnesium, and urea and severe endocrine dysfunction (e.g., severe hypothyroidism or hypoadrenalism).
- Absence of acute liver failure or decompensated chronic liver disease.
- Absence of neuromuscular-blocking drugs. A peripheral nerve stimulator should be used to confirm that neuromuscular conduction is normal unless it is certain that neuromuscular-blocking medications have not been administered.
- Ability to adequately examine the brainstem reflexes (e.g., may not be possible if major facial trauma prevents eye and/or ear examination).
- Absence of a cervical spinal cord injury. This may preclude apnea testing that is reflective of brainstem function.
- Absence of severe cardiopulmonary injury or disease, which may preclude the safe undertaking of apnea testing.

Observation Period and Establishing Irreversibility

It must be established that the loss of brain function is constant over time and irreversible. This is achieved by knowledge of the mechanism and natural history of the devastating brain injury and a period of observation (e.g., a minimum of 4–6 hours of features consistent with brain death). When brain death is suspected after a resuscitated cardiac arrest, a longer period of 24 hours observation is recommended before brain death testing, as there can be slow recovery of brainstem function after successful resuscitation. Similarly, after prolonged hypothermia, such as therapeutic cooling post cardiac arrest, a period of 24 hours post-rewarming is recommended because of the effects of hypothermia on neurologic function and the impact cooling may have on drug metabolism, as demonstrated by case reports that support a more conservative approach in such circumstances.[17,18]

In patients who are unresponsive with nonreactive pupils but appear to be spontaneously breathing, care must be taken that the ventilator is not autocycling/autotriggering on a spontaneous mode secondary to cardiac pulsations.

Situations Requiring Extra Caution

The UK has identified "red flag" categories where additional diagnostic caution is advised[19]:

1. Testing <6 hours of the loss of the last brainstem reflex
2. Testing <24 hours of the loss of the last brainstem reflex, where the etiology is primarily anoxic damage
3. Hypothermia—24-hour observation period after rewarming to normothermia recommended
4. Patients with any neuromuscular disorders
5. Steroids given in space-occupying lesions such as abscesses
6. Prolonged fentanyl infusions
7. Etiology primarily located to the brainstem or posterior fossa
8. Therapeutic decompressive craniectomy.

Clinical Examination

The following three clinical criteria need to be established for the neurologic determination of death:

- Unresponsive coma
- Absent brainstem reflexes
- Apnea (absence of spontaneous breathing)

A generic process for undertaking the clinical examination is suggested in Table 159.1. A number of countries have published education videos to assist clinicians.[20–22]

Protocols vary in the requirement of whether it must be possible to reliably test each of the brainstem reflexes bilaterally, or at a minimum unilaterally. Ancillary testing is required if it is not possible to meet the

TABLE 159.1 Process for the Clinical Examination in the Determination of Brain Death

Test	Response Consistent With Brain Death	Considerations
Responsiveness		
There should be unresponsive coma with no evidence of arousal or movement after noxious stimulation, other than spinal-mediated reflexes.		
Noxious stimuli should be applied in the cranial nerve distribution and all four limbs and trunk, observing for centrally mediated motor responses (e.g., pressure over the supraorbital nerve, sternal rub, and deep nail bed pressure).	There should be no motor response within the cranial nerve distribution or any response in the limbs secondary to cranial nerve stimulation. This equates to a Glasgow Coma Score (GCS) of 3.	Spinal reflexes may be present in patients with brain death (see later) and are not to be confused with a pathologic flexion or extension response.
Brainstem Reflexes **The cranial nerves should be examined sequentially and bilaterally**. **All testable brainstem reflexes must be absent for brain death to be determined**. **The presence of a brainstem reflex means brain death is not present and testing is then ceased.**		
Pupillary light reflex—cranial nerves II and III Shine a bright light into the eye and look for a pupillary constrictor response.	There should be absence of ipsilateral and contralateral pupillary response, with pupils fixed in a midsize or dilated position (~4–6 mm), in both eyes.	Constricted pupils are not consistent with brain death and suggest the possibility of drug intoxication or locked-in syndrome. Pupils can be any shape (round/oval/irregular). Ancillary testing is recommended if eye trauma or anophthalmia limits examination.
Corneal reflex—cranial nerves V and VII Touch the corneas, applying light pressure with sterile soft cotton wool or gauze, and examine the eyes for blinking or other response.	No eyelid movement should be seen.	Touching the sclera is not sufficient. Care should be taken to avoid damaging the cornea. Ancillary testing is recommended if eye trauma, anophthalmia, severe orbital edema, or prior corneal transplantation limits examination.
Reflex response to pain in the trigeminal distribution—cranial nerves V and VII Apply pain over the trigeminal distribution (e.g., pressure over the supraorbital nerve).	No facial or limb movement should be seen.	Ancillary testing is recommended in the presence of severe facial trauma and swelling that may preclude evaluation.
Oculovestibular reflex—cranial nerves III, IV, VI, and VIII Inspect the external auditory canal with an otoscope to confirm that the eardrum is visible. If the eardrum is not visible, the canal must be cleared before testing can occur. Elevate the head to 30 degrees to place the horizontal semicircular canals in the true vertical position. Irrigate with ≥30 mL of ice water using a syringe or a syringe attached to a catheter placed inside the auditory canal. Hold eyelids open and observe for eye movement for a minimum of 60 seconds. Test both sides separately.	No eye movement should occur in response to the cold water.	A ruptured eardrum does not preclude the test. Ancillary testing is recommended in the setting of severe eye trauma, anophthalmia, or a fracture of the base of the skull or petrous temporal bone that may obliterate the response. Testing for the oculocephalic reflex (rotating the head briskly horizontally to both sides) examines the same reflex pathways and is not required in addition to the oculovestibular reflex and should not be undertaken in the presence of a cervical spine injury.
Gag reflex—cranial nerves IX and X Touch the posterior pharyngeal wall, on both sides, with a tongue depressor or cotton swab. A laryngoscope or video laryngoscope may assist in obtaining a good view of the pharynx for stimulation.	No gag response should be seen.	If the patient is orally intubated, the gag reflex may be difficult to discern.
Cough/tracheal reflex—cranial nerve X Stimulate the tracheobronchial wall to the level of the carina with deep endotracheal placement of a soft suction catheter.	No cough response should be seen.	The efferent limbs for this reflex are the phrenic nerve and the nerves of the thoracic and abdominal muscles. Therefore it cannot be assessed in patients with high cervical cord injury; in this setting, ancillary testing is recommended.

TABLE 159.1 Process for the Clinical Examination in the Determination of Brain Death—cont'd

Apnea Testing

The test seeks to demonstrate a lack of spontaneous breathing in the setting of a sufficient respiratory center stimulus. Many guidelines suggest reaching a partial pressure of carbon dioxide in arterial blood ($PaCO_2$) of ⩾60 mm Hg (8 kPa).

Apnea testing should be undertaken ONLY if all the earlier reflexes are absent.

Preoxygenate (inspired oxygen concentration 100%) for >5 minutes to prevent hypoxemia during the test, and adjust the ventilator settings such that the $PaCO_2$ normalizes at 40–45 mm Hg (5.3–6 kPa). Throughout the procedure, monitor the patient's percentage blood oxygenation saturation (SpO_2).	If any respiration attempts are seen (that is, abdominal or chest excursions or activity of accessory respiratory muscles, or if there is end-tidal CO_2 evidence of a breath), the test is ceased and the patient is reconnected to the ventilator, as the criteria for brain death have not been met.	Usually $PaCO_2$ rises by ~3 mm Hg (0.4 kPa) for every minute of apnea.
Disconnect the endotracheal tube (ETT) from the ventilator, with or without the provision of oxygen. Common methods for providing oxygen include the use of a self-inflating bag with attached continuous positive airway pressure (CPAP) valve to prevent atelectasis or inserting a small cannula via the ETT to approximately the level of the carina to deliver oxygen at 4–6 L/min.		Some protocols require that a pH goal is also met, (e.g., <7.30) and/or that in the setting of prior CO_2 retention that a rise (e.g., increase of >20 mm Hg = 2.7 kPa) above a known chronic baseline is achieved.
Expose the chest and abdomen and observe continuously for any spontaneous breathing. End-tidal CO_2 monitoring can be very helpful.		If starting from normocapnia, the $PaCO_2$ is likely to be >60 mmHg (8 kPa) after 8–10 minutes.
An arterial blood gas (ABG) is taken after approximately 8–10 minutes to document the rise in $PaCO_2$ to above 60 mm Hg (8 kPa). If the patient is stable and point-of-care ABG testing is available, await the return of the result before reconnecting the ventilator in case the required change in $PaCO_2$ has not been achieved.		Patients may become hypoxic or develop hemodynamic instability. If hypoxia (SpO_2 <88%) occurs, give 1–2 mandatory breaths and continue apnea testing. Vasopressors may be adjusted to support blood pressure.
At the end of testing, return the patient to mechanical ventilation.		If the test cannot be completed due to cardiorespiratory instability, it should be ceased and an alternative approach to undertaking the test be used or, alternatively, an ancillary test may be needed. Alternative approaches to achieving the $PaCO_2$ goal while maintaining oxygenation include providing oxygen via a self-inflating bag with CPAP valve, preapnea recruitment maneuvers, and induction of hypercarbia with CO_2 or carbogen before disconnecting from the ventilator.
		Care must be taken if a tracheal catheter is used, as wedging, trauma, or a size that is large relative to the tracheal diameter may result in barotrauma. High oxygen flow rates can cause CO_2 washout with failure of the $PaCO_2$ to rise.
		If the CPAP circuit on the ventilator is used, care must be taken to identify autotriggering/autocycling, which may be misinterpreted as spontaneous breathing.

local standard because of inability to adequately examine at least one or both eyes and ears.[23]

Family presence during the clinical examination should be offered, with appropriate explanation and support, as family members may find witnessing the testing useful to their acceptance and understanding of death, especially the apnea test component. Diagrams, the use of nationally endorsed testing forms, and viewing neuroimaging and reports may also assist the family in their understanding of the patient's prognosis and the concept of brain death.

When preconditions are satisfied, then clinical examination alone is preferable for the routine determination of brain death without reliance on ancillary testing (see later).

Number of Examinations

A single clinical examination, including apnea testing, is the minimum standard for determination of brain death in adults.[24] Most jurisdictions require two examinations. If two examinations are performed, an intervening period is unnecessary because the prerequisite of irreversibility will have already been demonstrated by knowledge of the mechanism and natural history of the devastating brain injury, along with a suitable observation period before initiating testing. All that may be required is enough time to allow for physiologic stabilization between tests. Many clinicians will use this time to update the family and invite them to witness the second examination.

Spinal Reflexes

The preservation of spinal reflexes after brain death has been described for decades.[25] Spinal reflexes can be either spontaneous or provoked by noxious stimuli such as pain, passive neck movement, hypotension, and hypoxemia after terminal removal of the ventilator or during the apnea test.[26] They never involve the brainstem cranial nerves.

Prevalence is up to 50% of patients with brain death and is the result of a functioning spinal arc with loss of higher center inhibitory control.

Spinal reflexes can be simple or complex and may be upsetting when observed by family members and staff.[27] It is essential that these movements are explained and forewarned to families and staff.

The most common movements described are finger and toe jerks, the undulating toe reflex, triple flexion response, pronation-extension reflex, facial myokymia, and myoclonus.[26,28] Rarely, marked upper extremity and torso movements may occur, such as the Lazarus sign, in which there is bilateral arm flexion; shoulder adduction; and sometimes flexion of the trunk, hips, and knees.

Other physiologic signs that are compatible with brain death include sweating, blushing, tachycardia, normal blood pressure without the need for pharmacologic support, and an absence of diabetes insipidus.[29]

Observations that are incompatible with brain death include decerebrate or decorticate posturing, true extensor or flexor motor responses to painful stimuli, seizures, and limb movement elicited by stimulation of the cranial sensory nerves or facial movement elicited by stimulation of the body or limbs.

Ancillary Testing

Ancillary testing is required if the preconditions for clinical examination alone to determine brain death cannot be met. This may include the presence of confounding conditions that cannot be resolved or the inability to complete all aspects of the clinical examination, including the apnea test. Ancillary tests may also be required if there is uncertainty in the interpretation of aspects of the clinical examination, including whether movements are centrally or spinal-mediated. Other reasons for undertaking ancillary tests include a desire to determine brain death earlier than the required observation period allows, if national policies or practices require them, and, for some families, ancillary tests may assist in providing greater understanding and certainty of brain death, especially if they have not witnessed the clinical examination.[30] It is recommended that the clinical examination be completed to the fullest extent possible before undertaking an ancillary test.

Most ancillary testing is on the premise that demonstrating absence of cerebral blood flow and/or perfusion in a person with a supported somatic circulation correlates with permanent loss of brain function. An exception is EEG, which measures brain activity. The ideal test would have no false positives (incorrect diagnosis of brain death) or false negatives (incorrect ruling out of brain death). Various techniques have been described and validated, generally against clinical brain death testing. Local availability and preferences tend to guide use[6]:

1. Digital subtraction angiography (three- or four-vessel cerebral angiography)—Long regarded as the gold-standard ancillary test for this purpose, cerebral angiography in brain death demonstrates flow obstruction at the level of the carotid siphon and the foramen magnum.[31,32] Even cerebral angiography is subject to interoperator variability because of, for example, the vigorousness of contrast injection, but it is widely accepted as specific and sensitive.[33]
2. Radionuclide imaging (cerebral scintigraphy)—Radiotracer uptake should not occur in brain parenchyma in the setting of brain death. Intravenous injection of an agent such as Tc-99m labeled hexamethylpropyleneamine oxime (HMPAO), which normally crosses the blood-brain barrier and persists in brain parenchyma, together with planar or single-photon emission computed tomography (SPECT) detection is used.[34] Although there have been case reports of false-positive tests, the specificity is thought to be high.[35]
3. Computed tomography (CT) angiography/perfusion—Being relatively easily available and noninvasive, CT has obvious appeal as an ancillary modality. It was evaluated initially using a 7-point and then a more sensitive 4-point scoring system.[36,37] A Cochrane review identified only moderate sensitivity and therefore could not recommend CT angiography as a mandatory investigation.[38]
4. Transcranial Doppler (TCD)—Although portable and noninvasive, TCD is operator dependent and reliant on detection of a suitable acoustic window.[39] A systematic review and meta-analysis reported very high sensitivity and specificity when compared with clinical brain death testing.[40]
5. Magnetic resonance imaging (MRI)—Various techniques involving MRI have been evaluated in brain death (e.g., diffusion-weighted imaging [DWI], susceptibility-weighted imaging [SWI], gradient-recalled echo [GRE], magnetic resonance angiography [MRA]), but techniques suffer from uncertain specificity and the logistic impediments of transporting ventilated patients to the MRI scanner.[31]
6. EEG—In contrast to the aforementioned techniques, EEG is a test of cerebral function and not blood flow. It is a common mandatory test in algorithms for brain death determination in some jurisdictions and importantly requires clinical preconditions to be met (e.g., normothermia and absence of confounding sedative or metabolic effects).[6,41] Because of its limited utility and case reports where overreliance upon it has contributed to misdiagnosis, some countries now advise against its use.[17,23,42,43]

Repeat Testing

If clinical examination or ancillary tests demonstrate that complete and irreversible loss of brain function has not yet occurred, consideration should be given to repeating these tests after a suitable interval.

Brain Death Determination in Children and Neonates

International guidelines for the diagnosis of brain death in children and term infants are consistent with those for adults, particularly in their preference for clinical determination, with ancillary testing having a similar secondary role when clinical testing alone is not possible or reliable.[3,23,44,45] In these guidelines the observation periods, requirements for repeat testing, and other criteria are generally more conservative in the newborn and early infant period.

MANAGEMENT OF THE BRAIN-DEAD ORGAN DONOR

As discussed earlier, the diagnosis of brain death is independent of any organ donation considerations. When patients and families have agreed to donation after death, the optimal physiologic support of potential donors maximizes donation and transplant outcomes.

In 1995 Wheeldon and colleagues published the experience of a UK center of standardized donor cardiorespiratory optimization instituted by the retrieval team upon arrival at the donor hospital that increased the number of hearts and other organs recovered and transplanted.[46]

In 1999 the United Network for Organ Sharing (UNOS) in the United States introduced the Critical Pathway for the Organ Donor that recommended defined physiologic goals and a consistent and active approach to donor management. In a pilot introduction of the pathway, the numbers of organs transplanted per brain-dead donor increased by 11.3%, including a 19.5% increase in hearts transplanted.[47]

Since that time various guidelines and bundles of care have been developed to guide the physiologic management of patients with the potential to donate organs for transplantation after brain death.[23,48–54] Studies have also confirmed that being able to meet prespecified donor management goals, including in more marginal or expanded-criteria donors, results in more organs transplanted per donor, as has also been observed with the involvement of intensivists in leading donor management, particularly in optimizing lung use.[55–58]

In addition to general supportive care, specific treatment to counter the common sequelae of brain death such as hypotension, hypothermia, and diabetes insipidus is usually required. The provision of specific hormonal therapy (thyroid hormone, vasopressin, and steroids) is controversial because of a lack of high-level evidence to support its efficacy.

Pathophysiology of Brain Death

The pathophysiologic sequelae of brain death include hemodynamic changes, activation of inflammatory and coagulation pathways, and loss of autoregulatory brain functions, including the hypothalamic – pituitary axis, all of which can affect multiple organ systems.

During the development of brain death, raised ICP may lead to the classic physiologic responses first described by Cushing, with compensatory arterial hypertension and bradycardia.[59] Brainstem compression and ischemia can result in a marked sympathetic response, with tachycardia and tachyarrhythmias, hypertension, and high blood levels of catecholamine resulting in intense vasoconstriction and increased afterload—the "autonomic storm." Acute myocardial ischemia with dysfunction, electrocardiographic changes, and myocyte necrosis have been demonstrated in animals and humans.[60,61] Raised pulmonary hydrostatic pressure may cause neurogenic pulmonary edema that is accentuated by capillary endothelial damage. This is followed by loss of autonomic function and respiratory drive, leading to hypotension and apnea, and hypothalamic – pituitary dysfunction, with loss of temperature regulation and the development of diabetes insipidus.

Not all patients exhibit these classic features, and occasionally brain death can develop without any instability and is only recognized by the loss of neurologic function.

General Principles of Management

The approach to managing the potential organ donor is similar to that of other intensive care patients. The same expert treatment should be provided following the general principles of critical care management.

Awareness of the specific perturbations that may occur in brain death, in addition to consideration of the patient's underlying condition, will help with anticipating problems and the timely institution of appropriate treatment.

The physiologic goals are similar to those in any other critically ill patient, and the usual spectrum of monitoring and interventions should be employed, including the use of central venous and arterial vascular access.

Communication may be required between the intensive care team and transplant and/or surgical retrieval team regarding organ suitability and assessment or provision of specific physiologic supports and can be facilitated via the donor coordinator.

The use of coordinated care guidelines, bundles of care, and checklists increases the likelihood of medical suitability of donors and maximizes successful organ transplantation. Box 159.1 provides guidance and suggests aims for the clinical management of potential donors with brain death.

Cardiovascular Effects and Support

Cardiac arrhythmias occur commonly during the development of brain death as a result of the autonomic changes, endogenous catecholamines, and myocardial ischemia, and subsequent to brain death from hypovolemia, electrolyte abnormalities, hypothermia, and inotropes.[63]

All types of arrhythmias can be seen, including bradycardia and both supraventricular and ventricular tachyarrhythmias. Cardiac arrest has been reported to occur in 1%–25% of potential donors with brain death, and this can be reduced in frequency with careful physiologic management.[57,64,65]

Hypotension and circulatory shock develop in the majority of patients with brain death and may have multiple causes, including loss of sympathetic tone leading to vasodilatation; hypovolemia from diabetes insipidus, osmotic agents for prior treatment of raised ICP, and blood loss; cardiac dysfunction that is either acute or preexisting; and potentially hypothalamic – pituitary function.

Treatment Approach

The hypertension and tachycardia associated with the development of brain death are usually self-limited, and no treatment is required. If antihypertensives are used, short-acting agents are preferable (e.g., esmolol, nitroglycerin, sodium nitroprusside, nicardipine, labetalol), as longer-acting agents may exacerbate subsequent hypotension. It is unknown whether reducing hypertension and tachycardia protects the heart or other organs from catecholamine-mediated injury.

Arrhythmias can be minimized by maintaining normal serum electrolyte concentrations, body temperature, and blood pressure. Standard treatment (e.g., amiodarone, cardioversion) is used for atrial and ventricular arrhythmias. Bradycardia in patients with brain death is resistant to the vagolytic effects of atropine.[66] In the situation of bradycardia associated with low cardiac output, epinephrine, isoprenaline, dobutamine, dopamine, and/or pacing are recommended.

In the event of a cardiac arrest, cardiopulmonary resuscitation may result in recovery of cardiac function and successful transplantation, although some local policies require informed consent for its use from families of patients planned for donation.

Vasoactive agents are required in 80%–90% of brain-dead organ donors.[67,68] Arterial pressure goals should maintain organ perfusion based on individual patient characteristics (often MAP >70 mm Hg).

BOX 159.1 Donor Care and Physiologic Goals

General
- Monitoring: ECG, pulse oximetry, intraarterial pressure, CVP, core temperature, urine output (hourly), ABGs (4-hourly), consider cardiac function monitoring
- Routine tests: Daily or as required: CXR; ECG; full blood examination; clotting profile; urea, creatinine, electrolytes, including magnesium, calcium and phosphate; liver function tests
- Core temperature 36–38°C*
- Elevate head of bed at 30 degrees, eye care, mouth care, other routine care

Cardiovascular
- MAP 70–100 mm Hg
- Euvolemia, with CVP 4–10 mm Hg
- Adequate cardiac output and organ perfusion: urine output ~1 mL/kg/h (range 0.5–3 mL/kg/h); lactate <2 mmol/L; good capillary refill
- If hypotension: IV infusion of vasopressin (≤2.4 U/h) and/or norepinephrine or phenylephrine
- If bradycardia with low cardiac output – IV infusion of epinephrine or isoprenaline or dobutamine or dopamine and/or pacing
- If low cardiac output – IV infusion of epinephrine or dobutamine or dopamine or milrinone

Respiratory
- Regular tracheal suctioning; positioning side-to-side; maintain tracheal tube cuff inflation
- Prevent atelectasis – PEEP >5 cm H_2O; lung recruitment maneuvers; bronchoscopy as required
- Maintain ventilation and prevent lung injury – $PaCO_2$ 35–45 mm Hg; tidal volume of 6–8 mL/kg predicted body weight; plateau pressure <30 mm Hg
- Maintain oxygenation – SpO_2 92%–95% by adjusting FiO_2 and PEEP (PEEP >5 cm H_2O)

Intravenous Fluid and Metabolic Management
- Sodium 135–145 mmol/L: if sodium >145 mmol/L give additional free water (intravenous 5% glucose, or sterile water via a central venous catheter)
- Urine output ≈1 mL/kg/h (range 0.5–3 mL/kg/h)
- If polyuric >300 mL/h ± rising serum sodium, assume diabetes insipidus and give DDAVP 4 μg every 6 hours or as required and/or commence vasopressin IV infusion (≤2.4 U/h)
- Potassium 3.5–5 mmol/L; phosphate >0.7 mmol/L; magnesium >0.7 mmol/L – supplement as required
- Blood glucose level 4–14 mmol/L; if >14 mmol/L – IV infusion of insulin
- Continue enteral feeding or total parenteral nutrition
- Hb >70 g/L: consider blood transfusion if Hb <70 g/L and/or if bleeding; if bleeding, consider transfusion of clotting factors and other hemostasis strategies

Additional Hormonal Supportive Treatment†
- Give methylprednisolone 15 mg/kg IV single bolus and/or hydrocortisone 50 mg every 6 hours if requested by lung transplant team and/or if hemodynamic instability despite previous measures
- Give triiodothyronine (T_3) 4 μg IV bolus followed by 3 μg/h by IV infusion if requested by heart transplant team and/or if hemodynamic instability despite previous measures

ABGs, Arterial blood gases; *CVP,* central venous pressure; *CXR,* chest x-ray; *DDAVP,* 1-D amino-8 D arginine vasopressin desmopressin; *ECG,* electrocardiogram; *FiO_2,* fraction of inspired oxygen; *Hb,* hemoglobin; *IV,* intravenous; *MAP,* mean arterial pressure; *$PaCO_2$,* partial pressure of carbon dioxide in arterial blood; *PEEP,* positive end-expiratory pressure; *SpO_2,* percentage blood oxygen saturation.
*Some protocols recommended hypothermia (34–35°C) if the kidneys will be used for transplantation.[62]
†Hormonal supportive treatment may include steroids, thyroid hormone, vasopressin, and insulin.

This is achieved by intravenous fluid administration to target euvolemia and vasopressor agents. There is little evidence for the preferential use of either colloids or crystalloids, noting that hydroxyethyl starch should be avoided, given it can cause renal injury.[69] Vasopressin may be preferable if there is concurrent diabetes insipidus, and norepinephrine and phenylephrine are other vasopressor agents frequently used. In patients with low cardiac output, inotropic agents such as epinephrine, dobutamine, dopamine, or milrinone are recommended. A single prospective multicenter study demonstrated improved kidney graft function after transplantation when the donor received a dopamine infusion before donation, but this finding has not been repeated.[70]

Echocardiography or invasive cardiac function monitoring may be necessary in hemodynamically unstable patients or those for whom cardiac function assessment and optimization are high priorities.

If cardiopulmonary instability is refractory to these interventions, initiation of extracorporeal membrane oxygenation (ECMO) or placement of an intraarterial balloon pump can be considered, noting ECMO use is increasingly common in some jurisdictions in donation procedures such as normothermic regional perfusion.[71–73]

Diabetes Insipidus and Fluid and Electrolyte Therapy

In normal health, vasopressin, also known as *antidiuretic hormone* (ADH), is released by the posterior pituitary gland and has both vasopressor and antidiuretic effects through acting on V1 and V2 receptors, respectively. In brain death there is commonly, but not universally, a deficiency in ADH resulting in diabetes insipidus, as evidenced by brisk hypo-osmolar polyuria leading to hypovolemia, hyperosmolality with hypernatremia, and hemodynamic instability if left untreated.[74,75]

Early human studies indicate that deficient vasopressin occurs in up to 80% of brain-dead individuals.[76,77] Current outcome registries in Australia and New Zealand indicate that 77% of brain-dead organ donors develop diabetes insipidus that requires treatment with vasopressin or the synthetic vasopressin analogue desmopressin (1-D amino-8 D arginine vasopressin [DDAVP]).[68]

Treatment Approach

Treatment of diabetes insipidus is vital for donor stability. Attempts to treat with intravenous fluid alone leads to hypothermia because of the infusion of relatively cool fluids, electrolyte disturbance, and donor instability.

Diabetes insipidus is best treated early before significant hypovolemia and metabolic derangement develop. Polyuria (e.g., urine output ≥3 mL/kg/h) and/or rising serum sodium are sufficient triggers to begin treatment, as formal confirmation with paired urinary and serum osmolarity can delay treatment, resulting in donor instability.

Suitable agents include either vasopressin or DDAVP. DDAVP is highly selective for the V2 renal receptor subtypes, has no significant vasopressor activity, and may be the preferable agent to treat diabetes insipidus in the absence of hypotension. It is usually given as an intravenous bolus of between 2 and 6 μg every 6–8 hours or as required, noting it has a much longer half-life than vasopressin.

Vasopressin may be used to treat both diabetes insipidus via its action on V2 renal receptors and hypotension through its pressor effect by acting on V1 receptors on vascular smooth muscle. It must be given by intravenous infusion because of a short half-life (10–35 minutes). The usual dose range is 0.5–2.4 units per hour titrated to blood pressure and urine output. Although some guidelines suggest dose ranges of up to 4 units per hour, there is concern that doses higher than 2.4 units per hour may cause potentially deleterious vasoconstriction of renal, mesenteric, pulmonary, and coronary vasculature.[48,78]

Whether vasopressin to treat hypotension in brain death provides any advantage over other vasoactive agents in terms of efficacy in donor support and transplant outcomes is not known.

Both vasopressin and DDAVP can be administered concurrently in the potential organ donor to control diabetes insipidus and hypotension.

Hypernatremia and fluid volume loss resulting from diabetes insipidus should be corrected with salt-free fluid such as intravenous 5% glucose or with sterile water administered via a central venous catheter if there is resistant hyperglycemia.

Serum electrolytes should be monitored every 2–4 hours to guide fluid and electrolyte replacement, and electrolytes should be maintained within the normal ranges.

Endocrine Effects and Hormonal Supportive Treatment

There is less certainty about the frequency and impact of anterior pituitary gland dysfunction in brain death. Blood flow to the anterior pituitary can remain intact through perfusion from subsidiaries of the external carotid arteries, and there is uncertainty as to the occurrence and clinical relevance of reduced levels of thyroid hormone and cortisol in brain death.[79]

Observational studies in human donors with brain death tend to report a reduction in the free plasma triiodothyronine (T_3) concentration, but findings are variable with respect to changes in thyroxine (T_4) and thyroid-stimulating hormone (TSH).[76,77,80,81] These changes in thyroid hormone levels and TSH in brain death may simply constitute sick euthyroid syndrome, which is commonly seen in critically ill patients without brain injury.

Studies have also failed to identify a consistent association between circulating thyroid hormone concentrations in the brain-dead donor and the donor hemodynamic status, requirement for vasoactive drugs, or cardiac function.[80–83]

Published case series and retrospective audits of the effect of thyroid hormone in brain-dead donors tend to find a beneficial effect of thyroid hormone administration on donor hemodynamics, number of organs procured or transplanted, and/or graft survival.[84] In contrast, all randomized controlled trials have reported no benefit of thyroid hormone administration either alone or in combination with other hormonal therapies.[85–91]

Two recent systematic reviews, which included meta-analyses of placebo-controlled randomized controlled trials, concluded that thyroid hormone does not add hemodynamic benefits or result in an improved number or quality of organs procured for transplantation and cannot be recommended in the routine management of the brain-dead potential organ donor.[92,93]

Despite this, the use of thyroid hormone in brain-dead organ donors in the United States increased from 25% to 75% during 2000–2012.[94]

As with thyroid hormone, there is controversy as to the occurrence of clinically significant adrenal hypofunction in human brain death. A number of small studies in potential donors with brain death have found normal or high levels of cortisol and adrenocorticotropic hormone (ACTH), no association between serum cortisol levels and severity of hypotension, and no serial fall in serum cortisol with the development of brain death.[76,77,80]

In contrast, other small studies have found brain death is associated with low cortisol levels, along with deficient response to ACTH stimulation, as compared with patients with less severe brain injuries.[95,96] Studies of steroid administration to brain-dead patients with a poor response to synthetic ACTH have, however, been inconsistent in terms of the reported hemodynamic benefit.[96,97]

In a European multicenter observational study, steroid use in organ donors with brain death was associated with a lower dose and shorter duration of vasopressor support.[97]

Recent systematic reviews of the use of steroids in brain-dead potential donors have similarly found positive associations on donor hemodynamic and oxygenation status, organs procured, and graft function in observational studies, but neutral outcomes in the small randomized controlled trials that have occurred.[98,99]

In contrast, two large, double-blinded, placebo randomized controlled trials on steroid use (50 mg hydrocortisone every 6 hours) in critically ill patients with septic shock found steroids improved blood pressure and facilitated earlier weaning of vasopressor agents.[100,101]

Apart from hemodynamic reasons, other rationales for administering steroids to potential donors with brain death include their immunomodulatory and antiinflammatory effects.

Brain death is associated with high levels of cytokines, higher than those that occur in patients with similar types of injury though without brain death.[102] Activation of inflammatory cascades in the donor may affect organ function and likelihood of rejection episodes in the recipient.[103–105] A neutrophilic pulmonary infiltration is observed in brain death, and elevated concentrations of interleukin (IL)-8 in donor bronchoalveolar fluid correlate with early graft failure.[106,107] Higher plasma donor IL-6 concentrations are associated with fewer transplanted organs and reduced recipient survival.[108]

High-dose steroids may modulate immune function and decrease inflammation in the donor, with the potential to improve recipient graft function. High-dose methylprednisolone administration to the donor has been associated with improved donor lung oxygenation and increased organ retrieval rates, in addition to less ischemia-reperfusion injury and acute rejection in liver recipients, although no benefit on posttransplantation acute renal failure was observed in a double-blinded, placebo-controlled study when 1000 mg of methylprednisolone was administered to brain-dead kidney donors.[109–111]

Treatment Approach

The available evidence does not support the routine administration of thyroid hormone in potential organ donors with brain death. Thyroid hormone administration may provide benefit in donors who are hemodynamically unstable and/or heart donor candidates who have borderline cardiac function (e.g., <45% left ventricular ejection fraction) despite optimization of volume state with fluid therapy, vasoactive agents, and other general supportive care, including correction of electrolyte abnormalities.

It is suggested that replacement thyroid hormone improves the metabolic and hemodynamic status in brain death by reactivation of mitochondrial energy metabolism.[112]

Although the use of thyroid hormone in these circumstances is based on low-level evidence, T_3/T_4 use may be justified in that there is little indication that thyroid hormone causes harm.

Despite this uncertainty, thyroid hormone, in conjunction with other hormonal therapies, remains part of the recommended management of cardiothoracic organ donors in the UNOS Critical Pathway for the Organ Donor.[113]

T_3 may be initiated with a 4-μg intravenous bolus followed by infusion of 3 μg/h.[48,51] Intravenous T_3 may be preferable to other formulations because of its biologic potency and immediate availability to

tissues. Alternatively, T_4 may be given initially with a 20-μg intravenous bolus followed by infusion of 10 μg/h. Thyroxine requires conversion to the biologically active T_3, and so its onset of action and efficacy are less certain. Thyroxine may also be administered enterally if the intravenous formulation is not available, although impaired enteral absorption may further limit efficacy.

Physiologic stress-dose steroids (e.g., intravenous hydrocortisone 50 mg every 6 hours) may improve blood pressure and reduce vasopressor doses required. High-dose corticosteroid administration (e.g., methylprednisolone 1000 mg or 15 mg/kg intravenously) may reduce the potential deleterious effects of the inflammatory cascade that follows brain death on donor organ function and improve transplant recipient outcomes. It has been suggested, however, that low-dose as compared with high-dose steroids may have no different effect in terms of organs retrieved and transplanted.[114]

Blood for tissue typing should be collected before high-dose steroid administration, as steroids have the potential to suppress human leukocyte antigen expression.

Respiratory Effects and Support

Patients with brain death, as with other critically ill patients, are at risk of pulmonary atelectasis, aspiration, sputum retention, pneumonia, and edema from fluid overload; cardiac dysfunction; and neurogenic mechanisms.

During the development of brain death, the autonomic storm leads to systemic vasoconstriction and increased vascular resistance, which causes decreased left ventricular output and increased retrograde pulmonary venous pressure, resulting in increased hydrostatic pressure across pulmonary capillary membranes.

Deterioration of the donor's respiratory status can result in the lungs becoming unsuitable for transplantation, in addition to jeopardizing donor maintenance and donation in general.

Treatment Approach

Routine respiratory care should continue, including suctioning, positioning side-to-side and turning, and keeping the head of the bed at 30 degrees elevation, with attention to maintaining tracheal tube cuff inflation to avoid pulmonary aspiration. Techniques that reduce atelectasis and lung-protective ventilation strategies should be used such as lung recruitment maneuvers, positive end-expiratory pressure (PEEP) 5–10 cm H_2O, tidal volumes of 6–8 mL/kg of predicted body weight, plateau pressure less than 30 cm H_2O, and maintaining the fraction of inspired oxygen (FiO_2) at the lowest level to keep an oxygen saturation (SpO_2) of 92%–95%.[115–117]

Fiberoptic bronchoscopy can be considered for suctioning and clearing bronchial obstructions and may be requested by lung transplant teams. Secretions should undergo microscopy and culture and antibiotics started if there is suspicion of a pulmonary infection, although there is no role for routine antibiotic prophylaxis.

Higher rates of lung donation are associated with a minimal donor-positive fluid balance, and diuretics may be used to treat pulmonary edema.[118] Euvolemia is compatible with donation of all organs, including lung and kidneys.

As there is an association between steroid use, donor lung oxygenation, lung recovery, and transplantation, some lung retrieval teams will request methylprednisolone 15 mg/kg, but this lacks support from randomized controlled trials.[109]

Hypothermia and Temperature Management

Loss of hypothalamic thermoregulation, reduced heat production, and inability to conserve heat by vasoconstriction or generate it by shivering renders the brain-dead individual poikilothermic (body temperature varies with ambient temperature). The tendency to hypothermia is exacerbated by exposure and administration of intravenous cold fluids. Adverse effects include cardiac dysfunction, arrhythmias, platelet dysfunction, coagulopathy, and a leftward shift of the oxyhemoglobin dissociation curve, with reduced oxygen delivery to tissues.

Treatment Approach

Hypothermia is easier to prevent than reverse. Keep room temperature ≥24°C and use warming blankets, humidification and heating of inhaled gases, and warmed intravenous fluids if large volumes are required.

A recent multicenter randomized controlled trial in brain-dead donors showed a reduction in the incidence of delayed kidney graft function in recipients when mild hypothermia (34°C–35°C) in the donor was induced and maintained until retrieval surgery.[62] Concern about the potential negative impact of donor hypothermia on other organs has been raised, although a follow-up and safety analysis demonstrated no adverse effects on donor physiology or extrarenal graft survival and improved 1-year graft survival for kidneys from standard-criteria donors who received mild hypothermia.[119,120] Many published protocols, however, continue to recommend targeting normothermia, and widespread uptake of induced hypothermia for donor management may not occur until further evidence is available to support its utility.[23,54]

Other Aspects of General Care and Nutrition

Continuing enteral feeding in the donor up until the time of organ retrieval surgery may have beneficial effects on organ function in transplant recipients by restoring energy reserves, reducing cytokine generation, and protecting against ischemia and reperfusion injury.[121,122]

Hyperglycemia is common after brain death because of catecholamine surges and infusion of glucose-containing fluids.[48,67] Hyperglycemia should be treated as per standard approaches for critically ill patients and insulin be given by infusion to maintain blood glucose within the normal range. High doses may be required because of insulin resistance, in which case glucose-containing intravenous fluids should also be avoided.

Transfusion of blood and blood products is occasionally necessary. Anemia is commonly the result of intercurrent bleeding exacerbated by coagulopathy, and hemodilution the result of fluid administration and repeated blood sampling. Coagulopathy may occur secondary to tissue damage in trauma, particularly neurotrauma-induced fibrinolysis and thrombocytopenia, or it can be caused by hemodilution and is worsened by hypothermia.[123] Transfusion of blood, coagulation factors, and platelets may be required to correct severe anemia or coagulopathy, especially in the setting of active bleeding, hypotension, or shock. Procurement should be expedited if there is a worsening coagulopathy and bleeding.

KEY POINTS

- Brain death is the complete and irreversible absence of brain function characterized by loss of capacity for consciousness, unresponsive coma, brainstem areflexia, and apnea.
- Brain death may result from a devastating brain injury caused by hemorrhagic or ischemic stroke, traumatic brain injury, hypoxic-ischemic brain injury, tumor, infection, and other causes of intracranial hypertension or cerebral edema.
- The neuroprotective phase of care in the management of devastating brain injury requires mechanical ventilation to prevent cardiorespiratory arrest after the loss of central control of breathing. Therefore brain death occurs in patients receiving mechanical ventilation almost exclusively in the hospital and usually within intensive care units.
- Brain death is associated with somatic physiologic changes that include hemodynamic instability, activation of inflammatory pathways, and loss of the autoregulatory functions of the brain.
- After the diagnosis of brain death, provision of optimal supportive treatment of potential donors is important in maximizing donation opportunities, organ function, and transplant recipient outcomes.
- Donor management includes careful hemodynamic and respiratory support; maintaining normal electrolytes and euvolemia; and specific treatment to counter the common sequelae of brain death that include hypotension, hypothermia, and diabetes insipidus. The provision of specific hormonal therapies such as thyroid hormone, steroids, and vasopressin is of uncertain benefit.

Donation After Cardiac Death (Non–Heart-Beating Donation)

Stephanie Grace Yi and R. Mark Ghobrial

HISTORICAL PERSPECTIVE

The increasing gap between the number of organs available for transplantation and the number of patients listed for transplantation has become a rate-limiting step in reducing both wait times and wait list deaths in patients awaiting transplantation. Before the passage of the first US brain death law in the state of Kansas in 1970,[1] donation after cardiac death (DCD, or donation after circulatory death) was the primary mode of organ donation in the United States. Donor death was determined according to traditional cardiopulmonary criteria—that is, absence of pulse and blood pressures without cardiac activity.

Early organ procurement strategies were relatively crude and variable, which in turn prolonged warm DCD ischemia time (time from donor circulatory arrest to cold perfusion) and resulted in poor outcomes.[2] The impact of the variability of circumstances surrounding donor death, and thus the duration of ischemic time, on DCD graft outcomes did not become apparent until experiences with organs donated after brain death (DBD) increased.

The need for diagnosing brain death was a culmination of critical care physicians' growing ability to maintain physiologic organ function in patients with little or no hope of neurologic recovery after central nervous system (CNS) insults. The concept was first introduced at a CIBA Foundation meeting in England in 1965 and was subsequently endorsed with formal diagnostic criteria by Harvard Medical School in 1968.[1,3] A new debate was sparked over the precise definition and timing of death and the concept of futile care. Acceptance of this medically, philosophically, and legally novel concept of certifying death while maintaining perfusion in a potential donor to guarantee procurement with minimal warm ischemia time[4] and graft damage revolutionized transplantation. Because early experience with DBD organs showed superior outcomes, use of DCD organs declined and was subsequently abandoned.[5]

The success of DBD organs along with the refinements in medical and surgical techniques exponentially increased the number of transplants performed in the United States. The 1984 National Organ Transplant Act led to the formation of the United Network for Organ Sharing (UNOS), a nonprofit entity that provided a basis for standardizing organ procurement organizations (OPOs) throughout the United States, and the Organ Procurement and Transplantation Network (OPTN). Early national OPTN data showed that 10,794 deceased donor transplants were performed in 1988.[6] Six years later, these numbers increased by nearly 50% to 15,210 transplants. Moreover, the number of lung grafts from deceased donors increased annually from 33 to 708.[6] Intestinal transplantation also increased with the introduction of DBD donors. The first intestinal transplant was performed in 1990; by 1994, 96 patients with intestinal failure received intestinal transplants.[6] Concomitant advances in critical care reduced mortality in patients with end-stage organ disease, thereby resulting in increasing wait lists and decreased attrition. This is referred to as the growing "gap" between organ supply and transplantation demand. For example, despite the increased number of transplant centers and use of living donors in 1995, only 33% of registrants waiting for kidney transplant underwent transplantation.[6] However, the rate of transplantation decreased to 10% during 1998 to 2002.[7]

Moreover, the numbers of young and previously healthy DBD donors stagnated because of several statutory changes in areas of gun control, automobile safety (airbags, seatbelts, and lowering of legal blood alcohol limits), and helmet use. This decreased traumatic fatalities and changed the face of DBD organ donors.[8] The demographics of a typical DBD donor transitioned from a young healthy person who was rendered brain dead because of a devastating head trauma to an older person with medical problems who was rendered brain dead because of a neurovascular insult. This transformation eroded some benefit of using a DBD donor and prompted a search for other options.

Because the use of live donor organs has not kept pace with the growing deficit of organ donors, strategies such as regenerative medicine, mechanical devices, and xenotransplantation (use of grafts derived from animal donors) for treating end-organ diseases have been explored. However, these strategies are not ready to replace durable organ replacement. Further, the activity surrounding social and legislative approaches, including increased public awareness, donor registration activities, and interest in presumed consent (requiring individuals to opt out of organ donation to prevent consideration for donation at death), may have peaked because of cultural and philosophical objections. Therefore transplantation is again being performed using organs procured from DCD donors.

In the early 1990s, the Maastricht German transplant group rekindled interest in DCD organs[9] by showing equivalent long-term outcomes in recipients receiving both DCD and DBD renal transplants.[10,11] Similar findings from preliminary data have been made regarding DCD liver,[12] lung,[13,14] heart,[15] and pancreas transplants.[16] The University of Pittsburgh Medical Center (UPMC) introduced the nation's first institutional policy to permit and regulate DCD.[17] The need for such a policy arose when several patients/families were asked to participate in donation after previously electing withdrawal of life-sustaining treatment. This request fell outside the current parameters of donation policies and guidelines. The UPMC policy became the first concrete model to use cardiopulmonary criteria to determine death for organ procurement.[18] This policy highlighted a milestone in the evolution of transplantation. Since then, DCD has been adopted by many OPOs and hospitals nationwide. By December 2006 OPTN bylaws required that all OPTN members have a DCD donor protocol in effect.[18] Currently, The Joint Commission now requires that all accredited institutions develop and implement standardized DCD policies.[19]

After more than a decade of ongoing scrutiny surrounding ethical issues and outcome assessment, several key issues regarding DCD remain controversial in both the lay and medical communities. These include (1) criteria for identifying potential DCD donors, thus avoiding the financial and emotional burden of "failed" DCD; (2) optimization of DCD donor management; and (3) standardization of DCD procurement protocols to ensure a successful multidisciplinary effort with reproducible results. These issues are explored in this chapter after a brief discussion on the definition and current status of DCD.

IDENTIFICATION AND CATEGORIZATION OF POTENTIAL DONATION AFTER CARDIAC DEATH DONORS

Although seemingly straightforward, successful use of a DCD donor involves identification and classification of potential donors, appropriate diagnosis of death, and compliance with local policy of mandated wait time between pronouncement of death. The initial step in DCD organ transplantation is the recognition of potential donors with sufficient time to prepare and preserve optimal organ function before procurement. DCD is defined as organ procurement after the determination of death, which is characterized by an irreversible cessation of cardiopulmonary functions.[20] Critical care physicians and OPO staff must be familiar with diagnoses and clinical circumstances that qualify a patient as a potential DCD donor. Candidates are patients in whom withdrawal of futile life-sustaining treatment is being planned. Because optimal preservation of organ function is facilitated by coordinated perimortem care, graft quality can be compromised in situations where a patient's wishes regarding organ donation are unknown or where DCD is not offered as an option until late. Organ suitability may decline while attempts are being made to educate staff and families. Moreover, a treating physician must ensure that for patients on life support, withdrawal of life support must be independent of the decision to donate organs. At present, an OPO is responsible for coordinating surgical recovery and for preserving and transporting organs and tissues.[21] An OPO should be notified within 1 hour as soon as a patient's death is imminent from natural causes or withdrawal of life support.

The once-popular practice of managing potential DCD donors by placing vascular and/or intraperitoneal catheters to infuse cold organ preservation solution before the availability of consent for procurement[22] has now largely been abandoned. This practice stimulated contentious debate from both the medical and lay communities. Unlike several European countries, no US state adopted this presumed consent into law.

Management of DCD donors is facilitated by a classification scheme developed by the Maastricht group in 1994[23] and revised in 2000.[24] An international consensus conference was held in Paris in 2013 to clarify the Maastricht classification.[25] Maastricht categories define potential donors by circumstances under which cardiovascular death occurs. A distinction is made between donors whose cardiopulmonary failure is uncontrolled or emergent (categories 1, 2, and 4) and those whose death according to cardiopulmonary criteria occurs in a controlled manner after withdrawing futile life-sustaining support (category 3). Prior versions of the classification had a category 5, which is medically assisted cardiocirculatory death or euthanasia. This category has been mostly removed, except in Belgium and the Netherlands, where euthanasia is legal. The revised Maastricht classification is outlined in Table 160.1. Recent initiatives in the northeast United States involve training prehospital personnel to rapidly converse with preconsented victims of unsuccessful resuscitation after cardiopulmonary arrest (category 2) to determine potential DCD donors.[26] Category 3 donors constitute the majority of US and European DCD donors.[24] It is difficult to compare DCD outcomes according to Maastricht categories because few authors use this classification when reporting DCD results. Therefore, for uniformity, the remainder of this chapter focuses on category 3 donors.

TABLE 160.1 Maastricht Donation After Cardiac Death Categories

Category	Description	Condition
1	Cardiac arrest outside hospital and no resuscitation attempted	Uncontrolled
• 1A	• Out of hospital	
• 1B	• In-hospital	
2	Cardiac arrest followed by unsuccessful resuscitation either inside or outside hospital	Uncontrolled
• 2A	• Out of hospital	
• 2B	• In-hospital	
3	Cardiac arrest after planned withdrawal of life support	Controlled
4	Cardiac arrest in a brain-dead patient awaiting organ procurement	Uncontrolled Controlled

Adapted from Thuong M, Ruiz A, Evrard P, et al. (2016). New classification of donation after circulatory death donors definitions and terminology. *Transpl Int*. 2016;29(7):749–759.

Category 3 standardization is outlined in Fig. 160.1 (the UNOS Critical Pathway for DCD).[27] Typical patients may have the following characteristics: absence of or hyperactive respiratory drive, lack of adequate respiratory muscle strength, and severe hypoxemia or inadequate circulation in the absence of treatment with inotropic or vasopressor drugs. These patients are usually supported using ventilators or mechanical circulatory assistance such as ventricular-assist devices (VADs) or intraaortic balloon pumps. These patients may have also experienced severe neurologic insults but may not have met brain death criteria. Conscious patients usually develop degenerative neuromuscular diseases or end-stage cardiopulmonary diseases and are often ventilator or VAD dependent. These patients or their families may decide to discontinue life-sustaining support and request their organs to be donated.

The other category of potential DCD donors includes patients with impending cardiopulmonary death, the timing of which is either predictable based on patient-/family-requested withdrawal of care or unpredictable because of premature cardiac arrest before withdrawal. Given the lack of perfusion in DCD donors, prompt identification of death is needed to minimize organ ischemia, especially if uncontrolled cardiac arrest occurs. Organ procurement from DCD donors under uncontrolled conditions is technically feasible but is not physiologically ideal because of the inherent ischemic insult.

Various modalities have been proposed to help physicians identify death based on the absence of cardiac sounds, pulse, respiration, and response to stimuli. Confirmatory tests such as intraarterial monitoring or Doppler studies recommended by the Institute of Medicine (IOM)[28] can be used to expedite the confirmation of death; however, these tests are not widely accepted at present. A DCD work group assembled in 2006[20] indicated that electrocardiographic silence was not required for determining death but was sufficient to show the absence of circulation.

However, there is no agreement on the observation time required to rule out spontaneous unassisted cardiopulmonary resuscitation or autoresuscitation. The DCD work group[20] and the Society of Critical Care Medicine (SCCM)[29] recommend that potential donors be observed for

Critical Pathway for the Organ Donor

Collaborative Practice	Phase I Referral	Phase II Declaration of Brain Death and Consent	Phase III Donor Evaluation	Phase IV Donor Management	Phase V Recovery Phase
The following professionals may be involved to enhance the donation process. *Check all that apply.* ❍ Physician ❍ Critical care RN ❍ Organ Procurement Organization (OPO) ❍ OPO coordinator (OPC) ❍ MedicalExaminer (ME)/ Coroner ❍ Respiratory ❍ Laboratory ❍ Pharmacy ❍ Radiology ❍ Anesthesiology ❍ OR/Surgery staff ❍ Clergy ❍ Social worker	❍ Notify physician regarding OPO referral ❍ Contact OPO ref: Potential donor with severe brain insult ❍ OPC on site and begins evaluation Time _____ Date _____ ❍ Ht_____ Wt _____ as documented ❍ ABO as documented _____ ❍ Notify house supervisor/ charge nurse of presence of OPC on unit	❍ Brain death documented Time _____ Date _____ ❍ Pt accepted as potential donor ❍ MD notifies family of death ❍ Plan family approach with OPC ❍ Offer support services to family (clergy, etc) ❍ OPC/Hospital staff talks to family about donation ❍ Family accepts donation ❍ OPC obtains signed consent & medical/social history Time _____ Date _____ ❍ ME/Coroner notified ❍ ME/Coroner releases body for donation ❍ ***Family/ME/Coroner denies donation—stop pathway—initiate post-mortem protocol—support family.***	❍ Obtain pre/post transfusion blood for serology testing (HIV, hepatitis, VDRL, CMV) ❍ Obtain lymph nodes and/or blood for tissue typing ❍ Notify OR & anesthesiology of pending donation ❍ Notify house supervisor of pending donation ❍ Chest & abdominal circumference ❍ Lung measurements per CXR by OPC ❍ ***Cardiology consult as requested by OPC (see reverse side)*** ❍ ***Donor organs unsuitable for transplant—stop pathway—initiate post-mortem protocol—support family.***	❍ OPC writes new orders ❍ Organ placement ❍ OPC sets tentative OR time ❍ Insert arterial line/ 2 large-bore IVs ❍ Possibly insert CVP/Pulmonary Artery Catheter ❍ See reverse side	❍ Checklist for OR ❍ Supplies given to OR ❍ Prepare patient for transport to OR ❍ IVs ❍ Pumps ❍ O_2 ❍ Ambu ❍ Peep valve ❍ Transport to OR Date _____ Time _____ ❍ OR nurse ❍ reviews consent form ❍ reviews brain death documentation ❍ checks patient's ID band
Labs/Diagnostics		❍ Review previous lab results ❍ Review previous hemodynamics	❍ Blood chemistry ❍ CBC + diff ❍ UA ❍ C & S ❍ PT, PTT ❍ ABO ❍ A Subtype ❍ Liver function tests ❍ Blood culture X 2 / 15 minutes to 1 hour apart ❍ Sputum Gram stain & C & S ❍ Type & Cross Match _____# units PRBCs ❍ CXR ❍ ABGs ❍ EKG ❍ Echo ❍ Consider cardiac cath ❍ Consider bronchoscopy	❍ Determine need for additional lab testing ❍ CXR after line placement (if done) ❍ Serum electrolytes ❍ H & H after PRBC Rx ❍ PT, PTT ❍ BUN, serum creatinine after correcting fluid deficit ❍ Notify OPC for ___ PT >14___ PTT < 28 ___ Urine output ___ < 1 mL/Kg/hr ___ > 3 mL/Kg/hr ___ Hct < 30 / Hgb >10 ___ Na >150 mEq/L	❍ Labs drawn in OR as per surgeon or OPC request ❍ Communicate with pathology: Bx liver and/ or kidneys as indicated
Respiratory	❍ Pt on ventilator ❍ Suction q 2 hr ❍ Reposition q 2 hr →	❍ Prep for apnea testing: set FiO_2 @ 100% and anticipate need to decrease rate if PCO_2 < 45 mm Hg	❍ Maximize ventilator settings to achieve SaO_2 98 - 99% ❍ PEEP = 5cm O_2 challenge for lung placement FiO_2 @ 100%, PEEP @ 5 X 10 min ❍ ABGs as ordered ❍ VS q 1° →	❍ Notify OPC for ____ BP < 90 systolic ____ HR < 70 or > 120 ____ CVP < 4 or > 11 ____ PaO_2 < 90 or ____ SaO_2 < 95%	❍ Portable O_2 @ 100% FiO_2 for transport to OR ❍ Ambu bag and PEEP valve ❍ Move to OR →
Treatments/ Ongoing Care		❍ Use warming/cooling blanket to maintain temperature at 36.5° C - 37.5 °C ❍ NG to low intermittent suction	❍ Check NG placement & output ❍ Obtain actual Ht _____ & Wt _____ if not previously obtained	→	❍ Set OR temp as directed by OPC ❍ Post-mortem care at conclusion of case
Medications			❍ Medication as requested by OPC →	❍ Fluid resuscitation—consider crystolloids, colloids, blood products ❍ DC meds except pressors & antibiotics ❍ Broad-spectrum antibiotic if not previously ordered → ❍ Vasopressor support to maintain BP > 90 mm Hg systolic ❍ Electrolyte imbalance: consider K, Ca, PO_4, Mg replacement ❍ Hyperglycemia: consider insulin drip → ❍ Oliguria: consider diuretics ❍ Diabetes insipidus: consider antidiuretics ❍ Paralytic as indicated for spinal reflexes	❍ DC antidiuretics ❍ Diuretics as needed ❍ 350 U heparin/kg or as directed by surgeon
Optimal Outcomes	The potential donor is identified & a referral is made to the OPO.	The family is offered the option of donation & their decision is supported.	The donor is evaluated & found to be a suitable candidate for donation.	Optimal organ function is maintained.	All potentially suitable, consented organs are recovered for transplant.

Shaded areas indicate Organ Procurement Coordinator (OPC) Activities.

This Critical Pathway was developed under contract with the U.S. Department of Health and Human Services, Health Resources and Services Administration, Division of Transplantation.

Fig. 160.1 UNOS donation after cardiac death critical pathway. (From United Network for Organ Sharing. Critical pathway for donation after cardiac death. 2011. https://unos.org/wp-content/uploads/unos/Critical_Pathway_DCD_Donor.pdf.)

at least 2 minutes but not more than 5 minutes to ensure the absence of spontaneous circulation. These recommendations pertain to the period between the loss of circulation and declaration of death and not between the declaration of death and organ procurement. Fugate and colleagues identified variability among DCD protocols within the United States, particularly for defining the observation of potential donors to rule out autoresuscitation.[30] Although most centers followed the 2- to 5-minute observation period, there was variability in the definition of the period starting either before or after declaration of death, thus implying a total of 10 minutes. A prospective study by Dhanani and colleagues on the timing of determination of death in DCD donors showed that the longest period of arterial blood pressure[31] resumption after declaration of death was 89 seconds.[32] Moreover, only 4 of 41 patients examined showed return of blood pressure after cessation; however, this only lasted between 1 and 172 seconds. Given the variability and limited data on the duration of observation, specific guidelines for the precise minimal duration of irreversible circulation are warranted. At present, local protocols are used to stipulate the requirements of the determination of death and duration of observation time before organ procurement.

An important part of identifying potential DCD donors includes predicting the occurrence of rapid physiologic deterioration and death in less than 30–60 minutes (depending on the organ to be procured) after withdrawing life-sustaining treatment.[20] Failure of a potential donor to progress to cardiac death within the prescribed time disqualifies the donor because of the extent of organ warm ischemia time (WIT). Factors such as age, comorbidities, and preterminal vasopressor requirement can be used as predictors; however, no strict criteria have been universally adopted.[33] Lewis and colleagues from the University of Wisconsin developed a tool that uses clinical parameters to predict the suitability of DCD candidates.[34] This resulted in the development of guidelines to predict the likelihood of circulatory death within 2 hours after withdrawing life support. The authors proposed four readily obtainable clinical criteria: (1) requirement for vasopressors to support blood pressure, (2) absence of primary brain injury, (3) history of mechanical ventilation for ≥6 days, and (4) respiratory rate of less than 20 breaths/minute (in the absence of mechanical ventilation). They noted that presence of two or more of these indicators accurately predicted death within 60 minutes after withdrawing life-supporting treatments, with a sensitivity and specificity of 81% and 78%, respectively. Munshi and colleagues observed that controlled ventilation, oxygenation, vasopressor use, Glasgow Coma Scale/Score, and brainstem reflexes consistently predicted time to death in DCD donors.[35] Other novel predictors, such as physician opinion and simultaneous withdrawal of all support, are promising and warrant additional study. Robust analysis of retrospective DCD data would enable intensivists and OPO staff to more precisely identify potential DCD donors, help minimize the financial impact on hospitals and donors that "fail to progress," and prevent unnecessary stress and disappointment for families during a psychologically vulnerable time.

Familiarity with relative and absolute contraindications for DCD, some of which overlap those associated with DBD, is important. These include the multiple-operated abdomen, active sepsis, active or recent extracranial primary malignancy, and active infections such as hepatitis B or COVID-19. With regard to virologic status, OPOs are well versed in performing rapid serologic testing to rule out latent viral infections and should be involved as early as feasible to initiate testing.

CURRENT STATUS OF DONATION AFTER CARDIAC DEATH

Volume

UNOS disseminates US transplant-related data and has reported DCD statistics since 1994.[6] Data are available on the UNOS website (www.unos.org) and in UNOS annual reports. The annual number of DCD donors increased steadily from the mid-1990s to the early 21st century (Table 160.2). In all, 42 DCD recoveries were performed in 1993, which represented <1% of the total recoveries in that year. In 2012 DCD recoveries showed a 12-fold increase of 12% of all organ procurements. The rate of DCD donations in the United States continues to increase steadily from 2012, comprising nearly 20% of all donors in 2018.[6]

Outcomes

Despite ethical controversies, the real barrier to the widespread acceptance of DCD graft use is the poor outcome observed in early DCD experiences. Suboptimal organ function characterized by primary nonfunction, delayed graft function (DGF), and/or abbreviated graft survival have traditionally threatened the success of DCD organs because of the ischemic insult associated with cardiopulmonary arrest.[5] Although these observations were valid at that time, they accumulated during early experiences with transplantation and were thus inherently confounded by era bias.

On a cellular level, DBD and DCD organs show different injury profiles. DBD is characterized by a surge in serum catecholamines because of brain death, which induces hypotension and subsequent organ hypoperfusion. Animal studies have shown that hemodynamic instability of DBD organs may be further exacerbated by inflammatory cytokines such as interleukin (IL)-1, IL-6, and IL-8 that directly affect renal grafts.[36] In vivo studies evaluating DCD kidney grafts have shown less upregulation of inflammatory markers[37]; however, these studies showed that prolonged WIT induced alternative pathways of injury, such as those related to hypoxia. Rosenberger and colleagues found that hypoxia-inducible factors were correlated with renal allograft

TABLE 160.2 Number of Donations After Cardiac Death Organs as a Percentage of Total Deceased Donor Organs Procured by Year[6]

Year	# Deceased Donors	# DCD Donors	DCD as a Percentage of Total Donors
1993	4861	42	0.86
1995	5362	64	1.20
1997	5478	78	1.43
1999	5825	87	1.49

DCD, Donations after cardiac death.

ischemia time.[38] The increased incidence of DGF with DCD renal grafts was associated with a hypoxia-specific injury. The primary lesson from the early DCD era was that the metabolically active renal cortex, biliary epithelium, pulmonary alveoli, and pancreatic islets were sensitive to ischemia, with warm ischemic injury manifesting as acute tubular necrosis, ischemic-type biliary strictures (ITBSs), pulmonary fibrosis, and impaired beta-cell function, respectively. These manifestations were postulated to result in both poor initial graft function and long-term complications.[39–41] However, contemporary outcomes for each organ have improved.

Kidneys

Recent data have shown equivalent outcomes for DCD vs. DBD grafts. Early experience with DCD kidneys showed that graft survival in recipients of controlled DCD kidney grafts is equivalent or comparable to that of DBD.[42] Long-term outcomes of DCD kidneys also had similar graft outcomes to DBD kidneys.[42,43] A recent study by Gill and colleagues observed slightly improved allograft survival from DCD kidneys compared with DBD if warm ischemia time was less than 48 minutes.[44] Similarly, Butler and colleagues did not observe a difference in likelihood of graft loss for DCD vs. DBD allografts.[45] Although DCD kidneys have comparable graft survival rates to DBD kidneys, DCD kidneys have higher rates of DGF. Donor age of >60 years (compared with donors' age of <40 years)[46] and prolonged cold ischemia time (CIT; >24 vs. <12 hours) have been cited as factors affecting DCD graft function.[47]

Pancreas

Much of the available outcome data on the transplantation of DCD pancreatic grafts are derived from cases of simultaneous pancreas-kidney (SPK) transplants. These data show that graft and patient survival rates in recipients of DCD pancreatic grafts are similar to those in recipients of DBD pancreatic grafts.[16,48–50] Transplantation of DCD pancreas-alone grafts by using the same protocols as those used for DCD SPK grafts has provided favorable results, although there was a higher odds of graft thrombosis compared with DBD organs.[16] Fortunately, these findings were not observed in the setting of heparin administration. Donor selection (i.e., age) had a higher impact on graft outcomes vs. DCD status. More experience is needed to confirm these findings.

Liver

Early studies on recipients of DCD liver grafts have provided mixed results, with both graft and patient survival rates being significantly lower compared with those in recipients of DBD liver grafts.[51] In addition, these studies reported higher recipient morbidity and mortality rates.[52,53] Recent studies have observed equivalent patient and graft outcomes[54]; however, outcomes may be influenced by recipient and donor selection.[55] DCD liver grafts are more sensitive to WIT, thus requiring experienced personnel to complete a procurement limit of 25–30 minutes after circulatory arrest (compared with 60 minutes for renal grafts).

Lungs

Rapidly increasing use of DCD lung grafts, with improved outcomes, has encouraged clinicians to consider using these previously declined grafts.[56–58] Registry data from the Internal Society for Heart and Lung Transplantation (ISHLT) showed a 30-day mortality rate of <3% and 1-year survival rate of 89% that were not statistically different compared with those observed with DBD grafts.[59] Updated ISHLT registry data demonstrated excellent long-term survival among lung transplant recipients who received a DCD organ vs. DBD.[58] Additional data from the United Kingdom Steering Group for DCD lung transplants showed equivalent 1-year survival outcomes for DCD and DBD grafts ($P = .9$).[60]

Heart

Data describing DCD cardiac transplantation are scarce. The first DCD heart transplant was performed in 1967, but this technique was abandoned largely because of organ quality and use of DBD donors. With growing wait lists, the use of DCD heart organs is currently being revisited. Farr and colleagues estimated that in the United States, almost 60% of DCD donors had hearts that met criteria for transplantation but were being discarded.[61] The UK has one of the largest experiences with DCD heart donors. Messer and colleagues described the early experience in the UK of 50 DCD heart transplants, reporting a 100% 30-day survival rate in recipients who received DCD and matched DBD organs.[62] The same group also reported comparable 1-year survival (85% vs. 88%, $P = .98$) in DCD and DBD heart transplant recipients, respectively.[63] In the United States, the first DCD adult heart recipient was performed in 2020 as part of a multicenter clinical trial.[64] Australia,[65] Spain,[66] and Belgium[67] have also published case reports describing their early experience.

Innovation in DCD

Pulsatile perfusion pumps are being widely used to improve the quality of donor organs, especially in the context of DCD. The different types of perfusion pumps include normothermic machine perfusion (NMP), normothermic ex vivo machine perfusion, and hypothermic machine perfusion. The goal of perfusion pumps is to reduce ischemic injury to the allograft before implantation. Hypothermic, or cold perfusion pumps, are used with DCD kidney grafts. Lodhi and colleagues reported a decreased risk of DGF associated with pulsatile perfusion compared with cold storage in recipients of DCD kidney grafts.[68] A meta-analysis by Bathini and colleagues on the use of cold perfusion pumps suggested an improved trend of 1-year graft survival.[69] A recent Cochrane review also observed hypothermic machine perfusion as being superior to static cold storage.[70] NMP leverages the circulation of warm, oxygenated blood to reduce kidney injury. In an early study by Valero and colleagues, NMP was observed to considerably reduce primary graft non-function (PGNF) and DGF.[71] There are emerging data that pharmacologic intervention during NMP may provide organ-directed therapy against renal ischemia-reperfusion injury.[72]

To combat the ischemic-reperfusion injury to the liver allograft, machine perfusion is being studied as a way to optimize DCD liver allografts. Schlegel and colleagues observed less graft loss in DCD livers treated with hypothermic oxygenated perfusion compared with standard cold storage.[73] Dutkowski and colleagues observed similar findings, including decreased liver enzymes, biliary complications, and 1-year graft survival.[74] Although machine perfusion continues to be investigational, more centers are enrolling in trials investigating DCD liver pumps.

One evolving strategy for maximizing DCD graft function in lung donors is ex vivo or extracorporeal lung perfusion (EVLP). There are growing data on DCD lungs.[75] EVLP allows for the assessment of the graft after resolution of edema via the biochemical markers. The lung allograft is connected to a circuit, which allows oxygenation and perfusion into the procured organ.[76] Cypel and colleagues reported similar rates of primary graft dysfunction, 30-day mortality, and 1-year survival with EVLP compared with those with control lung grafts.[77,78] Long-term outcomes from the Toronto Lung Transplant Program demonstrated no difference in chronic lung allograft dysfunction and allograft survival up to 9 years posttransplant.[79]

The use of normothermic preservation (NRP) is being studied as a means to reduce ischemic injury at the time of procurement for DCD

heart organs. There are four techniques for DCD heart procurement: direct procurement and cold storage, direct procurement and ex situ heart perfusion, NRP and ex situ machine perfusion, and NRP with cold storage. Proponents for NRP with cold storage have demonstrated that this technique allows for a functional assessment of the heart before retrieval and transplantation.[80] This allows for a less stringent time constraint for organ implantation with no significant consequences to outcome.[81]

PRINCIPLES OF DONATION AFTER CARDIAC DEATH DONOR MANAGEMENT

Because every organ from a DCD donor sustains some degree of unavoidable ischemic damage, several protective strategies to increase graft viability have been proposed. Interventions can be considered in premortem or intraoperative phases.

Premortem

During the premortem phase, early placement of large-bore arterial and venous catheters for perfusing cold preservation solution in the donor can help minimize ischemia time.[21] This is followed by administration of systemic anticoagulants such as heparin (such as 30,000 units) along with recombinant tissue plasminogen activator (50 mg) to prevent vascular thrombosis during the low flow state.[82,83] The use of vasodilators such as phentolamine can prevent agonal vasospasm induced by hypoxia and surging catecholamine levels.[84] Lastly, ischemic preconditioning via brief ischemic challenges can trigger protective mechanisms that allow compensatory tissue physiology at the time of cardiac arrest, which is suggested to be mediated by heat shock proteins.[85,86]

The use of these premortem measures is limited because they are not a part of standard end-of-life care and because some authors suggest that these measures potentially hasten death.[87] The SCCM and IOM indicate that these medications and devices can be used as long as they do not cause any significant harm to the patient[29,88] and as long as family consent is obtained wherever practical. That they are of no direct benefit to the patient is countered by the fact that they improve the likelihood that the patient's wish of organ donation will ultimately be realized.

Operative

The conduct of operative procedure is dictated by the tenets mentioned earlier. The procurement team is not physically present at the time of death, and recovery of organs is accomplished expeditiously with careful coordination of numerous personnel, equipment, and resources. To do so, the operative team prepares and drapes the patient upon arrival to the operating room (OR). The team outlines the necessary instruments and maneuvers requested by OPO staff to ensure a seamless procedure. The team is then escorted from the OR and is notified by the OPO staff if the patient is pronounced within the prescribed time frame. After withdrawal of life support and before incision, the OPO staff will complete a monitoring form that details minute-by-minute hemodynamic and oxygenation data.

Once the patient has been pronounced, the operative team returns gowned and gloved and infuses cold perfusate through a cannula or a standard terminal aortic cannula placed during the premortem phase after rapidly accessing the abdomen. Next, rapid but careful in situ cold dissection is performed because the potential for vascular injury increases without the benefit of pulsatile flow to assist the identification of aberrant anatomy. Finally, organs are packaged and implanted in the recipient as soon as possible to mitigate the added negative impact of CIT.

The two most common contingencies that the team must be prepared for are unexpected cardiac arrest while awaiting withdrawal of life support and failure to progress after withdrawal. Appropriate intravenous access, a ventilator, and a special supply cart must be available and stocked with an oxygen tank, cardiac monitor, and adequate supply of sedatives and narcotics. The patient's wishes regarding resuscitation leading to donation must be determined from the patient or family as early as possible.

Approaches to DCD in European Union Countries

DCD donors are increasingly used in Europe, making up upwards of 40% of deceased donor organs in countries where DCD is accepted.[89] In Belgium, France, Spain, and the UK, DCD organs have nearly doubled between 2008 and 2016.[90] The highest DCD activity has been reported in the UK, Spain, Russia, the Netherlands, Belgium, and France. Table 160.3 summarizes the activity of European countries with DCD programs.

DCD policies vary among the countries who use DCD donors. The "no touch" period, or time between cessation of circulation and respiration and determination of death, ranges from 5 to 30 minutes. Italy has a 20-minute "no touch" period policy, which some attribute as the reason for slow DCD program development. The overall time for retrieval also ranges from 1 to 4 hours. In the UK Potential Donor Audit, successful retrieval after 4 hours without transplant compromise was reported.[91] This resulted in a 30% increase of available DCD organs. In contrast, Australia limits the withdrawal time to 90 minutes.

Both controlled and uncontrolled DCD are used in Europe, with better outcomes in the controlled cohort. Spain, France, Italy, the UK, the Netherlands, Belgium, Switzerland, Austria, and Russia have protocols for uncontrolled DCD. As mentioned previously, Belgium and the Netherlands consider DCD after euthanasia. In controlled DCD, practices regarding antemortem and postmortem interventions also vary. Types of antemortem interventions are cannulation of vessels and heparin before withdrawal of life support. Manara and colleagues argue that use of cannulas in this setting is justified based on the donor/recipient risk-benefit profile.[91] Not all countries request donor family/representative authorization for cannulation or other antemortem intervention.

The use of NRP to reduce warm ischemic injury has invigorated the use of DCD organs in both thoracic and abdominal transplant in Europe.[92,93] This is most evident in regions where longer "no touch" times have previously discouraged DCD programs. In Italy, NRP has allowed DCD donors to increase nearly threefold over the last 2 years.[94] NRP has also been used to improve posttransplant outcomes in DCD livers, kidneys, hearts, and lungs. Spain and the UK have demonstrated improved graft survival and decreased biliary complications in the recipient.[95] The UK has the largest series in the successful use of NRP for DCD heart transplantation.[62]

DETERMINATION OF DEATH: THE EXACT SCIENTIFIC CONCEPT?

The 1980 Uniform Determination of Death Act (UDDA) established that death is determined when there is irreversible cessation of circulatory and respiratory functions.[96] Most often, death is declared based on the cessation of cardiac and pulmonary functions; however, the required asystole is perhaps the single most contentious issue in the debate surrounding DCD.[83,97] Simply, the longer you wait, the more uncertainty there is about quality of the organs, and the shorter you wait, the more uncertainty there is on whether the person is dead.[98]

As the limits of life-sustaining practices are expanded, medical professionals are encouraged to maintain focus with reference to the

DCD, Donation after cardiac death; *cDCD,* controlled DCD; *uDCD,* uncontrolled DCD.
Data from Lomero M, Gardiner D, Coll E, et al. Donation after circulatory death today: An updated overview of the European landscape. *Transpl Int.* 2020;33(1):76–88.

UDDA. The term *irreversible* can be interpreted as a shifting paradigm or, as per Wilner and colleagues, a concept that is subject to serial displacement by advancing clinical science. Wilner and colleagues further highlighted that the question of death is thus reformulated to explore whether the morally relevant time of death is reached when death is certain despite the administration of all possible medical interventions or whether death is assured once all ethically permissible remedies have been used.[7] Lizza argued that because of medical and technologic advances, death cannot be solely understood on the basis of biologic factors.[99] As the debate continues regarding the time at which death is irreversible, it is logical that once a principled decision is made not to correct a loss of function, the loss becomes irreversible.[100]

No investigator has documented autoresuscitation after >89 seconds of combined circulatory and respiratory arrest.[32,101] However, the standard applied by most US hospitals ranges from a 2- to 5-minute asystolic interval (pulselessness, apnea, and unresponsiveness). This broad standard is addressed by American Society of Anesthesiologists' statement that the "2 to 5 minute time interval takes into consideration that there is no literature to support auto-resuscitation of the heart following two minutes of circulatory arrest, while observing an endpoint of five minutes minimizes warm ischemic damage to perfusable organs."[102] Because of the paucity of empiric evidence, IOM continues to encourage investigators to perform additional studies on this matter.

A final logistic issue in the determination of death is the management of patients who progress very slowly to be considered for donation. This occurs in approximately 5%–10% of potential donors.[33] Most programs disqualify donors from solid organ donation if cardiac activity is noted 60 minutes after withdrawal of life support because these donors do not meet the criteria for death and their organs would have sustained excessive warm ischemic injury. Therefore contingency plans should be devised so that these patients receive appropriate end-of-life care.

Vincent and colleagues summarized this into the following: identification of no reasonable hope or survival for the patient and recognizing their organs may benefit others.[103] Thus the terminal phase should be kept at a minimum. These authors believed that an open discussion is necessary to help facilitate such action, so that these bioethical principles remain relevant for both donors and recipients.

DCD IN THE ICU SETTING

Although use of DCD organs has gained acceptance within the international transplant community,[90] it is less common in the United States compared with other countries. Kidney transplantation from DCD donors is nearly half that in the United States compared with the UK, in which 40% of donors are DCD.[89] Although the primary barriers to DCD use include concern for inferior graft quality and outcomes compared with DBD, there are additional barriers from a systems standpoint that may also affect utilization rates. This section will review some of these barriers attributed to low use of DCD organs.

As the majority of DCD donors are in the intensive care unit (ICU) setting, healthcare professionals are on the front line for identification and referral for the DCD donation process. One of the barriers to DCD acceptance in the ICU setting may be psychological distress caused by the process of DCD. In a pilot study by Zellweger and colleagues, caregivers in the ICU expressed feelings of conflict and stress during the withdrawal decision and donation process.[104] Less than half did not feel completely supported during the withdrawal process. However, 94% of respondents believed that DCD was a viable means for increasing organ donation. This study highlights the importance of psychological support for caregivers in managing the demands of DCD.

In a qualitative study by Squires and colleagues, specific barriers to DCD organ donation among frontline ICU workers in Canada included the need for DCD education, a systematic and standardized screening process for DCD donors, and communication templates for family discussions about DCD.[105] In a subanalysis, intensivists reported three additional barriers to DCD donation: public perception that DCD donation is unethical, personal religious views, and lack of legislation mandating DCD. In an early study by Vincent and colleagues, ICU nurses felt inadequately informed, which may have been associated with their unease toward DCD donors.[106] These identified barriers are useful in creating educational tools and policy regarding public acceptance of DCD.

In the United States, there is variation in DCD practices among OPOs. A survey by Choubey and colleagues showed substantial differences in DCD procurement practices across OPOs, with many centers not conforming to current societal recommendations regarding DCD.[31] This has led to a push for creating best practice guidelines and standardizing DCD protocols across OPOs.[107] The intention is to optimize outcomes in an effort to increase use of these organs.

FINAL CONSIDERATIONS

Despite the success of DCD kidney, liver, lung, and pancreatic grafts, several unmet challenges and questions remain regarding the transplantation of these grafts. These fall within the realms of medical and ethical concerns. One area of likely future research concerns the real numeric advantage of using DCD grafts. Although the number of DCD grafts used in the United States has increased, there is still a significant gap between DCD and DBD grafts[6] (Fig. 160.2). It is unclear whether the identification of DCD donors will convert would-be DBD donors to DCD donors. In addition, it is unclear whether the decrease in the number of wait-list recipients will shift the cost and burden from wait-list complications to posttransplant complications, with longer lengths of stay, increased readmissions, increased complexity of diagnostic evaluations and immunosuppressive drug regimens, and increased rate of recipient morbidity and mortality. These questions can be better answered as more prospective data are collected.

Another issue of concern is in the evaluation of pediatric donors for DCD. This is a field in which there has been resistance, given ethical concerns with DCD, although the current professional consensus is that pediatric DCD donation can be practiced in an ethical manner similar to adults.[4] It had been estimated that use of DCD organs from pediatric donors may increase organ donation by 42% if these patients were evaluated for DCD.[108] This is another growing area that may see more traction in the near future.

Lastly, public perception also plays a role in the acceptance of DCD donation. An emphasis on patients' and families' wishes is paramount for the success of any DCD program. There is public concern that the likelihood of receiving aggressive life support will be compromised by consenting for organ donation.[109] These misperceptions are particularly damaging when the overriding goal of the transplant community is to maintain and build public support of maximizing organ donation. Such misconceptions can be remedied by larger educational programs and standardization of practices across OPOs.

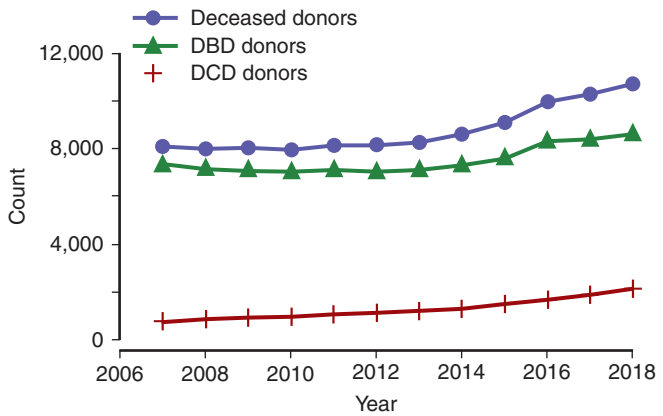

Fig. 160.2 The number of transplants in the United States performed using donation after brain death (*DBD*) and donation after cardiac death (*DCD*) grafts.[6] (From Israni AK, Zaun D, Hadley N, et al. OPTN/SRTR 2018 annual data report: Deceased organ donation. *Am J Transplant.* 2020;20[s1]:509–541.)

CONCLUSION

An Opportunity for Standardization

Appropriate management of DCD donors requires the integration of several fundamental principles for protecting the rights and interests of donors and for preventing the care of DCD organs from superseding the care of the dying patient. Debate arises in the paradox that can emerge from attempts to protect those interests while preserving the suitability of potential grafts. Hence, the role of an intensivist and/or palliative care physician (terminal care of patients and pronouncement of death) and managing OPO must be rigidly defined. The two factions must travel distinct paths to achieve their shared ultimate goal. Ozark and colleagues summarize this by stating "as a general rule two discussions—whether to forego life-sustaining therapy and whether to donate organs—must be made separately and on their own individual merit."[110] Ideally, discussion regarding the withdrawal of life-sustaining treatment should come first to prevent bias by the issue of transplantation.

The push for optimal palliative care is the hallmark of recent critical care management initiatives.[29,111,112] Dying patients who also wish to be DCD donors present a special challenge because they require care that is not only comparable to that given to all dying patients but also sensitive to the concerns described earlier. The SCCM has offered recommendations specific to DCD.[113] These guidelines are supplemented by individual transplant center reports and the UNOS Critical Pathway (see Fig. 160.1) and provide direction for intensivists caring for patients who wish to become DCD donors. It is vital that all healthcare providers involved in this process be comfortable with, and knowledgeable about, their specific role so that the patient's wishes can be respected.

Because pain relief is the single most important goal in palliative care in the final hours of life, there is a firm ethical, legal, and medical justification for using analgesics and anxiolytics in this scenario. As some patients require higher doses than others, medications should be given with the knowledge that unintended effects such as hypotension or respiratory depression may compromise organ viability. Therefore it is critical that the interest of the dying patient be represented by a completely different entity than that responsible for representing the interests of the donor. If any question arises regarding the practitioner's ability to maintain an objective position, consultation from hospitals' palliative care and ethics teams should be obtained.

In 2006 in the first criminal case against a transplant surgeon for the death of a donor, the defendant allegedly administered high doses of an analgesic and anxiolytic to a potential donor to hasten his death before organ procurement.[97] Although the surgeon was acquitted, the case highlighted the potential legal ramifications of recovery teams' involvement in the care of a dying patient. There is a consensus that "medications given to provide comfort are reasonable, even if they might hasten death," but "no medication whose purpose is to hasten

death should be given to the patient."[19] Failure to attend to potential DCD donors' comfort in contemporary practice is considered suboptimal end-of-life care and should be managed only by the physicians caring for the patient.

The need for data collection during DCD evaluation is to standardize definitions of death without variability among hospitals or OPOs. For instance, the definition of the start of WIT remains variable, with some advocating a threshold of systolic blood pressure of <80 mm Hg, a mean arterial pressure of 50 mm Hg, a systolic blood pressure of <50 mm Hg, or a decrease in arterial oxygen saturation to <80%.[114] The lack of a universal definition renders comparison of outcomes between centers and organs difficult. Although the asystolic interval to be observed remains a matter of institutional policy, it is prudent to recommend the development of standardized criteria. Highly sensitive maneuvers used to document the absence of circulation, such as intra-arterial pressure monitoring or echocardiography, may be helpful if a short asystolic interval is used.

There is debate regarding the optimal location of life-support withdrawal. Arguments for ICU withdrawal stem from proponents who prefer to provide families a normal setting to grieve, albeit briefly, at the bedside of their loved one. Others argue that effective and expedient progression to donor status allows for a more successful procurement and can only occur in the operating room. At present, there is no standard protocol, and each facility is responsible for dictating a protocol for their institution.

The widening gap between suitable donors and patients in need of transplant continues to be the only issue that keeps solid organ transplantation from achieving its complete potential in offering improved survival to patients with end-stage organ disease. Because current practices and outcomes have shifted the paradigm of binary cadaveric donor (DBD vs. DCD) to a spectrum of standard criteria to extended criteria, the ultimate impact of the estimated 22,000 DCD donors annually[115] on the actual number of organs available for transplantation will remain unclear until sufficient data are obtained under similar protocols. Although ethical questions regarding DCD persist, the process, which is increasingly practiced among transplant centers, accommodates the needs of dying patients and those of patients awaiting transplantation. Several organizations, including the SCCM,[113] American Society of Transplant Surgeons (ASTS),[83] UNOS, IOM,[88] and World Health Organization (WHO) have endorsed the concept and issued relevant guidelines. As experience grows, attitudes change, and outcomes improve, DCD may have a significant impact on the number of organs available for transplantation and thus the quality of life of patients awaiting and receiving cadaveric organs.

KEY POINTS

- Before DBD, procurement of organs from donors was referred to as non–heart-beating donation or DCD.
- DCD organs are subjected to a variable duration of WIT, which negatively affects early and late graft function.
- DCD organ procurements were reintroduced to expand the donor pool and reduce wait times and wait-list deaths.
- DCD kidney, liver, pancreas, lung, and heart grafts are increasingly used, and outcomes have now improved with experience.
- In the contemporary era of ICU care and donor shortages, DCD may be the only effective method of organ donation for terminally ill patients who do not meet DBD criteria but wish to donate organs.

ANNOTATED REFERENCES

Choi E-K, Fredland C, Zachodni C, et al. Brain death revisited: The case for a national standard. *J Law Med Ethics.* 2008;824–836.
This review provides a comprehensive evaluation of the current status of brain death determination and identifies the shortcomings of the brain death determination process, including the lack of standardized definitions. The authors present viable solutions to the most troubling problems with the current status of brain death determination.

Howard RJ, Missed opportunities: The Institute of Medicine Report: Organ donation: Opportunities for action. *Am J Transplant.* 2007;7(1):14–16.
This commentary summarizes the current landscape of deceased organ donation and highlights the author's opinion that the "Institute of Medicine Report, Organ Donation: Opportunities for Action" paper misses many opportunities for organ donation. The author identifies specific verbiage in the report that does not aim to change public perception regarding the opportunities for donation, especially with DCD, and provides an argument for incentives in donation.

Kotloff RM, Blosser S, Fulda GJ, et al., Management of the potential organ donor in the ICU: Society of Critical Care Medicine/American College of Chest Physicians/Association of Organ Procurement Organizations consensus statement. *Crit Care Med.* 2015;43(6):1291–1232.
Stemming from a multidisciplinary task force, 13 subcommittees from the Society of Critical Care Medicine, the American College of Chest Physicians, and the Association of Organ Procurement Organizations provided a consensus statement regarding death determination using neurologic criteria, donation after circulatory death determination, authorization process, general contraindications to donation, hemodynamic management, endocrine dysfunction and hormone replacement therapy, pediatric donor management, cardiac donation, lung donation, liver donation, kidney donation, small bowel donation, and pancreas donation. Their recommendations are summarized in this important document, which provides critical care practitioners with essential information and practical recommendations related to management of the potential organ donor, based on the available literature and expert consensus.

Siminoff LA, Alolod GP, Wilson-Genderson EYN, et al. A comparison of request process and outcomes in donation after cardiac death and donation after brain death: Results from a national study. *Am J Transplant.* 2017;17(5):1278–1285.
This qualitative study evaluated factors associated with family consent for DCD or DBD based on OPO communication. Sociodemographic characteristics and race were statistically associated with the likelihood of DCD or DBD donation; however, distinction between the two types of donation may not be notable to families. This paper proposes communication strategies to improve the public acceptance of DCD.

Solomon M. *Maximizing Benefits, Minimizing Harms: A National Research Agenda to Assess the Impact of Non-Heart-Beating Organ Donation, Non-Heart Beating Organ-Transplantation: Practice and Protocols. By the Committee on Non-Heart-Beating Transplantation II: The Scientific and Ethical Basis for Practice and Protocols, Division of Health Care Services, Institute of Medicine.* Washington, DC: National Academy Press; 2000.
This report summarizes the discussions and insight from an important organ donation workshop organized by the Department of Health and Human Services held in Washington, DC, on May 24–25, 1999. During the workshop, hospital and organ procurement members provided recommendations for the development and implementation of non–heart-beating-donor protocols. The committee developed these recommendations as steps towards an approach to non–heart-beating-donor organ donation and procurement consistent with underlying scientific and ethical guidelines, patient and family options and choices, and public trust in organ donation.

Conversations With Families of Critically Ill Patients

Margaret L. Isaac and J. Randall Curtis

Nearly a quarter of the deaths in the United States occur in the intensive care unit (ICU),[1] and the majority of patients who die in the ICU have had life-sustaining measures limited or withdrawn.[2,3] A decision to withhold or withdraw life support is often preceded by a family conference addressing the goals of care and treatment plans. Family conferences addressing the care of critically ill patients can be watershed events, clarifying the prognosis, defining goals of care, and providing support to family members and surrogate decision makers. Because most critically ill patients lack decisional capacity,[4] families and other surrogates are often centrally involved in medical decision making; in fact, 95% of the time, the decision to withhold or withdraw life support is made with the help of a surrogate.[5] Coping with a critically ill family member is challenging for surrogate decision makers, and many feel ill equipped to be involved in decisions on behalf of their loved ones. The care of most critically ill patients should involve explicit discussions with surrogate decision makers about goals of care and treatment plans. Skilled communication by an interdisciplinary ICU team is associated with improved outcomes for patients and family members.[6,7]

Leading an effective family conference requires specific teachable clinical skills, and our aim is to present an evidence-based approach to communication with families of critically ill patients. This chapter first provides an introduction to medical decision making, with a particular emphasis on shared decision making. We discuss a rationale for the importance of family conferences for all critically ill patients and address practical issues, including the considerations of physician reimbursement and billing. We then present an evidence-based approach for family conferences, highlighting competencies and protocols that have been developed to improve physician-family communication. Finally, we address issues of culture, language, and spirituality as they relate to the care of critically ill patients and their families.

MEDICAL DECISION MAKING

Models of Medical Decision Making

Physician-patient or physician-surrogate involvement in decision making regarding life-sustaining treatments can be conceptualized on a spectrum, with parentalism at one end, autonomous decision making at the other, and shared decision making in between. Shared decision making describes a relationship in which information is passed back and forth between physician and patient or surrogate, and both parties share opinions about treatment choices before a decision is jointly reached. There is a consensus among multiple critical care societies in Europe and North America that shared decision making should be the default model for physician-patient and physician-surrogate decisions regarding continuing, withholding, or withdrawing life support in the ICU setting.[8,9] Although most patients and family members prefer a shared decision-making approach,[10] there is considerable heterogeneity among patients and families with regard to their desired level of decision control. In the interest of patient- and family-centered care, it is imperative to individualize one's approach. One study showed that American physicians use the full spectrum of decision-making models but do not routinely assess the surrogates' desired level of involvement in medical decision making: rather than individualizing their approach to match surrogate preferences, individual physicians often have one approach that they use with all surrogates.[11]

Surrogate Decision Makers

The experience of family caregivers and surrogate decision makers is undeniably challenging. Surrogates struggle with emotional conflict and competing values, attempting to honor the wishes of their loved one, meet their own psychological needs, and promote harmony within the broader family.[12] Caregivers are often under tremendous stress and have higher rates of psychological symptoms than the general public.[13] Specifically, the prevalence of anxiety and depression symptoms in family members of critically ill patients is remarkably high,[6,14] and the symptoms of posttraumatic stress have been shown to be present in a majority of family members of critically ill patients.

In addition to the affective difficulty inherent in coping with a sick loved one, surrogate decision makers are asked to participate in complex medical decision making with which they may have very little prior experience. One study showed that 82% of family members who were asked to participate in medical decision making demonstrated symptoms of posttraumatic stress 90 days after patient discharge or death.[15] Communicating clearly about the goals of care and the withdrawal of life-sustaining interventions, in addition to exploring patients' and families' wishes, can contribute to family support and satisfaction.[16] Interprofessional family support interventions involving regular family conferences and emotional support in between meetings have been shown to improve surrogate ratings of communication quality and patient-centered care and a reduction in ICU length of stay.[17]

Though clinicians may be familiar and comfortable with the fast pace of ICUs, the tempo of medical decision making can pose a particular challenge to surrogate decision makers. One study showed decreased family satisfaction associated with a longer ICU stay, but also showed increased satisfaction when the process of withdrawing life-sustaining interventions was prolonged, suggesting family members may need time to adjust.[18] This indicates that families may benefit from time to come to terms with medical decisions and their personal feelings of loss.

Substituted Judgment and Best-Interest Standards

Substituted judgment is upheld as the highest standard for surrogate decision makers.[19,20] In the absence of an existing and specific healthcare directive, clinicians ask that surrogate decision makers imagine what the patient would want were they able to participate actively in decision making. Despite widespread endorsement of the substituted judgment standard by the medical community, ethical and practical concerns have been raised,[21] including the fact that patients frequently change their minds regarding medical decisions and preferences, making an estimation of a patient's wishes more difficult. This is especially true among patients who have not completed an advance directive.[22–24] That said, though many patients evolve and change with regard to treatment preferences, most studies evaluating preference stability have shown that a majority maintain consistency in their wishes regarding medical decisions,[25,26] particularly patients who have engaged in advance care planning and those who are seriously ill.[27]

Some authors have raised concerns about the accuracy with which surrogate decision makers can predict what choices patients would make.[21] A meta-analysis by Shalowitz and colleagues[28] found that surrogate decision makers were 68% accurate in their predictions regarding patient treatment preferences. In cases in which surrogates are inaccurate in substituted judgments, their stated preferences on behalf of the patient more closely represent their personal beliefs about end-of-life care.[29,30] A majority of seriously ill and older patients prefer to defer complex decision making to their physicians and family rather than having their advance directive strictly followed,[31] perhaps reflecting the understanding that it can be difficult to imagine what one's preferences might be given the many variables and perhaps unimaginable subjective experience of being critically ill.

Although there is significant variability in the amount of decisional leeway that patients would like their designated surrogates to have, the majority of patients prefer the implementation of a substituted judgment standard over the best-interest standard.[32] Furthermore, there is heterogeneity in the factors weighed by surrogates in medical decision making, including substituted judgment, but also factors such as shared experiences with the patient and the personal values and preferences of the surrogate decision maker.[33,34] Most of the time, clinicians do not explicitly frame the roles and responsibilities of surrogates.[35] Although this is a complex issue, substituted judgment should be a preferred standard for decision making when possible. By using phrases such as "Your role is to bring the voice of [the patient] into the room. What do you think they would say if they could be a part of this decision today?," the more abstract principles of substituted judgment can effectively frame a surrogate's responsibility.

Role of Advance Directives

The absence of an advance directive has been identified as a barrier to effective end-of-life care in the ICU setting,[36] although significant and valid concerns have been raised as to their usefulness and relevance.[37] Advance directives were not widespread in the past, with some prior studies describing rates of advance directive use between 5% and 11%.[38–40] More recent data suggest that about a third of patients in the United States have completed some type of advance directive.[41] Although advance directives have not consistently been shown to change the type of care provided to dying patients,[37,42] some studies have shown that the presence of an advance directive is associated with higher family assessment of the quality of the dying process for patients in the ICU,[43] greater use of hospice, improved communication,[44] an increased frequency of do not attempt to resuscitate (DNAR) orders, and better quality of life in the final week of life.[45] Advance directives can be helpful to surrogate decision makers, lessening the burden involved in attempting to employ accurate substituted judgment. Importantly, advance directives should be completed as part of a process of advance care planning that allows patients, their family members, and clinicians to explore the patient's values, goals, and preferences before documenting those preferences in an advance directive. Therefore although more progress needs to be made in the role advance directives play in guiding end-of-life care, there is value in advance care planning for those patients who ultimately require critical care.

FAMILY CONFERENCES IN THE ICU

Importance of Family Conferences for All Critically Ill Patients

Robust communication among clinicians (physicians, nurses, and other clinicians) and families of all critically ill patients is important, not only for families of patients who are imminently dying. Family members who felt that communication in the ICU was inadequate were at higher risk for posttraumatic stress disorder,[15] even those with loved ones who survived their ICU stay. Furthermore, families of patients who survived their ICU stay are actually more likely to be dissatisfied with their ICU care with respect to domains such as inclusion in decision making, communication, emotional support, and respect and compassion shown to family, in addition to the consideration of family needs.[46]

Practical and Logistic Considerations

Practical and logistic issues can shape the experience of surrogate decision makers in a critical care setting. Even physical space can have an important effect: a French study[47] found that family members of patients in private ICU rooms had a lower incidence of anxiety and depression symptoms compared with families of patients in multibed rooms. The same group also found that the absence of a dedicated room for family conferences was associated with increased anxiety symptoms among family members of critically ill patients.[14] Accessibility of physicians and the access to information also correlate with family satisfaction; inaccessibility has been correlated with conflicts related to prognosis,[48] suggesting that surrogate decision makers are more satisfied when clinicians are accessible, clear, and comprehensive in their communication.

Evidence-Based Approach to Communication During Family Conferences

Patients and families are consistent in defining high-quality care in the ICU: timely, clear, and compassionate communication by clinicians; clinical decision making focused on patients' values; patient care maintaining comfort and dignity; and family care with open access and proximity to patients, interdisciplinary support in the ICU, and bereavement care for families of patients who die.[49]

Family conferences in the ICU setting are challenging, both for families and clinicians, but it is important to remember that the optimal skills to facilitate these sessions are both teachable and can be rooted in evidence. Using these skills has the potential to improve

outcomes for both patients and family members. Studies suggest that planning conferences early in the ICU stay is beneficial[50]: family conferences held within the first 72 hours of ICU stay are associated with both decreased use of critical care resources among patients who die[51] and higher family assessments of the quality of death and dying.[43] Consistent communication across the medical team is also important; having a "preconference" before family meetings can ensure that families are given a consistent message.[52] As discussed earlier, having a dedicated room for family conferences is also associated with decreased anxiety among family members.[14]

It should come as no surprise that empathic communication is one of the cornerstones of leading an effective family conference. Focusing on listening to concerns of family members is particularly important. Most physicians spend a majority of time talking rather than listening when meeting with patients and families.[53] Families have been shown to have higher levels of satisfaction and lower levels of perceived conflict with clinicians who speak less and listen more.[6,53] Family satisfaction is associated with the use of empathic statements, although this is a commonly missed opportunity: one study found that one-third of physicians in the ICU missed an opportunity to use empathic statements in family meetings.[54] Table 161.1 summarizes categories and examples of empathic statements that can be used by clinicians in family conferences. The "Ask-Tell-Ask" approach advocated by Back and colleagues[55] (Table 161.2) is a helpful tool to assess baseline knowledge and evaluate the understanding of the information provided.

Assurances to families and surrogates that patients will not be abandoned before death and that efforts will be made to provide comfort and minimize suffering and statements of explicit support for medical decisions to either continue or withdraw life-sustaining interventions are associated with higher levels of family satisfaction.[56] The use of the VALUE mnemonic (value, acknowledge, listen, understand, and elicit, summarized in Table 161.3) to enhance clinician-family communication has been shown to improve mental health outcomes, including symptoms of depression, posttraumatic stress disorder, and anxiety in family members.[6] Interestingly, family meetings using this tool were somewhat longer than the usual care meetings, and the percentage of family speech was also higher. In addition, patient-centered interventions such as the Three Wishes Project (3WP), which allow patients and families to express

TABLE 161.1 Empathic Communication in Family Conferences

Category	Sample Statements
Empathy about surrogate decision making	*Withholding or Withdrawing Life Support*: "This is really hard. There's not a right answer to this situation."
	Determining Patient's Wishes: "It is very difficult to be in a position like this where you have to put your own personal feelings aside and try to advocate for what you think he would want."
	Fear of Making a Mistake: "Many families in your situation worry they will look back and think, was there something we missed or something that could've been done earlier? In her case, I do not think that would be true."
Empathy about critical illness in a loved one	*Making Sense of the Disease Process*: "I know it is very important to try and understand as best as possible what happened to see if we can make sense of this."
	Difficulty in Understanding Medical Information: "This is a lot of information to take in. Please feel free to ask any questions you might have."
	Physical Changes: "It must be really hard to see your loved one like this."
	Receiving Bad News: "It is hard to understand why something bad just can happen to anyone, and when it is someone you love and care for, that is even more difficult."
	Uncertainty: "We pretty much have to take it day by day, and I know that this uncertainty makes things even more challenging."
Empathy about confronting death in a loved one	*Helplessness*: "It must be so difficult facing this loss and feeling like there is nothing you can do to change things."
	Dying: "Letting go is so difficult, but I believe you are doing her a great service by honoring her wishes at this time."

TABLE 161.2 "Ask, Tell, Ask" Approach to Discussing Difficult Communication Tasks

Step	Function	Sample Phrases
Ask	Ask the patient/patient surrogate to describe his or her understanding of the medical disease and prognosis.	"It would help me to know what your other doctors have told you about your father's illness."
Tell	Explain to the patient/patient surrogate, using simple, straightforward language, what you understand about the medical disease and prognosis.	"Unfortunately, it looks like your father's illness is getting worse. With a disease as serious as his, 9 out of 10 patients will die within 1 month, and 1 out of 10 will be alive at 1 month. If your father survives this illness, it is very likely he will have significant disability and will likely be unable to live independently."
Ask	Assess the patient's/patient surrogate's understanding.	"I want to make sure that I explained things clearly. Can you tell me, in your own words, what I just told you about your father's illness?"

Box 161.1 Protocol for Conducting a Family Conference With Key Steps in Bold

Before the Conference

- Plan the specifics of the location and setting: a quiet, private place.
- **PRE-MEET:** Conduct a "preconference" with all interdisciplinary team members to review the conference, ensuring that team members share a similar understanding of medical details, the prognosis, the treatment options, and the goals of the discussion.

During the Conference

- **INTRODUCE**: Review names and roles of the team members and the family.
- **ASSESS:** Ask the family for their understanding of the current situation to gauge their level of understanding.
- **UPDATE:** Provide an update to the family and ask the family about the patient's values and goals.
- Discuss the prognosis frankly in a way that is meaningful to the family.
- Review the principle of substituted judgment: "What would the patient want?"
- Make a recommendation about treatment.
- **EMPATHIZE:** Provide empathy and support the family's decision.
- Acknowledge strong emotions, and use reflection to encourage patients or families to talk about these emotions.
- **PRIORITIZE**: Help the family prioritize important issues and potentially conflicting values or goals.
- **ALIGN**: Explicitly align the clinician's, patient's, and family's goals wherever possible.

Summarizing the Conference

- Summarize the discussion and plans.
- Ask what questions the family might have.
- Ensure a basic follow-up plan, and make sure the family knows how to reach you for questions.
- Document the discussion in the medical record.

Adapted from Whitaker K, Kross EK, Hough CL, et al. A procedural approach to teaching residents to conduct ICU family conferences. *J Palliat Med.* 2016;19:1106–1109 and Curtis JR, Patrick DL, Shannon SE, et al. The family conference as a focus to improve communication about end-of-life care in the ICU: Opportunities for improvement. *Crit Care Med.* 2001;29:N26–N33.

individual wishes in the ICU at the end of life (including examples such as dressing in one's own clothing and postmortem tributes), have been found to be valuable to families, staff, and providers.[57]

Box 161.1 provides a summary of an approach to conducting and teaching family conferences adapted from prior publications.[58,59] This can be a helpful guide, although it should be adapted to the individual goals and circumstances of each family conference.

Discussing Prognosis

Despite the ethical responsibility to inform patients about prognosis, many clinicians are uncomfortable doing so and identify this task as one of the most difficult parts of their job.[60] In one study,[61] clinicians did not discuss the survival prognosis in over one-third of family conferences in which the attending physician anticipated there would be a discussion of withholding or withdrawing life-sustaining interventions or discussing serious news. Because patients with a poor prognosis are more likely to decline life-sustaining treatments,[62,63] discussion of the prognosis is critically important. Interestingly, surrogates rely upon far more than just the prognostic information provided to them by physicians,[34] although most try to balance their assessment of the patient with the information provided by physicians in understanding prognosis. Surrogates also report that they understand and appreciate explanations of the uncertainty involved in prognostication,[64] although evidence suggests that the surrogates' understanding of prognostic information is low, even when they rate the quality of prognostic communication highly.[65]

Experts recommend framing prognosis numerically rather than using nonspecific terms (e.g., "1 in every 10 patients" rather than "uncommon" or "low risk"), framing prognosis both positively and negatively, and using consistent denominators when presenting rates of risk (e.g., "9 in every 10 patients with illnesses as severe as your father's will die before leaving the hospital" and "1 in every 10 patients with illnesses as severe as your father's will survive to leave the hospital").[66] In addition, family members of critically ill patients report that they prefer numeric estimates.[67] Despite these recommendations and preferences of family members, a minority of critical care physicians use numeric estimates in discussing prognosis[68] and/or verify whether or not surrogate decision makers have understood the information provided (e.g., such as using a "teach-back" method). Using an empathetic approach with statements such as "I hope" and "I worry" can also be an effective method of building trust and connection and capturing the uncertainty in estimating prognosis.[69]

Discussing Resuscitation

Most patients and their families have little personal experience with the critical care setting or with cardiopulmonary resuscitation (CPR). Knowledge of the probability of survival from CPR affects patients' choices about code status.[63] Unfortunately, many people base their assumptions on the likelihood of surviving CPR on information from the lay media, such as medical dramas on television, which dramatically overrepresent favorable resuscitation outcomes.[70,71] Consensus guidelines have highlighted specific recommendations in discussing resuscitation with patients,[72] some of which may also help guide discussions with surrogate decision makers. The authors recommend that, among other events, admission to a critical care unit should serve as a trigger for a discussion of resuscitation preferences.

Another important recommendation is that the discussion be framed to review the overall goals of care rather than merely focusing on code status. It is also important to make a distinction between life-sustaining interventions and CPR, describe cardiac arrest and care plan options (including palliative care) in detail, and offer quantitative information about the patient's likelihood of surviving to hospital discharge. Discussing longer-term survival and functional status after resuscitation, offering a code status recommendation, and focusing on trust and rapport building are also important. In summary, CPR in the critical care setting is best addressed in the context of the greater goals of care, including a candid discussion of the likelihood of CPR survival and care alternatives, such as palliative and symptom-focused care.

Billing and Reimbursement

According to the guidelines from the Center for Medicare & Medicaid Services (CMS), US physicians are permitted to bill for time spent

consulting with surrogate decision makers either in person or by telephone. Furthermore, critical care clinicians are permitted to bill for critical care time for these discussions, provided that the patient is unable to participate in giving a history and/or making treatment decisions and the discussion is necessary for determining a treatment decision. Documentation for these conversations must include:

- The medically necessary treatment decisions for which the discussion was needed
- That the patient is unable to participate in giving history and/or making treatment decisions
- The necessity of the discussion and a summary of the medical details to support this necessity[73]

Palliative care clinicians in the United States are recognized as an independent medical subspecialty by Medicare and, as such, can bill for their consultative services. Previously, prolonged service codes, frequently used in palliative care billing, required that additional time is spent "face-to-face" with the patient, meaning that time spent in meetings outside of the patient's room between clinicians and surrogate decision makers was not compensated. This changed in 2009, such that clinicians can now bill for prolonged service time spent charting, reviewing records, coordinating care with other clinicians, and importantly, meeting with surrogate decision makers outside of the patient's room.[74] Claims have been denied for palliative care specialists who are credentialed in the same specialty as the primary team physician, although these denials have been successfully appealed.[74] Of course, specifics regarding the billing for both critical care and palliative care specialists change over time, so clinicians will be well served to familiarize themselves with the most updated billing guidelines.

Role of the Interdisciplinary Team

The complexity of critical care requires the involvement of a multidisciplinary team, and interprofessional shared decision making has emerged as a standard for high-quality critical care.[75] However, conflicts between nurses and physicians are common,[76] particularly in the setting of end-of-life care, and are a source of significant work stress and burnout.[77–79] Enhanced nurse-physician communication and collaboration have been associated with higher patient satisfaction[80,81] and a lower incidence of anxiety and depression symptoms among families of critically ill patients,[14] in addition to lower rates of burnout among nurses and physicians.[77,78] Improving communication among the multiple clinicians within the ICU (i.e., physicians, nurses, respiratory therapists, social workers, and spiritual care providers) would undoubtedly improve not only workplace relationships and stress but also patient care and integrated communication with families and surrogate decision makers.[82]

Palliative care specialists are an increasingly common hospital resource. Involvement of a multidisciplinary palliative care team is associated with increased patient satisfaction and decreased rates of ICU admission after hospital discharge and significant cost savings.[83]

Role of Protocols and the Importance of Individualization

Many of the communication strategies that have shown efficacy were implemented using interventions designed with specific protocols. The tenets of patient-centered care affirm the importance of tailoring communication and interactions to specific patients and their families, rather than resorting to a scripted dialogue. However, given the many missed opportunities in the current level of communication with patients and surrogate decision makers in the critical care setting,[84] it is reasonable to look to communication approaches that have been rigorously developed and studied. Specific guidelines on communication techniques and strategies are intended as a starting point, and clinicians are encouraged to integrate these with their personal approach and authentic voice and to adapt their approach to the individual patient or family.

Culture, Language, and Spirituality

Cultural considerations are fundamental in talking with families and surrogate decision makers from diverse backgrounds. Using language interpreters and cultural mediators is critical in facilitating communication with patients and families who speak different primary languages than clinicians. Ideally, the role of an interpreter transcends mere strict literal translation. Interpreters with additional training can assume the role of a cultural mediator, helping to interpret content bidirectionally, bearing in mind that patients and families frequently participate in many cultures simultaneously, with intersectionality mediating how these cultures manifest in beliefs and actions. Although cultural competence be helpful in designing structures and systems that can best help a diverse group of patients, cultural humility—a stance of openness and curiosity about an individual patient—protects against generalizations, biases, and assumptions and promotes patient-centered care.

Even with the most skilled cultural mediators, there are challenges inherent when language discordance exists. Interpretation of family conferences is a difficult process that can include critical errors, and it is difficult to provide emotional support for families in this circumstance.[85,86] Implementing best practices (e.g., a preparatory meeting with interpreters before the clinical encounter, speaking slowly, confirming the patient's or family's understanding, and debriefing with the interpreter after the clinical encounter) can facilitate better communication and decrease the potential for misunderstandings.[87,88]

Spiritual Issues

Spiritual needs figure prominently for many critically ill patients and their families, often explicitly or tacitly shaping decision making about medical care,[89] although these considerations are rarely discussed in family conferences.[90] Increased family satisfaction has been associated with the assessment of spiritual needs.[16] Exploring underlying spiritual beliefs and values can be extremely important in supporting families and in finding common ground on medical decisions through shared decision making. In addressing spiritual concerns, clinicians should use caution in not stepping beyond one's role as a clinician or trying to resolve existential and spiritual questions[89]; rather, the focus should be on assessing potential spiritual needs and then making referrals for spiritual care providers.[91]

CONCLUSION

Conferences with families of critically ill patients are crucial and are one of the more formidable clinical challenges faced by critical care clinicians. Many approaches to medical decision making exist, and there is significant variability among patients and patient surrogates regarding their preferred role. There is a consensus that shared decision making should be the preferred approach of clinicians, although care must be taken to assess the family's desired role in medical decision making and individualize one's approach accordingly. Having a critically ill family member and functioning as a surrogate decision maker are incredibly challenging for families, but stress associated with this situation can be mitigated through integrated, thoughtful, and empathic communication by physicians and other members of the critical care team.

KEY POINTS

- The quality of family conferences can have an important impact on outcomes for patients and families.
- Shared decision making is an optimal default strategy, though some patients and families may prefer more or less decision control.
- Meeting frequently with patients and family members throughout an ICU stay is associated with higher satisfaction.
- Framing the role of surrogate decision makers, specifically related to the substituted judgment standard, is important.
- Allowing families to speak more, using empathic statements, and providing expressions of nonabandonment are associated with higher family satisfaction after family conferences.
- Using other members of the healthcare team, including translators and spiritual care providers, can help bridge gaps in understanding during and after critical illness.

Resource Allocation in the Intensive Care Unit

Gordon D. Rubenfeld

INTRODUCTION

Two truisms of economics are that the supply of goods and services is finite and that supply is never sufficient to meet all demands. The tension between supply and demand for food, water, energy, education, and other goods and services creates economies. All societies must determine how goods and services will be allocated to individuals. Although the term *rationing* connotes a specific process of allocation during circumstances of severe resource limitation (for example, rationing coupons to allocate gasoline during World War II), rationing is just a synonym—an emotionally laden synonym—for resource allocation. In this chapter the terms are used interchangeably. Although rarely recognized as such, rationing decisions occur every day in all aspects of medicine.[1] Critical care services are uniquely poised to raise difficult questions about allocation. First, this high-technology, labor-intensive area of health care is a major driver of rising healthcare costs.[2] Second, the evidence for many intensive care services, including the evidence for admission to the intensive care unit (ICU) itself, is limited. Finally, the decision not to provide intensive care services compared with, for example, the decision not to get magnetic resonance imaging (MRI) for low back pain or not to provide antibiotics for an apparently viral respiratory infection is a rationing decision with an identifiable life in the balance.

Market-based economies allocate many resources on the basis of ability to pay, but other strategies exist (Table 162.1).[1] In developed nations, some goods and services—for example, health care and education—are treated differently than luxury goods and are allocated by society using criteria other than an individual's purchasing ability. Because medical resources are finite, it is impossible to provide every effective treatment in every case where it might offer benefit and the patient desires the care. That does not mean that clinicians are aware on a daily basis of the burden of this reality. Sometimes the decisions are explicit with immediate repercussions—for example, the selection of one patient to receive a heart transplant when several might benefit from the sole available organ—or the decision to admit one patient to the last ICU bed when several patients are critically ill who would benefit from ICU admission. More frequently, the decisions are subtle and occur even when the supply of the therapy is not absolutely limited (e.g., the decisions to use cheaper antibiotics, sedative medication, imaging modalities, or nursing ratios) when more expensive options might be beneficial or, more frequently, the decision to use an ICU bed in cases of small benefit (e,g., observation of low-risk surgical patients for complications). Finally, allocation decisions can be completely implicit and almost hidden because they occur at a system level. For example, the decision to build an ambulatory care clinic instead of adding ICU beds is an allocation decision with profound implications for the delivery of critical care services that is nearly hidden to the individual clinician.

Although common and necessary, allocation decisions are stigmatized in medicine. Allocation decisions bring two major ethical principles into conflict. The principle of beneficence guides clinicians to act solely in their patient's best interests, whereas the principle of justice directs clinicians to act fairly.[2] This conflict may explain why euphemisms are frequently used to describe decisions that are essentially decisions to ration resources. For example, "triage," "optimization," "prioritization," "cost-effective," "waste," and "basic health care" all indicate some form of allocation decision.[3–5] The purpose of this chapter is to explore these decisions in their many guises as they occur in critical care and to offer some guidance to the clinician for constructing processes for allocating resources in their ICU.

ALLOCATION VERSUS EVIDENCE-BASED MEDICINE

Decisions based solely on the evidence of efficacy of medical care are *not* rationing decisions. There is no medical obligation to provide and no societal obligation to pay for care that is harmful or ineffective. In fact, clinicians use special terms to describe interventions that fall into these categories, including "futile," "not standard of care," "medically inappropriate," "wasteful," or "experimental."[3,4] For example, an intensivist who decides not to transfuse a critically ill patient with blood with a hemoglobin of 73 g/L is *not* rationing blood even though blood is an expensive and limited resource because there is evidence that this transfusion in many critically ill patients is of no benefit and may be harmful.[5] The decision not to use human growth hormone, an expensive medication, in chronically critically ill patients is not a rationing decision because this treatment has not been shown to be effective and may be harmful.[6]

Unfortunately, the assessments of benefit and harm are not as straightforward as the terms would suggest, and the line between effective, ineffective, and experimental often lies in the eyes of the individual clinician. Decision science has taught us that medical decision making is a complex process that frequently obscures the true rationale of the choice.[7] In fact, judgments allegedly based solely on objective evidence of safety and benefit often incorporate a variety of subjective values and biases.[8] These may include the value the clinician assigns to being wrong; the value assigned to trying to "rescue" a patient in imminent danger of death; the clinician's tolerance for uncertainty; the impact of the decision on the clinician's finances; biases about the patient's race, gender, functional status, or age; and the cost or availability of the resource.[9] These transitions from statements that summarize the evidence of benefit to recommendations that incorporate cost and other values are often very subtle. This is particularly problematic for many treatments in critical care where there is an absence of evidence of efficacy, no clear harm, and, for individual clinicians, strong beliefs about efficacy. For example, the authors of a recent systematic review of colloid resuscitation in critical care conclude that "there is no evidence from randomized controlled trials that resuscitation with colloids reduces the risk of death compared with crystalloids in patients with trauma, burns and following surgery."[10] This is a statement of their summary of evidence of efficacy. Like many treatments in critical

TABLE 162.1 Strategies for Allocating Resources

Principle	Definition
Autocracy	To each according to the will of one
Democracy	To each according to the will of the majority
Equality	To each according to an equal share
Lottery	To each according to an equal chance
Capitalism	To each according to their ability to buy
Personal worth	To each according to their contribution to the community
Utilitarianism	To each so that the utility of the community is maximized

care, the evidence neither supports nor completely refutes the use of colloids as resuscitation fluids in the critically ill. However, the authors conclude, "As colloids are not associated with an improvement in survival, and as they are more expensive than crystalloids, it is hard to see how their continued use in these patient types can be justified outside the context of randomized controlled trials." Although the first statement may be a fair summary of the evidence, the recommendation against using colloids in the second sentence is fundamentally a rationing or allocation assessment based on cost-effectiveness. It incorporates an implicit strategy that only recommends treatments that have demonstrated benefit related to their cost. One might conclude from the authors' review that colloid resuscitation is experimental or that its benefit is likely to be small; however, the reasoning for recommending against its use is based on the cost of the treatment. Presumably, if colloid fluids were the same price as crystalloids, the authors might reach different conclusions even though the cost does not change the evidence of efficacy.

The preceding example shows how assessments of cost can creep into evidence-based recommendations for therapy even without formally discussing allocation. Because clinicians and payers may be reluctant to admit that they are incorporating cost or availability into the rationale for a decision, they may find decisions of futility or appropriateness less ethically problematic than rationing. In fact, these judgments may implicitly contain assessments of cost by incorporating cost into the definition. Because scientific studies can never statistically *prove* a therapy is ineffective, when is there sufficient evidence to move a treatment or diagnostic device from experimental care to standard care? Does this distinction matter if the person is paying for their own care or if it is paid for by a third party? Given the statistical challenges of proving inefficacy, when is there sufficient evidence, in the absence of demonstrated harm, that a treatment is ineffective as opposed to not yet of proven efficacy? These decisions are frequently made by consensus bodies using subjective or poorly characterized criteria but usually avoiding an explicit assessment of cost. In 1989 the Oregon Health Plan attempted to extend healthcare benefits to more people by creating a prioritized list of health benefits—essentially rationing care. To develop this list, the Oregon Health Services Commission was convened.[11] It ranked treatments by their effectiveness from therapy for acute head injury with loss of consciousness (#1), anal fissure (#579), and hepatorenal syndrome (#743, near the bottom) and funded them in order based on available resources. Interestingly, although treatments were selected based on funding and the overall process was essentially a rationing plan based on cost-effectiveness, the rank list itself was not particularly correlated with formal cost-effectiveness assessment, indicating that other, potentially subjective, factors took precedence.[12]

At the bedside, clinicians also tend to subtly incorporate cost into their assessment of evidence-based recommendations. The amount of evidence required to convince clinicians to adopt treatments that are risky or expensive will always be more than treatments that are safe and cheap. For example, consider the decision to elevate the head of the bed of mechanically ventilated patients to prevent ventilator-associated pneumonia. Although the evidence supporting its effect on reducing mortality or ICU length of stay is limited, it is inexpensive and safe and has become part of routine ICU care. Conversely, kinetic beds, topical prophylactic antibiotics, and special endotracheal tubes, which are more expensive and may raise safety issues, have had considerably less uptake despite evidence supporting their use.[13]

Judgments about the evidence-based efficacy of treatments that are supposed to be independent of cost are further complicated by the motivation of the decision maker. It would be difficult for an insurance company that is assessing whether a specific therapy is experimental or standard of care to be unbiased when its decisions affect its profits.[14] Alternatively, surgeons who developed a procedure may be committed to its benefits in a way that compromises an objective evaluation. The complexity of the assessment of efficacy and costs points to the importance of making allocation decisions as objective, explicit, and public as possible.

ALLOCATION STRATEGIES

Given that an intervention is effective, clinicians will face decisions to allocate resources at the bedside. These decisions are usually separated into macro-allocation decisions (involving groups of people and usually made at a managerial or health policy level) and micro-allocation decisions (made at the bedside and involving identifiable specific cases). A hospital's decision not to hire additional ICU nurses is a macro-allocation decision. A nurse manager's decision to allocate a specific patient to share a nurse in the ICU rather than to receive 1:1 nursing is a micro-allocation decision. This chapter is primarily concerned with bedside allocation, or micro-allocation decisions, which clinicians make on a routine basis. There is an important interaction between micro- and macro-allocation decisions because macro-allocation decisions ultimately affect individuals, and macro-allocation regulations are an effective strategy for implementing allocation (Table 162.2).

There are a number of approaches to allocating resources (see Table 162.1). Although these are all feasible, they are not all equally ethical. The principles of equality, fairness, justice, and due process make some strategies less acceptable. The principle of utilitarianism directs resource allocation to maximize the "utility," or benefit, of the most people for any given amount of resources. To the extent that "utility" can be measured by measuring patient outcomes like health-related quality of life and to the extent that we can estimate the effects of medical treatments on utilities, we can theoretically calculate exactly which set of medical treatments to pay for to maximize the benefit to the population. These studies are called *cost-effectiveness analyses* and are the quantitative realization of the philosophic theory of utilitarianism. Allocating medical resources through cost-effectiveness analyses has important limitations. First, medical cost-effectiveness analyses cannot tell how much money to allocate to medical as opposed to other goods and services, just how to maximize health outcomes for any selected outlay of resources. Second, cost-effectiveness analyses may not fully account for some factors that society values. For example, cost-effectiveness analysis routinely treats all human lives as equally valuable; however, society often places a very high value on identifiable lives in imminent danger of death and may not value additional years of life in the elderly as much as years of life in the young.[15] Cost-effectiveness and other utility-based allocation

TABLE 162.2 Allocation Decisions at Different Levels

	Decision Maker	Decision	Rationale
Not an allocation decision	Physician	Not to use human growth hormone in chronically critically ill patients	Evidence of harm in critically ill patients
	President of insurance company	Not to offer routine chest computed tomography screening for lung cancer	Lack of sufficient evidence of benefit
	Healthcare minister	Not to offer basic medical coverage to all people in the country	Endorses other goals than equal access to health care: for example, the importance of choice or the value of free market
Macro-allocation decision	Physician	Not to admit routine postcoronary artery bypass patients to the intensive care unit (ICU)	Limited ICU beds used for patients with more severe illness
	President of insurance company	Not to increase reimbursement for septic shock when new, expensive drug is approved	Hopes to limit cost of care for patients to increase profitability of insurance company
	Healthcare minister	To capitate reimbursement for hospital care	By providing single fee for all care, hopes to limit costs so that increased outpatient services can be provided
Micro-allocation decision	Physician	Decision not to admit a debilitated, elderly man with urosepsis to the ICU despite a request by the patient's primary care physician	The intensivist felt the patient was moribund and that the ICU's resources could be used to better effect on other patients
	President of insurance company	Denial of claim to pay for lung transplant for 73-year-old man with pulmonary fibrosis	Treatment specifically not covered by contractual arrangement with insured patient.
	Healthcare minister	Not applicable	Not applicable

strategies fail to account for the value society places on rescuing lives in imminent peril—a not uncommon occurrence in the ICU.[16] Standard economic analyses may not value equal distribution as much as optimal distribution and, to this end, may discriminate in settings that society finds unacceptable.[17] Finally, cost-effectiveness analysis is a mathematical technique that generates comparative outcomes for populations of patients rather than an evaluation in single cases. It is worth pointing out that the term *cost-effective* is frequently misused both in informal clinical conversation and in the literature.[18] It is incorrect to speak of a treatment as being "cost-effective" without a comparator. Cost-effective does not necessarily, and actually rarely, means cost saving. Cost-effective does not necessarily mean the least expensive or the most effective of treatment options.

Cost-effectiveness analysis is a methodology that provides a ranking of treatments, which provides someone who has the authority to make decisions with the information to *compare* various strategies.[19] For example, one can compare the cost-effectiveness of captopril versus no captopril in survivors of myocardial infarction with using fluoxetine versus imipramine for major depression to decide whether to use captopril, fluoxetine, both, or neither. Cost-effectiveness analyses provide a ruler, a shared metric, usually in terms of dollars per life-year or dollars per quality-adjusted life year (QALY) that allows treatments to be compared with allocation (rationing) decisions on which treatments to provide when all effective treatments cannot be paid for. Valid cost-effectiveness ratios require an estimate of a numerator (the *cost* of one therapy compared with another) and a denominator (the *effect* of the therapy on survival or quality of life). Without evidence of effectiveness from randomized trials, estimates of cost-effectiveness are problematic and must be modeled on other data. Although we have data in critical care on strategies to reduce gastrointestinal bleeding, duration of mechanical ventilation, and ICU-acquired infections, the number of treatments that can demonstrate an improvement in QALYs is very limited.[20–22] Therefore the denominator for cost-effectiveness analyses in critical care can frequently only be expressed as dollars per event: for example, dollars per gastrointestinal bleed or ventilator-associated pneumonia prevented.[23] These ratios, sometimes referred to as *cost-benefit analysis,* cannot be used to compare a treatment to prevent gastrointestinal bleeding with a treatment to prevent catheter-related infections or with a treatment to improve weaning because they are all expressed with different denominators. Cost-effectiveness analyses with non-QALY denominators can be helpful in bedside rationing decisions when the intervention is known to be safe and equally or more effective and *reduces cost.* For example, special beds in the ICU have been shown both to prevent decubitus ulcers and to reduce the overall costs of care even when the cost of the bed is factored in. Therefore the cost-effectiveness ratio, expressed in dollars per decubitus ulcer prevented, is a negative number.[24]

ILLUSORY COST SAVINGS

If cost-effectiveness analyses are difficult in critical care because of a paucity of data for the denominator, the numerator—cost—is also challenging to calculate.[25] Since the earliest days of intensive care, technologic, workforce, and organizational innovations have been proposed as opportunities to reduce the exorbitant cost of critical care. In 1972 an optimistic author wrote, "[The] more promising approaches to cost reduction are all in an early stage of development now. Both deprofessionalization of the ICU by wider use of allied health personnel, and the automation of therapeutic functions are just beginning to be applied."[26] Despite implementation of both of these measures, there is little evidence that cost increases in hospital or ICU-based care have been curbed by technologic innovation. In fact, the opposite has occurred. This is not surprising because technologic innovation in other areas of health care, although often associated with better outcomes, is rarely a source of cost savings.

Cost analyses are problematic in medical care, and critical readers must be able to identify cost savings that are real and that will appear in their budgets as opposed to savings in indirect costs that will be

accrued elsewhere.[27] There are several common, but problematic, arguments about cost reduction in critical care: (1) that reduced ICU length of stay will reduce the cost of care in the ICU, (2) that reduced test ordering will reduce the cost of care in the ICU, and (3) that fewer admissions of futile-care patients will save money. It is important to recognize that not all calculated cost savings will be realized at the ICU or hospital level.

ICU costs are frequently inferred from length of stay. For example, in a cost-effectiveness analysis of antibiotic-coated catheters, the authors assigned a cost of $9738 to a catheter-related bloodstream infection.[28] Epidemiologic studies show that patients with catheter-related infections spend more time in the hospital, even after controlling for severity of illness.[29] The cost of a catheter-related infection is, in part, derived by simply multiplying the estimated number of extra days patients with such infections spend in the hospital by the cost (based on hospital charges) of a day in the ICU or ward. In fact, we do not really know whether using antibiotic catheters shortens ICU length of stay because the randomized trials demonstrating that antibiotic-coated catheters prevent infection were not sufficiently powered or did not show a reduction in mortality or length of stay.[22] Even if the antibiotic-coated catheters reduce length of stay, money "saved" by reducing length of stay is a different kind of money than money spent in buying the catheters. By reducing length of stay, the ICU will be able to care for more patients, but they will be sicker and more expensive patients.

Identifying treatments for specific conditions in the ICU that reduce overall costs, even if they have no effect on QALYs, is extremely useful to the intensivist allocating resources. Implementing economically dominant strategies is an easy allocation decision, as they do not worsen patient outcomes and reduce costs. However, predicting the actual effect of any decision on actual costs in an ICU or hospital is complex because each hospital performs cost-accounting and budgeting in idiosyncratic ways. The effect of different payor mixes, contracts for nursing and respiratory therapist labor, allocation of indirect costs, and whether the ICU budget is fixed or grows with the number of patients served all influence whether allocation decisions accrue savings that can be appreciated at the ICU level. For example, the drug acquisition costs of once-daily medications are frequently higher than medications given more frequently. However, labor costs are associated with administering medication more frequently that may offset the costs of the once-daily medication. Unfortunately, unless there is a sufficient workload reduction from changing to once-daily medication to actually firing a nurse, there will be little realized savings. This is because labor costs are not infinitely scalable. If there is 15% less work to do, you may not be able to hire 15% less nursing hours. Patients who need 1:1 nursing care will continue to need this level of care regardless of whether the nurses are administering once-daily medication or not. It may be that changing medication routines improves care by more efficient use of nursing time, but this may not be reflected in a cost reduction. A reasonable question for ICU managers who are considering a cost-saving intervention is whether it will reduce the amount of staff that need to be hired or whether it can reduce acquisition costs for equipment or medication. If it will not, then cost savings is not likely to be realized in the ICU.

The cost estimate used in many cost-effectiveness analyses assumes that every day in the ICU costs the same. This is certainly true for what the hospital charges, from which these ICU costs were derived. However, this is not true in reality. The first few days in the hospital and ICU are far more expensive than the last days.[30] Patients are more likely to require active interventions and closer nursing care in the early days in the ICU. Clearly, interventions that reduce ICU length of stay cannot reduce early days in the ICU and simply eliminate later lower-cost days. This is rarely accounted for in the cost analyses. This was validated at the national level as US healthcare costs peaked during a period when hospital inpatient days declined by 40%.[31] Therefore cost analyses may overestimate cost savings likely to be realized by reducing length of stay when this leads to a reduction in marginal low-cost days, and these days are merely shifted to other areas with similar or greater costs.

Reducing test ordering in the ICU has been offered as a technique for cost reduction. This, too, is a perfectly reasonable option to be offered on clinical grounds. Overtesting yields increased false positives, which may lead to clinical complications in search of diseases that never existed. However, the actual cost reduction that will be seen at the ICU level by reducing test ordering is likely to be overestimated in a simple charge-based analysis of test ordering. The actual marginal cost of performing the 101st arterial blood gas once you have already purchased the analyzer and paid for the technician time to perform 100 arterial blood gases is minimal. If reductions in test ordering are of sufficient magnitude to staff the laboratory with fewer people or to forego purchasing new equipment, then significant cost reductions can be realized. In fact, depending on how indirect costs in the hospital are allocated, it is possible that a reduction in test ordering will place the clinical laboratory under considerable budgetary constraints. Fewer tests may reduce the amount of money that the laboratory director receives to cover staff costs, which may not decrease in the same proportion as test ordering. Therefore clinicians should be wary of bedside testing device claims of reduced testing costs. There may or may not be valid clinical reasons to have bedside laboratory testing; reducing overall hospital costs is unlikely to be one of them.

Patients may be admitted to the ICU even when they have a negligible chance of survival. It seems reasonable to assume that if these patients receive care outside the ICU that the resources that would have been expended without benefit in the ICU would be saved. On its face, this appears to be the sort of painless cost saving that intensivists should look for. Unfortunately, a careful analysis of the potential savings from limiting care at the end of life shows that it is a relatively small amount of overall healthcare spending; that implementing these strategies may worsen overall health outcomes by affecting care that nonterminal patients receive; and that care would have to be withheld from young patients, some of whom would have had prolonged survival, to achieve any savings.[32]

STRATEGIES FOR BEDSIDE ALLOCATION OF RESOURCES IN THE ICU

Ultimately, allocation decisions will occur at the bedside in the ICU. A number of studies demonstrate that under settings of restricted access to ICU beds, physicians allocate these beds on the basis of severity of illness. In these situations the average severity of illness in the ICU increases as it does on the hospital ward.[33] The empiric research on ICU bed rationing is limited and complex because some authors do not distinguish between allocation made for efficacy (futility) from those made because of lack of beds or cost-effectiveness.[34] In fact, most clinicians in the United States do not perceive that they do any rationing at all and, if anything, feel that too much intensive care is provided to patients.[35] When they occur, rationing decisions may not always be driven by bed availability and prognosis and are also guided by arbitrary factors including age, gender, reimbursement, and physician power in the institution.[36] One of the few studies to actually document rationing through "revealed preferences" (actual behavior as opposed to stated rationale) looked at goals-of-care conversations with patients who had a sudden

decompensation on the ward. The more ICU beds were available, the less likely physicians were to have goals-of-care discussions to avoid ICU admission and the more likely they were to admit to the ICU.[37] However this study failed to find an association with mortality, suggesting that within the limits of the study, the physicians' rationing of ICU beds when limited had no negative effect. This study also suggests that similar rationing could occur safely when ICU beds were not limited but physicians did not behave that way. It is important that clinicians plan in advance of these difficult decisions so that their deliberations are explicit, open, and guided by principles rather than ad hoc case-by-case decisions.

SPECIAL SCENARIOS

Pandemic and Disaster Triage

The pandemics of SARS (2002), H1N1 (2009), Western African Ebola (2014), and COVID-19 (2019) and disasters like Hurricanes Katrina and Sandy (2005, 2012) and the Tohoku earthquake (2011) have focused policy makers on the demands these can place on the public health system in general and on critical care systems in particular. In developed countries, it is rare for critical care providers to have to choose between patients, both of whom could benefit from critical care. Although investments in preparedness are ongoing in many developed countries that include stockpiling of medication and ventilators, the likelihood that clinicians will have to ration lifesaving ICU resources during a disaster is real. There have been several responses to this inevitable clinical challenge: ethical, empiric, and legal.

Bioethicists have long struggled with the "lifeboat" scenario where only one person can be saved out of many who could be saved. In fact, the "ethics committee" was born out of the need to allocate dialysis and organ transplants.[38] There has been rapid growth of publications and online resources devoted to pandemic planning and ethical triage.[39] The issues are complex and extend beyond resource allocation—for example, whether healthcare professionals have a duty to provide treatment during an outbreak that poses risks to themselves and families or how care for severely ill patients not affected by the disaster should proceed. Conceptually, the allocation solutions are no different from the ones outlined at the beginning of this chapter; however, the absolute scarcity of resources, youth of the afflicted, and medical risk to providers make the decisions significantly more pressing. The issues relate to whether one should include factors other than prognosis in deciding on allocation: for example, social value, service value during the crisis, and age.[40,41] The principles are far from resolved, and perhaps the most valuable contribution of these deliberations is their focus on the need for transparent processes to be developed in advance of the crisis. Whether or not any of these rules can be enforced under the incredible pressures of life and death decisions at the bedside, where some of the critically ill patients may very well be colleagues who are ill after an infection acquired during the care of other patients, is completely untested.

Empiric solutions to disaster triage that rely on objective estimates of prognosis to guide end-of-life decisions are not new.[42] Unfortunately, previous attempts to ration intensive care based on computerized prognostication in any formal fashion has met with public disapproval.[43] Because of their inherent uncertainty, the literature on objective probability estimates in critical care generally criticizes their use as tools to make individual decisions about withdrawing life-sustaining treatments. Nevertheless, objective prognostic tools have been proposed for pandemic triage. They are clinically intuitive, relying on inclusion criteria (respiratory failure requiring mechanical ventilation or hypotension requiring vasopressors) and exclusion criteria (severe chronic comorbidities, age >85, metastatic cancer). Then patients are assigned a triage category based on the Sequential Organ Failure Assessment (SOFA) score and its trajectory.[44] Applying these criteria requires training and external adjudication in some cases.[45] Not surprisingly, patients excluded from the ICU and those who had life-sustaining treatment withdrawn under the hypothetical implementation of these triage criteria had significant survival rates, emphasizing that these triage rules will result in deaths that otherwise could have been avoided.[45]

Primarily as a result of Hurricane Katrina and subsequent lawsuits, there has been an interest in developing a legal framework about institutional and personal liability during disasters. If a clinician makes a triage decision to withdraw life support from one patient and provide it to another, can she be sued or prosecuted? The legal framework for resolving these issues derives from Good Samaritan statutes that protect civilian volunteers from legal liability related to their activities. Three laws passed in Louisiana after Katrina protect physicians and nurses from civil liability in the absence of gross negligence or willful misconduct and require a review panel before criminal indictment for activities that occur during a declared disaster.[46]

Global Critical Care

Getting accurate data on the burdens of global critical illness is almost impossible because many countries have insufficient resources to have ICUs or track these illnesses. Estimates of the rates of critical illness globally based on epidemiology in developed countries, which may be gross underestimates of what would be seen in developing countries, are astounding.[47] There are even more limited data on the availability of critical care services globally. However, viewed on a global level, it certainly appears that health care, and particularly critical care, is allocated based primarily on the wealth of the country.[48]

CONCLUSION

Allocation of resources in medicine is an unavoidable process. Clinicians do have control over whether these decisions are implicit or explicit, are made after open discourse or with no discussion, and whether the decisions are informed by evidence or not. Clinicians in the ICU may, in fact, face fewer implicit allocation decisions than their colleagues in other areas because of the imminent risk of death in the ICU and society's value for protecting those lives. In fact, there is relatively little empiric evidence of how often intensive care services are rationed. The effect of different interventions on actual costs will vary depending on local factors, including reimbursement and indirect cost allocation. Allocating ICU beds is the most challenging allocation decision most intensivists will face. The best time to handle these decisions is before they occur. Public, explicit triage and discharge criteria that are developed in collaboration with ICU users (emergency department, surgery, oncology) well in advance of the actual decisions are essential for fair and efficient use of intensive care resources. It is important that when cost-saving decisions are considered that the entire healthcare system be evaluated. Formal economic evaluation is crucial, as some treatments in the ICU, despite their expense, are likely to be more cost-effective than diagnostic and therapeutic regimens routinely offered.

THE FUTURE

Predictions about rationing of healthcare services are particularly challenging. In addition to making predictions about the future of critical care and critical illness, one must make predictions about the funding and delivery of healthcare services, international migration,

and disasters. My crystal ball makes several assumptions. The ICU of the near future will look very familiar to the intensivist of today. Patients will have more noninvasive monitoring, their complex information will be better organized, they will be more likely to receive noninvasive ventilation, and they will be managed with less sedation and more mobilization; but there will be no magic bullets for sepsis, genomics and personalized medicine will not make it to the routine care of critically ill patients, and patients will still require intensive and expensive nursing care. The aging population at risk for sepsis and respiratory failure will drive demand for critical care services. Successes in other fields—notably cardiovascular medicine, transplant medicine, and oncology—will turn rapidly fatal diseases into slowly fatal diseases marked by multiple visits to the ICU, some of which will be successful. Finally, the changes in healthcare funding will be incremental. At some point, and it may be quite soon for the United States, the costs of providing limitless and frequently wasteful health care to some and inadequate health care to others will become politically untenable. Although advocates for healthcare reform in the United States argue that shifting to a single-payer model will solve these problems painlessly, these benefits will be one-time savings in overhead costs. Countries with single payers like Canada and the United Kingdom are facing medical inflation curves that are similar to the United States. It is likely that only a crisis will drive explicit discussions about allocation of expensive, marginally effective life-sustaining treatments.

KEY POINTS

- Allocation of resources is synonymous with rationing and is an inevitable part of medical practice.
- Clinicians often use a variety of euphemisms, including triage, optimization, prioritization, and cost-effective care, to obscure what are essentially allocation decisions.
- Clinical decisions that are based solely on the evidence of risk, benefit, or patient utilities are not rationing decisions because they do not incorporate cost or availability.
- Clinicians may implicitly incorporate cost or availability into their judgments of the evidence of risk or benefit in an attempt to avoid an explicit decision incorporating cost.
- Allocation can occur at the macro level, where decisions affect populations of patients, or at the micro level, where decisions affect individually identifiable patients.
- Cost-effectiveness analysis is a quantitative methodology that applies a utilitarian approach to allocating resources to maximize the benefit to a population for any specified cost.
- Cost is difficult to measure in complex endeavors like medical care.
- Claims to reduce cost by reducing the length of stay, ordering tests, or admitting patients who will likely die should be examined critically.

ANNOTATED REFERENCES

Hadorn DC. Setting health care priorities in Oregon. Cost-effectiveness meets the rule of rescue. *JAMA.* 1991;265(17):2218–2225.
A rigorous application of cost-utility analysis fails to capture the value we place on saving identifiable lives. Whether this value is rational and whether it should be perpetuated is an important question; however, this analysis shows why rescue must be considered in any attempt to prioritize healthcare spending.

Luce JM, Rubenfeld GD. Can health care costs be reduced by limiting intensive care at the end of life? *Am J Respir Crit Care Med.* 2002;165(6):750–754.
Challenges the notion that significant reductions in ICU costs can be achieved by limiting intensive care at the end of life. The authors argue that although there are many very good ethical and medical reasons not to continue care for patients in the ICU when their prognosis is grim, the cost savings from these decisions are not likely to be enormous.

Marshall MF, Schwenzer KJ, Orsina M, et al. Influence of political power, medical provincialism, and economic incentives on the rationing of surgical intensive care unit beds. *Crit Care Med.* 1992;20(3):387–394.
An interesting and honest analysis of what happened when ICU beds were in scarce supply without an explicit plan for their allocation. The power and income generation of individual surgical attendings drove ICU allocation decisions.

Mehlman MJ. The legal implications of health care cost containment: A symposium: Health care cost containment and medical technology: A critique of waste theory. *Case W Res Law Rev.* 1986;36:778–877.
A scholarly analysis that brings rigor to terminology used loosely by medical professionals.

Reinhardt UE. Spending more through "cost control": Our obsessive quest to gut the hospital. *Health Aff (Millwood).* 1996;15(2):145–154.
A leading health economist challenges the notion that reducing hospital length of stay will reduce overall healthcare expenditures. Data from the United States show that marked reductions in hospital length of stay were not associated with a reduction in the rate of growth of medical expenditures. Instead, the author argues that costs were merely shifted from the hospital to other settings.

Basic Ethical Principles in Critical Care

Nicholas S. Ward, Nicholas J. Nassikas, Thomas A. Bledsoe, and Mitchell M. Levy

BACKGROUND

Since the inception of the practice of medicine, there have been ethical challenges for doctors and other health care professionals. Many of the challenges, such as who has the authority to make key decisions (autonomy vs. paternalism) and what the boundaries of life are at the beginning and the end, have existed for a long time. However, the ever-changing landscape of modern technology has presented new and unforeseen questions surrounding when new technologies should be applied and when they exceed ethical boundaries—technologies such as life support and genetic manipulation. Finally, changes in society and its values have led to new ethical challenges. Ethics exist as a perceived set of rules that are formed and judged by the culture in which they exist. Different cultures can have very different ethical systems. In many countries, not only are there very diverse cultures but these cultures continue to change and evolve. The net result of these forces is that modern ethics can change as well. Things once thought unethical may become ethical or vice versa.

The practice of medicine in intensive care units (ICUs) has been the source of many ethical challenges. These are often driven by conflicts surrounding death, a common occurrence in ICUs. Our ability to keep human beings alive has increased steadily, and thus rules and beliefs surrounding when not to continue life support have been tested on a regular basis. Once firmly fixed concepts, such as death or "brain death," are now coming under increasing attack. In other areas, the concept of patient autonomy has been used to request life-prolonging therapies once thought "futile." Finally, ICU physicians are increasingly finding themselves caring for patients who are unable to express their wishes and must rely on some kind of surrogate decision maker, which can add further ethical challenges.

GOALS OF CARE AND MEDICAL DECISION MAKING

Surrogate Decision Making

Modern medicine has embraced the concept of shared decision making between patients and their physicians based on the principles of autonomy honoring the patient's wishes, beneficence (trying to help), and nonmaleficence (not doing harm).[1,2] This approach, as noted, is often more complicated in the ICU. Whether decisions are made to continue with aggressive and likely quite burdensome care or to withdraw such care,[3] there will often be some tension within the care team or between the care team and members of the patient's family (who may be conflicted themselves).[4] In the ICU, as in other medical situations, this model of shared decision making affirms that patients have an ethical (and in many places a legal) right to determine the goals of their medical care. Choosing which health-related goals to pursue for a patient who has temporarily or permanently lost decision-making capacity is an imperfect science, but an individual patient's wishes regarding care may have been made known in advance of a serious medical illness to the physician or to a specific preferred surrogate decision maker or to family or friends. The process by which patients, with or without the assistance and participation of their physicians, family members, or other close personal relations, plan for future medical care is called *advance care planning*.[5] In general, the results of these deliberations are known as *advance directives*; defined broadly, they may be verbal or written and may be quite specific or very general. In this process, the patient may designate a preferred decision maker or health care proxy, may lay out general goals and values related to illness and medical treatment, and may determine what kind of care he or she would want in the settings of some anticipated situations. Subsequently, the advance directive helps direct medical care in the case of the patient's incapacity and comes into play only if the patient is unable to make his or her current wishes known.[6] For example, a patient who awakens after a surgical procedure and is deemed to have decision-making *capacity* (see later) is asked outright about his or her wishes, and the advance directive is no longer necessary.

Advance directives have ethical authority in whatever form (including verbal), as long as the directive was promulgated within the requirements of valid informed decision making (see later) as a tool for formally bringing the patient's values into consideration at a time when the patient is not capable of supplying them himself or herself. As noted, this method of approximating the patient's goals and values in times of serious illness is not perfect, and the reliability of a specific advance directive as "authentic representations of autonomous patient choices" is often suspect.[7] Advance directives specific enough to guide the day-to-day clinical decision making in the ICU are rare; more commonly, the ICU physician is left to work with a surrogate to understand the priorities of the patient and then to make shared decisions for the patient. Even in situations in which the physician "knows what the patient would want," the prudent clinician will seek counsel from individuals who know the patient well to mitigate the risk of paternalism. Who then may and should act as surrogate? How should that surrogate make decisions for the ill patient?

In some cultures, physicians often turn to the "next of kin" for surrogate decision making. However, the legal status of surrogates varies from country to country, and in many jurisdictions this individual has no de facto legal or even ethical grounds for assuming this role. (However, in some cultures, religion, and legal traditions, serious decisions about life-sustaining care are not made by individuals, but rightfully by the religious authority or clan leadership.) In a culture that favors individual autonomy, the best surrogate decision maker is the one chosen in advance by the patient.[8] Often this individual comes from the patient's valued community; usually, this individual is a member of the patient's family or close social circle. In those jurisdictions in which such a hierarchy has been determined by law, a typical sequence might

be (1) spouse, (2) eldest child, (3) next child, (4) parent, (5) sibling, and (6) close friend. Once a surrogate decision maker has been named, it may be helpful for the patient to clarify the role of the surrogate, from simply "tell the doctors what I want" to "use your judgment to make the best decision about my care." Interestingly, when asked whether they would prefer that their advance directives be followed no matter what or that their care be discussed with their chosen surrogate, a majority of patients would cede authority to the surrogate along the lines of "use your judgment."[9]

Even in situations where the appropriate decision maker is not the patient, it is helpful to have documented that the patient agrees with this approach. Similarly, some statement of the values to be used when deciding about medical treatment can be helpful.

Documentation of advance directives allows patients to make their values regarding and wishes for future care known, either formally or informally. As noted, these directives may also designate a specific surrogate decision maker who then has ethical and often legal standing to make medical decisions for the patient. In the absence of advance directives, the legally appointed surrogate or, in the absence of such a surrogate, those who know the patient well make decisions for the patient using substituted judgment based on his or her knowledge of the patient's health-related values. When no information is available about a patient's wishes or values, the decision makers should apply a "reasonable-person" or "best-interest" standard. In such cases, consultation with an ethics committee may be helpful.

Advance Directives

As noted, advance directives are formal or informal instructions to health care providers, family members, or others involved in a patient's care regarding treatment that may be required while the patient is unable to participate in medical decision making. The earliest form of advance directive was the "living will." Classically, the living will is restricted in terms of both scope and applicability. Living wills are usually reserved for patients with terminal illnesses and are typically restricted to statements about forgoing medical treatments that would "only prolong my dying"; they typically make explicit statements about the acceptability of discontinuing intravenous fluids and artificial nutrition if death is imminent and there is no significant hope for recovery. They usually do not provide instructions in the case of nonterminal illness and typically do not name a surrogate. A more generally useful legal document is the one that gives statutory authority to an individual to make medical decisions for a patient in the case of incapacity. This document is sometimes referred to as a *durable power of attorney for health care*. Similar to a durable power of attorney that provides legal decision-making authority for financial and other matters in the case of incapacity, this document provides legal standing to a named surrogate with regard to health care decisions. These documents typically provide an opportunity for an individual to give general information about health care preferences in a variety of situations. Some also provide an opportunity for the person to make a statement about the quality of life and the kind of life that would and would not be worth living. Preferences for organ donation, wishes for spiritual care, and even funeral arrangements are sometimes included.

Additionally, a number of advisory documents have been developed, including "values histories" and the medical directive developed by Linda and Ezekiel Emanuel.[10] These documents may present a series of increasingly dire scenarios and ask about overall preferences ("do everything possible to prolong life," "continue aggressive care but reevaluate often," "keep me comfortable, but do not provide care that prolongs my life"), or they may ask more general questions about what makes the person's life "worth living." It is hoped that this information will be helpful to a surrogate who must decide whether to continue supportive care in the case of irreversible injury or damage or even to continue disease-oriented care in the case of critical illness and impaired decision-making capacity.

For a variety of reasons, advance directives have not achieved wide popularity. When they exist, they are often not specific enough to provide meaningful guidance.[11] Even when a detailed directive exists, questions often remain about whether the individual was adequately informed and, in some cases, whether the individual had decisional capacity at the time. For example, a patient's advance directive says that she would never want to be on life support, but when she is asked about mechanical ventilation in the case of reversible respiratory failure from pneumonia, she says of course she would want that. Thus following a legally executed advance directive without verifying what was meant by the patient and whether the written wishes apply to the current illness can be quite problematic. It could in fact result in a preventable death in a patient who, with proper education, would wish to be treated.

A more limited form of advance directive, known as a *code status,* is frequently sought on admission to the hospital. A code status is an advance directive that is specifically limited to a patient's (or surrogate's) preferences regarding cardiopulmonary resuscitation (CPR) and other measures in the event of a cardiopulmonary arrest. In many hospitals and other health care institutions, as a matter of policy, any patient who suffers a cardiac arrest is treated with interventions designed to attempt to reverse the life-threatening derangement, including CPR, electrical defibrillation, and intubation and mechanical ventilatory support. Because a patient who suffers a cardiopulmonary arrest will die in a very short time without interventions, the discussion about code status is as much about how a patient wishes to die as it is about whether he or she wishes to live. Tomlinson and Brody distinguished three distinct rationales for a do-not-resuscitate (DNR) status[12]: (1) CPR has such a low likelihood of producing the desired outcome that it is effectively "futile," (2) there would be an unacceptable quality of life after CPR, and (3) there is already an unacceptable quality of life and cardiopulmonary arrest would be a welcome deliverance. Although often conflated with wishes for treatment of a variety of current or future medical conditions, a decision about CPR may not give much useful information about a patient's preferences regarding other aspects of his or her illness. A patient may choose aggressive disease-oriented measures well into a severe illness but still choose to forgo resuscitation in the event of an arrest. This approach may be voiced in a statement such as, "I want to fight this thing with all I have, but when it is my time, I want to go quickly without suffering." Such a statement would be an opportunity to address resuscitation status in addition to addressing overall goals of care (see later).

Many ICU patients who are actively receiving intensive disease-oriented care have a DNR code status. Such a directive may save surrogates and family members from the emotionally difficult task of removing life-supporting care. A patient's acceptance of DNR status may signify acceptance of the limits of medical science; refusal of DNR status in the setting of progressive irreversible illness may be an indication that the patient has an incomplete and perhaps unrealistic understanding of the illness. Further discussion addressing knowledge deficits or unspoken fears may increase the likelihood that the patient's true wishes will be followed.

A number of common errors may occur when discussing the code status. The first is failure to convey accurate information about the likelihood of success after an attempt at resuscitation. Many patients have an unrealistic impression of the utility of this intervention.[13] Another type of error is failure to address postresuscitation issues, when caregivers mistakenly assume that "do everything in the case of a cardiopulmonary arrest" also means the patient wishes the care team

to continue to "do everything" afterward. Patients who undergo CPR will most likely be incapacitated for at least a period after the resuscitation, even in the best scenarios. A third type of error is to not take the opportunity to identify a preferred surrogate decision maker, given the significant risk of temporary or even permanent brain injury after the attempt at resuscitation.

Any discussion of advance directives should attempt to answer at least three questions: (1) In the event of a cardiac arrest, do you want the health care team to attempt resuscitation? (2) If you become incapacitated, who do you want to make decisions for you? (3) If you were left significantly impaired after an attempt at resuscitation, under what circumstances would you want us to discontinue life-sustaining care? Additionally, preferences for resuscitation are best understood in the context of an individual's values, beliefs, relationships, and culture.[7]

Many problematic end-of-life issues can be traced to a focus on interventions ("Would you wish to be intubated?") without an adequate exploration of values ("What do you value about your life? What are the things that make your life worth living?"). It is also a mistake to think about advance directives as an issue limited to end-of-life situations. Advance directives are really just part of informed consent for any treatment, and discussion of advance directives is an important aspect of good medical care.

Informed Decision Making (Informed Consent)

In the United States, individuals are free to develop their own conceptions of happiness or a good life. By extension, choices about medical tests or treatment are made by patients in ways that maximize the likelihood of that good being achieved. This is called *patient autonomy,* and some would call it one of the core principles that define the relationship between a doctor and a patient. Respecting autonomy requires respect for the values and wishes of the individual. Additionally, the exercise of autonomy requires adequate information, the power of reason, and freedom of choice. Shared decision making happens when an autonomous individual has a conversation with the physician that incorporates the patient's values (autonomy) and the values of the physician.

Brock discussed the basic requirements for informed consent and identified three critical elements: the person giving consent must be competent, informed, and able to make a decision free from coercion.[13] *Competence* has several critical elements.[14] First, the decision maker must be capable of understanding relevant information, which involves both memory and mental processing. Second, it requires the ability to attend to and retain information, the ability to manipulate information, and the ability to foresee consequences. The third element is the ability to formulate and communicate choice. Some standards of competency strengthen this requirement by demanding the ability to communicate a *stable* choice (in this case, ambivalence may be a sign of incompetence).

To adequately participate in medical decision making, patients must have enough information to weigh the risks and benefits of various medical interventions. In the past, the standard for being informed was the standard practice of other physicians in the community.[15] Subsequently, *informed* came to mean what a "reasonable person would want to know." Because the main point of informed consent is to respect the rights and values of individuals, it is most appropriate to address this issue in terms of what a particular patient needs to know.[16] In general, patients need to know about the illness and its natural history to make informed decisions about medical care. They need information about the effectiveness of treatment, the risks of treatment, and the likelihood of success with treatment. This information must be presented in a way that is understandable to the patient, at an appropriate educational level, and is in the patient's language. Whether enough information has been transmitted can be assessed at the most basic level by simply asking a patient whether he or she has any questions. Brock writes of "informed understanding" and notes that this "permits an informed exercise in self-determination and promotes a decision most in accord with the patient's well-being."[13] In addition, this approach values autonomy.

The decision must also be voluntary—that is, free of coercion. The decision maker must have the freedom to accept or refuse the intervention or test being proposed. Consent given as a result of undue coercion is generally not valid.

Informed consent in the ICU raises some special issues. First, as mentioned earlier, the decision maker is often a surrogate rather than the patient. The surrogate decision maker should have access to all relevant information the patient would need to make informed decisions; however, the surrogate should not routinely be given confidential information *simply because the patient is no longer competent*. An example may be helpful in illustrating this point. An HIV-positive patient in the ICU has designated a family member as his surrogate; however, the family is unaware of his HIV status. The ICU physician believes a central line is indicated for continued care and seeks informed consent from the family member. In this case, it may be possible to obtain true informed consent for the procedure without divulging the patient's HIV status. Alternatively, a decision about a test or treatment specifically related to the patient's HIV status may require that this information be divulged to the surrogate for him or her to make an informed decision.

The adequacy of a properly designated surrogate is usually assumed but should be questioned in two situations. The first is when the surrogate acts in contrast to the patient's known wishes. Anyone who knows that the surrogate's directions conflict with the patient's expressed wishes has an obligation to work with the surrogate to come to a treatment decision more in keeping with the patient's wishes or to seek outside assistance from the hospital ethics committee or the hospital's legal department. The second situation occurs when there is doubt about the surrogate's competence, specifically his or her ability to retain and process information. Again, the ethics committee or the risk management department can be of help in this situation. An important study by Schneiderman and colleagues[17] demonstrated the value of ethics consultation for ICU patients in whom a conflict arose regarding a value-based treatment decision. In that randomized controlled trial, patients receiving an ethics consultation had shorter ICU and hospital stays and a decrease in the use of "nonbeneficial treatments." This study led to a call in the literature for more frequent use of ethics consultations in the ICU.[18–20]

FUTILITY

It is often said that "it is futile to define futility," and this has never been truer than in the current era of medical care. Many diseases that were once thought to be untreatable are becoming treatable, and diseases with high mortality rates are seeing a decline. It is now common for ICUs to have patients who would have been considered too old or too sick to warrant critical care decades ago. As more of these patients go on to survive the ICU, the boundaries of medical futility get pushed back even further.

There are many definitions put forth for the term *medically futile,* but most prove inadequate for practical use. The term has been generally used to describe either a patient who simply could not be kept alive (i.e., refractory shock) or a patient in whom death was inevitable in the near future (i.e., advanced cancer). The term *terminally ill* probably better describes the second situation. Nevertheless, these concepts have often been invoked as a justification for limiting lifesaving

interventions or denying admission to the ICU. However, this has become problematic. With modern medical interventions such as extracorporeal membrane oxygenation and others that can support vital organ functions, there are fewer times when physicians cannot keep a patient alive. Additionally, as patients with advanced illnesses are increasingly treated in ICUs with the goal of only a few more weeks or days of life, it becomes clear that one person's definition of *terminally ill* may not be the same for another.

In 2015 several key professional societies (American Thoracic Society, American Association of Critical Care Nurses, American College of Chest Physicians, European Society for Intensive Care Medicine, and Society of Critical Care Medicine) jointly produced and published a statement addressing conflicts of this nature. Notably, the authors chose to avoid using the word *futility* whenever possible, given its subjective nature, and instead use the wording *requests for inappropriate care* to describe situations in which patients or family request care that the physicians feel is of no benefit based on poor prognosis. The statement made several recommendations for physicians addressing such requests.

First, institutions should try to prevent intractable treatment conflicts through proactive communication and early involvement of expert consultants. The term *potentially inappropriate* should be used, rather than *futile,* to describe treatments that have some chance of accomplishing the effect sought by the patient but clinicians believe that competing ethical considerations justify not providing them. If there is disagreement, clinicians should explain and advocate for the treatment plan they believe is appropriate. Conflicts regarding potentially inappropriate treatments that remain intractable despite intensive communication and negotiation should be managed by a fair process of conflict resolution; this process should include hospital review, attempts to find a willing provider at another institution, and opportunity for external review of decisions. Finally, when time pressures make it infeasible to complete all steps of the conflict resolution process and clinicians have a high degree of certainty that the requested treatment is outside accepted practice, they should seek procedural oversight to the extent allowed by the clinical situation and need not provide the requested treatment.

The group further recommended that the use of the term *futile* should be restricted to the rare situations in which surrogates request interventions that simply cannot accomplish their intended physiologic goal. Clinicians should not provide futile interventions. The medical profession should lead public engagement efforts and advocate for policies and legislation about when life-prolonging technologies should not be used.[21]

Controversies Emerging From New Technology and Cultural Change

Advances in medicine and cultural changes have introduced new ethical challenges. Technologies such as extracorporeal membrane oxygenation (ECMO) and continuous venovenous hemofiltration (CVVH) can keep patients who would otherwise have died alive longer, forcing physicians to consider limited resources—distributive justice—and balance an obligation to respect the patient's wishes—autonomy—with concerns by some providers that the care may only be inflicting harm—nonmaleficence. Postmortem gamete retrieval (PMGR) now helps people create life under circumstances that otherwise would have been impossible, while introducing ethical questions pertaining to informed consent, surrogate decision making, and conflicts of interest. At the same time, the rules and beliefs surrounding these new technologies are being tested on a regular basis.

In addition to the challenges posed by new technologies, the increasing interest in complementary and alternative medicine (CAM) presents ethical issues. Given the incredible variety of therapies sought by patients that exist outside traditional medicine, assessing the potential efficacy and harm of the therapies can be difficult. On the one hand, a patient's decision to pursue an alternative medicine such as acupuncture falls within the realm of autonomy, yet on the other hand, if the CAM is used at the exclusion of an effective therapy, a physician's tacit approval may test the principle of nonmaleficence. Today, medical pluralism, or the use of CAM practices in conjunction with conventional medical practices, is widely encouraged, and thus these ethical challenges are unlikely to disappear.

In summary, ethics in critical care are founded on the same four primary directives common to all disciplines of medicine. Critical care decision making presents special challenges because these decisions often involve the life or death of patients who are unable to participate in the decision-making process. Although the balance between physician and patient responsibility for decision making may vary across cultures, the primary directive for physicians to act in the best interest of their patients is universal.

KEY POINTS

- Ethics in medical care is based on four fundamental principles: beneficence, nonmaleficence, autonomy, and justice.
- In the United States, competent patients have the right to make their own decisions about health care.
- The process of making known one's wishes regarding future care is called *advance care planning.*
- In the absence of an advance directive, a surrogate decision maker attempts to make medical decisions for a patient using substituted judgment. When no specific information is available about a patient, decision makers apply a "reasonable-person" standard and sometimes resort to a "best-interest" standard.
- Discussions about advance directives should be rooted in the patient's values and goals for medical care and the appropriateness of specific interventions.
- Shared decision making is a process that combines patient autonomy and physician judgment.
- New technologies are introducing ethical challenges for physicians and patients.

Building Teamwork to Improve Outcomes

Daleen Aragon Penoyer, Carinda Feild, and Joseph Abdellatif Ibrahim

The intensive care unit (ICU) is a complex environment with multiple professionals practicing together to provide patient care. Although technology and care options for critically ill patients have advanced, resulting in improved patient outcomes, they add to the complexity of care and knowledge needed by critical care providers. Nontechnical skills, such as teamwork and communication, are also essential for effective, efficient, and safe care provided by a multitude of professionals in a variety of roles. This chapter addresses the importance of teamwork in critical care, components of effective teamwork, the impact of teamwork on outcomes, strategies to build effective teamwork, and barriers to teamwork in critical care.

THE IMPORTANCE OF TEAMWORK IN CRITICAL CARE

Patients admitted to the ICU have a high acuity, are older, and require complex and costly care by interdisciplinary critical caregivers. The caregivers' charge is to carry out evidence-based protocols and guidelines of care while meeting the individual needs of the patient and family. This takes place in a fast-paced environment with constant change and states of readiness. Care requires considerable coordination across caregivers working in concert, executing their contribution to the care of patients in this complex environment. With the increased need for ICU beds, efficient use of resources and throughput of patients across the healthcare system are of high priority. The emphasis on using current best evidence to guide practice, advances in critical care research, and knowledge makes keeping up with best practices difficult. With the challenge of providing quality care in the complex ICU environment, teamwork is essential for efficient care in the ICU.[1–3]

Healthcare regulatory agencies, commissions, and professional organizations also value team collaboration to achieve quality outcomes. The Society of Critical Care Medicine (SCCM) focuses on delivering the right care at the right time with an integrated team of dedicated experts. In 2015 the American College of Critical Care Medicine updated the 2001 guideline on processes of care and ICU structure,[4] reaffirming recommendations for intensivist-led, high-performing multidisciplinary teams as a key part of delivering effective care. Further, an expert panel conducted a systematic review on shared decision making in the ICU and recommended that clinicians consider using a interprofessional decision-making process whereby information is exchanged, there is deliberation among the team, and treatment decisions are made jointly.[5] In a concise definitive review, Donovan and colleagues[3] (2018) found robust literature to support an interprofessional approach as part of achieving high quality of care in the ICU. They illustrated the patient and family surrounded by a host of interprofessional care team members, integrating care through an intersection of unique expertise with valued contributions toward a common goal.

The importance of teamwork and collaborative practice extends to health professional education. The Association of American Medical Colleges (AAMC), along with five other health professional programs, created the Interprofessional Education Collaborative (IPEC) to advance interprofessional education. The IPEC revised their expert report in 2016,[6] outlining core competencies related to teamwork across interprofessional teams. Currently, a multitude of health professions include interprofessional teamwork in their accreditation standards and competencies. These include but are not limited to nursing, pharmacy, respiratory therapy, nutritional support, physical and occupational therapy, and social work.[7] Goldman and colleagues[2] (2017) found interprofessional competencies are important for affecting competencies in skills and beliefs, but that organizational, environmental, and resource factors greatly affect the ability of team members to enact these competencies in the real-world setting.

Leaders are gaining an appreciation for how organizational structures and processes affect patient outcomes and the importance of highly functional teams. The best systems are those that allow teams to function at the highest level to reduce costs and improve patient outcomes. Successful hospitals are those that attract, train, and retain expert team members in an environment where they experience meaningful work and thrive within effective teams. Top hospitals build environments with top-notch teamwork, are intolerant of poor performance, and are supportive of team members who vocalize concerns.

COMPONENTS OF EFFECTIVE TEAMWORK

Broadly, *teamwork* is defined as two or more people working dynamically together to accomplish a common goal. Important components include communication, competence, trust, cooperation, coordination, respect, interdependence, accountability, conflict resolution, and shared decision making.[8,9] Although the term *teamwork* is widely used to describe interventions across teams and is valued by caregivers,[10,11] results from some qualitative and ethnographic studies indicate that in their work together, critical caregivers are performing activities that are more indicative of interprofessional communication interactions such as collaboration, coordination, and networking,[12] rather than what are considered "idealized"

definitions of teamwork, as defined by a shared team identity, interdependence, integration, and shared responsibility.[13,14]

Historically, healthcare professionals have practiced as individuals, demonstrating autonomy in their respective field of practice supported by its own body of research. ICU patients require complex and multifaceted interventions by an interdisciplinary team of experts. This process requires moving away from isolated practice toward collaborative practice with other healthcare providers. Ongoing interaction among the interdisciplinary team focused on patient-centric goals fosters greater collaboration and communication and can optimize patient care and outcomes. Through the exchange of ideas and expertise, practitioners become familiar with the nature and scope of one another's practice and are able to assess individual competence. This can build trust and promote the understanding of the unique contributions of team members and their interdependence for providing care. Focusing on the common goal to provide the best possible care for patients is key to minimizing team conflict.[8,15–17]

Over time, trust and open communication promote respect. Team members begin to appreciate each other's skills, knowledge, and judgment. In collaborative practice, responsibility is shared, so that goal setting and decision making occur jointly.

Being a good team player is key to a team's success. Given the ethical obligation to provide the best care for patients, every team member has the responsibility to make an optimal contribution during team communications or rounds, speaking up and providing relevant input, and listening actively to others' input while maintaining an open mind. Mutual support among the team (encouraging expression of ideas and positive professional communication) is important to build confidence in and perceived value of the team. These actions can lead to collective intellectual capital by the team and potentiate clinical effectiveness.

Team leadership is also critical to performance. Good leaders generate two-way trust, respect, and communication. They have vision, self-confidence, enthusiasm, tolerance, and a commitment to excellence. They are organized and prepared, fulfill commitments, inspire shared missions, grow new leaders, model behaviors, challenge processes, tolerate ambiguity, and remain calm. Leaders who think out loud help novices develop their teamwork skills and competence. Leaders set the tone for the function of the group and must demonstrate respect for the collective contribution of its members. Team members must ask for help when needed and express concerns without retribution in an environment that is psychologically safe. To have high-quality ICU teamwork, each team member should possess some leadership characteristics, as team leadership often changes, depending on the issue at hand.

IMPACT OF TEAMWORK ON OUTCOMES

Despite the support for teamwork and the development of an interdisciplinary team model for the care of critically ill patients, research on the relationship to outcomes is limited.[4,11,18] ICU patients are highly susceptible to medical errors. Severity of illness, intervention complexity and number, invasive devices, and ICU length of stay (LOS) put critically ill patients at a higher risk for adverse events and errors. One comprehensive review of critical incidents in intensive care showed an increased incidence of adverse events when there was a deficit in nontechnical skills, including elements of teamwork.[19]

Ineffective communication and poor teamwork have been identified as significant contributors to patient errors and critical incidents in the ICU.[8,9] Improved communication may reduce adverse events and errors.[20,21]

A systematic review and meta-analysis demonstrated improvements in outcomes with pharmacist participation on the ICU team. Interventions by pharmacists during ICU team rounds were associated with reduced odds of mortality, lessened LOS, and reduction in preventable/nonpreventable adverse drug events.[22] Another initiative was aimed at improving early mobility in ICU patients through active engagement of the multidisciplinary team. Multidisciplinary team engagement significantly improved rates of mobilization within the first 24 hours of ICU admission.[23] A pediatric study on the effect of team training for resuscitation demonstrated that training increased the chance of survival after in-hospital cardiopulmonary arrest.[11]

Whereas some studies have shown improvement of team performance outcomes associated with improved teamwork, research on patient outcomes are less often seen.[11] Intensivist-led multidisciplinary teams have been espoused as an ideal model for critical care. However, insufficient numbers of trained intensivists exist to meet current or future demands, and a limited number of ICUs have implemented intensivist staffing.[18] Furthermore, outcome studies on intensivist-led care demonstrate mixed findings.[4,18] One large patient cohort study compared the mortality outcomes from hospitals with daily multidisciplinary team rounds with and without intensivist models.[18] Hospitals with high intensivist staffing and multidisciplinary team care had the greatest reduction in odds ratio of death. Interestingly, hospitals with multidisciplinary care but low physician staffing also had significant odds reduction in mortality, reinforcing the idea that patients benefit from care by a multidisciplinary team. Mortality has been significantly reduced in patients with acute lung injury cared for by multidisciplinary teams led by full-time critical care physicians.[24] A literature review summarized that the team model for ICU care delivery was associated with reduced mortality, ICU and hospital LOS, and cost of care.[25]

One hospital in Illinois implemented evidence-based bundles of care and a multidisciplinary daily goals rounding tool, resulting in decreased ICU LOS, improved protocol compliance, reduced ventilator-acquired pneumonia (VAP), bloodstream infections, falls, and pressure ulcers in surgical ICU patients.[26] Multidisciplinary teams developed to respond to shock in nontrauma patients resulted in decreased time to treatment, intensivist arrival, and admission to the ICU.[27] This led to a significant reduction in mortality and improved patient outcomes.

Teamwork and Team Outcomes

Engaging in interprofessional teamwork has an overall impact on the team itself. In a narrative review of the effects on team training in critical care, Low and colleagues[11] summarized several outcomes. Overall, interdisciplinary team members were positive and satisfied with the programs and found them useful for clinical practice. Most often, team members acquired new skills and abilities to manage difficult clinical situations, frequently augmented by simulation. When using team tools such as checklists, they had improved behavioral outcomes, including role clarity, improved communication, and conflict resolution. Overall, although the clinical skills and behaviors were enhanced, other aspects, such as sustainability of learning or comparison of training programs, were less studied.

Hellyar and colleagues[28] implemented a case study investigation process in the ICU that included interprofessional peer review as a means of improving teamwork and optimizing patient outcomes from learnings achieved. This strategy demonstrated significant increases in the percentage of team members who felt free to speak up on issues that could potentially affect patient care, more open communication between nurses and physicians, and perceived improvement of teamwork across the interprofessional team. Additionally, there was a reduction in caregiver burnout and an accompanying reduction in central line– and catheter-related urinary tract infections.

When teamwork increases the efficiency of care, an increased sense of accomplishment can occur.[29,30] Research has shown that nurses preferred communicating with attending physicians over first-year residents and valued shared understanding and open, accurate communication, citing this as a predictor of nurse job satisfaction.[31] When a higher level of nurse-physician communication was reported, medication errors were reduced,[32] and when the timeliness of communication improved, the prevalence of pressure ulcers decreased through timely reporting of relevant information.[33] This further reinforces the notion that good communication and teamwork may translate into better overall care.

STRATEGIES TO ESTABLISH BETTER TEAMWORK

Because teamwork is so important for practice in the ICU, it is vital that steps be taken to implement team structures and processes that can help build teamwork in critical care. Models to develop strong teamwork have come from industries with high risk for errors, including aviation, the military, and nuclear power. In these industries, effective teamwork is an important mechanism used to maintain safety, reduce errors, and increase efficiencies.[34,35] Team members use specific processes for communication, leadership, coordination, and decision making to achieve positive team performance outcomes.

Although health care is different from these industries, lessons can be learned to improve teamwork in critical care.[34] Applicable strategies include standardizing work processes and using checklists to ensure patients are consistently receiving care based upon the best current scientific evidence and to improve teamwork skills, collaborative engagement, and communication. All interdisciplinary team members should be able to speak up when they identify potential patient safety hazards, and mechanisms should be developed to openly identify areas of high risk for errors and harm. A blame-free culture encourages team members to recognize, report, and thus minimize errors and learn from mistakes. Much like in an assembly line, when one team member recognizes the potential for harm, it must be pointed out and managed expeditiously.

Reader and colleagues[35] consolidated the research literature on the relationship between teamwork and patient outcomes in critical care. They emphasized that effective teamwork is crucial to provide optimal patient care in the ICU and good leadership is vital for team interaction and coordination. Four key performance competencies are needed to build effective teams in the ICU: (1) communication, (2) coordination, (3) leadership, and (4) decision making.

Another strategy to engage ICU interdisciplinary teams is involvement in quality improvement initiatives.[4] Participation in quality efforts is known to improve patient safety, reduce mortality, and decrease costs and LOS, among others. Adoption of evidence-based guidelines is also associated with coordinated care by the interdisciplinary team and improved outcomes.[4]

Barriers to Team Performance

Implementing teamwork strategies within health care has its challenges. Barriers to implementing a critical care team model can include local customs, hospital patterns, and reluctance to change despite proven benefit.[25] Hierarchic and status differences can present a barrier to team function and the ability of team members to openly contribute to the plan of care if they are not convinced that their input is valued.[8,36]

Several factors may influence the ability of teams to function at the highest level. Although the intensivist-led model for high-performing interprofessional teams is recommended,[4] there remain insufficient numbers of qualified physicians trained in critical care to meet demands. Costa and colleagues[37] found that having daytime high-intensity physician staffing did not show a significant impact on mortality, and other studies show mixed results with regard to intensity of intensivist staffing. Sufficient evidence, however, concludes that an intensivist-led highly functional team improves ICU care and may improve outcomes. The benefit of high-intensity 24/7 intensivist staffing remains unclear. Increasing reliance on team function for protocolized and systematic care and engagement of advanced practice professionals in the ICU may reduce the continuous need for supervised care by an intensivist-led team.[9,37] Other recently identified barriers are at the organizational level, where the environment is not conducive to practicing learned team competencies. Insufficient space for interaction, time, and resources to carry out team-related activities may reduce the ability to make optimal impacts from teamwork interventions and training. Organizational priorities on patient throughput and LOS, staffing concerns, and efficient workflow influence the overall environment where teamwork takes place and the ability to enact effective teamwork and collaboration across the team.[2,12,14] Even when intensivists are engaged with the interprofessional team, organizational characteristics and environment can affect the degree of effective teamwork and communication. Ensuring that the intensivist or other team leader can overcome barriers to effective communication is important to foster an environment of open communication and psychological safety.[9]

Educational Programs Used to Develop Teamwork in the ICU

Many practitioners in the ICU have not been trained in teamwork activities and are unfamiliar with the nontechnical skills required to perform well on a team.[19] Individual team members' knowledge, skill, and personality characteristics influence their effectiveness on teams. Because teamwork competency is being promoted as an essential practice needed by healthcare providers, interprofessional team training and experiential learning are needed, particularly in high-risk units like ICUs. Dirks[38] summarized key components in a comprehensive teamwork training program for the interprofessional team. This program emphasized strategies and structures to support teams and major components on teamwork behaviors and communication skills.

Programs to improve patient safety and collaboration in the ICU have been developed using a crew resource management (CRM) approach.[11,39] One group identified five key components needed for hospital CRM training: communication, task management, situational awareness, decision making, and leadership.[40] Program content included interpersonal communication; conflict resolution; nonthreatening critique of team performance; and methods to improve system processes for care, such as checklists, handoff improvements, and debriefing after errors.

Simulation-based learning is another mechanism for training the team to function under specific circumstances and is widely used in medical professional education.[41] Team learning in scenario-based simulation exercises allows professionals to learn their roles and practice safely under circumstances outside of stressful clinical settings.

Examples of using simulation for team training include managing septic shock using high-fidelity mannequins and scenario-based videos,[42] resuscitation and management of acute respiratory failure, airway management, myocardial ischemia, trauma, and shock.[43] Simulation-based learning can be used to improve handoff communication and reduce errors in relaying critical information across teams,[44] build teamwork competencies, and CRM. In one study, a critical event simulation was used for an interprofessional team in a surgical-trauma-burn ICU, which resulted in significant improvement in retention of teamwork skills and knowledge. Using simulation for team training is

an effective strategy for emphasizing roles and responsibilities across the interprofessional team.[41]

Multiprofessional Support for Teamwork in Critical Care

Key professional organizations support teamwork enhancements to drive improvements in practice. SCCM promotes an intensivist-led model for care by a team of multidisciplinary experts with supportive guidelines for characteristics of multidisciplinary teamwork (sccm.org).

The American Association of Critical Care Nurses actively supports teamwork within their healthy work environment initiative. Their website has tools to evaluate and promote teamwork (aacn.org). The Institute for Healthcare Improvement promotes quality improvement with teamwork as a key component in their initiatives, and their website (ihi.org) also has many useful team-building tools. The Agency for Healthcare Research and Quality has a comprehensive, evidence-based program to improve communication and teamwork skills among healthcare professionals called TeamSTEPPS. Information on this comprehensive program is housed on their website (teamstepps.ahrq.gov).

EXAMPLES OF INITIATIVES REQUIRING AN INTERPROFESSIONAL APPROACH IN CRITICAL CARE

Adoption and Implementation of Evidence-Based Care Guidelines and Protocols

Many opportunities exist for collaboration and teamwork in developing and executing patient care initiatives. Examples where interdisciplinary team members intersect for care include sedation awaking with agitation/delirium management, ventilator management and the use spontaneous breathing trials, palliative care, sepsis and other emergent care, and early mobility.[3]

Collaborative Practice Teams

Collaborative practice teams (CPTs) are groups of interdisciplinary team members assembled for a particular patient population to address issues related to clinical practice and outcomes. They design initiatives to drive evidence-based practice and improve quality of care. Critical care CPT composition depends on the patient population and disciplines involved in the care of those patients and should capture expertise from multiple disciplines (e.g., physicians, nurses, respiratory therapists, physical therapists, pharmacists, nutritionists, social workers, clergy, administrators, risk managers, infection control, and quality and safety personnel). Examples of CPT initiatives are disease-specific protocols, care "bundles," order sets, and quality programs. Some teams are formed to manage urgent clinical conditions, such as medical emergency response teams who respond to calls on clinical deterioration, sepsis,[42] stroke, and shock.[27]

Daily Interdisciplinary Team Rounds

Daily ICU rounds provide a forum for the individual interprofessional team members, with their respective roles, to exchange information and make decisions about the patient care plan.[3,9] Daily rounds also provide opportunities to augment new clinical initiatives. O'Brien and colleagues[45] redesigned multidisciplinary rounds using a structured approach and Lean-inspired methods. After soliciting barriers and insufficiencies from team members, the team implemented a tool kit to standardize key elements for discussion during rounds. Results showed improved communication and participation of nurses in rounds and reduced communication errors. Communication regarding the plan of care by the team can be facilitated by using a daily goals checklist during rounds. Checklists and protocols for care facilitate team functioning and provide a structure and guidelines for team actions and streamlining care.[9] Team accountability for assignments and goals established during rounds occurs during reviews for completion at day's end. This approach has demonstrated improved team and patient outcomes.[26,46,47]

CONCLUSION

As we struggle to increase patient safety, prevent harm, decrease chaos, and improve outcomes, mechanisms to integrate complex behavior into functional teamwork have become increasingly important. Harmonious and efficient integration of personnel and their respective expertise in the complex critical care environment is key to the delivery of high-quality intensive care. Ideally, care will be coordinated and delivered by a team with a high degree of mutual respect, who values and listens to all contributions, resulting in care that is optimized, efficient, and timely.

KEY POINTS

- An emphasis on collaborative teamwork to improve outcomes and reduce costs has increased as the care of the critically ill has become more complex and resources more limited.
- Key skills required for teamwork include communication, competence, trust, cooperation, coordination, respect, interdependence, accountability, conflict resolution, and shared decision making.
- Barriers to ICU teamwork include increasing patient acuity, rapidly evolving evidence-based practice, lack of teamwork competencies and training, insufficient physician-led multidisciplinary teams, and the stressful nature of intensive care practice.
- With the increased focus on teamwork, several models of teamwork in the critical care environment and increased resources have become available.
- Research shows that improved processes in teamwork and communication can lead to improved patient outcomes and healthcare team satisfaction.
- The interdisciplinary team has an opportunity to partner together through adoption and implementation of evidence-based care guidelines and protocols, CPTs, and daily rounding teams to drive quality improvements in the care of the critically ill.

ANNOTATED REFERENCES

Alexanian JA, Kitto S, Rak KJ, et al. Beyond the team: Understanding interprofessional work in two North American ICUs. *Crit Care Med.* 2015;43:1880–1886.

The authors of this paper conducted an ethnographic, qualitative study to evaluate ways that healthcare professionals work together in the ICU setting. They used direct observations and interviews of members of the multidisciplinary team. They found that although the term "teamwork" is used often to describe the interactions in the ICU, the type of work that they observed was more like interprofessional work, such as collaboration, coordination, and networking, as compared with teamwork behaviors, which include shared team identity, clarity, interdependence, integration, and shared responsibility.

American Association of Critical Care Nurses. AACN's Healthy Work Environments Initiative. Available at http://www.aacn.org/wd/hwe/content/hwehome.pcms?pid=1&&menu=.

The AACN has established an initiative to promote healthier work environments that allow teamwork to flourish. The website includes descriptions of ingredients for success in creating healthy environments, tools for assessing teams, and links to many other helpful resources.

Donovan AL, Aldrich JM, Gross AK, et al. Interprofessional care and teamwork in the ICU. *Crit Care Med.* 2018;46:980–990.
This concise definitive review was conducted to determine the importance of interprofessional care in the current intensive care unit setting. They defined interprofessional care as the care that a team of multiple healthcare professionals with overlapping expertise provide in partnership with other members of the healthcare team towards a common goal. They emphasize that all disciplines play an important role to meet the complex needs of patients. They advocate for inclusion of patients and families as partners in their care. In summary, they found a robust body of evidence to support the inclusion of the interprofessional team as a care model in the ICU.

Institute for Healthcare Improvement (IHI). http://www.ihi.org/ihi.
The IHI has been very successful in teaching teams to use a rapid-cycle change process to improve care delivery and patient outcomes. The website includes information on process improvement, tools for implementing change and evaluating progress, and guidance for addressing specific patient and system problems.

Michalsen A, Long AC, Ganz FD, et al. Interprofessional shared decision-making in the ICU: A systematic review and recommendations from an expert panel. *Crit Care Med.* 2019;47:1258–1266.
This systematic review of four papers evaluating the effect of interprofessional decision making on quality of care was done and recommendations for action were made. Interprofessional shared decision making should be a collaborative process regarding decisions for patient care. Clinicians should engage in interprofessional decision making to foster balanced treatment decisions. Clinicians and hospitals should develop a climate conducive to shared decision making. Clinicians involved in decision making should have a structured approach for interdisciplinary collaboration. The authors concluded that further studies are needed to determine the impact of interprofessional shared decision making in the ICU.

Weled BJ, Adzhigirey LA, Hodgman TM, et al. Critical care delivery: The importance of process of care and ICU structure to improved outcomes: An update from the American College of Critical Care Medicine task force on models of care. *Crit Care Med.* 2015;43:1520–1525.
This article outlines a revision in a previous guideline from 2001 on practice models of care in the ICU. After the task force review, four key recommendations were made: (1) an intensivist-led, high-performing, multidisciplinary team dedicated to the ICU is an integral part of effective care delivery; (2) process improvement is the backbone of achieving high-quality outcomes of care; (3) standardized protocols, bundles of care, and order sets are useful to measure processes and outcomes and are recommended for use; and (4) support by institutions for a comprehensive quality improvement program, including tele-ICU programs, should be implemented.

Severity of Illness Indices and Outcome Prediction

David Harrison, Paloma Ferrando-Vivas, and James Doidge

Predicting outcome is a time-honored duty of physicians, dating back at least to the time of Hippocrates.[1] The need for a quantitative approach to outcome prediction, however, is more recent. Although a patient or family members will still want to hear a prognosis, there is increasing pressure to measure and publicly report medical care outcomes and assess the value of care.[2,3] deliver comparative information website (www.leapfroggroup.org).[4] enacts penalties and provides incentives for providers based on quality.[5] Public reporting of intensive care unit (ICU) performance, in the form of risk-adjusted mortality rates, is now mandated in some European countries[6] and Veterans Administration (VA) hospitals in the United States[7] and used in many ICUs in the United States.[8] Thus clinicians need to understand the science behind these systems[9] and how risk adjustment models may properly be applied. Risk adjustment systems allow performance (process of care) to be evaluated independent of the presenting condition (baseline risk).

Prognostication based on clinical observation is affected by heuristic bias, inaccurate estimation of the relative contribution of multiple factors, false beliefs, and human limitations such as fatigue.[10] Outcome prediction models, on the other hand, will consistently replicate an estimate when considering relevant data. This presupposes that the model has been well developed and includes the most important predictive variables. Over time, we have learned that accepting patients in transfer,[11] sociodemographic factors,[12] and the point at which an outcome is assessed[13] can lead to misinterpretation of supposedly objective measures. This chapter discusses what can (and should) be measured, how benchmarking models are created and assessed, how they are applied in clinical practice, how this information may be used, and the pitfalls and confounders associated with their use.

WHAT SHOULD BE MEASURED

What is perceived as "quality" depends not only on individual subjective experience but also on integrating multiple perceptions and understanding the limitations of any one observation. Table 165.1 lists over 80 potential metrics categorized into process measures (what is done) or outcomes (what is achieved) in three categories: quality, efficiency, and patient/family experience. Process measures are important insofar as they provide guidance to interpreting outcomes that are out of range. A high urinary catheter utilization rate will affect the rate of catheter-associated urinary tract infections. Fig. 165.1 displays a "radar" plot where every variable has been normalized, such that 1.0 indicates performance at benchmark and the red-shaded areas indicate concern. In this hypothetical example, the neuro ICU appears to have issues with prolonged hospital length of stay (LOS), possibly related to hospital-acquired conditions. The medical ICU appears to excel at research, publication, and education, while having some issues with patient experience and wait times. Some metrics, such as mortality rate and LOS, will be determined primarily by a patient's underlying physiology and health status. Thus rates are normalized using the ratio of observed to expected events and creating standardized rates.

Designation as an ICU, 24-hour availability of consultants, an adverse event reporting system, routine multidisciplinary rounds, a standardized handover process, rate of catheter-related bloodstream infections, unplanned extubation rates, ICU readmission rate, and reporting and analysis of the standardized mortality rate (SMR) have been considered key indicators.[14] The SMR is one of the most frequently used adjusted outcomes measured worldwide.[6]

Mortality is a commonly chosen ICU and hospital outcome because it is unambiguous and readily available from a variety of data sources. Mortality, although clearly important, does not necessarily reflect quality of care or other important issues such as patient/family satisfaction, return to work, quality of life, or even cost, as early death results in a lower cost than prolonged hospitalization.[15] There is a poor correlation between hospital rankings based on death and those based on other complications.[16] A retrospective cohort study from 138 US ICUs contributing to Project IMPACT from 2001 to 2008 found that none of the 10 common performance indicators (e.g., mortality, readmission, LOS, bundle compliance) consistently correlated with the other 9.[17] There is also little standardization on how mortality should be defined—traditional ICU or hospital rates are subject to discharge bias,[13] but time-based outcomes (30-day, 1-year mortality rates) require intensive manual processes. Regionalized health information organizations or health information exchanges could make data collection easier but are not yet widely available.[18]

Other potential outcomes of interest include morbidity, organ failure, complications, ICU or hospital LOS, ICU or hospital readmission, and health-related quality of life after hospital discharge.[19] With electronic medical records (EMRs) and good coding, comorbidities may be identified by International Classification of Disease (ICD-9) and ICD-10 codes,[20] but administrative records may not reflect all relevant events.[21] ICU LOS is difficult to use as a proxy for quality of care because the frequency of distribution is usually skewed by long-stay outliers.[22] In addition, early death shortens the LOS, resulting in competing risk effects. It is difficult to develop accurate models for ICU LOS at admission,[23] and discrimination is usually inferior to that of mortality models based on the same database. A variety of regression methods have been applied to LOS prediction, with somewhat disappointing results.[24] More success has been achieved by combining variables from ICU day 1 and day 5; variables with the most impact include mechanical ventilation, the PaO_2:FiO_2 (arterial oxygen partial pressure/fraction of inspired oxygen) ratio, physiologic components, and day 5 sedation.[25]

TABLE 165.1 Possible Metrics for Evaluating ICU Performance

Process Measures	Quality Metrics	Efficiency	Experience	Optional (Local)
Daily wakeup/screen for weaning readiness	ICU SMR	ICU LOS	Patient satisfaction	Trainee performance
Glucose control	Hospital SMR	Hospital LOS	Family satisfaction	Publications
Lung protective ventilation (Vt/IBW)	1-year SMR	ICU occupancy (95% CI)	Delirium rate	Funded research
Semirecumbent position (HOB at 30)	Sentinel events	Bed turnover rate	Tracheostomy rate	Local research
Stress ulcer prophylaxis	CNS events (CVA)	ED to ICU transfer time	% transfer to SNF	Regional transfers in
Mobilization of patients	Cardiac events (MI)	ICU to SD/floor time	Rehabilitation days	Workload (TISS)
Communication (daily goal transfer)	Respiratory events	Readmission to ICU	1-year QOL/PICS	Organ donation rate
Antibiotic stewardship	Renal events (AKI)	Hospital readmission	Noise levels in ICU	Autopsy rate
Medicine reconciliation	GI events (GIB)	Cost/discharge	EOL care and DNR rate	
Handwashing	EMR (no cut/paste)	Cost/day	N:P staffing ratio	
DVT prophylaxis	DVT and HIT rates	Transfusion rates	MD:patient ratio	
Central line use and insertion	CLABSI rate	Ratio acute/LTAC days	Provider engagement	
Foley use and early removal	CAUTI rate	Palliative care referrals	Collaborative practice	
Ventilator and NIV utilization rates	VAP rate	Ventilator days	Procedure complications	
Assessing sedation RASS/CAMICU				

AKI, Acute kidney injury; *CAMICU,* confusion assessment method–intensive care unit; *CAUTI,* catheter-associated urinary tract infection; *CLABSI,* central line–associated bloodstream infection; *CVA,* cerebrovascular event; *DVT,* deep venous thrombosis; *ED,* emergency department; *EMR,* electronic medical record; *GIB,* gastrointestinal bleeding; *HIT,* heparin-associated thrombocytopenia; *ICU,* intensive care unit; *LOS,* length of stay; *MI,* myocardial infarction; *N:P,* nurse to patient; *RASS,* Richmond Agitation-Sedation Scale; *SMR,* standardized mortality ratio; *SNF,* skilled nursing facility; *TISS,* Therapeutic Intervention Severity Score; *VAP,* ventilator-associated pneumonia.

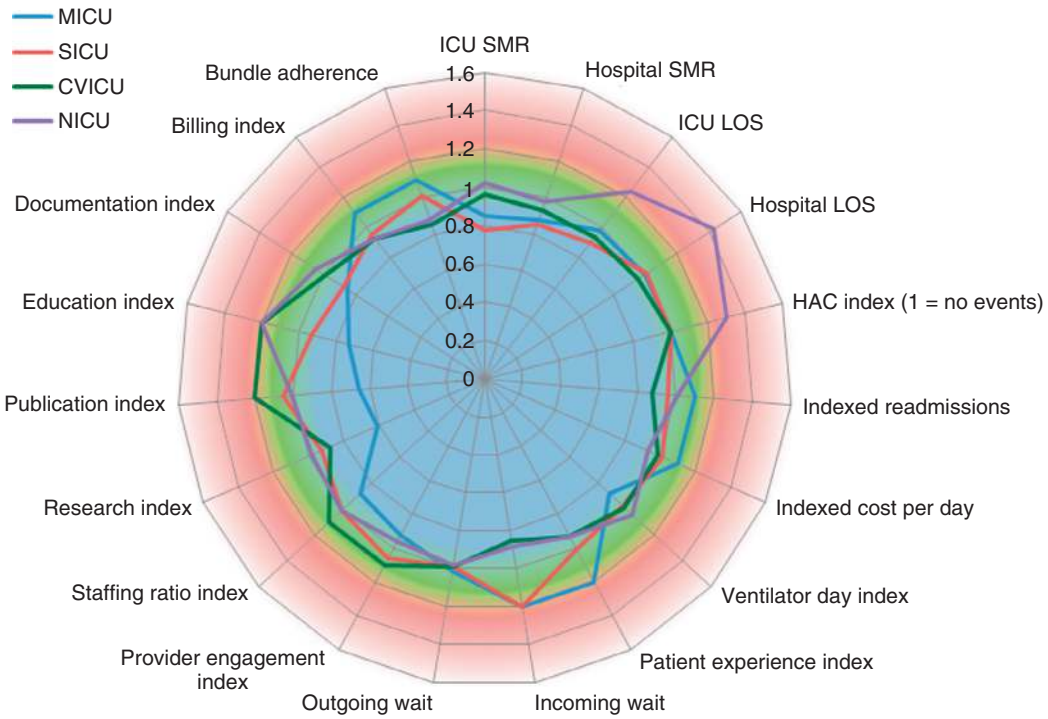

Fig. 165.1 Radar display of three hypothetical intensive care units, demonstrating a balanced scorecard approach to outcome assessment. Domains include metrics for quality of care (standardized mortality and hospital-acquired conditions); efficiency (standardized length of stay, readmissions, costs); subjective experience (family satisfaction, provider engagement, quality of life, wait times); and unit-specific measures such as publications, education, and quality of documentation. *CVICU,* Cardiovascular intensive care unit; *HAC,* hospital-acquired conditions; *ICU,* intensive care unit; *ICU SMR,* intensive care unit standardized mortality ratio; *LOS,* length of stay; *MICU,* medical intensive care unit; *NICU,* neuro intensive care unit; *SICU,* surgical intensive care unit.

Patients readmitted to ICUs have increased hospital mortality and LOS. However, readmission rates are difficult to interpret without careful case-mix adjustment.[26] Readmission rates are affected by triage decisions when ICU beds are constrained, but one study suggests that readmissions are only slightly higher with bed constraints, and, in any case, do not appear to affect short-term patient outcomes.[27] In a retrospective study of 263,082 first-admission patients in 105 US hospitals, the median unit readmission rate was 5.9% (interquartile range [IQR], 5.1%–7.0%). Hospitals with high readmission rates, however, did not have higher standardized mortality rates or LOS after case-mix adjustment.[28]

Patient satisfaction is an outcome highly valued by purchasers of health care, but it is subjective and requires substantial effort to quantify successfully.[29] Evaluation of ICU performance requires a combination of indicators, but risk adjustment has mostly been developed for short-term mortality outcomes, with only a few studies risk-adjusting for other indicators.

DATABASES AND DEFINITIONS

The quality of a risk stratification system largely depends on the quality of the underlying database. Retrospective studies using existing data are quicker and less expensive but may be compromised by missing data, imprecise definitions, interobserver variability,[30] and changes in medical practice over time. Data derived from discharge summaries or insurance claims do not always capture the presence of comorbid disease[31] if the number of reportable events is truncated. Such coding bias is most apparent in severely ill patients.[22] A variety of methods can assess the quality of the database, such as reabstraction of a sample of charts by personnel blinded to the initial results. Kappa analysis is a method for quantifying the rate of discrepancies between measurements (values) of the same variable in different databases (i.e., original and reabstracted). A kappa value of 0 represents random agreement and of +1.0 represents perfect agreement, but this statistic must be interpreted in light of the prevalence of the factor being abstracted.[32]

MODEL DEVELOPMENT

Once data integrity is ensured, there are several possible approaches to relate outcome to the presenting condition.[9] The empiric approach is to use a large database and subject the data to a series of statistical manipulations (Box 165.1). Typically, death, one or more specific morbidities, and resource consumption (LOS) are chosen as outcomes (dependent variables). Factors (independent variables) thought to affect outcome are then evaluated against a specific outcome using univariate tests to establish the magnitude and significance of any relationship.[9]

WHAT INDEPENDENT VARIABLES AFFECT OUTCOME?

ICU-specific systems typically adjust for patient physiology, age, and chronic health condition. They may also assess admitting diagnosis, location before ICU admission or transfer status, cardiopulmonary resuscitation (CPR) before admission, surgical status, and mechanical ventilation use. An ideal approach would use only variables that characterize a patient's initial condition, can be statistically and medically related to outcome, are easy to collect, and are independent of treatment decisions. There is also benefit to serial assessment of the condition, as the influence of independent variables may vary throughout the hospitalization.[33] The Glasgow Coma Scale[34] (GCS) is frequently used as a component of ICU severity scores but can be difficult to calculate correctly in sedated patients. The Full Outline of UnResponsiveness score,[35] which includes information on brainstem reflexes and respiration, may be an alternative as a mortality predictor.

BOX 165.1 Steps in Developing a Severity-of-Illness Model

- Precisely define outcome(s) of interest.
- Identify and define candidate predictor variables (data analysis, expert opinion).
- Collect data, and ensure its accuracy (reabstraction, kappa analysis).
- Examine continuous variables, and transform or dichotomize as necessary.
- Perform univariate analysis (chi-square, Fisher's exact, Student's t-test) against outcome(s).
- Perform multivariate analysis (logistic regression, neural nets, Bayesian, others).
- Examine and adjust for interactions among variables.
- Develop a score or equation that relates independent variables to outcome.
- Test calibration of model (goodness of fit, typically Hosmer-Lemeshow method).
- Test discrimination of model (ROC area C-statistic, sensitivity, and specificity).
- Validate model with independent data, split sample, or jackknife techniques.
- Obtain external validation in new settings, and customize as needed.
- Publish in peer-reviewed journal.

ROC, Receiver-operating characteristic.

Measured variables such as "cardiac index" or "hematocrit" are preferred over "use of inotropes" or "transfusion given" because the criteria for intervention may vary. Widely used models rely on common measured physiologic variables (heart rate, blood pressure, and neurologic status) and laboratory values (serum creatinine level and white blood cell count). Models may consider age and chronic health status and include interaction terms when variables are not independent. Items chosen for inclusion in a scoring system should be readily available and relevant to involved clinicians. Specialized scoring systems become necessary for specific patient populations (pediatric, burn, trauma, cardiac surgery) whose underlying physiology or treatment course differs from that of the general adult ICU population. For example, left ventricular ejection fraction and reoperative status are important predictors of outcome in the cardiac surgical population but are neither routinely measured nor directly relevant to other population groups.[36]

If the independent variable is dichotomous (yes/no, male/female), a two-by-two table can be constructed to examine the odds ratio and a chi-square test performed to assess significance (Table 165.2). If multiple variables are being considered, the level of significance is generally set smaller than $P = .05$, using a multiple comparison correction.[37]

TABLE 165.2 Two-by-Two Contingency Table Examining Relationship of MOF After Open Heart Surgery (Outcome) to a History of CHF (Predictor) in 3830 Patients*

Predictor Variable: History of CHF	OUTCOME VARIABLE: MOF	
	Yes	No
Yes	121	846
No	166	2697

*The odds ratio is defined by cross-multiplication (121 × 2697) ÷ (846 × 166). The odds ratio of 2.3 indicates patients with CHF are 2.3 times as likely to develop postoperative organ system failure as those without prior CHF. This univariate relationship can then be tested by chi-square for statistical significance.

CHF, Congestive heart failure; *MOF,* multiple organ failure.

Data from Higgins TL, Estafanous FG, Loop FD, et al. ICU admission score for predicting morbidity and mortality risk after coronary artery bypass grafting. *Ann Thorac Surg.* 1997;64:1050–108.

If the independent variable under consideration is continuous (e.g., age), a Student's t-test is an appropriate choice for statistical comparison. With continuous variables, consideration must be given to whether the relationship of the variable to outcome is linear, exponential, or segmented across its range. Fig. 165.2 shows the relationship of ICU admission serum bicarbonate to mortality outcome in cardiac surgical patients[38]; data points have been averaged with adjacent values to produce a smoothed graph.[39] Serum bicarbonate values higher than 22 mmol/L at ICU admission imply a relatively constant risk. Below this value, the risk of death rises sharply. Analysis of this locally weighted smoothing scatterplot graph suggests two ways for dealing with the impact of serum bicarbonate on mortality. One would be to make admission bicarbonate a dichotomous variable (i.e., >22 mmol/L or <22 mmol/L). The other would be to transform the data via a logarithmic equation to make the relationship more linear. Cubic splines analysis[40] can be helpful when the relationship between independent and dependent variables is not linear or cannot be described by a simple transformation.

Univariate analysis assesses the forecasting ability of variables without regard to possible correlations or interactions between them. Linear discriminant and logistic regression techniques can evaluate and correct for overlapping influences on outcome. For example, both a history of heart failure and depressed left ventricular ejection fraction predict poor outcome in patients presenting for cardiac surgery.[41] As might be expected, there is considerable overlap between the population with systolic heart failure and those with low ejection fraction. The multivariate analysis in this specific instance eliminates history of heart failure as a variable and retains only measured ejection fraction in the final equation to avoid double-counting of this general risk.

Because linear discriminant techniques require certain assumptions about data, logistic techniques are more commonly used.[9] Multiple logistic regression produces an equation with a constant, a beta coefficient and standard error, and an odds ratio that represents each term's effect on outcome. Table 165.3 displays the results of the logistic regression used in the Mortality Probability Model III ICU admission model (MPM_0 III).[42] There are 17 variable terms, and a constant term, each with a beta value that, when multiplied by the presence or absence of a factor, becomes part of the calculation of mortality probability using a logistic regression equation. The odds ratios reflect the relative risk of mortality if a factor is present.

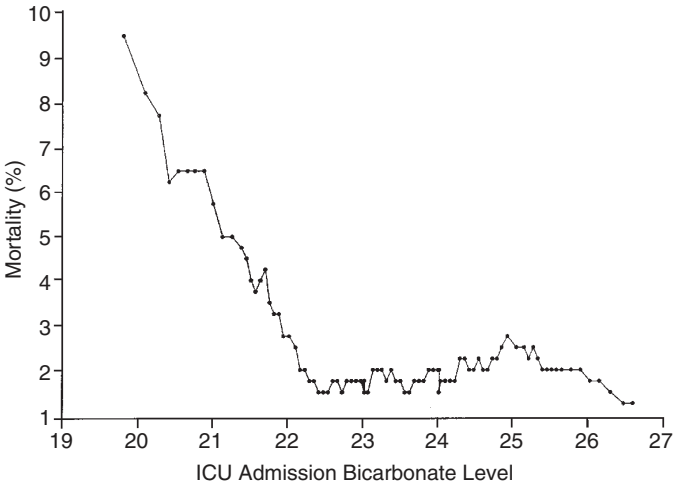

Fig. 165.2 A locally weighted smoothing scatterplot (LOWESS) analysis of the relationship between intensive care unit (*ICU*) admission bicarbonate level (*x*-axis) and mortality (*y*-axis). Individual patient data are grouped and averaged with surrounding data to produce a smooth plot. In this instance, the mortality rate appears to be stable with admission serum bicarbonate levels of 22 mmol/L and above but rises rapidly with lower values. Admission bicarbonate level of less than 21 mmol/L was given prognostic weight in the model that used these data. (Data from Higgins TL, Estafanous FG, Loop FD, et al. ICU admission score for predicting morbidity and mortality risk after coronary artery bypass grafting. *Ann Thorac Surg.* 1997;64:1050–1058.)

TABLE 165.3 Variables in the MPM_0 III Logistic Regression Model

Variable	Odds Ratios (95% Confidence Intervals)	Coefficients (Robust Standard Errors)
Constant	NA	−5.36283 (0.103)
Physiology		
Coma/deep stupor (GCS 3 or 4)	7.77* (5.921, 10.201)	2.050514 (0.139)
Heart rate ≥150 bpm	1.54 (1.357, 1.753)	0.433188 (0.065)
Systolic BP ≤90 mm Hg	4.27* (3.393, 5.367)	1.451005 (0.117)
Chronic Diagnoses		
Chronic renal insufficiency	1.71 (1.580, 1.862)	0.5395209 (0.042)
Cirrhosis	7.93* (4.820, 13.048)	2.070695 (0.254)
Metastatic neoplasm	24.65* (15.970, 38.056)	3.204902 (0.222)
Acute Diagnoses		
Acute renal failure	2.32 (2.137, 2.516)	0.8412274 (0.042)
Cardiac dysrhythmia	2.28* (1.537, 3.368)	0.8219612 (0.200)
Cerebrovascular incident	1.51 (1.366, 1.665)	0.4107686 (0.051)
GI bleed	0.85 (0.763, 0.942)	−0.165253 (0.054)
Intracranial mass effect	6.39* (4.612, 8.864)	1.855276 (0.166)
Other		
Age (per year)	1.04* (1.037, 1.041)	0.0385582 (0.001)
CPR before admission	4.47* (2.990, 6.681)	1.497258 (0.205)
Mechanical ventilation within 1 hour of admission	2.27* (2.154, 2.401)	0.821648 (0.028)
Medical or unscheduled surgical admit	2.48 (2.269, 2.719)	0.9097936 (0.046)
Zero factors (no factors other than age from previous list)	0.65 (0.551, 0.777)	−0.4243604 (0.088)
Full code	0.45 (0.416, 0.489)	−0.7969783 (0.041)
Interaction Terms		
Age × Coma/deep stupor	0.99 (0.988, 0.997)	−0.0075284 (0.002)
Age × Systolic BP ≤90	0.99 (0.988, 0.995)	−0.0085197 (0.002)
Age × Cirrhosis	0.98 (0.970, 0.986)	−0.0224333 (0.004)
Age × Metastatic neoplasm	0.97 (0.961, 0.974)	−0.0330237 (0.003)
Age × Cardiac dysrhythmia	0.99 (0.985, 0.995)	−0.0101286 (0.003)
Age × Intracranial mass effect	0.98 (0.978, 0.988)	−0.0169215 (0.003)
Age × CPR before admission	0.99 (0.983, 0.995)	−0.011214 (0.003)

BP, Blood pressure; *bpm,* beats per minute; *CPR,* cardiopulmonary resuscitation within 24 hours preceding admission; *GCS,* Glasgow Coma Scale; *GI,* gastrointestinal; ×, interaction between each pair of variables listed.

Odds ratios for variables with an asterisk (*) are also affected by the associated interaction terms.

Reprinted with permission from Higgins TL, Teres D, Copes WS, et al. Assessing contemporary intensive care unit outcome: an updated mortality probability admission model (MPM_0-III). Crit Care Med 2007;35:827–835.

The challenge in building a model is to include sufficient terms to deliver reliable prediction while keeping the model from being cumbersome to use or too closely fitted to its unique development population. Generally accepted practice is to limit the number of terms in the logistic regression model to 10% of the number of patients having the outcome of interest to avoid "overfitting" the model to the developmental data set. It is important to identify interaction among variables that may be additive, subtractive (canceling), or synergistic and thus require additional terms in the final model. In the earlier example, seven interaction items were added to reflect important observations in elderly patients,[43] where the very old without significant comorbidity frequently have better outcomes than unhealthy younger individuals.

The patient's diagnosis is an important determinant of outcome,[44] but conflicting philosophies exist on how disease status should be addressed by a severity adjustment model. One approach is to define principal diagnostic categories and add a weighted term to the logistic regression equation for each illness.[45] This acknowledges the different impact of physiologic derangement by diagnosis. For example, patients with diabetic ketoacidosis have markedly altered physiology but a low expected mortality; a patient with an expanding abdominal aneurysm, conversely, may show little physiologic abnormality and yet be at high risk for death. Too many diagnostic categories, however, may result in too few patients in each category to allow statistical analysis for a typical ICU, and such systems are difficult to use without sophisticated (and often proprietary) software.

The other approach is to ignore disease status and assume that factors such as age, chronic illness, and altered physiology will suffice to explain outcome in large groups of patients. This method reduces manual data collection and avoids issues with inaccurate labeling of illness in patients with multiple problems and the need for lengthy lists of coefficients but could result in a model that is less accurate[46] and somewhat dependent on having an "average" case mix.[47] Regardless of the specific approach, age and comorbidities (metastatic or hematologic cancer, immunosuppression, and cirrhosis) are given weight in nearly all ICU models to help account for the patient's physiologic reserve or ability to recover from acute illness. Yet many influential variables (e.g., frailty[48] in elders, mental illness,[49] paraplegia) increase the risk of poor outcome but are seldom incorporated into models. For example, acutely intoxicated patients tend to have low in-hospital mortality but striking rates of long-term mortality, particularly when street drugs are the intoxicating agent.[50] Do-not-resuscitate (DNR) orders are a strong confounder in mortality evaluations[51] but have only been included as a scoring variable in more recent models.[42]

VALIDATION AND TESTING MODEL PERFORMANCE

Models may be validated on an independent data set or by using the development set with methods such as jackknife or bootstrap validation.[52] Two criteria are essential in assessing model performance: calibration and discrimination. *Calibration* refers to how well the model tracks outcomes across its relevant range. A model may be very good at predicting good outcomes in healthy patients and poor outcomes in very sick patients yet unable to distinguish outcomes for patients in the middle range. The Hosmer-Lemeshow goodness-of-fit test[53] assesses calibration by stratifying the data into categories (usually deciles) of risk. The number of patients with an observed outcome is compared with the number of predicted outcomes at each risk level. If the observed and expected outcomes are very close at each level across the range of the model, the sum of chi-squares will be low, indicating good calibration. The *P* value for the Hosmer-Lemeshow goodness-of-fit *increases* with better calibration and should be nonsignificant (i.e., >.05). Special precautions apply when using the Hosmer-Lemeshow tests with very large databases,[54] where massive numbers can produce significance without clinical importance.

The second measurement of model performance is *discrimination,* or how well the model predicts the correct outcome. A classification table (Table 165.4) displays four possible outcomes that define sensitivity and specificity of a model with a binary (died/survived) prediction and outcome. Sensitivity (the true-positive rate) and specificity (the true-negative rate, or 1 minus false-positive rate) are measures of discrimination but will vary according to the decision point chosen to distinguish among outcomes when a model produces a continuous range of possibilities. The sensitivity and specificity of a model when using 50% as the decision point will differ from that using 95% as the decision point. The classification table can be recalculated for a range of outcomes by choosing various decision points: for example, 10%, 25%, 50%, 75%, and 95% mortality risk. At each decision point, the true-positive rate (proportion of observed deaths predicted correctly), the false-negative rate (proportion of survivors incorrectly predicted to die), and overall correct classification rate can be presented. The C-statistic, or area under a receiver-operating characteristic (ROC) curve, is a convenient way to summarize sensitivity and specificity at all possible decision points. A graph of the true-positive proportion (sensitivity) against the false-positive proportion (1 minus specificity) across the range of the model produces the ROC curve (Fig. 165.3).

TABLE 165.4 Classification Table

	ACTUAL OUTCOME	
Predicted Outcome	**Died**	**Survived**
Died	a	c
Survived	b	d

True-positive ratio = a/(a + b) (sensitivity)
False-positive ratio = c/(c + d)
True-negative ratio = d/(c + d) (specificity)
False-negative ratio = b/(a + b)
Accuracy (total correct prediction) = (a + d)/a + b + c + d

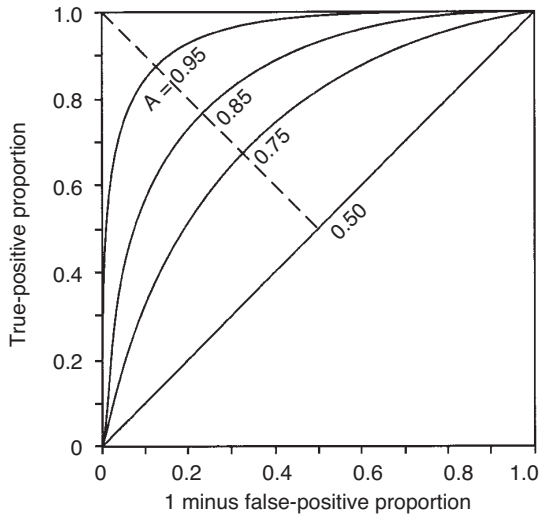

Fig. 165.3 Relative operating characteristic (ROC) curves. A coin toss gives an ROC of 0.5. In models that discriminate outcome, an increasing area under the curve, also called the *C-statistic,* is enclosed. (From Swets JA. Measuring the accuracy of diagnostic systems. *Science.* 1988;240:1285–1294.)

A model with equal probability of producing the correct or incorrect result (e.g., flipping a coin) will produce a straight line at a 45-degree angle that encompasses half of the area (0.5) under the curve. Models with better discrimination will incorporate increasingly more area under the curve to a theoretical maximum of 1.0. An area under the ROC curve (auROC) higher than 0.70 is acceptable, with higher than 0.80 considered excellent, and higher than 0.90 outstanding.[8] Most ICU models have ROC areas of 0.8–0.9 in their development set, although the ROC area usually decreases when models are applied prospectively to new data sets. The ROC analysis is valid only if the model has first been shown to be well calibrated.

A model may discriminate and calibrate well on its development data set yet fail when applied to a new population.[55] Discrepancies in performance can also relate to differences in surveillance strategies and definitions[55] and can occur when a population is skewed by an unusual number of patients having certain risk factors, as could be seen in a specialized ICU.[47] Large numbers of low-risk ICU admissions will result in poor predictive accuracy for the entire ICU population.[56] The use of sampling techniques (i.e., choosing to collect data randomly on 50% of patients rather than all patients) also appears to bias results.[57] Models deteriorate over time[58] owing to changes in populations and medical practice. These explanations should be considered before concluding that quality of care is different between the original and later applications of a model.

STANDARDIZED MORTALITY RATIO

Application of a severity of illness scoring system involves comparison of observed outcomes with those predicted by the model. The SMR is defined as observed mortality divided by expected mortality and is generally expressed as a mean value ±95% confidence intervals (CIs), which will depend on the number of patients in the sample. SMR values of 1.0 (± the CI) indicate that the mortality rate, adjusted for presenting illness, is at the expected level. SMR values significantly lower than 1.0 indicate performance better than expected. Small differences in scores, as could be caused by consistent errors in scoring elements, timing of data collection, or sampling rate, cause important changes in the SMR.[58,59] Different models applied to the same data set may produce discordant results, with the same hospital being identified as performing better than expected by one model and worse than expected by another.[46]

MODELS BASED ON PHYSIOLOGIC DERANGEMENT

Three widely used general-purpose ICU outcome systems are based on changes in patient physiology: the Acute Physiology and Chronic Health Evaluation (APACHE II,[60] APACHE III,[61] APACHE IV[44]), the Mortality Probability Models (MPM_0-II,[62] MPM_{24}-II,[33] MPM_0-III),[42] and the Simplified Acute Physiology Score (SAPS II,[63] SAPS III[64,65]). MPM_0-II and SAPS II were developed from the same data set and initially shared variables. All models have been regularly updated and are in at least their third generation. Although variables and weighting differ, all are based on the premise that as critical illness increases, patients will exhibit greater deviation from physiologic normal for a variety of common parameters such as heart rate, blood pressure, neurologic status, and laboratory values. Risk is also assigned for advanced age and chronic illness. Variables from these models have also been incorporated into the US VA hospital system model[66] (based on APACHE) and the California Outcomes Study[67] (similar to MPM_0-II and -III), in addition to models customized for international populations.

Acute Physiology and Chronic Health Evaluation

APACHE II was developed from data on 5815 adult medical and surgical ICU patients at 13 hospitals between 1979 and 1982; patients undergoing coronary artery bypass grafting, coronary care, or burn treatment were not part of the initial analysis. Severity of illness was assessed with 12 routine physiologic measurements plus the patient's age and previous health status.[61] Scoring was based on the most abnormal measurements during the first 24 hours in the ICU, with a maximum score of 71 points. The physiology score was then combined with coefficients to adjust the score for 29 nonoperative and 16 postoperative diagnostic categories, producing a mortality estimate.

APACHE II does not control for admission source or pre-ICU management, which could restore a patient's altered physiology and lead to a lower score and thus underestimate a patient's true risk.[68] Mortality estimates are most accurate for patients admitted directly from the emergency department and less so for interhospital and intrahospital transfers. Failure to consider the location before ICU admission could thus lead to erroneous conclusions about the quality of medical care.[69] Although the developers now consider APACHE II to have significant limitations based on its age, it is still in widespread use.

APACHE III, published in 1991, addressed limitations of APACHE II, including the impact of treatment time and location before ICU admission.[62] The number of separate disease categories was increased from 45 to 78. APACHE III was developed on a representative database of 17,440 patients at 40 hospitals, including 14 tertiary facilities that volunteered for the study and 26 randomly chosen hospitals in the United States. APACHE III went through several partial updates between 1991 and 2003.[45] Compared with APACHE II, the ranges of physiologic "normal" are narrower; deviations from normal are asymmetrically weighted to be more clinically relevant. Interactions between variables were considered, and five new variables (blood urea nitrogen, urine output, serum albumin, bilirubin, and glucose) were added, whereas the APACHE II variables serum potassium and bicarbonate were dropped. Information was also collected on 34 chronic health conditions, of which seven (AIDS, hepatic failure, lymphoma, solid tumor with metastasis, leukemia/multiple myeloma, immunocompromised state, and cirrhosis) were significant in predicting outcome. Customized models were developed for patient populations (e.g., cardiac surgery)[70] excluded from APACHE II. Overall correct classification for APACHE III was much improved over the prior model, and for the first time sequential scoring was introduced to update the daily risk estimate. APACHE III scores were also correlated with predictions for ICU LOS, need for interventions, and nursing workload.

APACHE IV was published in 2006[44] with refinements to address the impact of sedation on GCS, expand the number of diagnostic groups, and add or rescale predictive variables (Table 165.5). APACHE IV, based on a sample of 110,558 patients in the United States, has excellent discrimination (ROC area = 0.88) and impressive calibration (Hosmer-Lemeshow C-statistic 16.8, $P = .08$). Outcome assessment using the revised model differed substantially from prior versions. A hospital using APACHE III software in 2006, for example (calibrated to 1988–1989 results), might have congratulated themselves on a superb SMR of 0.799, whereas using APACHE IV would have revealed their SMR to be not different from the average at 0.997.

APACHE IV relies on physiologic abnormalities to account for 66% of the model's explanatory power. ICU admission diagnosis (using 116 categories) accounts for about 17%, with the remainder accounted for by age, chronic illness, location before admission, and interaction terms. There are limitations to the use of APACHE IV. First, the increased complexity of the model makes it impossible to use without dedicated software. The data entry burden, however, can be mitigated

TABLE 165.5 Variables Used in Acute Physiology and Chronic Health Evaluation IV

Variable	Coefficient	Odds Ratio
Emergency surgery	0.2491	1.28
Unable to access GCS	0.7858	2.19
Ventilated on ICU day 1	0.2718	1.31

by porting data into APACHE from a hospital's clinical information system. Second, APACHE IV was developed and validated in ICUs in the United States, and international differences in ICU resources, triage policies, models of care, and bed availability affect benchmarking performance in a new environment.[71] The authors also stress that "prediction for an individual contains variance" and that "a prediction is only an approximate indicator of an individual's probability of mortality."[44] As an example, they mention that the 95% CIs around a predicted mortality of 5% would typically be 3.9%–6.5% and that the absolute ranges of CIs widen as the predicted rate increases. APACHE IV has been recalibrated to APACHE IVa, and APACHE V is currently under development.

Mortality Probability Models

The original MPM was developed on 755 patients at a single hospital using multiple logistic regression to assign weights to variables predicting hospital mortality.[72] The MPM-II models were developed on an international sample of 12,610 patients and then validated on a subsequent sample of 6514.[33] A subscript (0, 24, 48, 72) designates time of the evaluation in approximate hours post admission. MPM-II, as with APACHE II, excluded pediatric, burn, coronary, and cardiac surgical patients and estimated hospital mortality risk based partly on physiologic derangement, using a smaller number of variables. However, MPM puts more weight on chronic illness, comorbidities, and age and less on acute physiologic derangement compared with APACHE. MPM models can use data obtained at ICU admission (MPM_0) and also at the end of the first 24-hour period (MPM_{24}), with the latter covering a time interval more comparable to APACHE. Whereas APACHE generates a score and then, with additional information, converts that score into a probability estimate of survival, MPM directly calculates a probability of survival from the available data. Because this involves a logistic regression equation, it is difficult to accomplish at bedside without a computer or programmable calculator.

The MPM_{24} variables account for differences in patients who remain in the ICU for 24 hours or longer versus those who die early or recover rapidly. This line of reasoning has been further extended to create 48- and 72-hour models,[73] although these have not yet been updated from MPM-II to MPM-III. Additional variables in MPM_{24}, MPM_{48}, and MPM_{72} but not MPM_0 are prothrombin time, urine output, creatinine, arterial oxygenation, continuing coma or deep stupor, confirmed infection, mechanical ventilation, or intravenous vasoactive drug therapy. Probability of death increases at 48 and 72 hours even if the MPM variables and coefficients are unchanged, implying that mortality risk is increasing in patients whose clinical profile remains unchanged over time.[74] The most important difference between MPM and APACHE is that the MPM_0 produces a probability estimate that is available at ICU presentation and is independent of ICU treatment. MPM also does not require specifying a diagnosis, which can be an advantage in complex ICU patients but may also make it more susceptible to error with changes in case mix[47] and generates, on average, a lower auROC.

MPM_0-II became the mortality benchmarking component for the Society of Critical Care Medicine's (SCCM) Project IMPACT database launched in 1996. By 2002 it was apparent that mortality predictions based on mid-1980s results were outdated, and average SMRs in Project IMPACT hospitals had drifted to 0.85.[74] MPM_0-III was developed from a population of 124,855 patients in 135 ICUs at 98 Project IMPACT hospitals. Hospital mortality in this population was 13.8% versus 20.8% in the MPM_0-II cohort.[42] All of the 15 variables from MPM_0 -II remained associated with mortality, but the relative impact had changed. For example, gastrointestinal bleeding was no longer a serious risk factor, presumably because of advances in resuscitation, endoscopic procedures, treatment of *Helicobacter pylori,* and availability of proton pump inhibitors since the original study. Additionally, two new variables were added: "full code" resuscitation status at ICU admission and "zero factor" or absence of all MPM_0-II risk factors except age. Seven age interaction terms were added to reflect the declining marginal contribution of acute and chronic medical conditions to mortality risk in the elderly.[43] MPM_0-III calibrated well (Hosmer-Lemeshow goodness-of-fit 11.62; $P = .31$) with an auROC of 0.823, similar to that of MPM_0-II. Although the ROC area is lower than with APACHE, MPM users do not need to specify a diagnosis, which may be difficult in a complex patient with multiple problems. The simplicity of data collection and ability to generate a prognosis soon after arrival (rather than at 24 hours) are advantages.

Limitations of the MPM_0-III include lower discrimination and use of a self-selected population of Project IMPACT participants in North America. Although in theory, extreme case-mix differences might affect MPM performance, in practice, SMRs obtained using MPM_0-III versus specially constructed subgroup models were nearly identical in the 135 ICUs studied, suggesting specialized subgroup models are not usually necessary.[75] MPM_0-III has been prospectively validated on an additional 55,459 patients at 103 adult ICUs in North America and calibrates well with more contemporary Project IMPACT hospitals (78 units participating in both studies plus 25 new participants).[76] The Project IMPACT database was also used to update the resource utilization "Rapoport Teres" graph that plots severity-adjusted mortality versus severity-adjusted LOS[77] (Fig. 165.4).

The California Intensive Care Outcomes Projects (CALICO) was developed to produce public reports comparing outcomes for patients treated in California ICUs as part of the larger California Hospital Outcomes Project mandated by the state of California.[68] After evaluating risk models available in the early 2000s, the California Healthcare Foundation and the National Quality Forum endorsed a modified and recalibrated version of the MPM_0-II model termed "ICU Outcomes Model," or $ICOM_{mort}$,[78] which has an auROC of 0.84 in prospective validation. The model includes 28 additional interaction terms and differs in patient exclusions from MPM-II and MPM-III. An additional model ($ICOM_{LOS}$) considers LOS. The CALICO project yielded several important findings, most notably that substantial (twofold) variation exists in mortality rates among hospitals, even after risk adjustment.[68] Beginning in 2007, California required every ICU in the state to report severity-adjusted mortality rates. A recent study of 936,063 patients comparing the California experience with that of Arizona, Nevada, and Texas (which did not have public reporting requirements) concluded that while outcomes in California had improved, mortality rates also decreased in the control states.[79]

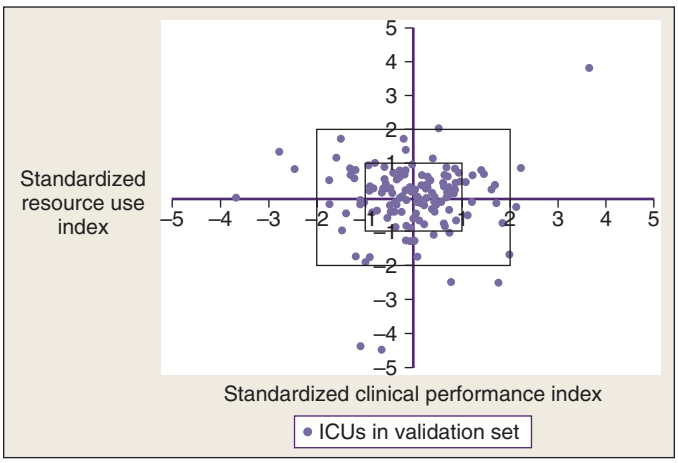

Fig. 165.4 Project IMPACT consolidates the display of mortality probability model (MPM) severity-adjusted mortality data (*x*-axis) with standardized resource use (weighted hospital days, *y*-axis). Hospitals within the 1 and 2 standard deviation boxes (most observations) are performing as expected. One hospital in the upper-right corner has superior performance in both dimensions. Four hospitals have longer-than-expected length of stay (negative numbers on standardized resource use), while being within range for mortality. Three hospitals have worse-than-expected adjusted mortality, whereas two have better-than-expected mortality; all are still within expected resource use. *ICUs,* Intensive care units. (From Nathanson BH, Higgins TL, Teres D, et al. A revised method to assess ICU clinical performance and resource utilization. *Crit Care Med.* 2007;35:1853–1862.)

Simplified Acute Physiology Score

SAPS II[64] was developed on 13,152 patients at 137 adult medical or surgical ICUs in Europe and North America, sharing the MPM-II data set. Like MPM and APACHEII, SAPS excluded burn patients, patients younger than 18 years, coronary care patients, and cardiac surgery patients. The outcome measure for SAPS II was vital status at hospital discharge. Seventeen variables were used in the SAPS II model: 12 physiologic variables; age; type of admission; and the presence of AIDS, metastatic cancer, or hematologic malignancy.

Not surprisingly, the SAPS II model also drifted out of calibration over time.[65] SAPS III, a multicenter, multinational study, collected data on 19,577 patients from 307 ICUs during the fall of 2002. When applied to this cohort, SAPS II underestimated hospital mortality, and although it discriminated well (ROC area, 0.83), calibration was poor, and model performance differed by geographic region. The final SAPS III model (Box 165.2), created based on 16,784 patients using logistic regression methods, contains 20 variables and has good discrimination (ROC area 0.848) and calibration (Hosmer-Lemeshow C-statistic = 14.29; $P = .16$).[66] Customized models were generated for seven worldwide regions to address geographic variation in population outcomes.

Intensive Care National Audit and Research Center Model

As noted earlier, risk adjustment models require validation and recalibration if they are to be applied in a new geographic setting.[55,80] The Intensive Care National Audit and Research Center (ICNARC) collected data on 216,626 critical care admissions in 163 adult general critical care units in England, Wales, and Northern Ireland from December 1996 to August 2003.[81] Logistic regression techniques were used to create the ICNARC model (Box 165.3), which includes 12 physiologic variables, age, source of admission, diagnostic category, and CPR status. This model has an ROC area of 0.863 and a Hosmer-Lemeshow C-statistic of 64.2. This study also evaluated performance

BOX 165.2 Variables Used in Simplified Acute Physiology Score III

- Age (in years)
- Comorbidities: cancer, cancer therapy (scored separately), chronic heart failure (NYHA IV), hematologic cancer, cirrhosis, AIDS
- Length of stay before intensive care unit (ICU) admission, days
- Intrahospital location before ICU admission
- Use of major therapeutic options before ICU admission (e.g., vasopressors)
- ICU admission: planned or unplanned
- Reason for ICU admission
- Surgical status at ICU admission: emergency, elective, or none
- Anatomic site of surgery
- Acute infection at ICU admission
- Lowest estimated Glasgow Coma Scale score (points)
- Total bilirubin (highest)
- Body temperature (highest)
- Creatinine (highest)
- Heart rate (highest)
- Leukocytes (highest)
- Hydrogen ion concentration (lowest pH)
- Platelet count (lowest)
- Systolic blood pressure (lowest)
- Oxygenation (P/F ratio)

AIDS, acquired immunodeficiency syndrome; *ICU,* intensive care unit; *NYHA,* New York Heart Association. *P/F,* arterial oxygen partial pressure/fraction of inspired oxygen (PaO_2/FiO_2).

BOX 165.3 Elements in ICNARC Score

- Highest heart rate
- Lowest systolic BP
- Highest temperature
- Lowest respiratory rate
- Mechanical ventilation (yes/no)
- Lowest PaO_2/associated FiO_2 (P/F ratio)
- Lowest pH
- Highest serum urea
- Highest serum creatinine
- Highest serum sodium
- Urine output (24 hours)
- Lowest WBC
- Paralyzed/sedated (yes/no)
- Lowest Glasgow Coma Scale score
- Age (years)
- Source of admission
- Diagnostic category
- CPR (yes/no)

BP, Blood pressure; *CPR,* cardiopulmonary resuscitation; *PaO_2/FiO_2,* arterial oxygen partial pressure/fraction of inspired oxygen; *WBC,* white blood cell count.

of APACHE II, APACHE III, SAPS II, and MPM-II on the same population. The ICNARC outperformed all other models in terms of discrimination (ROC area), but SAPS II had better calibration and MPM-II had the best accuracy of average prediction, although these differences were all relatively minor. ICNARC, having no exclusions, may be applied to all critical care admissions regardless of diagnosis, and it calibrates well in the United Kingdom. ICNARC has recently been externally validated in 23,269 patients in 24 Scottish critical care units, with good discrimination (0.848) and calibration.[82]

Veterans Affairs Intensive Care Unit Risk Adjustment Model

Arguably, the VA population in the United States could represent a specialized population, owing to being predominantly male (>97%). In 1996–1997, the VA developed a customized, automated ICU risk adjustment tool[67] based on APACHE variables; this model has been validated, updated, and recalibrated.[83] Risk predictors include age, mutually exclusive ICD-9 diagnosis/procedure groups, comorbid disease groups, admission source, and 11 laboratory values measured during the 24 hours surrounding ICU admission. Revisions to the model refit the predictor coefficients and expanded the number of diagnostic categories from 38 to 84. The model has an impressive ROC area (0.874–0.877) in two data cohorts and calibrates well by Hosmer-Lemeshow statistics. SMRs derived from the VA ICU model correlate well ($r^2 = 0.74$) with those of the National Surgical Quality Improvement Performance (NSQIP) tool developed for surgical postoperative assessment. The VA model, however, has not yet been tested internationally or outside of the VA population.

Specialized Models

MPM, SAPS, and early versions of APACHE excluded patients younger than age 18, burn patients, and coronary care and cardiac surgical patients. Murphy-Filkins and colleagues[47] reported that performance of severity of illness models deteriorates when critical population values are reached for individual scoring variables, as might be seen in a highly specialized ICU. For example, 20% of the patients in the MPM-II database were aged 75 or older. When this percentage of elderly patients was experimentally increased to 42%, the model became unstable. Similar changes were seen if the proportion of patients with cardiac dysrhythmias, cerebrovascular disease, intracranial mass effects, coma, CPR before ICU admission, emergency admission, or gastrointestinal bleeding differed substantially from baseline values. Thus severity of illness scoring systems should be used with caution when units become highly specialized to care for subsets of patients.

To address this issue, specific models have been developed for pediatric,[84] trauma,[85] and cardiac surgical populations.[41,86–88] ICU admission physiologic values in the cardiopulmonary bypass population are determined by routine hypothermia, hemodilution, and deliberate control of hemodynamics by the operating room team. Important variables for predicting outcome after cardiac surgery are ventricular function, coronary anatomy, and heart valve pathology and reoperation status.[36] The Cooperative CABG Database Project, analyzing 172,000 patients, identified seven core variables (urgency of operation, age, prior heart surgery, gender, ejection fraction, percent stenosis of the left main coronary artery, and number of major coronary arteries with >70% stenosis) to be predictive of mortality.[89] The independent variables predicting morbidity do not perfectly overlap those predicting mortality or LOS, suggesting that different scores may be required to best predict various outcomes. Currently, the two most widely used preoperative cardiac surgical models are the Society for Thoracic Surgeons model[90] in the United States and the EuroSCORE-II[91] in Europe; both have been updated from their original iterations.

The preoperative cardiac surgical models are useful for evaluating the results of an entire hospitalization but do not specifically address the ICU component of care. Operating room events can neutralize or amplify preoperative risk, depending on such events as reopening the chest, hemodynamic management in an emergency patient, and the degree of myocardial protection. In 5000 patients undergoing CABG, eight risk factors available at ICU admission appeared to predict hospital mortality, and an additional five factors also predict morbidity.[38] APACHE has also been successfully modified for use in cardiac surgical patients.[71]

Patients receiving prolonged mechanical ventilation (MV) are resource-intensive, and although their mortality can be accurately estimated, they have a disproportionate effect on ICU and hospital LOS, which is magnified with high hospital MV volume.[92] The ProVent model, measured on day 21 of MV, predicts overall 1-year mortality (48%) with acceptable discrimination and calibration[93] by assigning points for four categorical variables: age, platelet count, vasopressors, and hemodialysis.

SEQUENTIAL ORGAN FAILURE ASSESSMENT SCORE

The Sequential Organ Failure Assessment (SOFA) score was developed to quantify organ dysfunction of the respiratory, cardiovascular, hepatic, coagulation, renal, and neurologic systems. One to four points are assigned based on the degree of physiologic derangement; high scores imply poor outcome. A maximum SOFA higher than 15 is associated with more than 90% mortality.[94] SOFA is intended to be used sequentially, in part to address the issue that a first-day severity score has limited ability in predicting outcome when patients have a longer ICU experience with attendant events or complications. Although developed to assess organ failure rather than prognosis, SOFA (and similar scores, such as the Logistic Organ Dysfunction System [LODS][95] and the Multiple Organ Dysfunction Score [MODS])[96] correlates with mortality. The change in score during the first 96 hours can help with prognosis: regardless of the initial score, an increasing score is associated with more than 50% mortality.[97]

Most risk-adjustment models provide initial estimates for both ICU and hospital mortality, with the potential for updating predictions during the ICU stay. Although subjective, the Sabadell score allows ICU clinicians to categorize patients at ICU discharge into good prognosis (0 points), poor long-term prognosis (>6 months) with unlimited ICU readmission (1 point), poor short-term prognosis (<6 months) with debatable ICU readmission (2 points), and death expected during hospitalization (3 points). Age and the Sabadell score correlate with ward mortality after ICU discharge with good calibration (auROC, 0.88) and discrimination.[98] Patients with high predicted ward mortality would likely benefit from palliative care consultation. Conversely, less than 2% of patients with good prognosis die on the ward after ICU discharge.

ADMINISTRATIVE MODELS

Initial versions of the most popular models were developed by research teams using data largely collected manually using trained abstractors.[45] There has been interest in automating this process,[99] and with the widespread availability of electronic health records, real-time calculations have become routine. Although extracting relevant clinical variables can still be an informatics challenge, successful models based on administrative data have been developed for predicting in-hospital mortality for community-acquired pneumonia[100] and sepsis.[101] With automated data collection, these models can extend beyond just ICU admissions to encompass all hospitalized patients. The next iteration of APACHE will reportedly address outcomes across venues and allow automated outcome predictions for all hospitalized patients. The Multiparameter Intelligent Monitoring in Intensive Care II (MIMIC-II) database promises to promote research in epidemiology and clinical decision-rule creation by establishing a public-access, deidentified database.[102] Caution is raised by a large Dutch study, however, where SMRs calculated using administrative data were unfavorable to those calculated using modified SAPS II clinical data, especially in institutions with a more severely ill population.[103]

COMPARISONS AMONG MODELS

A number of papers have compared relative performance of the three most widely used ICU systems.[104–106] Using data from 11,300 patients in 35 hospitals participating in the CALICO Project, APACHE IV, MPM_0-III, and SAPS II all showed adequate discrimination and calibration, with APACHE IV delivering the best predictive accuracy, albeit with longer data collection time.[107] Substantial variation occurred in ICU risk-adjusted mortality rates between ICUs, regardless of the model used.

Performance of three models based on 24-hour data (APACHE II, APACHE III-J, and SAPS II) was compared with that of three models based on admission data (MPM-II, SAPS III, and SAPS III-A using Australian coefficients) for 1741 patients in an urban university-affiliated teaching hospital in Australia.[108] SAPS II and SAPS III-A fulfilled predetermined calibration and discrimination criteria, APACHE II failed both criteria, and the remaining models discriminated well but overpredicted mortality risk. There did not appear to be an advantage in using 24-hour data versus data available at admission. The improved results with SAPS III-A versus SAPS III again underscores the benefit of customizing models with local coefficients. A Brazilian study found APACHE IV, MPM_0-III, and SAPS III to have good discrimination (auROC 0.883, 0.840, and 0.855, respectively) but uniformly poor calibration, leading to overestimates of in-hospital mortality.[109] Calibration was particularly problematic with SAPS III, but APACHE IV and MPM_0-III also performed poorly at higher predicted mortality rates.

More recently, MPM_0-III, the $ICOM_{mort}$ modification of MPM (also known as the National Quality Forum or NQF model), and APACHE IVa were compared based on a database of 174,001 ICU admissions from 2008 to 2012 at 38 US hospitals.[110] Only 109,926 patients (63%) met inclusion criteria for all three models. APACHE IVa offered the best discrimination and calibration and excluded fewer patients than the other models. APACHE IVa overpredicted mortality by 1.5%, MPM_0-III overpredicted by 3.1%, and the ICOM-NQF model underpredicted by 1.2%. Calibration was best for APACHE IVa, which has implications for benchmarking using SMR when case mix varies among hospitals; this will be discussed later.

Table 165.6 summarizes the results of nine studies in which two or more of the risk-adjustment models were applied to a specific regional population. There is no consistent pattern to accuracy (discrimination), with examples of observed mortality higher than predicted, lower than predicted, as predicted, or predicted differently by different systems. There is also no consistent leader in calibration; it tends to be poor in many studies. Ratios of observed-to-expected mortality rates are influenced by case mix and by quality of care.[111]

TABLE 165.6 Regional Application of Severity Scoring Models

Study	Country	Systems	Findings
Arabi et al.[112]	Saudi Arabia	APACHE II	Predicted mortality similar to that observed for all systems (SMR 1.0–1.09)
	n = 969	$MPM\text{-}II_0$ and $\text{-}II_{24}$	Calibration best with $MPM\text{-}II_{24}$
		SAPS II	Discrimination best with $MPM\text{-}II_0$ followed by $MPM\text{-}II_{24}$, APACHE II, and SAPS; all ROC >0.79
Capuzzo et al.[113]	Italy	APACHE II	ROC area >0.8 both models
	Single center	SAPS II	Mortality in high-risk patients overpredicted by SAPS II and underpredicted by APACHE II
	n = 1721		
Katsaragakis et al.[114]	Greece	APACHE II	Good discrimination but poor calibration with both models
	Single center	SAPS II	Better performance with APACHE II
	n = 661		
Livingston et al.[80]	Scotland	APACHE II	Discrimination adequate (ROC areas 0.74–0.795)
	22 centers	APACHE III	
	n = 10,393	UK APACHE II	Observed mortality significantly different from that predicted by all systems
		$MPM\text{-}II_0$	APACHE II had best calibration followed by $MPM\text{-}II_{24}$ and SAPS II
		$MPM\text{-}II_{24}$	

TABLE 165.6 Regional Application of Severity Scoring Models—cont'd

Study	Country	Systems	Findings
Markgraf et al.[71]	Germany	APACHE II	Observed mortality higher than predicted by any model
	Single center	APACHE III	Worst discrepancy with trauma, respiratory, neurologic, and renal disease
	n = 2661–2795	SAPS II	Best calibration with APACHE II
			ROC area >0.8 all models
Moreno et al.[115]	Europe	MPM-II_0	Discrimination adequate (ROC 0.822 for SAPS II, 0.785 for MPM_0)
	89 centers	SAPS II	Both models overestimated risk of death
	n = 16,060		Large variations across subgroups of patients
Nouira et al.[116]	Tunisia	APACHE II	Observed mortality higher than predicted except with MPM_0
	3 centers	MPM-II_0 and II_{24}	Good discrimination, poor calibration for all models
	n = 1325	SAPS II	
Tan et al.[117]	China (Hong Kong)	APACHE II	Discrimination good (ROC area 0.87–0.88) but calibration poor
	Single center	SAPS II	Both models overpredict mortality
	n = 1064		
Metnitz et al.[118]	Austria	SAPS III	Original SAPS III overestimated mortality even with Central and Western Europe equation
	22 ICUs		Calibration improved with customization
	n = 2060		
Poole et al.[119]	Italy	SAPS III	Discrimination good
	147 ICUs		Calibration poor—general and South Europe
	n = 28,357		Mediterranean equations overestimated hospital mortality (SMR 0.73)

ICU, Intensive care unit; *ROC,* receiver-operating characteristic; *SMR,* standardized mortality ratio.

UTILITY OF SEVERITY OF ILLNESS INDICES

There are four major applications for severity of illness scoring systems:
1. Assessing ICU performance for quality improvement
2. Predicting and planning resource use and staffing
3. Comparing or stratifying populations in clinical research
4. As one factor to consider in guiding individual patient care

Risk-adjusted outcomes data will be shared with a variety of "customers," each of whom will have a different focus. In broad terms, clinicians and quality leaders will use data to drive improved care and efficiency, whereas patients, governments, and funders will be more interested in comparing performance among institutions.[15]

Quality Improvement and Benchmarking

Meaningful evaluation of ICU performance must consider both severity of illness of the patient population and characteristics of the institution. *Benchmarking* refers to the process of comparing an individual unit's performance against established case mix–adjusted standards with similar ICUs or with the units' own data over time. Benchmarking need not be for morbidity and mortality outcomes alone; severity adjustment also helps explain variations in cost and ICU LOS.[120] Outlier LOS status is only partially predicted by severity of illness, and factors such as long ward stays before ICU admission and absence of an intensivist-directed multidisciplinary care team increase LOS.[121]

The mortality rate and LOS for patients transferred to a referral hospital is higher than that of nontransferred patients,[122] and this referral bias[123] has implications in profiling hospital quality. Medical patients transferred from another hospital have higher acute physiology scores, but even after adjustment for case mix and severity of illness, experience longer hospital and ICU stays and have more than twice the risk of hospital mortality compared with directly admitted patients.[11] These authors suggest that a referral hospital with a 25% transfer-in rate would suffer a penalty when undergoing profiling. Conversely, transferring patients to a tertiary care center has beneficial effects to the exporting hospital, because death is attributed to the receiving hospital.[124] Transfer of mechanically ventilated patients from ICU long-term acute care (LTAC) facilities also significantly affects reported mortality and LOS.[125] Intrahospital transfers to a higher level of care after admission are also associated with excess mortality and LOS.[126] As noted earlier, discharge practices affect risk-adjusted rates, with a greater impact on large hospitals and when in-hospital, rather than 30-day mortality rates, are considered.[13]

Factors unrelated to quality of medical care or patient severity of illness thus affect public reporting of SMR results. Does the benchmarking tool play a role? SMR was calculated for 47 ICUs at 36 US hospitals using APACHE IVa and the ICOM-NQF models. Overall SMR was 0.89 using APACHE IVa and 1.07 using the NQF model. Disturbingly, the two models agreed on the significance and direction of the SMR only 45% of the time (Fig. 165.5). Units caring for more severely ill patients and with a higher percentage of patients receiving MV had the highest discordance.[127] SMR and SMR rank position of ICUs also depend on whether the endpoint is in-hospital mortality or mortality at 1, 3, or 6 months after ICU admission.[128] In an age of outcome-driven reimbursements, these discrepancies are financially important and also ethically troubling.[129] Public disclosure and rank-ordering ICUs on the basis of SMR or other metrics is thus highly problematic. Identifying hospitals with higher-than-expected mortality has no effect on market share[130] and, reportedly, does not improve process-of-care indicators.[131] Benchmarking relative performance among ICUs should likely be replaced by comparing improvement in performance over time. Furthermore, discrepancies between observed and expected outcomes should primarily be a marker to prompt more careful review.[132]

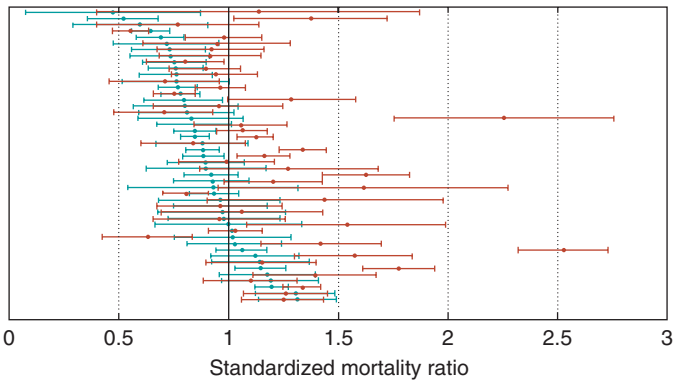

Fig. 165.5 Standardized mortality ratio (mean and 99% confidence interval) for 47 intensive care units (ICUs) evaluated using APACHE IVa *(blue)* and the ICOM-NQF *(red)* models. Over half of the performance assessments are discordant. (From Kramer AA, Higgins TL, Zimmerman JE. Comparing observed and predicted mortality among ICUs using different prognostic systems: Why do performance assessments differ? *Crit Care Med.* 2015;43:261–269.)

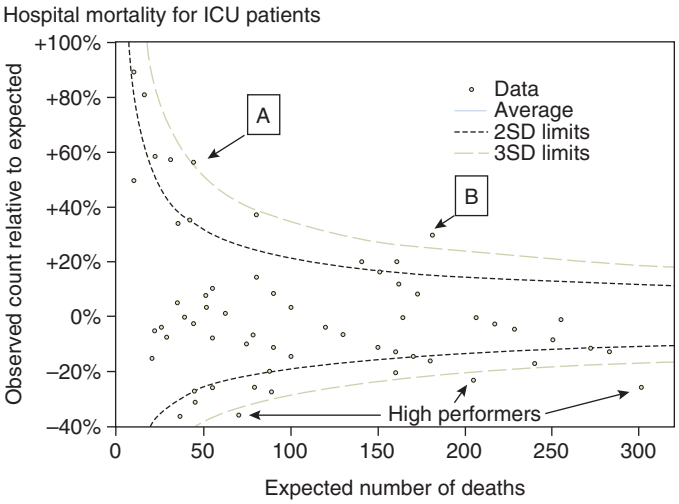

Fig. 165.6 Example of a funnel plot, using hypothetical data. The ratio of observed to expected deaths is plotted on the *y*-axis, with number of deaths on the *x*-axis. Two- and three-standard deviation (*2SD and 3SD*) limits are plotted, which helps identify two hospitals (A and B) as significant outliers ($P < .001$). Three hospitals ("high performers") have significantly fewer deaths than expected. Note that the observed count relative to expected (similar to the standardized mortality ratio [SMR]) is +50% (SMR 1.5) for the lowest-volume hospital, which is still within the 95% confidence intervals. Hospital B has a lower SMR at 1.35 (+35%) but, because of volume, can be identified as a significant outlier. *ICU,* Intensive care unit. A template for generating funnel plots like this can be downloaded from http://www.apho.org.uk/resource/item.aspx?RID=47242.

Case volume is an important consideration for evaluation and reporting. SMR should not be presented as a single number, but rather as a range that encompasses the 95% Cis based on sample size. Units with a low mortality rate require larger numbers of patients; this is well illustrated in a study by Dimick and colleagues examining the problems with small sample size when evaluating surgical mortality.[133]

Risk-adjusted mortality rates can be displayed over time—usually quarterly in smaller units and monthly in larger facilities. Standard statistical quality control charts and cumulative sums (CUSUM, a sequential technique) can be used to detect changes requiring investigation.[134] Exponentially weighted moving average control charts are said to signal the fastest compared with other types of risk-adjusted control charts.[135] For comparisons among institutions, funnel plots (Fig. 165.6) are preferable to league tables, as they incorporate volume-based control limits that reduce the risk of spurious interpretation inherent in a ranked list.[136] Other investigators have argued that funnel plots have difficulty identifying outliers with small volumes, while identifying divergence of statistical, but not clinical, importance when the numbers are large.[137]

Predicting and Planning Resource Use

The Therapeutic Intervention Scoring System (TISS) was developed as a method for quantifying patient care and severity of illness.[138] TISS was supplanted as a prognostic tool by the newer scoring systems once it was realized that application of technology depended on local availability and local practice. TISS is now used primarily to quantify nursing workload and costs.[139] The Rapoport-Teres graph (see Fig. 165.4) displays MPM risk-adjusted mortality on the *x*-axis and resource use (LOS) on the *y*-axis.[78] Similar displays are possible using other risk adjustment systems.

Use of Severity Indices In Clinical Research

Existing databases permitting severity adjustment make possible hypothesis-generating observations and conclusions about therapeutic choices in situations where randomized, prospective evaluations might not be permitted or funded. For prospective studies, severity scoring indices can be used to risk-stratify the population before randomization, thereby reducing the number of patients recruited and the cost of clinical trials. Clinical studies have also used scoring systems as part of inclusion criteria and to show that control and study groups have similar disease burdens.[140] Cytokine profiles correlate with APACHE and MPM scores in septic individuals[141]; however, severity scores were not designed for this purpose, and calibration has not been assessed in the clinical trial population. There is the danger that inclusion of age and chronic health points may exclude younger, previously healthy patients from trial entry.[142]

Uses of Severity Adjustment for Individual Predictions

The short answer is that risk-adjustment models are designed for evaluating groups and not for determining care of individuals. The problems with using scoring systems for individual patient care decisions arise from attempts to apply a probability estimate, which may range from 0 to 1, to an individual for whom the result will be 0 *or* 1. No model is accurate enough to predict that a given patient will certainly survive or invariably die, so scoring systems alone cannot dictate decisions to direct or withhold therapy. Sequential risk estimates, an approach explored by APACHE,[143] MPM,[33] and SOFA,[144] improve prognosis by incorporating data reflecting patient response to therapy over time. Objective predictions of the need for next-day life support are used by APACHE III and IV to guide triage and discharge decisions.[145] Increases in organ dysfunction scores after admission generally carry a poor prognosis,[146] although others have reported limited ability of the SOFA and MODS tools to discriminate outcome.[147] A meta-analysis of 46 studies suggests that 3%–7% of patients discharged from the ICU will die before hospital discharge[148]; ICU readmissions in this same population were 4%–6%.

Use of scoring systems to individualize therapy has not been well studied. Recombinant human activated protein C (rhAPC), now off

the market, considered an APACHE II score higher than 25 as a criterion for drug administration based on post hoc subgroup analysis of the PROWESS trial.[149] However, issues with this approach include wide variability in severity score between ICU admission and time of drug administration,[150] the confounding effect of DNR orders,[51] and bias against younger, previously healthy patients.[143] Further, an efficient emergency department may well stabilize the patients and lower the APACHE II score before arrival in the ICU.[151]

Objectively calculated severity scores are not necessarily more accurate than physician or nurse intuition when dealing with individual patients.[152,153] Accurate prognosis may be most difficult for patients with the highest risk of death. A multicenter study addressing the issue of medical futility found that divergent judgments on patient prognosis by doctors and nurses increased with higher SAPS II scores and longer ICU stays.[154] ICU physicians discriminate between survivors and nonsurvivors more accurately than SAPS II, MPM-I, or APACHE II.[153]

APACHE, SAPS, and MPM scores are *specific,* having more than 90% ability to predict survival, but are relatively *insensitive* in predicting death. Such information should not be taken as a rationale to rely on clinical judgment alone and forgo the use of formal scoring. The existing severity indices, despite their flaws, provide useful, objective information that can supplement clinical judgment for prognosis and triage, bearing in mind that patient autonomy and medical ethics also influence these decisions. Surrogates of critically ill patients generally appreciate reliable prognostic information but cope with unfavorable news in a variety of ways, including seeking information from other sources and avoiding or disbelieving prognostic information.[155]

PITFALLS IN THE APPLICATION OF SEVERITY OF ILLNESS INDICES

The use (and abuse) of databases for profiling ICUs and/or individual physicians is growing, despite flaws in administrative databases and problems identified with the application of statistical models[21] and physician profiling.[156] Assuming a properly developed model is applied, potential pitfalls in application fall into four major categories: data collection and entry errors,[157] misapplication of the model,[11,47,58] use of mortality as the sole criterion of outcome, and failure to account for sample size and chance variability[56,108,120] when reporting results (Box 165.4).

Errors in the EMR tend to propagate and become immortalized in the absence of a data collector who might note and correct artifacts and out-of-range values.[8] Upgrading hardware or software can lead to obscure errors. Determination of the diagnosis is prone to bias,[158] but using a system that is blind to diagnosis will be inaccurate if case mix is markedly skewed.[47] Less obvious is the fact that many models start the "clock" with ICU admission, the timing of which is not standardized[159] and frequently influenced by local conditions such as ICU bed availability.[160] ICUs also do not function in isolation in the process of care,[152] and the growing trend toward aggressive use of step-down facilities and offsite chronic ventilation and rehabilitation units raises the question of whether hospital mortality is valid when patients may be transferred to other facilities alive but are still technology dependent.[13,161] The issue of lead-time bias (pre-ICU stabilization) requires consideration; assessment is further complicated for patients with multiple ICU admissions,[161] whose second ICU admission during a single hospitalization is frequently excluded from subsequent analysis.[26] It is, for example, unclear which ICU stay should be counted for a patient who has a period of ICU observation after an uneventful vascular procedure and then develops complications requiring ICU readmission on the fifth postoperative day. It is increasingly necessary to evaluate the performance of an ICU *system,* which includes pre-ICU, ICU, and post-ICU care. Models now in development will address outcomes across the entire arc of care.

BOX 165.4 Potential Pitfalls in the Application and Reporting of Severity-Adjusted Outcome

Data Collection and Entry
- Inclusion of ineligible patients
- Missing variables and data management errors
- Substitution of available for properly timed data
- Transcription and data entry errors
- Improper communication between hospital clinical and risk adjustment applications
- Wrong diagnosis selected
- Administrative data reflective of clinical situation
- Deliberate "gaming" of the system—upcoding of comorbidities

Models
- Case-mix differences (critical threshold exceeded)
- Application to subsets of development population
- Changes in influence of variable with improving medical care
- Small clinical changes become large risk increments when continuous data are categorized.
- Lead-time bias

Outcomes
- Insufficient range of outcomes reported
- Use of proxy outcomes that inadequately reflect true status
- Patient lost to follow-up
- Chance variability masquerading as true difference
- Relationships of scores to resource use and costs reflect observed practice, not ideal

Reporting
- Confidence intervals not reported
- Inadequate sample size
- Physician of record misidentified
- Computational errors
- Misapplication of group data to individuals
- Misinterpretation of statistical significance as clinical significance

RECENT DEVELOPMENTS

The collection of large national databases has become established in several jurisdictions such as the United Kingdom, Finland, Australia, and New Zealand.[162] They have led to the accumulation of large bodies of illness severity scoring data exceeding >1 million patients, which has enabled the development of local recalibration of predicted mortality risk. For example, in the UK, the Intensive Care National Audit and Research Centre (ICNSARC) has developed a locally relevant prediction model ($ICNARC_{H\text{-}2018}$), which is calibrated to the UK critical care patient.[163] Similarly, the Australian and New Zealand Intensive Care Society (ANZICS) Centre for Outcome Research and Evaluation (CORE) has developed a risk prediction model for mortality calibrated to the local population (the ANZ Risk of Death model: ANZROD).[164] In each population such model outperforms generic US-developed models in accurately predicting outcomes. It is likely that such models will become more common as other national bodies create and maintain locally relevant ICU databases.

In the opposite direction, in the field of sepsis and of relevance to ICU clinicians, rapid assessment of severity with minimal information

has become relevant on a global scale outside of high-income countries and, in high-income countries, in the setting of emergency departments. In this regard, there has been much interest in the usefulness of a simple assessment of severity in patients with suspected infection called *qSOFA* (quick Sequential Organ Failure Score), which relies on the rapid assessment of patients with suspected infection by observing their respiratory rate, mental state, and blood pressure.[165] Such assessment allows the identification of patients with a higher illness severity and a high risk of requiring prolonged ICU stay and/or mortality and is being promoted as clinically useful.[166]

Finally, the increasing availability of EMR data, which is now routinely collected in many hospitals, can expand the data sources, their granularity, and their breadth and may allow a further evolution in prediction in the next decade in addition to providing electronic real-time information as the patient's condition changes.[167] More work in this field of dynamic digital illness severity scoring is expected in the next decade.

PEDIATRIC ILLNESS SEVERITY SCORES

Illness severity scoring systems developed for adults do not apply to children because the diagnoses are different, comorbidities are different, and normal physiologic values (e.g., heart rate, blood pressure, respiratory rate) are different and change according to age. Over the last 30 years several pediatric illness severity scoring systems have been applied children to specific populations and to a general severity of illness scoring system. Among such generic scoring systems are the Pediatric Index of Mortality (PIM),[168] the Pediatric Logistic Organ Dysfunction (PELOD) score,[169] and the Pediatric Risk of Mortality (PRISM).[170] Such systems carry similarities with the adult systems in terms of the principles applied, the use of physiology, the generation of predictive equations, and the probability of death. The SMR is also calculated and used to benchmark performance. However, pediatric illness severity scores have unique challenges because the databases used for their generation tend to be smaller in size and because mortality is a rare event. For example, the PRISM update of 2015 involved 10,078 admissions with a mortality rate of only 2.7%.[168] Despite such challenges, it achieved good model fit and validation and an auROC curve of between 0.88 and 0.9. Thus this new version (PRISM IV) provides a useful structure for an updated illness severity assessment in children, and the algorithm is now in the public domain for other users to take advantage of such improvements in prediction. However, the low mortality in pediatric ICUs of high-income countries has raised concern about the clinical validity of focusing on mortality as the outcome of interest and concern about the value of such information to low-income countries, where mortality is up to 10-fold higher. Given these observations, it is likely that high-income pediatric ICUs will focus on predicting functional outcomes rather than mortality, whereas low- or middle-outcome countries will need to develop locally relevant models.

CONCLUSION

APACHE, MPM, and SAPS are highly developed, prospectively validated tools useful for comparison of ICU performance in the care of groups of patients. Specialized models are available for burn, trauma, sepsis, cardiac surgery, and pediatric patients. When used as intended, these models allow stratification of patients for performance assessment, utilization management, clinical research, and dissemination of outcome results. Important implementation considerations include careful data collection, appropriate matching of the model and the population under study, and use of proper sample sizes and CIs in reporting results.

None of the models can perfectly predict the outcome for an individual patient.[169] However, this limitation is true of almost any test used in medicine and need not preclude the use of prognostic estimates for clinical decision support. Physicians must be alert to the limitations of severity-adjustment models in performance-based assessment because case-mix differences, inadequate sample sizes, or systemic errors in data collection can generate erroneous conclusions about the quality of care. In the end, what is measured is less important than what is done with the measurement. The encouraging news is that despite an increase in severity of illness between 1988 and 2012, risk-adjusted hospital mortality for patients admitted to ICUs has decreased significantly, an observation that would have been impossible without the benefit of severity of illness scoring systems.[170]

ACKNOWLEDGMENTS

We would like to acknowledge Dr Thomas L. Higgins, the author of the same chapter in the previous edition of this textbook. The present version is a revised version of his excellent treatment of this topic.

KEY POINTS

- Stratification of outcome based on risk factors is necessary when comparing outcomes obtained by different institutions, intensive care teams, and treatment strategies.
- Although mortality is readily defined and easily captured, it is insufficient as the sole measure of clinical outcome and does not capture other important endpoints such as complications, quality of life, or costs.
- Administrative data are plentiful but are typically less reliable than carefully collected clinical information. The quality of administrative databases can be improved by including laboratory information.
- Most outcome stratification models are developed empirically by performing univariate analysis of independent variables against a chosen outcome and are then refined using multivariate techniques.
- Model performance is assessed by measuring discrimination (typically by ROC-curve area) and calibration (typically by goodness-of-fit procedures).
- The SMR is created by dividing observed by expected mortality rates. Values less than 1.0, if statistically significant, suggest performance better than expected. SMR rankings can be problematic because of chance variation.
- The APACHE II through APACHE IV, the MPMs, and the SAPS are well-developed, prospectively validated models useful in adult general critical care units. The ICNARC and VA ICU models are also available. Customized models are useful in highly specialized ICUs or when evaluating population subsets such as pediatric, trauma, or cardiac surgery patients.
- Outcome predictions are intended for groups, not individuals. Mortality probability estimates range from 0 to 1.0, but an individual patient will either live or die. Mortality predictions also vary depending on when the data were geographically and temporally collected; results at ICU or hospital discharge do not necessarily correlate with 30-, 60- or 365-day results. Use of scoring systems to direct therapeutic choices has not been adequately studied, and risk-adjustment systems should never be the sole criteria for directing or withholding therapy in an individual patient.

ANNOTATED REFERENCES

Harrison DA, Gareth JP, Carpenter JR, et al. A new risk prediction model for critical care: The Intensive Care National Audit & Research Centre (ICNARC) model. *Crit Care Med.* 2007;35:1091–1098.

The ICNARC model uses patient physiology in addition to age, diagnostic category, source of admission, and the use of CPR before admission. In a population of 216,626 patients from England, Wales, and Northern Ireland between 1995 and 2003, this model discriminated better (ROC area 0.86) than APACHE II, APACHE III, SAPS II, or MPM-II. This study offers further evidence that geographic variation occurs and that misleading SMR results may occur when models developed in one environment are applied to a new population.

Higgins TL, Teres D, Copes WS, et al. Assessing contemporary intensive care unit outcome: An updated mortality probability admission model (MPM_0-III). *Crit Care Med.* 2007;35:827–835.
MPM-III was developed on 124,855 patients admitted to 135 ICUs at 98 hospitals in the United States (94), Canada (3), and Brazil (1) between 2001 and 2004. It corrects the drift in calibration since MPM-II and adds terms for "full code" resuscitation status at admission and for the absence of any MPM-II risk factor except age to account for better-than-expected outcomes in otherwise healthy elderly patients. Discrimination by ROC is 0.82, and the model calibrates well. Subsequent publications have prospectively validated the model, examined patient subgroups, and updated the "Rapoport-Teres" resource utilization graph used by MPM and Project IMPACT.

Kramer AA, Higgins TL, Zimmerman JE. Comparing observed and predicted mortality among ICUs using different prognostic systems: Why do performance assessments differ? *Crit Care Med.* 2015;43:261–269.
Two widely used contemporary models (APACHE IVa and the National Quality Forum–endorsed ICOM modification of MPM) were evaluated in a common data set of 89,353 consecutive unselected ICU admissions from 2008 to 2013. SMR was assessed and compared for each of the 47 ICUs. Surprisingly, the two models agreed on the significance and direction of the SMR only 45% of the time. Differences were most pronounced in units with a high percentage of mechanically ventilated and/or severely ill patients. Four hospitals were assessed as having inferior performance using the NQF model but superior performance using APACHE. In addition, two more hospitals would have been stigmatized by NQF results while being acceptable using APACHE. This study highlights the risk inherent in stigmatizing hospitals when performance depends on the benchmarking system used.

Metnitz PG, Moreno RP, Almeida E, et al. SAPS 3—From evaluation of the patient to evaluation of the intensive care unit. Part 1: Objectives, methods and cohort description. *Intensive Care Med.* 2005;31:1336–1344.

Moreno RP, Metnitz PG, Almeida E, et al. SAPS 3—From evaluation of the patient to evaluation of the intensive care unit. Part 2: Development of a prognostic model for hospital mortality at ICU admission. *Intensive Care Med.* 2005;31:1345–1355.
The SAPS 3 study used an international population of 19,577 patients in 307 ICUs. Regional variation in outcomes occur, and SAPS 3 has customized admission equations for Australasia, Central/South America, Central/Western Europe, Eastern Europe, North Europe, Mediterranean countries, and North America. ROC area is 0.85 with satisfactory calibration.

Nathanson BH, Higgins TL. An introduction to statistical methods used in binary outcomes modeling. *Semin Cardiothorac Vasc Anesth.* 2008;12:153–166.
This report is for those who enjoy getting "under the hood" of risk-adjustment models.

Render ML, Deddens J, Freyberg R, et al. Veterans Affairs intensive care unit risk adjustment model: Validation, updating, recalibration. *Crit Care Med.* 2008;36:1031–1042.
In total, 36,420 consecutive ICU admissions in 1999–2000 and a second cohort of 81,964 cases in 2002–2004 were used to update the VA-ICU model. ROC areas were good. The VA-ICU population is overwhelmingly male (97.2%) and somewhat older. ROC area was 0.89, comparable to APACHE IV in this population, and better than MPM_{24}-II (ROC 0.84), SAPS III (ROC 0.86), or the SOFA score (ROC 0.81).

Seferian ED, Bekele A, Ognjen G, et al. Comparison of community and referral intensive care unit patients in a tertiary medical center: Evidence for referral bias in the critically ill. *Crit Care Med.* 2008;36:2779–2786.
Patients referred to the Mayo Clinic medical ICU between 1996 and 2004 were more severely ill, had higher mortality and longer length of stay, and were more likely to receive an active ICU intervention compared with local patients. When adjusted for severity of illness, mortality was as expected. Unadjusted differences were not seen in the surgical ICU, although hospital mortality rate was lower in referral surgical patients. Referral bias likely occurs because of differences in prior care or the transfer process that are not captured by risk adjustment. This bias has potential impact on clinical trials.

Sinuff T, Adhikari NKJ, Cook DJ, et al. Mortality predictions in the intensive care unit: Comparing physicians with scoring systems. *Crit Care Med.* 2006;34:878–885.
This analysis of observational studies (one using SAPS II, two using MPM-II, six using APACHE II, and three computer models) found that ICU physicians and objective models have moderate accuracy in the first 24 hours of ICU stay but that physicians better discriminate between survivors and nonsurvivors (physician ROC area 0.85 + 0.03 versus 0.63 + 0.06 for scoring systems). The conclusion that neither physicians nor scoring systems are sufficiently accurate to determine end-of-life decisions in the first 24 hours of ICU care is well supported by the data.

Timmers TK, Verhofstad MHJ, Moons KGM, et al. Intensive care performance: How should we monitor performance in the future? *World J Crit Care Med.* 2014;3:74–79.
Mortality is a limited outcome; health-related quality of life is another important benchmark to be followed after ICU or hospital discharge. Items that we do not routinely measure at present (both clinical and nonclinical) should be quantified and addressed by future systems.

Vincent JL, Opal SM, Marshall JC. Ten reasons why we should NOT use severity scores as entry criteria for clinical trials or in our treatment decisions. *Crit Care Med.* 2010;38:283–287.
Whereas the seemingly objective nature of scores make it tempting to apply their predictions to individuals, it is important to remember that these tools were designed for evaluating large groups of patients, not for individual prognosis or decision making. The authors point out that interobserver variability in score calculation, age bias, and issues with the starting time of critical care call into question the use of these scores for patient enrollment into clinical trials.

Zimmerman JE, Kramer AA. A history of outcome prediction in the ICU. *Curr Opin Crit Care.* 2014;20:550–556.
A firsthand account of how APACHE evolved between 1979 and the present. Key points about model complexity, advances in computer technology, government support, and risk adjustment in the public realm are considered.

Zimmerman JE, Kramer AA, McNair DS, et al. Acute Physiology and Chronic Health Evaluation (APACHE) IV: Hospital mortality assessment for today's critically ill patients. *Crit Care Med.* 2006;34:1297–1310.
APACHE was the first widely used prognostic scoring system and has been periodically updated over the past 30 years. The latest iteration was developed on 110,558 patients in 2002–2003. APACHE IV has very good discrimination (ROC area 0.88) and calibration and corrects the systematic overestimation of mortality that developed since publication of APACHE III.

Long-Term Outcomes of Critical Illness

Florian B. Mayr and Sachin Yende

Despite a continuous increase in the incidence of critical illness syndromes such as sepsis and acute respiratory distress syndrome (ARDS), improvements in supportive care have resulted in improved survival over the past few decades.[1–4] For example, sepsis is estimated to affect between 30 and 50 million people each year worldwide.[5,6] Global sepsis mortality has declined from 30% in 1990 to 20% in 2017,[5] resulting in an increasing number of sepsis survivors with variable prognosis.[7,8] Half of patients recover, one-third die during the following year, and one-sixth have severe persistent impairments.[7] Impairments include development of an average of one to two new functional limitations; a threefold increase in prevalence of moderate to severe cognitive impairment; and a high prevalence of mental health problems, including anxiety, depression, or posttraumatic stress disorder, for which survivors will seek care from many types of clinicians (Table 166.1).[8–11] Current guidelines provide no recommendations on management for these complex patients after discharge, and there is a desperate need for improvement. According to an international survey of 1731 critical illness survivors, the majority reported dissatisfaction with or complete lack of support services after hospital discharge.[12]

Patients who survive their initial acute illness but consequently experience persistent organ failures necessitating prolonged intensive care meet the definition of chronic critical illness (CCI).[13,14] This illness is characterized by high hospitalization costs, frequent post–acute care use, and poor long-term survival. For example, a third of sepsis survivors are readmitted within 90 days, and rehospitalization after sepsis accounts for 12.2% of all US hospital readmissions and 14.5% of readmission costs.[15] The clinical and financial burden of CCI is expected to increase in the coming years because of both an aging population and improvement in short-term survival. In a population-based sample of five US states, we found that the prevalence of CCI based on a consensus definition has been increasing over time, with associated in-hospital costs exceeding $25 billion per year.[16] These findings underscore the importance of CCI to the field of critical care, particularly for healthcare policy and planning. Spending on CCI is likely to rise further as the population ages, because the prevalence of CCI increases dramatically with age.[16] The most common initial diagnoses that lead to CCI are acute respiratory failure requiring mechanical ventilation and sepsis. Hospital-acquired infections may contribute to mortality among hospitalized patients and to the burden of CCI.[17]

With this shift in critical illness epidemiology, traditional outcomes such as short-term mortality need to be complemented by patient-centered outcomes that capture long-term health-related quality of life (HRQoL), physical and mental functioning, time spent at home, hospital readmissions, and morbidity and mortality (Fig. 166.1).

In this chapter, we review recent advances in our understanding of long-term outcomes after critical illness. Most literature focuses on long-term outcomes after ARDS and sepsis. We describe the epidemiology, risk factors, clinical manifestations, management, and outcomes for each domain of post–intensive care syndrome (PICS).

COGNITIVE IMPAIRMENTS AFTER CRITICAL ILLNESS

Critical illness frequently results in new cognitive impairment, including deficits in memory, attention, and concentration. The reported incidence has been highly variable depending on study population and trial size, ranging from 4% to 62%.[18] Cognitive impairment after intensive care unit (ICU) admission is also taxing to patients and their families and carries an enormous societal cost estimated at $18 billion per year.[19]

Risk factors for long-term cognitive impairment, particularly preventable ones, are not well understood. A complicating factor is the uncertainty of whether critical illness and/or its treatment is the cause of the observed neurocognitive impairments or if it worsens preexisting subclinical disease. A prospective cohort study in elderly adults who had no known cognitive dysfunction at baseline showed that acute care or ICU hospitalization resulted in a greater cognitive decline and incident dementia compared with individuals who did not require hospitalization.[20] Similarly, Pandharipande and colleagues reported new severe cognitive deficits affecting memory, attention, processing speed, and executive function in a broad population of 328 ICU survivors that were detectable at 3 and 12 months after critical illness.[21] The etiology of cognitive impairments after critical illness is likely multifactorial and results from various factors that interact dynamically with preexisting and acute illness variables to produce adverse outcomes. Acute illness severity alone does not explain the cognitive impairments experienced by ICU survivors. Although current data do not suggest a clear association between age, acute illness severity scores, cumulative doses of analgesia and sedation, hypoxia, hypotension, hyperglycemia, and inflammation with adverse neurologic sequelae, the duration and severity of acute delirium have emerged as the strongest predictors of adverse cognitive outcomes in several recent studies.

In the study by Pandharipande and colleagues, longer duration of delirium was independently associated with worse cognitive performance at 3 and 12 months in tests of global cognition and executive function.[21] Similar findings were reported in a small prospective study of 77 patients with ARDS who had in-person cognitive testing 3 and 12 months after ICU discharge. The duration of delirium was an independent risk factor for cognitive decline at both time points even after adjusting for preexisting cognitive impairment, age, severity of illness, level of education, severity of sepsis, and cumulative exposure to sedatives.[20] Interventions to prevent or shorten delirium in critically ill patients are therefore much needed and center around promoting and improving the quality of sleep.[22] Ziprasidone and haloperidol, two drugs commonly used to treat ICU delirium, neither increased the number of days alive without coma or delirium nor reduced 90-day

TABLE 166.1 Common Sequelae in Survivors of Critical Illness

Neurocognition	Behavioral	Neuromuscular	Immune System	Caregiver & Family
Cognitive dysfunction	Depression	Polymyopathy	Immunosuppression	Caregiver burden/burnout
Attention deficits	Anxiety	Polyneuropathy	Inflammation	PTSD
Impaired executive function	Posttraumatic stress disorder (PTSD)	Chronic pain	Recurrent infection	Anxiety
Chronic fatigue	Insomnia		Exacerbation of chronic disease	Depression

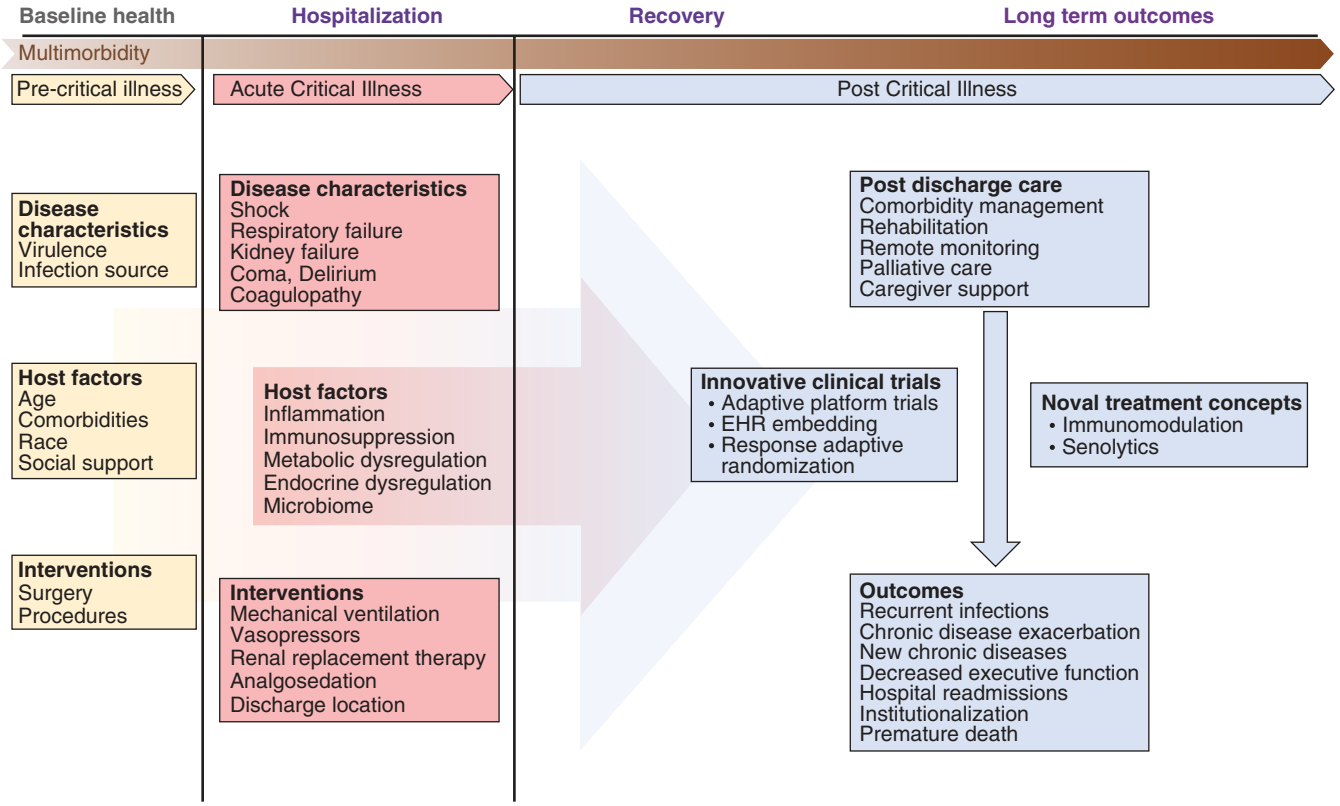

Fig. 166.1 Conceptual Model of Factors Contributing to Long-Term Outcomes After Critical Illness.
EHR, Electronic health record.

mortality, time to freedom from mechanical ventilation, and time to ICU or hospital discharge in a large multicenter placebo-controlled trial.[23] Nocturnal administration of low-dose dexmedetomidine (average dose 0.36 μg/kg/h) was recently reported to prevent delirium, reduce days spent with coma, and have an opiate-sparing effect in a randomized placebo-controlled trial in critically ill adults.[24] Interestingly, dexmedetomidine did not improve patient-reported sleep quality. An earlier systematic review also suggested potential for dexmedetomidine and quetiapine to prevent ICU delirium, but neither drug influenced long-term outcomes.[25]

Early identification of cognitive impairment should in theory expedite appropriate evaluations and treatment. Evaluation for cognitive dysfunction in the critical care setting must be brief, easy to administer, and widely applicable. Currently available tests such as the modified mini-mental state examination (MMSE) and Montreal Cognitive Assessment (MoCA), however, cannot be used to predict long-term cognitive dysfunction.[26,27] Evolving research suggests that patients who experience critical illness–induced delirium and persistent cognitive dysfunction may have a variety of abnormal findings on neuroimaging, including brain atrophy; leukoencephalopathy; and neuronal loss in the insula, frontal lobes, and thalamus.[28] In addition, a multicenter prospective cohort study in 321 critically ill patients showed generalized slowing on routine clinical electroencephalography (EEG) correlated with delirium severity, length of hospitalization, functional outcomes, and mortality and may be a promising biomarker to identify patients at high risk for adverse outcomes early during hospitalization.[29]

Integrated approaches specifically geared toward the management of mechanically ventilated patients have proven useful, with the most widely applied being the ABCDEF bundle.[30] Initially focusing on daily sedation interruption and spontaneous breathing trials, this bundle also emphasizes the importance of delirium management, delirium prevention, early mobility, and family engagement.[30] Despite never being formally tested in clinical trials, clinical practice suggests that the ABCDEF bundle is safe and may improve delirium outcomes in real-world settings.[31,32] These findings were confirmed in a recent prospective multicenter cohort of over 15,000 adults from the ICU Liberation Collaborative, in which use of the ABCDEF bundle was

associated with a reduced incidence of delirium along with improvements in other patient-centered outcomes.[33]

PSYCHIATRIC SEQUELAE OF CRITICAL ILLNESS

Psychiatric disorders, including depression, anxiety, and posttraumatic stress disorder (PTSD), are common among critical illness survivors. For instance, in a recent systematic review, Rabiee and colleagues reported that approximately 30% of ICU survivors had clinically significant depression.[34] Early post-ICU depressive symptoms were a strong risk factor for subsequent depressive symptoms, and post-ICU depressive symptoms were associated with substantially lower HRQoL. Patients exposed to mechanical ventilation and longer ICU lengths of stay are at higher risk for developing a new diagnosis of "mental illness" compared with noncritically ill hospitalized patients. Further study is necessary to better understand patient predisposition, illness, and treatment-specific determinants of affective morbidity and appropriate tools for diagnosis and monitoring. Another important and understudied area is the frequency of suicide after critical illness, particularly given the increasing prevalence with age and burden of chronic illness.[35–37]

Several studies have examined the relationship between critical illness and the development of PTSD. Schelling and colleagues were the first to introduce the concept of PTSD resulting from critical illness and traumatic experiences in the ICU.[38,39] Among their cohort of 80 long-term ARDS survivors, almost one-third reported impaired memory, nightmares, anxiety, and sleeping difficulties after ICU discharge, with a PTSD prevalence rate of 28%. A recent meta-analysis of prevalence, risk factors, and prevention/treatment strategies for PTSD symptoms in critical illness survivors reported clinically important PTSD symptoms in approximately one-fifth of critical illness survivors at 1-year follow-up.[40] Patients with underlying psychiatric comorbidities, benzodiazepine use, or early memories of frightening ICU experiences had the highest prevalence of PTSD. A randomized controlled trial in 35 French ICUs studied the use of an ICU diary filled by caregivers and family members on PTSD symptoms, anxiety, and depression in patients and family members at 3 months after ICU discharge. In this study, the overall prevalence of significant PTSD symptoms was 29.9% among ICU survivors and was not reduced by an ICU diary.[41] Equally disappointing, a nurse-led complex psychological intervention that was initiated in the ICU did not reduce the prevalence of self-reported PTSD symptoms at 6 months.[42]

CRITICAL ILLNESS–ASSOCIATED NEUROMUSCULAR DYSFUNCTION

ICU-acquired weakness is common in patients with ARDS and other complex critical illness. Regardless of disease process, muscles and nerves are injured, resulting in prolonged mechanical ventilation and poor functional outcomes. Previous research has highlighted the concept of a continuum of weakness that begins with muscle injury documented within hours of mechanical ventilation that may persist with incomplete recovery for years after ICU discharge.[43] Muscle weakness and impaired function constitute an important morbidity of severe critical illness.[44] In a recent prospective cohort study that used daily point-of-care ultrasound to measure diaphragm thickness in mechanically ventilated patients, almost 50% of patients had a 10% reduction in diaphragm thickness by ICU day 4. Diaphragm atrophy was associated with prolonged mechanical ventilation and ICU length of stay. Interestingly, development of increased diaphragm thickness as a marker of excessive inspiratory effort was also associated with prolonged mechanical ventilation.[45]

Critical Illness Polyneuropathy

Critical illness polyneuropathy (CIP) primarily manifests itself as a mixed sensorimotor neuropathy. CIP is quite common in patients with systemic inflammatory response syndrome and sepsis, with an occurrence of 70%–100% of patients with a longer ICU stay.[46] It affects limb and respiratory muscles, whereas facial muscles are usually spared.[46] Limb involvement is symmetric and most prominent in the proximal muscle groups of the lower extremities. Detection of the true incidence of CIP is complicated by lack of consensus on surveillance, timing, and nature and limitations of testing because of patient sedation or poor cooperation, formal definition, and diagnostic criteria.[47] Weakness may initially be absent or difficult to detect clinically in these patients, but subsequent electromyography testing will demonstrate abnormalities showing an initial primary axonal degeneration of the motor neurons, followed by the sensory neural fibers, and this coincides with acute and chronic changes of denervation noted on muscle biopsies in affected patients.[48]

In sepsis, the pathogenesis of CIP is linked to a perturbation in the microcirculation, with resultant axonal injury and degeneration. There is also evidence for a disruption of nerve action potential, which may be reversible over the course of the disease.[49] Other risk factors associated with the development of CIP include hyperglycemia, and tight glycemic control has been shown to reduce the incidence of CIP in critically ill patients.[50] The exact pathophysiologic link between glucose control and neuroprotection remains unclear but may involve preservation of mitochondrial functioning, calcium homeostasis, or modulation of nitric oxide production.[51–53] In contrast to earlier associations between neuromuscular dysfunction and use of neuromuscular blockers, subsequent research has not been able to corroborate this previous association.[54,55] Data on the association between glucocorticoid use and weakness remain controversial; however, a national multicenter prospective trial in acute lung injury survivors reported a significant association between mean daily corticosteroid dose with impairments in physical outcomes after 1 year.[56]

Critical Illness Myopathy

The reported incidence of critical illness myopathy (CIM) varies between 48% and 96% in prospective studies that have included muscle biopsy as part of their diagnostic evaluation.[47] Pathologically, CIM is characterized by a diffuse, nonnecrotizing myopathy associated with fatty degeneration of muscle fibers, fiber atrophy, and fibrosis.[43] This has been described in patients with sepsis and in those treated with corticosteroids and neuromuscular blockers. Patients clinically appear weak and paretic and are difficult to wean from the ventilator. They may be indistinguishable from patients with CIP. Muscle biopsy allows differentiation among these lesions.[43,47]

The pathophysiology of CIM entails catabolism, inflammation, and derangement of membrane excitability. Protein catabolism and an increase in urinary nitrogen loss are observed in CIM.[57] Muscle biopsies in affected patients show low glutamine, protein, and DNA levels. There is evidence for the upregulation of the calpain, caspase-3, and ubiquitin proteolytic pathways in concert with an increase in apoptosis,[57–59] but mitochondrial dysfunction and oxidative stress likely do not play a significant role.[60]

Early Mobility and Rehabilitation

The results of studies examining the effects of early mobilization and physical rehabilitation in ICU patients do not suggest any improvement in short- and long-term outcomes. Most recently, a single-center randomized controlled study in 312 mechanically ventilated

adults that evaluated early in-bed cycling and electrical stimulation of the quadriceps muscles in addition to standard early rehabilitation did not result in greater muscle strength at ICU discharge, more ventilator-free days, better walking capability, or better HRQoL at 6 months.[61] The heterogeneity of critically ill populations, inability to risk-stratify patients because of the lack of detailed understanding of underlying pathophysiology, and resulting lack of standardization are potential explanations for the negative results to date.[62]

CRITICAL ILLNESS–ASSOCIATED MORBIDITY AND PERSISTENT IMMUNE DYSFUNCTION

Critical illness survivors face a substantially elevated mortality after discharge from the hospital, a problem best documented for sepsis.[63,64] In addition, most severe sepsis survivors are either diagnosed with a new health condition or have worsening of existing health conditions, such as cardiac disease (including heart failure), chronic kidney disease, and chronic pulmonary disease, among others.[7]

More recent work suggests that patients with CCI experience concurrent immunosuppression and inflammation that are associated with persistent protein catabolism. Despite early enteral nutrition, there is a tremendous loss of lean body mass with proportional functional decline and poor wound healing. An estimated 30%–50% of patients with CCI progress into PICS.[65] Clinically, patients with PICS have recurrent nosocomial infections and poor wound healing and are often discharged to long-term acute care facilities where they experience recurrent infections, hospital readmissions, failure to rehabilitate, and an indolent death.

Acute sepsis is characterized by concurrent inflammation and immunosuppression, which persists in two-thirds of survivors and has been associated with an increased risk of hospital readmission and cardiovascular death, including atrial fibrillation, myocardial infarction, stroke, need for coronary revascularization, diabetes, and new-onset seizures.[66–70] Indeed, severe sepsis is a complex disease process with a plethora of potential mechanisms to explain how different aspects of sepsis and the short-term care of patients with sepsis may drive late sequelae. Some of these pathways may be more relevant to sepsis (i.e., immunosuppression), whereas others may be shared with other acute illnesses (i.e., inflammation). The recognition of persistent immunosuppression in many sepsis survivors has resulted in exciting and novel therapeutic approaches.[71–73] Several early clinical trials have demonstrated the safety and efficacy of immunomodulatory drugs such as interleukin-7 and immune checkpoint inhibitors in reversing biomarkers of immunodeficiency.[74–76] Whether these immunomodulatory drugs modify clinical disease trajectories and improve clinical outcomes is uncertain and an area of active research.

QUALITY OF LIFE

Each of the outcomes described earlier may adversely affect the quality of life after critical illness.[77] Approximately a third of sepsis survivors have significant impairments in various domains of quality of life 6 months after hospital discharge.[77] The impairments in cognition and physical function described earlier may persist, leading to problems in mobility and performing activities of daily living and lasting disability. Furthermore, although many sepsis survivors return home, approximately one-third require additional help at home or are in a skilled nursing facility, acute care hospital, or rehabilitation facility.[7]

CAREGIVER AND FAMILY BURDEN IN CRITICAL ILLNESS

Caregiver outcomes and their interaction with ICU survivors have gained importance in understanding the effect of critical illness on the family unit.[78] There is a considerable body of work evaluating these interactions in other medical conditions, such as stroke or cancer.[79,80] These data show that caregivers who are challenged in their caregiving contribute to poor outcomes and threaten home care for survivors. Studies indicate that most ICU survivors who received long-term mechanical ventilation required the assistance of a family caregiver 1 year after their critical illness.[81] Providing such care may result in PTSD, emotional distress, depression, anxiety, and reduced HRQoL.[22,82,83] In addition, caregivers experience significant burden because of a patient's physical and psychological dysfunction and lifestyle disruption associated with the challenges of managing complex care at home.

MODELS OF AFTERCARE FOR CRITICAL ILLNESS SURVIVORS

Most ICU survivors are discharged home and return to their primary care physicians and subspecialists for aftercare. Alternative care models such as ICU survivor clinics are rapidly expanding, where integrated care is provided at a single location focused on treating sequelae of critical illness.[84–86] Most of these programs are associated with large academic medical centers, and wide variation in staffing exists. Some clinics are led by a single discipline; others embrace a multidisciplinary team approach, including health and social services to address the frequent socioeconomic problems that patients and their caregivers experience during recovery from critical illness. However, clinic-based care may not be accessible to debilitated patients or those with poor social support. Innovative aftercare delivery models are currently being explored to address these barriers, including the use of mobile ICU recovery programs and of telemedicine services.[87,88] In addition, the importance of peer support has been recognized through which survivors and their families can facilitate their own recovery and improve their quality of life by relating to others with shared experiences. Several different models of peer support are currently being developed and piloted to help patients and families recover and grow in the postcritical care setting.[89]

PALLIATIVE CARE FOR CRITICAL ILLNESS SURVIVORS

One-third of older adult ICU survivors are discharged to post–acute care facilities, nearly half are rehospitalized, and 25%–65% die within the following year.[7] Baldwin and colleagues demonstrated in their single-center analysis that 90% of elderly ICU survivors that were discharged to a post–acute care facility had at least one potential palliative care need, but less than 3% of patients had received a palliative care consultation during their hospitalization. Since then, larger multicenter studies have confirmed that palliative care services are underused in both medical and surgical patients who are seriously ill and at high risk of poor long-term outcomes.[90–93] Palliative care focuses on providing relief from pain and stress to patients with serious illness and is often provided simultaneously with curative or life-sustaining treatments.[94] Palliative care also seeks to align treatment plans with patients' goals and therefore may facilitate transitions to hospice in older ICU survivors who often have high end-of-life healthcare resource use. Indeed, recent studies have demonstrated

that palliative care can have a meaningful effect on patients' quality of life and end-of-life care, reduce end-of-life use of acute care resources, and prolong survival.[91,95,96]

FUTURE DIRECTIONS

The findings that a large proportion of patients who survive critical illness have poor long-term outcomes, which may be attributed to a combination of CCI and preexisting poor baseline health, have implications for endpoints of future clinical trials. Traditionally, primary endpoints included only mortality. However, a comprehensive evaluation of new therapies should include assessment of long-term morbidity and mortality. Because such an assessment is time-consuming and often cost-prohibitive, particularly given decreasing federal funding for clinical trials,[97] short-term surrogate endpoints as proxies for long-term patient-centered outcomes are increasingly important in the early evaluation of novel therapeutic interventions.[98] With increasing insight into the pathophysiology of CCI,[65,66,99] future studies that combine big data, artificial intelligence, and wearable health technology to augment medical decision making,[100,101] in addition to refined approaches to clinical trial design,[102,103] are necessary to maximize chances of identifying successful novel interventions for distinct subgroups of critical illness survivors.

CONCLUSION

With the growth of intensive care and concurrent improvements in supportive care, patients are more likely to survive their initial episode of critical illness. Critical illness survivors subsequently face a wide array of problems, including developing functional deficits, neuromuscular and neuropsychological morbidity, and worsening of existing chronic diseases or development of new chronic diseases, which often result in permanent functional impairment. This results in ongoing high healthcare use, frequent hospitalizations, and substantial strain on families and caregivers. Despite exciting advances in the last few years, future research is needed to better understand the pathophysiology of CCI, to develop innovative ways to engage with patients and their caregivers to optimize the delivery of post-ICU care, and to improve patient selection and clinical trial design in a way that maximizes our chances of identifying interventions that will improve patient-centered outcomes.

ACKNOWLEDGMENT

All authors deny any conflict of interest. This material is the result of work supported with resources and the use of facilities at the VA Pittsburgh Healthcare System. The views expressed in this chapter are those of the authors and do not necessarily reflect the position or policy of the Department of Veterans Affairs or the US government. FBM is currently supported by a VA VISN4 Competitive Career Development fund and NIH K23GM132688.

KEY POINTS

- Despite a continuous increase in the incidence of critical illness syndromes such as sepsis and ARDS, improvements in supportive care have resulted in improved survival over the past few decades. Current guidelines provide few recommendations on how to manage these complex patients after hospital discharge.
- CCI is associated with in-hospital costs of >$25 billion per year, which underscores its importance to the field of critical care, particularly for healthcare policy and planning.
- Most ICU survivors are discharged home and return to their primary care physicians and subspecialists for aftercare. Innovative aftercare delivery models are currently being explored to reduce barriers to high-quality post-discharge care, including the use of mobile ICU recovery programs and telemedicine services.
- The recognition of persistent immunosuppression in many critical illness survivors has resulted in exciting and novel therapeutic approaches. Several early clinical trials have demonstrated safety and efficacy of immunomodulatory drugs such as interleukin-7 and immune checkpoint inhibitors on reversing biomarkers of immunodeficiency.
- Future studies that combine big data, artificial intelligence, and wearable health technology to augment medical decision making, in addition to refined approaches to clinical trial design, are necessary to maximize chances of identifying successful novel interventions for distinct subgroups of critical illness survivors.

Early Ambulation in the ICU

Erika L. Brinson, Angela K.M. Lipshutz, and Michael A. Gropper

Bedrest has historically been prescribed as an adjunct to the treatment of acute illness and to rehabilitation after surgery. Even as physicians and researchers began to realize the "evil sequelae of complete bed rest"[1] in both medical and surgical patients, this therapy remained commonplace in the intensive care unit (ICU). Indeed, healthcare providers in the ICU have traditionally focused their attention on normalizing the physiologic derangements that threaten their patients' survival. However, therapeutic advances and improvements in the management of critically ill patients have improved the outcomes in this patient population.[2–4] As survival from critical illness has improved, the long-term complications and associated therapies have become more apparent. A large proportion of these patients experience long-term cognitive, psychological, and physical disability, with less than half of critical illness survivors returning to their prior functional status 1 year after discharge.[5–8] Early mobilization and ambulation of critically ill patients are feasible, safe, and cost-effective interventions that improve physical, functional, and neuropsychiatric outcomes.[9–18]

THE PHYSIOLOGY OF BEDREST

Bedrest has, at one time or another, been promoted as therapy for almost all ailments. Hippocrates suggested that all pain could be relieved by bedrest.[19] However, as early as the 1940s, it was recommended that "the physician . . . always consider complete bed rest as a highly unphysiological and hazardous form of therapy."[1] Nonetheless, it was not until recently that the medical community began to acknowledge the ill effects of complete inactivity and immobility during critical illness.

Inactivity and immobility have profound effects on skeletal muscle. Disuse leads to reduced protein synthesis, accelerated proteolysis, and increased apoptosis, ultimately resulting in a catabolic state, atrophy, and physical weakness.[20,21] In a study of young, healthy volunteers, 28 days of bedrest resulted in a 0.4 ± 0.1 kg loss of lean leg mass and a 22.9 ± 3.5% reduction in leg extension strength.[22] When healthy volunteers were subjected to 28 days of bedrest and hydrocortisone to achieve plasma cortisol levels mimicking trauma or critical illness, leg extension strength decreased even further (28.4 ± 4.4%, $P = .012$), and the loss of lean leg mass was increased threefold compared with bedrest alone (1.4 ± 0.1 kg, $P = .004$).[23] Therefore it is apparent that both immobility and the systemic effects of critical illness contribute to the development of weakness in ICU patients.

ICU-ACQUIRED WEAKNESS

Neuromuscular weakness is a common complication of critical illness. Approximately half of ICU patients with sepsis, multiorgan failure, or prolonged mechanical ventilation have electrophysiologic evidence of neuromuscular dysfunction.[24] In patients with both sepsis and multiorgan failure, the incidence can approach 100%.[25] Electrophysiologic (EP) testing can detect weakness as early as 18–24 hours into the onset of critical illness.[25,26] Clinical evidence of weakness is present in a smaller, but significant, portion of ICU patients. The duration of bedrest is associated with worsening muscle weakness. Muscle strength has been estimated to decrease by 3%–11% with each additional day.[27,28] Many ICU survivors continue to have significantly impaired physical function and decreased quality of life for years after their hospitalization.[8,27]

One of the many causes of generalized weakness in the critically ill population is intensive care unit–acquired weakness (ICUAW), a clinical syndrome of acquired neuromuscular dysfunction with no identifiable causative factors other than critical illness and its treatment.[29] ICUAW is an umbrella term for different pathophysiologic entities, including muscle atrophy, critical illness polyneuropathy (CIP), critical illness myopathy (CIM), or a combination of polyneuropathy and myopathy called *critical illness neuromyopathy* (CINM).[28,30] The pathophysiology of ICUAW is complex and not well-understood; it includes the sequelae of bedrest and the effects of critical illness–induced cytokine production such as impaired microcirculation, metabolic derangements, increased protein catabolism, and changes in nerve and muscle membrane excitability.[31]

Diagnosis

The lack of a gold-standard diagnostic test has made it difficult to study ICUAW. Diagnosis of the pathophysiologic entities of CIP, CIM, and CINM requires advanced and/or invasive testing; EP evidence of axonal polyneuropathy confirms the diagnosis of CIP, whereas either EP and/or histologic findings of myopathy are used to diagnose CIM.[32] The Medical Research Council (MRC) muscle strength score is one of the most commonly used clinical evaluations of ICUAW.[29] It involves grading the strength of different muscle groups in each extremity on a scale from 0 to 5. The MRC sumscore, initially developed to assess muscle strength in patients with Guillain-Barré syndrome, involves testing strength in six different muscle groups bilaterally and adding these 12 scores together.[33] The result can range from 0 (paralysis) to 60 (normal strength), and the diagnosis of ICUAW requires a score less than 48. The MRC sumscore is nonspecific for ICUAW; therefore other causes of weakness in critical illness must be excluded. In addition, the MRC sumscore has many limitations in the critically ill, most notably the need for an awake, cooperative patient who is able to maximally contract all extremities.[29]

Routinely performing EP studies and muscle biopsies on all at-risk patients presents an obvious challenge, and using manual strength testing requires active participation. Developing a single diagnostic test that could be used even on comatose patients would facilitate

uniformity in study design and help determine the incidence, risk factors, and outcomes of ICUAW. Limited nerve conduction studies (NCS) and quantitative neuromuscular ultrasound have both been evaluated, and limited NCS in particular shows promise as a sole diagnostic tool. Peripheral muscle ultrasound may be able to detect muscle weakness and assist with early diagnosis, but further studies are needed to help standardize this technique.[34] Because of the current lack of an effective therapeutic option, making the early diagnosis of ICUAW does not affect outcomes, and as such, routine use of EP studies or quantitative muscle ultrasound in the ICU has not become standard practice.[30]

Risk Factors

A number of risk factors have been implicated in the development of ICUAW. Some of the earliest and most frequently identified factors are related to severity of illness and include the systemic inflammatory response syndrome, sepsis, and multiorgan failure.[28,30,35–42] The relationship between ICUAW and other factors, such as age, gender, corticosteroids, hyperglycemia, aminoglycosides, or neuromuscular blocking agents, is inconsistent.[4,24,27,28,42–45] Few, if any, studies have examined whether prehospital factors such as frailty or poor functional status are associated with developing ICUAW.[30] The presence of multiorgan failure as one of the most consistently associated risks lends support to the hypothesis that ICUAW may be another manifestation of multiple organ dysfunction syndrome (MODS).[28,30,37–40]

Implications

ICUAW increases the duration of mechanical ventilation, ICU and hospital lengths of stay (LOSs), healthcare–related costs, and mortality.[24,46–48] In addition, ICUAW is associated with significant long-term sequelae. As treatment of critical illness has improved, many more patients are surviving their acute illness but continue to suffer serious long-term effects, a phenomenon called *post–intensive care syndrome* (PICS).[49] PICS includes new or worsened impairments in many areas that affect quality of life, including physical, mental, and social health.[50] ICUAW is an important contributor to PICS.[49] Patients with respiratory failure requiring mechanical ventilation who were living independently before ICU admission rarely return to this level of functioning at 6-month follow-up.[51] Survivors of acute respiratory distress syndrome report poor functional status at 1 year after discharge despite normalization of their pulmonary function tests. Only 49% of such previously employed patients are able to return to work within 1 year of their critical illness as a result of muscle loss, weakness, and fatigue.[7] Five years after ICU discharge, 100% of survivors reported subjective weakness and decreased exercise capacity compared with their status before ICU admission.[8] Similarly, survivors of severe sepsis with no functional limitations before ICU admission developed significant limitations in their ability to perform activities of daily living and continued to develop functional limitations at a more rapid rate after hospital discharge.[5]

Prevention

Despite the serious long-term consequences of ICUAW, there have been few investigations aimed at prevention.[31,52] Because longer duration of bedrest is associated with increased severity and duration of ICUAW, early mobilization and ambulation have been suggested as possible interventions to prevent the weakness and functional decline associated with critical illness.[27,31] Studies assessing the amount of physical activity performed by patients in the ICU using actigraphy have demonstrated that patients are "profoundly inactive," suggesting there is significant room for improvement.[53] Decreasing the level of sedation may be one step to help facilitate this goal.[40] Minimizing sedation as much as possible offers a host of benefits,[54] including improving a patient's ability to participate in rehabilitation.

Neuromuscular electrical stimulation (NMES), whole-body vibration, and passive tilting have also been investigated as preventive measures that could be used with even heavily sedated or comatose patients, but the results thus far have been variable, and there are not enough data to recommend widespread use.[55–61] Passive movement in particular does not appear to produce the intensity needed to constitute an effective early rehabilitation intervention.[62]

In addition to mobilization and other attempts at neuromuscular stimulation, a small number of randomized controlled trials (RCTs) have evaluated interventions aimed at reducing or avoiding other possible risk factors of ICUAW.[40] Two older studies showed that intensive insulin therapy (IIT) may reduce ICUAW,[44,63] but because IIT is associated with increased risk of severe hypoglycemia and death, this approach is not recommended.[64] Corticosteroids have also been trialed, but have not been shown to reduce (and may even increase) the risk of ICUAW.[65] Attempts at improving nutritional support have also been unsuccessful in decreasing muscle wasting.[66]

EARLY MOBILIZATION AND AMBULATION IN THE ICU

Safety and Feasibility

Multiple studies have confirmed the safety and feasibility of physical therapy in the medical ICU population. Morris and colleagues performed a prospective cohort study of 330 patients in a university-based medical ICU and showed that an ICU mobility team was able to initiate an early mobilization protocol within 48 hours of mechanical ventilation, without observing any adverse events or accruing increased cost.[67] Similarly, in a study by Pohlman and colleagues, patients were successfully mobilized as early as 1 day after the initiation of mechanical ventilation.[9] Physical therapy was successfully provided on 90% of medical ICU days during mechanical ventilation, despite a potential barrier to mobilization (e.g., acute lung injury, administration of vasoactive medications, delirium, renal replacement therapy, or obesity) being present at 89% of the sessions. Minor adverse events, such as oxygen desaturation, increased heart rate, agitation, or ventilator dyssynchrony, occurred in 16% of sessions, but required cessation in only 4%. No unplanned extubations occurred. A prospective observational study of 1110 medical ICU patients, in which 5267 physical therapy sessions were conducted on 4580 patient days, revealed a physiologic abnormality or potential safety event in only 0.6% of sessions.[12] Only four (0.1%) of these occurrences required additional treatment or increased cost, and LOS was not increased.

A recent systematic review of safety data from 48 studies of early mobilization showed an incidence of 2.6% for potential patient safety events and that events requiring intervention were even more rare (0.6%).[68] The authors point out that adverse events are quite common in the ICU, even in the absence of mobilization. A quality improvement study by de Jong and colleagues found an adverse event frequency of more than 37% during routine morning turning of patients in a medical-surgical ICU.[69]

Furthermore, ICU rehabilitation programs aimed at reducing the time from ICU admission to active physical therapy are both feasible and sustainable in the long term. One RCT demonstrated that the introduction of a structured program led to earlier mobilization in sicker patients, who then achieved higher levels of mobility by time of discharge from the ICU.[70] Another RCT evaluated the effect of a rehabilitation program in a medical ICU and showed a sustained decrease in time to mobilization over a 5-year period.[71]

Some centers may not have the necessary staff or equipment to routinely ambulate patients who are mechanically ventilated. In these settings, or as an adjunct to other techniques, methods of early mobilization that can be performed in bed, such as cycle ergometry, are feasible.[58,72,73]

Fewer studies have evaluated the safety and feasibility of early mobilization and ambulation in surgical ICU patients, where issues such as wound healing, fractures, weight-bearing limitations, and incisional pain must be considered. A review of the evidence for early mobilization in critically ill trauma patients concluded that there is a lack of evidence in this population, but outlined injury-specific guidelines.[74] In a retrospective study of early mobilization in a trauma and burn ICU, Clark and colleagues reported no adverse events with physical therapy.[75] A prospective observational study of early mobilization in a surgical ICU showed that early mobilization can occur safely as early as ICU day 1,[76] and more recently, a multicenter RCT of 200 surgical ICU patients reported no serious adverse events with early mobilization.[77] Another small study showed intensive early rehabilitation was safe and feasible after liver transplantation.[78]

Early mobilization also appears to be safe in the neuro intensive care unit (neuro-ICU) populations.[79] The implementation of a comprehensive mobility initiative in a neuro-ICU resulted in a 300% increase in mobility among patients, with no significant adverse events, such as falls or inadvertent line disconnections.[80] Patients with a Glasgow Coma Scale of 8 or less can safely undergo early mobilization without incurring additional harm and are more likely to achieve functional independence at hospital discharge.[81] Patients with external ventricular drains (EVDs) can also safely be mobilized.[82,83] Case reports suggest that even patients with left ventricular assist devices[84] and those on extracorporeal membrane oxygenation (ECMO)[85–88] can safely participate in physical therapy programs. At our institution we routinely ambulate patients on ECMO and other extracorporeal life support systems.

One commonly cited barrier to early mobilization and ambulation is the femoral catheter. However these, too, need not be a barrier to safe physical rehabilitation. In a cohort of 239 patients with femoral venous, arterial, and hemodialysis catheters, 101 patients received physical therapy interventions for a total of 253 sessions over 210 ICU days.[89] The highest daily activity level was standing or walking, which occurred on 23% of days, and no adverse events were reported. However, only six patients had femoral hemodialysis catheters, and none of these patients achieved a level of standing or walking. Another cohort of 77 patients with 92 femoral catheters underwent a total of 210 physical therapy sessions with 630 mobility activities and similarly encountered no adverse events.[90] However, ambulation accounted for less than 10% of mobility activities, and it is unclear if any patients with hemodialysis catheters stood or walked. A more recent study of patients on continuous renal replacement therapy included only 4 physical therapy sessions with a femoral hemodialysis catheter in place; although there were no significant complications during these sessions, the authors concluded that the data are insufficient to draw conclusions regarding safety.[91] Based on these studies, femoral catheters need not be viewed as prohibiting mobilization, but caution must be taken with femoral hemodialysis catheters until there is more convincing evidence of safety. At our institution, we cautiously mobilize even patients with femoral venoarterial ECMO cannulae, with great care taken to minimize movement of the leg at the hip joint (Fig. 167.1).

Fig. 167.1 Patient Awaiting Lung Transplant Mobilizing While on Femoral Venoarterial extracorporeal membrane oxygenation (ECMO).

Outcomes

Observational studies have shown that early mobilization and ambulation are associated with decreased ICU and hospital LOS,[67,92–94] in addition to decreased incidence of delirium,[93] without an increase in cost.[18,67] Early mobilization and ambulation can even lead to cost savings.[16,17,94] In the trauma and burn population, early mobilization and ambulation have been associated with decreased airway, pulmonary, and vascular complications, including ventilator-associated pneumonia (VAP) and deep vein thrombosis.[75] In the neurosurgical ICU, increased mobility resulted in decreased restraint use, reduced infections (including VAP), and decreased ICU and hospital LOS.[80] For patients recovering from cardiac surgery, early mobilization can help prevent postoperative complications, improve functional capacity, and reduce hospital LOS.[95] Patients also report some less tangible benefits of rehabilitation, such as helping them to adapt to their new situation and regain a sense of autonomy after critical illness.[96]

Results of RCTs examining the outcomes of early mobilization in the ICU have been mixed. Two of the first RCTs to specifically look at early mobilization in the ICU showed significant benefits for critically ill patients. Burtin and colleagues randomized 90 medical and surgical ICU patients on ICU day 5 to bedside ergometry with standard treatment, including respiratory physiotherapy and active motor sessions of the upper and lower limbs, compared with standard treatment alone.[97] At hospital discharge, a 6-minute walking distance and the subjective feeling of well-being were significantly higher in the treatment group. Schweickert and colleagues randomized 104 medical ICU patients who had been mechanically ventilated for less than 72 hours to either daily sedation interruption plus early exercise/mobilization or daily sedation interruption plus therapy as ordered by the primary medical team.[13] Patients in the intervention group had less delirium, more ventilator-free days, and a faster return to independent functional status at the time of hospital discharge.

Over the past decade, numerous additional RCTs have examined the risks and benefits of early mobilization in the ICU,[58,59,70,72,73,77,78,98–110] but the results have been variable because of significant heterogeneity. But compared with standard therapy, early mobilization has been consistently shown to increase the number of patients who can stand,

increase ventilator-free days, decrease the incidence of ICUAW, increase walking distance at hospital discharge, and increase the likelihood of discharge to home from the hospital.[111] Additional RCTs of early mobilization, such as the TEAM trial,[112] are ongoing, as are investigations of early in-bed cycle ergometry, either alone or combined with amino acid supplementation,[72,113,114] and bedside treadmill training.[115]

One reason that recent studies may not have shown consistent benefit is the increasing prevalence of early mobilization in the ICU as part of standard care, particularly in units that have dedicated physical therapists[116]—the same ICUs are those most likely to take part in these studies. In some recent RCTs both the intervention and control groups had similar access to rehabilitation with only small differences in timing or frequency. For example, in one pilot study the intervention group received a specific physical therapy protocol within 48 hours of admission for sepsis, but 42% of patients in the standard care group also received physical therapy within 48 hours.[103,117] A Cochrane review of very early mobilization after stroke that failed to show a benefit found that the median delay to beginning mobilization was 18.5 hours in the intervention group, but was only 33.3 hours in the control group.[118] The design of these studies could make it difficult to detect significant differences in patients receiving early mobilization.

The Society of Critical Care Medicine, European Society of Intensive Care Medicine, American College of Chest Physicians, and American Thoracic Society have endorsed ICU liberation guidelines that include minimizing sedation and beginning physical therapy early in a patient's stay.[119–122] The ideal timing of early mobilization is still unclear, but recent reviews suggest initiation within 48–72 hours of admission to the ICU.[123,124] Rehabilitation should only begin once the patient has stable cardiovascular, respiratory, and neurologic status, but mechanical ventilation or infusion of vasoactive medications should not preclude mobilization. Caution must be exercised during each session. Major indicators for stopping include development of new clinical instability (cardiovascular, respiratory, neurologic, etc.), accidental device removal or malfunction, fall, or patient distress.[121] The most beneficial frequency and duration of rehabilitation sessions are currently unknown and require further study.[125]

EARLY MOBILIZATION PROGRAMS IN THE ICU

Implementation and Monitoring

Implementation of an early mobilization and ambulation program is an iterative process that requires a structured approach, transdisciplinary team, collaborative environment, and support from administration and senior management.[124] The use of a vetted framework, such as the Plan-Do-Study-Act (PDSA) model, the Six Sigma model,[126] or the four-step model for large-scale knowledge translation suggested by Pronovost and colleagues[127] increases the likelihood of success and sustainability of an intervention.

Planning and Engaging Phase

The first stage begins with summarizing and publicizing the evidence of early mobilization, including its safety, feasibility, sustainability, and effectiveness. Next, an interdisciplinary team, including physicians, nurses, physical therapists, respiratory therapists, senior executives, and other stakeholders, should be created. Social influence appears to be important for implementing and sustaining change, so identifying "champions" and having the support of local opinion leaders can be useful.[128,129] Once created, the team works with the frontline staff to navigate the early mobilization process and ensure a supportive and collaborative culture within the unit. Culture is of utmost importance, as "unnecessary immobilization" is a perception (sometimes justified) that may occur in ICUs where early mobilization is not ingrained in the culture.[130] The team should then create a protocol for early mobilization, explicitly defining inclusion and exclusion criteria, with the goal of capturing as many patients as possible and avoiding unnecessary exclusions. Implementing a formal protocol has been shown to decrease the time to first initiating mobilization and increase the number of rehabilitation sessions.[131]

Of course, clinicians should consider each patient's baseline, current clinical status, and clinical trajectory within the context of the prespecified criteria. Fig. 167.2 provides a sample algorithm for the delivery of physical therapy in critically ill patients.[93] Note that the type of physical activity performed depends on the status of the individual patient. Various methods of physical activity have been used successfully in the ICU, including traditional activities such as sitting on the edge of the bed, standing, sitting in a chair, and ambulating. However, other activities, such as cycle ergometry[58,72,73,97] and even video games,[132] are also safe and feasible. Careful consideration should be given to certain populations (e.g., trauma patients, neurosurgical patients, patients with open abdominal wounds)[133] and may require consultation with specialty services to delineate the appropriate activity level for these patients.[74] Additionally, the team should consider whether early mobilization will be implemented on its own or as part of a larger bundle of care processes such as the awakening and breathing, coordination, delirium monitoring and management, and early exercise and mobility (ABCDE) bundle[11,133] or the ABCDEF bundle, which also includes family engagement.[134,135]

Once a preliminary protocol has been identified, a sample patient can be used to assess workflow and potential barriers. Potential barriers should be discussed with all stakeholders, as perceived barriers may differ among disciplines. Table 167.1 describes a number of potential barriers to early mobilization and ambulation in addition to associated solutions.[93,136] Note that these barriers include not only patient-related variables (e.g., the presence of lines, tubes, and drains) but also the organizational, cultural, and environmental barriers. The latter include the lack of appropriate equipment (e.g., portable monitors and ventilators) and default bedrest orders. Cost is also a common concern, particularly among hospital administrators, despite evidence that early mobilization can be implemented with no additional cost and may indeed prove cost-saving.[16,17,94] Perceived barriers tend to decrease as providers gain more experience with early mobilization.[137,138]

The planning and engaging phase also includes the development of a measurement plan and specification metrics used to evaluate the program. These can be either process or outcome measures. Process measures include the percentage of patients being referred to physical therapy, the number of physical therapy sessions occurring per ICU day, and the time from ICU admission to ambulation. Possible outcome measures include the highest activity level achieved, incidence or duration of delirium, functional status at time of ICU discharge, ICU or hospital LOS, cost, patient and family satisfaction, hospital discharge destination, and mortality. The metrics chosen should be easily measured and reproducible. Ideally, data should be collected both before and after implementation of the program to ensure that a pre/post analysis can be performed. Adverse events should also be defined and recorded to ensure that the program is safe for patients, family, and staff.

Executing Phase

Pilot testing of the program in a subset of ICU beds may be prudent to help identify issues and optimize the protocol before dissemination to all critically ill patients. Unit-based marketing campaigns advertising and supporting the initiative should precede the initial rollout to

(From Engel HJ, Needham DM, Morris PE, et al. ICU early mobilization: From recommendation to implementation at three medical centers. *Crit Care Med.* 2013;41[9 Suppl 1]:S69–80.)

TABLE 167.1 Potential Barriers to Early Mobilization and Suggested Solutions

Barrier	Solution
Endotracheal tubes, central venous catheters, other lines and drains	Secure device
	Train staff in best practices
Hemodynamic derangements	Educate staff on evidence of safety
	Provide specific exclusion guidelines
Sedation	Integrate daily sedation holiday into PT/OT protocol
	Encourage sedative administration on an as-needed basis instead of continuous infusion
	Use validated sedation scoring system to evaluate sedative needs
Delirium	Normalize sleep-wake cycle
	Expose patient to sunlight during daytime hours
	Redirect and reorient patient frequently
	Minimize benzodiazepines and narcotics
	Monitor for delirium with validated scoring system
Inappropriate equipment	Purchase necessary equipment (portable monitors, portable ventilators)
	Consider options for bedside or in-room PT/OT if equipment purchase is not feasible
Insufficient staffing	Hire additional personnel
	Reorganize staff (example: shifting one nurse from night to day shift because PT/OT is more likely to occur during the day)
	Train and use nursing students and PT students taking an ICU elective
	Implement technologic solutions to maximize staff efficiency
Lack of physician referrals for physical therapy	Streamline physical therapy orders
	Use computerized order entry
	Make default activity order "ad lib"
	Perform joint PT/nursing/ICU team rounds to identify patients appropriate for mobilization
	Implement automatic referral for PT
Fear of intervention/cultural roadblock	Create ongoing dialogue to address stakeholder concerns
	Educate staff on safety and benefits of intervention
	Incorporate early mobilization into ICU culture
Lack of leadership	Recruit transdisciplinary team
	Identify PT champion
	Include senior management/hospital administrators

ICU, Intensive care unit; *OT,* occupational therapy; *PT,* physical therapy.

alert providers and remind staff of the benefits of physical therapy in the ICU. Members of the interdisciplinary team should be readily available to encourage and support frontline providers, answer questions, and quell anxieties associated with ambulating critically ill patients. Additionally, team members should continuously request feedback on the implementation process and the algorithm in use. They should also attempt to identify barriers not previously recognized, with the goal of rapidly making changes to address concerns and improve the program. Early achievements should be applauded and celebrated, acknowledging staff, patients, and families for their efforts. Once providers and staff are comfortable with early mobilization, consideration should be given to involving family in these efforts. Family engagement increases patient- and family-centered care, provides a sense of personhood to patients, gives meaning to the intervention, and has been shown to increase compliance with early mobilization protocols.[139]

Evaluating and Improving Phase

The evaluation phase continues indefinitely. Evaluation can be both qualitative (e.g., in the form of informal interviews, focus groups, and surveys) or quantitative. The quantitative assessment is composed of the metrics previously defined in the planning phase. One feasible and reliable way to evaluate the success of an early mobilization and ambulation program is to use an ICU mobility scale. Hodgson and colleagues developed and validated an 11-point mobility scale.[140] This scale (Table 167.2) describes the highest level of activity achieved by a patient on a given day, ranging from a score of 0, which indicates no activity (patient lying in bed), to 10, which indicates being able to walk independently without an assistance device. In a study of 100 medical, surgical, and trauma ICU patients, the scale was a feasible tool with high interrater reliability among nurses and physical therapists of various levels. Other important metrics include the incidence of delirium, ICU and hospital LOS, hospital discharge destination (i.e., home versus rehabilitation facility or skilled nursing facility), and incidence of adverse events. Ongoing improvement should take place in response to issues, staff concerns, or poorly performing metrics. Metrics that improve initially and then show a decrement indicate a problem with sustainability and should trigger an in-depth review of the program and re-engagement of frontline staff.

TABLE 167.2 ICU Mobility Scale

	Classification	Definition
0	Nothing (lying in bed)	Passively rolled or passively exercised by staff but not actively moving.
1	Sitting in bed, exercises in bed	Any activity in bed, including rolling, bridging, active exercises, cycle ergometry, and active assisted exercises; not moving out of bed or over the edge of bed.
2	Passively moved to chair (no standing)	Hoist, passive lift, or slide transfer to the chair, with no standing or sitting on the edge of the bed.
3	Sitting on edge of bed	May be assisted by staff, but involves actively sitting on the side of the bed with some trunk control.
4	Standing	Weight bearing through the feet in the standing position, with or without assistance. This may include use of a standing lifter device or tilt table.
5	Transferring bed to chair	Able to step or shuffle through standing to the chair. This involves actively transferring weight from one leg to another to move to the chair. If the patient has been stood with the assistance of a medical device, they must step to the chair (not included if the patient is wheeled in a standing lifter device).
6	Marching on spot (at bedside)	Able to walk on the spot by lifting alternate feet (must be able to step at least four times, twice on each foot), with or without assistance.
7	Walking with assistance of two or more people	Walking away from the bed/chair by at least 5 m (5 yards) assisted by two or more people.
8	Walking with assistance of one person	Walking away from the bed/chair by at least 5 m (5 yards) assisted by one person.
9	Walking independently with a gait aid	Walking away from the bed/chair by at least 5 m (5 yards) assisted by a gait aid, but no assistance from another person. In a wheelchair-bound person, this activity level includes wheeling chair independently 5 m (5 yards) away from the bed/chair.
10	Walking independently without a gait aid	Walking away from the bed/chair by at least 5 m (5 yards) without a gait aid or assistance from another person.

CONCLUSION

ICUAW is a common complication of critical illness and adversely affects the long-term function of ICU survivors. Although current understanding of the most effective means of preventing and treating ICUAW is limited, early mobilization and ambulation appears to be an important component. When performed with care, early mobilization of critically ill patients is safe, feasible, and cost-effective with very few contraindications. Taking a structured approach to implementing an early mobilization and ambulation program increases the likelihood of success and sustainability.

KEY POINTS

- A large proportion of survivors of critical illnesses experience long-term cognitive, psychological, and physical disability, with less than half of survivors returning to prior functional status and/or work by 1 year after ICU discharge.
- Prolonged periods of inactivity and immobility lead to reduced protein synthesis, accelerated proteolysis, and increased apoptosis. This ultimately results in a catabolic state, atrophy, and clinical weakness.
- Early mobilization and ambulation have been suggested as possible interventions to prevent weakness and functional decline associated with critical illness.
- Early mobilization is safe, feasible, and sustainable in various ICU populations.
- Mobilization is beneficial, decreasing the incidence and duration of delirium, reducing ICU and hospital LOS, improving functional status, and increasing the likelihood of being discharged home from the acute care hospital.
- Early mobilization therapy should be considered in all critically ill patients.

An excellent review of the safety data regarding mobilizing critically ill patients. Because safety concerns are often a barrier to widespread implementation of early mobilization, this paper importantly showed that few significant adverse events happen during rehabilitation sessions.

Schaller SJ, Anstey M, Blobner M, et al. Early, goal-directed mobilisation in the surgical intensive care unit: A randomised controlled trial. *Lancet* 2016;388(10052):1377–1388.

The first multicenter international randomized controlled trial of early, goal-directed mobilization in surgical ICU patients. The authors showed that early mobilization improved patients' mobilization throughout their ICU admission, shortened length of stay in the ICU, and improved functional mobility at discharge.

Schweickert WD, Pohlman MC, Pohlman AS, et al. Early physical and occupational therapy in mechanically ventilated, critically ill patients: A randomised controlled trial. *Lancet.* 2009;373(9678):1874–1882.

One of the first randomized controlled trials of early mobilization, which included mechanically ventilated patients in medical ICUs. They found that early rehabilitation was safe and well-tolerated and resulted in better functional outcomes at hospital discharge, shorter duration of delirium, and more ventilator-free days.

Mass Critical Care

Ariel L. Shiloh and David C. Lewandowski

Natural and man-made disasters have always been a part of life and are occurring with increasing frequency. They create varied degrees of chaos owing to mismatch of resources and needs, and they place a huge burden on healthcare systems. Restoring an affected society to its present status requires extraordinary efforts and incurs substantial costs. Thousands of people are injured physically and emotionally as the result of such events, and their effects continue long after worldwide attention has disappeared.

The devastating events of September 11, 2001, in the United States, subsequent acts of bioterrorism, and emerging infectious disease pandemics have brought new challenges to the field of disaster management and multidisciplinary hazard mitigation. Even though war- and terrorism-related disasters have gathered much attention, natural disasters have occurred with increasing frequency over the past decades. This has been attributed to the growth of human population in geographically disaster-prone areas, rapid industrialization, and increasing exposure to toxic and hazardous materials (HazMat).[1–3]

Analyses of the response of different healthcare systems to major disasters in the past have demonstrated the need for a more clearly identified planning process to attend to the response to multihazard events.[4] This provides a basic understanding of common disaster scenarios and highlights the role of intensivists in the medical response to disasters. It is important for practicing critical care clinicians to keep in mind that their role is first and foremost as a first receiver rather than a first responder; well-trained intensivists may be of much greater value remaining in the hospital setting rather than quickly mobilizing to the field, where their lack of situational preparedness may make them more of a hindrance than an asset.[5]

BACKGROUND

Major disasters occur regularly and cause widespread human death and suffering.. In the last decade, over 2.6 billion people have been affected by disasters and emergencies, with an annualized mortality of 90,000 people.[6] Even though the numbers of geophysical disasters such as earthquakes and volcanic eruptions have remained fairly constant, recent years have seen the highest number of weather-related disasters.[6] As populations grow and occupy spaces that are vulnerable to different hazards, disasters will increase in severity and impact. Events since the September 2001 terrorist attacks have brought attention to the effects of man-made disasters on the healthcare system and the need to anticipate and plan for such low-probability yet catastrophic events. Although there is basic similarity in the response to them, each type of disaster presents responders with unique demands. After any disaster, healthcare systems are tasked with preventing excessive deaths, mitigating suffering, and dealing with an often overwhelming inadequacy of resources. Over the past few years, disaster medicine has grown into a unique specialty to deal with planning and preparing for such cataclysmic events. It shares a common ideal with public health: "greatest good for the greatest number."[3]

A fundamental part of designing a medical response to disasters is to coordinate with healthcare personnel across the hospital system so that they overcome natural differences associated with each group and maximize efficient use of scarce resources. Because the sickest of all viable patients will require intensive care, critical care physicians can play an invaluable part in coordination efforts. In addition to their usual role of being caregivers for patients in the intensive care unit (ICU), intensivists will be expected to help in triage decisions, transport critically ill patients, and treat the multitude of injured in a rational order. They can also help by providing essential medical care at the actual disaster site via mobile ICU teams. It is thus important for critical care physicians to be familiar with the basics of disaster management, acquire organizational and leadership skills, practice delivery of unconventional critical care, and be familiar with different disaster-related medical syndromes.

TERMINOLOGY

Physicians and healthcare personnel should be familiar with the basic nomenclature and terminology in disaster medicine. Clear, common, and concise definitions are important to effective communication and evoking appropriate responses in disaster situations. Uniform use of terminology across healthcare systems provides a basis for analyzing and constructing an effective disaster plan and response by all responders.[7] Controversies surrounding the definitions of *disasters, hazards,* and *casualties* are included in the discussions that follow.

The word *disaster* connotes a subjective assessment that has various meanings to different people and has an inherent bias, depending on the person using it. For example, a local, state, or federal "disaster declaration" implies commitment of financial and other resources. Similarly, a disaster in one community is not necessarily the same in another. Currently, there is no uniformly accepted definition for the word *disaster*.[7] De Boer and colleagues recognize the lack of a meaningful definition for the word and instead propose the term *medical severity index*.[8] This term, however, has not gained sufficient acceptance for routine use. Different modifiers can lead to different definitions of the term *disaster*. They include the type of disaster; geographic area involved; timing; onset of the event; size of the community affected; baseline resources available; and physical, psychosocial, and economic injuries caused by the event. However, from a healthcare standpoint, the most important variable that defines a disaster is its functional impact on the healthcare facility.[7] Despite various attempts to clear this confusion, the issue remains unresolved.[7,9,10] What follows

are the commonly used definitions in disaster medicine from a healthcare perspective:

Hazard. An event with the potential to cause catastrophic damage. It may be a "naturally" occurring phenomena, such as volcano eruptions, or "man-made," such as nuclear power plant accidents.[11]

Emergency. A natural or man-made event that significantly disrupts the environment of care (e.g., damage to an organization's buildings caused by severe winds, storms, or earthquakes), resulting in disrupted care and treatment (e.g., loss of utilities, such as power, water, or telephones, because of floods, civil disturbances, accidents, or emergencies within the organization or in its community); or resulting in sudden, significantly changed, or increased demand for the organization's services (e.g., bioterrorist attack, building collapse, or plane crash in the organization's community).

Disaster. A hazardous event causing physical, psychological, social, economic, or even political effects on a scale such that the stricken community needs extraordinary efforts to cope with it and often outside help or international aid.[9,10] Medical disasters form a subset of this category, in which physical and/or psychosocial injuries exceed the medical response capabilities of the community affected.

Casualty. Any person suffering from physical and/or psychological damage by outside violence leading to death, injuries, or material losses. Again, the word has no standard definition and is sometimes used to imply injury, death, or both. It may also bear financial implications, because federal reimbursement may be approved only for people classified as casualties.[7,9,10]

Potential injury-creating event (PICE) system. A new system developed to overcome the differences in disaster nomenclature. It uses the functional impact on the healthcare facility as the only determining factor to define an "emergency" or "disaster." It uses four modifiers to communicate the impact caused by the situation on the healthcare facility.[7]

Multicasualty incident. A hazardous event that, regardless of its size, is containable by local emergency medical services (EMS). From an operational standpoint, an event becomes a multicasualty incident when its impact exceeds the day-to-day response routine to the EMS. Adjustments within the local response system are required to cope with this demand without the need to request outside help (level 1 response).[12]

Mass-casualty incident. A hazardous event that overwhelms local response capability. It is likely to impose a sustained demand for health services rather than a short, intense peak typical of many smaller-scale disasters. This may require a level 2 response (neighboring and regional resources are activated) or a level 3 response (state, interstate, and federal resources are activated in the rescue and recovery process).[13]

Hazard vulnerability analysis (HVA). The identification of potential emergencies and the direct and indirect effects these emergencies may have on the organization's operations and the demand for its services.[14]

CLASSIFICATION OF DISASTERS

Natural disasters arise from the forces of nature and include earthquakes, volcanic eruptions, hurricanes, floods, fire, and tornadoes. In addition, infectious disasters can be classified as epidemic or pandemic. Man-made disasters are the result of identifiable human causes and may be further classified as complex emergencies (e.g., terrorist attacks) and technologic disasters (e.g., industrial accidents).[15] Other classifications include those based on onset (acute vs. insidious disasters), predictability, duration, and frequency. From a public health perspective, disasters must be defined by their effect on people and the healthcare system. The concept of functional impact to the healthcare system is paramount.[15,16]

The PICE system attempts to create uniformity to address the wide spectrum of situations.[7] The two major aims of this system are to communicate both the operational consequences to a hospital or community and the type and amount of outside assistance needed. Four modifiers for an event are chosen from a standardized group of prefixes, and a stage is assigned (Table 168.1). *Column A* (first prefix) describes the potential for additional casualties. For example, a finite number of people injured in an airplane crash is a "static event," whereas an ongoing fire is a "dynamic" event. *Column B* (second prefix) describes whether local resources are sufficient ("controlled") or overwhelmed. If they are overwhelmed, the two modifiers "disruptive" and "paralytic" indicate whether they must be simply augmented or totally reconstituted. Paralytic PICEs are the most daunting of all situations, and they can be either destructive or nondestructive (Table 168.2). *Column C* describes the extent of geographic involvement. The *PICE stage* refers to the likelihood that outside medical help is required (Table 168.3). This PICE model provides important concepts for disaster planners, researchers, and responders. Using this system, disasters can be described both prospectively and retrospectively. PICE is a valuable tool for use in planning and disaster mitigation, but the system warrants validation on a wider scale. It may also require further refinement to delineate the type of aid needed by an affected community.[7] Regardless of the type of classification used to categorize disasters, certain unique features are associated with each kind of disaster. It is important to understand the common effects of different natural and man-made disasters to predict their impact and plan effectively. Some common disaster situations are reviewed next.

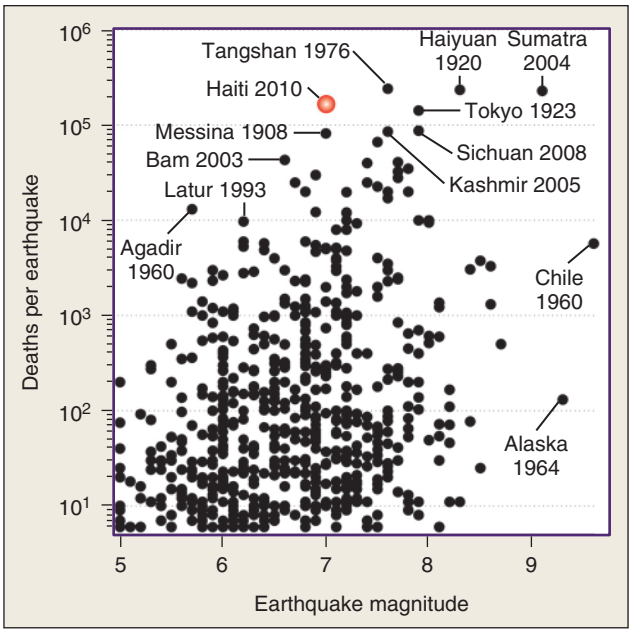

Fig. 168.1 Deaths from earthquakes since 1900. The toll of the Haiti quake is more than twice that of any previous magnitude 7.0 event and fourth worst since 1900. (From Hough SE, Bilham R. *After the Earth Quakes: Elastic Rebound on an Urban Planet.* New York, NY: Oxford University Press; 2006; and Bilham R. The seismic future of cities. *Bull Earthq Eng.* 2009;7:839–887.)

NATURAL DISASTERS

Earthquakes

Earthquakes are a model of a disaster that results in significant mortality,[17] as can be seen in Fig. 168.1. A homogeneous population well trained in both basic trauma and life support and the architectural design of the housing and public facilities of the stricken area are the two major determinants of outcomes for earthquake victims. The massive earthquakes in recent years in Turkey, Taiwan, Sumatra, Kashmir, Sichuan, and Haiti have shown us that a sound engineering design for earthquake resistance in civil structures such as schools and hospitals has a major impact on outcomes. In addition, urban earthquakes generate massive fiscal impact on the world in terms of reconstruction grants provided by wealthier countries for devastated urban areas. Moderately destructive earthquakes in the developing world usually cost up to $10 billion in reconstruction; the needs of developing countries with urban earthquakes may cost an order of magnitude more.

Despite extensive experience and published literature dealing with medical response to earthquakes, the earthquake in Haiti shows that we are frequently doomed to relearn the lessons forgotten.

The Haiti earthquake occurred on January 12, 2010, and was of magnitude 7.0 on the Richter scale, resulting in some 230,000 mortalities and 1.5 million homeless. Let us consider first the military medicine response delivered, especially in the face of continuous exposure of the military medicine establishment to mass-casualty management in the wars in the Middle East.

Responders from the very experienced Israel Defense Forces (IDF) were air-deployed within 48 hours of the Haiti earthquake. This team has had extensive experience over the years with international response and consists of 230 people. The team unpacked and built their portable hospital within 8 hours, and during 10 days of operation treated more than 1100 patients in a facility designed to provide 60 inpatient beds, including 4 intensive care beds and one operating room.[18] Most of the first wave of casualties presented with crushed limbs with open infected wounds, and the later arrivals presented with sepsis and poor chance of outcome. Despite the repeated experience from prior earthquakes showing that victims of crush syndrome and acute renal failure require emergency dialysis to prevent death, this facility relied on other international teams for dialysis. Their major dilemmas were practical implementation of the triage algorithm by military personnel to a civilian population. The simple priorities were urgency, resources available, and probability of saving life. Patients with brain injury, paraplegia caused by spine injuries, or a low Glasgow Coma Scale score were immediately transferred to other facilities, because no neurosurgical capabilities were available. A triage panel of three senior physicians relieved individual physicians of personal accountability. Half of the intensive care capability was always dedicated to postoperative care, with the remaining two beds used for prolonged intensive care; only patients who were expected to stabilize within 24 hours were placed in these beds. The very early discharge policy permitted this facility to treat more than 100 patients per day.

Second, let us consider the response of the US military, which had a considerable portfolio on providing disaster relief in catastrophic events such as the Indonesian tsunami that devastated Sumatra. The US Naval Ship (USNS) *Comfort,* one of the hospital ships of the Military Sealift Command, was deployed as part of the mission termed *Operation Unified Response*. It started accepting casualties within 7 days of the earthquake. The ship is a 1000-bed facility that includes 75 ICU beds, blood bank, hemodialysis, pathology, physical therapy, morgue, and radiology with computed tomography and ultrasonography capability. It is staffed with 1000 active-duty US medical personnel, including three physician intensivists, and it was allocated to stay up to 6 months.[19,20] The first wave of casualties were critically ill trauma patients airlifted from field hospitals by US helicopters. Within 72 hours, the *Comfort* admitted 254 patients, and the census rapidly increased to 430, more than a third of them pediatric cases. A team of six internists provided 24/7 coverage. Dozens of patients underwent mechanical ventilation simultaneously; the open-bay design did not allow for isolation, and the nurse-to-patient ratio

was about 7:1. A large volume of hemodialysis was provided to patients with crush syndrome, leading to rapid depletion of dialyzers and dual-lumen dialysis catheters. The discharges exceeded admissions in about 2 weeks, and after a total of 629 admissions, the ship completed its mission. Although the standard of care exceeded community expectations, the US Navy personnel followed naval protocol and standards.

Third, let us consider the relearning of the lessons of civil-military collaboration in disaster response.[21] A volunteer medical team with civilian personnel under the auspices of the international medical corps flew to the Dominican Republic and reached the Hôpital de l'Université d'Etat d'Haïti in Port-au-Prince after a long bus ride on January 17, 2010. There were more than 800 injured in the partially destroyed facility, with the primary diagnoses being crush injuries, compartment syndrome, infected fractures, and hemorrhagic shock. One physician and one nurse were covering up to 80 critically ill patients in the wards. An aftershock of 5.9 magnitude resulted in an exodus of casualties and higher rates of heat stroke in dehydrated hypovolemic patients exposed to tropical temperatures. Destruction of the prison system released 4000 criminals into the community, and no security was available until the arrival of a US airborne infantry regiment. With the arrival of the USNS *Comfort* on January 20, evacuation of the most critically ill patients started, but a triage list developed rapidly, with ship facilities accepting preferentially complicated injuries, obstetric patients, and maxillofacial injuries. Patients with pelvic fractures, closed head injuries, complete spinal cord lesions, and mechanical ventilation cases were of too high acuity for the USNS *Comfort*. Family structures became fragmented, as separation of children from parents occurred. Yet the collaboration of civilian and military medical personnel was considered a success.

Next, let us consider the experiences of academic centers delivering care to victims of the Haitian earthquake onsite.[22] The Miller School of Medicine of the University of Miami and Project Medishare had the advantage of long experience of collaboration with Haiti and close geographic proximity, and they were able to provide emergency relief within 20 hours. Within 8 days, they were able to establish a field hospital at the city airport, and by January 21, 140 patients were transferred into the upgrade facility. The well-organized command center with satellite links for telephone and Internet access was available. A joint adult-pediatric triage team accompanied by Creole-speaking medical staff of Haitian origin was used. Multiple surgeries were performed under local peripheral nerve blocks, with guillotine amputations being frequent. The highest-acuity patients were transferred to the IDF field hospital or the USNS *Comfort*. The command center eventually provided psychiatrists to manage the posttraumatic stress syndrome and a buddy system for the follow-up support.

Finally, one must consider the critical care response from New York City. Although many small teams and a large volume of supplies were dispatched, an organized response was delivered under the leadership of Dr. Ernest Benjamin, division chief of critical care in surgery at Mt. Sinai Hospital. Dr. Benjamin arrived in Port-au-Prince 3 days after the initial event, and after rapid assessment of needs and resources, organized the deployment of the 27-member critical care team to his home country, which arrived on January 20. The team remained onsite for 2 weeks and was responsible for postanesthesia and postoperative care delivery, with Dr. Benjamin being deputized as the director of critical care and recovery at the national hospital. The home institution effectively secured anonymous donations of private jets able to transport the team personnel and some 3000 pounds of medical supplies per flight. The team delivered intensive care with minimal technology but with kindness and dignity toward the suffering population. This was a truly integrated response with both language and cultural sensitivities and capabilities, which are very important in catastrophic situations that will take decades for the local population to recover from.[23]

Experience in managing catastrophic international disasters continues to accumulate with unfortunate regularity. The preceding discussion suggests that combinations of dialysis, orthopedic surgery, pediatric trauma, security, transportation, posttraumatic stress treatment, and cultural and language sensitivities are crucial in earthquakes. Disasters produce well-defined syndromes with well-defined mortalities. It is the recovery phase that continues to require persistence and improvement. One of the most experienced managers and thought leaders in disaster management, Dr. Eric Noji, enumerated the most important factors in public health after disasters: environmental health, epidemic management, immunization, controlling the spread of human immunodeficiency virus/acquired immunodeficiency syndrome, management of dead bodies, nutrition, maternal and child health, medical services, and thorough public health surveillance. It is a common error to deliver a few weeks of heroic quality care and then abandon the population to the ravages of destroyed infrastructure, including public health organization.[24]

Volcanic Eruptions

A volcano is a hill or a mountain built around a vent that connects with reservoirs of molten rock below the earth's surface.[25] Different types of eruptive events occur, including pyroclastic explosions, hot ash releases, lava flows, gas emissions, and glowing avalanches (gas and ash releases). Lava flows tend not to result in high casualties because they are easily avoidable. The "composite" type of volcano is associated with a more violent eruption from within the chimney. These eruptions are associated with air shock waves, rock projectiles (some with high thermal energy), release of noxious gases, pyroclastic flows, and mud flows (lahars). Pyroclastic flows and lahars are often fast moving and are the main cause of damage and deaths from volcanoes, as evidenced by the small eruption of the Nevado del Ruiz in Colombia that killed more than 23,000 people.[26] The release of ash and its subsequent rapid buildup on building structures can be substantial, causing them to collapse within hours. Ash is also responsible for the clogging of filters and machinery, causing electrical storms and fires, and interfering with communications. Ash is a main cause for respiratory-related syndromes and conjunctival and corneal injury. A variety of toxic gases (e.g., carbon dioxide, hydrogen sulfide, sulfur dioxide, hydrogen chloride, hydrogen fluoride, and carbon monoxide [CO]) are released during eruptions, causing bronchospasm, pulmonary edema, hypoxemia, cellular asphyxiation, topical irritation of skin and other mucosal surfaces, and death.[27] Damage to health infrastructures and water systems can be severe. Problems related to communication (ashes cause serious interference) and transportation (poor visibility and slippery roads) are likely. On the basis of the initial assessment, various needs can be anticipated. Reducing the risk for vulnerable groups of being exposed to ash, raising awareness of the risk associated with ash (health and mechanical risk), and maintaining food security conditions over the long term (lava, ash, and acid rain cause damage to crops and livestock) can help limit suffering.[28]

Hurricanes, Cyclones, and Typhoons

The large rotating weather systems that form seasonally over tropical oceans are variously named, depending on their geographic region of origin.[29–31] They consist of a calm inner portion called the *eye,* surrounded by a wall of rain and high-velocity winds. On the basis of central pressure, wind speed, storm surge, and potential destruction, their severity is graded on a scale of 1–5 (Saffir-Simpson scale).[30] They are among the most destructive natural phenomena. Cyclones during 1970 and 1991 in Bangladesh claimed 300,000 and 100,000 lives,

respectively, because of flooding.[32] The most devastating hurricane ever to hit the United States occurred in 1900 at Galveston, Texas. It claimed an estimated 8000–12,000 lives.[33] The greatest damage to life and property is not from the wind but from secondary events such as storm surges, flooding, landslides, and tornadoes. Ninety percent of all hurricane-related deaths occur from storm surge–related drowning.[1] The most common injury patterns include lacerations (during the cleanup phase), followed by blunt trauma and puncture wounds. Late morbidity can be the result of postdisaster cleanup accidents (e.g., electrocution), dehydration, wound infection, and outbreaks of communicable diseases.[31,34] Data from Hurricane Katrina confirmed data from previous meteorologic events. The leading mechanisms of injuries are fall, lacerations, and piercing injuries, with cleanup being the primary activity at the time of injury.[35] Resources may have to be provided for an extended period after the initial inciting event, and significant resources may have to be provided for patients with chronic medical illnesses.[34,36]

Floods

There are three major types of floods: flash floods (caused by heavy rain and dam failures), coastal floods, and river floods. Together, they are the most common types of disasters and account for at least half of all disaster-related deaths.[37,38] The primary cause of death is drowning, followed by hypothermia and injury caused by floating debris.[39,40] The impact on the health infrastructures and lifeline systems can be massive and may result in food shortages. Interruption of basic public services (e.g., sanitation, drinking water, and electricity) may result in outbreaks of communicable diseases.[38,40] Another concern is the increase in both vector-borne diseases (e.g., malaria and St. Louis encephalitis) and displacement of wildlife (e.g., poisonous snakes and rodents).[39,40]

Landslides

Landslides are more widespread than any other geologic event. They are defined as downslope transport of soil and rock resulting from natural phenomena or man-made actions. Landslides can also occur secondary to heavy storms, volcanic eruptions, and earthquakes. Landslides cause high mortality and few injuries. Trauma and suffocation by entrapment are common. Pending an assessment, needs can be anticipated, such as search and rescue, mass-casualty management, and emergency shelter for the homeless.[41,42]

Pandemic 2009 H1N1 Influenza A Virus

Pandemic H1N1 2009 is a new strain of influenza A virus that was first identified in Mexico and the United States on March 18 and April 15, 2009, respectively. It originated from the quadruple reassortment swine influenza (H1N1) virus closely related to the North American and Eurasian swine lineage. However, this new virus circulated only in humans, with no evidence of transmission between humans and animals.

Within weeks, the virus quickly spread worldwide through human-to-human transmission. On April 26, 2009, the Strategic National Stockpile of the Centers for Disease Control and Prevention (CDC) began releasing 25% of the supplies in the stockpile for the treatment and protection from influenza.[43] On June 11, 2009, the World Health Organization (WHO) declared the 2009 H1N1 influenza a global pandemic, generating the first influenza pandemic of the 21st century, with more than 70 countries reporting cases of H1N1 infection. By June 19, 2009, all 50 states in the United States, the District of Columbia, Puerto Rico, and the US Virgin Islands had reported cases of 2009 H1N1 infection. More strikingly, the CDC Emerging Infections Program estimated the number of hospitalizations and deaths in people aged 64 years and younger. The virus was most likely to strike children, young adults, and those with underlying pulmonary and cardiac disease. Pregnant women in their second and third trimester were also at high risk. Patients requiring intensive care had a remarkable prevalence of obesity.[43]

Influenza vaccines are most effective not only to prevent but also to mitigate the severity of illness. The pandemic H1N1 influenza vaccine was promptly developed by the WHO and national authorities. A national influenza vaccination campaign was launched in the United States in October 2009, and the first H1N1 vaccine was made available at that time. Despite the rapid response of the authorities, developing countries in the Southern Hemisphere experienced delays and shortages of the vaccines. Thus research and developmental work have been encouraging for developing a "universal" influenza vaccine that could provide efficacious cross-reactive immunity and induce broad protection against different variants and subtypes of the influenza virus.[44]

Data show that about 8% of H1N1 patients were hospitalized (23 per 100,000 population); 6.5%–25% of these required being in the ICU (28.7 per million inhabitants) for a median of 7–12 days, with a peak bed occupancy of 6.3–10.6 per million inhabitants; 65%–97% of ICU patients required mechanical ventilation, with a median ventilator duration in survivors of 7–15 days; 5%–22% required renal replacement therapy; and the 28-day ICU mortality was 14%–40%.[45–51] Critical care capacity is a key element of hospital surge capacity planning.[10] The proportion of ICU beds occupied by patients with H1N1 varied. In Australia and New Zealand, it peaked at 19%,[7] whereas in Mexico, many patients required mechanical ventilation outside the ICUs.[6] To match the surge capacity with increasing ICU demands during a pandemic is a difficult task, because uncertainty exists for many of these parameters. The disease brought a surge of not only critically ill patients but also patients who required prolonged mechanical ventilation and ICU management. Hospitals should maximize the number of ICU beds by expanding ICUs and other areas with appropriate beds and monitors. Elective procedures should be minimized when resources are limited, and critical care capacity should be augmented.

Safe practices and safe respiratory equipment are needed to minimize aerosol generation when caring for patients with influenza. These measures include handwashing and wearing gloves and gowns; using N95 respirators, which reduce the transmission of epidemic respiratory viruses; staff training in personal protective equipment (PPE); minimizing the use of bag-mask ventilation and disconnection of the ventilator circuit; and avoiding the use of heated humidifiers on ventilators, Venturi masks, and nebulized medications.[52]

When the number of critically ill patients far exceeds a hospital's traditional critical care capacity, modified standards of critical care to provide limited but high-yield critical care interventions should be the goal to accommodate far more patients. Triage criteria should be objective, transparent, and ethical and applied justifiably and publicly disclosed. The ICU triage protocols for pandemics should only be triggered when ICU resources across a broad geographic area are or will be overwhelmed despite all reasonable efforts to extend resources or obtain additional resources.[53] The Sequential Organ Failure Assessment score, though not validated, has been proposed to determine qualification for ICU admission during mass critical care.

The major characteristics of 2009 H1N1 influenza A infection were the rapidly progressive lower respiratory tract disease leading to acute respiratory distress syndrome (ARDS) with refractory hypoxemia. A substantial number of H1N1 ICU patients required advanced ventilatory support (ranging from 1.7% to 11.9%) and rescue therapies, including high levels of inspired oxygen and positive end-expiratory pressure (PEEP), inverse ratio ventilation, airway pressure release

ventilation, neuromuscular blockade, inhaled nitric oxide, high-frequency oscillatory ventilation, extracorporeal membrane oxygenation (ECMO), volumetric diffusive respiration, and prone-positioning ventilation.[46,49,51,54] ECMO was successful in managing refractory hypoxemia in these patients in two studies. The median durations of therapy and survival rates to ICU discharge were 10 days and 15 days—71% and 67%, respectively.[55,56]

As of March 13, 2010, the CDC estimates of 2009 H1N1 influenza cases, hospitalizations, and deaths in the United States since April 2009 were 60 million cases, 270,000 hospitalizations, and 12,270 H1N1-related deaths, respectively.[57] The virus did not mutate during the pandemic to a more lethal form. Widespread resistance to oseltamivir did not develop. The WHO declared an end to the H1N1 pandemic on August 10, 2010. The H1N1 virus is expected to take on the behavior of a seasonal influenza virus and to circulate for some years.

Ebola Outbreak (2014–2016)

In late 2013, Ebola virus disease (EVD) became an international disaster of crisis proportion in West Africa, primarily in the countries of Liberia, Sierra Leone, and Guinea. This became the largest outbreak of EVD in history, greater than all previous epidemics combined, with a total number of 28,616 suspected cases and 11,310 deaths, all in the aforementioned countries; additionally, there were 36 suspected cases and 15 deaths outside of those countries.[58–61] This point cannot be overemphasized: although the mortality of confirmed cases has been documented to be as high as 68% in the affected nations of West Africa, if patients are quickly recognized and given appropriate aggressive supportive care, the case fatality ratio drops dramatically. There are, to date, no specific approved pharmacotherapeutic interventions available to cure EVD; however, the VSV-EBOV Ebola vaccine has been shown to be safe and highly effective and was fast-tracked to use by the epidemic.[62] The dramatically decreased case fatality ratio noted in developed nations is related to strict enforcement of isolation, hygiene, and use of supportive care.

With regard to the scope of the issue, the CDC predicted that the number of confirmed EVD cases would double approximately every 20 days, with estimated cases ranging as high as 1.4 million. From a mass-casualty perspective, it rapidly became clear that the aforementioned nations of West Africa did not have an adequate governmental infrastructure to create Ebola treatment units, nor were they able to strictly implement the necessary public health infrastructure of hygiene and isolation. At that point, important nongovernment organizations (NGOs) such as Médecins Sans Frontières, Red Cross, WHO, and worldwide military support intervened to create the lacking infrastructure.[63,64]

From the initial outbreak to December 2015 the WHO, with its partners, achieved unprecedented progress in combating the disease. From an environment of minimal diagnostic tools and scant medical personnel emerged 24 rapid diagnostic laboratories, a phase III trial of the VSV-EBOV vaccine, and a global network of thousands of healthcare professionals ready for rapid deployment in the Foreign Medical Teams (FMTs) Registry. These efforts were achieved through a three-phase approach. Phase 1 (August–December 2014) was of a rapid scale-up of the response. This consisted of increasing the number of treatment centers, rapidly hiring and training teams in safe dignified burials, empowering social mobilization, and launching the UN Mission for Ebola Emergency Response (UNMEER). Phase 2 (January–July 2015) emphasized increasing capacities for case finding, contact tracing, and community engagement. Phase 3 (August 2015–2016) focused on interrupting all chains of transmission. This was achieved by rapidly identifying all cases, contacts, and deaths; establishing safe facilities; developing multidisciplinary response teams; incentivizing local communities to comply with public health goals and local response; supporting survivors; and ending human-to-human transmission of the virus in the affected populations and countries.[65]

When patients with EVD first started appearing in the United States, it required some fundamental reevaluation of the role of the CDC in such events. Normally the agency is tasked with providing information and guidance to both healthcare facilities and state and local health departments, but given the rapid, complex, and international nature of this particular epidemic, the routine approach of having state health departments manage these situations with oversight by the CDC was not particularly effective. The president created the role of "Ebola Response Coordinator" to help provide a coordinated federal oversight for the US approach to this disease. In addition, the CDC created Ebola "SWAT teams" that were sent in real time to appropriate locations to ensure appropriate resource allocation to hospitals, and, if necessary, transfer patients with suspected EVD to properly equipped regional centers. For example, in New York State, the governor mandated that eight medical centers (five in New York City alone) were to be designated centers for patients with suspected EVD and that all hospitals needed to develop strategic plans for initial management of patients with suspected EVD.[66]

The CDC's response to the Ebola virus epidemic was the largest in the agency's history, in an area of the world with little operational experience. The CDC developed relationships with health ministries of local West African governments, US governmental agencies, and NGOs and developed a Global Rapid Response Team in June 2015.[67]

Interestingly, despite the extremely low number of actual patients who were diagnosed with EVD in the United States, a challenging problem was media management; an initial lack of clear federal leadership rapidly led to confusion, fear, and misinformation being spread throughout the country. As an example, the PPE recommendations from the CDC were not aligned with the recommendations from the WHO. This left hospital officials confused about the best manner in which to protect their employees. Eventually, the recommended approach became more aggressive, and there was agreement between the CDC and WHO regarding PPE.[61,68–73]

In conclusion, major important lessons were learned during the outbreak of EVD, many of which have clear-cut implications for future epidemics. First, it became clear that for many developing nations, the existing governmental infrastructure is inadequate to provide appropriate containment, public health infrastructure, and treatment facilities; early aggressive intervention by a combination of NGOs and militaries is required to quell the spread. Second, the standard existing paradigm of local and state health agencies providing adequate resources, information, and guidance to health facilities may not be adequate; a rapid top-down federalized approach may be required. Clearly, more resources must be allocated to our federal and international health agencies to prepare for such possible events in the future.

OTHER NATURAL DISASTERS

Tornadoes occur most commonly in the North American Midwest. Over 4115 deaths and 70,000 injuries have been ascribed to them during the years 1950–1994. They cause widespread destruction of community infrastructure. Injuries most commonly seen are complex contaminated soft tissue injury (50%), fractures (30%), head injury (10%), and blunt trauma to the chest and abdomen (10%).[74,75] Firestorms, wildfires, tsunamis, winter storms, and heat waves are other natural phenomena capable of creating mass injuries from thermal burns, airway injury, smoke inhalation, heat-related disorders, and hypothermia.[76–79]

MAN-MADE DISASTERS

Transportation Disasters

Transportation accidents can produce injuries and death similar to those seen in major natural disasters. Some of the largest civilian disasters in North America have been related to the transportation of HazMat.[80] Motor vehicle accidents, railway accidents, airplane crashes, and shipwrecks are some of the common transportation accidents. They cause a wide range of injuries, including multiple trauma, fractures, burns, chemical injuries, hypothermia, dehydration, asphyxiation, and CO inhalation. The hazard risk to a healthcare facility increases with its proximity to a chemical plant or highway, and such factors should be considered in the emergency preparedness plan of a hospital.[81]

Weapons of Mass Destruction

Weapons of mass destruction (WMDs) are those nuclear, biological, chemical, incendiary, or conventional explosive agents that pose a potential threat to health, safety, food supply, property, or the environment. Since the terrorist attacks in September 2001 and intentional release of anthrax spores in the United States, there is growing concern around the world about the possible threat of chemical, biological, or nuclear weapons being used against a civilian population. The incidence of use of WMD to cause death and injury is rare. However, biological and chemical weapons are relatively accessible, and WMDs are thought to be available to most foreign states and terrorist groups. In response to a WMD incident, healthcare personnel will be called on to manage unprecedented numbers of casualties in an environment of panic, fear, and paranoia that accompanies terrorism. Because most attacks occur without warning, the local healthcare system will be the first and most critical interface for detection, notification, rapid diagnosis, and treatment. The best defense in reducing casualties will therefore rest on the ability of medical and public health personnel to recognize symptoms and provide rapid clinical and epidemiologic diagnosis of an event. This requires that healthcare providers be well informed of potential biological, chemical, and nuclear agents. They must have a heightened index of suspicion and be able to identify unusual disease patterns to determine whether WMDs are the etiologic agents of illness. Physicians will need to practice appropriate surveillance and reporting and develop knowledge of mass decontamination; use of proper PPE; and safety protocols related to a biological, chemical, or radiologic event.[82–84] Salient characteristics and brief management strategies of different WMD are discussed here.

Biological Weapons

Biological weapons can be either pathogens (disease-causing organisms such as viruses or bacteria) or toxins (poisons of biological origin). Compared with other WMDs, biological weapons are characterized by ease of accessibility and dissemination, difficulty in detection because of their slow onset of action, and their ability to cause widespread panic through the fear of contagion. They can be spread through various means, including aerial bombs, aerosol sprays, explosives, and food or water contamination. Multiple factors, including particle size of the agent, stability of the agent, wind speed, wind direction, and atmospheric conditions, can alter the effectiveness of a delivery system. The CDC has classified biological weapons into three categories (Table 168.4) based on the ease of dissemination; ability to cause high mortality, public panic, and social disruption; and requirement for special action for public health preparedness.[85] Category A agents are of particular concern because they can cause widespread disease through their ease of transmission, result in high mortality rates, cause panic and social disruption, and require special attention during public health preparedness. General features that should alert healthcare providers to the possibility of a bioterrorism-related outbreak include[86] the following:

1. A rapidly increasing disease incidence (e.g., within hours or days) in a normally healthy population
2. An epidemic curve that rises and falls during a short period
3. An unusual increase in the number of people seeking care, especially with fever or respiratory and gastrointestinal complaints
4. An endemic disease rapidly emerging at an uncharacteristic time or in an unusual pattern
5. Lower attack rates among people who had been indoors, especially in areas with filtered air or closed ventilation systems, versus people who had been outdoors
6. Clusters of patients arriving from a single locale and large numbers of rapidly fatal cases
7. Any patient presenting with a disease that is relatively uncommon and has bioterrorism potential (e.g., pulmonary anthrax, tularemia, or plague)

The main steps involved in managing a bioterrorist attack are containment, notification, confirmation, and directed antibiotic treatment and prophylaxis. In the event of a suspected bioterrorist attack, the CDC has issued protocols for early notification of local and state public health department agencies.[87] The Association for Professionals in Infection Control and Epidemiology in cooperation with the CDC devised the "Bioterrorism Readiness Plan," with a template for healthcare facilities to serve as a reference document to facilitate preparation of bioterrorism readiness plans for healthcare facilities. This tool guides infection-control professionals and healthcare epidemiologists in the development of practical and realistic response plans for their institutions in the event of a bioterrorism attack.[88] The reader is referred to other documents for a review of

TABLE 168.4 Triage Classification

Groups	Color	Symbol	Type of Injury
Priority I (emergent)	Red	R	CRITICAL: likely to survive if simple* care given within minutes
Priority II (catastrophic)	Blue	B	CATASTROPHIC: unlikely to survive and/or extensive or complicated care needed within minutes
Priority III (urgent)	Yellow	Y	URGENT: likely to survive if simple† care given within hours
Priority IV (nonurgent)	Green	G	MINOR: likely to survive even if care delayed hours to days
Priority V (none)	Black	X	Dead

*Simple: Care that does not require unusual equipment or excessive use of time or personnel.
†Assigned THIRD priority (after YELLOWS) when there are so many casualties that if resources are used in vain to try to save BLUE cases, the YELLOWS will needlessly die.

bioterrorism and critical care,[89,90] in addition to other resources and websites (Box 168.1).

Chemical Weapons

Chemical incidents are accidental or intentional events that threaten to or do expose responders and members of the public to a chemical hazard. Agents that have been commonly used as chemical weapons are also used in industrial processes. Most industrial incidents occur at an interface between transport, storage, processing, use, or disposal of hazardous chemicals, where these systems are more vulnerable to failure, error, or manipulation. The catastrophic effect of these agents has been used several times in the past for military purposes, and with the proliferation of these weapons, civilian populations are now faced with a significant threat.[91] Typically, chemical warfare agents are classified into the following categories[92]:

Nerve agents (e.g., tabun, sarin, VX, and soman) are organophosphates that inhibit an enzyme, anticholinesterase, resulting in the overstimulation of both muscarinic and nicotinic receptors. Muscarinic symptoms include lacrimation, bronchorrhea, bronchospasm, miosis, salivation, rhinorrhea, vomiting, and diarrhea. Nicotinic receptor stimulation produces muscle fasciculations, flaccid paralysis, tachycardia, and hypertension. They can also produce central nervous system effects (i.e., seizures and coma). Death is usually from respiratory failure. They are extremely toxic and have a rapid effect. Sarin presents as a vapor threat, and the onset of symptoms is within seconds, with a peak effect in 5 minutes. Exposed victims who are asymptomatic after 1 hour are unlikely to be contaminated. VX represents a liquid exposure, with as little as a drop being lethal. The onset to action and death is less than 30 minutes. The cardinal rule in decontaminating patients is to remove and dispose of all articles of clothing. Therapy is directed toward the predominating symptoms. Atropine is used for the relief of muscarinic symptoms, pralidoxime chloride (2-PAM) is used for nicotinic effects, and benzodiazepines are used for the central nervous system manifestations. Most of the care is supportive and includes mechanical ventilation for respiratory failure and treatment of arrhythmias.[93]

Vesicants (e.g., mustard gas and lewisite) cause wounds on the skin and mucosal surfaces. They are capable of causing second-degree burns of the skin within 4–8 hours. Airway injury and edema can be severe and are dose dependent. Of concern to the ICU physician is the need for correcting fluid losses and maintaining the airway.

Pulmonary agents (e.g., chlorine gas and phosgene gas) mainly affect the respiratory system, inducing inflammation of the airway and the lung and leading to ARDS and death. Treatment is mainly supportive.

Cyanides bind to cytochromes in the mitochondria and inhibit cellular oxygen use. In smaller doses they cause tachypnea, headache, dizziness, anxiety, and vomiting. With higher doses, seizures, respiratory arrest, and cardiac arrest occur. They are highly toxic, and sufficient levels can cause death within 5 minutes of inhalation. They are most commonly inhaled but can also be absorbed through the skin. Care is primarily supportive with supplemental oxygen. Specific therapy is with amyl nitrates, sodium nitrite, and sodium thiosulfate.

Unlike biological weapons, disease secondary to release of chemical agents is likely to be more obvious, rapid in onset, and homogeneous. However, they pose serious problems for emergency care providers because of their potential to cause a large number of casualties rapidly and their potential for secondary contamination. Any emergency medical or public health response to a major incident involving a chemical warfare agent will require coordination among local, state, and federal organizations. First responders should be aware of access to specialized local and federal response teams, basic triage, demarcation of the contaminated area, use of handheld devices for agent detection and identification, use of PPE, and knowledge of appropriate medical treatment and antidotes.

Nuclear Weapons and Radiation Accidents

A variety of terrorist applications of radiation exist that could produce varying degrees of damage to public infrastructure and operations, human casualties and illnesses, and most important, fear.

Radiation devices include radionuclides from the healthcare industries (e.g., brachytherapy and radiation oncology sources). The consequences of the exposure are dose and source dependent.

Radionuclide dispersal devices are also known as *dirty bombs*. These have limited nuclear yield but can contaminate a wide area.

Improvised nuclear devices are made of uranium or plutonium constructed by a nongovernmental source and limited by the critical mass of nuclear material. They yield less destructive power than a conventional nuclear warhead but are still capable of contamination effects.

Tactical and strategic nuclear weapons are those that are created by governments and vary in yields from 0.5 kiloton to greater than 1 megaton. Their destructive capacities are enormous, and they contaminate a vast perimeter of space depending on the yield.

Approximately 50% of the energy released from a nuclear bomb is from the blast and shock waves, giving a majority of the survivors blast-related injuries and creating extensive infrastructure damage. About 35% of the energy released is thermal radiation (in orders of tens of millions of degrees), giving rise to high-degree skin burns. Depending on the size of the device and the altitude of detonation, an electromagnetic pulse is generated with the explosion. This is capable of disrupting all electrical equipment within 20 kilometers to several hundreds of kilometers.[94] The radiation-related energy released gives rise to external contamination, systemic irradiation, and internal contamination-related illness. Immediate ionizing radiation consists of gamma, beta, neutron, and a small amount of alpha radiation. Residual radiation occurs in the forms of induced radiation and fallout. Induced radiation occurs because of neutron-induced gamma activity of the immediate soil, silicon, manganese, aluminum, zinc, copper, and sodium. The half-lives of the various substances are a few minutes to 15 hours. *Fallout* is the fusion of various radionuclides generated in the fission reaction with condensation, producing a snowflake-like debris

that falls to earth. Fallout is a potential form of delayed radiation exposure and can cause internal contamination.[94]

Surviving hospitals and staff near an impact area should serve as a triage center and transport victims to unaffected centers elsewhere through the notification of the National Disaster Medical System Hospital Activation System.[95] Other agencies that have to be notified include the Federal Bureau of Investigation, Nuclear Regulatory Commission, Department of Energy, and Department of Defense. Large-scale decontamination should be managed outside the hospital area as far as is possible, but plans for indoor decontamination should also be in place. A radiation emergency area (both in and out of the hospital) should be designated, with checkpoints nearing the cold zone. Management plans for the safe disposal of human waste and bodies should be in place so as not to increase the exposure risk. Triage of patients should be done on the basis of doing the greatest good for the greatest number. On the basis of predictive models, isolated irradiation, burns, and blast-related injuries would constitute 40% of injuries. Combined injuries would account for the rest. Attending to trauma victims should take precedence over all other medical issues, because a given patient is not likely to succumb immediately from radiation injury.

Patient care should begin with the use of universal precautions and PPE.[94] Dosimetry readings of the area may help during triage, defining those with systemic irradiation injury (possibly received >450 rad exposure). In determining patient viability, three parameters are of the most use: time of onset of vomiting, decrease in the absolute lymphocyte count over a 24-hour period, and presence of conventional trauma burns.[96] Victims who are not viable or who have lethal doses of radiation exposure are likely to benefit from supportive/palliative care.

Hazardous Materials Disasters

HazMat are substances potentially toxic to the environment or living organisms. Full-scale disasters from HazMat are relatively rare, but isolated incidents are among the most common in the community and are not limited to chemicals but can include various biological and radiologic materials. Knowledge of the types of industries present in the community would be helpful in developing a potential plan to deal with likely HazMat situations. Management of a HazMat situation requires attention to several key points: identification of the offending agent, appropriate PPE of responders, prompt containment of the agent, demarcating areas for decontamination (including removal and disposal of clothes and waste from the decontamination), and resuscitation of victims. Injuries secondary to release of HazMat can present as chemical burns, inhalational injury, and a variety of systemic injuries.[97,98]

Armed Conflict

Armed conflict continues to be the most preventable and most destructive of man-made disasters in terms of human physical and emotional suffering, economic loss, and environmental destruction. Specific healthcare issues during these conflicts that are relevant to the intensivist include trauma from blast injuries, projectiles, and crush-related injuries; communicable diseases caused by the breakdown of public infrastructure and mass displacement of populations; and burns and radiation-related injury.

MEDICAL DISASTER SYNDROMES

Disaster situations present with many unique medical syndromes that require specific therapy. Treatment of these entities is often difficult because of a large volume of patients, lack of qualified medical personnel onsite, and inadequate supplies and equipment. It is important to emphasize that initial recognition of the medical syndromes and appropriate intervention are critical to minimizing morbidity and mortality. Appropriate triage, knowledge of field management of each syndrome, flexibility to adapt to each situation, ability to ignore natural differences among different specialties, and recognition of limits of medical care that can be provided in overwhelming situations are key to a good disaster medical response. In the following paragraphs, we discuss commonly encountered medical syndromes in a disaster situation.

Blast Injuries

Bombs contain an array of compounds such as nitroglycerin, trinitrotoluene, and others that are encased in a metal or plastic case. Decomposition of the solid or liquid compound into gas leads to massive dissipation of energy and pressure that creates a blast wave (shock wave). This destructive effect can be increased by the presence of nuts, nails, and bolts in the casing. Water transmits blast waves more efficiently than air, with the greatest impact being on structures that are the deepest.[99] There are four types of blast injuries:

1. *Primary blast injury* is caused solely by the blast wave and almost always affects air-filled structures such as the lung, ear, and gastrointestinal tract. The presence of tympanic membrane rupture may indicate exposure to a high-pressure wave and is thought to correlate with more severe organ injury.
2. *Secondary blast injury* is caused by the rapid acceleration of small fragments caused by the blast injury.
3. *Tertiary blast injury* is a feature of high-energy explosions. They result from the collision of the flying victim against a hard surface.
4. *Miscellaneous blast-related injuries* encompass all other injuries caused by explosions. They include flash burns, inhalation injuries, and blunt trauma.

The most common injuries associated with fatality in blast incidents include subarachnoid hemorrhage (66%), fracture of the skull (51%), lung contusion (47%), tympanic membrane rupture (45%), and liver laceration (34%). Unfortunately, the extent of the blast injury cannot be assessed during the course of rapid triage examinations. In the absence of overt trauma, a focused physical examination should include examination for ruptured tympanic membrane, hypopharyngeal contusions, hemoptysis, and auscultation for wheezing. The presence of a ruptured tympanic membrane is almost always an indicator that the patient has been exposed to a blast wave powerful enough to cause serious damage. The thorax is frequently involved in a blast injury, manifesting with wheezing, hemoptysis, pneumothorax, hemothorax, and air embolism. Patients may have myocardial contusion as well. The presentation of serious pulmonary injury may be delayed. Pulmonary barotrauma is the most common fatal primary blast injury. Patients with nonpenetrating lung injury will likely have hypoxia requiring support ranging from oxygen therapy to mechanical ventilation. This may result from pulmonary contusion, systemic air embolism, and disseminated intravascular coagulation. Acute gas embolism, a form of pulmonary barotrauma, is also associated with blast injuries. Air emboli most commonly occlude blood vessels in the brain or spinal cord, resulting in neurologic symptoms that must be differentiated from the direct effects of trauma. Patients thought to have gas embolism require decompression treatment. Administering 100% oxygen by tight-fitting face mask and left lateral recumbent position may help. Definitive treatment is with the use of hyperbaric oxygen. Patients with blast injury of the lung are likely to present with abdominal injuries that are usually more delayed. These include delayed bowel perforation and liver lacerations. The former may warrant exploratory laparotomy.[100–103]

Blast victims receiving general anesthesia have an increased mortality rate; other forms of local and spinal anesthesia are preferred, and general

anesthesia should be deferred if possible for 24–48 hours. Intensivists should be aware of the increased need for resuscitation equipment, ventilators, and movement in and out of the operating room during such situations.

All patients with significant burns, suspected air embolism, radiation or white phosphorus contamination, abdominal signs of contusion/hematoma, or clinical evidence of pulmonary contusion or pneumothorax should be admitted to the hospital. Patients with tympanic membrane rupture and suspected pneumothorax should get some form of chest imaging, and a significant observation period may be warranted. Other investigations must be judiciously ordered, keeping in mind the limited availability of resources in a mass-casualty incident. Screening urinalysis for presence of hematuria, tests for CO poisoning (explosion in a closed space or associated with fire) and cyanide toxicity (because of combustion of plastics), and assessment of acid-base status may be indicated. Using abdominal computed tomography to rule out intestinal hematomas should be dictated by clinical signs and symptoms. Pregnant patients with blast injuries warrant special consideration, and appropriate consultation is necessary to rule out blast injury to the fetus.[101] Supplemental oxygen, maintaining spontaneous respiration, and low PEEP (if mechanical ventilation is required) are guiding principles. Routine corticosteroids and antibiotics are not warranted.

Exposure to white phosphorus explosives (e.g., in hand grenades) deserves special mention. Using a Wood's light in a darkened resuscitation suite or operating room may help identify white phosphorus light particles in the wound. White phosphorus injury can cause lung injury through irritation, in addition to severe hypokalemia and hyperphosphatemia with cardiac arrhythmias and death. External burns should be lavaged with 1% copper sulfate solution. This forms a blue-black cupric phosphide coating and prevents combustion so that the particles can be safely removed.[104]

Crush Injury Syndrome

Crush injury syndrome refers to systemic manifestations of extensive muscle damage caused by entrapment of victims under collapsed buildings or debris. Reported incidence depends on the type of disaster, ranging from 2% to 40%. Metabolic alterations from the release of muscle constituents into the circulation include myoglobinemia leading to acute renal failure, hyperkalemia, hyperphosphatemia, and disseminated intravascular coagulation. Muscle damage that occurs is caused by not only direct crush injury but also by vascular injury and insufficiency leading to altered compartment pressures and reperfusion injury. Inelastic fascial sheaths encase skeletal muscles in the forearm and lower leg and are particularly vulnerable to dramatic increases in compartment pressures, resulting in compartment syndrome. An intracompartmental pressure greater than 40 mm Hg lasting longer than 8 hours defines this syndrome. Pressures as high as 240 mm Hg can be seen with crush injuries. Compartment syndromes are seen with limb fractures, use of military antishock trousers, pneumatic splints, vascular injuries, and crush injuries. The affected limb may present with severe pain associated with passive stretch or extension, flaccid paralysis, and sensory loss. Capillary refill and peripheral pulses are usually present unless the compartmental pressure equals the diastolic pressure. Diagnosis requires a high degree of clinical suspicion and entails prompt bedside measurement of compartmental pressures. A simple and easy method that can be performed in the hospital or field hospital is using an 18-gauge needle attached to a mercury manometer. In an ICU, pressure transducers used to measure central venous pressures can be attached to the 18-gauge needle to obtain the same information.[105]

Resuscitation of patients with crush injury (any victim crushed or immobilized for more than 4 hours) should begin in the field. After adequate intravenous access is achieved, isotonic fluid replacement with normal saline (rate of 1–1.5 L/h) should begin even before extrication of the crushed limb. If fluid therapy is delayed, the incidence of renal failure increases to 50%; delays of 12 hours are associated with a 100% incidence. Occurrence of renal failure is associated with a mortality rate of 20%–40%. Urinary alkalinization with sodium bicarbonate and mannitol or acetazolamide administration is used to maintain urine pH above 7.5. Although this is widely used, there are no prospective randomized controlled trials to support it. Dialysis may be indicated if aggressive fluid resuscitation fails, and this may create a huge demand for dialysis machines in disaster situations. Peritoneal dialysis if the abdomen is intact and continuous arteriovenous hemofiltration may be other useful options. However, the latter option is complicated by hemorrhage problems related to the use of heparin and immobilization. Life-threatening infections are common and may be increased in the presence of a fasciotomy. In unsalvageable limbs, it may be advisable to perform on-field amputations to avoid the systemic effects of crush injury syndrome. For this purpose, ketamine is the anesthetic and analgesic of choice because of its safety profile in the field.[105]

Particulate Health Problems

Many disasters result in the release of copious particulate matter, causing a wide spectrum of respiratory illnesses, including cough, wheezing, smoke inhalation injury, reactive airways disease, and ARDS. Volcanic eruptions with associated pyroclastic flows and ash fall are some of the most devastating producers of particulate matter. Mortality arises from suffocation by ash in the upper airways, ARDS, and inhalation burns. The massive building collapse and fires associated with the 2001 World Trade Center terrorist attack caused significant pulmonary complaints among rescue personnel.[106]

Smoke inhalation injury resulting from exposure to noxious products of combustion in fires may account for as many as 75% of fire-related deaths in the United States. The three primary mechanisms that lead to injury in smoke inhalation are thermal damage, asphyxiation, and pulmonary irritation. Combustion uses oxygen in the airways and causes a decrease in fraction of inspired oxygen, leading to hypoxemia. Increased CO levels decrease the oxygen-carrying capacity of the blood and cause myocardial depression. Combustion of plastics, polyurethane, wool, silk, nylon, rubber, and paper products can lead to the production of cyanide gas, resulting in anaerobic metabolism and decreased oxygen consumption. Rarely, we may also find methemoglobinemia, which reduces oxygen-carrying capacity.[107] Mortality rate with smoke inhalation alone is about 10% but increases to about 77% in the presence of major burns or respiratory failure. Early deaths are mostly caused by airway compromise or metabolic poisoning. Laboratory work-up should include co-oximetry; CO, methemoglobin, and cyanide levels (if there is discordance in measured saturation and pulse oximetry readings); blood lactate levels (a level >10 mmol/L that is refractory to restoration of adequate ventilation, oxygenation, and perfusion is considered a surrogate marker of cyanide toxicity) on blood gases; and a calculated alveolar-arterial pressure gradient. Initial blood gas measurements and chest radiograph may be normal. Carboxyhemoglobin level obtained in the emergency department does not correlate with tissue hypoxia or long-term neurologic sequelae; ideally, a carboxyhemoglobin level at the scene would be most valuable.

Serial bronchoscopy is indicated in the first 18–24 hours to assess airway edema and sloughing. Early bronchoscopy can be of diagnostic and therapeutic value, particularly when lobar atelectasis is present. High-flow humidified oxygen is critical to reverse or prevent hypoxemia. About 50% of patients with an inhalation injury require tracheal intubation, and this increases in patients who have burn injuries. The need for intubation is determined by the need to maintain airway

patency and pulmonary toilet and to provide positive-pressure ventilation. Positive-pressure ventilation with PEEP increases short-term survival and is associated with decreased tracheobronchial cast formation. Cyanide toxicity (levels >0.1 mg/L) should be promptly treated using a cyanide antidote kit. Recommendations for the use of hyperbaric oxygen in the setting of CO poisoning include CO levels greater than 25%–30%, neurologic compromise; metabolic acidosis; or electrocardiographic evidence of myocardial ischemia, infarction, or dysrhythmias. Hyperbaric oxygen has been used in cyanide toxicity but has not been proven effective. The role of corticosteroids is controversial, and they can be detrimental if given in the presence of cutaneous burns. Empirically administered antibiotics are also in dispute. Common pitfalls in the initial management of smoke inhalation are using initial PaO_2 to predict adequacy of oxygenation, placing small-diameter nasotracheal tubes, intubating without applying PEEP, and restricting fluids for concomitant inhalation and burn injury.[107,108] General measures that could be employed in a field setting include simple airway protection by clearing any particulate matter in the airway, supplemental oxygen, and nebulizer treatment if available. Patients with preexisting asthma and emphysema should be observed for exacerbations.

Acute Radiation Syndrome

Ionizing radiation can be either charged or uncharged particles (photons). Beta particles are capable of penetrating a few centimeters of tissue. Gamma rays and x-rays are capable of penetrating through tissue and concrete. Gamma, x-ray, and beta radiations are considered low linear energy transfer radiation. Alpha particles have no penetrating power past the keratinized layer of skin, but they take on clinical significance if they are internalized by ingestion or inhalation. Neutron emission (e.g., from nuclear reactors, nuclear devices, and industrial moisture detectors) is a highly potent radiation that penetrates deep and creates denser ionization trails. Alpha and neutron emissions are considered high linear energy transfer radiation and have more biological effects than low linear energy transfer radiation by a factor of up to 20. When the process of ionization occurs in living tissue, it denatures cellular DNA. This leads to impaired mitosis and subsequent organ failure. Large doses of radiation are considered to cause more biological destruction than fractionated doses. Systemic radiation illness and lethality from it can result from as little as 450 rad. Precise measurements of the amount of radiation after a nuclear accident will be delayed. Hospital gamma cameras are an invaluable resource for helping determine the exposure in an individual. Higher systemic doses are suggested by shorter onset of prodromal symptoms such as nausea, vomiting, and diarrhea. Serial absolute lymphocyte counts will screen those patients who have psychogenic vomiting. Acute radiation syndrome has four distinct phases[83,94,96]:

1. *Prodromal phase*, characterized by nausea, vomiting, and diarrhea. Other symptoms of eye burning, abdominal pain, and fever can also occur with higher doses. This phase may last from 0 to 2 days, depending on the dose received.
2. *Latent phase,* in which the patient will have a period of relative well-being because of subsidence of the inflammation. However, ultimately the damaged cells will not be able to repair or regenerate. This may last for 2–3 weeks.
3. *Manifest phase,* in which the cellular deficits of various organs affected will become apparent. Mature cells of the skin slough off, revealing an atrophic dermis. Endothelial cells are not replaced, leading to vascular permeability. Mucosal linings slough, causing mucositis and diarrhea. Hematopoietic progenitor cells fail to produce cell lines, leading to anemia, thrombocytopenia, and neutropenia. Fibrosis of organ beds develops. This may last for up to 3 weeks.
4. *Recovery phase/death,* in which some stem cells may proliferate and lead to slow recovery, or there will be symptoms of progressive organ failure leading to death.

For radiation syndrome to occur, radiation must be of the penetrating type in a sufficiently large dose (>0.7 Gy), must be external, and must occur within a short time. The disease complex has three syndromes: bone marrow, gastrointestinal, and cardiovascular/central nervous system. Serial absolute lymphocyte counts should be measured immediately on suspicion of exposure (every 3 hours), because lymphocytes are among the most radiosensitive cells and reach nadir within 2 days, platelets reach nadir in 15–30 days, and neutrophils at about 30 days. Patients are immunocompromised and susceptible to infections, including septic shock. Gastrointestinal syndrome leads to mucosal sloughing, decreased nutrient absorption, and translocation of bacteria and endotoxin. Veno-occlusive disease may also develop if the dose is large enough. Cardiovascular and central nervous system disease develops with doses greater than 5000 rad, and death can occur in as little as 3 days from myocarditis, capillary leak, pulmonary edema, and brain edema. Pneumonitis and subsequent fibrosis can lead to respiratory failure and the need for ventilator support. Treatment of acute radiation syndrome (ARS) is supportive. If internal contamination is thought to have occurred, enhancement of excretion and specific antidote therapy are warranted. For inhalational contamination, bronchoalveolar lavage may be necessary, and for ingestion, gastric lavage and purgative management are warranted. Plutonium and transuranic elements can be treated with chelating agents such as calcium or zinc diethylenetriamine pentaacetic acid. Radiocesium can be treated with Prussian blue, which helps enhance excretion in feces. Radioiodine exposure can be treated with potassium iodide. Uranium excretion can be enhanced by the alkalinization of urine and with potassium supplementation.

Psychological Trauma

The psychological component in a traumatic event is often overlooked, with the major focus usually being on physical health issues. Studies evaluating the emotional impact from disasters indicate that a majority of victims, first responders, and mortuary volunteers will suffer some form of psychological trauma. Intensivists should be aware that behavioral changes may be the result not only of the catastrophic insult but also organic causes such as head injury, inability to take predisaster psychiatric medications, and toxin or chemical exposure. Groups at risk, such as children, adolescents, and victims who have been exposed to traumatic stressors of bereavement, witnessing death, and situations evoking guilt, fear, or anger, should receive prompt psychiatric and posttraumatic counseling. Interventions, such as debriefing, eye movement desensitization and reprocessing, and critical incident stress management, may help minimize emotional suffering and morbidity.[109]

Other Syndromes

Burns, blunt trauma, intraabdominal injury, head injuries, penetrating trauma, and hypothermia are some of the other disaster syndromes encountered in the field. Specific discussion of these entities is beyond the scope of this chapter; please see other reviews.[5]

DISASTER PREPAREDNESS

For intensivists to be able to deal with a disaster, it is paramount that they be a part of the disaster-planning effort. Disaster planning includes development of action programs to minimize loss of life and damage during a disaster, provide the greatest good for the greatest number of people, train healthcare personnel and civilians, coordinate

response efforts, maintain adequate supplies of equipment and personnel, and rehabilitate the community after the disaster. Knowledge of potential disasters to which the community is prone should be an integral part of the planning process. Having an understanding of what the resources and capabilities are of the community, hospital, and its ICU on a continual basis and provision for modular expandability are vital for any successful emergency response. The mere existence of a disaster plan does not ensure that the hospital system is actually prepared.[110] The following paragraphs elucidate some of the common issues and misconceptions related to disasters and common principles useful in designing a disaster plan. Subsequently, a pragmatic view is presented of the role of the ICU physician in a disaster situation.

Common Issues and Misconceptions in Disaster Planning

Typically, the hospital nearest to the disaster site will receive the bulk of the casualties. It is thus important to conduct a careful survey of a disaster plan's jurisdiction to identify potential sites (i.e., industries, nuclear reactors, and highways) and likely types of hazardous events that could occur in the area. Hospitals in the nearby area receive few disaster victims, and an average have at least 20% of their beds vacant. Disaster plans would thus need to include transfer agreements between hospitals and nearby ICUs to meet bed shortages by activating the National Disaster Medical System Hospital Activation System.[95,110,111]

Very few casualties actually require hospital admission. A study of 29 mass-casualty incidents found that less than 10% of casualties required overnight admission under usual criteria (even though more were admitted because they were involved in the disaster rather than because of severity of their condition). Large numbers of casualties with minor conditions will appear at the nearest hospitals, often on foot or in private vehicles, police cars, buses, taxis, and other nonambulance forms of transport. Field triage stations are often bypassed, and this in turn causes enormous strain on the emergency department services.[112]

Most of the logistical problems faced in disaster situations are not caused by shortages of medical resources, but rather from failure to coordinate their distribution.[110] Inexperienced volunteers may not be familiar with the triage system or principles of personal safety, and massive numbers of volunteers can present serious administrative challenges. This results in disorganization and inefficiency.[97] Technical hazard sheets designed by the WHO for most disasters also suggest that medical personnel, blood donors, and blood products should not be sent empirically to a disaster site.[113]

Principles in Disaster Planning

Existing Preparedness Requirements

In developing disaster plans, hospitals must take into account the broad national and local requirements imposed by various governmental agencies. Common agencies involved in this process include the Centers for Medicare & Medicaid Services (CMS) and The Joint Commission (TJC). The CMS's conditions for emergency preparedness and services establish minimum requirements for hospitals that participate in Medicare or Medicaid programs. Similarly, TJC standards apply to a full range of hospitals and are focused on four areas: (1) emergency preparedness management plan (Standard EC 4.1), (2) security management plan (Standard EC 2.1), (3) HazMat and waste management plan (Standard EC 3.1), and (4) emergency preparedness drills (Standard EC 4.2). Readers are referred to the TJC website for the most up-to-date standards.[114]

Hazard Vulnerability Analysis

This is the first step of any disaster plan, with the main aim of identifying potential hazardous events and situations that can occur in or around the healthcare facility. This process of evaluating and predicting hazard risk is not restricted to geographic events but extends to institution-specific variables such as utility failures, local threats of gang-related activity, and presence of a local high-risk industry such as a chemical or nuclear power plant. TJC requires a formal documented HVA that is integrated with the emergency management plan, setting priorities among potential emergencies and also defining the hospital's role in the local community-wide emergency plan.[114]

Incident Command System

The Incident Command System (ICS) is designed to provide the basic architecture of an emergency management response. Major barriers to medical response arise from the lack of coordination among various public and healthcare agencies and from the lack of operational integration of various medical specialties. The ICS incorporates all these agencies and ensures a cooperative and effective response to a crisis. The concept of ICS resulted from the analysis of the devastating wildfires in Southern California in 1970 and has since been modified and successfully adapted to different disaster situations related to healthcare facilities.[100–102] The ICS specifies a common terminology and a command structure with five functional sections:

1. *Command:* Unified command staff responsible for overall management of the incident.
2. *Operations:* Performs the actual response work under the directives of the command center.
3. *Planning:* Gathers relevant information and develops response strategies as the situation progresses.
4. *Logistics:* Responsible for facility-wide supplies, equipment, personnel, and services. It also provides for basic services to personnel of the command center.
5. *Finance:* Authorizes expenditures, maintains records, and provides documentation of the incident.

A designated person will have the authority to declare an emergency. All personnel involved in the command system should be aware of the exact predetermined location of the command center. The plan should also provide protocols that will guide notification and the sequence of mobilization of these personnel in a disaster situation. The command system must also have independent telephone lines to ensure uninterrupted communication with the external world in a disaster situation. Once initiated, the ICS has a built-in chain of command that is responsible for triage of patients and allocation of personnel and resources.[115]

Triage

Appropriate triage is a vital function during an emergency management response. This is a dynamic process that is not necessarily confined to the disaster site or the emergency department, but rather is carried through several levels of the medical response pathway of a disaster response. Modern triage is based on the likelihood of survival in relation to the resources available at the time of the decision.[116] Problems often encountered in the triage process include the following[117]:

1. Lack of medical direction at the scene. Making triage decisions in a chaotic situation requires skill and experience and can often initially seem confusing and unmanageable. Lessons from the first Persian Gulf War showed that on-field triage was correct only 70% of the time. It is necessary to entrust experienced physicians with this job and to have simple and clear guidelines for the decision-making process. In addition to emergency physicians and trauma surgeons, critical care physicians bring with them the expertise to deal with complex and time-bound situations and are thus well suited to head a triage team.

2. Lack of interorganizational planning. Dynamic management of the triage process requires interorganizational coordination and flow of information. Up-to-date assessment of medical resources and personnel should be communicated from the command center to the triage site, and similar communication should occur from the scene to the command center. This will allow for rational and appropriate triage based on the availability of resources.
3. Transport of victims from the site by nonambulance vehicles to nearby hospitals.
4. There is no universally accepted form of triage. A recommended system uses a color-coded system to sort out disaster victims.[116]

Major Utilities, Supplies, and Equipment

Disaster plans and drills should factor in the possibility of internal and external power outages and related disruptions (ventilator and monitoring device failures, communication failures including breakdown of cellular phones, and elevator failures) and water and gas supply shortages. The plan should have an up-to-date inventory of all supplies and capabilities of the facility. The numbers of ventilators in use and their absolute capacity, inventory of various ICU supplies, and vendor lists should be readily available if there is sudden demand for supplies. The disaster plan should allow for at least 2 days' worth of supplies. Regular drills will help identify various bottlenecks and provide knowledge of the absolute capacity of devices, equipment, and services in a disaster situation. Plans to evacuate critically ill patients to nearby hospitals in the event of failure of backup systems should be addressed. Since the anthrax attacks and the resulting strain on antibiotic supplies in 2001, more attention has been paid to the national repository of lifesaving pharmaceuticals and medical supplies called the *National Pharmaceutical Stockpile Program*. This response is a component of the CDC's larger Bioterrorism Preparedness and Response Initiative and is composed of a stockpile of pharmaceuticals, vaccines, medical supplies, and equipment to augment local and state resources in a disaster situation. After a federal decision to deploy, a "push package" will arrive by ground or air in 12 hours or less at any location in the United States. A CDC team accompanying the push package will then define shipments in the second phase.[118]

Security and Casualty Reception

Security is a major concern during natural or man-made disasters. Desire to seek immediate medical evaluation, panic, and curiosity are factors that place the healthcare facility and its personnel under enormous strain. Internal and external traffic control, protection of personnel involved in the response effort, and strict enforcement of staging and triage areas are key security-related issues. Law enforcement plays a more critical role during terrorist attacks or bioterrorism, and failure to maintain order will lead to rapid overwhelming of the facility's resources and a disorganized medical response. Because most victims will arrive at the hospital by foot or by personal vehicles, provision must be made for a predetermined staging area with adequate mass decontamination facilities and respiratory protective equipment.[114,119]

ISSUES UNIQUE TO THE INTENSIVE CARE UNIT

The responsibility of caring for the most serious salvageable casualties in natural and man-made disasters will ultimately involve the critical care physician. As opposed to the overwhelming shortage of resources, lack of coordination among various agencies and specialties has been often cited as the main contributing factor to an ineffective emergency medical response. This response therefore requires the cooperation of not just physicians but also among prehospital medical personnel, nurses, and ancillary services such as radiology and laboratory services.[53]

Possible roles for the intensivist as part of a disaster management planning team include the following:

1. Clear role definition and understanding of the overall organization of the emergency response plan
2. Knowledge of the usual limit, surge capacity, and absolute limit of ICU resources
3. Construction of appropriate staffing models

CRITICAL CARE IN UNCONVENTIONAL SITUATIONS

Mobile ICU Teams

There have been numerous examples in the medical literature describing extended critical care through mobile ICU teams. Using mobile ICU teams has not been restricted to disaster settings but has also been used throughout the world during peacetime. Various factors that have to be considered in forming ICU teams are discussed next.

Personnel

On the basis of the anticipated needs of the disaster, appropriate specialists and ancillary personnel are chosen. Given the complexity and inherent unpredictability of staffing for disaster management, a flexible and adaptable approach must be taken to staffing such events.[120]

Training

Adequate predeparture training is essential for a coordinated and effective response. In addition, interaction and onsite training ensure effective functioning of a foreign medical unit and allow for the smooth transition of care to local physicians when the foreign team departs.[96]

Casualty Assessment

Studies from the past and also the experience of the IDF in providing care to earthquake victims in Turkey showed that the effectiveness of mobile ICU teams was limited by time. It may take 3 days to mobilize such an effort, and crucial time is lost before delivery of care. Efforts must thus be made to epidemiologically assess the efficacy of such teams. They should include review of the overall effort and adequacy of the ICU teams, outcome of victims, operational costs, and analysis of the structure and process of the ICU in the field.[120]

CRITICAL CARE TRANSPORT

Common principles involved in the safe transport of patients include the following[120]:

1. Rapid assessment of the severity of injuries, recognition of the need for transport, and anticipation of problems during transport
2. Safe movement of patients in and out of vehicles, continuous monitoring of vital signs, and recognition and treatment of problems encountered during transport
3. Documentation of the events during transport and provision of a detailed report to the admitting personnel

Types of Transport

Ground Transport

Ground ambulances have the advantage of rapid deployment, high mobility, and lower cost. However, patients and equipment are subject to significant deceleration and vibration forces. Equipment may vary depending on the size of the ambulance and usually includes blood pressure and electrocardiograph monitors, pulse oximeters, ventilators, and in some cases, modern support devices such as intraaortic balloon pumps.

Air Transport

It is beyond the scope of this chapter to provide a full detailed discussion of fixed-wing or rotary aeromedical transport, but it may be necessary during certain disasters to extricate victims via air.[120]

CONCLUSION

Understanding the characteristics of different disasters, developing an interdisciplinary approach to hazard mitigation, and knowledge of related clinical syndromes are key to an effective medical disaster response. To ensure an integrated and effective response to future disasters, it is necessary for critical care physicians to understand the fundamental principles in disaster medicine and participate in the disaster-planning process.

KEY POINTS

- Disaster medicine is a unique specialty that has evolved over the past few years. It shares a common ideal with public health: "greatest good for the greatest number." Critical care medicine forms an indispensable part of this science because intensive care physicians not only care for the sickest of the salvageable patients in any hospital but also bring with them their clinical expertise in triage, resuscitation, and help in providing care outside the domains of the unit through mobile ICU teams.
- Clear, common, and concise definitions are important in effective communication and evoking appropriate responses to disaster situations. The concept of functional impact of a disaster on the healthcare system is paramount while classifying disasters.
- It is important to understand the common effects of different natural and man-made disasters to predict their impact on the healthcare system. Even though man-made disasters such as terrorist attacks have gained attention, the numbers of geophysical disasters such as earthquakes, floods, and hurricanes have remained fairly constant and place the greatest burden on the healthcare system.
- Disaster situations produce many unique medical syndromes that require specific therapy. Knowledge and immediate recognition of different medical syndromes with appropriate interventions is critical to minimizing morbidity and mortality.
- Disaster planning includes developing action programs to minimize loss of life and damage during a disaster, training healthcare personnel and civilians, coordinating response efforts, maintaining adequate supplies of equipment and personnel, and rehabilitating the community after the disaster. Knowledge of potential man-made and natural disasters to which the community is prone should be an integral part of the planning process. Common principles involved in the creation of an emergency response plan should be followed and applied from an ICU perspective.
- With their natural role of caring for critically ill patients, intensivists bring with them unique abilities that can be applied to a disaster situation: a multidisciplinary approach to patient care, management skills, procedural expertise, and flexible attitudes.
- Intensivists can also provide care outside the domains of the ICU through mobile ICU teams and transport of critically ill patients. Various factors have to be considered in forming such teams and in the safe transport of patients.

Telemedicine in Intensive Care

Alejandro J. Lopez-Magallon, Joan Sánchez-de-Toledo, and Ricardo A. Muñoz

Worldwide, there is a need for novel strategies to alleviate the lack of specialized medical care, including critical care medicine. Societal changes in demographics, epidemiology, and culture, in addition to significant technologic advances, have positioned telemedicine as a useful tool to narrow the gap between available and needed medical care. Thus far, it has proved to be a disruptive technology, potentially altering traditional paradigms in the critical care environment, particularly in medical education, team organization, medical licensing, quality improvement, disaster response, and research. A recent report estimated that 13% of non–federal-funded hospital adult intensive care unit (ICU) beds were supported by some form of ICU telemedicine program.[1] Despite its relative novelty and rapidly changing technology and legislation, additional information has accumulated in the last few years suggesting potential features that can be leveraged to achieve an ideal model of tele-ICU care. Here we present our perspective for the current state-of-the-art and practical considerations on these matters (Fig. 169.1).

DEFINITION

Telemedicine can be described as the use of electronic information and telecommunications technologies to support and promote long-distance clinical health care, patient and professional health-related education, public health, and health administration. Technologies include videoconferencing, the Internet, store-and-forward imaging, streaming media, and terrestrial and wireless communications.[2]

Potentially related benefits may include improved access and enhanced efficacy, quality, and efficiency in the delivery of healthcare services, in addition to equality in distributing scarce resources and the reduction of costs.

Although we can track the use of telecommunications with this purpose to the first half of the 20th century in Australia[3] and decades later with the National Aeronautics and Space Administration (NASA)[4] and the space race,[4] it was not until the past 2 decades when critical technologic developments allowed for an explosive increase in its use as an alternative for overcrowded traditional models of care.

Traditionally, telemedicine modalities can be classified into store-and-forward, real-time, or remote monitoring. In store-and-forward, medical information is sent electronically to a remote physician for assessment offline, without direct simultaneous interaction between a remote medical team and a telemedicine physician. In the real-time mode, a direct video interaction exists between a telemedicine physician (or a physician extender) and a remote patient, physician, or medical team. Finally, remote monitoring implies the monitoring of a patient from a distance using different technologies depending on the physiologic system to be followed.[5]

TELEMEDICINE IN INTENSIVE CARE

The implementation of a new tele-ICU program should focus on each one of the following aspects:

1. Telemedicine-related laws and regulations at state and national levels
2. Technologic platform
3. Staffing
4. Model of care

Telemedicine-Related Laws and Regulations

There are basic elements that any telemedicine program should consider to comply with national and state laws, in addition to technical regulations pertaining to the particularities of the telemedicine interaction (Box 169.1). The American Telemedicine Association has published core guidelines for baseline technical requirements and telemedicine operations and guidelines for tele-ICU operations in particular.[5] Policies that foster telemedicine use are being promoted in most states (state parity laws) and should be consulted to adjust the tele-ICU program model accordingly, given that they will affect reimbursement and credentialing.[6] In broad terms, signed patient consent must be obtained and patient confidentiality should be preserved at all times regardless of the model of care used in any tele-ICU program. A practitioner licensed in the state where the medical care is being delivered is mandatory during the teleconsultation, and by-proxy credentialing issues should be addressed between connecting hospitals. The Interstate Medical Licensure Compact is an agreement between 29 states, the District of Columbia, and the territory of Guam, offering an expedited way for licensure in those states participating in the compact.[7] Moreover, documentation of the telemedicine consult should be in the patient's medical record.

Finally, the unique setting of virtual telepresence results in distinct communication needs that are different from the regular onsite, traditional team interactions and "telemedicine etiquette" (Box 169.2). They should be kept in mind during telemedicine consultations to be efficient in the art of "the systematic finding and delivery of bad news to the remote team."

Technologic Platform

Robust information technology (IT) department support is needed to ensure seamless and safe communication between the tele-ICU team and remote ICUs.

The cost-efficiency of a tele-ICU technologic platform reached a critical point a few years ago, when data transmission migrated from costly dedicated optical cable networks to wireless encrypted communication via the Internet.[8]

The technologic infrastructure should conform with the IT policies of the enterprise. Devices must have up-to-date security software, and systems must comply with all current and applicable state and federal

Fig. 169.1 Telemedicine suite. Wall screens, from *left to right panels*: Panoramic room cameras, ICU summary snapshot, room video cameras, and AI sniffing algorithm. Remote monitoring screens not shown. Telemedicine stations for access to remote EMR. *AI,* Artificial intelligence; *EMR,* electronic medical record; *ICU,* intensive care unit.

BOX 169.1 Telemedicine-Related Laws and Regulations

- National telemedicine laws
- State parity laws US
- Patient confidentiality/consent (Health Insurance Portability and Accountability Act)
- By-proxy credentialing

BOX 169.2 Telemedicine Etiquette

- Identify yourself and the remote team
- Ensure patient confidentiality
- Respect the remote team's work
  - Listen to the remote team first
  - Connect in time
  - Keep teleconsultations as brief as possible
- Comply with telemedicine laws and regulations
- Objectively evaluate the patient
- Provide advice based on the best available evidence

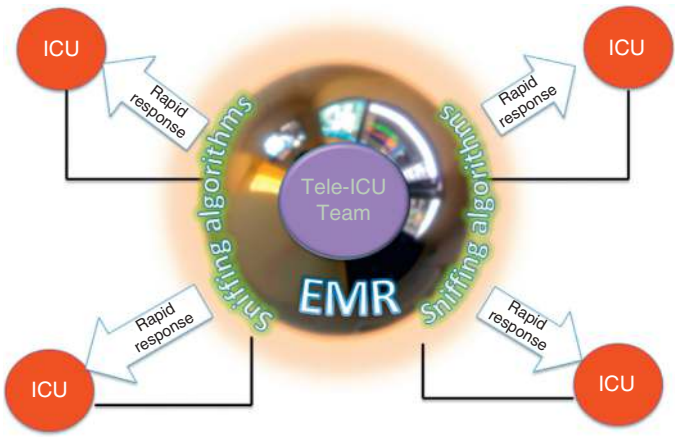

Fig. 169.2 Diagram of a state-of-the-art tele-ICU. An electronic database with physiologic data and other medical information is updated in real time in the EMR. A tele-ICU team works on surveillance of patient information assisted by remote monitoring, EMR, and sniffer algorithms. Once a dangerous trend is detected, the patient is reviewed with the remote team and a response is elicited. *EMR,* Electronic medical record; *ICU,* intensive care unit.

laws and regulations governing the use of medical devices and medical information: Food and Drug Administration (FDA), Health Insurance Portability and Privacy Act (HIPAA), Health Information Technology for Economic and Clinical Health (HITECH), and Waste Electrical and Electronic Equipment (WEEE).[5] Depending on the scope of the particular tele-ICU program, minimal hardware could include a simple telemedicine cart on both ends, escalating to a fully autonomous robotic telepresence with access to remote electronic medical records (EMRs), medical imaging, and monitoring systems supplemented with automated rapid response algorithms[9,10] (Fig. 169.2).

Staffing

Given the significant disparity between available and needed qualified specialists to meet current safety standards, the Leapfrog group has endorsed telemedicine as an appropriate alternative to reach these goals.[11] It would be wise then to redesign the workflow of the existent and future ICU staffing considering the telemedicine time. In those tele-ICU programs with staff dedicated mainly to telemedicine, a minimum amount of time of direct clinical practice must be ensured to maintain proficiency.

Reimbursement for telemedicine care remains a significant challenge. In a national survey, 55% of respondents reported not billing for telemedicine services.[12] A number of tele-ICU ventures have jumpstarted their programs with the assistance of grants. A common arrangement is also a contractual arrangement between connecting hospitals.

Model of Care

Clinical models for tele-ICU can be classified in the following manner:

- Continuous care model: Continuous care is monitoring of the patient without interruption for a defined period (e.g., on an 8-, 12-, or 24-hour basis).
- Scheduled care model: Scheduled care occurs with a periodic consultation on a predetermined schedule (e.g., during patient rounds).
- Responsive (reactive) care model: In this model virtual visits are prompted by an alert and are unscheduled (e.g., telephone call, page, monitor alarm).[5]

Tele-ICU in Adult Patients

Different models of care have been adapted for telemedicine in the critical care environment.[13] These models can range from physician-to-physician consultation with limited[14] tele-ICU team involvement to fully autonomous telemedicine team intervention without the need of the presence of a physician in the remote place. Consequently, reports in the intensive care settings have shown conflicting findings related to any effect from a telemedicine system in patient outcomes.[15]

The reason for these discrepancies is not completely understood, and the quality of reported data has been suboptimal. In a systematic literature review and meta-analysis, Young and colleagues investigated more than 721 critical care and telemedicine articles and 2683 critical care or telemedicine abstracts, including 13 studies with more than 41,000 patients in their final analysis. The tele-ICU coverage was associated with a significant reduction in ICU mortality and length of ICU stay but not with in-hospital mortality or length of hospital stay. There was a significant degree of heterogeneity in the studies included in their analysis and a striking degree of variation in how tele-ICU coverage was defined, the hospitals where it was evaluated, and the impact that tele-ICU coverage had on patient outcomes.[16]

Kahn has proposed a conceptual model to describe potential factors influencing program success (Fig. 169.3).[17] In this model, the effectiveness of a tele-ICU program was influenced by characteristics of both target hospitals and ICUs, in addition to the telemedicine unit itself. When optimal, these characteristics may facilitate timely interventions and guideline adherence, leading to improved quality and efficiency of care. When suboptimal, telemedicine fails to change practice patterns and thus fails to improve quality.[17] Using a novel ethnographic approach to evaluate 10 telemedicine programs, this same team found that the effectiveness of a tele-ICU program was influenced by the interaction of factors within the domains of leadership of both the tele-ICU program and the facility providing remote care, the perceived value of the program by front-line care providers, and the organizational characteristics of the telemedicine program.[18]

A growing body of evidence has accumulated over the years, suggesting a decrease in mortality and better quality of life associated with implementing tele-ICU programs in the critical care process. Lilly and colleagues, in a multicenter report including 432 patients from 56 different ICUs, observed that those tele-ICU interventions with early intensivist case involvement, adherence to best ICU practices, reduced response times to alarms, and that encouraged use of performance data were associated with lower mortality and length of stay (Fig. 169.4).[19,20] Likewise, in a program led by nurses screening best practices in ICU patients, Kahn and colleagues found improvements in the quality of care and a decrease in mechanical ventilation days and length of stay but no impact on mortality.[21]

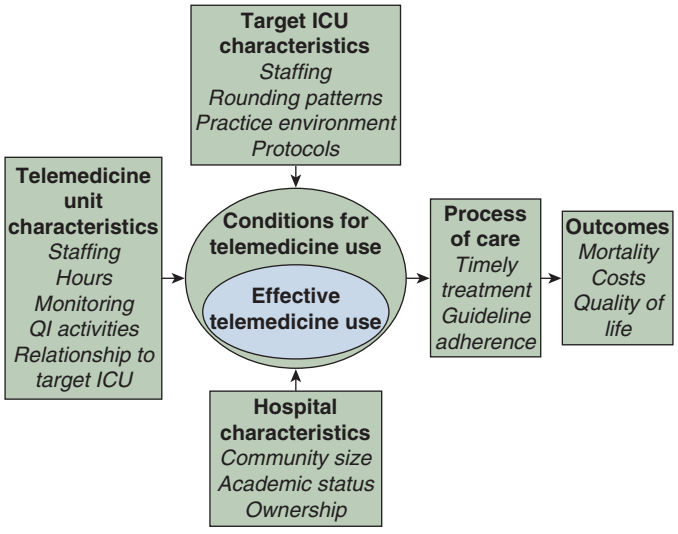

Fig. 169.3 Conceptual model for ICU telemedicine effectiveness. Under this model, the effectiveness of ICU telemedicine is determined by identifiable characteristics of the target hospital, the target ICU, and the telemedicine unit. *ICU,* Intensive care unit; *QI,* quality improvement. (From Kahn JM. ICU telemedicine: From theory to practice. *Crit Care Med.* 2015;42:2457–2458.)

Tele-ICU in Pediatric Patients

The disparity between available and needed expertise in critical care may be even more acute in children. The Institute of Medicine has reported that most children receive emergency care in general hospitals. Although children make up 27% of all emergency department (ED) visits in the United States, only 6% of these EDs are properly equipped for pediatric emergencies. This likely affects the quality of care delivered to children presenting to EDs and, more acutely, in those located in underserved and rural communities.[22]

Telemedicine consultation for pediatric critical care shares similarities with the adult setting, in addition to differences arising from the unique challenges offered by different and fragmented demographics, a wide range in patient size and physiology, and the coexistence of congenital malformations, among others. Consequently, a verbatim translation of an adult tele-ICU model for these patients may be unworkable, and proper adjustments should be made in maintaining a systematic approach in the teleconsultation format.

Reports related to the use of telemedicine in pediatric ICUs are relatively scarce, with some of them related with critical care consultation to rural and isolated populations. Heath and colleagues conducted 63 teleconsultations in 10 rural EDs. Most of the communications occurred without significant technical issues, and in 40% of them telemedicine was used to supervise the critical care transport team. A survey reported high satisfaction among consulting and referring physicians, with most of the providers perceiving telemedicine as improving patient care, being superior to telephone conversations, and allowing good provider-to-provider communication.[23] Yager and colleagues reviewed 56 consecutive telemedicine consultations for pediatric patients in the critical care setting. Communications occurred with the pediatric critical care fellow in 100%, nursing staff in 68%, and parents in 66% of their teleconsultations. Patient assessment, communication with the multidisciplinary care team, and communication with a patient's family were the outcomes most often cited that would not have been possible via telephone. A change in medical management was noted after 32% of encounters.[24]

The use of an appropriate pediatric tele-ICU can facilitate decision making in remote sites, allowing for a more selective referral of patients to tertiary centers. This is of particular interest in the neonate with cyanosis. In a study from a prospectively collected multicenter database in infants matched for gestational age, weight, and diagnosis, Webb and colleagues reported that telemedicine shortened the time to diagnosis and significantly decreased the need for transport of infants with mild or no heart disease. They also found that the length of hospitalization and intensive care stay and the use of indomethacin and inotropic support were less in telemedicine patients compared with patients in centers without the availability of telemedicine.[25]

More recently, Berrens and colleagues reported that rapid-response and code-response teams at a satellite facility supported via telemedicine by a pediatric intensivist were able to provide timely and reliable support, with no patients transferred from the satellite campus requiring a rapid escalation of care.[26]

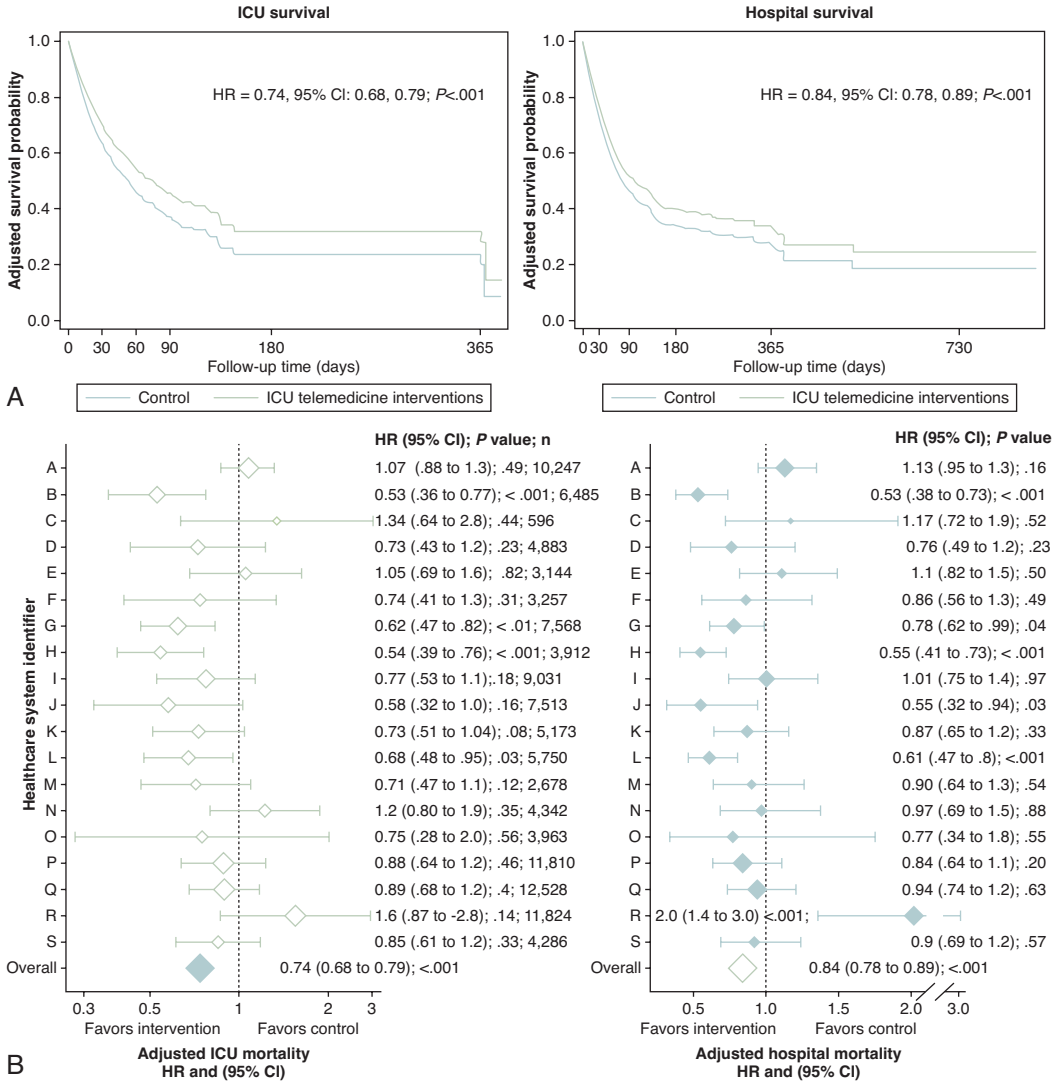

Fig. 169.4 **A,** Adjusted ICU-specific *(left)* and hospital-specific *(right)* survival estimated by Cox proportional hazards regression. Models adjusted for APACHE IV score, age, hospital, or ICU identifier (as a random effect); admission source; primary admission diagnosis; operative status; time from start of study enrollment; heart rate; admission and highest creatinine values; respiratory rate; admission hematocrit value; blood urea nitrogen; white blood cell count; Glasgow Coma Scale score; prothrombin time; anion gap; urine output (in the first 24 hours); base excess; and total bilirubin and albumin values. **B,** Adjusted ICU-specific *(left)* and hospital-specific *(right)* survival estimated by healthcare system. The *center of the diamond* represents the effect estimate, the *bars* represent 95% CIs, the *symbol size* is proportional to the number of observations for the corresponding healthcare system, and the overall effects are presented as *diamonds in the bottom row*. *CI*, Confidence interval; *HR,* hazard ratio; *ICU,* intensive care unit. (From Lilly CM, McLaughlin JM, Zhao H, et al; UMass Memorial Critical Care Operations Group. A multicenter study of ICU telemedicine reengineering of adult critical care. *Chest.* 2014;145:500–507, Fig. 2.)

We have reported our own experience with telemedicine in pediatric cardiac critical care in the international setting, eventually expanding to four hospitals in two Latin American countries. We conducted 1040 teleconsultations for 476 patients, 62% of them being in the most complex surgical patients. There was a difference in overall satisfaction, perception about telemedicine usefulness in education, and impact on medical practice among centers. We concluded that a "one-size-fits-all" approach may not be feasible in most international telemedicine settings, and prospective interventions should consider differences in staff composition, perception of needs, and patient population among centers.[27] In one of the international hospitals participating in our telemedicine program, we conducted a retrospective review of clinical records and a telemedicine database of patients admitted there during the initial 10 months of our program and compared with patients admitted during a preintervention period. We observed a shorter cardiac ICU and length of hospital stay in cardiovascular patients and a shorter preoperative and cardiac ICU length of stay in surgical patients.[28] We found also that the implementation of telemedicine-assisted interventions in their pediatric extracorporeal membrane oxygenation (ECMO) program delivered valuable diagnostic and therapeutic advice, was associated with significant changes in selection criteria and model of care, and provided a

significant increase in patient survival during the telemedicine period as compared with a historical cohort from the same institution (from 29.4% to 54.4%).[29]

Tele-ICU in Disaster Response

Probably one of the most compelling arguments for implementing a tele-ICU program is the continuous training and readiness for disaster response. In such dire situations and despite apparent preparedness, mid-course corrections or the need for improvisation is a common occurrence, including failure in logistics and communications. Although it is true that the very nature of natural or man-made disasters presents unique challenges in every new presentation, it is also true that many of these problems arise from the fact that once disaster response plans are made, they often end stored and forgotten, and the teams eventually become untrained. Reynolds and colleagues. published their experience with the use of a previously established tele-ICU program for disaster relief during the winter 2009 blizzards in the Baltimore metropolitan area. Given they had been using a telemedicine system for 5 years on a routine basis, they transitioned seamlessly to disaster response mode, conducting daily ICU rounds and coordinated care with the onsite team, assisted by robotic telepresence[30] together with remote access to EMR and imaging studies.

TELE-ICU IN THE FUTURE

Tele-ICU is an ever-growing field. The current supply-demand estimates in adult critical care project a need for tripling the capacity of ICU case days compared with 2006. This is not and will not be sustainable in the foreseeable future.[31] Hence, a different paradigm for ICU care needs to be developed. Telemedicine will undoubtedly be an integral part of this new approach, Tele-ICU programs will advance their integration with powerful artificial intelligence (AI) tools, allowing for earlier intervention and avoidance of adverse events,[10,11,32] perhaps enabling critical patients to be treated closer to their homes, family, friends, and support network while empowering local teams, providing best-evidence guidelines and quality assurance, and accelerating the decision-making process to expedite definite treatment or else more compassionate, palliative, or end-of-life care. Integration through a continuum from home and the community to the critical care environment will incorporate early preventive strategies aimed at well-being preservation and risk avoidance, rather than the current reactive approach toward already established critical care disease, connecting presently disjointed practices in ambulatory medicine and critical care.

KEY POINTS

- Tele-ICU has become a reliable strategy to enhance care in critically ill patients.
- Fields potentially affected by telemedicine include medical team organization, medical education and licensing, quality improvement, disaster response, and research.
- Tele-ICU operations should be in compliance with international, national, state, and local laws and regulations.
- A systematic approach including quality improvement interventions may yield the best results in patient survival and length of stay.
- Units with low-intensity day staffing may benefit the most from tele-ICU.
- Pediatric critical patients present unique challenges, but experience is growing rapidly.

ANNOTATED REFERENCES

American Telemedicine Association TeleICU Practice Guidelines Work Group. 2014. *Guidelines for TeleICU Operation*. Washington, DC: American Telemedicine Association. Available at https://www.americantelemed.org/resource_categories/practice-guidelines/ [americantelemed.org].
This document was endorsed by the American Association of Critical-Care Nurses and the Society of Critical Care Medicine, laying the basic organizational principles for tele-ICU operations.

Berrens ZJ, Gosdin CH, Brady PW, et al. Efficacy and safety of pediatric critical care physician telemedicine involvement in rapid response team and code response in a satellite facility. *Pediatr Crit Care Med.* 2019;20(2):172–177.
In this cross-sectional single-center study conducted in a tertiary pediatric center and its satellite facility to evaluate a telemedicine model to provide pediatric intensivist involvement in rapid response and code teams at the satellite facility, the authors found telemedicine critical care teams were involved in satellite campus rapid-response team activations 94.6% of the time with a median response time of 7 minutes, with a similar ratio of patients transferred to the pediatric ICU (PICU) when compared with the monthly rate at their main campus. They concluded that telemedicine was a reliable, timely, and effective alternative to facilitate critical care involvement in rapid-response and code teams at satellite facilities.

Kahn JM, Rak KJ, Kuza CC, et al. Determinants of intensive care unit telemedicine effectiveness. An ethnographic study. *Am J Respir Crit Care Med.* 2019;199(8):970–979.
The authors used an innovative approach conducting a qualitative study with an ethnographic evaluation of six tele-ICU programs and 10 target ICUs, including numerous interviews and focus groups, comparing results between effective vs. less effective programs. They suggest that the effectiveness of ICU telemedicine programs may be influenced by several potentially modifiable factors within the domains of leadership, perceived value, and organizational structure. It is a useful reference for new and established tele-ICU programs.

Lilly CM, McLaughlin JM, Zhao H, et al. A multi-center study of ICU telemedicine reengineering of adult critical care. *Chest*. 2014;145(3):500–507.
In this large, multicenter, nonrandomized, pre/post assessment of telemedicine interventions in more than 100,000 adult ICU patients, the authors found that interventions that increased early intensivist case involvement, improved adherence to ICU best practices, reduced response times to alarms, encouraged the use of performance data, and were associated with lower hospital mortality and length of stay.

Lopez-Magallon AJ, Saenz L, Lara-Gutierrez J, et al. Telemedicine in pediatric critical care: A retrospective study in an international extracorporeal membrane oxygenation program. *Telemed J E Health*. 2018;24(7):489–496.
In this retrospective, pre-post intervention study in an international pediatric ECMO program, we found that the implementation of telemedicine-assisted interventions was associated with significant changes in selection criteria and model of care and increased hospital survival. Valuable diagnostic and therapeutic advice was offered, with 19% and 17% of patients receiving a recommendation for diagnostic cardiac catheterization or additional surgical intervention, respectively.

Webb C, Waugh C, Grigsby J, et al. Impact of telemedicine on hospital transport, length of stay, and medical outcomes in infants with suspected heart disease: A multicenter study. *J Am Soc Echocardiogr.* 2013;28(9):1090–1098.
This was a prospective telemedicine intervention study conducted in nine pediatric cardiology centers comparing infants born at hospitals with telemedicine access to remote cardiology consultation with those without telemedicine access as controls. Telemedicine access shortened the time to diagnosis and decreased the need for transport in infants with mild or no heart disease. Also, length of stay and need for indomethacin or inotropic support were less in the telemedicine group. An important reference in the pediatric world making the case for telemedicine—enabling expedited access to specialty care, empowerment of local teams, and allowing more patients and families to stay closer to home.

Teaching Critical Care

Christopher K. Schott

INTRODUCTION

As a specialty, critical care medicine has many unique challenges when it comes to teaching trainees. The intensive care unit (ICU) is an environment with high stakes and time-sensitive decision making for acutely ill patients with multiple competing demands for time balanced against learners across multiple levels of training (medical students, residents, fellows) and backgrounds (internal medicine, surgery, anesthesia, emergency medicine, neurology, nurse practitioners, physician assistants, pharmacists, etc.).[1–3] Given these challenges, it is helpful to know that the skills necessary to be a high-quality, effective teacher are able to be learned with an understanding of the principles of adult learning in addition to developing a toolbox of methods to teach depending on the topic or circumstances. The goal of this chapter is to provide a review of adult learning theory and curriculum development to aid in learners' ability to acquire knowledge and skill for critical care.

THE ROLE OF THE EDUCATOR

Teaching success should be measured in terms of student performance, not the activities of the teacher. Delivering a carefully organized PowerPoint presentation, supervising problem-based workshops, or providing bedside clinical tutorials does not mean one has taught. Unless the learner has acquired new cognitive or psychomotor skills, teaching has not occurred.[4] An effective teacher takes responsibility for ensuring that students learn.

Stritter and Bowles described a model focused on the student.[4] In this model, the teacher assumes responsibility for the learner's success and creates an environment conducive to learning by managing the educational resources. The teacher as a "manager" creates specific educational objectives, motivates students, uses various educational strategies, evaluates learning, and provides effective feedback to ensure the learner achieves all the educational objectives.[4] Using this learner-centric approach, educators can start to think of themselves less as the "sage on the stage" presenting information and more as the "guide on the side" to help learners achieve success assimilating new information.[5]

ADULT LEARNING THEORIES

There are multiple theories that describe how individuals learn. In particular, there are several pillars that describe the principles of adult learning. Ôª øMalcolm Knowles's andragogy demonstrates the principles that drive adult learners: (1) learning is more self-directed; (2) learning is based on the scaffolds of prior experiences; (3) adults are more motivated to learn things directly related to their roles; (4) adult learning is more problem than topic centered; (5) there is a greater emphasis on internal or intrinsic motivation than extrinsic drivers; and (6) adults need to understand *why* there is a need to learn the material.[6,7] Kolb describes this model as "experiential learning," further supporting the need for adult learners to base new knowledge on both prior experiences and the ability to "play" with the novel concepts to help cement into more permanent learning.[8] This is essential to keep in mind when dealing with more mature learners composing a critical care team. Early learners, such as medical students or residents, may be driven more by external factors, such as a rotation evaluation or grade, compared with senior residents, fellows, or junior faculty who have more intrinsic motivation to recognize the need to learn material for their delivery of patient care.

This transitions into the importance of developing an appropriate learning environment. Learners retain more when they feel comfortable and safe as opposed to situations where there may be fear or anxiety.[7,9] This is derived from the "brain-based learning" principle of "relaxed alertness," whereby learners are inhibited from processing new information into long-term memory when the predominant emotion is a stress or fear response.[10] Therefore an optimal learning environment should strive to balance presenting learners with level-appropriate challenges in an environment where they feel safe to play, process, and retain the information they are being presented.

Together, these principles should guide educators on ways to optimize their students' or trainees' ability to successfully gain new knowledge and skills. The following sections describe different ways to deliver information and develop curricula based upon these learning theories.

CURRICULUM DEVELOPMENT

Educational objectives outline the skills and behaviors the learner will be able to demonstrate after the teacher has completed a lecture, daily bedside instruction, 1-month elective, or fellowship training. Objectives should be developed for every instructional activity because they are a road map. They guide the teacher in developing an appropriate curriculum, set unambiguous expectations for the learner, and serve as a reference for evaluation and feedback.[11,12] Developing educational objectives involves the following three steps.

First, using action verbs (e.g., defines, explains, demonstrates, identifies, summarizes, evaluates), the instructor describes a specific behavior the learner must perform to show achievement of the objective. An objective such as "teaches concepts of airway management" is not adequate because it defines what the teacher is doing and does not clearly describe what the learner should be demonstrating. Therefore it neither serves as a road map for the teacher or the student nor identifies a clear behavior the teacher can evaluate. Second, the teacher should describe the conditions under which the behaviors are to occur. For example "given a scenario using simulation, the student will evaluate the airway and demonstrate effective bag-mask ventilation." Finally,

the criteria for acceptable performance should accompany the objective—that is, "bag-mask ventilation will be followed by successful laryngotracheal intubation within 30 seconds." When written for a lesson plan or formal curriculum, the format of a learning objective should be "who" (learner) will "do what" (knowledge or skill being taught) by "when" (end of lecture, curriculum, or course) as measured by "how" (the method of evaluation).[13]

When teaching students a specific clinical skill—for example, how to manage a patient with hypotension—the teacher must establish that the learner has first mastered the lower cognitive domains, knowledge, and comprehension. This is called *scaffolding* and is based on a classical hierarchy of levels of comprehension described by Bloom.[14,15] Learners will not be able to initiate an appropriate treatment for hypotension or evaluate effectiveness of treatment unless they can first list the causes of hypotension and describe the effect of preload on stroke volume. The teacher can ask some simple questions to better understand what level of cognitive domain the student is at, as well as asking subsequent questions to advance the learner to the higher level. Using an example from the treatment of heart failure, a teacher could start with a comprehension-level question such as "What is the mechanism of action of furosemide?" This can advance to a higher level, such as analysis, with the instruction "Identify the differences in development, presentation, echocardiography, and treatment for patients with systolic versus diastolic heart failure." At the highest-level evaluation, an instruction might then be "Evaluate the evidence to support the role of angiotensin-converting enzyme inhibitors in the symptomatology, rates of hospitalization, functional status, and mortality for patients with systolic heart failure." Table 170.1 demonstrates Bloom's taxonomy, built against a hierarchy of learner competency (using the Dreyfus model of skill acquisition and the RIME framework) with example verbs to use when constructing questions for each learner level.[15-18]

Educational objectives specifically related to critical care medicine training programs should be developed in accordance with the expectations outlined in the Accreditation Council for Graduate Medical Education (ACGME) program. In addition to listing the specific cognitive and motor skills that must be taught, the ACGME has developed general core competencies that focus on patient care and not just knowledge acquisition.[19] The six competencies include medical knowledge, patient care, interpersonal and communication skills, professionalism, practice-based learning, and systems-based practice. In recent years, the ACGME has evolved from simply assessing trainees subjectively on these competencies to an evaluation system of milestones through clinical competency committees with better-defined anchors for expected progression based on each clinical specialty.[20] Examples of educational objectives for each competency and details of each specialty's milestones are available at www.acgme.org.

LEARNING EXPERIENCES

There are numerous instructional methodologies a teacher can use to achieve educational objectives. Because adult learners prefer active learning, a curriculum that requires them to process information, participate in problem solving, and defend clinical judgment increases their enthusiasm for learning.[21]

Although frequently used, traditional lectures are not an efficient learning method.[22] There are growing challenges to attending lectures with limited time and competing activities for medical trainees. Moreover, because didactic sessions are not interactive, the teacher does not have an opportunity to assess whether the learner understands the content and its applicability. In contrast, small group sessions that incorporate problem-based learning and interactive workshops are more effective because they engage the students, force them to defend their decisions, and explain how they evaluate outcomes.[22]

A more contemporary model of an efficient learning environment is that of the "flipped classroom."[23–26] A flipped classroom design is one where the students review the core content, such as renal replacement therapy, before attending the session and then use the time with the instructor to work through cases or problems and provide direct formative feedback. This provides the ability to present material individually to learners at their own pace while focusing on learner-centered activities to reinforce the new knowledge or skills in a classroom, small group, simulation, or clinical setting.[1] The growth of recording technology provides the opportunity for an instructor to prerecord core content lectures and allow their time in the classroom to be used more efficiently to answer students' questions and work through the material without needing to repeat static elements of the content. Additionally these prerecorded lectures can serve as an online reference library for students to return to for review or when they might subsequently encounter a particular topic in clinical practice.[27]

However, none of these methods teaches students or residents how to apply these skills to real-life situations. It is possible that giving students an opportunity to manage complex problems and anticipate consequences of their interventions in an environment where their mistakes do not result in untoward outcomes, where feedback is immediate, and where students can repeat their performance until they acquire these skills might improve retention of new knowledge and skills. Such instructional opportunities exist and have been available for years in the form of simulation.

Simulation is defined as any training device that duplicates artificially the conditions that are likely to be encountered in an operation and may include low tech, partial task trainers, simulated patients, computer-based simulation, and whole-body realistic patient simulation. Work in cognitive psychology and education theory suggests that more effective

TABLE 170.1 HIERARCHY OF LEARNING COMPETENCIES Comparing the RIME Framework, Dreyfus Model, and Bloom's Taxonomy With Example Verbs to Question Learners at Each Respective Level

RIME	Dreyfus's Skill Level		Bloom's Taxonomy Learner Level	Example Verbs for Questioning Learners
Educator	Expert	Master	Evaluation	Debate, Discuss, Judge
	Proficient Performer	Expert	Synthesis	Compose, Hypothesize, Predict
Manager	Competent Performer	Proficient	Analysis	Compare, Contrast, Classify
Interpreter	Advanced Beginner	Competent	Application	List, Construct
Reporter	Novice	Novice	Comprehension	Describe, Explain
			Knowledge	Who, What, When, Where, Why, How

learning occurs when the educational experience provides interactive clues similar to situations in which the learning is applied.[28,29]

What initially began as computerized software with a separate torso apparatus has evolved into complex whole-body computerized manikins. Current models, such as the Laerdal SimMan 3G simulator, provide trainees a high-fidelity manikin that can have spontaneous respirations, palpable pulses, pupils that react to light and can constrict (unequally if desired), sweat, seize, demonstrate cyanosis, and simulate various difficulties for airway management. Moreover, the trainees can practice skills such as bag-valve-mask ventilation, nasal or orotracheal intubations, cricothyroidotomy, chest tube placement, needle decompression, closed chest compressions, cardiac pacing, and electrical defibrillation, among other procedures, with real-time feedback provided.[30] These computerized human simulators require trainees to integrate cognitive and psychomotor learning along with multisensory contextual cues to aid in recall and application in clinical settings.[31,32] Several publications have demonstrated the success of using simulation to emphasize team-based, multidisciplinary models with the ability to conduct in situ to maximize authenticity for the learners.[33] Examples of learning objectives for fourth-year medical students using the simulator are listed in Table 170.2. Note that all objectives are written in terms of behaviors the student must perform, thus giving the teacher clear guidelines for evaluation.

Though no study has unequivocally demonstrated improvement in actual patient outcomes,[33] and despite not showing these results in published data to present, simulation addresses the fundamentals of adult learning discussed previously. Simulation provides hands-on experiences without any direct risk to patient safety and can simultaneously address the cognitive, psychomotor, and affective domains of learning that are essential to a successful curriculum. Moreover, organizations such as the Institute of Medicine endorse simulation as a tool to teach novice practitioners problem-solving and crisis management skills.

TABLE 170.2 Learning Objectives for Fourth-Year Critical Care Medicine Course

Respiratory Distress
- Evaluate a simulated patient in respiratory distress (tachypneic and hypoxemic).
- Initiate appropriate oxygen therapy.
- Evaluate effectiveness of therapeutic intervention.
- Demonstrate effective bag-mask ventilation.
- Insert intravenous catheter for resuscitation.
- Evaluate patient for potentially difficult airway.

Cardiovascular
- Evaluate a patient with hypotension.
- Initiate therapy for a patient with hypotension (initiate intravenous fluids).
- Order appropriate diagnostic tests for evaluation of a patient with hypotension.
- Evaluate effectiveness of therapeutic intervention.
- Evaluate a patient with sinus tachycardia, develop a differential diagnosis, and order appropriate diagnostic tests.

Arrhythmias
- Evaluate a patient with sinus tachycardia, develop a differential diagnosis, and order appropriate diagnostic tests.
- Demonstrate defibrillation of ventricular fibrillation and pulseless ventricular tachycardia.
- Demonstrate airway management and cardiovascular resuscitation for simulated patients with ventricular fibrillation, ventricular tachycardia, pulseless electrical activity, and asystole.

TEACHING SKILLS AND STRATEGIES

The high-stakes and time-sensitive environment of the ICU may place the perception of constraints on clinician-educators, resulting in a perception that it is challenging to successfully teach trainees. However, there have been several widely taught and well-published skills that can easily be done at the bedside or in the ICU with minimal preparation or consumption of time. One such skill is the "one-minute preceptor."[34]

The one-minute preceptor (OME), also referred to as the "five-step 'microskills' model," aims to guide the learner by reasoning through their understanding of a topic.[3,9,35,36] It uses structured questioning and serves as a learner-centric approach, aiding the learner to arrive at a teaching point in an efficient manner while the learner is presenting a patient or clinical quandary, particularly when the learner expresses uncertainty in their decision making. It follows the structure of (1) having the learner make a commitment, (2) probe for supporting evidence, (3) provide a general teaching point on the topic, (4) reinforce correct behaviors with positive feedback, and (5) correct errors with formative feedback.[3,9,35] This can be done over the course of only a few minutes but with lasting impact for the learner.[36] In the initial step (Step 1: Commit), the learner is unable to waffle in their decision making and must take ownership of it. Regardless of whether that decision is "correct" or not, in terms of the clinical context, this provides a starting point. The instructor can use this to explore how the learner arrived at this decision through their prior experiences and knowledge (scaffolding) to understand more about the learner's thought process (Step 2: Probe). If the learner's decision was "incorrect" in that clinical context, their thought process provides the instructor the roadmap on how they arrived at that conclusion and thus a framework to help redirect. If the learner arrived at a "correct" conclusion, the instructor can use this step to help expand the learner's understanding of the topic through additional questions, following Bloom's taxonomy, to help progress the learner to a higher level of competency. This is followed by a brief, general teaching point, made by the instructor, on the topic (Step 3: Statement). This serves as a demonstration of a teaching moment by the instructor on the topic while minimizing any misperceived judgment of the learner's sophistication. This transitions into providing reinforcement and positive feedback on what the learner did correctly (Step 4: Reinforce), helping solidify the appropriate decision making while building the learner's self-esteem. The process concludes with providing formative feedback (Step 5: Correcting errors) to provide ongoing guidance for the learner's growth. This must be done with appropriate tact so as to not judge, shame, or embarrass the learner while providing effective feedback to expand their understanding of the topic.

PROVIDING EFFECTIVE FEEDBACK

The final step in being a manager of learning is to effectively use feedback to enhance learning. Too often feedback is used to fulfill an administrative function; it is provided as a summative report once the rotation is complete. This is referred to as "evaluative feedback." Conversely, "formative feedback" is provided in real time with the goal of positively changing a learner's behavior or skills. Effective feedback enhances affective learning, but when used inappropriately or done poorly, can also inhibit learning.[37]

Students want feedback; they want to know how they are performing and how their performance can be improved. Most students receive inadequate feedback during their training. Explanations for lack of feedback include a teacher's concerns that the feedback will result in unintended consequences, will damage the student-teacher relationship, or

will result in students evaluating the teacher as having performed poorly. None of these consequences will occur if the feedback is delivered correctly. Formative feedback is the only way to ensure the success of students, telling them what they have done well and, if necessary, what they need to do to achieve an educational objective. Without effective formative feedback, the behaviors go uncorrected and the student develops a system of self-validation: "I did well because no one told me otherwise."

Often, residents may have difficulty even recognizing that they are receiving feedback when it occurs in the same context of educational sessions.[38] Therefore it is important to make it explicit to the learner that feedback is being given. This can be done through asking for an invitation ("Can I provide you feedback on how you did with that procedure?") while maintaining a safe environment for the learner and overtly using the word "feedback" when it is being delivered.

For feedback to effectively change behavior without causing unintended consequences, several rules should be followed. First, all feedback should be based on how the student performed regarding a specific goal and/or objective of the program.[37] This is another reason teachers must develop clear educational objectives. They serve not only as the framework for the curriculum but also as a reference for feedback. If feedback is provided in the context of specific performance, there should be no untoward consequence.[37] For example, if the goal is for the learner to demonstrate effective bag-mask ventilation with appropriate chest excursion and adequate oxygen saturation, then the goal was either achieved or it was not. This is a statement based on an objective and is not a personal affront unless the feedback contains judgmental language. Second, feedback must include a description of how to succeed. In the example presented, if the patient was not effectively ventilated, the teacher should suggest repositioning the head, inserting an oral airway, and performing two-person bag-mask ventilation so there is a better seal with the mask. Third, the specific behavior the learner demonstrated should be addressed and not just interpreted.[37] If students are late to rounds, do not assume they do not care or are lazy. Stating the expectation that rounds begin at 7 AM and that the expectation is for the trainee to be prepared by then assigns no judgment. Fourth, for feedback to be effective, it should be an expected component of the learning tools.[37] Therefore the key to providing feedback is for it to be timely and based on an objective behavior, not a subjective trait of the student. Students should be informed during orientation that they will receive daily feedback on their performance of the stated goals and objectives. In summary, feedback should be timely, specific, and behavioral-based with suggestions for improvement. Without successfully implementing feedback, the model of teaching described by Irby is incomplete.[21]

CONCLUSION

A teacher who begins every educational session with clear objectives, creates an environment where students want to learn, applies different educational strategies, evaluates learning, and provides formative feedback will help his or her students to successfully achieve the educational objectives. These guidelines are applicable for developing a bedside teaching session, a 1-month rotation, or a multiyear curriculum.

ACKNOWLEDGMENT

The author would like to thank and acknowledge the contribution of Dr. Paul L. Rogers for his work on previous editions of this chapter.

KEY POINTS

- A teacher, serving as a manager, develops educational objectives, motivates students, organizes the curriculum, evaluates performance, and provides feedback.
- Educational objectives are an essential component of any instructional activity, setting clear expectations for the learner and serving as a reference for evaluation by the teacher.
- Adults prefer active learning; therefore a curriculum that requires them to analyze, solve, defend, and evaluate increases their interest in learning. Medical simulation is an innovative addition to a critical care curriculum.
- The one-minute preceptor technique provides a model of questions instructors may use to guide learners efficiently and effectively.
- Formative feedback should be provided during instructional activity to ensure the student's success.

Difficult Airway Management for Intensivists

Thomas C. Mort and F. Luke Aldo

The critically ill patient, particularly the critically ill difficult airway patient, presents unique airway challenges in emergency situations outside the operating room. The risk of life-threatening complications, including anoxic brain injury, death, and long-term disability, are exaggerated in this patient group when undergoing urgent/emergent airway management in the remote location. Physical examination of the patient is helpful to identify difficult airway characteristics, yet many remain subtle or difficult to recognize in the urgent setting. Routine assessment in the elective operating room setting is more comprehensive when compared with the agitated, hypoxic, sedated, hemodynamically unstable intensive care unit (ICU) patient suffering deterioration leading to an airway intervention. Risk factors vary but include body mass index (BMI) >30, a history of difficult airway, past or current presence of head and neck tumor ± radiation therapy to the head/neck region, history of chronic obstructive pulmonary disease (COPD), current or past tracheostomy, cervical spine limitations, airway edema, mass effect, swelling (angioedema), and airway soilage (bleeding, emesis).

Critical care provided to the ICU patient is often multidisciplinary; hence, there are a variety of approaches and schema to manage the airway. Optimally, a standardized approach for airway management should be agreed upon within your institution that reflects the concerns for all specialties. Different specialties may prefer their own algorithms or guidelines for airway management, yet it is important that a standardized approach for airway management be agreed. Despite the presence of a multitude of guidelines and algorithms from regional, national, and international sources, the vast majority reflect very similar philosophies and schema to manage the known or suspected difficult airway patient. Adherence to the American Society of Anesthesiologists (ASA) guidelines is common, but not universal. Collaboration will enhance patient care and should improve safety and outcome. Combining the ASA difficult airway algorithm/guidelines with the Chimes' Vortex approach may be beneficial to all. The Vortex approach advances one's ability to visual the progression from bag-valve-mask (BVM) ventilation, placement of supraglottic airway (SGA) or endotracheal tube (ETT) via laryngoscopy, advising the team to use no more than three attempts (or fewer), which should prompt movement to a standardized surgical technique. The incorporation of this schema has resulted in a more comprehensive application of the algorithm and improved airway management decisions.

It is imperative to mention that the use of fiber-optic techniques is a mainstay for airway management in the ICU setting and beyond. Maintaining one's fiber-optic intubation and bronchoscopy skills is crucial for patient safety. Fiber-optic methods remain a gold standard for diagnostic airway dilemmas in the ICU setting; awake intubation and select asleep airway management scenarios (bronchoscopic techniques will be addressed in other chapters). Use as a primary or rescue airway technique is universal in nearly all algorithms and guidelines. In the ICU setting, it has maintained multiple and various diagnostic and therapeutic roles that may be lifesaving.

PREOXYGENATION AND PER-OXYGENATION

Indications

Care providers should make every effort to provide a source of oxygen to the patient before and during an airway intervention:

- 100% oxygen for 2–4 minutes via a tight-fitting mask via a resuscitation bag before induction is standard. Extending this time frame may help the patient if the SpO_2 is moving in an upward trajectory. If not improving or falling, then alternative plans need to be deployed (e.g., secure the airway with an ETT or SGA).
  - High-flow nasal cannula oxygen (HFNO) is potentially valuable when used in conjunction with preoxygenation with a tight-fitting mask. It is inexpensive, is readily available, is easy to apply, and has few negative effects (15–30 L/min). The elevated hypopharyngeal oxygen may reduce the incidence of desaturation when intubation is delayed or multiple attempts are required to secure the airway.
  - If the patient is already on noninvasive ventilation (NIV: continuous positive airway pressure [CPAP], bilevel positive airway pressure [BiPAP]), this can be used as a preoxygenation method as long as the airway is patent and the patient's effort is sustainable. Assure the FiO_2 is increased to 100% on the NIV assembly.
  - If nasal NIV is present, topicalization of the oropharynx may be employed. Full-face NIV is compatible with topicalization by carefully lifting the mask from the corner of the mouth and applying local anesthesia via an atomizer or syringe.
  - During awake fiber-optic intubation, ongoing oxygen delivery via nasal cannula is recommended. If asleep fiber-optic intubation is employed as a primary or rescue method, continuous ventilation and oxygenation support, in addition to positive-pressure lateralization of periglottic tissues, can be delivered via an endoscopy mask that allows passing of the bronchoscope through the mask via a built-in portal.

SUPRAGLOTTIC AIRWAY PLACEMENT

BEFORE THE PROCEDURE

Indications

SGA use for managing the airway:

- When bag-mask ventilation is ineffective or impossible:
  - Noninvasive maneuvers such as nasal and oral airway placement, jaw thrust, chin lift, two- or three-person efforts are ineffective or fail to maintain Spo_2 >90%

- Decision to use an SGA (e.g., laryngeal mask airway [LMA]) should be made rapidly to avoid desaturation or endangering the patient's safety.

Primary use when mask ventilation difficulty is anticipated:

Decision to use an SGA may be based on a known history of difficult mask ventilation. This could be done as a first step in managing the patient. After optimal positioning preoxygenation with 100% oxygen via a tight-fitting bag-mask assembly combined with HFNO (15–30 L/min), placement of the SGA occurs immediately after pharmacologic induction. Alternatively, topical anesthesia preparation will allow placement of the SGA device; establish effective ventilation, then induce. Additionally, airway preparation with topical anesthesia would allow "awake" intubation by a variety of airway adjuncts, though bronchoscopy and video-assisted laryngoscopy (VAL) are preferred by most clinicians.

Suspected difficulty based on Langeron's criteria (two or more factors) + other factors

- Obesity
- Edentulous
- Beard
- Age >55 years
- History of snoring, obstructive sleep apnea (OSA)
- Macroglossia
- Anatomic alteration of head/neck, dressing, cervical collar
- Poor positioning

Secondary use as a rescue airway device when ineffective or impossible mask ventilation exists or after difficult or failed direct or indirect laryngoscopy:

- After induction of unconsciousness/apnea, bag-mask ventilation not effective
- Upper airway collapse/obstruction (above SGA level)
- Upper airway bleeding (e.g., tongue malignancy) to separate bleeding from lower airway
- When intubation proves difficult or fails, an SGA can be placed to support oxygenation and then removed for further attempts or used as a conduit for intubation
- Bridge to support ventilation/oxygenation while other methods are pursued, equipment is gathered, personnel are summoned:
  - Ventilation/oxygenation before direct laryngoscopy/intubation
  - Fiber-optic bronchoscopy via SGA
  - Retrograde wire intubation: passing wire up through SGA, retrieve wire, remove SGA, then advance ETT in one of three methods: (1) preferably, pass the wire through the bronchoscope portal, advance the preloaded bronchoscope over the wire to below the glottis, remove the wire and advance the bronchoscope into the trachea; (2) advance an airway exchange catheter over the wire to just below the glottis, remove wire, then advance ETT into trachea with laryngoscopy assistance; or (3) least desirable, pass ETT over the wire with laryngoscopy assistance.
  - Surgical airway (cricothyrotomy, tracheotomy) with SGA in place, supporting ongoing oxygenation and ventilation
- Semielective use for ventilation/oxygenation support for procedures where bag-mask ventilation is known or suspected to be difficult/cumbersome/patient intolerant to procedure without airway support (e.g., OSA patient for upper endoscopy with moderate sedation)
  - Bronchoscopy in patients intolerant to sedation (OSA, obese, debilitated, cardiopulmonary cripple)
  - Percutaneous tracheostomy
  - Upper endoscopy (specially designed SGA with portal to pass endoscope/transesophageal echocardiography [TEE] probe, LMA Gastro-Teleflex)
  - TEE
  - Brief procedure requiring unconsciousness and airway control

Contraindications

- Absolute
  - Airway obstruction (supraglottic, glottic, or subglottic)
  - Patient unprepared (awake, no topical anesthesia)
  - Elective use with aspiration risk or full stomach
    - Emergency short-term use for rescue of difficult airway is acceptable.
- Relative
  - Anatomic alteration of supraglottic area, glottis, hypopharynx
  - Tumor, abscess, foreign body, swelling
  - Emergency short-term use for airway rescue is acceptable
  - Pregnancy, obesity, massive/multiple-injured patient
    - Emergency short-term use for airway rescue is acceptable

Equipment

- Equipment for mask ventilation
- Induction medications, topical anesthesia medications, and equipment for intubation
- Disposable or reusable SGA device
- Lubricating jelly
- Syringe for cuff inflation/deflation (cuff pressure <60 cm H_2O pressure)
- Tape to secure SGA
- Bite block optional (second-generation SGAs have a built-in bite block and gastric drainage port)
- SGA includes models similar to the original LMA (first generation) design and second-generation models from a variety of manufacturers
- Choice of device is often based on cost, comfort with product
- Evidence-based use exists for some, but not all, product offerings
- Sizes range from neonatal to large adult and will vary by manufacturer
- SGA sizes available should meet the needs of patient populations in your facility
- Access to manometer to measure cuff pressure (<60 cm H_2O); some SGA models have a built-in manometer
- SGA access in facility may be best on code cart, difficult airway cart, rapid-response care cart, resuscitation areas in any and all areas where airway management may take place, either elective, urgent, or emergent
- In the remote hospital location, SGA devices in a transportable airway bag or tackle box carried by the airway team is an excellent alternative.

ANATOMY

Though there are a variety of SGAs that occupy the periglottic area and surround the glottic opening with a cuff, most models differ very little except in the manufactured materials, their flexibility or rigidity, ease of use, weight, and effectiveness. Most, but not all (e.g., I-gel: Intersurgical and air-Q SP: Cookgas), have an inflatable cuff that lies in the hypopharynx and essentially seals the supraglottic region from the epiglottis down the cricopharyngeal sphincter. A sealed airway allows positive-pressure ventilation to be delivered but is limited by the effectiveness of the cuff seal/periglottic mucosal surface interface. Many will allow effective airway pressurization to 10–25 cm H_2O pressure before leaking, whereas other models are specifically designed to allow much higher sealing thresholds (25–35 cm). These latter models are particularly effective in generating ventilatory support for the obese and morbidly obese patient and when confronted by low pulmonary

compliance situations (congestive heart failure, acute respiratory distress syndrome, abdominal distention, pregnancy, ascites, and pulmonary fibrosis). The recently published Difficult Airway Society guidelines recommend the second-generation SGA based on higher cuff leak thresholds, improved intubating potential, and the presence of a bite block and gastric drainage capabilities. Many manufacturers now offer SGA models with a portal that allows passage of a suction catheter or nasogastric tube (NGT) to assist with evacuation of air or gastric contents from the esophagus and stomach (second-generation SGA). Although handy, access to the aerodigestive tract is not guaranteed, nor is the emptying process. Thus the assumption that these SGA models are acceptable in nonfasting patients or those at risk for aspiration is not supported by published literature. Despite this, any patient who has a failed airway may benefit from SGA placement even if the risk of aspiration is elevated.

In general, placement of the SGA can be performed in the exaggerated "sniff" position to the other extreme, a neutral cervical spine. Many SGA models are flexible (e.g., classic LMA-Teleflex) or foreshortened, semirigid, and curved to replicate the oro-hypopharyngeal curvature (e.g., ProSeal, Fastrach, Supreme LMA, or Aura-Once-Ambu). The SGA generally can be placed effectively when faced with little to no neck flexibility. The SGA is lubricated and then passed toward the roof of the mouth across the hard to soft palate, encouraging smooth advancement along the posterior throat so as to minimize getting hung up on the epiglottis. It typically comes to lie with its distal tip in the cricopharyngeal region. Unfortunately, the cuff end may buckle over on itself, come to lie over the glottic opening, or be displaced in a contorted position that impedes effective ventilation and oxygenation. The SGA may indeed be placed incorrectly but still function in near-perfect form with effective ventilation; it is a peculiar airway device. It can be forgiving, yet it still requires skill and finesse to place it properly in most situations. Guidance by a skilled and frequent user is the best method to learn the details of its proper use. Ideally, it lies just over the glottic opening and allows access to the trachea. However, the SGA is frequently malpositioned or the epiglottis is folded over to a lesser or greater degree, partially or completely blocking the pathway to the glottic opening, yet ventilation and oxygenation remain unabated. This may be adequate for airflow to and from but not for the passage of an ETT into the glottic opening. Hence, most generic SGA models do require fiber-optic–guided placement of an ETT because of the uncertain position of the SGA and its adjacent airway structures.

AFTER THE PROCEDURE

Postprocedure Care

The SGA used in the semielective, urgent, or emergent setting is often of short duration (2–20 minutes), because the goal is typically to intubate the trachea. Hence the SGA acts as a rescue oxygenation/ventilation device and/or an intubation conduit.

Complications

Complications are not necessarily because of the SGA itself.

- Common
  - Sore throat
  - Complications inversely related to the experience or skill of operator
- Infrequent
  - Inability to properly insert
  - Inability to ventilate despite proper positioning (laryngospasm, patient biting, kinking of SGA tube), contributing to negative-pressure pulmonary edema
  - Mucosal injury, pressure-induced damage, nerve/vascular injury of airway structures
  - Arytenoid dislocation, nerve damage, venous engorgement (all rare)
- Serious, rare complications
  - Obstruction of the glottic opening
  - Regurgitation/aspiration

OUTCOMES AND EVIDENCE

The LMA design offers a relatively short learning curve for the airway novice and affords fewer episodes of desaturation, less difficulty in maintenance of a patent airway, larger tidal volume than mask ventilation, and decreased arm and hand fatigue when compared with a conventional face mask. Its value in the ICU setting for assistance during emergency airway management is undeniable, especially during difficult intubation or when ventilation is not possible with a standard bag-mask assembly. Blind or fiber-optic–assisted tracheal intubation is an extremely attractive asset that the SGA device offers the clinician and provides an entirely novel rescue approach when conventional laryngoscopy and tracheal intubation prove troublesome or impossible. It is also useful in maintaining airway support in the ICU setting for patients who require repetitive general anesthetic or heavy sedation-analgesia for brief procedures, fiber-optic bronchoscopy, or diagnostic visualization of the airway. Recent work suggests that the SGA is better tolerated and produces fewer cardiovascular side effects than tracheal intubation. Insertion in the patient with an unstable cervical spine may be far easier than direct laryngoscopy because its insertion does not absolutely require neck manipulation.

The device may be difficult to place into the hypopharynx in the presence of a small mouth, a large tongue or tonsils, hypertrophied lingual tissue, or a posteriorly displaced pharynx. However, the SGA often proves easier to use than conventional methods of airway control such as direct laryngoscopy. The threat of gastric dilatation and regurgitation/aspiration may lead some to avoid its use in the critically ill, but its excellent track record and very low incidence of regurgitation/aspiration (1/1126 emergency insertions, Hartford Hospital, TCM) support its role as a primary airway rescue device when conventional methods fail. The role of the SGA as a rescue device in the elective and emergency setting is unparalleled, but further studies into its use in the emergency setting are needed to solidify its standing as the premier rescue airway device, regardless of which model is used. All recognized algorithms and airway management guidelines include the SGA as an integral component of management. Its multiple roles as a rescue device for difficult bag-mask ventilation and difficult intubation, as a conduit for bronchoscopic-assisted intubation, and as an oxygenation/ventilation bridge during front of neck access (FONA, surgical airway) support their recommendations.

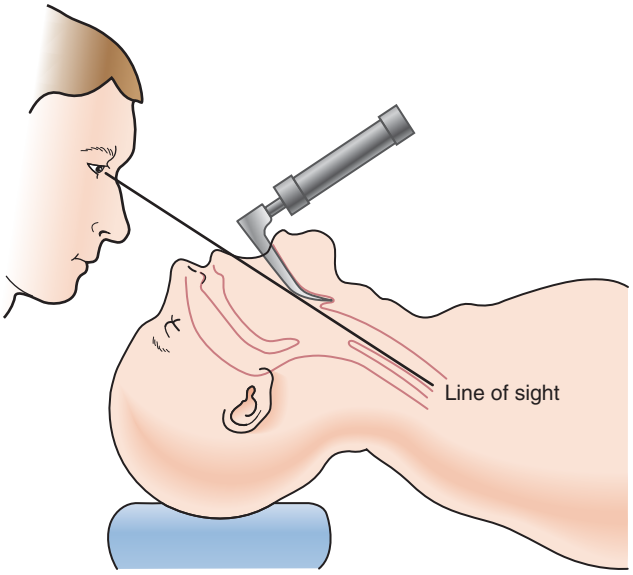

Fig. E1.1 Line of sight with direct laryngoscopy.

BOUGIE-ASSISTED INTUBATION

BEFORE THE PROCEDURE

Indications

- Exchange of ETT (Warning: most bougie models are approximately 55–65 cm in length and are shorter than the recommended airway exchange catheters. This may present a problem with maintaining control of the bougie during the exchange, owing to its length [component within the airway and the length outside the mouth available to thread new ETT]. Moreover, the bougie is typically 15F in caliber (4.7 mm diameter). Using the largest-caliber airway exchange catheter possible provides the best safety profile for ETT exchange.
- Assist with passing ETT into trachea when limited by the "line of sight"
  - Full view of laryngeal inlet (unable to pass ETT because of hang-up on cricoid ring)
  - Full grade 1 view but a restricted pathway to the glottis (e.g., boggy or edematous tissues, redundant pharyngeal mucosa). Thus when passing the ETT, the grade I view becomes partially or completely obstructed.
    - Grade II or III view of the larynx with laryngoscopy (conventional)
    - Grade II: posterior third of glottis visible (Lehane-Cormack classification) or more detailed classification (Cook-Yentis)
    - Grade III: no cords visible, only epiglottis visible; Cook-Yentis classification
      - Grade IIIa: only epiglottic edge visible
      - Grade IIIb: down-folded or floppy epiglottis is visible
    - Grade IV: no view of any airway structure; bougie use not recommended (Figs. E1.1 through E1.6)
  - Combined use with a videolaryngoscope (VAL) to assist with ETT placement
    - Channeled VAL devices (Pentax AWS, AirTraq)
    - Unchanneled VAL devices (GlideScope, McGrath, Storz C-Mac)
      - Very difficult to manipulate the standard bougie "around the corner" of the models with blades of excessive angulation (GlideScope, McGrath). These VAL models promote the likelihood of ETT delivery at an angle such that the tip impinges on the anterior tracheal wall or on the cricoid ring, thus limiting its advancement. Typically, ETT rotation will allow advancement, but bougie placement via the ETT may allow a well-lubricated bougie tip to slip off the impingement and allow ETT passage. A bougie with a maneuverable tip (anterior ↔ posterior movement) would potentially improve ETT placement through the glottic opening.
    - Excellent adjunct with conventionally shaped "Video C-Mac" and other conventional angled VAL blades.
    - Useful if ETT is located just proximal to glottic opening and the bougie is passed through the existing ETT and then manipulated into the trachea.
      - Use of the bougie to determine the location of the ETT (esophagus vs. trachea).
  - Hang-up test (Cheney sign).
  - Bougie tip will hang up on carina or mainstem bronchus, as opposed to simply passing unimpeded into the esophagus. Typically, a depth of 28–32 cm (carina) or deeper (32–36 cm, second bronchi) will allow confirmation of the bougie within the airway vs. the esophagus.
  - Useful in cardiac arrest or clinical situations in which it is difficult to discern proper ETT placement (i.e., cardiac arrest with no detectable $ETCO_2$ or access to such devices).

Contraindications

- Unfamiliar with its use
- Recent tracheobronchial reconstruction

Equipment

- A tracheal tube introducer "bougie" is an inexpensive, disposable, easily transportable airway device that requires minimal setup time, no battery or electrical power, and is noted on all the major airway management algorithm lists of desired airway devices that should be immediately available.
- A variety of manufacturers offer bougie models in 55- to 65-cm lengths, usually 14–15F in size.
- Solid and hollow bougie models are offered by some manufacturers.
- Distinct black markings along the length of the bougie assist the clinician with the depth of insertion.

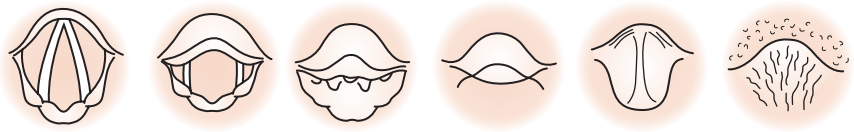

Fig. E1.2 Lehane-Cormack laryngeal view grading system with the Cook-Yentis modifications, grades I → IV.

Fig. E1.3 Cook-Yentis grade IIb laryngeal view with direct laryngoscopy achieves a very high success rate with bougie-assisted intubation.

Fig. E1.4 Cook-Yentis grade IIIa view with direct laryngoscopy achieves a respectable success rate with bougie-assisted intubation, especially when compared with blind passing of the endotracheal tube "around the corner."

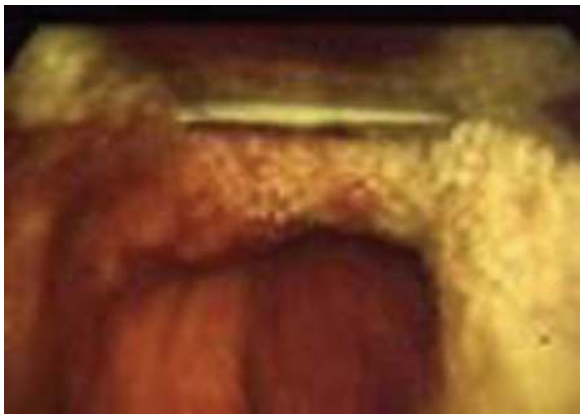

Fig. E1.5 A grade IV view, essentially no view at all of the laryngeal structures. The bougie is not indicated for a grade IV view, though in experts' hands and after failure of other techniques, careful blind passage combined with detection of tip hang-up (carina, mainstem bronchus) may allow blinded intubation. This is a last-ditch effort maneuver and is not recommended as a routine approach. It is best handled with an SGA, flexible fiber-optic bronchoscopy (FFB), or video-assisted laryngoscopy (VAL).

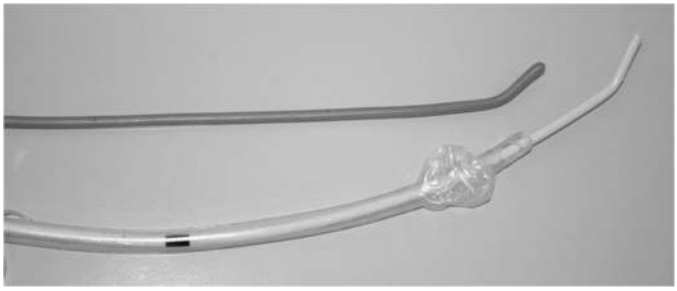

Fig. E1.6 Two bougie models are shown (tracheal tube introducer). Note the characteristic 30-degree angle. The Coude tip allows manipulation of the bougie underneath the epiglottis to increase its rate of passage through the laryngeal opening.

ANATOMY

Though the bougie is capable of assisting intubation in nearly all airway situations except when "no view" is possible, it is most commonly used as an adjunct with grade IIb, IIIa, and IIIb laryngeal views. Even when the laryngoscopy reveals a full view (grade I), the bougie may be useful when the mouth opening is small or narrow and/or the hypopharyngeal opening is narrow (OSA, obesity, swelling) and passing the ETT may actually obstruct the view of the glottic opening. In this case, the narrower, more colorful tracheal tube introducer can be passed into the trachea with little visual obstruction taking place. Conversely, the floppy epiglottis is a challenge that may be technically difficult with many different airway adjuncts. The bougie may either be used to elevate the floppy epiglottis or be maneuvered around by virtue of the Coude tip. Though useful, the success rate is often less than 50%, and other airway device alternatives may be needed (intubating laryngeal mask airway [ILMA], VAL, flexible fiber-optic bronchoscope [FFB] (Fig. E1.7).

PROCEDURE

- The bougie is grasped in the intubator's right hand at the 20- to 25-cm mark.
- It is passed alongside the laryngoscope with the 30-degree angled tip (Coude) anteriorly.
- The tip is advanced anterior to the arytenoids and into the larynx (grade IIa, IIb).

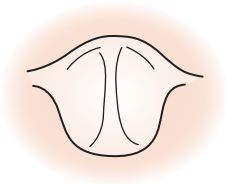

Fig. E1.7 A grade IIIb view; floppy or overhanging epiglottis may be difficult to navigate around with a variety of airway adjuncts. The bougie may be used to elevate the epiglottis and navigate into the trachea, but the success rate is substantially lower in the grade IIIb setting (30%–50%) compared with a grade IIIa (only leading edge of epiglottis visible, 80%–90%).

- The tip is then advanced underneath the epiglottis and past the vocal cords blindly (grade IIIa).
- The tip lifts the floppy epiglottis and is then advanced blindly past the vocal cords (grade IIIb).
- Advancement into the trachea to a depth of 22–26 cm in an average adult
  - Tip may "bounce" or "click" past the tracheal rings, suggesting tracheal placement.
  - This is a helpful sign but does not guarantee intratracheal placement.
  - Conversely, the lack of "clicks" does not guarantee the position of the bougie, nor does it rule out location within the trachea.
  - Ten to fifty percent of bougies passed into a grade III airway may enter the esophagus
    - Grade IIIa: 5%–12% may enter the esophagus
    - Grade IIIb: 30%–50% may enter the esophagus
      - Quickly deploy backup strategy (SGA, FFB, VAL)
      - Some may consider the bougie a poor choice in grade IIIb view
  - Tip may be gently advanced farther (28–36 cm) to contact carina/mainstem bronchus of second bronchi
    - Tip hang-up provides tactile feedback during blind passage
    - Detection of carina/bronchus is reassuring to operator
    - Advancement past 35–40 cm without hang-up strongly suggests the bougie is in the esophagus
    - Using hang-up or Cheney sign lowers the incidence and dangers of passing the ETT into the esophagus, bougie should be retracted to 23-25 cm depth, held securely then ETT may be advanced over the bougie
    - Eliminates the delay of verifying the ETT location by insufflation, capnography, auscultation
  - Decision time: passing the ETT
    - If time permits, generously lubricate the ETT
    - Smaller-sized ETTs pass over the bougie more easily than larger ones
    - Maintain tongue displacement with laryngoscopy/hand grasp
    - Pass the ETT, but do not force the advancement (an assistant should grasp the proximal end of the bougie to stabilize it)
    - Anticipate resistance at 16- to 17-cm depth because of impingement on arytenoid/vocal cord (two methods to remedy this) (Fig. E1.8).
      - Preemptively advance ETT while rotating in the counterclockwise (CCW) direction to allow ETT bevel tip to avoid impingement on the glottic structure.
      - If resistance is encountered, stop and withdraw ETT 1–2 cm and then rotate CCW and advance the ETT into the airway.
      - If ETT fails to pass, the patient may be ventilated and oxygenated with bag-mask ventilation (move the bougie to the corner of the mouth).

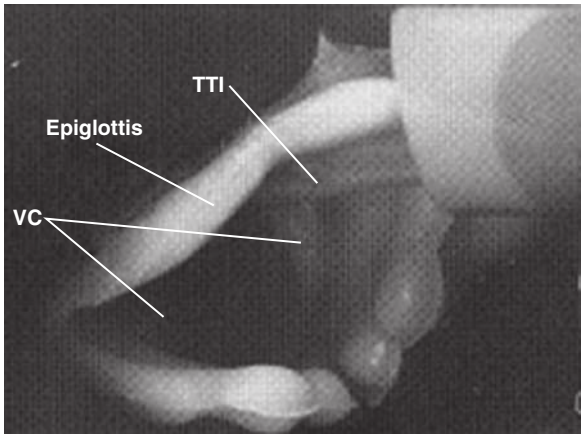

Fig. E1.8 Endotracheal tube (ETT) being passed over tracheal tube introducer (TTI, bougie) and getting hung up on the epiglottis and arytenoid. Continued advancement should be discouraged. Simply withdraw 1–2 cm, rotate ETT counterclockwise about 90 degrees, and readvance. *VC,* Vocal cord.

      - Change to a smaller-diameter ETT (to ease advancement over the bougie) and assume the glottic opening may be swollen, impeding entry.

AFTER THE PROCEDURE

Postprocedure Care

- After advancement of ETT into the trachea, stabilize the ETT in position, and remove the bougie. Be sure to hold the ETT in place as the bogie is removed.
- Standard methods of determining the ETT position are required.

Complications

- Inability to pass the bougie underneath the epiglottic edge (grade IIIa) or inability to lift the down-folded or floppy epiglottis (grade IIIb).
  - Depending on the skill and experience of the operator and the condition of the patient, time spent advancing the bougie should be limited so as not to endanger the patient's condition (SpO_2).
  - If unsuccessful, quickly move to another accessory device to secure the airway.
- Infrequent complications:
  - Minor tissue injury, airway trauma
  - Esophageal placement of bougie
  - Esophageal intubation (the hang-up test should eliminate this hazard)
- Serious, rare complications:
  - Mucosal laceration, bronchial/carina perforation if extreme force is applied to bougie advancement or the patient's underlying airway anatomy is compromised/diseased

OUTCOMES AND EVIDENCE

The simplicity of the trachea tube introducer makes it an attractive option for assisting with trachea intubation in the situation when a restricted laryngeal view is available with laryngoscopy. A variety of uses for the bougie make it a desirable addition to the difficult airway

cart or bag, made accessible at the bedside in the ICU and other remote locations in the hospital. The bougie is a suggested option in the management algorithms offered by anesthesiology societies in the United States, Canada, the United Kingdom, Germany, and many other countries.

INTUBATING MODEL OF THE SGA FOR EMERGENCY AIRWAY RESCUE (LMA MODEL [FASTRACH] INTUBATING LMA [ILMA] WILL SERVE AS AN EXAMPLE BUT OTHER BRANDS ARE AVAILABLE)

BEFORE THE PROCEDURE

Indications

- Emergency rescue of the airway when tracheal intubation is the goal
  - Failed conventional intubation attempts
  - Failed bougie-assisted intubation
  - Failed VAL intubation
  - May be a substitute for conventional SGA device after its failure to secure successful ventilation/oxygenation

Contraindications

- Inexperienced operator/airway team
- Major risk for regurgitation/aspiration (relative; loss or lack of airway is worse)
- Oral cavity inaccessible/trismus
- Similar to other SGA devices

Equipment

- Equipment for mask ventilation
- Induction medications, topical anesthesia medications, and equipment for intubation
- Disposable or reusable models of the ILMA, ETT, and stabilizing rod
- Lubricating jelly
- Syringe for cuff inflation/deflation
- Tape to secure SGA
- Bite block not needed
- Manometer to measure cuff pressure (<60 cm H_2O)

ANATOMY

The ILMA is similar to other SGA devices that occupy the periglottic area and surround the glottic opening with a cuff. Passing the ILMA into the oral cavity is easier than the comparative standard LMA, because it is designed with an intrinsic curve easing passage into the hypopharynx. The inflatable cuff lies in the hypopharynx and essentially seals the supraglottic region from the epiglottis down to the cricopharyngeal (upper) sphincter. The rigid construction of the ILMA is limited by its diameter, so adequate mouth opening is a prerequisite. The sealed ILMA allows positive-pressure ventilation to be delivered. Occasionally, the ILMA will afford effective ventilation if the standard LMA model fails, and vice versa (as could other brands).

In general, placement of the ILMA can be performed in the exaggerated "sniff" position or the other extreme, a neutral cervical spine. In the presence of cervical spine immobility, it is best to maintain stabilization yet remove the front collar to improve oral access. After cuff deflation, the ILMA is lubricated and then passed along the roof of the mouth across the hard to soft palate, encouraging smooth advancement along the posterior throat so as to minimize getting hung up on the epiglottis or causing its down-folding. The distal tip of the ILMA typically comes to lie in the cricopharyngeal region. Unfortunately, the cuff end may buckle over on itself, come to lie over the glottic opening, or be displaced in a contorted position that impedes effective ventilation and oxygenation (Figs. E1.9–E1.16).

PROCEDURE

- The ILMA is placed into the airway in a similar fashion as other SGA products. However, the shortened length of the ILMA model and its handle may be easier to place than the standard SGA model. Placement is augmented by passing it along the hard to soft palate posteriorly into the hypopharynx, posterior to the epiglottis. It too comes

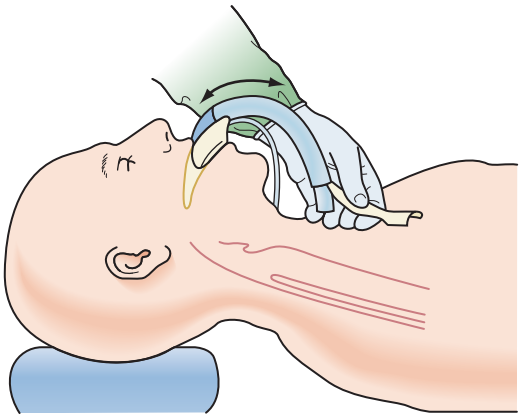

Fig. E1.9 Deflate the cuff, and lubricate with a water-soluble lubricant on the posterior surface. The lubricated intubating laryngeal mask airway is passed over the hard to soft palate along the posterior pharyngeal wall to the point where gentle resistance is felt.

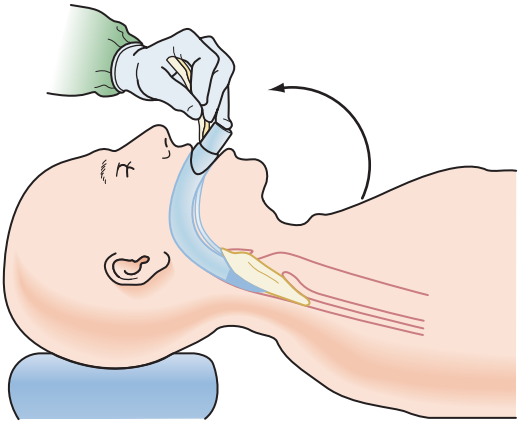

Fig. E1.10 Swing the mask into place in a circular movement, maintaining contact against the palate and posterior wall of the pharynx. Do not use the handle as a lever.

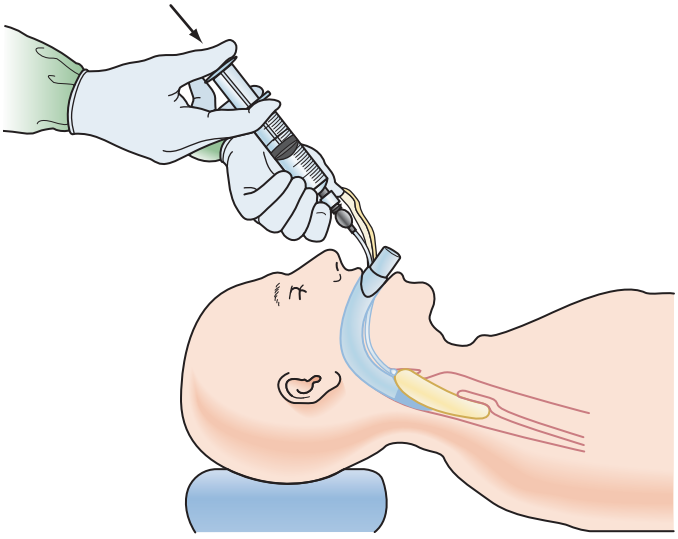

Fig. E1.11 Inflate the mask, without holding the tube or handle, with approximately 10–20 mL of airway to seal the airway. Apply a manual bag or anesthesia circuit and verify ventilation. If no ventilation (leak or resistance), assume misplacement of ILMA or down-folding of the epiglottis. Manipulate the ILMA in an up-and-down or in-and-out maneuver to optimize position. Recheck ventilation, and adjust location of the ILMA to optimize ventilation. Do not attempt to pass the endotracheal tube until effective ventilation is ensured.

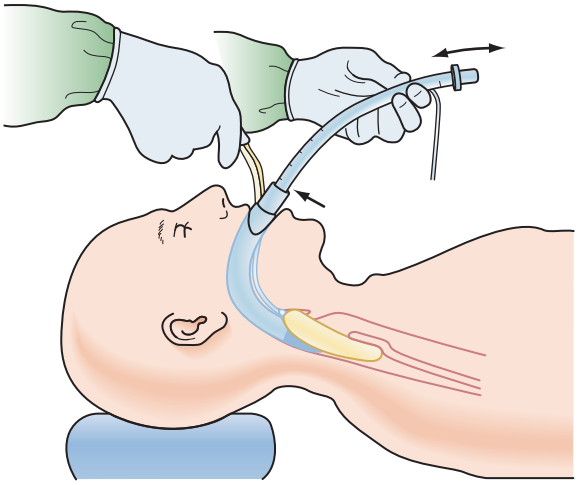

Fig. E1.12 Hold the ILMA handle while gently inserting the lubricated endotracheal tube (ETT) into the airway shaft. The provided ILMA-ETT is best suited for this, though a well-lubricated standard ETT may be used with fiber-optic guidance or may be used (with proper training and experience) blindly by inserting it "backward," meaning the concave curve of the ETT faces the nose as it is advanced into the ILMA shaft.

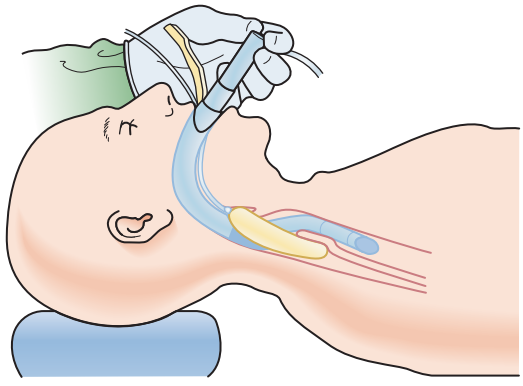

Fig. E1.13 Advance the ETT, inflate the cuff, and confirm intubation. If unable to pass, ensure adequate lubrication. If resistance is felt, the ILMA may be malpositioned or may have entrapped the epiglottis and thus block ETT advancement. Try the in-and-out maneuver to reposition the ILMA and free up the epiglottis if applicable.

to lie with its tip atop the cricopharyngeal area posterior to the arytenoids/glottis. The tip may fold over or under and impede air exchange or be sensed by an incomplete cuff seal (leak). This can be remedied by performing the "in-and-out" or "up-and-down" maneuver (simply moving the ILMA slightly inward and outward to free up the distal tip). Cuff inflation is followed by positive-pressure oxygen delivery. Successful placement allows the chest to rise and $ETCO_2$ detection, with no audible air leak, to approximately 15–25 cm H_2O pressure applied to the ILMA. Always confirm ventilation before attempting ETT advancement via the ILMA.

- Two maneuvers are handy to improve success in ILMA placement and intubation:
  - After ILMA placement, the Chandy maneuver #1 involves using the ILMA handle to optimize the positioning of the ILMA within the airway, with the goal of maximizing tidal volume, $ETCO_2$, and the feel of "bagging." The ILMA is held in this position in preparation for passing a lubricated ETT. The included LMA brand wire-reinforced ETT is an excellent ETT for passing, but it is suboptimal for long-term use in the ICU airway (if duration of intubation is >24–48 hours, one should consider changing the ETT over an airway exchange catheter to the standard ICU ETT model).
  - Limiting SGA insertion attempts to two to three is suggested by several sources. Once effective ventilation/oxygenation is established, passing an ETT may be the next objective. With the ILMA in the best ventilating position (Chandy #1), the Chandy maneuver #2 involves using the ILMA handle to slightly elevate or "lift" the ILMA (handle toward forehead, ILMA distal tip anteriorly) to improve the success rate of passing the ETT into the trachea, based on the ILMA portal being tilted toward the

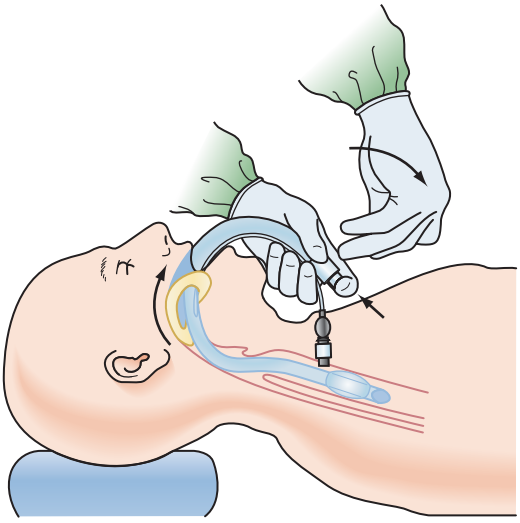

Fig. E1.14 Remove the ETT connector, and place the provided stabilizing rod onto the end of the ETT. Then ease the ILMA over the existing ETT and rod by gently swinging the handle caudally (keeping the ETT stable in position) until the ETT can be grasped at the level of the incisors.

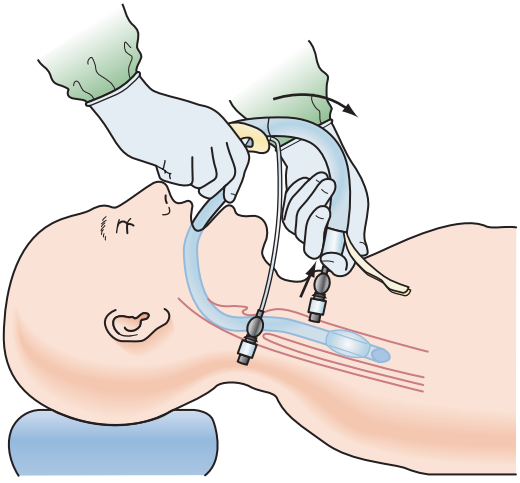

Fig. E1.15 Remove the stabilizing rod, and gently unthread the inflation line and pilot balloon of the ETT. Replace the ETT connector, and confirm ventilation and position per standard intubation procedures. If the ILMA has been used on a very challenging airway or the patient is unstable, delay removal of the ILMA from the existing ETT until stabilization takes place. Extubation of the airway is possible, so this maneuver should only be performed by those skilled in its execution.

glottic opening and away from the esophagus. This lift increases seal pressure and improves the alignment of the ILMA to the glottic opening and corrects any flexion the mask has undergone after its placement. Malposition or flexion of the mask while in the ventilating position may alter the pathway of the ETT as it exits the ILMA. Generous lubrication of the ETT to ease passage through the ILMA lumen is absolutely essential. Intubation of the trachea may be performed blindly or with fiber-optic assistance. The skill to successfully intubate the trachea is attained by practice coupled with instruction by an experienced individual. Practicing the technique before an emergency situation arises is in the best interest of patient care.

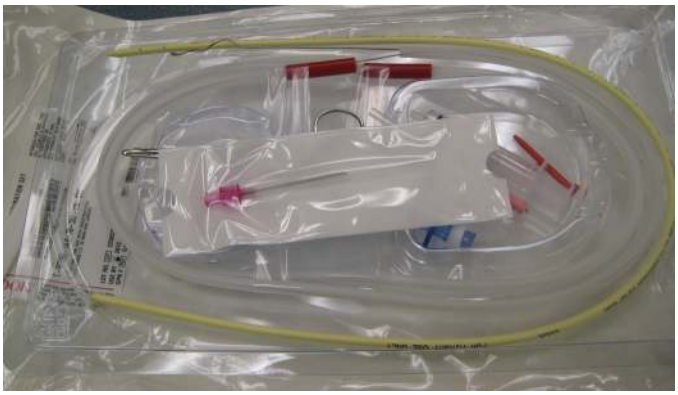

Fig. E1.16 Cook Critical Care prepackaged retrograde wire intubation kit. Use of the ILMA should be learned before its deployment in an emergency airway crisis. Training on a mannequin or humans under elective conditions by a skilled practitioner is best.

- Troubleshooting in the event of failure to intubate (typically caused by a down-folded epiglottis, ETT impaction on the periglottic tissues, too large or too small ILMA, or patient is resisting intubation because of inadequate sedation/analgesia/muscle relaxation/anesthesia).
  - If resistance is felt approximately 2 cm beyond the black transverse line marked on the ILMA ETT (or 15–16 cm marking on a standard ETT), the down-folded epiglottis may be blocking ETT advancement, as may the vestibular wall. Rotation of the ETT may allow passage if impeded by the vestibular wall. A down-folded epiglottis may need to be addressed by performing the "up-and-down" maneuver. This is a partial withdrawal of the inflated ILMA to a maximum of 6 cm, followed by reinsertion. This often frees the epiglottis from its down-folded position. Otherwise, FFB assistance is needed, or a different size ILMA may be tried.
  - If the ETT meets immediate resistance at 15–16 cm (black mark) or at a 4- to 5-cm depth past the black mark, then the ILMA is too large, and downsizing may help.
  - If resistance is encountered at 3 cm past the black mark, the ILMA may be too small. If an alternative-size ILMA is not available, external manipulation of the larynx either downward or caudally may assist with passing the ETT. Likewise, ETT rotation may be helpful.
  - The ILMA has an "epiglottis elevator bar" to assist in lifting the epiglottis up to afford improved ETT passage into the laryngeal inlet. When using bronchoscopic-guided ETT advancement, using the ETT tip to elevate the bar is best because the bronchoscope typically is not rigid enough to do so by itself.
  - Another miscellaneous yet quite important clinical situation that may prohibit intubation is excessive periglottic/glottic edema when viewing with the FFB. Massive airway edema may preclude advancement of the FFB-ETT owing to the inability to clearly identify the glottic opening; caution must be exercised to not advance the FFB tip into unrecognizable tissue planes. Excessive force on the FFB or ETT may lead to tissue injury and thus threaten the current airway patency by inducing further bleeding, edema, or swelling. Attaching a bronchoscopic swivel adapter to the ILMA itself or via the ETT may allow active application of positive pressure to the airway and promote lateralization of the edematous glottic tissues. This is analogous to the use of CPAP in OSA patients. The bronchoscopic adapter is too

narrow to allow an ETT to pass through it. To remedy this, an Aintree catheter (bougie-type catheter with a lumen that allows a proper-sized FFB to be placed within the catheter) is sized to fit through the adapter and its diaphragm. The Aintree-FFB assembly may be passed through the bronchoscopic adapter, down the ILMA, and used to visualize the glottic opening. Once advanced into the trachea, the Aintree remains within the trachea as the FFB is withdrawn. The ILMA is then removed over the Aintree, and the ETT is advanced over the Aintree catheter in similar fashion to a bougie, tube exchanger, or FFB.

- Blind intubation via the ILMA is useful and generally successful (90% within three attempts in the Hartford Hospital database for emergency intubations). Recent guidelines have leaned toward deploying bronchoscopic guidance for intubation so as to avoid blind insertion in the difficult airway situation. Moreover, recent societal recommendations have moved away from the ILMA toward the second-generation SGA models, despite an impressive track record of success with the classic SGA model (LMA) and the ILMA model design.

AFTER THE PROCEDURE

Postprocedure Care

- After "blind" intubation of the trachea, standard methods to confirm ETT position are pursued (chest auscultation, $ETCO_2$ detection, ETT misting, chest rise, etc.).
- After fiber-optic–assisted intubation, the same clinical confirmation of ETT position should be pursued, even though visualization of the ETT within the trachea with FFB is considered failsafe. The caveat here is that FFB confirmation, though failsafe under ideal conditions, may be limited by secretions, edema, soilage, operator inexperience, faulty battery power, and other limitations seen in the ICU airway.
- With the ETT-ILMA assembly in place, the ILMA has to be carefully removed from the patient while leaving the ETT within the trachea. Accidental tracheal extubation during ILMA removal could be disastrous.
- Step-by-step removal of the ILMA is outlined later.
- If one is unfamiliar with ILMA removal, a more experienced team should be summoned to assist with this task. Conversely, if the patient's clinical condition needs to be stabilized before its removal, at a minimum, the air should be removed from the ILMA cuff (leaving the ETT cuff inflated) to reduce the pressure effect on the pharyngeal mucosa.

Complications

- Common
  - As outlined under SGA
  - Inability to establish ventilation/oxygenation
  - Inability to intubate the trachea
  - Esophageal intubation
  - Obstructed advancement of the ETT through the ILMA
- Infrequent
  - Dental damage, mucosal injury
- Serious, rare complications
  - Regurgitation/aspiration (very rare)

OUTCOMES AND EVIDENCE

- The use of the ILMA has revolutionized airway management, especially in the emergency setting. It is an accepted component in the ASA airway management algorithm, in addition to all other algorithms offered by medical societies throughout the world. The presence of VAL has potentially altered the ILMA's role as a logical and rational first step toward airway rescue when conventional methods fail or are inappropriate. However, the clinician must be familiar with this device and have it readily available as a backup for VAL difficulties or failures.
- In the elective setting, the ILMA has an excellent track record for a high level of successful ventilation coupled with blind and FFB-assisted intubation. Its successful deployment in the acute care setting in the ICU, emergency department, or other remote locations outside of the operating room has been well received, though the success rate for both ventilation and intubation is tempered to a more realistic success rate of nearly 8–9 out of 10 patient encounters (Hartford Hospital database, TCM). Thus a backup plan must be in place to deal with ILMA failure and establish effective ventilation/oxygenation, and ultimately tracheal intubation, either blindly or with FFB assistance.

RETROGRADE WIRE INTUBATION

BEFORE THE PROCEDURE

Indications

- Secure the airway in the elective setting with the patient awake, with adequate local anesthesia topicalization or nerve blocks
  - Trismus, severe temporomandibular joint (TMJ) disease, limited cervical range of motion
  - Known difficult mask ventilation, intubation
- Secure the airway emergently in the setting that mask ventilation/oxygenation is effective
  - Retrograde wire-guided intubation, in the best situation, may require 2–5 minutes to complete; hence one must be able to maintain successful ventilation/oxygenation.
- Considered an effective airway rescue in the nonemergent pathway on the ASA difficult airway algorithm (*cannot* intubate, *can* ventilate) when oral or nasal intubation is impossible or failed for a variety of conditions
  - Any reason the patient is a "difficult airway"
  - Massive oral, nasal, or pharyngeal hemorrhage (must be able to locate wire)
  - Trismus (must open at least one fingerbreadth)
  - TMJ abnormalities limiting mouth opening (must open at least one fingerbreadth)
  - Structural deformities of oropharynx, congenital or acquired
  - Mass (cancer, tumor, polyp, or other if not directly in line of wire advancement)
  - Traumatic injuries making oral/nasal tracheal intubation difficult or impossible
    - Maxillofacial injuries
    - Cervical spine instability
- Secure the airway electively when difficult airway factors are known or suspected to exist and intubation by other means may be difficult or impossible.

Contraindications

- Absolute contraindications
  - Transection of trachea with retraction of distal end into the mediastinum
  - Fracture or other significant injury of the larynx or cricoid cartilage
  - Infection, cancer, mass at site of wire insertion (cricothyroid membrane) or in pathway of wire advancement
  - Unfamiliarity with the procedure
- Relative contraindications*
  - Infants and toddlers (<3 years)
  - Bleeding diathesis
  - Patients with massive neck edema, lack of landmarks

Equipment

- Guidewire (suggested >60 cm) matched to appropriate needle size allowing advancement
- 20-, 18-, 16-, or 14-gauge cutting needle on a syringe
- Cuffed 6.0 endotracheal tube
- Hemostat or Kelly clamp
- Alternative: manufactured retrograde wire intubation kit (Cook Critical Care) (see Fig. E1.16)
- Optional: FFB

ANATOMY

The cricothyroid membrane is located between the superior thyroid cartilage and the inferior cricoid ring. The cricothyroid membrane is located just 1.5–2 cm below the vocal cords, so care must be practiced when advancing a needle caudad, as the underside of the vocal cords could be impaled. Passing the ETT over the wire or obturator/wire may be met with resistance at the 16- to 17-cm depth, as the ETT tip may impinge on the vocal cords or arytenoids. This is the inherent danger of passing the ETT blindly over the wire or obturator/wire assembly. The location of the distal tip (having met resistance) may or may not be at the position below the vocal cords. This is the challenge of the retrograde wire method; knowing the location of the ETT tip is unknown when the decision is made to remove the wire. If the ETT tip is erroneously positioned above the glottis, then the access to the airway is denied with wire removal; hence, the advantage of using the FFB as an intubation guide (Fig. E1.17).

PROCEDURE

- Retrograde tracheal intubation
  - Needle insertion directed cephalad; operator should approach with dominant hand more caudad (e.g., right-handed operator on right side of patient)

*Relative contraindications may be overlooked in the emergency situation.

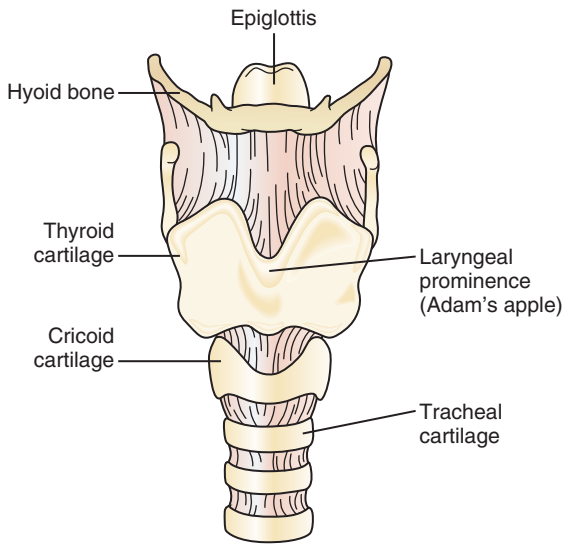

Fig. E1.17 Anatomic landmarks for access to the cricothyroid membrane.

- Puncture cricothyroid membrane with needle directed cephalad (Fig. E1.18). Aspirate air with syringe to locate air column (1–2 mL of saline in syringe; allow bubbles to percolate to verify the air column).
- Pass the guidewire through the needle aimed superiorly so that the distal end of the wire may be retrieved from the mouth (or if desired, nose) of the patient. Withdraw needle off wire.
  - Pull majority of wire out of the mouth (or naris)
  - Secure distal end of wire by clamping hemostat at the level of the cricothyroid membrane (Figs. E1.19 and E1.20).
- Three choices to pass ETT down the wire into the airway (nasal or oral): (1) wire assisted, (2) wire with obturator to reinforce wire, (3) flexible bronchoscope (loaded with ETT) passed over wire into airway
  - Wire assisted
    - Load lubricated ETT over oral (or nasal) end of wire, passing wire into tube through the Murphy eye.
    - Pull wire relatively taut and straight.
    - Advance ETT over wire into trachea to cricoid area and then, gradually relaxing cricothyroid end of wire, advance ETT to appropriate intratracheal location.
    - Release cricothyroid end of wire, and withdraw wire out of ETT.
    - Confirm ETT position (auscultation/capnography).
  - Wire with obturator to reinforce wire (Fig. E1.21)
    - Pass obturator over wire into airway until resistance is felt.
    - See manufacturer's instructions for Cook retrograde intubation kit.
    - Load lubricated ETT over oral (or nasal) end of wire/obturator.
    - Advance ETT into trachea to cricoid area.
    - Remove wire from cricothyroid membrane end, and then advance obturator distally into trachea.
    - Advance ETT to appropriate intratracheal location.
    - Confirm ETT position (auscultation/capnography).
  - FFB (loaded with smaller-sized ETT [6–7 mm]) (Fig. E1.22)
    - Advance wire through the suction portal of the FFB.
    - Grasp wire end from top of FFB.
    - Advance FFB down wire, observing the airway structures as you advance (Fig. E1.23).
    - Advancing the FFB to distal end of wire will occlude view and appear "pink" (backside of cricothyroid membrane). Correct position may be verified by darkening the room to transilluminate the cricothyroid membrane puncture site (Fig. E1.24).

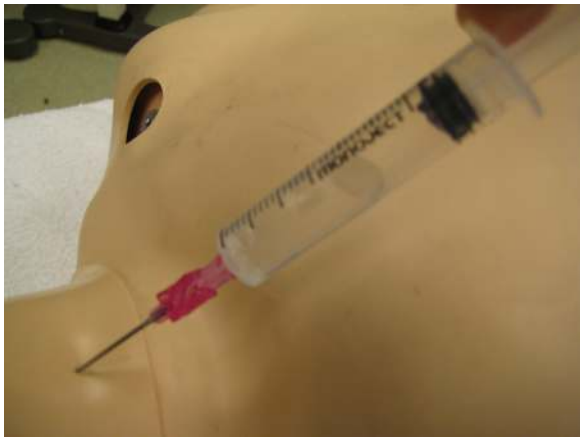

Fig. E1.18 Puncture of cricothyroid membrane, with air aspiration reflected in bubbling in saline-filled syringe.

Fig. E1.20 Advancing the wire from the neck to the oral cavity.

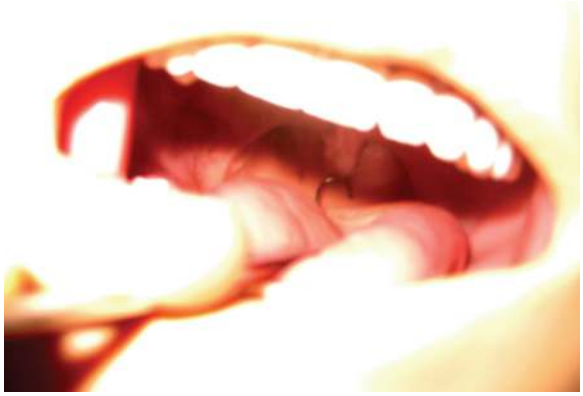

Fig. E1.19 Locating and retrieving the retrograde wire within the oral cavity.

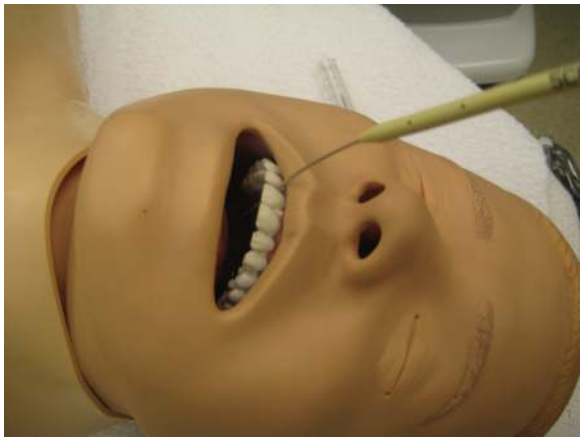

Fig. E1.21 Passing the Cook obturator over the retrograde wire to reinforce the wire to allow ease of passing the ETT into the airway.

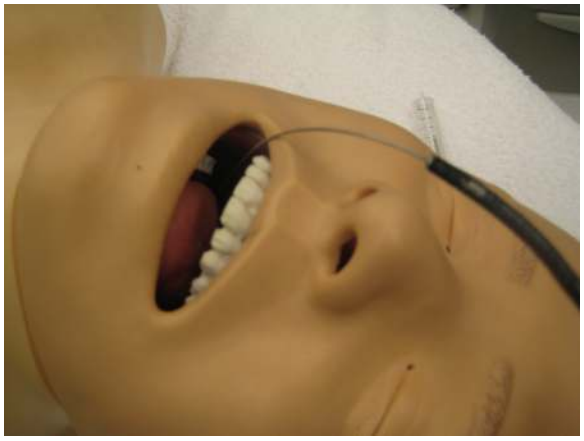

Fig. E1.22 A better choice than the obturator is the FFB passed over the wire via the suction port of the fiber-optic bronchoscope.

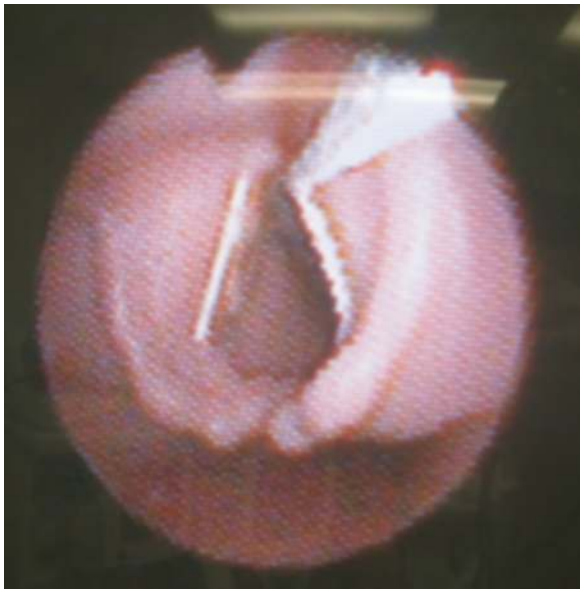

Fig. E1.23 Retrograde wire seen emerging from glottis.

- Once the FFB is below the vocal cords, the cricothyroid end of wire may be released as the fiberscope is advanced to the carina and wire and then pulled out of the fiberscope.
- Or the wire may be pulled out inferiorly through the cricothyroid puncture and fiberscope and advanced into the trachea.
- Advance the FFB tip into distal trachea, and advance the ETT into position and confirm.

AFTER THE PROCEDURE

Postprocedure Care

- After advancement of ETT into the trachea, stabilize the ETT in position.
- Standard methods of determining the ETT position are required.

Complications

- Inability to locate wire in oral cavity/nose
  - Use light (e.g., laryngoscope) to assist locating wire
  - Pick up wire with hemostat

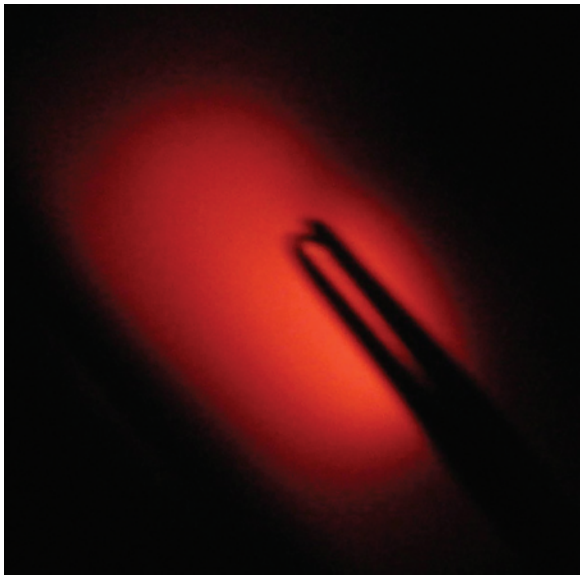

Fig. E1.24 Flexible fiber-optic bronchoscope (FFB) passed over retrograde wire, with tip of FFB at wire insertion site at the cricothyroid membrane, with transillumination of light from the FFB.

- Infrequent
  - Tissue injury when picking up wire with hemostat
  - Hematoma from injury to the cricothyroid artery
  - Subcutaneous emphysema
  - Infection at site of insertion (rare)
  - False tract from passing wire
- Serious but rare complications
  - Possible airway obstruction, loss of airway, laryngospasm

OUTCOMES AND EVIDENCE

Retrograde intubation, once a prominent adjunct before today's many varied airway devices, retains an important position in managing the difficult airway, but it has been relegated to a much less prominent role. It is important for clinicians to maintain the ability, knowledge, and equipment to perform this specialized method of securing the airway. Even in the best of clinical situations and manned by an experienced team, this method remains a relatively time-consuming technique that limits it to the nonemergency pathway, where ventilation/oxygenation is possible with either bag-mask ventilation or SGA or the patient is awake and breathing spontaneously.

NEEDLE CRICOTHYROTOMY WITH TRANSTRACHEAL JET VENTILATION

BEFORE THE PROCEDURE

Indications

Similar to cricothyrotomy.

- Impossible or failed oral or nasal endotracheal intubation owing to any of the following:
  - Difficult or impossible intubation (cannot ventilate, cannot intubate [CVCI])
  - Massive oral, nasal, or pharyngeal hemorrhage
  - Massive regurgitation or emesis
  - Masseter spasm, clenched teeth, TMJ limitations
  - Structural deformities of oropharynx, congenital or acquired
  - Stenosis/narrowing of upper airway
  - Mass (cancer, tumor, polyp, or other) with partial obstruction
- Airway obstruction (partial but not complete) above cricothyroid membrane
  - Nontraumatic versus traumatic
    - Oropharyngeal edema
    - Mass (cancer, tumor, polyp, or other) (Fig. E1.25)
  - Traumatic
    - Foreign body obstruction
    - Stenosis
- Traumatic injuries making oral or nasal endotracheal intubation difficult or potentially hazardous
  - Maxillofacial injuries
  - Cervical spine instability

Fig. E1.25 Classic example of when not to incorporate transtracheal jet ventilation (TTJV). This intratracheal tumor mass occludes more than 85% of the tracheal lumen. Providing high-pressure TTJV supports oxygen transfer into the pulmonary tree, but overpressurization of the thorax will likely occur, because egress of the transmitted pressure may be blocked by the mass and its potential ball-valve effect. Likewise, a glottic or subglottic mass (above the site of needle insertion) may equally disallow egress or relief of the pressure buildup with high-pressure TTJV, thus leading to barotrauma.

Contraindications

- Absolute contraindications
  - Endotracheal intubation can be accomplished easily and quickly, and no contraindications to endotracheal intubation are present.
  - Transection of trachea with retraction of distal end into the mediastinum
  - Fracture or other significant injury of the larynx or cricoid cartilage
  - Lack of egress of pressurized airflow (exhalation, must ensure good air in, bad air out) resulting in inability to relieve pressured insufflation from trachea
- Relative contraindications*
  - Infants and toddlers (<3 years)
  - Bleeding diathesis
  - Patients with massive neck edema or lack of landmarks
  - Acute laryngeal disease

Equipment

- Sanders handheld high-pressure ventilator
- 12-/14-gauge Jelco IV catheter on a syringe
- Optional: wire-reinforced needle-catheter (e.g., Cook Critical Care)
- Alternatively: ENK oxygen modulator system by Cook Critical Care (low-pressure choice). Requires 15 L/min oxygen supply. Oxygen delivery is derived by finger occlusion of the portals on the plastic assembly. Delivered in similar ratio as high-pressure transtracheal jet ventilation (TTJV). Newer products are being developed that allow more accurate pressure delivery and air egress in the hopes of improving oxygenation, reducing barotrauma, and improving patient safety.
  - Newer technology has advanced TTJV to help lower the risk of barotrauma during "jetting." The Ventrain (Ventinova Medical) is a single-use ventilation device designed to allow ventilation via small-gauge lumens. Its ventilation is not based on the continuous high pressure as the standard TTJV assembly, but on continuous and bidirectional gas flow for both inspiration and expiration, thus allowing gas flow during inspiration but actively removes gas from the trachea with expiration ventilation assistance (EVA). This assists the clinician when dealing with rescue catheter ventilation but also when the airway is obstructed.

ANATOMY

The thyroid cartilage consists of two approximately quadrilateral-shaped laminae of hyaline cartilage that fuse anteriorly to form the laryngeal prominence. The anterior superior edge of the thyroid cartilage, the laryngeal prominence, is known as the *Adam's apple* and is

* Relative contraindications may be overlooked in the true emergency situation, because it is more important to obtain an airway and avoid hypoxemia.

usually easily seen in men. It is probably the most important landmark in the neck when performing a cricothyrotomy. The cricoid cartilage is shaped like a signet ring with the shield located posteriorly and forms the inferior border of the cricothyroid membrane. The thyroid cartilage forms the superior border of the cricothyroid membrane.

The cricothyroid membrane is a dense fibroelastic membrane located between the thyroid cartilage superiorly and the cricoid cartilage inferiorly; the cricothyroid muscles bound it laterally. The cricothyroid membrane covers an area that is trapezoidal in shape. The average size of the cricothyroid membrane in the adult is approximately 22–30 mm wide and 9–10 mm high. Palpating a notch, a slight indentation or dip in the skin inferior to the laryngeal prominence, can identify the cricothyroid membrane. The cricothyroid membrane is located approximately 2–3 cm below the laryngeal prominence in an adult.

PROCEDURE

- Place the patient in supine position (shoulder roll to extend cervical spine forward if possible).
- Prep neck area if time permits.
- Locate cricothyroid membrane.
- Using a 12- or 14-gauge needle on a syringe, puncture the skin midline and directly over the cricothyroid membrane (2–3 mL saline in 5- or 10-mL syringe will assist visualizing bubbles when withdrawing syringe barrel to verify needle tip in "air space").
- Direct the needle at a 45-degree angle caudally, and carefully insert it through the upper half of the cricothyroid membrane, aspirating as the needle is advanced. Aspiration of air signifies entry into the tracheal lumen.
- Secure the needle (assign one person to maintain catheter position), and attach Luer-Lok end of high-pressure ventilator.
- Administer low-pressure airflow (5–10 psi initially) bursts of positive-pressure ventilation.
- Six to ten breaths per minute to maximize exhalation time (I/E ratio >1:5).
- Adjust pressure upward with the goal of visible chest wall excursions and life-sustaining saturation.
- Continue efforts to maintain airway patency to ensure egress of pressurized air (exhalation)
  - Jaw thrust, chin lift, neck extension
  - Oral airway, nasal airway, tongue retraction
  - SGA device, laryngoscopy
- TTJV is a short-term oxygen delivery strategy during airway management difficulties.
  - Alternative airway management methods should be pursued.
  - Continue efforts to secure the airway from above if feasible.
  - Pressurization of airway may allow previously failed rescue methods to succeed (i.e., drive airway upward through the glottis, thus revealing an otherwise collapsed, edematous, or unrecognizable airway).
- NOTE: Placing the catheter via the cricothyroid membrane before airway intervention (anticipating difficulty) is acceptable, because placement during a crisis is often hindered by a lack of landmarks, suboptimal positioning, and inexperience. If placed but not used, it can be simply removed with little consequence.

AFTER THE PROCEDURE

Postprocedure Care

- TTJV is considered a short-term "fix" to supplement oxygenation in a lifesaving fashion; ventilation (CO_2 exchange) may be limited.
- Continued efforts to secure the airway with advanced techniques (FFB, VAL, SGA) should be pursued.
- Creation of a surgical airway (tracheostomy) is possible with active TTJV taking place.
- Removal of the catheter is quick and usually with little consequence.

Complications

- Common
  - Kinking of the catheter (use wire-reinforced catheter)
  - Blockage or obstruction of the catheter (redirect or withdraw slightly)
- Infrequent
  - Subcutaneous emphysema of neck, thorax, face
  - Minor bleeding
  - Infection (rare)
  - Incorrect or unsuccessful catheter placement
- Serious but rare complications
  - Damage to the laryngeal cartilage
  - Serious hemorrhage because of severed blood vessel
  - Posterior wall perforation (concerning), but if followed by TTJV, devastating consequences may take place
  - Pressurization of intratracheal airway leading to barotrauma, pneumothorax or, worse, tension pneumothorax, pneumomediastinum, and pneumopericardium

OUTCOMES AND EVIDENCE

- Patient outcomes after TTJV are related to their coexisting condition
  - Recognized as lifesaving maneuver in many airway management algorithms
  - Lack of training, lack of practice, low frequency make it high risk
  - Successful catheter placement may be fraught with incorrect I:E ratio, excessive delivery of breaths (>12/min), lack of pressure egress
- Owing to the emergency nature of the procedure, randomized controlled studies in humans are not possible in the emergency setting.
  - The DART program at Johns Hopkins does not push TTJV because it interferes with the performance of a surgical airway (FONA) if subcutaneous emphysema results from TTJV. The ASA Closed Claim Analysis and the NAP4 suggested that TTJV is associated with significant complications and morbidity. Moreover, such complications detract from the effective pursuit of a surgical alternative.
- Technique used successfully in elective setting with proper equipment, trained and knowledgeable personnel performing TTJV.

NEEDLE AND SURGICAL CRICOTHYROTOMY

BEFORE THE PROCEDURE

Indications

- Impossible or failed oral or nasal endotracheal intubation because of any of the following:
  - Very difficult/impossible intubation (ventilation/oxygenation possible)
  - CVCI airway; can't intubate, can't oxygenate (CICO, UK version)
  - Massive oral, nasal, or pharyngeal hemorrhage
  - Massive regurgitation or emesis
  - Masseter spasm
  - Clenched teeth
  - Structural deformities of oropharynx, congenital or acquired
  - Stenosis of upper airway
  - Laryngospasm
  - Mass (cancer, tumor, polyp, or other)

FONA

- Airway obstruction (partial or complete) that cannot be cleared
  - Nontraumatic
    - Oropharyngeal edema
    - Laryngospasm
    - Mass (cancer, tumor, polyp, or other away from insertion site)
  - Traumatic
    - Foreign body obstruction (above level of insertion)
    - Supraglottic, glottic, or subglottic stenosis/narrowing (above insertion site)
  - Traumatic injuries making oral or nasal endotracheal intubation difficult or potentially hazardous
    - Maxillofacial injuries
    - Cervical spine instability
  - Elective versus urgent versus emergent
    - Elective: critical airway situation noted before induction, patient hemodynamically stable, oxygenation/ventilation adequate
    - Urgent: critical airway situation noted before or during induction, patient's hemodynamics and/or oxygenation/ventilation compromised
    - Emergent: critical airway situation during induction, patient hemodynamically unstable and/or oxygenation/ventilation deterioration

Contraindications

- Absolute contraindications
  - Endotracheal intubation can be accomplished easily and quickly, and no contraindications to endotracheal intubation are present.
  - Transection of trachea with retraction of distal end into the mediastinum
  - Fracture or other significant injury of the larynx or cricoid cartilage
- Relative contraindications*
  - Infants and toddlers (<3 years)
  - Bleeding diathesis
  - Patients with massive neck edema, lack of landmarks
  - Acute laryngeal disease (mass, tumor, infection over cricothyroid membrane)

Equipment

- Homemade
  - Guide wire
  - #20 scalpel blade
  - 14-, 16-, or 18-gauge cutting needle on a syringe (depending on wire gauge)
  - Cuffed 6.0 ETT on a dilator (with lumen)
  - Optional: cuffed, nonfenestrated, #4 and #5 tracheostomy tubes
  - Scalpel, #11
  - Trousseau dilator
  - Tracheal hook
  - 4 × 4 gauze sponges
  - Optional equipment: two small hemostats, surgical drapes, 1% lidocaine with syringe and needle
- Prepackaged (e.g., Melker Cricothyrotomy, Cook Critical Care) (Fig. E1.26)

ANATOMY

The thyroid cartilage consists of two approximately quadrilateral-shaped laminae of hyaline cartilage that fuse anteriorly to form the laryngeal prominence. The anterior superior edge of the thyroid cartilage, the laryngeal prominence, is known as the *Adam's apple* and is usually easily seen in men. It is probably the most important landmark in the neck when performing a cricothyrotomy. The cricoid cartilage is shaped like a signet ring with the shield located posteriorly and forms the inferior border of the cricothyroid membrane. The thyroid cartilage forms the superior border of the cricothyroid membrane (Fig. E1.27).

The cricothyroid membrane is a dense fibroelastic membrane located between the thyroid cartilage superiorly and the cricoid cartilage inferiorly; the cricothyroid muscles bound it laterally. The cricothyroid membrane covers an area that is trapezoidal in shape. The average size

*Relative contraindications may be overlooked in the true emergency situation, because it is more important to obtain an airway and avoid hypoxemia.

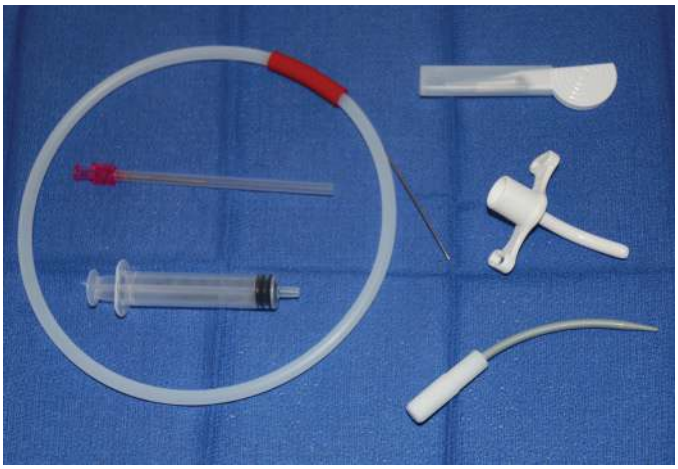

Fig. E1.26 Prepackaged surgical kit.

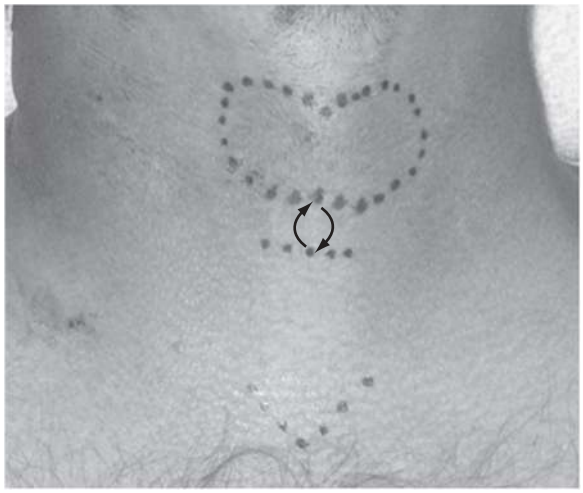

Fig. E1.27 Anatomic outline shows the sternal notch (lower "V"), the straight line (cricoid ring), and the two curved arrows that overlie the cricothyroid membrane, with the outline of the thyroid cartilage above the cricothyroid membrane.

of the cricothyroid membrane in the adult is approximately 22–30 mm wide and 9–10 mm high. Palpating a notch, a slight indentation or dip in the skin inferior to the laryngeal prominence, can identify the cricothyroid membrane. The cricothyroid membrane is located approximately 2–3 cm below the laryngeal prominence in an adult.

PROCEDURE: CONVENTIONAL APPROACH

- Place the patient in a supine position, hyperextended neck with shoulder roll if possible.
- Surgically prep the area using antiseptic solution (if applicable, time permitting).
- Palpate the cricothyroid membrane anteriorly, between the thyroid cartilage and cricoid cartilage.
- Immobilize the larynx—in the right-handed operator, the thumb and long fingers of the left hand are used to grasp the thyroid cartilage.
- Incise the skin—vertical and midline, approximately 2–3 cm in length from the depth of the thyroid cartilage, membrane, and cricoid cartilage.
- Prepare subcutaneous tissue—dissect down to the cricothyroid membrane.
- Incise the membrane—transverse, midline, and at least 1.5 cm long to facilitate ETT placement.
- Place tracheal hook on lower edge of thyroid cartilage and lift upward and cephalad.
- Alternatively, place tracheal hook on upper edge of cricoid ring and lift upward and caudad.
- Place ETT or tracheostomy tube—smaller diameter preferred (5.0–6.5 mm)
- Inflate cuff and confirm placement using auscultation and/or capnography.
- Secure the tube.
- Optional: FFB evaluation

PROCEDURE: STYLET-DILATOR METHOD

- Place the patient in a supine position, hyperextended neck with shoulder roll if possible.
- Surgically prep the area using antiseptic solution (if applicable, time permitting).
- Palpate the cricothyroid membrane anteriorly, between the thyroid cartilage and cricoid cartilage.
- Using a 14-gauge needle on a syringe, puncture the skin midline and directly over the cricothyroid membrane.
- Direct the needle at a 45-degree angle caudally, and carefully insert it through the upper half of the cricothyroid membrane, aspirating as the needle is advanced. Aspiration of air signifies entry into the tracheal lumen.
- Secure the needle, and advance the flexible end of the wire first.
- Once a sufficient amount of the wire is introduced into the trachea, remove the needle.
- Using a 20-blade scalpel, make a deep horizontal puncture.
- Insert the dilator and endotracheal tube assembly onto the wire, and gently advance through the cricothyroid membrane with a continuous downward twisting motion.
- Remove the dilator, inflate the endotracheal cuff, and connect the breathing circuit.
- Secure ETT, auscultate breath sounds, and confirm the return of CO_2.
- Optional: FFB evaluation of airway

PROCEDURE: SELDINGER TECHNIQUE—MELKER COOK CRITICAL CARE

- Supine position, hyperextended neck with shoulder roll if possible
- Surgically prep the area using antiseptic solution (if applicable, time permitting).
- Palpate the cricothyroid membrane anteriorly, between the thyroid cartilage and cricoid cartilage.
- Immobilize larynx as described earlier.
- Puncture the skin and the cricothyroid membrane with the puncture cannula with connected syringe.
- Aspiration of air confirms entry into trachea with needle directed caudad.
- Disconnect syringe from needle, pass the wire caudad into airway, and remove needle.
- Incise skin 0.5–1 cm on each side of the wire guide.
- Insert the dilator together with deflated airway catheter over the wire, through the skin, and into the trachea.
- Remove dilator, inflate cuff, and confirm correct tube placement.
- Secure ETT, auscultate breath sounds, and confirm the return of CO_2.

- Optional: FFB evaluation of airway

PROCEDURE: SURGICAL APPROACH—RAPID 4-STEP, MODIFIED 3-STEP (BOUGIE-ASSISTED) TECHNIQUE

- Supine position, hyperextended neck with shoulder roll if possible
- Surgically prep the area using antiseptic solution (if applicable, time permitting).
- Palpate the cricothyroid membrane anteriorly, between the thyroid cartilage and cricoid cartilage.
- Immobilize larynx as described earlier.
- Incise skin and cricothyroid membrane transversely with scalpel blade.
- Insert a tracheal hook through the incision; secure the cricoid cartilage with the hook.
- Move to a more ventral and caudal position (outward and downward direction with hook).
- Insert smaller-diameter ETT into opening of trachea.
- Three-step technique with Bougie assistance:
  - Midline incision into the skin followed by horizontal division of cricothyroid membrane
  - Advancement of elastic bougie through tracheal space into right mainstem bronchus
  - Advancement of ETT over bougie, removal of bougie
  - Secure ETT, auscultate breath sounds, and confirm the return of CO_2

AFTER THE PROCEDURE

Postprocedure Care

- Postprocedure care should include the insertion of an orogastric or nasogastric tube in cases of full stomach.
- Revision of the cricothyrotomy may be needed as soon as the patient is stable.
- Most cases have previous laryngeal damage or postobstruction pulmonary edema and will require ventilation in the ICU.

Complications

- Common
  - Kinking of the catheter, wire
  - Blockage or obstruction of the catheter
- Infrequent (potentially life-threatening)
  - Kinking of the catheter
  - Aspiration
  - Creation of false passage into the tissue
  - Subglottic stenosis
  - Laryngeal stenosis
  - Hemorrhage/hematoma
  - Esophageal/tracheal laceration
  - Mediastinal emphysema
  - Vocal cord injury
  - Minor bleeding
  - Infection
  - Incorrect or unsuccessful catheter placement
- Serious but rare complications
  - Damage to the laryngeal cartilage
  - Serious hemorrhage because severed blood vessel
  - False passage, loss of airway
  - Pneumothorax, tension component

OUTCOMES AND EVIDENCE

- Patient outcomes after needle cricothyrotomy are related to coexisting conditions.
  - Lowest survival rates are associated with cricothyrotomy undertaken during cardiac arrest (only 6%), compared with 76% for any other reason.
- Most common causes of death are patient comorbidities, followed by failure to achieve an airway, and last, by the procedure itself. Many airway-related deaths are caused by the lack of attempting surgical access at all or attempting it too late in the airway crisis. Move to a surgical airway sooner rather than later.
- Owing to the emergency nature of the procedure, randomized controlled studies in humans are not likely to be performed.
- Because cricothyroidotomy is a rarely performed but potentially lifesaving procedure of last resort in the patient with a failed airway, clinicians responsible for airway management must retain familiarity with the necessary equipment and relevant anatomy.
  - Gaining needle access to the CTM followed by high-pressure oxygen delivery is fraught with failure. It may derail efforts to access the airway via a surgical incision. Alterations of the FONA (e.g., subcutaneous air) may interfere with gaining access from the anterior neck region.
- Clinicians responsible for advanced airway management should review the anatomy and practice with the equipment needed for cricothyroidotomy several times per year.
- At the very least, clinicians should know who to call for assistance with gaining surgical access to the airway.
- Immediate access to needed equipment is imperative to optimize patient safety.
- Delay in starting surgical access, lack of equipment, and inexperience with the technique are the most common underlying reasons for poor outcome.
- Although an emergency surgical airway may be glamorized to be done rapidly, given common anatomic and positioning restraints (cervical collar, cardiopulmonary resuscitation [CPR], ongoing BVM, poor positioning, obese thick neck devoid of landmarks), it is the exception that it can be performed accurately in less than 45 seconds. Clinical experience suggests >1–3 minutes and well beyond this time frame in many instances.
  - The two main concerns with surgical airway access is that it is not tried at all or it is attempted too late.
  - If placing an ETT via the surgical access route, beware of depth of the ETT. It can easily be placed past the carina leading to mainstem bronchus intubation. Approximate depth should be 10 cm, and verification by bronchoscopy is recommended.

ESOPHAGEAL-TRACHEAL COMBITUBE: ALTERNATIVELY, THE RUSCH EASY TUBE (SMALLER—LATEX-FREE COMBITUBE LOOK-ALIKE AND THE KING LT-LARYNGEAL TUBE-SINGLE LUMEN, ESOPHAGEAL PLACEMENT, ONE SYRINGE FOR DUAL CUFF INFLATION)

BEFORE THE PROCEDURE

Indications

- Emergency airway device in the CVCI pathway
  - Provides rapid control of airway when intubation is impossible and other techniques of securing the airway fail
- Airway management when the patient situation disallows laryngoscopy or bag-mask ventilation because of positioning, confinement
  - Example: trapped in a car after motor vehicle crash and inability to perform laryngoscopy

Contraindications

- Absolute
  - Pediatrics or patients less than 4 feet tall
    - Pediatric sizes unavailable[36]
  - Airway obstruction (supraglottic and below)
  - Intact gag reflex
  - Recent upper esophageal surgery (i.e., Ivor Lewis esophagogastrectomy)
  - Caustic ingestion
  - Latex allergy
    - Combitube includes latex in its construction
    - Alternative product: EasyTube, Rusch Medical (latex free); similar in design to Combitube
- Relative
  - Elective/nonemergent situations

  Example: easy intubation, easy bag-mask ventilation
  - Esophageal pathology (proximal third, upper portion)
    - Example: patient with known esophageal varices; however, if patient is hypoxic and no other airway is possible, benefits clearly outweigh risks. Variceal location tends to be in the lower half of the esophagus.
  - Anatomic alteration of supraglottic area, glottis, hypopharynx
    - Tumor, abscess, foreign body, swelling
    - Emergency short-term use for airway rescue is acceptable.
  - King laryngeal tube
    - Responsive patients with an intact gag reflex
    - Patients with known esophageal disease
    - Patients who have ingested caustic substances

Equipment

- The Esophageal-Tracheal Combitube (Kendall-Sheridan, Argyle, NY) is available in two sizes: 41F (large adult) and 37F. It is a double-lumen soft plastic tube that is inserted into the mouth with or without laryngoscopy and advanced blindly into either the trachea or esophagus (>90% pass into the esophagus). The Combitube has two inflatable cuffs: a smaller distal cuff similar to that of a conventional ETT and a larger proximal cuff designed to seal the pharynx. Once placed, the practitioner must ventilate the proper conduit to deliver oxygen into the trachea. Understanding the Combitube's design is imperative to its successful use and fosters the ability to troubleshoot difficulties. The Combitube is joined by its recently introduced cousins: the Rusch EasyTube and King laryngeal tube (LT). The Rusch EasyTube is a latex-free alternative that is offered in a large model (similar to the Combitube 41F) and a smaller adult version (35F). The Combitube enters the esophagus in over 95% of cases; ventilation is through lumen #1 (blue connector). End-tidal CO_2 detection, pulse oximetry, and other confirmatory measures must be confirmed for all placements. The occasional placement in the trachea requires ventilation of the lungs through lumen #2 (Fig. E1.28).
- Another airway device that is gaining popularity for in-hospital and prehospital use is the King LT, which is blindly inserted into the hypopharynx with the distal tip inserted past the cricopharyngeal opening of the esophagus (not in the trachea). The ventilation portal comes to rest posterior and inferior to the epiglottis in proximity to the open glottis. It has two high-volume, low-pressure inflatable balloons similar to the Combitube (one that occludes the esophagus and one that inflates in the posterior oropharynx) yet requires fewer steps, because it is reliant on only a single site of inflation. The distal cuff is designed to seal the esophagus. The proximal cuff is intended to seal the oropharynx. Ventilation is achieved via a 15-mm connector (single portal as opposed to the Combitube's two) for attachment to a standard breathing circuit or

Fig. E1.28 King laryngeal tube (LT) *(upper)* and Combitube *(lower)* are both dual-balloon airway devices. Combitube has a long track record of excellent performance but is being challenged by the smaller-sized King LT, with its single pilot valve/dual cuff design and single ventilation portal.

resuscitation bag. The patient may breathe spontaneously via the King LT. CO_2 detection is adaptable to all three devices (Fig. E1.29).

ANATOMY

An understanding of basic airway, tracheal, and esophageal anatomy is required to interpret which lumen should be used to ventilate the patient. Also, if ventilation is unsuccessful, it is important to understand that the positioning of the Combitube may not be ideal, and it may have to be advanced or withdrawn slightly.

PROCEDURE: COMBITUBE

- The Combitube is an emergency airway management device for patients requiring rapid control of the airway, particularly when poor laryngoscopic visualization of the larynx makes tracheal intubation impossible.
- Insert appropriate-sized Combitube into patient's mouth, with or without laryngoscopy (the smaller-sized Combitube [37F] may be used in all adults <6 feet, 5 inches tall).
- Advance the Combitube blindly into either the trachea or esophagus.
- Stop advancing once the proximal depth indicator (two black rings) is at the level of the teeth.
- Inflate the smaller distal cuff and the larger proximal cuff that seals the pharynx.
- Ventilate through the proximal (blue, #1) lumen first, because 95% of Combitube placements result in an esophageal position and auscultate the lungs and stomach.
- If breath sounds are not heard but gastric sounds are, the Combitube has likely been placed in the trachea.
- Simply change ventilation to the distal (clear, #2) lumen, and recheck for breath sounds.
- If breath sounds are still not detectable by auscultation, the Combitube has likely been advanced too deeply into the esophagus, and the pharyngeal cuff is obstructing the glottis.
- If this occurs, deflate the pharyngeal cuff, withdraw the Combitube a few centimeters, and recheck for breath sounds.
- Once the appropriate lumen has been selected and ventilation appears adequate, confirm with capnography.

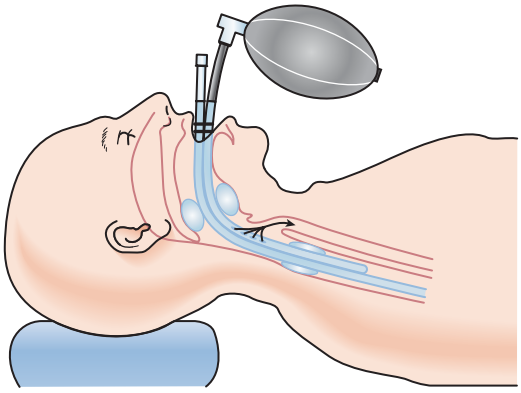

Fig. E1.29 Combitube in the esophageal position with both balloons inflated. Proper positioning of the eight side ventilation portals allow oxygen delivery into the glottis. If resistance is met when bagging, it is typically caused by two factors: (1) Combitube is positioned too deep, so some or all of the ventilation portals are occluded by esophageal mucosa (solution: withdraw Combitube to a more proximal position); or (2) upper inflated cuff has forced the epiglottis downward and is partially or completely obstructing the glottic opening (solution: withdraw Combitube to a more proximal position).

PROCEDURE: KING LARYNGEAL TUBE

The King LT is a supraglottic airway that uses two cuffs to create a supraglottic ventilation seal similar to the Combitube (hypopharynx and esophageal level). The King LT has a single ventilation port (15-mm connector) and a single valve and pilot balloon that simultaneously inflate both the pharyngeal and the esophageal balloons.

- Assuming the operator is familiar with the King LT, lubrication is applied and preoxygenation is completed.
- Sniffing position if possible, but not required.
- Hold the King LT at the connector with dominant hand. With nondominant hand, hold mouth open and apply chin lift.
- With the King LT rotated laterally 45–90 degrees such that the blue orientation line is touching the corner of the mouth, introduce tip into mouth and advance behind base of tongue.
- As tube tip passes under tongue, rotate tube back to midline (blue orientation line faces chin).
- Without exerting excessive force, advance tube until base of connector is aligned with teeth or gums.
- Inflate via the single pilot valve until sealed (40–80 mL, depending on King LT size).
- Gently ventilate to assess position (free-flowing I/E, large V_T).
- Depth markings give an indication of the distance from the vocal cords to the teeth.
- Confirm proper position by auscultation, chest movement, and verification of CO_2.
- If ventilation is met with high resistance, slowly withdraw device until ventilation improves.
- Intubation may be accomplished with the FFB-Aintree combination (Figs. E1.30 and E1.31).

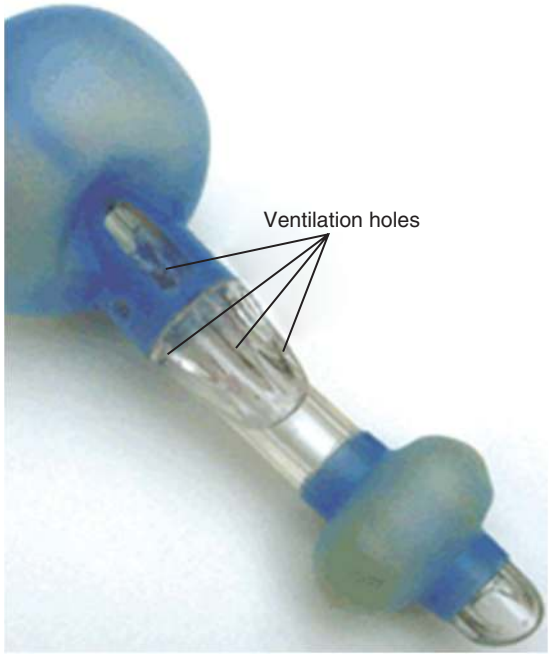

Fig. E1.30 Close-up view of King laryngeal tube and the ventilation holes that come to lie posterior to the glottic opening. The upper opening will emit an FFB or FFB-Aintree combo to visualize/intubate the trachea. (With permission from Ambu, Inc., Glen Burnie, Maryland.)

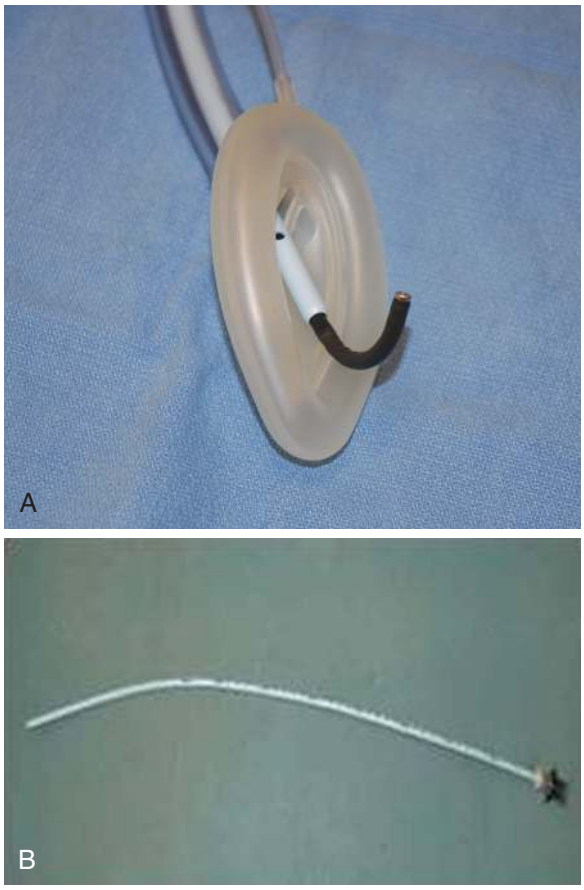

Fig. E1.31 A, The Cook-brand Aintree catheter acts as a "jacket" around the flexible fiber-optic bronchoscope (FFB), which is then passed (in this case) via the laryngeal mask airway to assist in visualizing the glottic opening. The Aintree-FFB combo can be passed via the ventilation portal of the King laryngeal tube (LT) to allow passage into the trachea. After removal of the FFB from the Aintree (which remains in the trachea), the King LT is removed over the Aintree. A lubricated endotracheal tube (ETT) is then passed over the Aintree, as it acts as a bougie. **B,** The Aintree catheter, a 56-cm-long, hollow catheter.

- The Rusch EasyTube is another alternative to these two products. It is available in two sizes: 41F and 28F, has a single lumen at the distal end, two separate cuffs for inflation (as does the Combitube), and a latex-free balloon and offers access to the upper airway (via a suction catheter, airway exchange catheter, or flexible bronchoscopy).

AFTER THE PROCEDURE

Postprocedure Care

- Once patient is stabilized and adequately ventilated and oxygenated, a more definitive airway should be secured.
  - It is an acute emergency airway device.
  - The three products are not intended for extended use in the emergency patient.
  - Intubation of the trachea is favored in most patients, so a plan should be developed to change to an ETT.
  - Changing to an ETT may be performed with the use of conventional and advanced airway devices.
  - If exchange is considered to be dangerous and risky (desaturation, massive edema, poor pulmonary compliance) or it proves to be impossible to identify the glottic opening, securing the airway surgically may be the best (or only) alternative.
  - When the three devices are in the esophageal position, surgical entrance into the trachea is not impeded by the airway device.

Complications

- Common
  - Difficulty maintaining a cuff seal to provide adequate positive-pressure ventilation
  - Regurgitation and aspiration would ideally be limited, but complete protection is not guaranteed.
- Serious but rare complications
  - Lacerations to the esophageal wall or pyriform sinus
    - Can result in subcutaneous emphysema, pneumomediastinum, pneumoperitoneum, and esophageal rupture
  - Ischemia of tongue/airway edema if left in place for long duration

OUTCOMES AND EVIDENCE

These devices, though relatively simple and timely to place, do require complete familiarization with their placement, cuff inflation features, and limitations. The King LT is popular as an elective airway support device and as a useful rescue airway device in cases of an unexpectedly difficult airway. Anecdotally, clinicians may prefer the King LT based on its smaller size and simplicity with one inflation portal. In essence, these devices can be considered "secondary SGA devices" in the rescue schema. Though each could serve as a rescue technique for failed DL ± Bougie or VAL, most guidelines recommend SGA such as a first- or second-generation SGA (i-gel, LMA Proseal, LMA Supreme, Ambu Aura, Fastrach LMA). Hence, the Combitube and others would serve as a reserve backup rescue for other SGAs (which have potential as an intubation conduit).

EVALUATION OF A CUFF LEAK IN THE ICU

BEFORE THE PROCEDURE

Indications

- Audible cuff leak in an intubated patient may represent a variety of problems
  - Tear/microperforation or macroperforation of ETT cuff
    - Remedy: exchange ETT
  - Broken pilot balloon line
    - Remedy: occlude line perforation, inflate cuff, clamp line with Kelly/hemostat (temporary, low risk)
    - Remedy: cut line, attach new pilot balloon/valve/line assembly, reinflate balloon (less temporary, may perform well long-term, low risk)
    - Change ETT (high risk) (Fig. E1.32).
  - Incompetent valve/pilot balloon perforation/dysfunction
    - Remedy: cut line, attach new pilot balloon/valve/line assembly, reinflate balloon (less temporary, may perform well long-term, low risk)
    - Remedy: inflate cuff, clamp line with Kelly/hemostat (temporary)
    - Remedy: change ETT (high risk)
- ETT cuff/tracheal wall incongruity (tracheomalacia, tracheal softening, tracheitis, overstretched poorly compliant cuff)
  - Remedy: advance ETT/cuff to alternative level in trachea (temporary, low risk)
  - Remedy: change ETT (high risk) or change tracheostomy to larger size, length, or cuff shape/design (moderate or high risk if trach >10 days old)
  - Presence of foreign body within trachea leading to airway leak (temperature probe, NGT, feeding tube)
    - Presence of tracheoesophageal fistula (TEF), bronchoesophageal fistula (BEF), or bronchogastric fistula (BGF). Often this condition is known to the care providers. Adjusting the depth of the ETT may be required. If a new diagnosis of a fistula is made, this may be a surgical emergency because of the potential for mediastinal spillage.
  - Dislocation of ETT (partial or complete extubation of the trachea) is typified by three potential locations within the airway:
    - Cuff between vocal cords (partial extubation)
    - ETT tip at level of vocal cords (complete extubation)
    - ETT tip/cuff in hypopharynx (complete extubation) (Figs. E1.33 through E1.35)
- Partial/complete extubation of the airway, masquerading as an ETT with a cuff leak, must be identified
  - It is imperative to check the status of the pilot balloon.
  - If the pilot balloon appears to be intact (holds insufflated air), the ETT tip/cuff location is likely not intratracheal.
  - If the "cuff" leak is erroneously identified as a malfunctioning ETT cuff and the airway team passes an airway exchange catheter (AEC), the misplaced distal tip of the ETT may allow passage of the AEC to areas external to the trachea (e.g., esophagus, pyriform sinus)

Fig. E1.32 Commercially available pilot balloon repair kit. Blunt needle is inserted into the cut end of the pilot valve line.

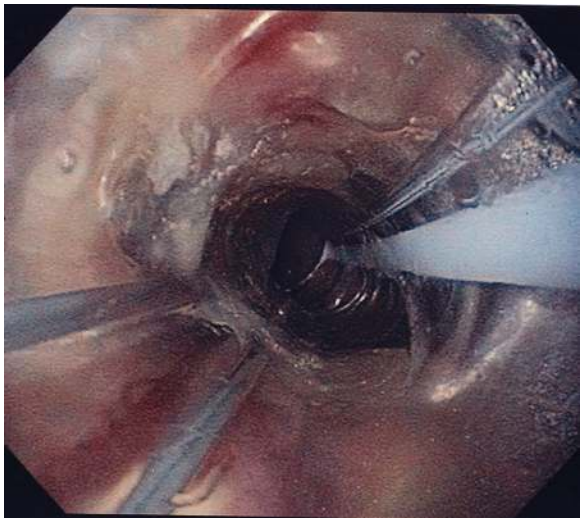

Fig. E1.33 This patient had a continuous "cuff leak" while supported on mechanical ventilation. The endotracheal tube (ETT) depth was 25 cm at the dentition, yet the ETT tip is just below the vocal cords when viewed with the FFB. The barely visible white vocal cords are "stretched" by the ETT and are located laterally in the picture. In the upper-right corner is the bluish edge of the lower portion of the ETT cuff. Distally at the ETT, one can see with the FFB that the posterior wall of the thyroid cartilage is visible (not seen in this picture).

Fig. E1.34 The ICU physician was called to evaluate an intermittent "cuff leak," difficulty passing the suction catheter, and waxing/waning oxygen saturation. The pilot balloon was intact and inflated. Flexible fiber-optic bronchoscopic examination found the endotracheal tube (ETT) tip was impaled on the vocal cord, with a view of the subglottic area via the Murphy eye of the ETT. The FFB was passed into the trachea via the Murphy eye, and the ETT was gently advanced into the trachea.

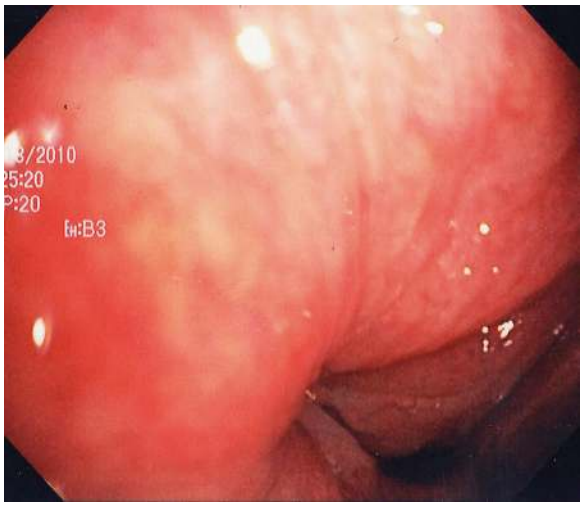

Fig. E1.35 The intensive care unit team was called to investigate a continuous "cuff leak" in this patient. The pilot balloon was intact; the fiber-optic bronchoscopic (FFB) view of the vocal cords from the tip of the endotracheal tube (ETT) reveals that the ETT tip is well above the glottic opening. The FFB was advanced into the trachea, and the ETT was then returned to the tracheal position.

- Two methods are strongly recommended to diagnostically and therapeutically manage the possible ETT tip/cuff dislocation:
  - First choice: FFB to diagnose the tip location and therapeutically allow reintubation of the trachea if possible (85% likely at authors' institution)
  - Second choice: laryngoscopy, preferably VAL versus direct laryngoscopy (DL), so as to allow improved visualization of the airway and possibly improve the margin of safety in this potentially life-threatening consequence of the intubated ICU patient
- Caveat: How reliable is the level of the ETT at the dentition line in determining where the tip is located (based on a database of 245 cases of partial extubation at the authors' institution)?
  - ETT at <20 cm at the dentition line: 55% were above the glottis
  - ETT at >20 cm: 73% at level of glottis or above glottis (hypopharynx)
  - Conclusion: There appears to be little correlation of ETT markings at the dentition line and the location of the ETT tip.
  - Overall, 51% of ETT tips were above the vocal cords, 32% were at the level of the vocal cords, and in 17%, the cuff was located between the vocal cords on examination.
- Caveat: Is there any difference in the incidence of complications when using FFB versus DL to diagnose and manage a dislocated ETT?
  - Managing this clinical situation with DL alone was fraught with complications such as severe hypoxemia, esophageal intubation, loss of the airway, bradycardia, and cardiac arrest.
  - Diagnostic and therapeutic management with FFB was an overall excellent choice, but it was not without its own problems. The ETT tip that was above the vocal cords was often centralized and easily advanced into the trachea, but approximately 15%–20% of these cases had the ETT tip abutting the vocal cords, pharyngeal wall, or other tissues that made it very difficult to advance the FFB into the trachea. Several of these ETTs had to be moved more proximal to allow FFB advancement, but this was not always successful.
  - Alternative airway management schema beyond the FFB must be available to rescue the airway in the event difficulty is encountered.

Contraindications

- Absolute
  - Difficult intubation and ETT can be salvaged by some other means than replacing it (e.g., repair of pilot balloon or clearing of obstructive luminal secretions via the CAM Resqu-Cath) (Figs. E1.36 through E1.38).
- Relative
  - Unprepared
    - Unless the situation is truly emergent, ETT exchange should not be attempted without properly preparing the patient and without having immediate access to difficult airway supplies.
  - ETT is not damaged
    - If the reason for exchange is for "cuff leak," for example, but the leak is the result of supraglottic positioning, not a damaged cuff, then adjustment of the ETT and not ETT exchange is appropriate. However, an overdistended ETT cuff may suffer from altered compliance because of stretching. Thus a new ETT may be advantageous.

Equipment

- Conventional intubation equipment
- Advanced airway rescue devices, including FFB and VAL
- Miscellaneous equipment
  - Kelly clamp/hemostat
  - Replacement pilot balloon kit

PROCEDURE

- Place patient on 100% oxygen.
- Review patient history, problem list, medications, level of ventilatory support.

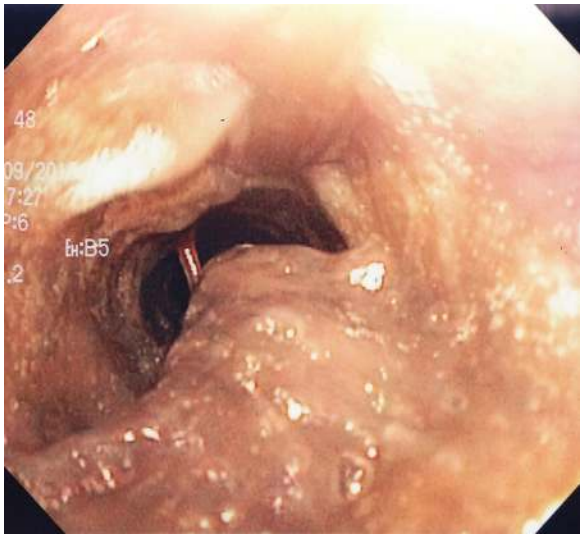

Fig. E1.36 This patient immediately failed a continuous positive airway pressure (CPAP) trial. Investigation with fiber-optic bronchoscopy (FFB) found significant biofilm accumulation at several levels of the endotracheal tube (ETT) lumen. A choice of exchanging to a new ETT was contemplated, but the patient was a known difficult airway. A catheter with an inflatable cuff (similar to a Fogarty catheter) that had a mesh covering for "traction" was passed and was able to remove 90% of biofilm blockage in less than 90 seconds on two passes.

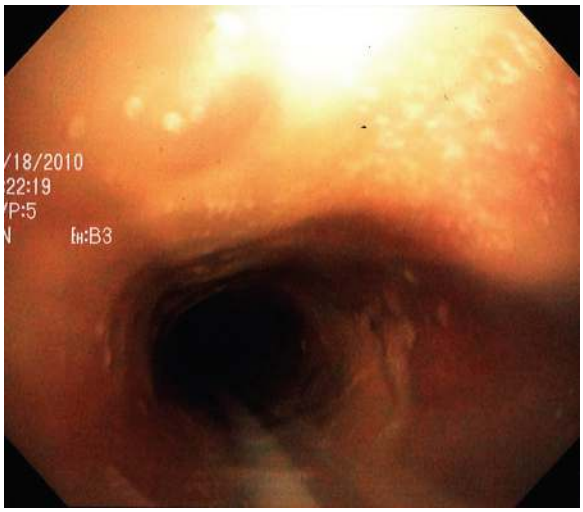

Fig. E1.37 The same endotracheal tube (ETT) as in Fig. E1.36, after a single pass of the biofilm removal catheter.

- Assemble conventional and rescue airway equipment, including capnography.
- Initiate sedation/analgesia if not already present, with or without muscle paralysis.
- Optimize positioning, perform FFB to determine level of the ETT tip if appropriate, and then advance the ETT over the FFB into the trachea.
  - Alternative rescue methods, personnel should be immediately available
- Second choice: examination of the airway (laryngoscopy, video-based preferable)
  - Extra caution when advancing laryngoscope blade into oropharynx, as the tip may puncture the overinflated ETT cuff in the "back" of the throat.

Fig. E1.38 **A,** A large biofilm plug removed following a single pass of the biofilm removal system. **B,** Close-up of the mesh-covered catheter cuff used to remove the tracheal lumen obstruction of biofilm.

- Consideration should be given to replacing the ETT when its cuff has undergone overinflation and may have altered compliance.

AFTER THE PROCEDURE

Postprocedure Care

- Reconfirm endotracheal placement with capnography.
- Assess depth of ETT with breath-sound auscultation, bronchoscopy, chest radiograph (delayed).

Complications

- Common
  - Inability to advance new ETT owing to tip embedded in the upper airway tissues
  - Hypoxemia
- Serious but rare complications
  - Loss of difficult airway
    - Most feared and worst outcome
    - Can be reduced by using FFB versus DL
    - Use VAL over DL
    - Ensure airway team has adequate supportive staff and immediate access to advanced airway equipment (including surgical staff)

OUTCOMES AND EVIDENCE

Partial extubation of the airway can be a life-threatening consequence of tracheal intubation in the ICU patient. Misdiagnosis or lack of understanding of this situation may lead to patient

morbidity and mortality. Being prepared, as is the case for any ICU airway situation, is in the best interest of patient safety. Running through the differential diagnosis of a "cuff leak" is imperative. The simplest task to complete is to inquire about the characteristics of the cuff leak (duration, amount of air placed in cuff, etc.) and to check its integrity. If the pilot balloon appears intact, it is reasonable to assume the ETT tip cuff is displaced at or above the vocal cords, and one should consider FFB for diagnostic and therapeutic management. Again, VAL is invaluable as both a diagnostic and therapeutic option.

EXTUBATION OF THE DIFFICULT AIRWAY

BEFORE THE PROCEDURE

Indications

- To optimize the safety of the ICU patient being readied for extubation, with special emphasis on the difficult airway patient
- Known difficult airway
  - Known difficult mask ventilation
  - Known difficult laryngoscopy
  - Known difficult intubation
- Suspected difficult airway
  - Obesity
  - Cervical spine precautions, hard collar, halo vest, limited range of motion
  - Edema, swelling, airway trauma, systemic reaction (sepsis, blood transfusion reaction, anaphylaxis)
  - Massive volume resuscitation
  - Evolving head/neck trauma, pathology, injury
  - Any limitation to the mouth/oral cavity/oropharynx
  - Excessive secretions, bleeding, bandages, alterations to anatomy
- *Difficult extubation* is defined as the clinical situation when a patient presents with known or presumed risk factors that may contribute to difficulty reestablishing access to the airway.
  - The subsequent intolerance of the extubated state poses an increased risk to patient safety.
  - An extubation strategy should be developed that allows the airway manager to (1) replace the ETT in a timely manner and (2) ventilate and oxygenate the patient while the patient is being prepared for reintubation and during the reintubation itself.
  - The practitioner should assess the patient's risk on two levels: the patient's predicted ability to tolerate the extubated state and ability (or inability) to reestablish the airway if reintubation becomes necessary. Weaning criteria and extubation parameters will not be discussed because they vary by locale, practitioner, and the patient's clinical situation.

Contraindications

- Absolute contraindications
  - When the clinical assessment of the patient is suggestive of a high risk for difficulty establishing an airway and airway management personnel with an expertise of handling such a patient are not present or they are not properly equipped to handle such a patient.
  - Patient fails routine accepted extubation parameters for your facility.
  - When the full complement of ICU personnel are unavailable for the extubation trial (e.g., nursing staff, respiratory therapy staff, airway team members).
  - When a backup plan/strategy has not been developed or the equipment/personnel to execute such a strategy are not available.
- Relative contraindications*
  - Establishing a surgical airway (tracheostomy) would be a better choice.
  - Delaying the extubation trial would be in the patient's best interest.

Equipment

- Conventional airway management equipment
- Advanced airway rescue equipment (difficult airway cart/bag)
  - FFB
  - Advanced VAL equipment
  - Airway exchange catheters
- Nursing staff
- Respiratory therapy staff
- Surgical assistance for a surgical airway (if indicated)
- Sedation/analgesia/muscle relaxant medications
- Postextubation oxygen delivery system
  - Nasal cannula
  - Face mask
  - CPAP, BiPAP

ANATOMY

- Patient assessment must be completed before the decision whether or not to extubate.
- Review of the patient's stay in the ICU, medications, problem list, surgeries, procedures, previous airway interventions, and current clinical condition would be standard to provide needed information to develop an understanding of the patient's current predicament.
- This evaluation would be supported by a clinical assessment of the patient's airway to evaluate inability to tolerate extubation from such causes as:
  - Airway obstruction (partial or complete)
  - Hypoventilation syndromes
  - Hypoxemic respiratory failure
  - Failure of pulmonary toilet
  - Inability to protect airway

*Based on personal preference, experience, and the patient's clinical condition.

- Evaluate for potential difficulty reestablishing the airway
  - Difficult airway
  - Limited access to the airway
  - Inexperienced personnel pertaining to airway skills
  - Airway injury, edema formation
- Risk factors for difficult extubation
  - Known difficult airway
  - Suspected difficult airway based on the following factors:
    - Restricted access to airway
    - Cervical collar, halo vest, limited range of motion
    - Head and neck trauma, procedures, or surgery
    - ETT size, duration of intubation
    - Head and neck positioning (e.g., prone vs. supine)
    - Traumatic intubation, self-extubation
    - Patient bucking or coughing
    - Drug or systemic reactions
      - Angioedema
      - Anaphylaxis
      - Sepsis-related syndromes
      - Excessive volume resuscitation
- ASA Practice Guidelines and other societies have suggested that a preformulated extubation strategy should include:
  - A consideration of the relative merits of "awake" extubation versus extubation before the return of consciousness (more applicable to the operating room setting)
  - An evaluation for general clinical factors that may produce an adverse impact on ventilation after the patient has been extubated
  - The formulation of an airway management plan that can be implemented if the patient is not able to maintain adequate ventilation after extubation
  - A consideration of the short-term use of a device that can serve as a guide to facilitate intubation and/or to facilitate ventilation/oxygenation

PROCEDURE

- Suggested three-step patient assessment
  - Review history, current conditions, medications, mental status as previously stated.
  - Assess airway; external evaluation supplemented with internal evaluation
    - Conventional laryngoscopy has limited clinical utility in the ICU patient.
    - In most patients, VAL allows the ability to "see around the corner," thus providing a view of the periglottic airway to determine if the airway is suitable for extubation; also provides valuable information regarding the ease or difficulty of viewing the airway anatomy in the event reintubation is needed after extubation.
  - Develop strategy for extubation, delay extubation, or secure via surgical means; extubation choices include
    - Conventional extubation (directly to oxygen source)
      - Extubation over an airway exchange catheter to maintain airway access
      - FFB-assisted airway evaluation/extubation
        - Transition to LMA until patient is "safe" to lose "airway access" (Fig. E1.39)
        - It may be appropriate to relocate the extubation procedure to the operating room. Requesting the presence of personnel capable of rapidly performing surgical access (Difficult Airway Response Team [DART], surgical airway team, etc.) may be appropriate in some instances.

Fig. E1.39 Laryngoscopic view (GlideScope) of a patient with a known difficult airway who is ready for an extubation trial. The airway was assessed to determine two factors: (1) the ease or difficulty of reintubating the trachea if extubation is poorly tolerated and (2) the status of the periglottic tissues (edema, swelling, and trauma) and whether they are compatible with tolerance of the extubated state. This airway view demonstrated residual edema and swelling, in addition to secretion buildup.

- Clinical decision plan for the difficult extubation
  - A variety of methods are available to assist the practitioner to maintain continuous access to the airway after extubation, each with its limitations and restrictions.
  - Though no method guarantees control and the ability to resecure the airway at all times, the LMA offers the ability for fiberoptic–assisted visualization of the supraglottic structures while serving as a ventilating and reintubating conduit, but is hampered by a limited time frame.
  - FFB is useful for periglottic assessment after extubation but requires advanced skills and minimal secretions. Moreover, it offers only a brief moment for airway assessment and continuous access to the airway after extubation.
  - Conversely, the AEC allows continuous control of the airway after extubation but without visualization, is well tolerated in the vast majority of patients, and serves as an adjunct for reintubation and oxygen administration. Patient intolerance, accidental dislodgment, and mucosal and tracheobronchial wall injury have been reported but are rare. Several brands of AECs are available in a variety of sizes. Cook Medical offers adult-appropriate sized AECs in 11F (3.7 mm diameter, 14F (4.7 mm), and 19F (6.3 mm). The best tolerated in adults is the 11F. However, reintubation over this AEC may be difficult with the larger-caliber, adult-sized ETT (7.0–9.0 mm internal diameter [ID]). Thus it is suggested to reintubate with a smaller 6.0 ETT to ease advancement into the trachea. This is only a short-term solution for most adults because they would be best served with a larger-caliber ETT. Thus tackling this problem is straightforward. If reintubation is required, pass a lubricated Aintree catheter (19F) over the 11F or 14F indwelling AEC. This will improve the ability to "railroad" a larger-caliber ETT into the trachea. Reintubation is best performed with laryngoscopic assistance to open the pathway to the glottic opening.
  - Carinal irritation may be treated with proximal repositioning, instillation of topical agents to anesthetize the airway, plus explanation and reassurance. Dislodgment may occur because of an uncooperative patient or a poorly secured catheter.
  - Observation in a monitored environment with experienced personnel should be given top priority, as should the immediate availability of difficult airway equipment in the event of extubation intolerance.

- Suggested extubation procedure for the difficult airway patient:
  - Acquire advanced airway rescue equipment.
  - Assemble personnel (respiratory therapist, nursing staff, and surgical staff).
  - Prepare circumferential tape to secure the airway catheter after extubation. Other ETT-holding devices may be adapted to secure an AEC.
  - Discussion with patient/family/airway care team.
  - Position patient upright; suction internal and external to ETT.
  - If obese, ramped position recommended.
  - Pass lubricated AEC to 23- to 26-cm depth (shorter adults <5 ft. tall may require a depth of 20–22 cm).
  - Remove the ETT while maintaining the AEC in its original position.
  - Wipe excess lubrication/secretions from the AEC before taping.
  - Secure the AEC with tape (circumferential) and mark AEC "airway only."
  - Oxygen: nasal, mask, or humidified oxygen.
  - Maintain NPO (nothing by mouth), provide pulmonary toilet.
  - Ensure availability of smaller-caliber ETT (6.0) for reintubation if needed. Aintree catheter to place over 11F or 14F AEC to increase caliber of catheter to augment the advancement of the ETT into the trachea
  - Maintain patient in monitored setting with skilled personnel available (Fig. E1.40).
- Clinical judgment and the patient's cardiopulmonary and other systemic conditions, combined with the airway status, should guide the clinician in establishing a reasonable period for maintaining a state of "reversible extubation" with the indwelling AEC. Table E1.1 shows a suggested time frame for maintaining the well-tolerated AEC. If significant head/neck and/or laryngeal/periglottic edema precludes extubation, several maneuvers may be implemented to assist in decreasing swelling and edema
  - Raise head of bed as much as tolerated.
  - Maintain even to negative in/out fluid balance.
  - Diurese if volume overloaded (common in ICU).
  - Pretreatment (12–24 hours before extubation) with corticosteroids if appropriate (controversial but may reduce postextubation stridor, breathing difficulties, reintubation, and laryngeal edema overall).
  - SAFETY NOTE: Administration of oxygen (low flow 1–2 L/min, medium flow 3–6 L/min, or high-pressure "jet" delivery) via the AEC cannot be recommended unless preparing for emergency reintubation (short-term only). Without proper egress of insufflated oxygen, even low-flow oxygen may lead to barotrauma and life-threatening consequences. Thus oxygen delivery around, not through, the AEC lumen, is recommended. Many experts favor not applying "jet" pressurized oxygen via the AEC because of (1) the rarity that most clinicians use jet ventilation and (2) the hazards of its use during an emergency.

TABLE E1.1 Time Frame* for Maintaining the Well-Tolerated Airway Exchange Catheter

Difficult airway only, no respiratory issues or airway swelling	1–4 hours
Difficult airway, no direct respiratory issues, potential for airway swelling	2–6 hours
Difficult airway, cardiopulmonary issues, multiple extubation failures	2–24 hours

*Time frame will vary according to patient condition, airway assessment, and tolerance of the presence of the airway exchange catheter.

Fig. E1.40 Patient on postoperative day 2 after an anterior-posterior four-level cervical fusion, laminectomy, and discectomy at two levels. She required an "awake" flexible fiber-optic bronchoscopy (FFB) intubation to allow induction of anesthesia. Being a known difficult airway to start with, her airway status only worsened with postoperative swelling and the addition of the halo vest that further restricted cervical movement. She was extubated over an airway catheter but developed rapid deterioration because of stridor, requiring emergency passage of a new endotracheal tube (ETT) over the airway catheter, which was accomplished in less than 20 seconds. A smaller-bore ETT was used (6.0) based on the assumption that airway swelling was the cause of the stridor and a smaller ETT would most likely pass more easily into a swollen airway.

AFTER THE PROCEDURE

Postprocedure Care

- Optimize patient positioning, pulmonary toilet, minimize sedation.
- Continuous close observation by trained personnel and immediate access to an experienced airway management team
- Failure to tolerate the extubated state may vary from 2% to 25% of all patients over a variable timeline such as 12–48 hours.
- The ICU setting is unpredictable. Patients may fail extubation because numerous alterations in the patient's condition can take place unexpectedly (e.g., new-onset dysrhythmia, flash pulmonary edema, acute neurologic changes, systemic reactions, aspiration).
  - Maintain AEC in place for 1–2 hours, at least. Some patients will tire or suffer deterioration in the 2- to 24-hour time frame. Extending the time the "reversible extubation" is maintained is recommended; however, it remains unpredictable for many patients.

Complications

- Patient intolerance of AEC (10%)
  - Assure distal tip is not irritating the carina/bronchus.
  - Hand holding, explanation may improve tolerance.
  - Local anesthetic application via AEC
- Infrequent
  - Removing AEC too early and reintubation required later
  - AEC is removed by patient or falls out inadvertently
  - Inability to reintubate tracheal via AEC (recommend laryngoscopic assistance, may require alternative strategy)

- Esophageal intubation if AEC is displaced
- Serious but rare complications
  - Possible airway obstruction, loss of airway, laryngospasm, mucosal damage
  - Distal tip of AEC, if advanced too distally, may perforate the tracheobronchial tree, tip misplacement into the aerodigestive tract
  - Barotrauma because of oxygen insufflation via the AEC

OUTCOMES AND EVIDENCE

The difficult airway patient being readied for extubation warrants a strategy that allows a predictable reintubation in a timely manner, and thus a "reversible extubation." Though regional or national guidelines that outline specific management schema for dealing with this clinical situation are not readily available, this outline offers "safety first" for the patient. Much emphasis is focused on placing the ETT into the trachea, yet the more difficult issue is replacing the ETT in a recently extubated airway, typically under adverse clinical conditions. Patient morbidity and even mortality (i.e., brain injury from anoxia) are real consequences of extubation of the patient with a difficult airway and should be respected and approached cautiously.

VIDEOLARYNGOSCOPE-ASSISTED INTUBATION

BEFORE THE PROCEDURE

Indications

Video-Assisted Laryngoscopy

- Routine tracheal intubation
- Emergency tracheal intubation
- Rescue of other failed intubation methods
- Viewing airway structures for educational/training purposes
- Exchange of tracheostomy tube
- Evaluation of airway structures for foreign body, trauma, edema, cuff leak
- Extubation evaluation of airway
- Assistance with advancement of TEE probe, feeding tube, NGT, esophageal dilator
- Evaluate ETT position in situ
- Types of VAL blades
  - Conventional angle (20–30 degrees) versus acute angle (60–70 degrees)
  - Channeled versus nonchanneled
  - Hybrid
- Advantages of VAL versus conventional DL (Figs. E1.41 and E1.42)
  - Full view of laryngeal inlet in majority of cases
  - Typically transforms laryngeal view one to two grades lower (better view)
    - Grade III view of the larynx with DL (grade III: no cords visible, only epiglottis visible) improves to grade I or II with VAL

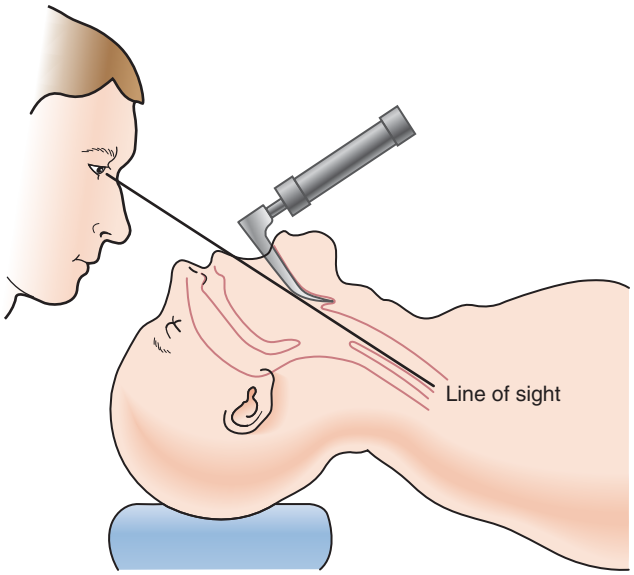

Fig. E1.41 Line of sight with direct laryngoscopy.

Fig. E1.42 Lines of sight for direct laryngoscopy (DL) versus videolaryngoscopy (VAL). There is approximately 30 degrees between the two methods that accounts for the ability to "see around the corner" when the laryngeal view is restricted with DL. Several manufacturers offer both conventional and acute angle blades. Conventional angle blades afford gaining experience with a "MacIntosh" blade combined with the advantage of video assisted visualization.

- Grade IV (no view of any airway structure) often improves to grade II (enough to allow ETT advancement)
- Improved line of sight of naked eye with DL, as operator must peer via the mouth opening around dentition, tongue, and the like; view is often restricted, even more so when the ETT is passed into the airway

Contraindications

- Unfamiliar with its use
- Recent tracheobronchial reconstruction
  - Inappropriate deployment because of trismus, oral cavity restrictions

Equipment

Five basic choices (not all-inclusive of models available, multiple manufacturers) (Figs. E1.43 through E1.50)

- Channeled VAL devices (groove or channel that is preloaded with ETT to assist with its passing)
  - Pentax AWS, AirTraq, King Vision
- Unchanneled VAL devices (must manipulate ETT freehand into trachea)
  - GlideScope, McGrath, Storz C-Mac, APA, VividTrac, Storz DCI Video Laryngoscope
- Acute angle blade assembly (e.g., 60–70 degrees, GlideScope, McGrath, Storz)
- Normal angle blade assembly (e.g., 20–35 degrees, GlideScope, McGrath, Storz)
- Hybrid blade (offering both styles)
- Alternatively, video optical stylet (ETT loaded on stylet, video-assisted intubation)
  - Clarus Shikani/Levitan/Pocket Scope Storz Brambrink, AincA, APA, Insight, J-Wand, Safe-CamVideo, SensaScope, and VivaSigt SL
- A variety of manufacturers offer models from disposable models (Airtraq-Prodol) to reusable models that range from $1500 (single device) to $30,000 (well-stocked cart).

Fig. E1.43 The Airtraq, a portable yet disposable channeled videolaryngoscope (VAL) device that offers excellent laryngeal viewing, given its relatively inexpensive cost and simple external design. (With permission from Prodol Meditec S.A.,Vizcaya, Spain.)

Fig. E1.44 The Pentax AWS, a portable, reusable channeled videolaryngoscope (VAL) with a disposable (clear) blade that has an adjustable video screen (black portion in photo) that adapts to various patient positions. An endotracheal tube (ETT) is preloaded into the channel of the blade to ease advancement into the larynx.

- Reusable models typically offer a disposable blade cover or video baton sleeve to speed its reusability between patient encounters.
- Most are easily transportable in an airway cart or bag or attached to an IV pole with wheels.

ANATOMY

Periglottic airway anatomy is typically visualized on a video-based screen, which equates to a much larger view as compared with the restricted view of the operator looking through the patient's mouth. Depending on the VAL device, the quality is excellent overall. Even the disposable model offers good color distinction, reasonable detail, and

Fig. E1.45 GlideScope AVL shown with video screen and two of several sizes of disposable video baton blades designed for neonatal to large adult. The optional specially shaped stylet that conforms to the blade's extreme 60 allows the operator improved access to advance the endotracheal tube to the laryngeal opening. (With permission from Verathon, Inc., Bothell, Washington.)

Fig. E1.46 The McGrath portable videolaryngoscope is easily transported and offers excellent video-quality images but on a smaller screen. To ease placement in patients with restricted oral access (e.g., halo vest, large chest/breasts, short neck), the device features a disposable clear blade and an adjustable video arm that can be disarticulated to allow the blade to be placed into the mouth and then reattached to the handle.

differentiation of various tissue pathologies. The more expensive models offer excellent quality, color, and detail, and some offer recording capabilities. Secretions, blood, and fogging may impede visualization. Adequate mouth opening is required to allow placement of the blade assembly. Moreover, adequate space between the chest, neck, chin, and mouth opening must be present to allow manipulation of the blade

Fig. E1.47 The Levitan FPS Scope is an optical stylet that assists the operator with visualization of the airway structures via the eyepiece. Elevation of the mandible-tongue complex with a manual jaw thrust or combining the optical stylet with direct laryngoscopy allows the stylet–endotracheal tube to be passed underneath the epiglottis and into the trachea.

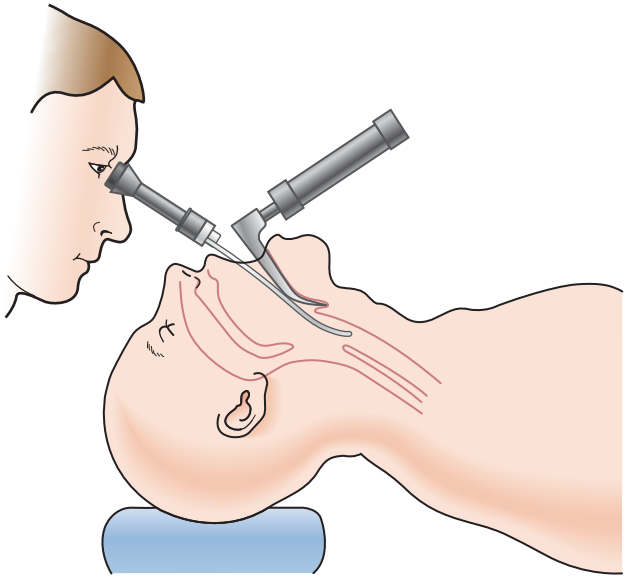

Fig. E1.48 Combining direct laryngoscopy with the optical stylet to achieve laryngeal visualization.

into the correct position to view the airway. The McGrath scope offers a disarticulating blade handle that allows placement of the blade followed by attachment of the handle, thus easing its placement in the restricted airway.

PROCEDURE

- Because of the variety of devices, the operator must be well versed in the individual device's limitations, indications and contraindications, method of placement, angulation within the oral cavity, video characteristics, and more.
- Because of the bulkiness of the VAL's blade, a minimum mouth opening is required to allow device placement into the oral cavity. Further, for the nonchanneled models, adequate space must exist to afford ETT manipulation.

Fig. E1.49 The view offered by a conventional laryngoscope; limited view of glottis structure owing to dependency of operator's line of sight.

Fig. E1.50 Same patient as Fig. E1.49 but with videolaryngoscope-assisted view, allowing operator full view of epiglottis, arytenoids, and glottic opening.

- Preparation of the patient for intubation will vary by the patient's condition, airway status, hemodynamic profile, equipment choice(s), and airway team's judgment and preference. One option for the patient with a known or suspected difficult airway or hemodynamic compromise (hypotension, cardiac tamponade, tension pneumothorax, pulmonary embolism, low ejection fraction, cardiogenic or any shock state), may be topical preparation followed by gentle intubation (with or without light sedation). Adequate topicalization or nerve blocks that will allow bronchoscopic-assisted intubation would allow VAL-assisted intubation. This is now a viable option in the high-risk patient because of airway or hemodynamic concerns.

- Use of any of these devices is a four-step process:
  - Placement into the oral cavity and advancement into the orohypopharynx
  - Optimizing the glottis view
  - Advancing the ETT either via the channel, freehand over a stylet that approximates the curve of the device's blade (nonchanneled), or advancing the ETT-optical stylet assembly to the glottic level and then advancing the ETT into the trachea
  - Smooth and gentle advancement into the mouth is required when manipulating the device, because the operator's attention is typically focused on the "view" and not the patient's dentition or airway tissues.

Fig. E1.51 Videolaryngoscope (VAL) view of a massively swollen airway. No features were discernible via direct laryngoscopy. VAL revealed massive edema but enough detail to allow placement of an endotracheal tube.

- Additional caveat for using VAL for airway management (Fig. E1.51)
  - Proper removal of the device to minimize patient injury and avoid extubation
  - Fundamentals of airway management must be practiced, even when use of high-tech equipment is incorporated. VAL may be able to overcome the lack of fundamentals.
    - Proper positioning is an absolute must (e.g., ramping the obese patient)
    - Secretions, vomitus, bleeding impede viewing.
    - Do not use equipment you are not trained to use.
    - Do not try a new technique or device in an emergency (do what you do best).
    - Remove the front of a hard cervical collar (maintain midline stabilization).
    - Secure the head to the bed frame for immobilization with 2-inch tape ± sandbags; this frees up valuable space that would otherwise be occupied by a colleague trying to maintain a midline position, which could interfere with airway management efforts.
    - If the airway should be secured awake, then do so (FFB, VAL, SGA).
    - Always have a backup plan for any VAL difficulty or failure.
    - VAL is only as good as the person holding it.
    - Do not practice in a cavalier manner just because you have VAL available.
    - The SGA has been displaced by VAL; SGA is an excellent VAL rescue device.
    - Never apply excessive force to the device "to make it fit."
    - Avoid forcing the advancement of the ETT with VAL (there is no visualization of the ETT until it passes the distally placed video chip).
    - Apply lubrication to the blade as needed, and to the ETT, to ease passage (this is particularly apropos for the patient with dry mucous membranes, e.g., CPAP or BiPAP therapy, mouth breather).
    - If VAL is your first choice and fails, consider trying DL in some cases.

    - An infamous quote regarding the use of VAL: VAL will often make a difficult airway an easy one, but it can make an easy airway a difficult one.
        - If you are applying excessive force or you are "just trying too hard," then you should change something, not try harder.
- To review the use of any individual VAL device, please refer to the product's website and review it through educational offerings.
- Review of the technique (which varies with each device) and its indications, contraindications, and limitations is imperative for operator confidence and patient safety.
- Practice on mannequins with proper instruction. Instruction by experienced personnel on the elective, healthy, normal-airway patient is a prerequisite to use in the difficult airway or emergency setting.
- Decision time: passing the ETT
    - If time permits, generously lubricate the ETT.
    - Smaller-sized ETTs pass over the bougie more easily than do larger ones.
    - Maintain tongue displacement with laryngoscopy/hand grasp.
    - Pass the ETT, but do not force the advancement (an assistant should grasp the proximal end of the bougie to stabilize it).

AFTER THE PROCEDURE

Postprocedure Care

- After advancement of ETT into the trachea and reverifying its position, stabilize the ETT in position, and remove the device.
- Though the video attributes allow observation that the ETT is through the glottis, removing the device may jeopardize its position. Once the device is removed, one is unable to confirm its position without again passing the device. Standard methods of determining the ETT position, such as capnography and chest auscultation, are recommended.

Complications

- Difficulty or failure achieving adequate laryngeal view (2%–10%)
    - Inadequate mouth opening, limited mandibular hinge movement
    - Secretions, blood, vomitus, fogging
    - Power failure (battery, electrical, system failure)
- Difficulty or failure to intubate trachea (2%–10%)
    - Inability to manipulate ETT correctly
    - Operator inexperience
    - Altered/traumatized/edematous/mass/distorted anatomy
    - Unable to pass ETT tip past glottis/cricoid ring: use bougie (through the ETT) for assistance
- Infrequent
    - Tissue injury, airway trauma (palatal or tonsillar pillar wall perforation, pharyngeal wall laceration/perforation)
    - Esophageal placement of ETT
    - Dental damage
- Serious but rare complications
    - Mucosal and tissue laceration/perforation leading to mediastinitis/pharyngeal abscess

OUTCOMES AND EVIDENCE

- The addition of the VAL technology is not new, but the era of lower-cost, more accessible models is afoot. DL is now being challenged as a first-line approach to airway management. Whether VAL replaces DL as the primary method of management is difficult to say, primarily because of economic issues.
- The overall usefulness of video-based visualization of the "easy" airway is questionable except for evaluation and educational purposes. However, its use for the restricted laryngeal view with DL, for the difficult airway (either known or presumed), and for its role as a rescue device for failed DL is without question a welcome addition to our airway arsenal.
- VAL serves a variety of roles in airway management in the ICU setting, well beyond simply tracheal intubation. Extubation evaluation, ETT exchange, rescue of DL failures, and its use as a primary management choice are but a few.
- The impact VAL imparts on ICU airway management is not currently reflected in the management algorithms offered by anesthesiology societies in the United States, Canada, the United Kingdom, Germany, and many other countries.
- Likewise, its presumed improvement in patient care is intuitive, but it must be proven through research and be evidence-based to warrant its ubiquitous inclusion in ICU airway management as a standard of care. The airway team must use it with caution, practice basic airway fundamentals, and develop a rescue strategy for VAL difficulty or failure, because they will occur regularly, especially in the high-risk ICU patient population.

ETT EXCHANGE

BEFORE THE PROCEDURE

Indications

Common Reasons in the ICU Setting

- Dysfunctional ETT (cuff, pilot balloon, narrowed lumen, biofilm, obstruction)
- Change location (nasal-to-oral, oral-to-nasal)
- Change size or type of ETT (7.0 → 8.0, double-lumen to single-lumen ETT)
- Similar clinical circumstances with tracheostomy tube exchange
- ETT exchange has been mentioned under other headings as it pertains to airway management procedures
- Elective versus urgent versus emergent conditions
  - May affect one's ability to accurately evaluate the airway situation
  - Primary reason to have trained personnel and an appropriately stocked difficult airway cart in the ICU setting
- Time permitting, review current patient medical/surgical history, airway procedures
  - Current ventilator settings
  - Current sedatives, analgesics, vasoactive agents
    - ETT secretion status, ETT patency, reason for exchange (clarify request) and substantiate that it is legitimate given the risks versus benefits.
    - Examine current ETT depth, size, patency, location.
    - Evaluate sedative-analgesic needs, cardiopulmonary response to procedure.
    - Assemble nursing, respiratory therapy, physician assistance as needed.
    - Assure immediate access to difficult airway cart, code cart, resuscitative drugs.
    - An imperative action by the airway team is a preexchange airway assessment. Performed externally and internally, this assessment will allow risk stratification, assessment of airway status, and planning of the exchange procedure. Preexchange laryngoscopy affords airway assessment as a segue to improved airway care. Assessment, best performed with VAL, may uncover partial/total ETT extubation masquerading as a "cuff leak" or offer a vital glimpse when there is overwhelming airway edema and secretions that render a high-risk warning for the exchange. In the case of elective ETT exchange (i.e., change of size or location), an alternative may be to delay or abort the exchange or choose to perform a surgical airway. Urgent or emergent exchanges (i.e., cuff perforation, narrowed lumen) may proceed but with a clear understanding of the airway status to optimize procedural planning.

Contraindications

- Inadequate equipment, personnel in high-risk patients
- Delay or abort exchange or alternatively, perform a surgical airway

Equipment

Equipment needs include all contents of the difficult airway cart, capable suction apparatus. and airway exchange catheters (AEC, various diameters) (see Figs. E1.43 through E1.50).

ANATOMY

Periglottic airway anatomy has been reviewed in previous sections. The primary concerns for an ETT exchange are access to the oral cavity via the nose or mouth and the patency of the airway in regard to adequate room to place the new ETT across the supraglottic, glottic, and subglottic regions. VAL offers a clear advantage over conventional DL or FFB methods.

PROCEDURE

- Multiple choices exist for ETT exchange. Currently, the safest method would be to maintain continuous access to the airway via an indwelling AEC or placement of both the existing and new ETT across the glottic opening. The latter is occasionally possible when, for example, the existing ETT is small (e.g., 6.0) in a tall male patient (relatively large glottic opening).
- Options for ETT exchange (oral to oral)
  - Blinded ETT removal followed by DL, VAL replacement (may be required with ETT obstruction or damage)
  - DL placement, ETT removal, and freehand replacement
  - FFB assisted (either passing FFB through glottis with or without existing ETT present)
  - AEC assisted (without the benefit of laryngoscopy to open the airway to provide a pathway for advancement)
  - Combined DL + AEC
  - VAL placement followed by removal and ETT replacement
  - Combined VAL + AEC
  - Combined VAL + FFB ± AEC
- ETT exchange options (nasal to oral, oral to nasal)
  - Similar to previous exchange options
  - Safest method for a location change would offer continuous airway access, thus, for example, VAL assessment followed by passing an AEC via the nasally placed ETT, backing out existing ETT above the glottis via the AEC, optimize VAL view, and then freehand ETT advancement. Once the ETT is in position, the AEC may be removed. Conversely, an ETT may be delivered via FFB or DL if visualization is adequate.
  - Maintaining continuous access affords "backtracking" if advancement of the new ETT is disrupted. Either the existing ETT or a new ETT may be readvanced into the airway over the indwelling AEC.
  - Fundamentals of airway management must be practiced, even when use of high-tech equipment is incorporated.
    - Proper positioning is an absolute (e.g., ramping the obese patient).
    - Secretions, vomitus, bleeding impede viewing. Apply suction to optimize view.
    - Assemble equipment and staff and discuss primary and backup plans.
    - 100% oxygen, suction ETT if applicable
    - Provide appropriate sedatives and analgesics and consider the pro/cons of neuromuscular blocking agents.
    - Before the exchange, assign tasks to team members to assure each is aware and comfortable with his or her role in the exchange.

  - Apply liberal lubrication to the blade and ETT to ease passage.
  - Double-glove for procedure. If gloves become slippery from lubrication, assistant can remove outer glove(s).
- "Mind the gap" between the ETT and the airway exchange catheter. An attempt to minimize the gap is imperative. The ETT will pass with less "wobble" and reduce hang-up on airway tissues. In some instances, a smaller AEC is the only option (double-lumen tube, existing small-caliber ETT, luminal narrowing or kink). The replacement ETT (e.g., 8-mm ETT) must be advanced over a smaller AEC with an increased risk of ETT hang-up, multiple attempts, delay in oxygenation, and other airway and hemodynamic complications. The smaller AEC may "bow" laterally in the airway when force is applied to the advancing ETT. The ETT may veer laterally and impinge on airway tissues, particularly the epiglottis, arytenoid, and vocal cords. Resistance may ensue. This major point promotes two important concepts: minimize the gap and deploy VAL to optimize viewing capabilities.
- If clinical conditions dictate that a smaller-diameter AEC be used, the Cook brand Aintree catheter (19F) can be used as a "jacket" for the 11F and 14F Cook AEC. Its placement on the AEC will reduce wobble, narrow the gap, and increase the "rigidity" of the AEC.
- Beware of the depth markings on the AEC and coordinate them with those markings on the ETT. It is imperative that personnel be assigned to stabilize the AEC during removal and replacement of the ETTs. Awareness of the AEC depth is important to minimize distal or proximal migration; both could have devastating consequences.
- The exchange method with the highest first-pass success rate, fewest attempts, lowest incidence of desaturation, and overall success is combining VAL and AEC, particularly in the known or suspected difficult airway patient.
- Further, data from the Hartford Hospital Exchange database strongly suggests that incorporating the larger-diameter AEC will markedly improve first-pass success and reduce desaturation and other airway-related complications. Thus there is an increasing incidence of complications when using the small-caliber AEC (14F and especially the 11F). If conditions dictate that the smaller-caliber AEC must be used, then augmenting the diameter of the 11F or 14 F AEC with the 19F Aintree catheter is recommended.

AFTER THE PROCEDURE

Postprocedure Care

- After advancement of ETT into the trachea and reverifying its position, stabilize the ETT in position, and remove the AEC.
- Standard methods of determining the ETT position, such as capnography and chest auscultation, are recommended. FFB may also be helpful.

Complications

- Passing an AEC into an ETT without knowledge of its relative location (e.g., intratracheal versus supraglottic position in unrecognized extubation masquerading as a "cuff leak") could lead to esophageal intubation, interruption of oxygen delivery, or loss of the airway. Hence, a preexchange laryngoscopy, preferably VAL based, is recommended.
- Airway-related.
  - Desaturation, esophageal intubation, regurgitation, aspiration
  - Mainstem bronchus intubation, mucosa injury, tracheobronchial wall injury, pneumothorax
  - Loss of airway, need for accessory devices
  - Lip, dental, tongue, pharyngeal injury
  - Tracheobronchial and/or ETT obstruction from distal soilage/secretions
- Hemodynamic-related
  - Tachycardia, bradycardia
  - Hypertension, hypotension
  - Dysrhythmia, cardiac arrest

OUTCOMES AND EVIDENCE

- Despite the serious clinical implications of ETT exchange, there is a relative paucity of evidence-based literature regarding best practice for ETT exchange. Maintaining continuous access to the airway is, however, a consistent recommendation. Many serious and potentially life-threatening complications can accompany exchange procedures. Recent evidence suggests patients with a known/suspected difficult airway or poor visualization offered by DL during the preexchange airway assessment may benefit greatly by incorporating VAL + AEC.
- The value of a preexchange airway assessment (VAL) is demonstrated in its ability to diagnose otherwise unrecognized partial/complete tracheal extubation masquerading as a cuff leak.
- Exchanging a double-lumen tube (DLT) to a single-lumen tube (or vice versa) typically is more difficult because of (1) the larger diameter, angled DLT possibly being difficult to place in general and (2) AEC-assisted exchange often entailing the use of a smaller-caliber AEC because the DLT's smaller luminal diameter will not accept the larger AEC.
- The overall usefulness of video-based visualization of the "easy" airway is questionable except for evaluation and educational purposes. However, its use for the restricted laryngeal view with DL, for the difficult airway (either known or presumed), and for its role as a rescue device for failed DL is, without question, a welcome addition to our airway arsenal.
- VAL serves a variety of roles in airway management in the ICU setting, well beyond simply tracheal intubation. Extubation evaluation, ETT exchange, rescue of DL failures, plus its use as a primary management choice are but a few.

Bedside Ultrasonography

Yanick Beaulieu and John Gorcsan III

Advances in ultrasound technology continue to enhance its diagnostic applications in daily medical practice. Constantly evolving, this tool has become invaluable for properly trained cardiologists, anesthesiologists, intensivists, surgeons, obstetricians, and emergency department physicians. Ultrasound can enable rapid, accurate, and noninvasive diagnosis of a broad range of medical conditions. Patients in the intensive care unit (ICU) present daily diagnostic and therapeutic challenges to the medical team. The availability of ultrasound instrumentation in critical care units has facilitated greatly the rapid evaluation and treatment of patients with a wide spectrum of conditions. Although transthoracic and transesophageal echocardiography (TEE) have been generally available for years for evaluating ICU patients, advances in ultrasound imaging, including harmonic imaging, digital acquisition, and contrast for endocardial enhancement, have improved the diagnostic yield. Modern techniques are simple and safe to use. Ultrasound devices continue to become even more portable than in the past, and hand-carried devices now are readily available for everyday clinical use (point-of-care ultrasound [POCUS]). The spectrum of POCUS is quite broad, and many of its key imaging applications are discussed elsewhere. In this chapter we place emphasis on echocardiography and cardiovascular diagnostics. The use of bedside ultrasound to facilitate central line placement and to aid in the care of patients with pleural effusions and intraabdominal fluid collections also is addressed.

USE OF BEDSIDE ULTRASONOGRAPHY IN THE INTENSIVE CARE UNIT

General Indications

Ultrasonography has become an invaluable tool for managing critically ill patients. Its safety and portability allow for use at the bedside to provide rapid, detailed information regarding the cardiopulmonary system[1] and to assess the function and anatomy of certain internal organs. It also can be used by the clinician to interrogate the pleural and intraabdominal spaces and to perform some invasive procedures safely. General indications for the performance of echocardiography in the ICU are listed in Box E2.1. Box E2.2 lists major indications for performance of primary TEE in the ICU. Other indications for the use of bedside ultrasonography by the intensivist in critically ill patients are listed in Box E2.3.

Technical Aspects

Acoustic Window in a Critically Ill Patient

The practical value of bedside ultrasonography in the management of critically ill patients is now widely accepted, despite the inherent limitations of the technique.[2] These limitations arise primarily from the suboptimal imaging conditions commonly encountered when performing studies of the critically ill. The constrained physical environment of the ICU also can compromise the quality of the images obtained. For an ultrasound study to be deemed adequate, a good acoustic "window" is required to allow accurate analysis. Ultrasonography uses the physical principle that sound is reflected from tissue interfaces, allowing a two-dimensional (2D) image of the anatomic structure studied to be constructed.[3] Anything hindering the reflection of this acoustic signal—air, bone, calcium, foreign body, or other interposed structure—interferes with ultrasound transmission and diminishes the overall quality of the examination. In the ICU, many patients are mechanically ventilated. In these patients, adequate imaging can be limited by complications such as pneumothorax, pneumomediastinum, or subcutaneous emphysema.[2] Other important factors limiting quality data acquisition in critically ill patients are related to surgical wounds and dressings, tapes, tubing, obesity, and chronic obstructive pulmonary disease. In addition, lack of patient cooperation and the impossibility of moving some patients into the optimal position for the desired examination contribute to a high prevalence of technically inadequate studies.[2]

Although ultrasonography permits evaluation of the structure and function of the heart and other important organs and structures, acquisition of data and interpretation of results are fraught with potential traps.[4] Performing an ultrasound examination requires a thorough knowledge of anatomy and instrumentation, including attention to gain control, grayscale settings, Doppler velocity settings, and transducer placement.

Preparation of the Patient

Before starting an ultrasound examination at the bedside in the ICU, certain important criteria should be met. The criteria vary, depending on the type of examination being performed (transthoracic echocardiography [TTE]; TEE; vascular, abdominal, or thoracic ultrasound) and on certain patient-related factors (e.g., presence or absence of mechanical ventilation, nasogastric tube, or surgical dressings).

An awake patient should be informed about the importance of the ultrasound investigation and should be provided with an explanation of how the clinician will perform the examination.[3] These steps are especially important when the examination uses the transesophageal route.

Positioning

Proper positioning of the patient is important for obtaining an adequate image. For performance of TTE and TEE in patients who are not mechanically ventilated, optimal imaging usually is obtained by having the patient in the left lateral decubitus position. Taking the extra 5 minutes to position the patient on his or her left side for TTE often

BOX E2.1 General Indications for Performance of an Echocardiographic Examination in the Intensive Care Unit

- Hemodynamic instability
  - Ventricular failure
  - Hypovolemia
  - Pulmonary embolism
  - Acute valvular dysfunction
  - Cardiac tamponade
  - Complications after cardiothoracic surgery
- Infective endocarditis
- Aortic dissection and rupture
- Unexplained hypoxemia
- Source of embolus

BOX E2.2 Major Indications for Performance of Primary Transesophageal Echocardiography Study in the Intensive Care Unit

- Diagnosis of conditions in which the superior image quality is vital (e.g., aortic dissection, assessment of endocarditis and its complications, intracardiac thrombus)
- Imaging of structures that may be inadequately seen by TTE (e.g., thoracic aorta, left atrial appendage, prosthetic valves)
- Echocardiographic examinations of patients with conditions that prevent image clarity with TTE (e.g., severe obesity, emphysema, mechanical ventilation with high level of PEEP, presence of tubes, surgical incisions, dressings)
- Acute perioperative hemodynamic derangements

PEEP, Positive end-expiratory pressure; *TTE,* transthoracic echocardiography.

BOX E2.3 Other Indications for Use of Bedside Ultrasonography by the Intensivist

- Central line placement
- Assessment of pleural effusions and intraabdominal fluid collections
- Urinary bladder scan
- FAST
- Intraaortic balloon counterpulsation
- Ventricular assist devices

FAST, Focused assessment of the trauma patient.

results in much improved image quality and minimizes aspiration risk. Adequate positioning of the patient depends on the structures being assessed (e.g., pleural space, peritoneal cavity, vascular structures, or bladder). Care must be taken when positioning a critically ill patient in bed, because these patients often have multiple vascular catheters, an endotracheal tube, drains, and other tubes or devices connected to them. When the ultrasound examination is performed to localize and mark pleural or abdominal fluid collections for subsequent drainage, it is crucial that the patient be placed in the same position used during the actual drainage of the collection. Risks of perforating surrounding organs (e.g., heart, spleen, liver, lungs, or bowel) and inducing significant morbidity are increased if the drainage is performed in a position different from the one used during marking.

Sedation

To optimize the ultrasound examination, the patient must be cooperative and nonagitated. Noninvasive procedures such as TTE and abdominal ultrasound usually are well tolerated, and additional sedation rarely is needed to perform them. When performing TEE, however, certain precautions need to be taken. Patients should fast (or have their tube feeds stopped) for at least 4 hours before the procedure. Topical anesthesia of the oropharynx also is helpful before insertion of the TEE probe, especially in patients who are not endotracheally intubated.[3] Even if adequate topical anesthesia is provided, insertion of the TEE probe still can cause significant discomfort and anxiety, so providing adequate sedation and analgesia is important. Frequently used sedative or analgesic agents include intravenous (IV) midazolam, fentanyl, and propofol. Dosing should be titrated according to clinical parameters, including arterial blood pressure, minute ventilation, and arterial oxygen saturation.[3] Sedative-induced hypotension is a frequent problem in patients with depressed ventricular function or decreased systemic vascular resistance, and occasionally patients may require transient support with IV volume infusion or vasopressor agent. If the patient is extremely uncooperative and biting, increased sedation, transient paralysis, and mechanical ventilation may be required to perform TEE safely.

Monitoring During the Procedure

Most ICU patients are monitored continuously for key respiratory, cardiac, or hemodynamic parameters. At a minimum, it is essential that patients undergoing an ultrasound examination in the ICU be monitored with noninvasive recording of blood pressure, pulse oximetry, and electrocardiogram. Even TTE or abdominal ultrasound examinations can be associated with inadvertent pulling of tubes or drains, and anxiety can be encountered during the procedure. Because of its more invasive nature, insertion of the TEE probe may induce discomfort and complications such as increased agitation and respiratory distress. These effects can be associated with substantial changes in blood pressure and ventilatory status. Administration of sedatives and sometimes paralytic agents can further alter hemodynamic and respiratory status.[3,5]

Safety

Performance of ultrasound examinations in the ICU provides data that previously required transport to the radiology suite. This is an important advantage for the critically ill patient, because transport out of and back to the ICU is known to be associated with an increased risk of complications.[6] Performance of bedside TTE ultrasound and of other noninvasive ultrasound examinations is safe and not associated with significant risks to the patient. Performance of the semiinvasive bedside TEE also is associated with a low incidence of serious complications (<0.5% in the general population and the elderly).[5] The reported mortality rate associated with TEE is 0.01%–0.03%.[7] Most patients undergoing TEE examinations in the ICU are receiving mechanical ventilation and have continuous monitoring of arterial blood pressure, electrocardiogram, and oxygen saturation.[8] Transient hypotension, typically attributable to administration of sedative medications, usually can be treated with vasopressors or IV fluids or both. The risk of injury to the pharynx or esophagus is greater in anesthetized and endotracheally intubated critically ill patients than in awake patients, because anesthetized patients cannot assist with probe insertion by swallowing and do not resist when insertion proves difficult.[8] Increased difficulty in directing the TEE probe also can be encountered in the presence of a nasogastric tube. Coagulopathy and thrombocytopenia, common problems in critically ill patients, can increase the risk of hemorrhage resulting from mucosal injury during blind insertion of the TEE probe. Daniel and colleagues[9] reported significant complications related to TEE in 18 (0.18%)

of 10,218 examinations. In 11 studies reporting on 943 patients undergoing TEE, the rate of complications was 1.7%.[5] Serious complications occurred in only two patients (0.2%). Colreavy and colleagues[8] studied the safety and utility of TEE performed by ICU physicians in 255 critically ill patients and reported that TEE was associated with a complication rate of only 1.6%. It is reasonable to conclude that bedside TEE is associated with few complications, given the high severity of illness.[5] Close monitoring of hemodynamic and oxygenation parameters is essential. Box E2.4 lists specific contraindications to the insertion of a TEE probe.

BEDSIDE ECHOCARDIOGRAPHY IN A CRITICALLY ILL PATIENT

Echocardiography can provide diagnostic information noninvasively regarding cardiac structure and mechanical function. The supplementary information provided by this technique can help determine the cause of hypotension refractory to inotropic support or vasopressor infusions.[3] It also can help in the diagnosis of a wide spectrum of other cardiovascular abnormalities (e.g., endocarditis) and guide therapeutic management. An adequate understanding of the proper use of echocardiography is a prerequisite for the intensivist. General indications for performance of an echocardiographic examination in the ICU are listed in Box E2.1.

Transthoracic Versus Transesophageal Echocardiography in a Critically Ill Patient

Accurate and prompt diagnosis is crucial in the ICU. The easiest and least invasive way to image cardiac structures is TTE.[3] This noninvasive imaging modality is of great value in the critical care setting because of its portability, widespread availability, and rapid diagnostic capability. In the ICU, TTE may sometimes fail to provide adequate image quality because of factors that potentially can hinder the quality of the ultrasound signal, as described previously. The failure rate (partial or complete) of TTE in the ICU has been reported to be 30%–40%.[10,11] Nonetheless, improvements have been made in transthoracic imaging (e.g., harmonics and contrast and digital technologies), resulting in a progressively lower failure rate of TTE in the ICU (currently 10%–5% in our institution).

TEE is particularly useful for evaluation of suspected aortic dissection, prosthetic heart valves (especially in the mitral position), detecting cardiac emboli, valvular vegetations, possible intracardiac shunts, wall motion abnormalities, and unexplained hypotension. TEE allows better visualization of the heart than TTE, especially of the posterior structures, owing to the proximity of the probe and favorable acoustic transmission.[1] Despite its limitations, TTE may provide complementary information. For example several areas of the heart and great vessels are difficult to visualize by TEE. The view of the left ventricular apex often is foreshortened with TEE, and an apical left ventricular clot can be missed. TTE usually is superior for visualization of the apex. Because of interposition of the left mainstem bronchus, the superior portion of the ascending aorta is another important area that may not be well visualized with TEE. The transducer position and angulation of TEE are constrained by the relative positions of the esophagus and heart. The relatively fixed relationship between the position of the probe and the heart often makes it impossible to align the Doppler beam parallel to the flow of interest (e.g., to evaluate the jet of blood resulting from aortic stenosis). In addition, the 2D imaging planes of TEE often make standard anatomic measurements more difficult to obtain.

As a result of the significantly improved technical quality of TTE, most ICU patients can be studied satisfactorily with this modality alone. Immediate TEE is still preferable, however, in certain specific clinical situations in which TTE is likely to fail or prove suboptimal.[11] The major indications for primary TEE in the ICU[12,13] are listed in Box E2.2. Even when TEE is necessary, data from the TTE examination are often essential for the final clinical interpretation.

BOX E2.4 Contraindications to Insertion of Transesophageal Echocardiography Probe

Absolute Contraindications
Esophageal pathologies
Stricture
Mass or tumor
Diverticulum
Mallory-Weiss tear
Dysphagia or odynophagia not previously evaluated
Cervical spine instability

Relative Contraindications
Esophageal varices
Recent esophageal or gastric surgery
Oropharyngeal carcinoma
Upper gastrointestinal bleeding
Severe cervical arthritis
Atlantoaxial disease

Hemodynamic Evaluation

Ventricular Function

Left ventricular systolic function. Evaluation of left ventricular performance by echocardiography is often paramount in the ICU. Accurate and timely assessment of systolic function should be an integral part of the medical management of hemodynamically unstable critically ill patients. Global assessment of left ventricular contractility includes the determination of ejection fraction (EF), circumferential fiber shortening, and cardiac output.

The simplest quantitative approach is to measure the mid–left ventricular short-axis dimension at end diastole and end systole to determine the percentage of fractional shortening. Fractional shortening is related directly to EF; normal fractional shortening is 30%–42%.[1]

$$\text{Fractional shortening} = \frac{\text{End-diastolic dimension} - \text{End-sytolic dimension}}{\text{End-diastolic dimension}}$$

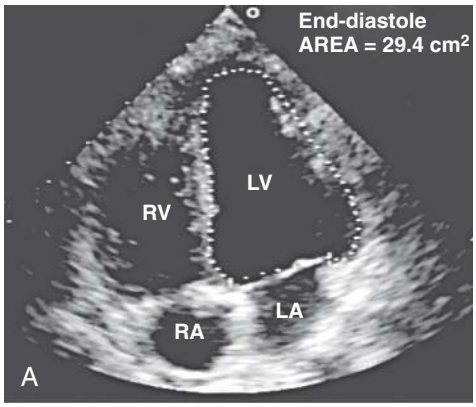
In the setting of regional wall motion abnormalities, fractional shortening may underestimate or overestimate global ventricular function and must be interpreted in light of what is seen in all of the 2D imaging planes of the ventricle.[14]

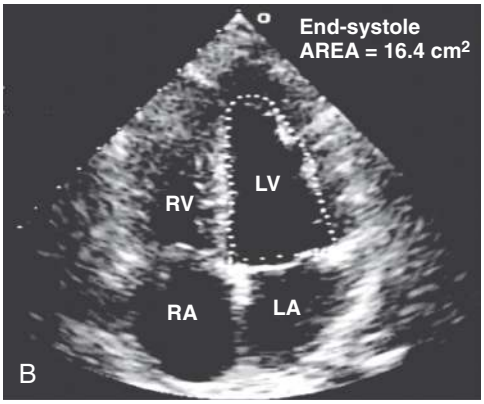
Global systolic ventricular function also can be assessed quantitatively by fractional area change (normal value is 36%–64%)[15] and by EF (normal value is 55%–75%) (Fig. E2.1):

$$\text{Fractional area change} = \frac{\text{End-diastolic area} - \text{End-sytolic area}}{\text{End-diastolic area}}$$

$$\text{Ejection fraction} = \frac{\text{End-diastolic volume} - \text{End-systolic volume}}{\text{End-diastolic volume}}$$

These measurements require good image quality, because endocardial border contours must be traced (see Fig. E2.1). Machine-integrated



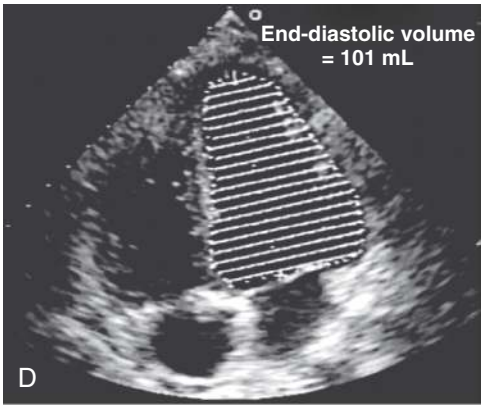


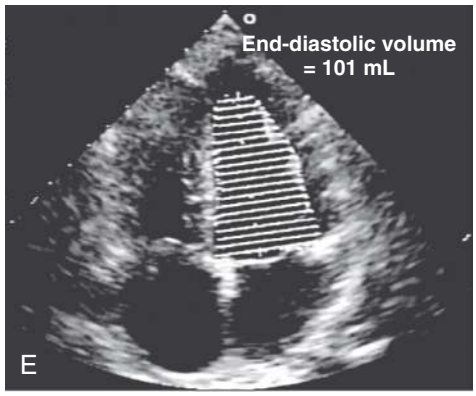
$$\text{Fractional area change} = \frac{\text{End-diastolic area} - \text{end-systolic area}}{\text{End-diastolic area}}$$

$$= \frac{29.4\ \text{cm}^2 - 16.4\ \text{cm}^2}{29.4\ \text{cm}^2}$$

$$= 44\%$$

C





$$\text{Ejection fraction} = \frac{\text{End-diastolic volume} - \text{end-systolic volume}}{\text{End-diastolic volume}}$$

$$= \frac{101\ \text{mL} - 39\ \text{mL}}{101\ \text{mL}}$$

$$= 61\%$$

F

Fig. E2.1 Fractional area change and ejection fraction calculation. Endocardial contour of the left ventricular cavity is traced at end diastole **(A)** and at end systole **(B)** in the transthoracic apical four-chamber view. Machine-integrated software computes the data and gives corresponding end-diastolic and end-systolic areas. Fractional area change can be calculated with these data **(C)**. Normal values are 36%–64%.[15] Corresponding end-diastolic **(D)** and end-systolic **(E)** volumes are computed using the modified Simpson method. The data are used to calculate the ejection fraction **(F)**. Normal values are 55%–75%. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

software uses the data to determine volumes, areas, and the resultant EF (see Fig. E2.1). In patients with regional wall motion abnormalities, more precise measures of stroke volume can be made by approximating ventricular volumes as a stack of elliptical disks on biplane imaging (modified Simpson method).[1,15]

In the critical care setting, defining the endocardial border may be suboptimal because of poor image quality.[10,16,17] In these cases, global ventricular function often is assessed qualitatively by visual inspection alone. This method has been found to be reliable when used by experienced clinicians.[18] By simple visualization of the kinetics and size of the cardiac cavities in real time, an experienced intensivist with a sufficient echocardiographic background can establish a functional diagnosis immediately.

Analysis of regional wall motion includes a numeric scoring system to describe the movement of the different regions of the left and right ventricles (1 = normokinesia; 2 = hypokinesia; 3 = akinesia; 4 = dyskinesia; 5 = aneurysmal change).[15] Visualized from the short-axis view of the left ventricle, a complete overview of myocardial areas perfused by the three major coronary arteries can be obtained (Fig. E2.2). If the TTE examination is technically difficult and the endocardium is poorly visualized, harmonic imaging and possibly contrast, if needed, can dramatically improve endocardial border visualization and subsequent evaluation of global systolic function (as discussed further later in this chapter). For the remaining few technically challenging cases with suboptimal TTE, performance of TEE allows for more precise evaluation of ventricular function in most critically ill patients because of the higher image quality that can be obtained with this echographic modality.

Left Ventricular failure in the intensive care unit. In a critically ill patient with unexplained hemodynamic instability, determination of cardiac function is an integral part of the medical management. Echocardiography is valuable in this setting because the clinical examination and invasive hemodynamic monitoring often fail to provide an adequate assessment of ventricular function. In a study by Fontes and colleagues[19] that compared pulmonary artery (Swan-Ganz) catheterization with TEE, the overall predictive probability for conventional clinical and hemodynamic assessment of normal ventricular function was 98%, whereas for abnormal ventricular function (EF <40%), it was 0%. Several other studies have reported similar results.[20–22] Assessment of

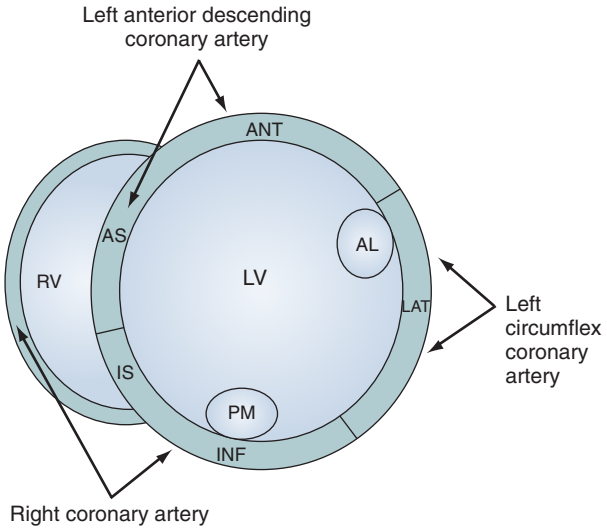


Fig. E2.2 Transthoracic short-axis echocardiographic view of the left ventricle (LV) and right ventricle (RV) at the midpapillary muscle level. In this tomographic view of the heart, areas of myocardium and papillary muscles (*AL,* anterolateral; *PM,* posteromedial) supplied by all three major coronary arteries are represented. *ANT,* Anterior; *AS,* anteroseptal; *INF,* inferior; *IS,* inferoseptal; *LAT,* lateral.

biventricular function is one of the most important indications for echocardiography in the ICU. In a study by Bruch and colleagues,[23] 115 critically ill patients were studied by TEE. The most common indication for TEE was hemodynamic instability (67% of patients). Of these hemodynamically unstable patients, 20 (26%) were found to have significant left ventricular dysfunction (EF <30%). In a study by McLean[24], the most common reason to request a TEE in the ICU was to assess left ventricular functioning. In most patients, left ventricular function was assessed adequately by TTE before TEE. In a study by Vignon and colleagues,[17] TTE allowed adequate evaluation of global left ventricular function in 77% of mechanically ventilated ICU patients. Although TEE was needed for most other indications, TTE was shown to be an excellent diagnostic tool for assessment of left ventricular function in the ICU (Fig. E2.3), even in the presence of positive end-expiratory pressure.

Several important points should be emphasized: (1) significant left ventricular dysfunction occurs commonly in critically ill patients; (2) ventricular function should be assessed in all patients with unexplained hemodynamic instability because this information is particularly important for guiding resuscitation and informing decisions regarding subsequent medical or surgical management; (3) it is now possible to obtain adequate information about ventricular function in most ICU patients using TTE, but TEE improves accuracy in patients with suboptimal imaging by TTE.

Sepsis-related cardiomyopathy. Classically, septic shock has been considered an initially "hyperdynamic" state characterized by normal or high cardiac output. Yet echocardiographic studies indicate that ventricular performance often is markedly impaired in patients with sepsis.[25–27] Parker and colleagues[28] were among the first to describe left ventricular hypokinesis in septic shock. They reported that survivors manifested severely depressed left ventricular EF, but that adequate left ventricular stroke output was maintained as a result of acute left ventricular dilation.[29] Jardin and colleagues[25] studied 90 patients with septic shock and performed daily bedside assessments of left ventricular volume and left ventricular EF using TTE. They observed that left ventricular EF was significantly depressed in all patients, resulting in severe reductions in left ventricular stroke volume. Of these patients, 34 (38%) eventually were weaned from hemodynamic support and showed gradual improvement in left ventricular EF and ultimately recovered. The remaining 56 patients (62%) eventually died of early circulatory failure or late multiple organ failure. In this subset, the degree of left ventricular dysfunction was actually less than in survivors but failed to improve over time. The severity of left ventricular dysfunction does not predict outcome. A paradoxical relationship between the degree of left ventricular dysfunction and the likelihood of recovery also has been described by others.[25,28,30,31] Among patients who survive, left ventricular dilation and systolic dysfunction usually are reversible.

Left ventricular EF might not be a reliable index of left ventricular systolic function in patients with early septic shock because this is a state characterized by low systemic vascular resistance that unloads the left ventricle.[25] Normal or supranormal EF in early sepsis might lead clinicians to make the wrong inference about cardiac reserve because

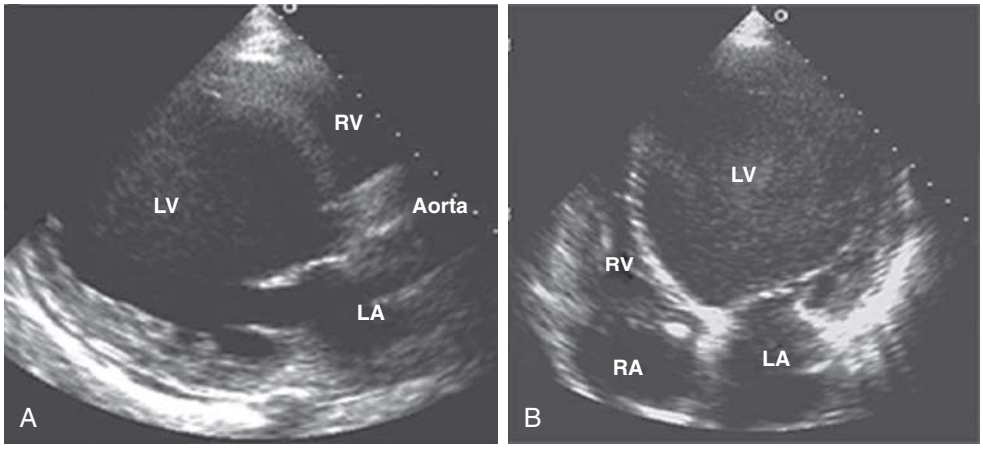

Fig. E2.3 Dilated cardiomyopathy. Transthoracic examination of a severely dilated left ventricle (LV) in the parasternal long-axis **(A)** and apical four-chamber **(B)** views. The 65-year-old patient presented with flash pulmonary edema and later was found to have severe diffuse coronary artery disease. *LA,* Left atrium; *RA,* right atrium; *RV,* right ventricle.

left ventricular EF might decrease when afterload is increased by the administration of vasopressor agents.

Left ventricular diastolic function. In the ICU, diastolic dysfunction should be suspected when ventricular filling pressure (pulmonary capillary wedge pressure) is elevated and EF is normal or supranormal.[1] The diastolic properties of the ventricle often are assessed by evaluating Doppler echocardiographic mitral inflow and pulmonary venous flow patterns. Mitral inflow, as measured by pulsed-wave Doppler directed at the tips of the mitral leaflets, is characterized by an early filling phase (E wave) followed by atrial systole, resulting in additional filling (A wave) (Fig. E2.4). The transmitral Doppler pattern always should be interpreted in conjunction with pulsed-wave Doppler of the pulmonary venous flow, which is characterized by a systolic phase (S), a diastolic phase (D), and an atrial phase (AR) from reversal of flow into the pulmonary veins during atrial contraction (Fig. E2.5). These filling patterns are related to the intrinsic diastolic properties of the myocardium and are influenced by many different factors, particularly left atrial pressure, heart rate, ischemia, ventricular hypertrophy, and valvular pathologies. Only modest correlation has been found between Doppler indices of diastolic function and parameters measured using more invasive means.[32,33] Integrated interpretation of mitral and pulmonary venous flow patterns may be useful for diagnosing abnormal myocardial relaxation (e.g., owing to hypertensive heart disease, hypertrophic cardiomyopathy, or coronary ischemia) or restrictive pathology (e.g., owing to cardiomyopathy, constrictive pericarditis, coronary artery disease, cardiac transplantation, or dilated cardiomyopathy). Nevertheless, these findings must be interpreted with caution when caring for critically ill patients, given the many different factors that can acutely influence flow patterns in this population of patients.

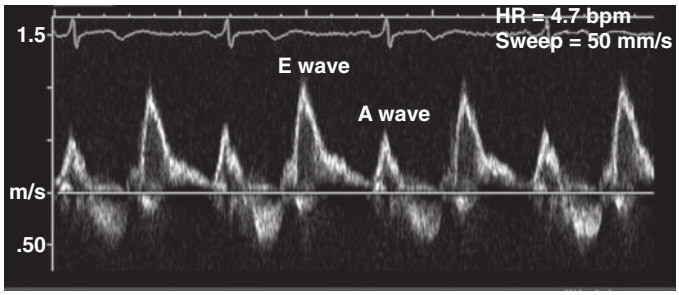

Fig. E2.4 Normal mitral inflow profile as measured by transthoracic pulsed-wave Doppler at the tips of the mitral leaflets. It is characterized by an early filling phase (E wave) followed by atrial systole (A wave), which results in additional filling. These filling parameters are related to intrinsic diastolic myocardial properties and can be influenced by many different factors (see text).

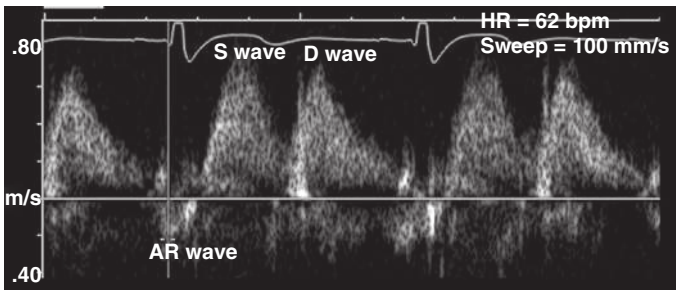

Fig. E2.5 Normal pulmonary venous flow profile as measured by transthoracic pulsed-wave Doppler with the sample volume placed in the right superior pulmonary vein. It is characterized by a predominant systolic wave (S), a diastolic wave (D), and an atrial wave (AR) (from reversal of flow into the pulmonary veins occurring during atrial contraction). The pulmonary venous flow profile always should be interpreted in conjunction with the transmitral Doppler pattern to have a more complete assessment of diastolic function.

Right ventricular function and ventricular interaction. Abnormal right ventricular function often plays an important and sometimes underestimated role in the pathogenesis of critical illness.[34–36] Based on an echocardiographic definition,[37] massive pulmonary embolism and acute respiratory distress syndrome are the two main causes of acute cor pulmonale in adults.[38] In the critical care setting, right ventricular function also can be altered by any other perturbations that increase right ventricular afterload, such as positive end-expiratory pressure or increased pulmonary vascular resistance (from vascular, cardiac, metabolic, or pulmonary causes). Depressed right ventricular systolic function is also often associated with right ventricular infarction, most commonly in the setting of inferior myocardial infarction. Acute sickle cell crisis, air or fat embolism, myocardial contusion, and sepsis are other causes of acute right ventricular dysfunction.

Adequate assessment of right ventricular function is important when caring for hemodynamically unstable, critically ill patients, specifically patients with massive pulmonary embolism and acute respiratory distress syndrome, because the diagnosis of concomitant right ventricular dysfunction may alter therapy (e.g., fluid loading, use of vasopressors, use of thrombolytics) and provide information about prognosis.[38,39] Echocardiographic examination of the right ventricle requires primarily an assessment of the size and kinetics of the cavity and septum.[37,40] Normally the right ventricle appears somewhat flattened. As it dilates, the apical region of the right ventricle becomes more rounded (Fig. E2.6). In the short-axis view, the right ventricle, which usually has a crescentic shape, becomes ovoid because of septal displacement and bulging of the right ventricular free wall (see Fig. E2.6).[1] Right ventricular size and function generally are evaluated by visual comparison with the left ventricle. Right ventricular diastolic dimensions can be obtained by measuring right ventricular end-diastolic area in the long axis, from an apical four-chamber view, using either TTE or TEE.

Because pericardial constraint necessarily results in left ventricular restriction when the right ventricle acutely dilates (i.e., there is ventricular interaction), one of the best ways to quantify right ventricular dilation is to measure the ratio between the right ventricular and left ventricular end-diastolic areas, an approach that compensates for individual variations in cardiac size.[37,40] Moderate right ventricular dilation corresponds to a diastolic ventricular ratio greater than 0.6; severe right ventricular dilation corresponds to a ratio greater than or equal to 1.0.[37,40] Right ventricular diastolic enlargement usually is associated with right atrial dilation, inferior vena caval dilation, and tricuspid regurgitation. When pressure in the right atrium exceeds pressure in the left atrium, the foramen ovale may open. Pressure and volume overload of the right ventricle can distort left ventricular geometry and produce abnormal motion of the interventricular septum. With conditions of high strain imposed on the right ventricle (volume or pressure overload or both), the interventricular septum flattens, and the left ventricle assumes a "D" shape (see Fig. E2.6).[4,37] This "paradoxical" septal motion also is seen at the interatrial level.

Because the two ventricles are enclosed within the relatively stiff pericardium, the sum of the diastolic ventricular dimensions must remain constant.[41] Acute right ventricular or left ventricular dilation can occur only if it is associated with an acute and proportional reduction in left ventricular or right ventricular diastolic dimension (i.e., ventricular interaction). With acute right ventricular dilation, septal displacement impairs left ventricular relaxation; the opposite occurs with acute left ventricular dilation. In these situations, the pressure-volume

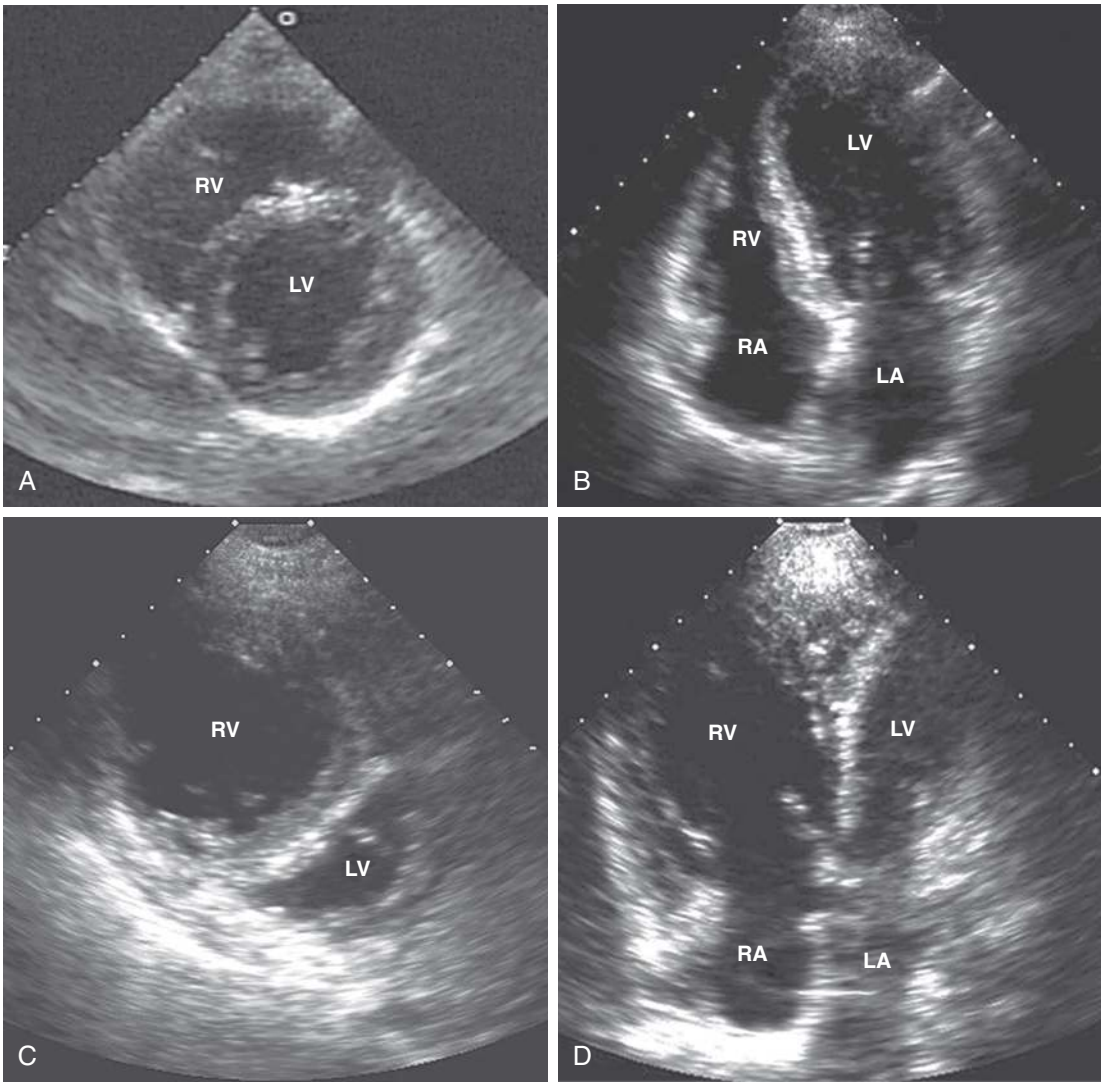

Fig. E2.6 Severe right ventricular failure and dilation. **A,** Normal transthoracic parasternal short-axis view of the left ventricle (LV) and right ventricle (RV) at the midpapillary muscle level. **B,** Normal transthoracic apical four-chamber view of the LV and RV. These pictures of a normal heart depict the relationship between the LV and RV, with the LV being normally larger than the RV and the interventricular septum bulging slightly toward the RV. **C,** Transthoracic parasternal short-axis view of the LV and RV in a patient with severe right ventricular failure and dilation. The right ventricular cavity is seen to be much larger than the left ventricular cavity. Because of the high volume and pressure in the RV, the interventricular septum is bulging toward the left. This gives the LV a characteristic "D" appearance. **D,** Transthoracic apical four-chamber view of the same patient shows the inverse relationship between the left ventricular and right ventricular sizes. The right ventricular dilation can occur only if associated with a proportional reduction in LV diastolic dimension ("ventricular interaction"). This reduction in left ventricular diastolic dimension significantly impairs left ventricular relaxation and changes the pressure-volume relationship of the left heart chambers. *LA,* Left atrium; *RA,* right atrium.

relationships of the left and right heart chambers are altered, and information obtained from a pulmonary artery catheter could be misleading (e.g., high filling pressures are recorded despite normal or even low circulating volume).

Pulmonary Embolism

Hemodynamic instability that arises from acute *cor pulmonale* is often a consequence of massive pulmonary embolism and occurs relatively commonly in the critically ill. Until fairly recently, contrast pulmonary angiography generally was regarded as the gold standard for the diagnosis of pulmonary embolism. Angiography is an invasive procedure, however, and carries the risk of major complications in patients with circulatory failure.[42] Contrast-enhanced helical computed tomography (CT) is an accurate and noninvasive test that has essentially replaced angiography for the diagnosis of pulmonary embolism. Even CT requires transportation of patients to a location outside of the ICU, however, and transport alone is associated with significant risks. Echocardiography is well suited for diagnosing pulmonary embolism because it can be initiated and completed within minutes at the bedside. Detection by TTE of acute right ventricular dilation and dysfunction (acute cor pulmonale) has good positive predictive value for massive pulmonary embolism and its consequences.[43,44] The finding of right

ventricular dilation and dysfunction is not specific for pulmonary embolism, however, because these findings may be observed with a variety of other conditions associated with increased right ventricular strain. In a study by McConnell and colleagues,[45] patients with acute pulmonary embolism were found by TTE to have a distinct regional pattern of right ventricular dysfunction characterized by akinesia of the mid–free wall but normal motion at the apex. These findings contrasted with findings obtained in patients with primary pulmonary hypertension who had abnormal wall motion in all regions. Regional right ventricular dysfunction had a sensitivity of 77% and a specificity of 94% for the diagnosis of acute pulmonary embolism; positive predictive value was 71%, and negative predictive value was 96%. Therefore the presence of regional right ventricular dysfunction that spares the apex should raise the level of clinical suspicion for the diagnosis of acute pulmonary embolism.

Central pulmonary emboli are present in approximately half of all patients with findings suggestive of pulmonary embolism and acute cor pulmonale on TTE.[5] Emboli lodged in the proximal pulmonary arteries usually cannot be visualized directly.[5] Because other clinical conditions can produce acute cor pulmonale in the ICU, better visualization of the pulmonary arteries is needed to achieve high accuracy for the diagnosis of pulmonary embolism. This goal can be achieved by using TEE. TEE has good sensitivity for detecting emboli lodged in the main and right pulmonary arteries, but has limited capability to detect more distal or left pulmonary emboli.[5,46,47] If an embolus is visualized, the diagnosis is made. If the study is negative when the index of suspicion for pulmonary embolism is high, however, TEE must be followed up by a more definitive test such as angiography or helical CT. Also, when there is high clinical suspicion for pulmonary embolism but no thrombi are visualized using TEE, the potential for nonthrombotic causes of pulmonary embolism (e.g., air or fat emboli) must be kept in mind.

The demonstration of acute cor pulmonale with echocardiography has important prognostic and therapeutic implications.[48,49] The presence of cor pulmonale with massive pulmonary embolism is associated with increased mortality incidence, whereas the absence of right ventricular dysfunction is associated with a better prognosis.[39] There is no consensus on the precise indications for administration of thrombolytics in massive pulmonary embolism complicated by acute cor pulmonale.[50,51] A safe and reasonable strategy for managing critically ill patients with suspected massive pulmonary embolism is as follows:

1. Initially perform bedside TTE, looking for the presence of regional right ventricular dysfunction, as described earlier. If the TTE examination is suboptimal, TEE should be performed.
2. If echocardiography is inconclusive or negative and the clinical suspicion of a pulmonary embolism remains high, a definitive confirmatory radiologic test (preferably helical CT with contrast) should be performed.

Assessment of Cardiac Output

Measurement of cardiac output remains a cornerstone in the hemodynamic assessment of critically ill patients. Thermodilution is considered the gold-standard approach for determining cardiac output in most ICUs. Measurement of cardiac output using thermodilution requires placement of a pulmonary artery catheter (or at least central venous and arterial catheters)—an invasive and potentially inaccurate method. Unreliable values are particularly common in the presence of tricuspid regurgitation related to high pulmonary artery pressure. Several methods for determining cardiac output have been described using 2D imaging and Doppler echocardiography. With this technique, stroke volume and cardiac output can be determined directly by combining Doppler-derived measurements of instantaneous blood flow velocity through a conduit with the cross sectional area of the conduit. Blood flow can be calculated through various cardiac structures, including the pulmonary valve,[52] mitral valve,[53,54] and aortic valve.[55–58] In the absence of intracardiac shunts, blood flow through these structures should be the same (continuity equation).[59] Of these methods, the one using the left ventricular outflow tract and aortic valve as the conduit is probably the most reliable and most commonly used. There is excellent agreement with thermodilution in most situations.[55–58] The left ventricular stroke volume is obtained by measuring the cross sectional area of the left ventricular outflow tract (area [cm^2] = (left ventricular outflow tract diameter [cm^2]) × (π/4), assuming that just below the aortic annulus, the left ventricular outflow tract is circular) multiplied by the transaortic flow velocity time integral derived from a spectral Doppler tracing. The stroke volume obtained is multiplied by the heart rate to give the cardiac output: cardiac output = cross sectional area × velocity time integral × heart rate (Fig. E2.7). With TTE, the left ventricular outflow tract diameter usually is obtained from the parasternal long-axis view, just below the insertion of the aortic valve leaflets. The Doppler interrogation is performed through the aortic valve from the apical view (see Fig. E2.7). With TEE, the left ventricular outflow tract diameter usually is obtained from the five-chamber view of the left ventricle. The transgastric view usually is used to obtain an apical long-axis view of the aortic valve through which Doppler interrogation is performed.[60] With either TTE or TEE, obtaining an accurate left ventricular outflow tract diameter and Doppler signal is essential to have an accurate cardiac output calculation. Because the measure of the left ventricular outflow tract diameter has a second-order relationship with the cross sectional area (see previous formula), it is crucial that this measure be determined precisely. For the Doppler signal to be reliable, the Doppler sample must be parallel to the transaortic flow with an angle of incidence not exceeding 20 degrees so as to avoid underestimation of transaortic velocity. Using TTE in critically ill patients, McLean and coworkers[61] showed an excellent correlation (r = 0.94) between cardiac output determined by the left ventricular outflow tract Doppler method and the thermodilution method. Other studies have shown similar results.[55] In a study by Feinberg and colleagues,[58] cardiac output determined by TEE Doppler imaging was obtainable in 88% of 33 critically ill patients, and there was good correlation (r = 0.91) with the thermodilution method. Descorps-Declere and colleagues[60] also showed transgastric pulsed Doppler measurement across the left ventricular outflow tract with TEE to be a clinically acceptable method for cardiac output measurement in critically ill patients (r = 0.975 compared with the thermodilution method).

Another promising ultrasound-based technology for estimating cardiac output noninvasively in adults uses a small transesophageal Doppler probe to measure blood flow velocity waveforms in the descending aorta combined with a nomogram (based on height, weight, and age) that estimates aortic cross sectional area. This minimally invasive esophageal probe can be inserted easily in sedated patients and left in place safely for several days to provide continuous monitoring of cardiac function.[62,63] Several technical problems can limit the accuracy of cardiac output measurements by esophageal Doppler monitoring,[62] however, and although initial results are promising,[64–66] more studies are needed to make a decision regarding the accuracy of this technique in critically ill patients.

Assessment of Filling Pressures and Volume Status

Adequate determination of preload and volume status is important for the proper management of critically ill patients. Invasive pressure measurements to assess left ventricular filling are commonly used at the bedside to make inferences regarding left ventricular preload. These pressure measurements correlate only weakly with left ventricular volume, however.[67] Data from invasive monitoring using pulmonary

$$= 5.569\ \text{mL/min}$$

Fig. E2.7 Calculation of the stroke volume and cardiac output from the left ventricular outflow tract (LVOT). **A,** LVOT diameter obtained from the transthoracic parasternal long-axis view, just below the insertion of the aortic valve leaflets. In this example, the LVOT diameter is 2.17 cm. **B,** Doppler interrogation (with pulsed-wave Doppler) is performed from the apical view with the sample volume being placed in the LVOT, just below the aortic valve. **C,** Spectral Doppler tracing from the LVOT from which the transaortic flow velocity time integral (VTI) is derived. In this example, the VTI is 17.3 cm. **D,** The left ventricular stroke volume (SV) is obtained by measuring the cross sectional area (CSA) of the LVOT (area [cm^2] = LVOT diameter [cm^2] × $\pi/4$) and multiplying by the transaortic VTI derived from the spectral Doppler tracing. The stroke volume obtained is multiplied by the heart rate to give the cardiac output (CO). *LA,* Left atrium; *LV,* left ventricle; *RV,* right ventricle.

artery catheterization may be misleading because ventricular compliance is altered secondary to numerous factors.[68,69] Differences in diastolic compliance among patients may account for the weak correlation between pressure and volume and may limit the ability to use pressure measurements alone to derive information concerning left ventricular preload, a volume-based variable.[14] Parameters that can be measured using 2D echocardiographic imaging are left ventricular end-diastolic volume and left ventricular end-diastolic area. Using Doppler interrogation, additional information—mainly transmitral diastolic filling pattern and pulmonary venous flow—can be evaluated.

Two-dimensional imaging. Echocardiography has been validated for left ventricular volume measurements.[15] Subjective assessment of left ventricular volume by estimating the size of the left ventricular cavity in the short-axis and long-axis views is often adequate to guide fluid volume therapy at the extreme ends of cardiac filling and function. More precise quantitative values are desirable, however, and can be obtained by using endocardial border tracing (as described earlier). The normal left ventricular end-diastolic volume as determined by echocardiography is 80–130 mL,[15] and the normal left ventricular end-diastolic volume index is 55–65 mL/m^2.[15] Left ventricular end-diastolic area measured in the left parasternal short-axis view at the level of the midpapillary muscle is commonly used to estimate volume status (Fig. E2.8). The normal values for left ventricular end-diastolic area in the short-axis view are 9.5–22 cm^2.[15]

Two-dimensional TTE evaluation of ventricular dimensions has been found to be useful in assessing preload and optimizing therapy.[25,70] Nevertheless, suboptimal image quality may preclude adequate visualization of the endocardial border by TTE. This potential limitation of TTE has been partially circumvented in recent years with the advent of harmonic imaging and contrast echocardiography (see later). In cases in which endocardial border visualization remains suboptimal, TEE is the modality of choice. With TEE, left ventricular volume can be estimated rapidly by subjective assessment of the left ventricular size. Quantitatively, it is estimated most often by determining the left ventricular cross sectional area at the end of diastole, most commonly using the transgastric short-axis view at the level of the midpapillary muscle. This section is used because of the reproducibility of the view and because changes in left ventricular volume affect the

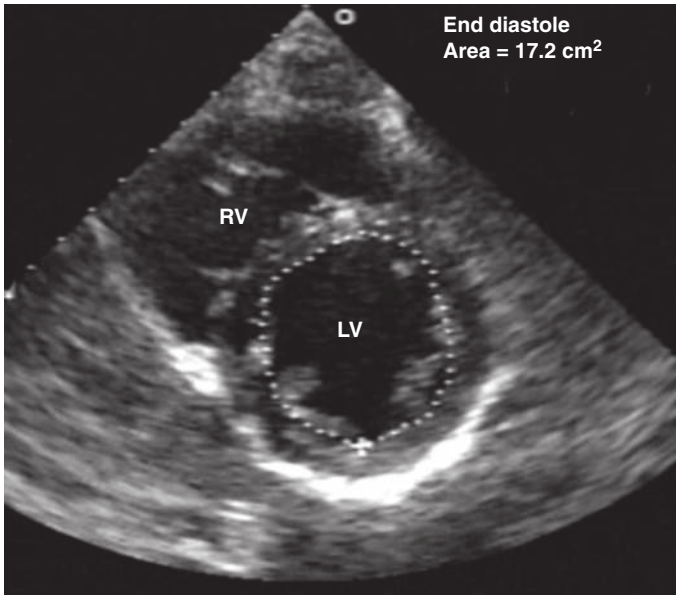

Fig. E2.8 Calculation of left ventricular end-diastolic area in the transthoracic short-axis view at the level of the midpapillary muscle by endocardial contour tracing. Values of normal left ventricular end-diastolic area in the short axis range from 9.5 to 22 cm^2.[15] The level of the midpapillary muscle is used because of the reproducibility of the view and because changes in left ventricular volume affect the short axis of the ventricle to a greater degree than the long axis. *LV,* Left ventricle; *RV,* right ventricle.

short axis of the ventricle to a greater degree than the long axis.[14] The end-diastolic area must be measured consistently from the same reference section. End-diastolic area measured with TEE correlates well with left ventricular volume determined by radionuclide studies.[70]

Systolic obliteration of left ventricular cross sectional area accompanies decreased end-diastolic area and is considered to be a sign of severe hypovolemia (Fig. E2.9). Although a small end-diastolic area generally indicates hypovolemia, a large end-diastolic area does not indicate adequate preload in patients with left ventricular dysfunction. Also, when systemic vascular resistance is low, as in early sepsis, left ventricular emptying improves because of reduced afterload. In these situations, it may be difficult to differentiate hypovolemia from low systemic vascular resistance by echocardiography alone, because both conditions are associated with decreased end-diastolic area. Knowledge of left ventricular end-diastolic volume or absolute preload does not allow for accurate prediction of the hemodynamic response to alterations in preload.[71] Tousignant and colleagues[72] investigated the relationship between left ventricular stroke volume and left ventricular end-diastolic area in a cohort of ICU patients and found only a modest correlation ($r = 0.60$) between single-point estimates of left ventricular end-diastolic area and responses to fluid loading. Based on the assumption that changes in end-diastolic area occur because of changes in left ventricular volume, the determination of this area and its subsequent degree of variation after a fluid challenge could help better assess preload responsiveness. Studies have shown that changes in end-diastolic area measured by TEE using endocardial border tracing are closely related to changes in cardiac output and are superior to measurements of pulmonary artery occlusion pressure for predicting the ventricular preload associated with maximal cardiac output.[73]

Circulating volume status also can be assessed by 2D echocardiography by indirectly estimating right atrial pressure; this is often done by assessing the diameter and change in caliber with inspiration of the inferior vena cava (Fig. E2.10). This method has been shown to discriminate reliably between right atrial pressures either less than or greater than 10 mm Hg.[74] A dilated vena cava (diameter >20 mm) without a normal inspiratory decrease in caliber (>50% with gentle sniffing) usually indicates elevated right atrial pressure. In mechanically ventilated patients, this measure is less specific because of a high prevalence of inferior vena cava dilation.[75,76] A small vena caval dimension reliably excludes the presence of elevated right atrial pressure in these patients.[75,76]

Doppler flow patterns. Analysis of the Doppler signal at the level of the mitral valve and pulmonary vein offers additional information about preload.[77,78] These Doppler profiles can be obtained by either

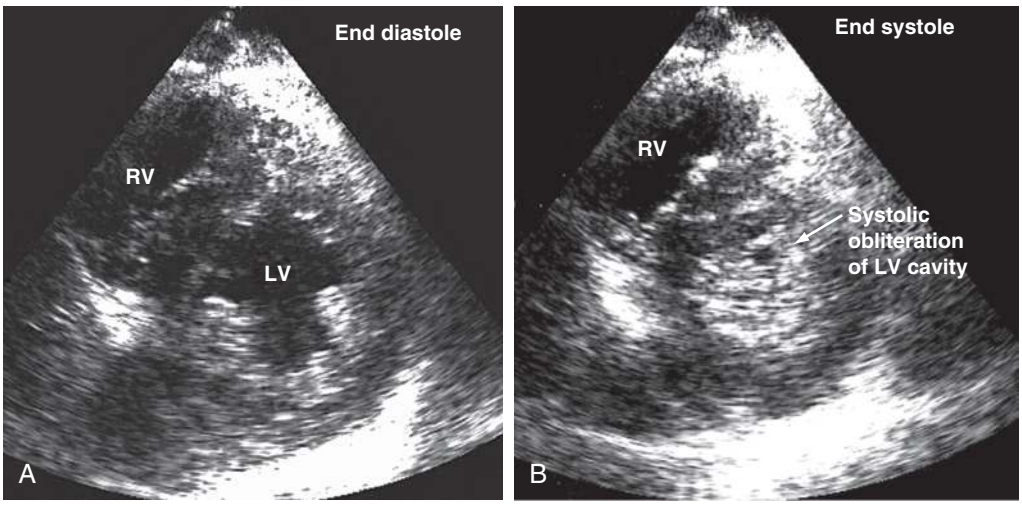

Fig. E2.9 Systolic obliteration of the left ventricle (LV) in a patient with severe left ventricular hypertrophy and dehydration. This transthoracic parasternal short-axis view shows the LV at end diastole **(A)** and at end systole **(B)**. Nearly complete obliteration of the left ventricular cavity is seen at end systole. Systolic obliteration of the cross sectional area accompanies decreased end-diastolic area and is considered to be a sign of severe hypovolemia. In this case, the patient presented with hypotension and was found to be severely dehydrated because of a viral gastroenteritis. *RV,* Right ventricle.

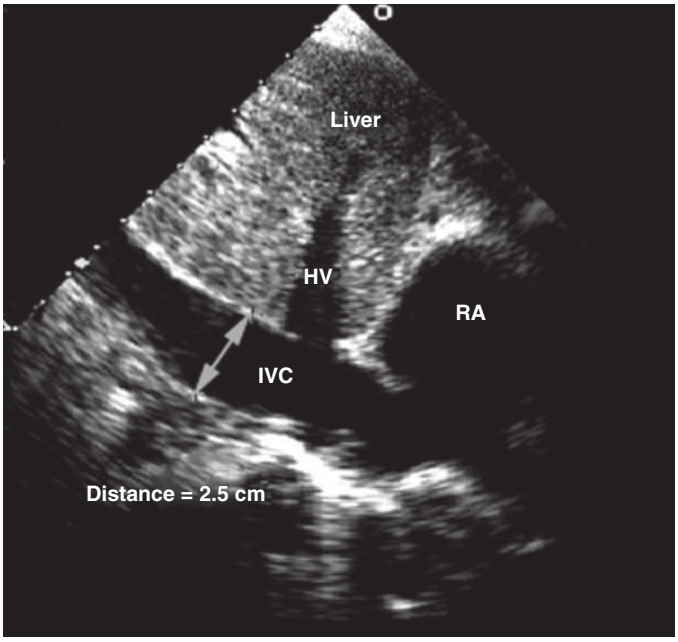

Fig. E2.10 Indirect assessment of circulating volume status on two-dimensional echocardiography by assessing the diameter and change in caliber with inspiration of the inferior vena cava (IVC). This method has been shown to discriminate reliably between right atrial pressures of less than or greater than 10 mm Hg. A dilated vena cava (>20 mm) without the normal inspiratory decrease in caliber (>50% on gentle sniffing) usually indicates elevated right atrial pressure. A small vena cava reliably excludes elevated right atrial pressure in these patients. In this case, the IVC was dilated at 2.5 cm with minimal respiratory variation in a patient spontaneously breathing. The right atrial pressure was estimated to be approximately 10–15 mm Hg. Images were obtained in the subcostal view. *HV,* Hepatic veins; *RA,* right atrium.

TTE or TEE. Transmitral parameters that have been studied include the relation of early to late transmitral diastolic filling (E/A ratio), isovolumetric relaxation time, and the rate of deceleration of early diastolic inflow (deceleration time).[1]

A decrease in preload causes a significant reduction in the E wave (early filling flow wave) velocity at the mitral level in conjunction with a decrease of the S wave (systolic flow wave) in the pulmonary vein. In clinical practice, the E/A ratio is easy to assess; the normal value of this ratio is approximately 1.[1,3] In conjunction with normal left ventricular contractility, a low E/A ratio is usually characteristic of inadequate preload.[79]

Pulmonary venous flow also can be used to assess left atrial pressure. A normal pulmonary venous flow pattern showing a predominance of flow during systole (S phase) compared with early diastole (D phase) usually indicates that left atrial pressure is less than 8 mm Hg, whereas the opposite predominance of flow (in the absence of significant mitral regurgitation) usually indicates elevation of left atrial pressure.[1]

Transmitral and pulmonary vein Doppler patterns strongly depend on intrinsic and external factors and are not affected purely by the loading conditions of the left ventricle. It is crucial that interpretation of Doppler parameters be done in conjunction with a global analysis of cardiac function and other available hemodynamic or anatomic variables.

Hypovolemia in the Intensive Care Unit

Precise and rapid assessment of volume status is crucial when caring for hemodynamically unstable ICU patients. Hypovolemia is one of the most common causes of hypotension in the ICU. As was discussed in detail earlier, bedside echocardiography offers a quick and reliable way of estimating volume status by evaluating cardiac dynamics and left ventricular dimensions and area. The finding of end-systolic cavity obliteration offers a reliable sign of hypovolemia. Other changes in the volume status are usually associated with subtle changes in left ventricular cavity size, so only this extreme is reliable to make the diagnosis of hypovolemia by echocardiography. In general, TTE has good sensitivity for diagnosing the presence of a small hyperdynamic left ventricle, the most typical finding in hypovolemic patients with underlying normal cardiac function; TEE is particularly useful in the immediate postoperative setting (Video E2.1).

When dynamic left ventricular obstruction is present, cardiac output is often low, and even in the presence of marked hypovolemia, pulmonary artery occlusion pressure is typically high. Paradoxical worsening of hypotension after intravascular volume loading may be the first clue to dynamic left ventricular obstruction in critically ill patients. It is important that this entity be recognized early and that the pathophysiologic process be well understood, because inadequate management of this condition can lead rapidly to worsening of hemodynamic status and death. Dynamic obstruction of the left ventricle can present in different forms. One of these forms is dynamic left ventricular outflow tract obstruction. Although dynamic left ventricular outflow tract obstruction is often seen in association with asymmetric septal hypertrophy, it also can occur in other situations.[80,81] Dynamic left ventricular outflow tract obstruction is thought to be caused by the Venturi effect. This effect results when excessive acceleration of blood through a conduit produces a decrease in its lateral distending pressure. In the left ventricular outflow tract, such a decrease in pressure leads to a suction phenomenon that draws the anterior mitral leaflet and chordae inward toward the interventricular septum.[82] This systolic anterior motion of the mitral valve leads to contact between the mitral leaflet and the septum that creates an obstructive subaortic pressure gradient and distortion of the mitral valve leaflet coaptation (Fig. E2.11).[82] By 2D echocardiography, the left ventricle appears to be small and hyperdynamic, and there is motion of the anterior leaflet (or chordae, or both) toward the septum in systole (see Fig. E2.11). With color Doppler, a "mosaic" pattern of flow is seen in the left ventricular outflow tract, owing to the high velocity and turbulence. Variable degrees of asymmetric mitral regurgitation also may be present (see Fig. E2.11). Continuous-wave Doppler shows the presence of a significant gradient in the left ventricular outflow tract. Dynamic left ventricular obstruction also can be present without systolic anterior motion. In the presence of reduced afterload, dehydration, or significant catecholaminergic stimulation, patients with a small hypertrophied left ventricle (typically seen in elderly patients with chronic hypertension) can develop midventricular obstruction because of hyperdynamic systolic obliteration of the left ventricular cavity (see Fig. E2.9).[83] These physiologic factors may predict the development or worsening of left ventricular dynamic obstruction. Interplay of these factors with preexisting ventricular hypertrophy predisposes the patient to develop cardiogenic shock from this combined loss of preload and presence of dynamic left ventricular obstruction. Dynamic left ventricular obstruction has also been described in patients with acute myocardial infarction, mostly in association with apical infarction.[81,84,85]

In a study by Chenzbraun and colleagues,[85] four ICU patients with hemodynamic instability were found to have a small hyperdynamic ventricle on TEE. Of these four patients, three had pulmonary artery occlusion pressure greater than 20 mm Hg. A study by Poelaert and colleagues[20] that evaluated the diagnostic value of TEE compared with pulmonary artery catheterization showed that pulmonary artery catheterization failed to diagnose the presence of hypovolemia in 44% of patients when TEE showed systolic obliteration of the left ventricular cavity, supporting a

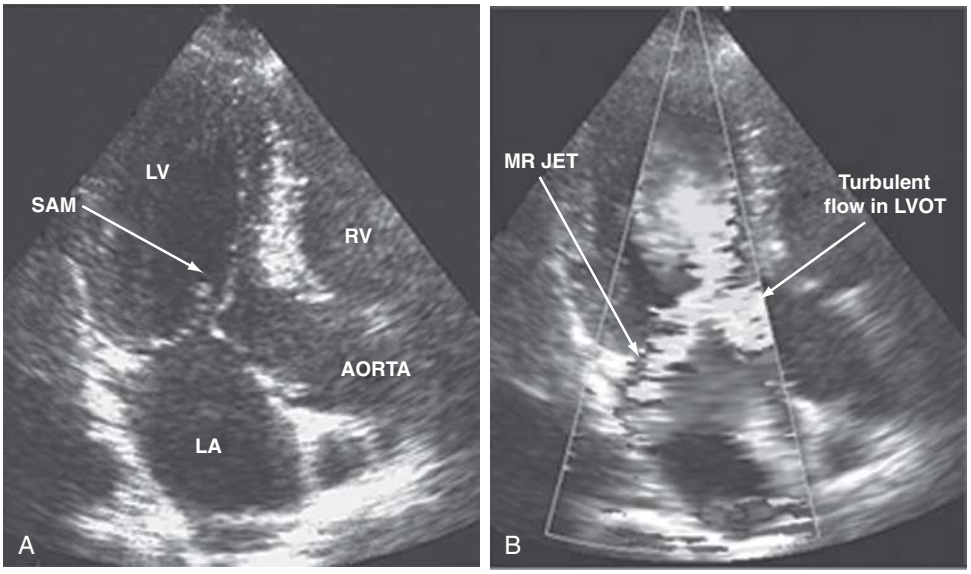

Fig. E2.11 Systolic anterior motion (SAM) of the mitral valve in a patient with asymmetric left ventricular hypertrophy and dehydration. Two-dimensional transthoracic apical long-axis view shows movement of the anterior leaflet of the mitral valve *(arrow)* toward the interventricular septum during systole **(A)**. This creates a subaortic dynamic obstruction. The resulting high velocity and turbulence in the left ventricular outflow tract (LVOT) gives a "mosaic" pattern of flow on color Doppler **(B)**. A variable degree of asymmetric mitral regurgitation (MR) also may be present secondary to the systolic anterior motion, as shown in this example. *LA,* Left atrium; *LV,* left ventricle; *RV,* right ventricle.

diagnosis of hypovolemia. TTE and TEE have been shown to play key roles in making the diagnosis of hypovolemia and left ventricular dynamic obstruction, leading to a dramatic impact on therapy.[19,21,22,82–85]

Assessment of Pulmonary Artery Pressure

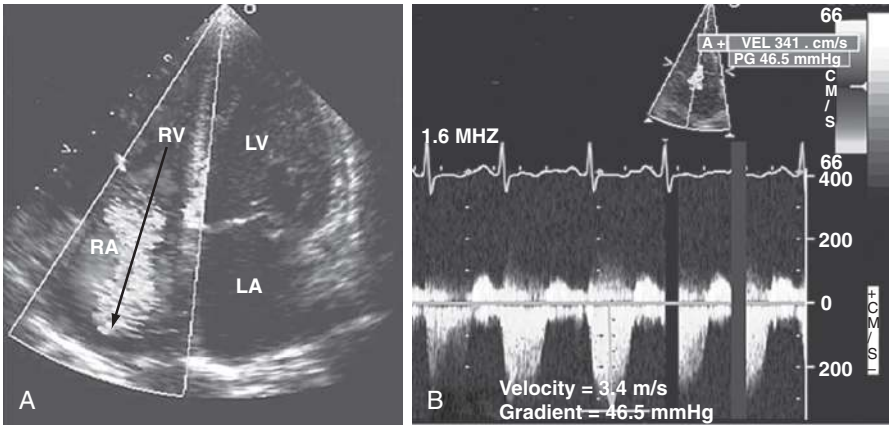
Pulmonary hypertension occurs commonly in critically ill patients and is a manifestation of various pulmonary, cardiac, and systemic processes. Pulmonary hypertension is said to be present when systolic pulmonary pressure exceeds 35 mm Hg, diastolic pulmonary pressure is greater than 15 mm Hg, and mean pulmonary pressure is greater than 25 mm Hg.[59] Many helpful echocardiographic methods have been validated for noninvasive estimation of pulmonary artery pressure.[59,86] Systolic and diastolic pulmonary artery pressures are determined from the tricuspid and pulmonary regurgitation velocities (some degree of regurgitation is essential to be able to obtain a Doppler signal and subsequently estimate pulmonary artery pressure). Tricuspid regurgitation is present in more than 75% of healthy adults[59] and in approximately 90% of critically ill patients.[87] Peak tricuspid regurgitation velocity, usually obtained by continuous-wave Doppler from the right ventricular inflow or the apical four-chamber view position, reflects the pressure difference during systole between the right ventricle and the right atrium (Fig. E2.12).[88–90] Peak systolic pulmonary artery pressure is determined from the peak tricuspid regurgitation Doppler velocity using the modified Bernoulli equation[91]: $\Delta P = 4 \times$ (peak tricuspid regurgitation velocity).[2] To this peak systolic pressure gradient between right ventricle and right atrium is added the estimated right atrial pressure (see previous section) to obtain the peak right ventricular systolic pressure. In the absence of pulmonic stenosis or right ventricular outflow obstruction, peak right ventricular systolic pressure equals systolic pulmonary artery pressure (see Fig. E2.12). Echocardiography also can determine diastolic pulmonary artery pressure by applying the modified Bernoulli equation using the regurgitant Doppler velocity of the pulmonary valve to obtain the gradient between the pulmonary artery and the right ventricle at end diastole. To this is added the estimated right atrial pressure (equivalent to right ventricular end-diastolic pressure in the absence of tricuspid stenosis) to obtain end-diastolic pulmonary artery pressure: end-diastolic pulmonary artery pressure $= 4 \times$ (peak pulmonary regurgitation velocity)^2 + estimated right atrial pressure. Approximately 70% of critically ill patients have an adequate Doppler signal of pulmonic insufficiency for this calculation.[92] Tricuspid and pulmonary regurgitation are present simultaneously in more than 85% of subjects.[93]

Assessment of Valvular Function and Integrity

Attention has been drawn to the limitations of the physical examination for the detection of cardiovascular abnormalities.[94,95] This problem is enhanced in acutely ill patients in the ICU, and many cardiovascular abnormalities may be concurrent with noncardiac illness without being clinically suspected.[96] Significant valvular abnormalities are a good example of such cardiovascular pathologies that can be present in a critically ill patient without being clinically recognized.[96] Even with invasive monitoring, significant valvular pathologies may be missed. The most common indications for bedside echocardiography for evaluation of valvular apparatus in the ICU patient population are for suspected endocarditis,[8,24] acute aortic or mitral valve regurgitation,[97,98] and prosthetic valve dysfunction.[16] Echocardiography is uniquely suited to the evaluation of valvular heart disease because of its ability to help determine the etiology and severity of valvular lesions. In the ICU, TTE can provide valuable information concerning valvular integrity and function,[16] but it may be suboptimal and not sensitive enough to detect endocarditis, a dysfunctional mitral valve, or prosthetic valve dysfunction; TEE is often warranted. TEE is especially important for the fine detail of mitral valve pathology, such as a torn chordae tendineae and flail scallop (Video E2.2).

Valvular Regurgitation and Prosthetic Valve Dysfunction

In a patient with unexplained hemodynamic instability and a grossly normal TTE examination, performance of subsequent TEE is



$$\text{Systolic PAP} = 4 \times (\text{peak TR velocity})^2 + \text{estimated RA pressure}$$
$$= 4 \times (3.41)^2 + 10$$
$$= 46.51 + 10$$
$$= 56.5 \text{ mm Hg}$$

C

Fig. E2.12 Calculation of systolic pulmonary artery pressure (PAP). **A,** Color Doppler transthoracic apical four-chamber view showing a significant tricuspid regurgitation (TR) jet from right ventricle (RV) to right atrium (RA). The peak TR velocity is measured by placing the continuous-wave Doppler in the center of the TR jet *(arrow).* **B,** Spectral continuous-wave Doppler profile of the TR jet. Peak TR velocity (3.41 m/s) and peak systolic PAP gradient (46.5 mm Hg) can be obtained with this modality. **C,** Peak systolic PAP also can be determined from the peak TR Doppler velocity using the modified Bernoulli equation: $\Delta P = 4 \times (\text{peak TR velocity})^2$. To this peak systolic pressure gradient between right ventricle and right atrium is added the estimated right atrial pressure (determined to be 10 in this example) to obtain the peak right ventricular systolic pressure. In the absence of pulmonic stenosis or right ventricular outflow obstruction, peak right ventricular systolic pressure is equal to systolic PAP. *LA,* Left atrium; *LV,* left ventricle.

important to rule out the presence of significant undetected valvular pathology. Common valvular pathologies that can be missed are mitral regurgitation and prosthetic valve dysfunction. In some situations, TTE may provide better imaging than TEE for evaluation of anterior structures such as the aortic valve (native or prosthetic) and for Doppler measurements. TEE is clearly superior to TTE for evaluation of mitral valve pathologies (native and prosthetic). In a study of ICU patients by Alam,[16] TTE compared with TEE was shown either to miss or to underestimate the severity of regurgitation of St. Jude and bioprosthetic valves in the mitral but not in the aortic position.

With acute severe mitral regurgitation, the diagnosis may be clinically difficult because the murmur is often of short duration and low intensity (because of rapid pressure equalization between the left ventricle and the relatively noncompliant left atrium). By TTE, the size of the regurgitant jet in acute mitral regurgitation may appear small and lead to underestimation of severity.[99] Because of its close anatomic proximity, TEE provides a more precise evaluation of the degree of mitral regurgitation (Fig. E2.13) and provides crucial diagnostic information regarding the cause for mitral regurgitation. The diagnosis of acute mitral regurgitation represents a medical emergency that may necessitate urgent surgery, so the threshold to perform a TEE when this entity is suspected should be low.[8,10,97] Also, several investigators have confirmed the superior accuracy, sensitivity, and reliability of TEE over TTE for dysfunction of mitral prostheses, in which ultrasonic shadowing of the left atrium often occurs with the standard transthoracic studies.[100–103] TEE may be especially useful to detect obstruction of prosthetic valves from thrombus (Video E2.3).

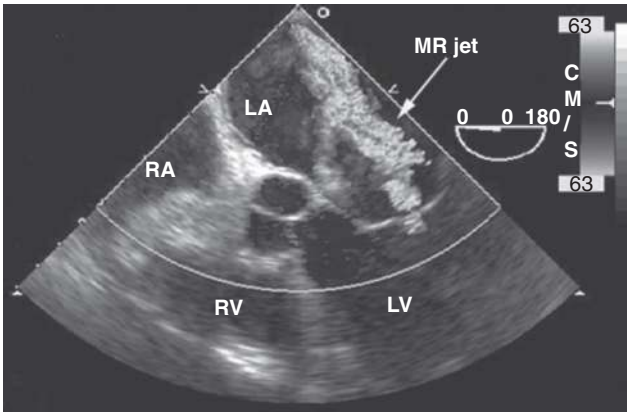


Fig. E2.13 Severe mitral regurgitation (MR). Transesophageal five-chamber view shows severe MR with a large regurgitant jet *(arrow)* going far posteriorly in the left atrium (LA). In this case, systolic flow reversal in the pulmonary veins (another echocardiographic sign of severe MR) also was present (not shown on this picture). Because of its close anatomic proximity, transesophageal echocardiography is an excellent tool for the precise evaluation of the degree of MR. *LV,* Left ventricle; *RA,* right atrium; *RV,* right ventricle.

Traumatic Valvular Injuries

Traumatic valvular injuries associated with myocardial injury may present as acute regurgitation. Bedside exclusion of major damage to the aorta, valves, and myocardium is important in the posttrauma context.[104,105] Valvular injuries may occur as a consequence of blunt or penetrating injury. Most frequently the aortic valve is injured; less commonly the mitral and tricuspid valves are injured.[106] Valvular dysfunction is usually the result of a torn leaflet or rupture of a papillary muscle or chordae.[106] In trauma patients, TEE is the bedside imaging modality of choice to detect these pathologies.[104,105] In a study by Chirillo and colleagues assessing the usefulness of TTE and TEE in the

recognition and management of cardiovascular injuries after blunt chest trauma, TTE provided suboptimal imaging in 62% of patients, and the poor quality of images obtained was the main cause for the low sensitivity of TTE compared with TEE.[105a]

Evaluation of the Pericardial Space

Echocardiography is an essential instrument for the diagnosis of pericardial disease. In the ICU, the most common clinical indication for assessment of the pericardial space is suspected tamponade. The pericardium is a potential space that can become filled with fluid, blood, pus, or, uncommonly, air. Presence of fluid in this compartment is detected as an echo-free space. Pericardial fluid usually is detected easily with TTE. The parasternal long-axis and short-axis views together with the apical views usually reveal the effusion (Fig. E2.14). In many critically ill patients with suboptimal TTE image quality, the subcostal view is often the only adequate window available to detect the presence of a pericardial effusion. In these ICU patients with poor acoustic windows and in the postcardiac surgical setting, TEE may be needed to assess the pericardial space adequately.

In addition to assisting in the diagnosis of pericardial effusion and tamponade, 2D echocardiography can assist in its drainage, as pericardiocentesis can be performed safely under 2D echocardiographic guidance.[107,108] By determining the depth of the effusion and its distance from the site of puncture, it is possible to optimize needle placement. Echocardiography also can be used for immediate monitoring of the results of the pericardiocentesis.

Cardiac Tamponade in the Intensive Care Unit

The most common causes of cardiac tamponade in the ICU are listed in Box E2.5. Echocardiographic 2D signs of tamponade are a direct consequence of increased pericardial pressure, leading to diastolic collapse of one or more cardiac chambers (usually on the right side first)

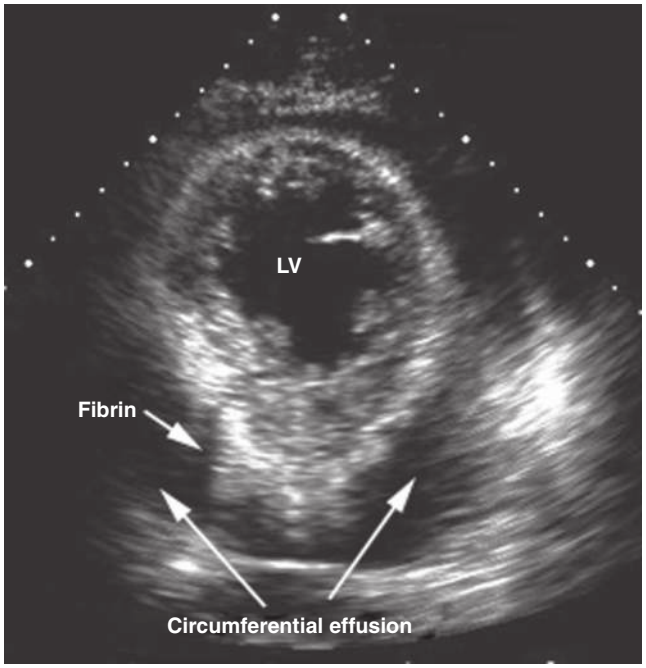

Fig. E2.14 **Large pericardial effusion.** Transthoracic parasternal short-axis view shows a large, predominantly echo-free space around the left ventricle (LV). This space represents fluid in the pericardium. In this case, the large circumferential pericardial effusion was bloody at pericardiocentesis. Particulate matter (e.g., fibrin and clots) can be visualized as denser echoes around the heart and floating in the effusion.

BOX E2.5 Most Common Causes of Cardiac Tamponade in the Intensive Care Unit

- Myocardial or coronary perforation secondary to catheter-based intervention (i.e., after intravenous pacemaker lead insertion, central line placement, or percutaneous coronary interventions)
- Compressive hematoma after cardiac surgery
- Proximal ascending aortic dissection
- Blunt or penetrating chest trauma
- Complication of myocardial infarction (e.g., ventricular rupture)
- Uremic or infectious pericarditis
- Pericardial involvement by metastatic disease or other systemic processes

(Fig. E2.15). Usually, collapse of the right ventricular free wall is seen in early diastole, and right atrial wall collapse is seen in late diastole.[14] This latter sign is sensitive but not specific for tamponade. It is, however, specific for a hemodynamically significant effusion if the right atrial collapse lasts longer than one-third of the R-R interval.[14,109] In the presence of a massive effusion, the heart may have a "swinging" motion in the pericardial cavity. This finding is not always present in cardiac tamponade, because the amount of fluid in the pericardial space may be small but still cause tamponade physiology, depending on the acuity with which the effusion accumulates and the compliance of the pericardium. In post-sternotomy patients, tamponade may be missed by TTE (even in cases in which imaging quality seems adequate) because hematomas causing selective cardiac chamber compression are often in the form of loculated clots located in the far field of the ultrasound beam in the posterior heart region (even when the anterior pericardium is left open).[110] The right atrium and right ventricle may be spared in such cases secondary to postoperative adhesions or tethering of the right ventricle to the chest wall anteriorly.[110]

Another (indirect) sign of a hemodynamically significant pericardial effusion on 2D imaging is plethora of the inferior vena cava with blunted respiratory changes.[1] The latter sign is less valuable in mechanically ventilated patients, because they often have a stiff, dilated inferior vena cava even in the absence of a pericardial effusion (Video E2.4).

Doppler findings of cardiac tamponade are based on characteristic changes in intrathoracic and intracardiac hemodynamics that occur with respiration. Because of ventricular interaction, mitral inflow velocity (E wave) decreases after inspiration and increases after expiration. Reciprocal changes occur with respect to tricuspid inflow velocity. With tamponade, the exaggerated inspiratory-expiratory variation of the inflow velocity (E wave) over one respiratory cycle should be greater than 40% on the left and greater than 80% on the right.[111] In critically ill patients, however, mechanical ventilation, bronchospasm, significant pleural effusion, and respiratory distress can alter intrathoracic and intracardiac hemodynamics and make these Doppler findings less reliable. A significant pleural effusion sometimes causes significant respiratory Doppler variations of the inflow velocities that disappear when the effusion is drained.[112] The presence of arrhythmia also makes the Doppler findings difficult to interpret. In some circumstances, echocardiographic signs of tamponade may be subtle or absent, so one must keep in mind that the diagnosis of tamponade remains a clinical one and that the echocardiographic signs must be analyzed in conjunction with the clinical findings.

Complications After Cardiac Surgery

Bedside echocardiography has proved to be of particular value in the critical care management of patients with hemodynamic instability after cardiothoracic operations.[7,8,83,113–115] TTE is often severely limited in this group of patients.[5,8] TEE is the modality of choice in this setting

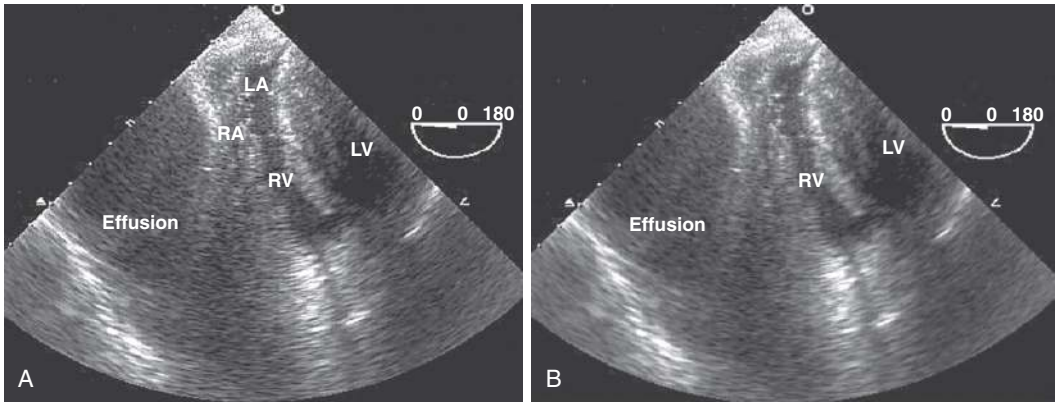

Fig. E2.15 Cardiac tamponade. Transesophageal four-chamber view **(A)** shows the presence of a large effusion that severely compresses the right atrium (RA) and right ventricle (RV), which appear slitlike. The left ventricle (LV) also is small because of indirect compression and underfilling. Transgastric short-axis view **(B)** of the same patient shows the large pericardial effusion and severely compressed ventricular chambers. This postcardiotomy patient was in profound shock and was brought back to the operating room emergently for reexploration and drainage of the effusion. *LA,* Left atrium.

because it provides detailed information that can help determine the cause of refractory hypotension. The most frequent echocardiographic diagnoses encountered in these patients are left ventricular or right ventricular failure, tamponade, hypovolemia, and valvular dysfunction. Schmidlin and colleagues[116] studied 136 patients after cardiac surgery and showed that a new diagnosis was established or an important pathology was excluded in 45% of patients undergoing TEE. A therapeutic impact was detected in 73% of cases. The main indications for TEE in this study were control of left ventricular function (34%), unexplained hemodynamic deterioration (29%), suspicion of pericardial tamponade (14%), cardiac ischemia (9%), and "other" (14%). Reichert and colleagues.[113] performed TEE in hypotensive patients after cardiac surgery. Left ventricular failure was found in 27% of patients, hypovolemia in 23%, right ventricular failure in 18%, biventricular failure in 13%, and tamponade in 10%. Comparison with hemodynamic parameters showed agreement on diagnosis (hypovolemia versus tamponade versus cardiac failure) in only 50% of the cases. Echocardiography identified two cases of tamponade and six of hypovolemia that were not suspected based on standard hemodynamic data. In five patients with hemodynamic findings suggesting tamponade, unnecessary reoperation was prevented because TEE ruled out this diagnosis. Costachescu and colleagues[22] also showed the superiority of TEE compared with conventional monitoring with pulmonary artery catheterization in diagnosing and excluding significant causes of hemodynamic instability in postoperative cardiac surgical patients.

Infective Endocarditis

In the ICU, occurrence of infective endocarditis is not uncommon, and rightfully is considered quite often in the differential diagnosis of febrile patients. Suspicion of infective endocarditis was the second most common indication for performance of an echocardiogram among centers reporting their experience, as summarized in a review article by Heidenreich.[5] Nearly all critically ill patients are at risk for iatrogenic infection, bacteremia, and subsequent endocarditis because of the presence of multiple indwelling catheters, severe underlying diseases, malnutrition, and prolonged mechanical ventilation. Classic clinical findings suggesting endocarditis[106] are unusual among this patient population. Echocardiography is the test of choice for the noninvasive diagnosis of endocarditis. Fowler and colleagues[117] studied patients with *Staphylococcus aureus* bacteremia referred for TEE and showed that endocarditis ultimately was diagnosed in 25%. Only 7% of these patients had physical findings suggesting endocarditis. Absence of clinical stigmata is especially likely if the infection presents acutely. Because the consequences of untreated endocarditis are devastating and often ultimately fatal, it is important that the infection and its complications be recognized promptly and treated appropriately.[59]

The echocardiographic features typical for infective endocarditis are[59,118] (1) an oscillating intracardiac mass on a valve or supporting structure or in the path of a regurgitant jet or an iatrogenic device, (2) abscesses, (3) new partial dehiscence of a prosthetic valve, or (4) new valvular regurgitation. Sensitivity for the echographic diagnosis of endocarditis is 58%–62% for TTE and 88%–98% for TEE.[119,120] TEE is particularly useful for detecting small vegetations[121] and detecting vegetations on prosthetic valves. TEE also has been shown to be superior to TTE for diagnosing complications of endocarditis such as aortic root abscess, fistulas, and ruptured chordae tendineae of the mitral valve.[16] Among ICU patients, sensitivity of TTE for the diagnosis of endocarditis is often poor because the quality of the transthoracic study is commonly suboptimal. The sensitivity of TEE for suspected infective endocarditis usually is excellent in the ICU (Fig. E2.16). In a study by Font and colleagues,[97] a search for vegetations was the indication for 51 (46%) of 112 TEE studies performed for critically ill patients. TEE increased the detection rate by 27% compared with TTE. Suspicion of endocarditis represented 29% of the indications for TEE in a study of ICU patients by Chenzbraun and colleagues[85]; 9 (27%) of 31 patients with suspected infective endocarditis had a positive study for endocarditis. All positive studies were in patients who had an increased likelihood for infective endocarditis before the examination, as indicated by the presence of fever, positive blood cultures, new-onset murmur, prosthetic valve, or new-onset heart failure (alone or in combination). None of the patients with native valves and no clinical features of endocarditis produced a TEE study diagnostic of infective endocarditis, and in none of them was the diagnosis of infective endocarditis made subsequently. The findings from this study indicate that TEE is not useful as a screening procedure in septic patients without high clinical likelihood for endocarditis. The clinical probability of endocarditis should guide the use of TEE. Clinical factors considered "high risk" include intracardiac prosthetic material, positive blood cultures (in particular, *S. aureus*), evidence of peripheral emboli, and history of previous endocarditis[8,16] (Video E2.5).

As concluded by Colreavy and colleagues,[8] performance of TEE in the ICU for suspicion of infective endocarditis should be (1) cases associated with a clinical likelihood of endocarditis and a negative TTE examination, (2) suspected prosthetic valve endocarditis,

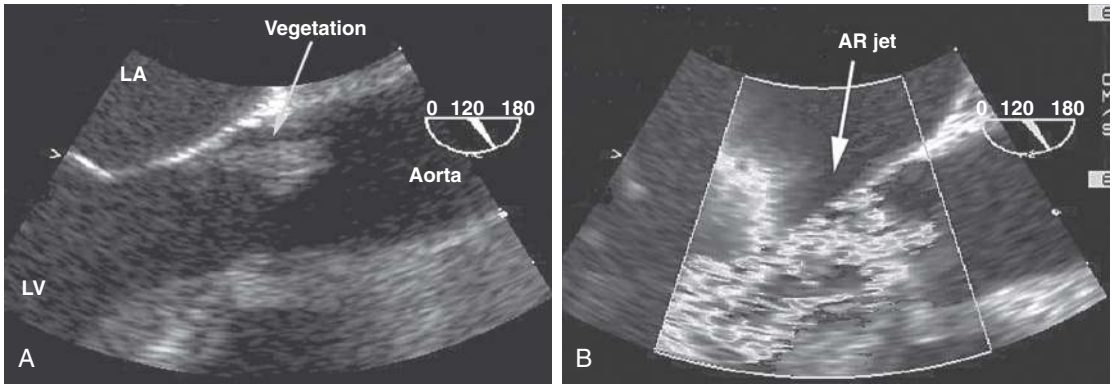

Fig. E2.16 Infective endocarditis of the aortic valve. A 55-year-old patient was admitted to the ICU with fever, chills, hypotension, and respiratory distress for which he had to be intubated. He had 4/4 positive blood cultures for *Staphylococcus aureus*. Transthoracic echocardiography was performed initially, but the quality was suboptimal, and no definite conclusion could be reached. Subsequent transesophageal echocardiography revealed a large vegetation on the left aortic coronary cusp, as seen in the midesophageal view at 120 degrees **(A)**. Color Doppler examination **(B)** revealed the presence of associated severe aortic regurgitation (AR). The patient was treated with antibiotics and emergent aortic valvular surgery. *LA,* Left atrium; *LV,* left ventricle.

(3) assessment of complications in known cases of endocarditis, and (4) cases of *S. aureus* bacteremia when the source is unknown or blood cultures remain positive despite antibiotic therapy. When assessing a patient for infective endocarditis by echocardiography, one must keep in mind the noninfectious causes of vegetations that may result from tumors, myxomatous degeneration, marantic endocarditis, Lambl excrescences, valve thrombus, and suture material in patients with repaired native or prosthetic valves.

Assessment of the Aorta

In the ICU, use of bedside echocardiography for assessment of suspected aortic pathologies provides many advantages over CT or aortography: there is no need for IV contrast administration, there may be less time delay, there is no need for transportation of a critically ill patient, and cardiac morphology and function can be evaluated at the same time.[3] For many years, aortography has been the gold standard for the investigation of suspected injuries of the aorta.[3] The advent of noninvasive modalities such as CT, magnetic resonance imaging (MRI), and TEE with their excellent sensitivity and specificity to diagnose aortic pathologies has decreased the need for aortograms.

Suspected aortic pathologies can be encountered in different ICU settings. The aorta may have to be imaged to rule out dissection, rupture, aneurysm, aortic debris, or aortic abscess. TTE is a good initial imaging modality for evaluation of the proximal aorta (ascending aorta and arch),[59] but the descending thoracic aorta cannot be adequately assessed and visualized with this modality. Because of the close anatomic relationship between the thoracic aorta and the esophagus, TEE allows optimal visualization of the entire thoracic aorta (Fig. E2.17). As described earlier, a blind spot exists in the distal portion of the ascending aorta and the proximal portion of the transverse aorta where its imaging can be suboptimal.[122,123]

Aortic Dissection and Rupture

Patients presenting with suspected aortic dissection need emergency diagnosis and treatment. Different noninvasive tests have been advocated for evaluation of suspected aortic dissection, including

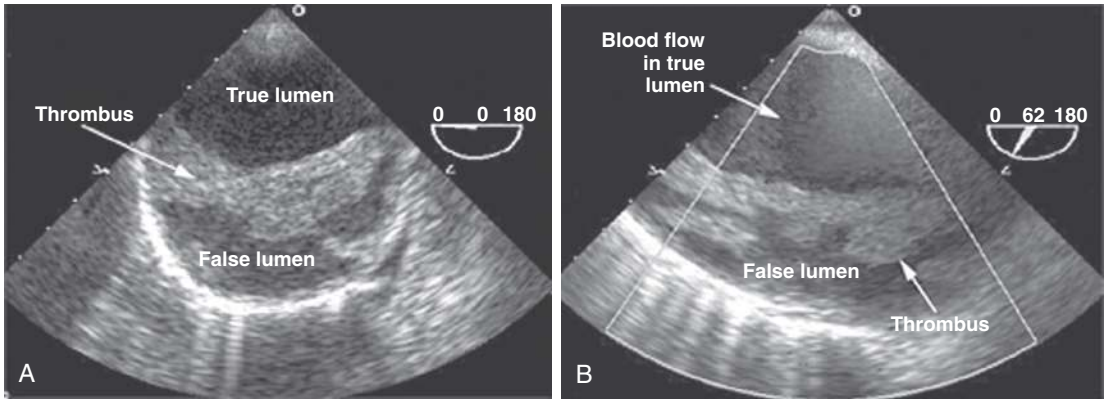

Fig. E2.17 Dissecting thoracic aortic aneurysm. A 65-year-old patient presented to the emergency department with severe ripping chest pain radiating to the back. The initial electrocardiogram was unremarkable, and the chest x-ray showed a widened mediastinum. The patient underwent transesophageal echocardiography, which revealed the presence of a large dissecting aneurysm of the descending thoracic aorta. The short-axis view **(A)** revealed the presence of a large aneurysm with a true and a false lumen. The false lumen was filled with thrombus *(arrow).* On the longitudinal view with color Doppler **(B)**, blood flow in the true lumen is visualized. The patient was taken emergently to the operating room.

TEE, CT, and MRI.[5,124] Nienaber and colleagues[124] compared all three modalities and found that they had similar sensitivities (98%). MRI had higher specificity than TEE (98% vs. 77%). A limitation of the study was that single-plane TEE was used. With multiplane TEE, specificity is improved to greater than 90% (see Fig. E2.17).[122] TTE was compared with CT and aortography in a multicenter European cooperative study,[125] it was shown that TEE was superior compared with both alternative modalities for the diagnosis of aortic dissection (sensitivity 99%). Other studies have confirmed the high accuracy of TEE.[125–128] A negative TEE examination for the diagnosis of aortic dissection, even in a high-risk population, has high negative predictive value.[129] Most centers use contrast CT scanning as the first choice for suspected aortic dissection, but TEE is an option in patients who cannot receive contrast, such as those who have advanced renal disease or are too unstable to be transported to the CT scanner (Video E2.6).

Another common indication to perform emergency aortic imaging in the ICU is to assess patients with blunt or penetrating chest trauma.[3] These patients are at high risk of life-threatening aortic injuries such as traumatic dissection and rupture, and prompt diagnosis and treatment are critical. Exclusion of major trauma to the ascending and descending aorta at the bedside is important in this context.[105] The value of TEE on admission for trauma patients with enlarged mediastinum and hemodynamic instability, with or without a combination of several other symptoms (e.g., pleural effusion, decreasing hematocrit, thoracic vertebral fracture), has been stressed by many authors.[130–133] Patients usually have a contained hematoma around the aortic dissection.[131] Transection of the thoracic aorta usually is seen at the level of the ligamentum arteriosum.

Additional helpful features of TEE in evaluating aortic pathologies are the ability to detect or assess extension of dissection into the proximal coronary arteries; the presence of pericardial or mediastinal hematoma or effusion; the presence, severity, and mechanism of associated aortic valve regurgitation; the point of entry and exit between the true and false lumens; the presence of thrombus in the false lumen; and ventricular function.[16] When TEE findings are equivocal or negative in cases of suspected thoracic aortic disease, other imaging modalities such as aortography, CT, or MRI should still be performed.

Assessment for Intracardiac and Intrapulmonary Shunts

In critically ill patients, clinical suspicion for an intracardiac or intrapulmonary shunt most often is raised in the context of unexplained embolic stroke or refractory hypoxemia. In such cases, the presence of a right-to-left shunt must be excluded. Common origins of right-to-left shunt are atrial septal defect or patent foramen ovale at the cardiac level[5] and arteriovenous fistula at the pulmonary level.[5] To be able to detect the presence of such a shunt at the bedside, a contrast study often is needed, because the shunt is usually not well visualized with 2D echocardiography alone. Color-flow imaging increases the detection rate of intracardiac shunt to some extent, but usually only when the shunt is large. Accordingly, a contrast study should be performed routinely as part of a TEE or TTE examination when evaluating a patient with unexplained embolic stroke or refractory hypoxemia in the ICU. For this purpose, agitated saline contrast is usually used. Approximately 0.5 mL of air is mixed with 10 mL of normal saline and is vigorously agitated back and forth between two syringes connected to the patient by a three-way stopcock. After an adequate echocardiographic view of the right and left atrial cavities has been obtained, the agitated saline is forcefully injected IV. After injection, the contrast is seen in the vena cava, right atrium, right ventricle, and pulmonary artery. In the absence of a shunt, only a minimal amount of contrast should be seen in the left-sided cavities, because most of the microbubbles from the agitated saline are unable to pass through the pulmonary capillaries. If an intracardiac shunt is present, such as an atrial septal defect or patent foramen ovale, left-sided contrast is observed immediately after right-sided opacification, and the contrast is seen going through the interatrial septum (Fig. E2.18). Performance of a Valsalva maneuver by the patient during contrast injection increases the sensitivity of the bubble study to detect right-to-left shunting. In mechanically ventilated patients, a maneuver equivalent to a Valsalva may be performed by inducing sudden release of sustained airway pressure previously achieved by inflating the lungs manually. This maneuver reverses the atrial transseptal gradient and may help

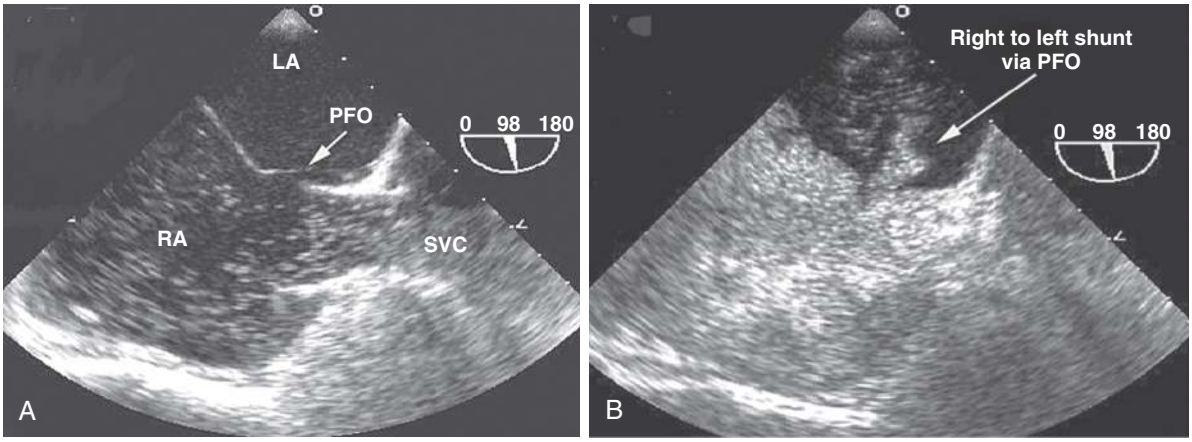

Fig. E2.18 Positive bubble study shows the presence of a right-to-left shunt via a patent foramen ovale (PFO). Transesophageal echocardiography was performed in a patient hospitalized in the ICU for pneumonia. He presented with refractory hypoxemia that was out of proportion to the underlying minor pulmonary process. Transesophageal echocardiography was obtained (multiplane transducer at 98 degrees) and showed the presence of a PFO with a significant right-to-left shunt caused by elevated right atrial pressure. Soon after contrast injection **(A)**, the bubbles are seen arriving in the right atrium (RA) from the superior vena cava (SVC). A few seconds later **(B)**, a complete opacification of the right atrium is reached, and the bubble contrast is clearly seen shunting through the PFO from the right atrium to left atrium (LA).

uncover a patent foramen ovale that would not have been seen otherwise. Right-to-left shunting also can be caused by the presence of pulmonary arteriovenous fistulas. These often are associated with end-stage liver disease (hepatopulmonary syndrome). With this type of shunt, contrast is seen to appear in the left atrium from the pulmonary veins instead of through the atrial septum; this finding is best detected by TEE, which usually permits visualization of all four pulmonary veins. The characteristic of intrapulmonary versus intracardiac shunt is that there is a longer delay (three to five cardiac cycles) for contrast to migrate from the right- to the left-sided cavities in the presence of an intrapulmonary shunt.[5]

Other types of intracardiac shunts also can be encountered in the ICU. After myocardial infarction, patients can develop cardiogenic shock resulting from acute development of a ventricular septal defect and resultant left-to-right shunt. Physical examination and invasive hemodynamic monitoring (pulmonary artery catheterization) sometimes can miss this diagnosis. Echocardiography reveals a disrupted ventricular septum with a high-velocity left-to-right shunt. This kind of shunt usually is well visualized without use of contrast. The diagnosis can be established by 2D and Doppler TTE in approximately 90% of cases.[134] Penetrating cardiac trauma is often associated with intracardiac and extracardiac shunts, and TEE is becoming the preferred tool for perioperative early identification of occult shunts.[14] Identification of these shunts is paramount in these critically ill patients, because missing them may lead to cardiac tamponade and rapid death. TEE has been shown to be superior to angiography and TTE to visualize these lesions.[135–137]

Unexplained Hypoxemia

Patent foramen ovale is present in 25%–30% of healthy individuals.[59,106] Usually it allows only minimal and intermittent right-to-left shunting. When the right atrial pressure is disproportionately increased and exceeds left atrial pressure, the patent foramen ovale can widen and significantly raise the importance of the right-to-left shunt, with resultant significant hypoxemia. In a critically ill patient, this increase in right-sided pressure can occur from pulmonary hypertension secondary to acute respiratory distress syndrome or pulmonary embolism, right ventricular failure (from infarction or pulmonary hypertension), or severe tricuspid regurgitation, which is often seen in the ICU for a variety of reasons. In critically ill patients, TEE is in general more useful than TTE for evaluation of patent foramen ovale, atrial septal defect (see Fig. E2.18), and pulmonary arteriovenous fistula[138] because of the close proximity of the lesion to the ultrasound transducer.

Patients with patent foramen ovale and persistent refractory hypoxemia despite ventilator and hemodynamic manipulation sometimes need to have catheter-based septal defect closure devices inserted. TEE is crucial to assist in the performance of this procedure.[139]

Source of Embolus

In the setting of acute unexplained stroke, echocardiography often is required to determine whether a potential embolic source of cardiac origin is present. TEE is the modality of choice for this purpose. Possible cardiac sources of emboli to the arterial circulation include left atrial or appendicular thrombus, left ventricular thrombus, thoracic atheromatosis, and right-sided clots (from right atrium, right ventricle, vena cava) combined with a right-to-left intracardiac shunt (leading to a paradoxical embolus). Cardiac tumors and vegetations are other potential sources of emboli from cardiac origin that must be considered.

When cardioversion is considered for a critically ill patient with atrial fibrillation or flutter, performance of TEE is helpful in evaluating the left atrium and appendage for the presence of thrombus (Fig. E2.19). If no intracardiac clots are documented, cardioversion can be performed with minimal embolic risks.

USE OF CONTRAST AND HARMONIC TECHNOLOGY TO ENHANCE TRANSTHORACIC EXAMINATIONS WITH POOR IMAGE QUALITY IN A CRITICALLY ILL PATIENT

Using standard echocardiographic methods, endocardial delineation is suboptimal in approximately 30% of cases.[140] However, two developments in ultrasound have improved the quality of endocardial border definition: harmonic imaging and IV contrast echocardiography.[141] Dramatic improvements in image quality have been achieved with the development of harmonic imaging. This technology exploits the formation of ultrasound signals that return to the transducer at a multiple of the transmitted (fundamental) frequency, referred to as the *harmonic frequency*.[1] Signals are received by the ultrasound transducer at twice the transmitted frequency. This "second harmonic imaging" results in images with better contrast between the myocardium and cardiac chambers and improved endocardial definition compared with fundamental imaging.[142–144] Most current ultrasound equipment includes harmonic imaging as a standard feature.

In critically ill patients with poor acoustic windows, endocardial visualization still may be inadequate despite the use of second harmonic imaging.[140] In these patients, contrast agents capable of producing left ventricular cavity opacification with an IV injection can be helpful in delineating endocardial borders. Several contrast agents are currently available that contain albumin microspheres filled with perfluorocarbon gas, allowing for the passage of contrast through the lungs with appearance of contrast in the left ventricle.[1] The chamber is opacified by the contrast agent within 1 minute of administration and

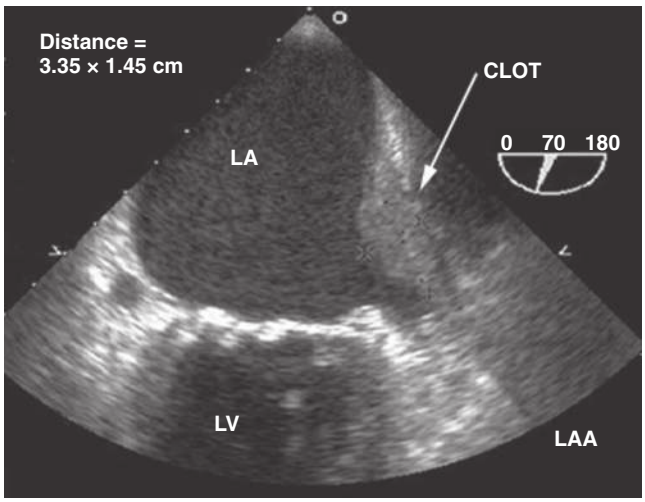

Fig. E2.19 Large clot in the left atrial wall and left atrial appendage (LAA). A 72-year-old patient hospitalized in the ICU for urosepsis developed rapid atrial fibrillation. She was initially anticoagulated and rate-controlled. Despite resolution of the septic picture, she remained in atrial fibrillation 4 days after its onset. The patient underwent transesophageal echocardiography before undergoing a planned electrical cardioversion. The midesophageal view with multiplane transducer at 70 degrees revealed the presence of a large clot (3.35 × 1.45 cm) in the posterolateral wall of the left atrium (LA) extending into the LAA. With these findings, the patient's anticoagulation regimen was intensified, and the cardioversion was not performed. *LV,* Left ventricle.

allows improved endocardial border detection. The presence of contrast also enhances Doppler signals.[145] Studies have examined the impact of these newer modalities of harmonic imaging and contrast in the ICU. Reilly and colleagues[146] assessed the benefits of contrast echocardiography for the evaluation of left ventricular function in 70 unselected ICU patients; 22 patients (31%) were receiving mechanical ventilation. Left ventricular EF could not be obtained at all in 23% of patients with standard imaging, but when harmonic imaging was employed, left ventricular EF was unobtainable in only 13% of patients. When contrast imaging was employed, left ventricular EF was measurable in all the patients. EF was confidently determined in 56%, 62%, and 91% of patients with standard imaging, harmonic imaging, and contrast imaging. In this study, contrast imaging was safe and dramatically improved the capacity to evaluate left ventricular EF and regional wall motion reliably compared with fundamental and harmonic imaging. Yong and colleagues[141] extended these observations by comparing the results of harmonic and contrast imaging with an independent standard (i.e., TEE) in 32 consecutive critically ill patients who were considered technically very difficult. Estimation of EF was possible in 31%, 50%, and 97% with fundamental imaging, harmonic imaging, and contrast imaging. Quantification of EF by contrast enhancement correlated best with TEE ($r = 0.91$).

In critically ill patients with suboptimal TTE image quality, contrast echocardiography combined with harmonic imaging provides a noninvasive and safe alternative to TEE for determination of regional and global left ventricular function (Fig. E2.20).[140] It is a rapid and simple technique that can be performed at the bedside in the ICU, with positive impact on interpretation of left ventricular function. Before using TEE, this technique should be considered in critically ill patients when simple TTE is inadequate for the evaluation of left ventricular function.[140]

COMPARISON BETWEEN BEDSIDE ECHOCARDIOGRAPHY AND PULMONARY ARTERY CATHETER IN THE INTENSIVE CARE UNIT

Since its introduction into clinical practice in 1970, pulmonary artery catheterization has been a standard hemodynamic monitoring technique for critically ill patients in the ICU.[147–149] Pulmonary artery catheterization provides clinicians with indices of cardiovascular function to assist in therapeutic decision making. Pulmonary artery catheterization can be a useful diagnostic tool, aiding in the management of critically ill patients. Nevertheless, misinterpretation of the data it provides can lead to excessive morbidity and mortality.[63,147,150,151] Conventional monitoring using a pulmonary artery catheter has been shown to be limited in the evaluation of global ventricular function,[19,21] and echocardiographic studies have established that pulmonary artery occlusion pressure often does not allow accurate assessment of left ventricular preload.[26,152,153] The frequent changes in ventricular compliance and loading conditions occurring in critically ill patients can affect systolic and diastolic function. In such cases, conventional monitoring does not enable early detection of acute changes in function, and it does not allow the clinician to discern systolic from diastolic changes.[19]

In critically ill patients, echocardiography, particularly TEE, has the ability to clarify diagnosis and define pathophysiologic process more precisely than pulmonary artery catheterization. In a prospective study of limited scope, Benjamin and colleagues[21] found that TEE-derived data disagreed with the pulmonary artery catheterization evaluation of intracardiac volume in 55% of cases and with the pulmonary artery catheterization assessment of myocardial function in 39% of cases. These authors also reported that the post–pulmonary artery catheterization therapeutic recommendations were different from the

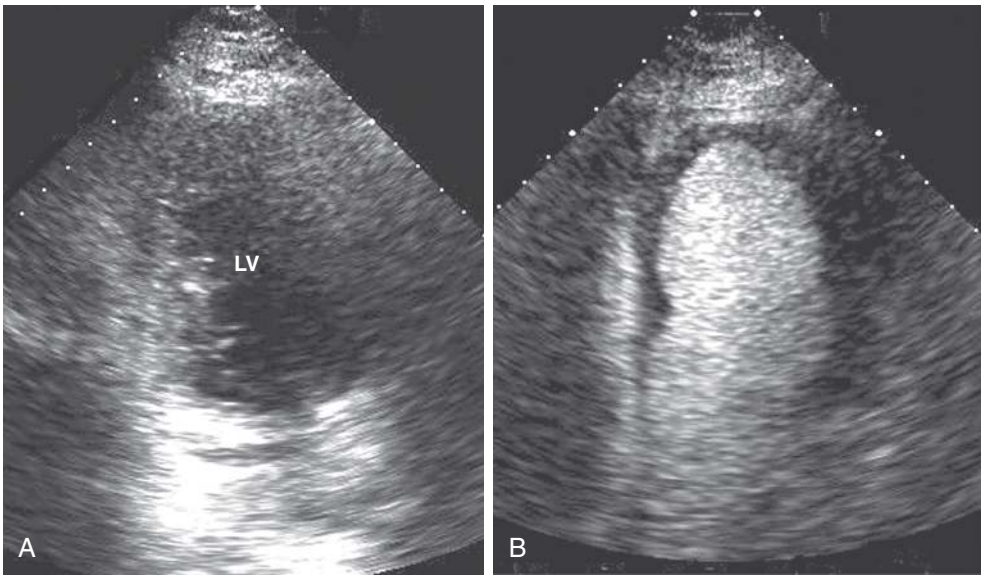

Fig. E2.20 Use of contrast agent to improve endocardial border delineation in a critically ill patient with suboptimal transthoracic image quality. A suboptimal transthoracic apical two-chamber view **(A)** of the left ventricle (LV) obtained from a ventilated ICU patient with hemodynamic instability. The poor endocardial resolution makes regional and global ventricular function hard to assess. Same transthoracic two-chamber apical view **(B)** in the same patient after contrast injection. A dramatic improvement in endocardial border definition is noted. Contrast echocardiography combined with harmonic imaging provides a noninvasive, safe alternative to transesophageal echocardiography for determination of regional and global left ventricular function.

post-TEE therapeutic recommendations in 58% of patients. In a retrospective analysis of 108 critically ill patients who underwent a TEE, Poelaert and colleagues[20] found that of 64% of patients with pulmonary artery catheterization, 44% underwent therapy changes after TEE (41% in the cardiac and 54% in the septic subgroup). Also, these investigators found that in 41% of patients without pulmonary artery catheterization, TEE led to a change in therapy. They concluded that TEE produced a change in therapy in at least a third of ICU patients, independent of the presence of pulmonary artery catheterization.[20]

Another significant advantage of echocardiography in the ICU is the speed with which it can be performed relative to pulmonary artery catheterization. In the study by Benjamin and colleagues,[21] TEE was performed in 12 ± 7 minutes versus 30 minutes or more for pulmonary artery catheterization insertion. In a study by Kaul,[154] the average time required to place a pulmonary artery catheter and record the data was 63 ± 45 minutes versus 19 ± 7 minutes to complete bedside TEE. Reported complications of pulmonary artery catheterization include pneumothorax, hemothorax, bacteremia, sepsis, cardiac arrhythmias, pulmonary artery rupture, cardiac perforation, and valvular damage.[21] Compared with pulmonary artery catheterization, bedside echocardiography has a better safety profile, as discussed previously in this chapter.

A major advantage of pulmonary artery catheterization versus TEE, however, is that the catheter can more easily serve as a continuous monitoring technique to assess the response to a therapeutic intervention.[21] Of course, this potential advantage may provide little benefit in patients in whom the information is misinterpreted or inadequate. In some ICUs, echocardiography has completely replaced pulmonary artery catheterization for assessment of circulatory status of mechanically ventilated patients.[38]

Despite having multiple limitations, pulmonary artery catheterization still has a role in the ICU and remains a useful diagnostic tool when used by physicians who have extensive experience with it.[20,155] A combination of invasive pressure monitoring and TEE probably offers the most complete bedside evaluation of morphology and intracardiac hemodynamics and provides a more precise pressure-volume evaluation of left ventricular and right ventricular function and filling.[20,22]

IMPACT OF BEDSIDE ECHOCARDIOGRAPHY ON DIAGNOSIS AND MANAGEMENT IN A CRITICALLY ILL PATIENT

Echocardiography often provides unexpected diagnoses in critically ill patients. Compared with TTE and invasive hemodynamic monitoring, TEE frequently provides different or additional information. This information often is important for adequate and optimal adjustment of therapy. Several studies have examined the impact of bedside echocardiography, particularly TEE, on the management of critically ill patients. Published studies have reported changes in management after TEE in 30%–60% of patients,[17,20,156,157] leading to surgical interventions in 7%–30%.[17,98,157,158] Impact varies depending on the type of ICU population being studied. Several studies have reported the clinical impact of urgent TEE in hemodynamically unstable patients.[157,159,160] In a prospective study of surgical ICU patients by Bruch and colleagues,[23] echocardiography altered management in 50 (43%) of 115 patients. Alterations in medical management induced by TEE included administration of fluids and initiation or discontinuation of inotropic agents, anticoagulants, or antibiotics. These findings are similar to those reported in patients in medical or coronary care ICUs.[10,158] In a retrospective study done by Colreavy and colleagues[8] of a mixed medical and surgical ICU population, TEE findings led to a significant change in management in 32% of all studies performed. In a prospective study by Heidenreich and colleagues[161] of 61 critically ill patients with unexplained hypotension, new diagnoses not made with TTE were made in 17 patients (28%), leading to surgical intervention in 12 (20%). Prospective randomized trials to study the ultimate impact of bedside echocardiography on mortality and morbidity in the ICU are needed. Such studies would be difficult to do, however, given the growing use and importance of this technology in the critical care setting.

OTHER APPLICATIONS OF BEDSIDE ULTRASONOGRAPHY IN THE INTENSIVE CARE UNIT

Central Line Placement

Central venous catheterization is performed frequently in critically ill patients. Placement of a central venous catheter is not without risk and can be associated with adverse events that are hazardous to patients and expensive to treat.[162–164] Complications can be seen in 15%–20% of cases.[165–167] As described in a review by McGee and Gould,[168] complications related to central venous line placement are most often mechanical (arterial puncture, local hematoma, hemothorax, pneumothorax), infectious (catheter colonization and related bloodstream infection), and thrombotic. Complications are influenced by patient factors (obesity, coagulopathy, previous failed catheterization), site of attempted access, and operator experience.[169] As previously reported, only approximately 38%–65% of patients are cannulated on the first attempt using a blind method.[170,171]

The use of ultrasound guidance during central venous catheterization has been well shown to reduce the risk of complications, mostly so for the internal jugular route. Ultrasound guidance also speeds catheter placement, decreases the number of attempts before successful placement, and improves the overall rate of successful placement. Ultrasound can be used to help localize and define the anatomy of the vein, with subsequent placement of the central venous catheter by the standard use of anatomic landmarks at the site identified by ultrasound, using the knowledge that a vein is patent and of adequate size. Ultrasound also can be used to provide real-time 2D ultrasound guidance to locate the vein and subsequently introduce the needle through the skin and into the vessel. Multiple studies have reported the superiority of ultrasound-assisted cannulation of the internal jugular vein in ICU patients, compared with the external landmark–guided technique.[170–172] Trials looking at ultrasound guidance after failure by the landmark method reported success rates ranging from 33% to 100%.[169,173–175] A meta-analysis[175] of the literature comparing guidance using anatomic landmarks only versus guidance using ultrasound for the placement of central venous catheters indicated that ultrasound guidance significantly decreases placement failure by 64%, decreases related complications by 78%, and decreases the need for multiple placement attempts by 40%. Data showing superiority of the ultrasound guidance technique are consistent and strong for the internal jugular vein approach, but less so for subclavian venous catheterization.[175–177]

Some patients can be identified in whom cannulation may be more difficult or in whom consequences of a complication could be more serious.[169] In these patients (Box E2.6), central venous cannulation may be laborious and risky, and ultrasound guidance should be considered. Hatfield and Bodenham[169] showed the benefit of portable ultrasound when central venous access was difficult. As suggested by this study and others,[178] ultrasound guidance is particularly beneficial when used in difficult cases or when a competent operator fails after a few attempts using surface landmarks.

BOX E2.6 Criteria for Difficult Central Venous Access

- Limited access sites for attempts (e.g., local infection, other catheters present)
- Difficult-to-identify surface landmarks (e.g., local swelling or deformity, severe obesity)
- Previous complications (e.g., pneumothorax, arterial puncture)
- Previous catheterization difficulties (e.g., multiple sites attempted, failure to gain access, >3 punctures at one site)
- Uncorrected coagulopathy (APTT >1.5×; INR >1.8; platelets <50,000/μL)
- Patient unable to tolerate supine position
- Known underlying vascular anomalies

APTT, Activated partial thromboplastin time; *INR,* international normalized ratio.

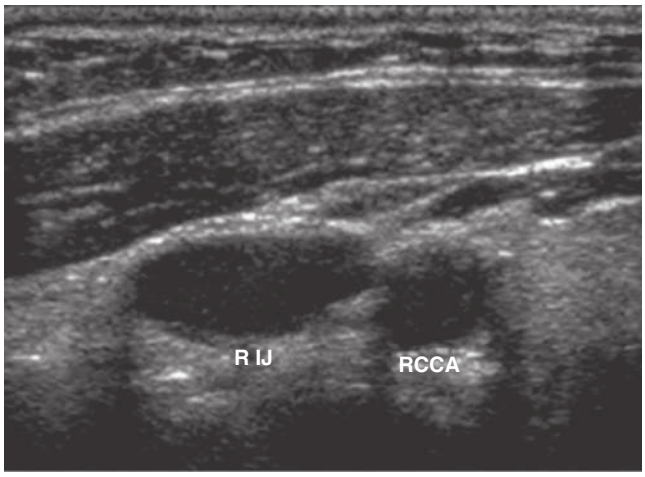

Fig. E2.21 Transverse view of normal anatomy of the right internal jugular (RIJ) vein and right common carotid artery (RCCA). Ultrasound examination helps determine the anatomic relationship, size, and patency of the vessels. Knowledge of these important vessel characteristics helps determine if the anatomy is suitable for central vein catheterization at a low risk. If the vessel anatomy is normal and the operator is experienced, subsequent venous catheterization can be done by the surface landmark technique or under real-time ultrasound guidance. If high-risk characteristics are identified (see Box E2.6), however, real-time ultrasound guidance (or selection of a different access site) would be preferred. (Courtesy Dr. Kurian Puthenpurayil.)

Ultrasound guidance is useful for operators with varying levels of experience.[169,175] The technique is easy to learn and can be self-taught with some practical assistance from radiologists or other experienced sonographers.[169,179,180] Familiarity with the anatomy and equipment is easy to obtain safely at the bedside.

Most large vessels that are catheterized usually can be imaged by ultrasound. Different types of ultrasound modalities can be used to help guide central vessel cannulation, including 2D ultrasound, Doppler transducer, Doppler with the probe in the needle, and fingertip pulse Doppler. With 2D imaging, fluid such as blood in vessels is black because there is nearly complete transmission of ultrasound.[169] Color Doppler mode helps delineate the flow patterns in vessels. Doppler-only equipment that provides no images has shown equivocal results in studies of vascular access.[176,181]

With 2D imaging, arteries are characteristically small, pulsatile, and difficult to compress with the probe.[169] Veins are usually larger, are nonpulsatile (except in the presence of severe tricuspid regurgitation), easily compressible, and distend when the patient is placed with the head down or when a Valsalva maneuver is performed.[169]

Vessels can be examined in the transverse and longitudinal views. The transverse view permits identification of the vein and arteries based on the sonographic characteristics mentioned earlier and clarifies their positions relative to one another (Fig. E2.21). The transverse and longitudinal views enable the sonographer to monitor in real time the passage of the needle through the skin and the anterior vessel wall. Ultrasound guidance also ensures detailed and accurate control of the needle (Fig. E2.22).[169]

During vessel examination, the sonographer specifically should assess the presence and patency of the vein (Fig. E2.23), the distensibility and compressibility of the vein, the position of the vein relative to the surrounding arteries (Fig. E2.24), and the presence of a thrombus in the vein (Fig. E2.25).[169] Ultrasound identification of certain anatomic characteristics such as small vessel size (<5 mm), intraluminal thrombus, and anterior location of the artery relative to the vein helps the physician identify unfavorable vessel anatomy and choose another catheterization site. A study by Levin and colleagues[182] indicated that 2D ultrasound guidance for the insertion of radial artery catheters was easy to use and increased the rate of success of insertion at first attempt. It was determined to be a useful adjunct to arterial catheter insertion. More studies are needed in the use of ultrasound for cannulation of peripheral arterial conduits.

Assessment of Pleural Effusions and Intraabdominal Fluid Collections

In critically ill patients, atelectasis and pleural effusions are frequent and often are present at the same time. Patients in the ICU are most often supine, and chest x-rays performed in this position offer limited sensitivity for the diagnosis of pleural effusion.[183] In many instances, neither atelectasis nor infiltration can be differentiated from pleural effusion. An alternative diagnostic method is needed to provide better results. Decubitus chest radiographs may show if fluid is free flowing, but this approach cannot localize or characterize the effusion precisely. CT of the chest shows the amount and distribution of fluid and is superior to plain lateral decubitus films. CT also can differentiate fluid from atelectasis and reveal information about the lung parenchyma. Chest CT requires transport to the radiology suite, however, which can be hazardous in unstable critically ill patients. Ultrasound examination of the pleural space has proved to be valuable for diagnosis of effusion.[184–188] The value of ultrasound for localizing fluid before catheter drainage or simple thoracentesis is well recognized. Ultrasound is especially valuable for localizing loculated or small effusions before a drainage procedure. In mechanically ventilated patients, blind thoracentesis can be hazardous, especially if the effusion is small or if the patient is on a high level of positive end-expiratory pressure.[189] Lichtenstein and colleagues[189] evaluated the feasibility and safety of ultrasound-aided thoracentesis in 40 mechanically ventilated patients. No complications occurred in the 45 ultrasound-aided thoracenteses, all performed by ICU physicians.

Basic skill required to detect a pleural effusion may be acquired in minutes and improves with experience.[190] In most instances, the pleural tap does not have to be done under real-time ultrasound guidance. A critically ill patient first must be positioned adequately on the back or on the side. Scanning of the pleural space is performed with the ultrasound probe. The probe must be oriented upward and downward, laterally and medially, and anteriorly and posteriorly so as to obtain a complete anatomic assessment of the area. The pleural fluid is usually hypoechogenic and appears black. The surrounding solid structures (soft tissue, diaphragm) and organs (lung, liver, heart, spleen) are visualized as structures with different degrees of echogenicity around the

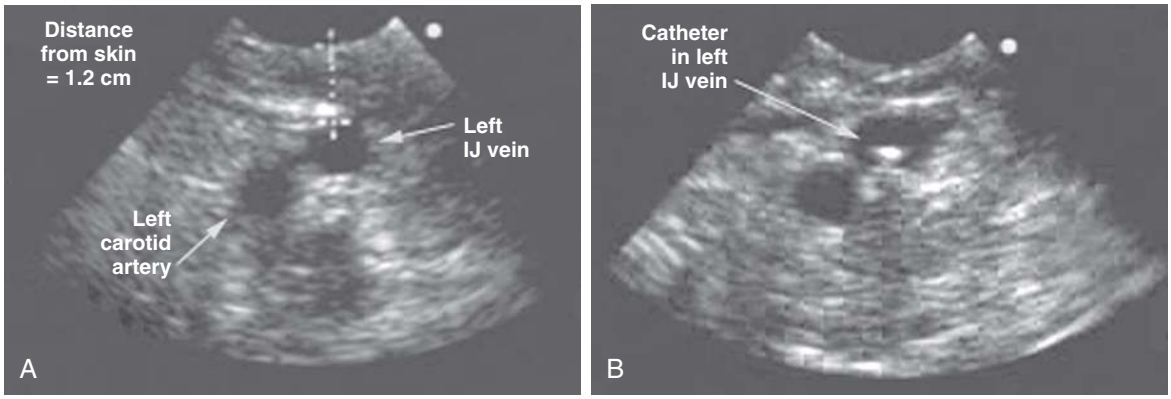

Fig. E2.22 Transverse view of left carotid artery and left internal jugular (IJ) vein. The distance from the skin to the anterior wall of the vein is measured before insertion of a central venous catheter **(A)**. Knowledge of this distance prevents the operator from going too deep with the needle when searching for the vein; this helps decrease the incidence of pneumothorax. After insertion, the catheter position in the jugular vein is confirmed **(B)**.

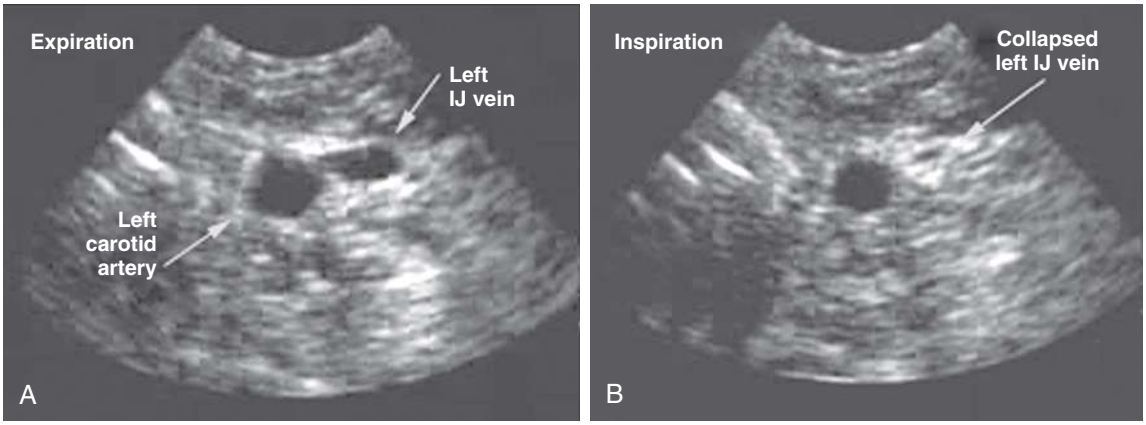

Fig. E2.23 Transverse view of the left carotid and internal jugular (IJ) vein in a spontaneously breathing patient sitting in bed at a 30-degree angle. The patient was febrile and dehydrated. A near-total collapse of the vein (which is of small caliber) can be appreciated on inspiration **(B)** compared with expiration **(A)**.

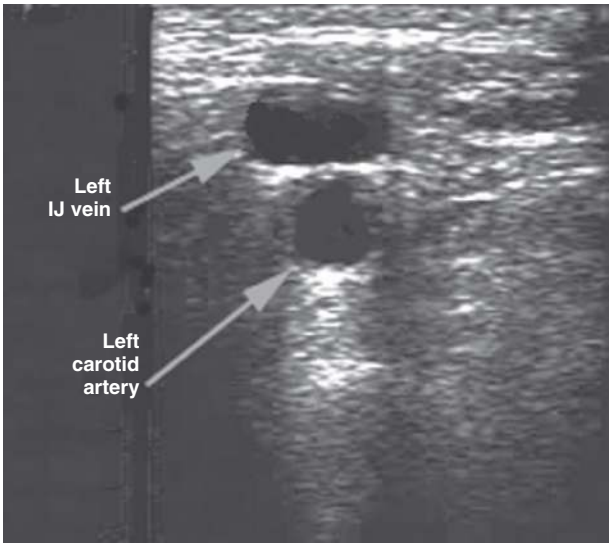

Fig. E2.24 Transverse view of left internal carotid artery and left internal jugular (IJ) vein. Notice the relative position of the jugular vein directly overlying the carotid artery. This type of anatomy is common on the left side and, when present, significantly increases the risk of procedure failure or arterial puncture.

effusion (Fig. E2.26). The presence of an aerated lung causes "airy artifacts." Ribs usually yield artifactual anechoic images. When the effusion has been well assessed, one must determine the feasibility of safely doing a thoracentesis. One must check for the absence of interposition of lung, heart, liver, or spleen during the respiratory cycle[189] to avoid puncturing these organs, which potentially can cause catastrophic complications. When an optimal and safe position for thoracentesis has been determined, the skin should be marked and disinfected, and the patient should remain in the exact same position as was used during the ultrasound examination. Optimally, the puncture should be done within seconds to minutes of the marking.

The same diagnostic and therapeutic procedures described earlier can be applied for intraabdominal fluid collections in a critically ill patient. Evaluation for intraabdominal fluid collection or abscess is restricted to areas that are not impeded by gas-filled structures[191] and include the regions around the liver and gallbladder, spleen, kidneys and lateral retroperitoneal areas, and pelvis around the uterus and bladder.[191] Fluid that does not change shape with probe pressure or patient positioning most likely represents a loculated collection.[191] Echogenic material and diffuse echoes on ultrasound within a fluid collection suggest the presence of particulate matter (e.g., fibrin or clots) and may represent an exudate or blood collection. As with pleural effusions, intraabdominal fluid collections can be percutaneously

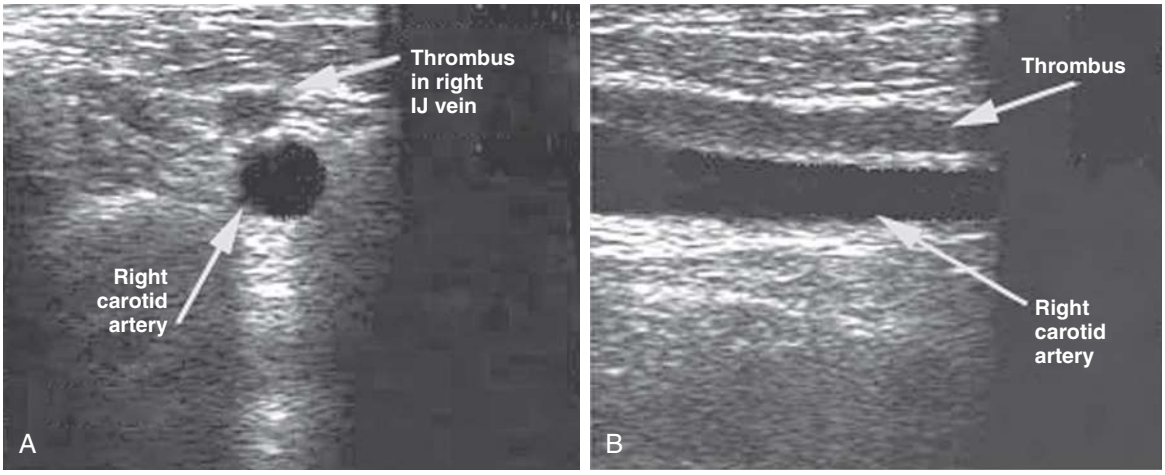

Fig. E2.25 Transverse **(A)** and longitudinal **(B)** views of the right carotid artery and right internal jugular (IJ) vein. Complete thrombosis of the right IJ vein can be appreciated. Notice the small caliber of the thrombosed vein and the increased echogenicity of the thrombotic material within it. The vessel could not be compressed by probe pressure.

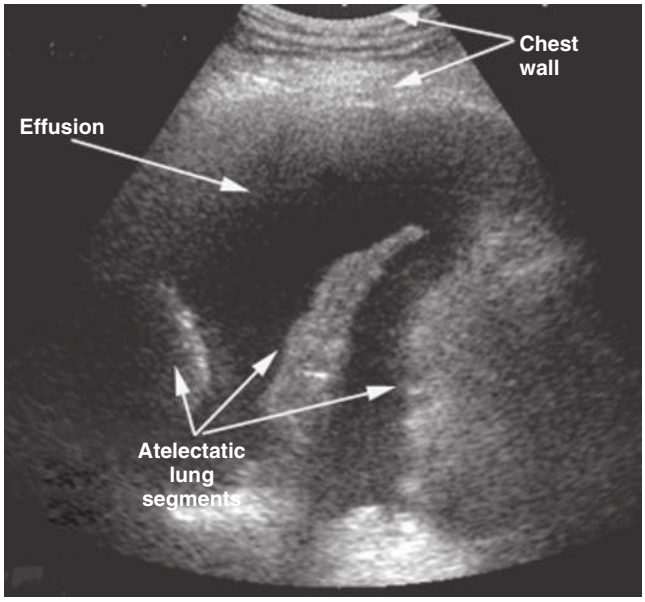

Fig. E2.26 Transverse view of a right pleural effusion. Collapsed atelectatic lung is well visualized "floating" in the effusion. (Courtesy Dr. Kurian Puthenpurayil.)

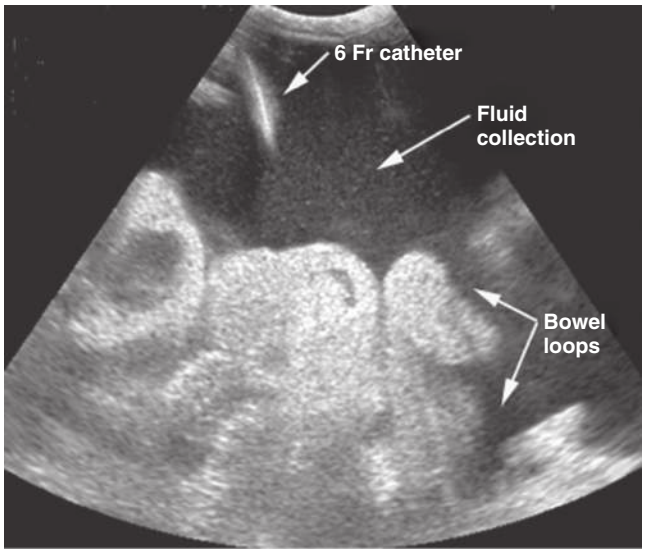

Fig. E2.27 Transverse view of a left lower quadrant abdominal collection. Echogenic, particulate material can be seen floating in the collection. Loops of bowel also are well visualized. A 6F catheter was inserted under ultrasound guidance to drain the collection, which was found to be chylous. Fluid collection with echogenic material and diffuse echoes on ultrasound are suggestive of particulate matter (e.g., fibrin or clots) and may represent an exudate or blood collection. (Courtesy Dr. Kurian Puthenpurayil.)

sampled or drained safely at the bedside under real-time ultrasound guidance (Fig. E2.27).

Urinary Bladder Scan

Bladder scanning devices are portable units that can provide a measurement of urine volume in the bladder (Fig. E2.28) and avoid bladder overdistention and reduce the need for unnecessary catheterization.[191,192] Studies have shown that frequent catheterization is a major risk factor for urinary tract infections that can be costly to medical centers.[193–195] Use of a portable bladder scanning device to reduce the incidence of nosocomial urinary tract infections was described by Moore and Edwards.[196] Bedside ultrasound assessment of volume in the urinary bladder also can be helpful to evaluate oliguria or anuria to rule out obstruction of the urinary catheter.

Focused Assessment of the Trauma Patient

Since the early 1990s, bedside ultrasound has been used in the United States as an additional diagnostic modality for use in determining the presence of intraabdominal injury after blunt trauma.[197] It is performed in the trauma bay during the secondary survey (as described in Advanced Trauma Life Support) or as part of the primary survey in hemodynamically unstable patients.[191,198–202] The focused assessment for sonographic examination of trauma (FAST) should be performed for a specific purpose, usually identification of hemoperitoneum, hemothorax, or tamponade.[191] FAST seeks to determine the presence of fluid in four areas: (1) the subxiphoid region in the pericardial sac,

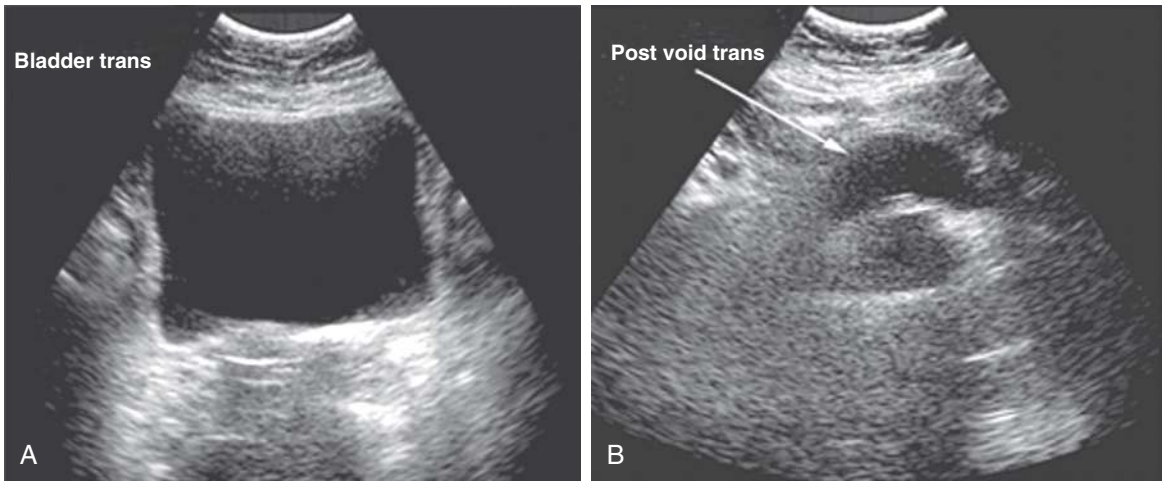

Fig. E2.28 Urinary bladder. Suprapubic transverse view of a full urinary bladder **(A)**. This "square" appearance of the bladder with a concave superior wall is typical of a moderately full bladder. When overdistended (i.e., in the presence of a low urinary tract obstruction), the bladder is large and adopts a round, globular shape (not shown). Suprapubic transverse view of an empty bladder **(B)**. When empty, the bladder can become small and commonly may be difficult to identify. (Courtesy Dr. Kurian Puthenpurayil.)

(2) the right upper quadrant in the Morison pouch, (3) the left upper quadrant in the splenorenal recess, and (4) the pelvis in the pouch of Douglas or rectovesical space (Fig. E2.29).[19] Because the FAST examination is noninvasive and quickly performed at the bedside, it is ideal for detecting intraabdominal injury in the resuscitation area. It has now been incorporated into the trauma resuscitation algorithm of most level I trauma centers in the United States.[191,203]

Use of the FAST examination has been shown to diminish the need for more invasive diagnostic measures such as diagnostic peritoneal lavage and subsequent exploratory laparotomy.[204,205] The FAST examination has been shown to be most accurate when performed for evaluation of hemodynamically unstable patients.[203,206–208] Studies have suggested that its use as a screening tool for blunt abdominal injury in hemodynamically stable trauma patients may result in underdiagnosis of intraabdominal injuries.[202,203,209]

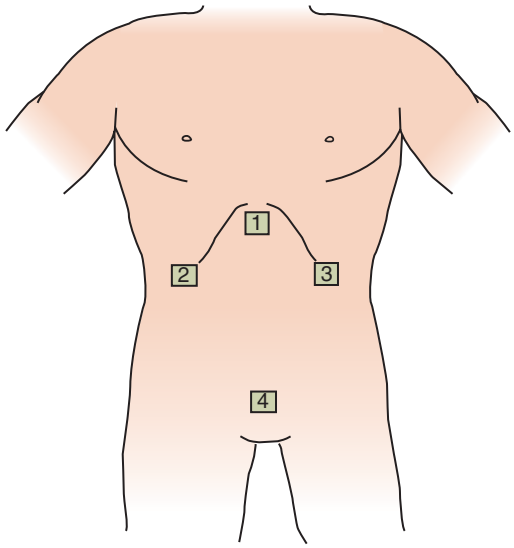

Fig. E2.29 Focused assessment for sonographic examination of trauma (FAST). The FAST examination seeks to determine the presence of fluid in four areas: (1) the subxiphoid region in the pericardial sac, (2) the right upper quadrant in the Morison pouch, (3) the left upper quadrant in the splenorenal recess, and (4) the pelvis in the pouch of Douglas or rectovesical space.

Intraaortic Balloon Counterpulsation

Bedside TEE may be helpful in different aspects of intraaortic balloon counterpulsation management. Before insertion, TEE can rule out the presence of significant aortic regurgitation, which would represent a contraindication to intraaortic balloon counterpulsation use. After insertion, TEE can confirm the position of the intraaortic catheter in the descending thoracic aorta, ensure correct functioning of the balloon (visualization of inflation and deflation), and rule out the presence of important complications of aortic catheter insertion (e.g., aortic dissection). TEE also may be used for monitoring of the ventricular function while separating the patient from the intraaortic balloon counterpulsation device.

Ventricular Assist Devices

Different complications are likely to occur after ventricular assist device implantation, such as bleeding and hemodynamic instability. Maintenance of ventricular assist device flow is a key indicator of the overall status of the system. In the postoperative period, low ventricular assist device flow is usually the result of hypovolemia and right ventricular dysfunction. TEE can be helpful for the diagnosis and monitoring of both of these conditions. Right ventricular failure has been shown to occur in approximately 20%–25% of patients being supported with an isolated left ventricular assist device.[210] With prosthetic circulatory support devices, there can be dramatic changes in ventricular volumes and hemodynamic conditions and substantial direct and indirect changes to the contralateral ventricle because of ventricular interactions. TEE can help the clinician monitor and understand these ventricular interactions.[211] It also can help assess adequacy of flow and the patency of the inflow and outflow cannulas to eliminate the presence of a thrombus and collapse or displacement of the cannulas. It also can motivate an urgent return to the operating room if a cardiac tamponade is diagnosed. If hypoxemia supervenes in the ICU, the presence of a patent foramen ovale has to be ruled out. For patients placed on extracorporeal membranous oxygenation

support, bedside TEE also can be used to monitor ventricular function during weaning of the circulatory assistance.

Performance of Bedside Ultrasonography by the Intensivist

In acute situations in the ICU, it may be difficult to have a cardiologist or sonographer available on immediate call on a 24-hour basis to perform a bedside ultrasound examination. The value of immediate bedside echocardiography for aiding in the diagnosis and management of acute hemodynamic disturbances has been well shown in the literature in the ICU and the emergency department.[212,213]

Ultrasound technologies are not exclusive to the radiologist or cardiologist. Appropriately trained emergency department physicians, surgeons, anesthesiologists, and ICU specialists have been using ultrasound devices with great success. Anesthesiologists were instrumental in many of the pioneering studies of TEE in the operating room and ICU.[4,22,214,215] Successful performance of bedside echocardiography by noncardiologist intensivists also has been well shown in the literature.[8,21,216] A study by Benjamin and colleagues[21] showed that a limited TEE examination performed and interpreted by intensivists (after training under the supervision of two cardiologists) is feasible and provides rapid, accurate diagnostic information that can have a dramatic impact on the treatment of critically ill patients.[21] The safety and utility of performance of bedside ultrasound by the intensivist for various other purposes in the ICU (central venous cannulation, thoracentesis, paracentesis) also have been well shown.[170–172,189]

With the increasing popularity of ultrasound devices—particularly lightweight, portable, handheld devices—there is controversy regarding the advisability and use of noncomprehensive "goal-directed" examinations performed by clinicians without cardiology or radiology training.[104] Studies with these portable devices that provide basic 2D and Doppler flow imaging showed they can provide important anatomic information[216–220] but that even in highly skilled hands, they may provide suboptimal imaging or diagnostic capabilities in the ICU.[218] Inappropriate interpretation or application of data gained by a poorly skilled user may result in adverse medical, ethical, and social consequences.[104] To avoid misusing the technology, adequate training is essential.

The era of a technology-extended physical examination[219] seems to have arrived, and there seems to be a role for a user-specific, focused ultrasound examination.[104,221] An examination said to be "targeted," "focused," and "limited" may often equate with "incomplete," "inadequate," or "inaccurate." Training must be individualized and tailored to specific needs, and appropriate user-specific application depends directly on the training and expertise of the user.[104] Provided that adequate expert backup is available, the training of intensivists in performing focused or more comprehensive bedside ultrasound examinations is not only feasible but also can be done safely and rapidly and yield information pertinent to the management of critically ill patients. General guidelines in training for TTE and TEE have been developed by the American Society of Echocardiography in association with the American Heart Association and the American College of Cardiology.[222] Since 1996 the American Society of Anesthesiologists and Society of Cardiovascular Anesthesiologists also have developed practice guidelines for perioperative TEE.[223] The importance of adequate training and subsequent maintenance of competence cannot be overemphasized; inappropriate use or misapplication potentially could temper the acceptance and limit the value of performance of bedside ultrasonography by the intensivist.

Training of intensivists and emergency department physicians in the performance of emergency bedside ultrasonography should facilitate acquisition of answers to clinical questions that may strongly affect medical and surgical management decisions. As has been mentioned by different authors,[190,224] training in echocardiography and general ultrasonography should be incorporated into the critical care fellowship, with special emphasis on TEE as part of the training program.

KEY POINTS

- As a result of improvements in transthoracic imaging, most ICU patients now can be adequately studied with TTE.
- TEE is particularly useful in the ICU for the assessment of unexplained hypotension, suspected aortic dissection, valvular vegetations, source of cardiac or aortic emboli, prosthetic heart valves (especially mitral), and detection of intracardiac shunts.
- The use of ultrasound guidance during central venous catheterization has been well shown to reduce the risk of complications, improve rapidity of catheter placement, and improve overall success of the procedure.
- Successful performance of bedside ultrasonography by intensivists in a limited examination has been shown to be feasible and potentially to provide rapid diagnostic information that can have a dramatic impact on the treatment of critically ill patients.
- Adequate training and maintenance of competence is crucial for the intensivist to perform bedside ultrasonography safely and efficiently, because inappropriate interpretation or application of data gained by a poorly skilled user may result in adverse consequences.

Central Venous Catheterization

Judith L. Pepe and Jennifer L. Silvis

BEFORE THE PROCEDURE

Indications

- Inability to achieve the clinical goal by peripheral intravenous catheterization
  - Relatively fast flow rate is required
  - Rapid, massive intravascular volume resuscitation
    3.5-inch, 8.5F introducer catheter offers the fastest flow rate. However, a 2-inch, 16-gauge peripheral catheter has a faster flow rate than the longer 16-gauge, centrally inserted triple-lumen catheter.
  - Peripheral venous access cannot be found
- Cardiopulmonary resuscitation and shock states
  - Peripheral catheters are often difficult to place in shock states
  - Drug administration is often more effective by central infusion
- Administration of agents irritating to peripheral veins
  - Concentrated potassium and sodium chloride solutions
  - Total parenteral nutrition solutions
  - Chemotherapy agents
  - Vasopressors and inotropes
- Central venous pressure monitoring
- Pulmonary artery pressure monitoring
- Transvenous pacemaker insertion
- Hemodialysis
- Plasmapheresis
- Venous access for frequent blood sampling or for measurements of central venous oxygen saturation ($ScvO_2$)
- Inferior vena cava filter placement
- Extracorporeal life support cannulation

Contraindications

- No absolute contraindications if experienced or supervised operator unless skin infection located at planned insertion site(s)
- Relative contraindications
  - Severe coagulopathy (including thrombocytopenia): Consider a femoral vein central catheter or peripherally inserted central catheter (PICC)
  - Local skin infection
  - Ipsilateral arteriovenous fistula
  - Ipsilateral venous thrombosis
  - Inferior vena cava filter: Avoid passing the guide wire beyond 20 cm during central line insertion from the jugular site in order to prevent entanglement

Equipment

- Ultrasound with small linear array probe (5–15 MHz)
- Sterile sheath, gel, and needle guide for ultrasound
- Catheter size and length appropriate for the site, side and indication (e.g., 16 cm for right internal jugular and right subclavian, 20 cm for left internal jugular or subclavian, single lumen, multilumen, 8.5F introducer)
- Insertion kit, including 10-mL syringes, needles, guide wire, suture material, and local anesthetic
- Sterile saline flush solution
- Sterile fenestrated barrier drape for head-to-toe patient coverage
- Four sterile towels
- 2% Chlorhexidine gluconate sterile prep stick
- Sterile gown and gloves for the operator and assistant(s)
- Cap to cover hair and mask with a face shield or protective glasses for the operator and assistant(s)
- Sterile central line dressing kit
- Shoulder roll (for subclavian vein catheterization)

Anatomy

The pertinent anatomy varies depending on the chosen site of central venous catheterization and is important to thoroughly understand, even when using ultrasound guidance. All relevant landmarks should be included in the sterile field. For internal jugular venous catheterization, identification of the triangle formed by the two heads of the ipsilateral sternocleidomastoid (SCM) muscle is imperative. It is also important to note the location of the angle of the mandible, the clavicle, and the sternal notch (situated between the medial ends of the right and left clavicles). The carotid artery pulse should be located and protected during placement of the needle tip into the internal jugular vein. For subclavian vein catheterization, the middle portion of the clavicle, insertion point of the clavicular head of the ipsilateral SCM muscle, and sternal notch should be identified. Femoral vein catheterization requires identification of the junction of the middle and distal third of an imaginary line drawn from the pubic tubercle to the anterior superior iliac spine to define the course of the inguinal ligament. The ipsilateral femoral arterial pulse should be located as well.

Ultrasound

Ultrasound should be used to facilitate internal jugular and femoral venous access if the equipment and expertise are available. Use of anatomic landmarks generally is the preferred approach for accessing the subclavian vein. Ultrasound guidance allows for a higher rate of first-pass success, reduced procedural time, and decreased complications. Ultrasound of the chosen site, which can be supplemented with the use of color Doppler, identifies surrounding structures, landmarks, and their spatial relationships with the targeted vessel. Color Doppler imaging can aid with distinguishing venous from arterial structures. Real-time, dynamic ultrasound guidance assists the practitioner in obtaining precise venipuncture and is preferred over using ultrasound merely

for static marking of the insertion site. Complete imaging of the guide wire tract is accomplished by following the wire from the point of skin insertion to venipuncture and visualizing the wire within the lumen of the vein in both short (cross sectional view) axes and long (longitudinal view). The short-axis view (Fig. E3.1) is obtained by placing the ultrasound probe perpendicular to the course of the targeted vessel. The long-axis view (Fig. E3.2) is then obtained by rotating the ultrasound probe 90 degrees.

Procedure

Internal Jugular Vein (Middle Approach)

- See Video E3.1.
- Obtain informed consent from the patient or surrogate decision maker.
- Gather all necessary equipment.
- Place the patient in the supine position.

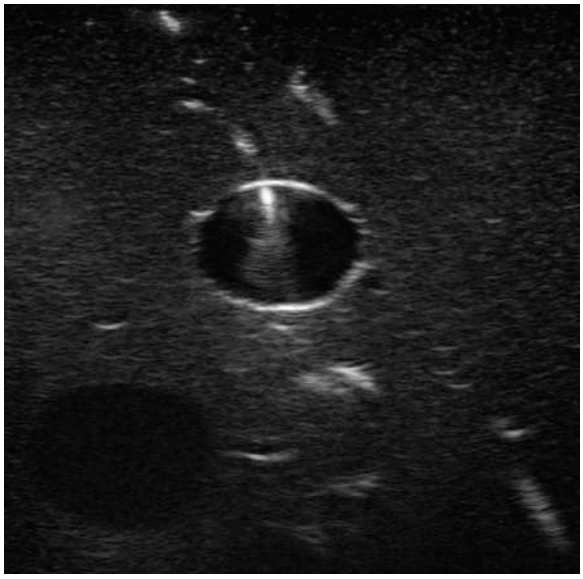

Fig. E3.1 Short-axis view demonstrating guide wire inside vein.

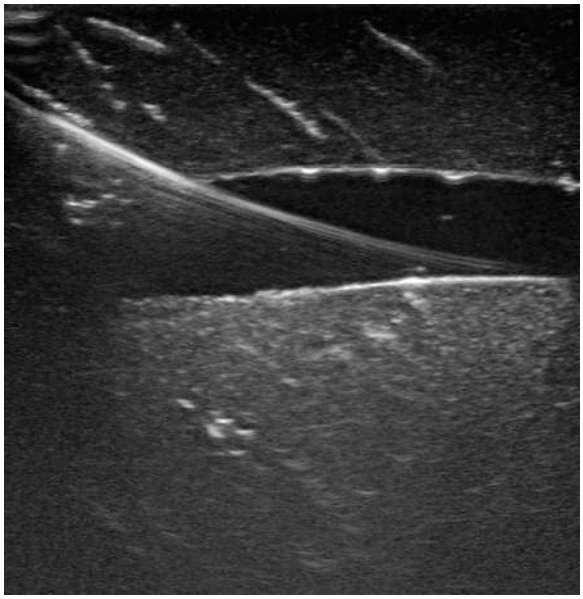

Fig. E3.2 Long-axis view confirming guide wire in vein.

- Position the bed at a comfortable height, with 15–30 degrees Trendelenburg.
- Rotate the patient's head away from the side of insertion.
- Perform a "time out" to verify patient, procedure, laterality, and consent.
- Perform nonsterile ultrasound to confirm the patency and depth of the internal jugular vein and the location of surrounding structures.
- Open the equipment using sterile technique.
- Wash hands and don a cap, face shield mask, sterile gown, and pair of gloves.
- Use a 2% chlorhexidine "prep stick" to prepare the area bounded by the ear lobe, mandible, chin, neck, and sternal notch past the midline; 2 cm inferior to the clavicle; and 2 cm posterior to the sternal head of the SCM muscle.
  - Preparing a wide area is preferred to facilitate conversion to the ipsilateral subclavian approach if the internal jugular approach proves unsuccessful.
- "Square off" (frame) the sterile area with four sterile towels.
- Place the head-to-toe fenestrated sterile drape.
- Place the ultrasound probe in a sterile sheath with gel, and position the correct needle guide on the probe.
- Find these anatomic landmarks: apex of the triangle formed by two heads of the SCM muscle, sternal notch, clavicle, and carotid pulse.
- Maintain awareness of anatomy while using ultrasound to guide needle insertion.
- Locate the internal jugular vein with the ultrasound probe in the short axis, and confirm that the vessel collapses easily with compression and is nonpulsatile.
- Inject local anesthetic into the skin and surrounding region at the proposed insertion site.
- Ensure that all materials needed for catheter placement are within easy reach on the sterile field.
  - Flush all catheter lumens, and then place caps on all ports except the distal port.
- Place the access needle with attached syringe onto the needle guide of the ultrasound probe.
- Advance the needle into the internal jugular vein under direct vision using ultrasound while applying gentle aspiration pressure on the syringe.
- Confirm the presence of the needle within the vein lumen by ultrasound imaging and by aspiration of free-flowing, nonpulsatile, venous-colored blood. Note that mild pulsations may be transmitted from the artery in close proximity.
- Remove the needle from the needle guide on the ultrasound probe.
- If ultrasound is unavailable, insert the needle at the apex of the SCM triangle (middle approach) and advance the needle toward the ipsilateral nipple at a 30- to 45-degree angle while applying gentle aspiration pressure on the syringe.
- Place the curved end of the guide wire through the syringe and/or needle into the vein. Never lose control of the distal end of the guide wire.
- Using ultrasound, confirm the course of the guide wire in the internal jugular vein in both the long and short axes.
- Remove the syringe and needle over the guide wire.
- Using a scalpel, make a small nick in the skin at the wire insertion site.
- Place a dilator over the wire, and advance the dilator into the soft tissues to establish a tract.
- Remove the dilator, leaving the guide wire in place.
- Place a catheter (single lumen or multilumen) over the wire into the vein:
  - 16 cm for the right internal jugular
  - 20 cm for the left internal jugular

- Remove the guide wire and place a cap on the distal port.
- Aspirate blood via all catheter lumens, and then flush each lumen with sterile saline.
- Secure the catheter to the skin with suture material.
- Place a sterile dressing.
- Clean up and safely discard all sharp objects into a "sharps" container.
- Order a chest x-ray to check catheter position.
  - Skilled operators may use ultrasound to confirm normal post-procedure lung sliding, assess for pneumothorax, and confirm catheter tip location.

Subclavian Vein (Infraclavicular Approach)

- See Video E3.2.
- Obtain informed consent from the patient or surrogate decision maker.
- Gather all necessary equipment.
- Perform a "time out" to verify patient, procedure, laterality, and consent.
- Place the patient in the supine position with the ipsilateral arm adducted.
- Place a shoulder roll under the patient, positioned vertically between the scapulae.
- Position the bed at a comfortable height, with 15–30 degrees Trendelenburg.
- Rotate the patient's head away from the side of insertion. Perform a time-out to verify correct patient, procedure, and consent.
- Open the equipment using sterile technique.
- Wash hands and don a cap, face shield mask, sterile gown, and pair of gloves.
- Use a 2% chlorhexidine prep stick to prepare the area bounded by the ear lobe, mandible, chin, neck, and sternal notch past the midline; 2 cm inferior to the clavicle; and 2 cm posterior to the sternal head of the SCM muscle.
  - Preparing a wide area is preferred to facilitate conversion to the ipsilateral internal jugular approach if the subclavian approach is unsuccessful.
- "Square off" (frame) the sterile area with four sterile towels.
- Place the head-to-toe fenestrated sterile drape.
- Find these anatomic landmarks: midportion of ipsilateral clavicle and sternal notch.
- Inject local anesthetic into the skin and surrounding region at the proposed insertion site.
- Ensure all materials needed for catheter placement are in easy reach within the sterile field.
  - Flush all catheter lumens and place caps on all ports except the distal port.
- Insert the needle (beveled edge in caudad direction) with attached syringe into the skin 2 cm inferior to the midportion of the clavicle, directing the needle slightly cephalad toward the clavicle in the direction of the sternal notch.
- "Walk" down the clavicle with the needle until it advances just deep to the inferior surface of the clavicle.
- While applying gentle aspiration pressure on the syringe, continue to advance the needle in the direction of the sternal notch until aspiration of free-flowing, nonpulsatile, venous-colored blood occurs, signaling entry into the subclavian vein.
- Introduce the curved end of a guide wire through the syringe and/or needle into the vein. Never lose control of the distal end of the guide wire.
- Remove the syringe and needle over the guide wire.
- Using a scalpel, make a small nick in the skin at the wire insertion site.
- Place the dilator over the guide wire, and advance the dilator into the soft tissues to establish a tract.
- Remove the dilator, leaving the wire in place.
- Place a catheter (single lumen or multilumen) over the wire into the vein.
  - 16 cm for the right subclavian
  - 20 cm for the left subclavian
- Remove the wire and place a cap on the distal port.
- Aspirate blood via all catheter lumens, and then flush each lumen with sterile saline.
- Secure the catheter to the skin with suture material.
- Place a sterile dressing.
- Clean up and safely discard all sharp objects into the "sharps" receptacle.
- Order a chest x-ray to check the catheter position.
  - Skilled operators may use ultrasound to confirm normal lung sliding and to assess for pneumothorax and catheter tip location

Femoral Vein

- Obtain informed consent from the patient or surrogate decision maker.
- Gather all necessary equipment.
- Perform a "time out" to verify patient, procedure, laterality, and consent.
- Place the patient in the supine position with the ipsilateral thigh in slight abduction.
- Reverse Trendelenburg position may assist vein visualization and access in hypovolemic shock.
- Perform nonsterile ultrasound to confirm patency and depth of the femoral vein and the location of surrounding structures.
- Open the equipment using sterile technique.
- Wash hands and don a cap, face shield mask, sterile gown, and pair of gloves.
- Use a 2% chlorhexidine "prep stick" to prepare an area bounded by the lateral midthigh, medial midthigh, and pubis in the midline, extending 2 cm superior to an imaginary line connecting the pubis and anterior superior iliac spine.
- "Square off" (frame) the sterile area with four sterile towels.
- Place the head-to-toe fenestrated sterile drape.
- Place the ultrasound probe into a sterile sheath with internal conducting gel and position the correct needle guide on the probe.
- Find these anatomic landmarks: pubic tubercle, anterior superior iliac spine, and femoral artery pulse.
- Inject local anesthetic into the skin and surrounding region at the proposed insertion site.
- Ensure that all materials needed for catheter placement are in easy reach within the sterile field.
  - Flush all catheter lumens and place caps on all ports except the distal port.
- While applying gentle aspiration pressure on the syringe under ultrasound guidance, insert the needle at a 90-degree angle into the skin medial to the femoral artery pulse in a short-axis ultrasound view.
  - The femoral vein will be located caudal to the junction of the middle and medial thirds of an imaginary line drawn from the pubic tubercle to the anterior superior iliac spine.
- Continue to apply gentle aspiration pressure to the syringe during needle advancement under ultrasound guidance until the needle is present within the vein on ultrasound and a return of free-flowing, nonpulsatile, venous-colored blood is present.
- Place the curved end of the guide wire through the syringe and/or needle and into the vein. Never lose control of the distal end of the guide wire.

- Using ultrasound, confirm the presence of the guide wire in the femoral vein in both the short and long axes.
- Remove the syringe and needle over the guide wire.
- Using a scalpel, make a small nick in the skin at the wire insertion site.
- Place the dilator over the guide wire, and advance the dilator into the soft tissues to establish a tract.
- Remove the dilator, leaving the guide wire in place.
- Place the catheter (single lumen or multilumen) over the guide wire into the vein.
- Remove the wire and place a cap on the distal port.
- Aspirate blood via all lumens, and then flush each lumen with sterile saline.
- Secure the catheter to the skin with suture material.
- Place a sterile dressing.
- Clean up and safely discard all sharp objects into the "sharps" receptacle.

AFTER THE PROCEDURE

Postprocedure Care

- Obtain a chest x-ray.
  - To confirm the location of the internal jugular and subclavian venous catheter tip at the atriocaval junction
  - To rule out the presence of a hemothorax, pneumothorax, or apical cap
- Inspect the catheter insertion site daily to detect the development of infection.
- Monitor for arrhythmias, as catheter migration may occur.
- Maintain proper local dressing care to minimize complications.
- Access all ports in a sterile manner at all times.

Complications

- Common
  - Cardiac arrhythmias
  - Arterial puncture
  - Hematoma
  - Catheter malposition
  - Venous thrombosis
  - Catheter-related bloodstream infection
- Infrequent
  - Pneumothorax
  - Hemothorax
  - Chylothorax (thoracic duct injury)
    More common with left internal jugular or subclavian vein catheterization
  - Local nerve injury
  - Entanglement with vena cava filter
  - Tracheal perforation
  - Endotracheal tube cuff rupture
- Serious, rare complications
  - Air embolus
  - Cardiac tamponade

Outcomes and Evidence

- Femoral vein catheters have a higher incidence of infectious and thrombotic complications compared with subclavian vein catheters.
- Lowest infection rates are associated with subclavian vein catheters.
- Infection of central venous catheters is diminished by paying careful attention to sterile insertion technique.
- Antibiotic-treated, noncuffed central venous catheters are associated with a lower rate of device-related bloodstream infection than nontreated catheters but a higher rate when compared with PICCs.
- Use of ultrasound to guide insertion is beneficial in reducing mechanical complications and in improving rates of successful cannulation, especially when accessing the internal jugular and femoral vein or when the operators are inexperienced in the mechanics of the procedure.
- For many purposes, PICCs may be more cost-effective and have lower complication rates than centrally inserted venous catheters.
- Deep venous thrombosis caused by PICCs may relate to catheter diameter.

Arterial Cannulation and Invasive Blood Pressure Measurement

Phillip D. Levin and Yaacov Gozal

Peripheral artery cannulation is one of the most commonly performed invasive procedures in the intensive care unit (ICU),[1] and the resulting arterial line is an integral part of intensive care patient management. Arterial line usage varies according to unit type, patient age, and severity of illness, ranging from approximately 22% of medical ICU patients to over 50% of surgical ICU patients. There are three main indications for arterial line insertion: (1) to allow continuous beat-to-beat monitoring of blood pressure; (2) to provide pain-free, convenient, and repeated access to arterial blood for the assessment of pulmonary and cardiovascular function (including measures of pulse pressure variation and semi-invasive cardiac output measurements using transpulmonary thermodilution); and (3) to provide a source of blood for blood tests as required without the need for repeated venipuncture, including continuous measures of blood chemistry (such as continuous glucose measurement). A review of the relevant anatomy, equipment, and techniques for arterial line placement is provided in this chapter along with some of the more common complications.

SITES OF INSERTION

An arterial line can be inserted into almost any palpable peripheral artery. The most common sites in clinical practice are the radial artery (employed in up to 78% of ICU patients), the femoral artery (employed in up to 45%), and the dorsalis pedis artery. Axillary and ulnar artery cannulations are performed somewhat more rarely; brachial and temporal artery cannulation is not recommended. Cannulation of the carotid arteries is absolutely contraindicated for obvious reasons. Each arterial site has advantages and disadvantages.

The Radial and Ulnar Arteries

The radial artery originates in the antecubital fossa at the level of the neck of the radius as a terminal branch of the brachial artery. The artery runs down the length of the forearm laterally. For the distal part of its course, it is covered only by fascia and skin and lies above the radius, where it is easily palpated. At the level of the wrist the artery winds laterally around the radius and enters the posterior aspect of the hand. It terminates by dividing into the superficial and deep palmar arches, which are anastomosed with the ulnar artery. The radial artery lies near the superficial branch of the radial nerve in its distal course.

The ulnar artery is the other terminal branch of the brachial artery, also originating in the antecubital fossa at the level of the radial neck. It is usually larger than the radial artery. The ulnar artery runs medially along the length of the forearm. As opposed to the radial artery, for most of its course the ulnar artery lies deep to the muscles of the forearm, becoming superficial only toward the wrist. The ulnar artery lies close to the ulnar nerve in its distal course.

When compared with the ulnar artery, the radial artery is superficial for a longer part of its course, is easily palpated above the radius, and is less closely associated with neural structures. It is, however, a smaller artery. The radial artery is cannulated within a few centimeters of the anterior wrist creases, where it lies conveniently over the radius.

Advantages

Advantages of radial artery cannulation include huge experience and safety, peripheral position, double blood supply to the dependent territory (by the ulnar artery), and easy compression in the event of bleeding.

Disadvantages

Disadvantages include technical difficulties because of the small size of the vessel or vasoconstriction (the radial artery pulse may not be palpable when blood pressure is less than 80 mm Hg) and inaccurate blood pressure measurements (when compared with the central circulation).

The modified Allen test has been proposed as a screening tool before radial artery cannulation to ensure the presence of adequate distal collateral circulation. The Allen test has, however, been found to have high interobserver variability and to lack sensitivity and specificity.[2] It is not widely used. Radial artery catheterization for coronary angiography has been compared in patients with normal and abnormal Allen tests with no significant adverse events occurring in patients with an abnormal Allen test.[3] It might be prudent, however, to avoid insertion of an arterial catheter into the radial or ulnar artery when the other artery is known to be absent or occluded.

Positioning for Cannulation

The forearm should be supine and the wrist slightly extended and supported (Video E4.1).

The Axillary and Brachial Arteries

The axillary artery is a continuation of the subclavian artery, beginning at the outer border of the first rib. The artery is surrounded by the cords of the brachial plexus. Its position relative to the other structures

of the axilla varies according to the position of the arm. The artery ends at the inferior border of the teres major muscle, where it becomes the brachial artery. The brachial artery runs down the upper arm to the elbow. Initially, it is medial to the humerus, but distally it spirals anteriorly to end as the radial and ulnar arteries approximately 1 cm distal to the elbow. The brachial artery lies near the ulnar and median nerves in its proximal course and near the median nerve in its distal course.

Advantages

The axillary artery is a large artery, and pressure measurements reflect the central circulation.

Disadvantages

The arm position required for axillary artery cannulation may be contraindicated or difficult for some patients. Care should be taken if a long catheter is used, because its tip might be proximal to the origin of the brachiocephalic artery/left common carotid artery. In this case embolic material from the line (i.e., air bubbles or thrombus) could be introduced into the brain. The risk of line infection may also be higher relative to other sites.

Positioning for Cannulation

For axillary artery cannulation, the arm should be bent at the elbow and raised above the head (abducted and flexed to 90 degrees). The pulse can then be palpated in the axilla.

The brachial artery is punctured where it is palpable medially on the anterior aspect of the elbow. Generally, cannulation of the brachial artery is not recommended, because it is associated with specific and potentially severe complications (see later). Despite this, large case series with low complications rates have been published.[4]

The Femoral Artery

The femoral artery originates as a continuation of the external iliac artery at the level of the inguinal ligament. At the level of the inguinal ligament, it lies midway between the anterior superior iliac spine and the symphysis pubis. Distal to the inguinal ligament, the artery lies medial to the femoral nerve and lateral to the femoral vein and is superficial, being covered only by fascia, fat, and skin. The femoral artery runs down the thigh and terminates as the popliteal artery in the knee.

Advantages

The femoral artery is a large artery that is easier to locate and puncture than the radial artery. Blood pressure measurements reflect central blood pressure, and the femoral artery is palpable at a lower blood pressure than the radial artery. The femoral arterial line has a lower rate of catheter malfunction and greater longevity (compared with the radial artery).

Disadvantages

In obese subjects, adipose tissue and skin folds may create difficulties in the approach to the groin. The skin over the puncture site also can be compromised by chronic inflammatory changes or fungal infections, and the artery itself may be very deep and difficult to locate. The insertion site also may be difficult to keep clean and well dressed. The risk of hemorrhage into the retroperitoneal space (which may initially be undetectable clinically) is unique to this site. Hemorrhage (either retroperitoneal or percutaneous) is also a risk when removing femoral artery catheters, particularly in patients with deranged clotting. The femoral artery is a common site for vascular surgery in the leg, and this represents a strong relative contraindication to arterial cannulation.

Position for Cannulation

In a supine patient, assistance may be required in retracting abdominal and thigh adipose tissue to allow access to the groin.

Dorsalis Pedis

The dorsalis pedis artery begins anterior to the ankle as a branch of the anterior tibial artery. The artery runs distally in the foot between the tendons of the extensor digitorum longus and extensor hallucis longus. It terminates as it turns in to the foot toward the sole between the first two metatarsal bones. During its course over the foot the artery is covered only by fascia and skin and is easily palpable.

Advantages

The dorsalis pedis is an easily accessible, compressible small artery.

Disadvantages

This artery is the most distant from the central circulation. Vasoconstriction can affect the quality of the arterial signal. In addition, the distance from the central circulation may result in an artificially elevated systolic pressure reading that is caused by interaction of the arterial pressure wave on smaller and smaller arteries.

Position for Cannulation

The foot is placed in a neutral position with slight extension of the ankle.

Additional Considerations

From this discussion of relative anatomy, the features of the arteries commonly used for monitoring become clear: all are superficial, covered only by fascia and skin, easily palpable, and easily compressible. The specific artery chosen for insertion of an arterial line should be influenced by the experience of the operator, ease of palpation, contraindications, and limitations in positioning.

After adequate positioning, the chosen arterial line insertion site should be cleaned and sterilized with a solution containing >0.5% chlorhexidine in 70% alcohol. For femoral or axillary artery insertion, maximum sterile barrier precautions should be used—cap, mask, sterile gown, sterile gloves, and full body sterile drapes. For insertion of peripheral artery cannulas, the operator should, at a minimum, don a cap, mask, and sterile gloves and use a small sterile fenestrated drape at the insertion site.[5] Local anesthesia (approximately 1 mL of 1%–2% lidocaine *without epinephrine*) should be infiltrated around the insertion site using a small-gauge (24- to 26-gauge) needle. Epinephrine should be avoided as an additive to the local anesthetic in order to prevent arterial spasm.

EQUIPMENT

Before actually inserting the arterial cannula, the monitoring equipment, cables, arterial line setup, and adhesive tape/sutures should all be prepared and checked. Beyond the arterial cannula, the arterial line setup consists of noncompliant tubing; three-way taps (stopcocks), a pressure-transducing device, a flush system, and the monitor. The arterial cannula is connected to a short length of tubing and then to at least one three-way tap. This tap is used for blood sampling and may also be used for zeroing the setup. The three-way tap is, in turn, connected to the pressure-transducing device, which is connected to the monitor. The pressure transducer is also connected to the flush system. The flush system consists of a bag of intravenous fluid under pressure from which all air has been removed. The fluid bag is compressed to a pressure greater than the arterial pressure using a pressure bag or cuff. The flush system maintains a continuous but slow (3 mL/h) flow of fluid

through the system and into the artery to maintain cannula patency. The arterial line system may include additional three-way taps, connections to other pressure monitoring sites (e.g., central venous pressure), and damping devices as required.

Sets for Arterial Cannulation and Insertion Technique

A multiplicity of arterial cannulation sets exists, falling into three main groups: sets based on a cannula-sheathed needle (equivalent to the normal intravenous catheter) with or without an additional wire, sets based on the Seldinger technique, and sets used for direct arterial cutdown techniques.

The simplest technique for arterial line insertion employs a 20-gauge catheter-over-needle arrangement. A simple 20-gauge intravenous cannula can be used, although catheters specifically made for arterial puncture are available. Such a catheter is suitable for the smaller arteries (radial or dorsalis pedis). After appropriate positioning, the patient's pulse is palpated with the nondominant hand and the cannula inserted at an angle of 45–60 degrees to the skin and into the artery using the dominant hand. The cannula and needle may be advanced until blood flashback is seen in the needle, and then the cannula is threaded into the artery (in a manner similar to intravenous insertion). Alternatively a through-and-through technique can be employed. In this technique, the needle and cannula are inserted directly through both the front and back walls of the artery without seeking blood flashback. The needle is withdrawn partially or fully from the cannula. The cannula is then slowly drawn back until the blood flashback is seen and subsequently threaded into the artery. In the event that blood flashback is not seen, the needle should not be reinserted into the cannula because it may perforate the side or cut off a distal segment.

Occasionally, difficulty may be found in inserting the cannula despite good backflow of blood through it. In this circumstance, the arterial line wire may be of use. The wire fits through the cannula (after the needle has been removed) and may be manipulated into the artery. The wire need only be inserted a few centimeters beyond the catheter tip (into the artery), and the cannula can then be threaded. As a precondition to wire insertion, good backflow of blood must be noted through the cannula, and under no circumstances should the wire be inserted with force, because this can lead to perforation or dissection of the artery.

Some cannula-over-needle sets include a wire that is preconnected to the needle/cannula apparatus. These sets are available for both smaller and larger arteries and represent a combination of the guide wire and Seldinger techniques. The artery is punctured by one of the techniques described earlier using the needle and cannula assembly. Blood flashback is seen in the tube housing the wire. Once blood is seen to return, the wire is advanced through the needle while it is still (at least partially) within the cannula and into the artery. The cannula is then advanced over the wire into the artery.

For larger or deeper arteries (femoral and axillary), sets based on the Seldinger technique are available. Using this technique, the artery is punctured with a needle, the wire is inserted through the needle, the needle is removed, and the catheter is inserted over the wire. This differs from the wire technique described earlier, because the wire is inserted through the needle, and then the needle is removed before the cannula is inserted.

Arterial cannulation can be very challenging, especially in patients with severe peripheral vascular disease or low blood pressure. Under these circumstances, additional equipment may be required to help locate the artery. Both Doppler and ultrasound probes may be useful.

The Doppler probe provides an auditory signal corresponding to blood flow. The characteristic arterial pulse form is easily distinguished from venous blood flow. The point of maximal Doppler response lies directly above the artery and may help in directing the needle to localize the artery.

By using ultrasound with a high-frequency probe the artery may be visualized. On short axis it is seen as a pulsating echogenic (white) ring on cross section. The arterial catheter needle can also be seen on ultrasound (as a straight echogenic line) and can thus be directed into the artery. Needle insertion can be performed either out of plane using the short-axis image or in-plane using the long-axis view. Two recent meta-analyses demonstrated that use of ultrasound increases the chances of first-time success and decreases the time required for insertion.[6,7]

Cutdown techniques are rarely required in adults. This issue for pediatric patients is addressed in Chapter 228.

Once inserted, the arterial cannula should be well fixed to the patient to prevent accidental removal and connected to the flush/pressure transduction system. Consideration can be given to using a sterile semipermeable dressing to cover the insertion site with the addition of adhesive tape. Once the presence of an adequate waveform on the monitor has been confirmed, the next step is to zero the system.

Zeroing

The importance of accurate zeroing cannot be overstated—zeroing problems reflect one of the most common sources of error in pressure-transduction systems. Zeroing has two main functions: the first is to equilibrate the monitor, and the second is to correct for the contribution of the fluid column in the pressure-transduction system between the patient and the pressure transducer.

The pressure transducers in use today are rugged, inexpensive, and accurate. They convert pressure applied from the artery via the fluid-filled tubing to the transducer into electrical energy. The electrical signal generated by the transducer is then amplified in the monitor to produce a waveform on the screen and a numeric measure of blood pressure. The conversion of mechanical pressure into an electrical signal requires an "excitation voltage" to be provided by the monitor to the transducer. The standard responsiveness of the transducer is 5 μV/V excitation voltage/mm Hg, and atypical excitation voltage is 6 V. Therefore the pressure transducer produces 30 μV/mm Hg pressure applied from the artery. Typically, this signal is amplified 1000 times by the monitor, so that for each 100 mm Hg of blood pressure, the monitor output is 3 V. Before their first use, and periodically during their use, the interaction of the excitation current, the transducer response, and the monitor amplification requires resetting—in the first instance to standardize the system and thereafter to compensate for any drift. This calibration is achieved by zeroing or standardizing the measurement to atmospheric pressure, which thereafter is the zero reference point for further measurement. With current semiconductor equipment, calibration to a mercury manometer is not required.

The arterial line is zeroed by exposing the pressure transducer to atmospheric pressure, for example, by turning one of the three-way taps such that it is closed to the patient and the transducer is open to room air. The zero procedure is activated on the monitor and the system left untouched for a few seconds until a flat line appears on the arterial monitor tracing and the monitor reads zero. The three-way tap is then closed to air and opened to the patient, and blood pressure can be measured. The zero point (the three-way tap used for zeroing) can be near to the patient or near to the transducer. It is important to consider that the pressure measured by the monitor will represent the patient's arterial pressure plus any contribution made by the column of fluid in the pressure tubing between the patient and the zero point.

To illustrate this point, consider the change in pressure reading if the pressure transducer is lowered by 100 cm to the floor. In addition to the patient's blood pressure acting on the pressure transducer, a column of water 100 cm long is present and contributes to the pressure

reading. The blood pressure reading is in millimeters of mercury, so it will increase by 100/1.36, or by 73 mm Hg. If the pressure transducer is raised relative to the patient, then the pressure recorded by the monitor will decrease in a similar manner. Appropriate zeroing of the pressure transducer can compensate for these differences. Continuing the example provided earlier, while the transducer is 100 cm lower than the patient, the three-way tap near the patient's radial artery is closed to the artery and opened to room air. The monitor is rezeroed. Now the zero incorporates the contribution made by the 100-cm column of water in the tubing, and when the arterial pressure is measured again, it will once more be accurate. Although this example is extreme, smaller changes in relative position are common; the transducer is attached to the patient at the level of the shoulder while supine. The patient is subsequently repositioned from supine to sitting. The shoulder is raised by 20 cm relative to the femoral artery, and the pressure recorded on the monitor decreases by 20/1.36 = 15 mm Hg. This change might not cause a change of therapy if arterial pressure is being measured. However, if intracranial pressure (ICP) is being measured, for example, a 15 mm Hg inaccuracy in the measurement could be critical. By convention, for arterial pressure measurement, the zero point is set at the height of the right atrium (i.e., the midaxillary line in the supine patient).

Damping

Another potential source of error in the measurement of blood pressure using the arterial line results from the interaction between the arterial pressure wave and the physical properties of the arterial line setup. This interaction can lead to underdamping (resonance or overshoot) and a spuriously high blood pressure reading or overdamping with a spuriously low blood pressure.

The arterial pulse waveform can be described as a summation of component sine waves with frequencies that are mainly in the range of 3–5 Hz. The arterial line set tubing has a natural frequency that is usually greater than 20 Hz. If the natural frequency of the arterial line set is decreased, it can approach the component frequencies of the arterial pulse waveform, and resonance may occur or increase, resulting in underdamping. Resonance/underdamping modulates the pressures measured. The main effect will be an increase in the recorded systolic blood pressure. A decrease in the recorded diastolic blood pressure may also occur, whereas, typically, mean blood pressure will not be affected. Perhaps the most common cause of underdamping is the use of an excessive length of pressure tubing between the arterial insertion site and the pressure transducer. Underdamping also may be a problem when measuring central arterial pressures and in the presence of severe vasoconstriction.

Overdamping decreases the transfer of energy from the artery to the pressure transducer. It results from the absorbance of energy by the fluid contents of the arterial set tubing and the tubing wall itself and from the friction between them. Damping is quantified by the damping coefficient (zeta), a measure of the time required for the system to come to rest after activation. Increased damping decreases the recorded systolic pressure and, to a lesser extent, increases the recorded diastolic pressure; mean pressure is affected the least. Damping is increased by the use of compliant, kinked, or partially occluded tubing and by loose connections and leaks (Box E4.1).

To obtain an accurate measure of the blood pressure from the arterial line, the system must be properly balanced. One method to assess balance uses the "fast flush test." This test is performed by activating the flush device for a few seconds and then releasing it. On activation of the flush device, the pressure measured rises to a plateau. After release, the pressure waveform drops abruptly and small, sharp waves may be seen (Fig. E4.1). In a balanced system, there should be only one such sharp wave. Fig. E4.1A shows a system that is underdamped; there are multiple sharp waves after release of the flush. The reason for the underdamping in this case was the use of an excessive length of pressure tubing. Fig. E4.1B shows the effect of removing the excess length of pressure tubing. Only one sharp wave follows the flush, indicating that the system is now well balanced. An alternative correction that could have been applied (if the tubing length was required) might have been to increase the damping coefficient with the aid of a dampening device. Using this device is similar in effect to introducing a small air bubble into the arterial line tubing; however, its use does not incur the risk of air embolus.

Figures for the natural frequency and damping coefficient of an arterial line setup can be approximated from a tracing of the fast flush test. The natural frequency of the arterial line setup can be calculated from the cycle length of the sharp waves, whereas the damping coefficient can be calculated from the rate at which the waves decline in amplitude. Fig. E4.2 shows an enlargement of the flush release in the underdamped arterial line tracing in Fig. E4.1A and illustrates the calculation. Based on this tracing, the natural frequency was calculated at 22.7 Hz, and the damping coefficient was 0.34. Removal of the

BOX E4.1 Causes of Underdamping (Overshoot) and Overdamping

Causes of Underdamping

Central pressure measurement
Long pressure tubing
Marked vasoconstriction

Causes of Overdamping

Air in tubing
Blood clots
Compliant tubing (not stiff-walled pressure tubing)
Kinked arterial catheter
Leaks in system (hole in tubing)
Loose connections

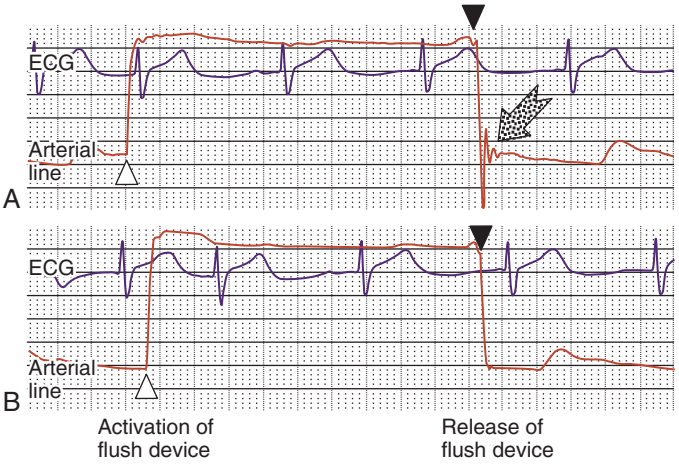

Fig. E4.1 The fast flush test, electrocardiogram (*ECG*), and arterial line tracings. **A,** The underdamping or overshoot with multiple sharp waves after the release of the flush device *(speckled arrow).* **B,** A balanced system, with only one sharp wave after flush release. The *white arrowheads* indicate the beginning of the system flush, whereas the *black arrowheads* represent its termination.

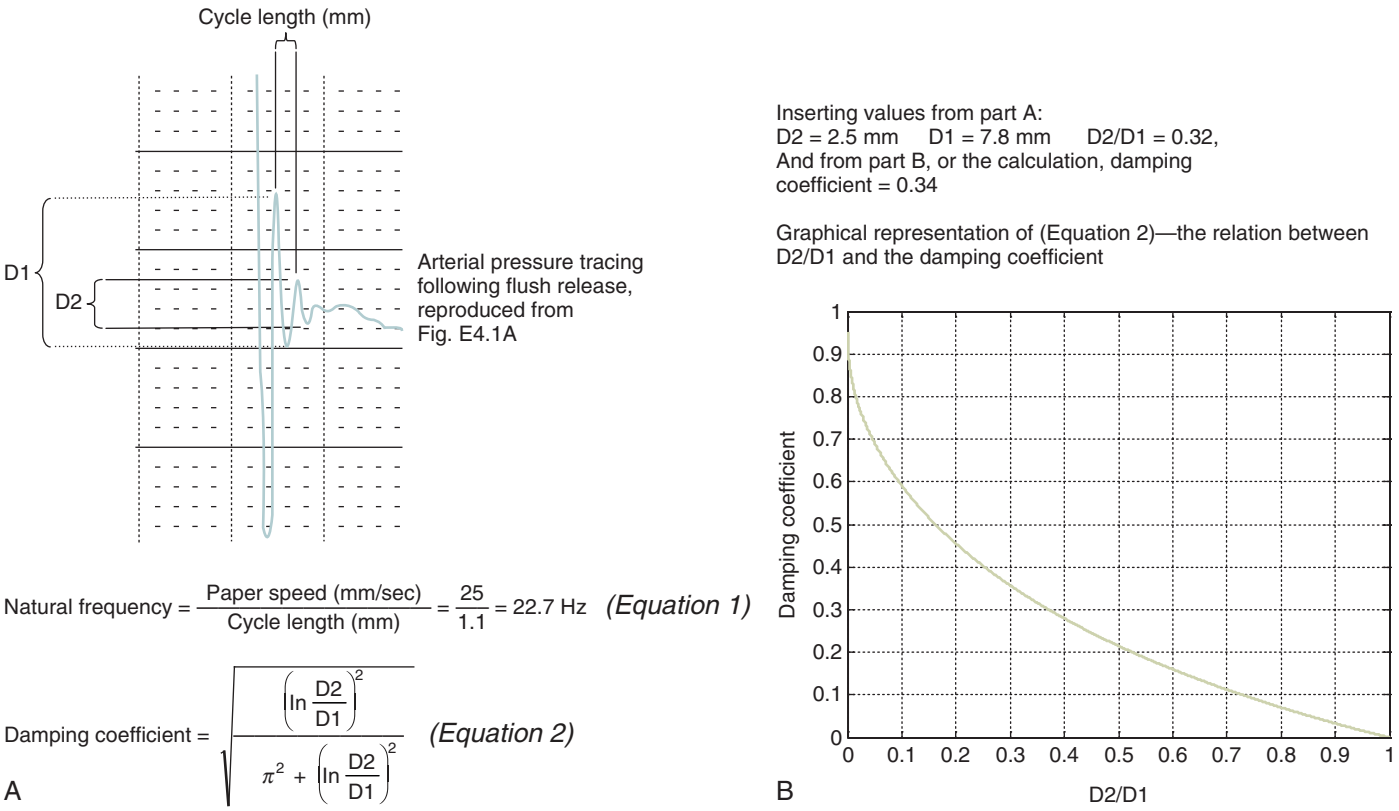

Fig. E4.2 Calculation of natural frequency and damping coefficient. (Adapted from Gardner RM. Direct blood pressure measurement—dynamic response requirements. *Anesthesiology.* 1981;54:227–236.)

excess tubing (producing the tracing in Fig. E4.1B) resulted in a natural frequency of 50 Hz, whereas the damping coefficient was unchanged.

Flush Solutions

To maintain patency and prevent thrombosis of the arterial catheter, it must be continually flushed. Numerous additives have been proposed to achieve this aim, including heparin (the most commonly used), sodium citrate, papaverine, and normal saline. The infusion of heparin through the arterial catheter has been shown to be more effective than normal saline in maintaining patency and/or arterial pressure measurements. However, a recent Cochrane review revealed clinical and statistical heterogeneity in the seven studies and 606 patients included and prevented the definitive demonstration of an advantage to heparin over normal saline.[8] When used, the concentration of heparin in the arterial line flush is usually less than 10 units/mL, with 1 unit/mL being common. Concentrations as low as 0.25 unit/mL, infused at 3 mL/h, are efficacious.

Sodium citrate (1.4% solution) has been suggested as a flush solution that avoids the potential complications associated with the use of heparin and has been found to be equally effective. Papaverine is an additional alternative. Dextrose-containing solutions are not recommended for flushing the arterial line.[5]

The use of flush solutions, although beneficial, is associated with potential complications, mainly in their effect on blood test samples obtained through the arterial line, as described later. However, infusion of the wrong flush solution—including potassium-containing solutions, x-ray contrast, antibiotics, and others—can also lead to complications.[9] Using the wrong solution has been reported in 30% of ICUs.[10]

COMPLICATIONS

The cumulative experience with arterial lines in patients in ICUs is huge; therefore there is a considerable body of literature concerning complications. Overall, major complications are rare—15/17,840 (0.084%) in one study.[11] Complications are associated with the introduction and maintenance of a cannula in the artery and with its use. Common complications have been collected into series, whereas individual case reports describe a wide spectrum of rarer occurrences. The more common complications are described.

Vascular and Local Complications

Vascular and local complications vary from the clinically mild (small hematoma formation, insignificant bleeding) to catastrophic (permanent ischemic limb damage). A summary of 78 studies concerning the incidence rates for vascular and local complications of radial, femoral, and axillary arterial lines has been published and is summarized in Table E4.1.[12] Temporary arterial occlusion is common for all sites; the smaller radial artery is at greater risk than the larger femoral and axillary arteries. Arterial occlusion occurs in part as a result of mechanical obstruction of the artery by the cannula and in part by the formation and propagation of thrombus. Despite its high incidence, arterial occlusion is not detrimental in the majority of cases.[12] The arteries recannulize rapidly (within a week),[13] and permanent ischemic sequelae of arterial cannulation are, fortunately, rare.[12] Attempts have been made to correlate a wide variety of factors with increased risk of arterial obstruction, and some of these are summarized in Box E4.2. The use of Teflon catheters has been associated with a decreased risk of arterial thrombosis, whereas outcome is independent of the age of the patient.

TABLE E4.1 Vascular Complications of Arterial Lines per Site

Site	Temporary Occlusion	Hematoma	Bleeding	Permanent Ischemic Damage	Pseudoaneurysm
RADIAL					
%	19.7	14.4	0.53	0.09	0.09

AXILLARY					
%	1.18	2.28	1.41	0.2	0.1
N	930	744	711	989	1000

BOX E4.2 Factors Associated With Increased Risk of Arterial Obstruction

- Use of smaller arteries (radial and dorsalis pedis vs. femoral or axillary[12])
- Large catheter size
- Multiple insertion attempts
- Presence of hematoma
- Female sex
- Preexisting peripheral vascular disease
- Prolonged shock
- Use of vasoconstrictor drugs

Catheterization of the brachial artery is generally not recommended because of potentially severe complications. These include forearm ischemia (secondary to mechanical obstruction of the artery by the catheter and/or thrombus), compartment syndrome (described in case reports[14]), and damage to the median nerve (from either ischemia, direct mechanical trauma, or pressure secondary to a hematoma). Anticoagulation has been associated with a number of these complications[14] and represents a relative contraindication.

Despite the widespread recommendation not to cannulate the brachial artery, its use has been reported in 3% of ICU patients and up to 20% of operating room patients.[4] Wider experience has been described in other specialties (e.g., angiography, single puncture for blood gases, and long-term access to the arterial circulation) and provides an indication of potential complication rates. In a study of 10,500 patients undergoing cardiac angiography via the brachial artery, surgical intervention was required for 0.57%, most commonly because of hand ischemia. The incidence of median nerve damage after cardiac catheterization via the brachial artery is 0.2%–1.4%, whereas vascular angiography performed through the brachial artery in 1326 patients was associated with a brachial artery thrombosis rate of 0.28% for men and 1.24% for women.[15] Long-term cannulation of the brachial artery has been described in a study of 225 transbrachial intrahepatic cannulas (in situ for up to 14 months) and was associated with diminished radial pulses in 88 (39%) patients and ischemic symptoms of the forearm in 16 patients (8%). Brachial artery thrombosis had an incidence of 1.7%.

In clinical practice, the territory supplied by an artery that has been cannulated should be closely monitored. Pain, weakness, changes in sensation, pallor, or decreased temperature all suggest compromised arterial blood flow and should prompt the immediate removal of the arterial cannula. Usually removing the catheter will be sufficient to restore adequate blood flow.

Erroneous Blood Test Results

In 2008 the United Kingdom National Patient Safety Agency reported on two deaths related to erroneous results from blood tests obtained from the arterial catheter. In one of these, the arterial flush solution was changed from 0.9% sodium chloride solution to 5% glucose. Arterial blood glucose evaluations increased, and in parallel the insulin dose increased. After the patient lost consciousness, blood was sent to the laboratory, and a glucose concentration of 0.1 mmol/L was detected. The patient never regained consciousness.[9] A second similar case report was published in 2013.[16]

As reflected in these cases, the most common cause of an unreliable blood test result is either dilution or contamination of the sampled blood with flush fluid. In addition to glucose measurements, removal of inadequate "dead space" from the arterial line setup before obtaining blood for hemoglobin estimation may lead to a diluted sample and a falsely low hemoglobin level, and if heparin from the flush solution is introduced into a test of the activated partial thromboplastin time (aPTT), this test will be markedly prolonged. Heparin in higher concentrations may also artifactually decrease the pH and arterial partial pressure of carbon dioxide ($PaCO_2$)? measurements. If sodium citrate is used in the flush solution and inadvertently introduced into blood samples, spurious hypocalcemia and a low pH might be reported along with increased glucose.[17]

The solution to the problem of flush contamination lies in the withdrawal of an adequate dead space of flush solution and diluted blood before obtaining the blood for testing. The interaction between heparin in the flush solution and the measurement of aPTT is particularly problematic and has been repeatedly studied in an attempt to determine the minimum dead-space volume required to obtain a reliable test result.[18] Five to six times the tubing volume from the artery to the sampling three-way tap (i.e., the dead-space volume) should be withdrawn before the blood for this test to obtain a reliable result.

Whether this dead-space volume should be discarded or returned to the patient depends mainly on maintenance of sterility and speed of sampling. Sterility can be maintained using a closed system, such that the dead-space blood is maintained in an internal reservoir. Specially designed systems exist with internal reservoirs; however, a simpler double-tap arrangement has also been described. In this system, an extra three-way tap is added distal (i.e., farther away from the patient) to the sampling port. A syringe is attached to the extra three-way tap. The dead-space blood is drawn into this syringe, and the blood sample is taken from the more proximal (i.e., closer to the patient) tap. After blood sampling, the dead-space blood can be returned.

Blood cultures obtained from the arterial line represent another test in which results might be compromised. The sensitivity of cultures

drawn in this way is similar to or slightly higher than that of blood cultures obtained by venipuncture; specificity, however, is lower.[19,20] The lower specificity presumably reflects introduction of organisms into the culture bottles from the three-way tap or the catheter itself.

Anemia

The ease with which blood specimens can be obtained from the arterial line and the requirement for frequent testing in critically ill patients may lead to the removal of considerable volumes of blood. The effect of an arterial line in increasing blood test use was first reported in 1986. In this study, patients with an arterial line in the ICU had blood drawn 3.4 times per day, leading to blood loss of 41.5 mL per day and a total of 762 mL. This was in contrast to non-ICU patients without an arterial line who had blood drawn 1.1 times per day, 12.4 mL/day, and a total of 175 mL for their whole admission. Despite efforts to reduce iatrogenic blood loss, similar findings were published in 2015.[21] Among 1894 cardiac surgery patients, the median phlebotomy volume remained high at 332 mL (vs. 118 mL for ward patients).[21] Phlebotomy contributes to the development of anemia among ICU patients and has been implicated as a cause for blood transfusions. Relatively simple steps can reduce the blood loss associated with tests. Such steps include return of dead-space blood (as described earlier), use of pediatric-sized sample tubes, communication with the various laboratories to define the minimal blood volume required for various tests,[22] and point-of-care testing. Despite their simplicity, these steps are infrequently employed.[23]

Heparin-Induced Thrombocytopenia

The use of heparin can be associated with a syndrome of thrombocytopenia and thrombotic events usually appearing after approximately 5 days of heparin therapy.[24] Heparin-induced thrombocytopenia (HIT) is thought to be mediated by immunoglobulin G (IgG) antibodies that develop in response to immunization against the heparin/platelet factor 4 (PF4) complex; these are called *HIT antibodies.*[24] The attachment of these antibodies to the heparin/PF4 complex on the platelet surface activates the platelets and induces thrombosis. Both venous and arterial thrombi can occur. The presence of HIT antibodies does not, however, inevitably lead to thrombotic episodes. For example, up to 50% of cardiac surgery patients develop HIT antibodies, but thrombotic events are relatively rare (2%–3%).[25] The diagnosis of the HIT syndrome is therefore based on the presence of the antibodies, thrombocytopenia, and thrombotic events.[24]

The overall incidence of this syndrome is reported to be approximately 5%. It is more common in women than in men[24] and in surgical as compared with medical[26] or obstetric patients[27] and is also more common after the use of unfractionated heparin than low-molecular-weight heparin.[24] A single dose of heparin is sufficient to induce HIT,[28] and the presence of as little heparin as that found bound to heparin-coated central venous catheters may be sufficient to sustain the immune response. The development of HIT antibodies has been linked with the administration of heparin in intravascular device flushes and also with low doses of heparin used in arterial flush solutions.

Treatment for HIT syndrome includes the cessation of administration of all sources of heparin, including those in the line flush solutions. The use of other anticoagulants for thrombotic episodes is recommended. Removing heparin from flush solutions also may be indicated in the presence of HIT antibodies and thrombocytopenia before any thrombotic events.[24]

After the decline in HIT antibody levels, the short-term use of heparin for certain indications (e.g., cardiac surgery) is considered acceptable.[24] It is prudent, however, to avoid heparin in the arterial line for patients with a history of HIT until further evidence of the risk of repeated episodes of HIT becomes available.

Infection

A patient may develop a bloodstream infection from the arterial line by one of three main routes. Infections have been introduced via infected equipment, such as reusable transducer domes or infected flush solutions; however, with the advent of disposable equipment and improved flush systems, the significance of this route of infection has declined. Two potential routes of infection remain: from the skin puncture site along the catheter and through the three-way taps.[5,29] The predominant organisms associated with arterial line infection are gram-positive cocci (*Staphylococcus aureus* and *Staphylococcus epidermidis*), although gram-negative rods may also be found.[13]

Defining a precise rate of infection for the arterial line is not straightforward, because a multiplicity of definitions of catheter-related bloodstream infections is used in different studies, and variables have not been standardized among studies. Clinical, research, and surveillance criteria exist for defining catheter-related infection. Clinical criteria include presence of signs of infection (e.g., fever, increased white blood cell count) associated with an arterial line in place longer than 96 hours with signs of local infection and no other source of sepsis. Whereas these criteria might be useful in clinical practice, they are too broad for research purposes. Surveillance criteria, such as those defined by the Centers for Disease Control and Prevention (CDC), include any significant bloodstream infection in the presence of a vascular catheter and no other source of sepsis.[5] This definition overestimates the incidence of catheter-induced bloodstream infection because it includes bloodstream infection from occult sources other than intravascular lines.[5] Research criteria can include the use of arterial line tip cultures (often quantitative or semiquantitative), usually correlated to venous blood culture results. Combinations of these definitions have been employed.[13]

With regard to arterial line variables, virtually every aspect of line insertion and maintenance (for either central venous or arterial catheters) has been examined for an effect on infection rate. Factors that have been evaluated include type of skin preparation solution used,[30] insertion site, dressing type and care,[5,29,31] arterial catheter length, site of insertion, catheter material, type of flush solution, and frequency of set changes (Box E4.3). Consistency is not found in the results of all these studies, and not all these factors have been standardized from study to study, possibly confounding direct comparisons.

Despite this variability, a meta-analysis reported that the rate of bloodstream infections related to arterial lines was 1.7 infections/1000

BOX E4.3 Factors Potentially Associated With a Change in the Infectious Risk of the Arterial Line[5]

Increased Risk

Cutdown technique versus percutaneous insertion
Duration of cannulation >96 hours
Axillary artery site
Frequent arterial line set changes

Decreased Risk

Teflon catheters (vs. polyvinyl chloride)
Heparin (in central venous pressure and pulmonary artery catheters)
Use of chlorhexidine-containing skin preparation solutions
Factors not associated with a change in infectious risk
Femoral versus radial artery insertion site
Dorsalis pedis versus radial artery insertion site[13]
Duration of catheterization >96 hours
Systemic antibiotic prophylaxis before insertion

catheter-days and that 1.5/100 arterial catheters was found to cause a bloodstream infection.[32] These rates compared with 2.7 infections/1000 catheter-days and 3.6 infections/100 catheters for unmedicated central venous catheters (CVCs), 0.2 and 0.2 for antiseptic-coated CVCs, and 2.5 and 4.3 for antibiotic-coated CVCs.[32] The implication is that the infection rate associated with arterial catheterization is higher than generally assumed and may be higher than for the newer types of CVCs.

The CDC summarized these diverse findings into these recommendations: use the radial, brachial, or dorsalis pedis sites rather than femoral or axillary arteries; use a minimum of cap, mask, sterile gloves, and a small sterile fenestrated drape for peripheral artery insertion and full sterile barrier precautions for axillary and femoral sites; use >0.5% chlorhexidine in 70% alcohol for skin preparation; do not change arterial catheters routinely; change the pressure monitoring sets and transducers every 96 hours; and do not use dextrose in the flush solution.[5] Despite these recommendations, and particularly the requirement for sterile precautions, less than half of physicians replying to a web-based survey adhered to them, indicating a need for education surrounding arterial catheter insertion.[33]

In clinical practice, it is unlikely that an arterial cannula present for less than 96 hours is the cause of an infection. If the arterial line has been present for more than 96 hours and no other source of sepsis is identified, strong consideration should be given to removing or replacing the arterial catheter. The presence of redness or pus at the arterial cannula introduction site should further increase the index of suspicion of an arterial line–related infection.

Finally, in view of these potential complications, the benefit of arterial cannulas in the ICU has begun to be questioned. Needless to say, there are no randomized controlled studies showing mortality benefit or harm from arterial cannulation. A recent retrospective study in a well-defined but limited population of hemodynamically stable patients with respiratory failure showed no difference in 28-day mortality.[34] This study has led to calls to reassess the necessity for arterial cannulation in the ICU population in a similar manner to the assessments performed on pulmonary artery catheters.

KEY POINTS

- The common sites of arterial line insertion are the radial, femoral, and dorsalis pedis arteries. These arteries are superficial; covered only by skin, fascia, and fat; and are easily compressible.
- The arterial line can be inserted using a simple catheter-over-needle arrangement (with or without a guide wire) or a set based on the Seldinger technique.
- Guide wires should only be used when backflow of blood is present to avoid arterial damage.
- Doppler or ultrasound can be helpful for difficult line insertion.
- Errors in pressure measurement can arise from incorrect zeroing, overshoot, or damping.
- When zeroing, the height difference between the arterial puncture site and the transducer must be taken into account.
- Overshoot and damping affect the systolic blood pressure more than the diastolic or mean pressure.
- The fast flush test can be used to assess underdamping or overdamping.
- Low-concentration heparin is the most common arterial line flush solution. Sodium citrate, papaverine, and saline have been used.
- Arterial obstruction is very common after catheter insertion, although rarely detrimental.
- Obstruction may be mechanical from the catheter or result from thrombosis.
- Small arteries, female gender, and shock are risk factors for thrombosis.
- Pain, weakness, changes in sensation, pallor, or decreased temperature should prompt immediate catheter removal.
- The majority of blood tests obtained from the arterial line will be accurate.
- The type of flush solution used may interfere with certain tests.
- Particular care should be taken when interpreting the aPTT and blood culture results in samples drawn from the arterial line.
- Five to six times the dead-space volume might be required for accurate tests, which may be reinfused with appropriate precautions.
- Anemia can result from the volumes of blood drawn from the arterial line. Simple steps can reduce this blood loss.
- HIT is a syndrome defined by thrombocytopenia and thrombotic events in the presence of PF4 complex antibodies.
- Even very small doses of heparin can induce or maintain HIT. All sources of heparin should be removed if HIT is suspected, including from arterial line flush.
- The rate of bloodstream infections related to the arterial line has been estimated to be 1.7 per 1000 catheter-days, whereas 1.5 in 100 arterial catheters cause infection.
- Insertion technique, duration of cannulation, site, insertion site, and frequency of set changes have all been related to an increased infection risk.
- Comparisons of studies relating to infectious risk are difficult because of differing definitions of infection and study methodology.
- The CDC recommends the following: Use a >0.5% chlorhexidine in 70% alcohol solution for skin cleaning, do not change arterial catheters routinely, change the pressure monitoring sets and transducers every 96 hours, and do not use dextrose-containing flush solution.

ANNOTATED REFERENCES

Martin C, Saux P, Papazian L, et al. Long-term arterial cannulation in ICU patients using the radial artery or dorsalis pedis artery. *Chest.* 2001;119:901–906.
This is a prospective observational study examining the complications of dorsalis pedis artery (DPA) (131 patients) versus radial artery (RA) cannulation (134 patients) in consecutive groups of patients. The study showed that arterial occlusion was very common (present to some degree in 63% of the DPA patients and 76% of the RA patients) but clinically asymptomatic.

Bedside Pulmonary Artery Catheterization

Jean-Louis Vincent

BEFORE THE PROCEDURE

Indications

- Need for continuous monitoring of pulmonary artery (PA) and right atrial (RA) pressures, cardiac output, and mixed venous oxygen saturation (SvO_2), providing that:
  - The data collected will help in the management of the patient
  - The same measurements cannot be reliably obtained by a less invasive method

Contraindications

- Absolute contraindications:
  - Tricuspid or pulmonary valve endocarditis
- Relative contraindications:
  - Tricuspid or pulmonary valve mechanical prosthesis
  - Right heart mass (thrombus and/or tumor)
  - Complete left bundle branch block (risk of complete heart block)

Equipment

- Sterile gowns, gloves, and mask
- 8F to 9F gauge introducer
- Sterile saline solution for flushing
- Volume-limited syringe for pulmonary artery catheter (PAC) balloon
- Pressure monitor transduction system and connector tubing

ANATOMY

The inflated balloon of the PAC facilitates the catheter progression through a branch of the PA. The distal lumen of the PAC measures the pressure downstream. It is assumed that there is a continuous column of blood between the distal lumen and the left ventricle (LV), and therefore the PA balloon-occluded pressure (PAOP) is equal to left ventricular end-diastolic pressure (LVEDP). PAOP reflects the pressure where the nonflowing blood (in the obstructed vessel) joins the blood flowing from the nonoccluded branches of the pulmonary artery. PAOP is actually intermediate between pulmonary capillary pressure and left atrial (LA) pressure. There are conditions, however, in which this theoretical continuous column of blood is interrupted, and in these circumstances PAOP no longer reflects LVEDP.

PROCEDURE

See Video E5.1.

- Check the patient's electrocardiogram (ECG), coagulation profile, and serum electrolyte panel. One should consider correcting major clotting disorders. If the patient already has a temporary pacemaker, it may be better to place the catheter under radiographic guidance to avoid dislodging the pacemaker.
- Inflate the catheter balloon as a test before catheter insertion.
- Connect the distal lumen to the pressure-monitoring system, and flush all lumens with sterile saline solution.
- Zero-reference the pressure transducer to the mid-chest position.
- Slide the protective sleeve onto the catheter to maintain sterility for further manipulations.
- Place the sterile field.
- Give local anesthesia.
- Insert the introducer into a central vein, preferably the internal jugular or subclavian, using the Seldinger technique.
- Pass the catheter through the hemostatic valve of the introducer.
- Inflate the balloon once the catheter tip has passed about 15 cm.
- Advance the catheter for another 15 cm. It should pass into the right ventricle (RV) and give an RV pressure waveform (Fig. E5.1).
- Advance the catheter farther to pass into the PA and finally to obtain a PAOP waveform.
- Once a PAOP waveform has been obtained, deflate the balloon to return to the PA waveform.
- Once the catheter is in place, check the position with a chest radiograph. In the vast majority of cases, the tip is in the right lung. The tip should be within 2 cm of the cardiac shadow.
- All pressures should be measured at end expiration, when alveolar pressure should be closest to atmospheric pressure.

Procedural Precautions

- Always have the PA trace displayed on the monitor.
- Never withdraw the catheter without first deflating the balloon.
- Do not insert large lengths of catheter without observing a pressure change, because this maneuver may lead to looping and knotting of the catheter.
- There may be difficulties in reaching the RV or PA as a result of RA or RV dilatation, tricuspid regurgitation, or abnormalities of the central veins. An option may be to advance the catheter with the balloon partially deflated during inspiration, repositioning the patient in a head-up or right lateral position, or flushing the catheter with iced saline to make it more rigid.
- If the PAOP trace is obtained when the balloon is inflated with less than 1 mL of air, or if there is a progressive elevation of pressure when the balloon is inflated ("overwedging"), the catheter tip is too advanced and should be withdrawn by a few centimeters to decrease the risk of PA rupture/infarction.

AFTER THE PROCEDURE

Postprocedure Care

- The PAC can be kept in situ for several days but should be removed as soon as it is no longer required for patient care.
- Balloon rupture can be identified by failure to wedge and failure of the syringe plunger to spontaneously deflate the balloon.

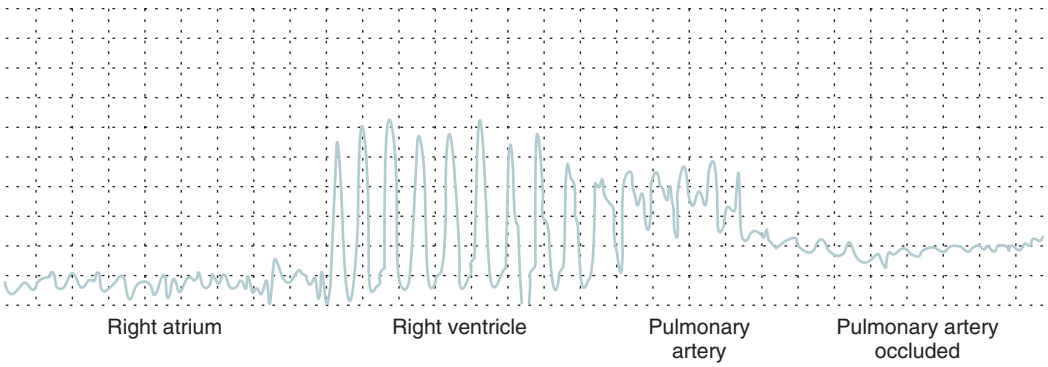

Fig. E5.1 Pressure Traces as the Pulmonary Artery Catheter is Advanced.

Interpretation of Measured Pressures

See also Table E5.1.

- The PA waveform has a systolic and diastolic pressure with a dicrotic notch corresponding to closure of the pulmonary valve.
- The PAOP, like the central venous pressure (CVP), has a venous waveform with a, c, and v waves corresponding to LA contraction, closure of the mitral valve, and passive LA filling, respectively.
- The a wave coincides with the point of maximal filling of the LV and is therefore the value that should be used for measurement of LVEDP. A large-amplitude a wave with an increase in measured PAOP suggests LV ischemia and decreased ventricular compliance.
- A large v wave on the PAOP trace represents mitral regurgitation or an acute volume load to the LA, as occurs with septal rupture. The PAOP level should be measured without consideration for this v wave.
- The RA pressure waveform can look like an RV waveform if there is significant tricuspid regurgitation.
- In cardiac tamponade, RA pressure and PAOP are high and similar, as they equilibrate with pericardial pressures.
- A "dip-and-plateau" waveform may be seen in the RV pressure tracing in constrictive pericarditis, restrictive cardiomyopathy, RV infarction, and massive pulmonary embolism. This pattern is caused by impaired ventricular filling during diastole.

Measurement of Cardiac Output With the PAC

- Cardiac output is measured using thermodilution.
- Measurement is based on the *indicator dilution principle:* when an indicator substance is added to a stream of flowing blood, the flow rate is inversely proportional to the mean concentration of the indicator at a downstream site. In the case of thermodilution, the indicator used is temperature, using a thermal filament to generate heat (warm thermodilution).
- The old technique included bolus injections of 5% dextrose solution or saline injected through the proximal port of the PAC. The thermistor proximal to the balloon then recorded the temperature change in the PA, and a temperature-time curve was displayed.
- Today, catheters provide a semicontinuous method in which a thermal filament is mounted on the PAC 14–25 cm from the tip. The filament intermittently generates pulses of heat, and the temperature change is recorded by the thermistor in the PA. These pulses of heat are pseudorandom to minimize the influence of other sources of temperature change such as infusions or respiratory fluctuations. The cardiac output is updated every 30–60 seconds and is time-averaged over the previous 3–6 minutes.

Complications

Complications that are unique to the PAC and not just the result of insertion of a central venous catheter can be divided into those caused by placement and the longer-term complications caused by its presence:

- Placement
  - Common
    - Arrhythmias, most commonly premature atrial or ventricular contractions that are self-limiting and can occur on insertion or withdrawal of the catheter.
  - Rare
    - Knotting of the catheter; a knot generally can be removed by placing a guide wire through the PAC to undo the loop or by pulling the loop tight against the introducer sheath and removing the whole unit.
    - Tricuspid pulmonary regurgitation or chordae tendineae rupture can occur if the catheter is withdrawn with the balloon inflated.
- Presence of the catheter
  - Common
    - Arrhythmias, most commonly premature atrial or ventricular contractions that are self-limiting and can occur on insertion or withdrawal of the catheter.
    - Catheter-related infections.

TABLE E5.1 Interpretation of the Measured Pressure Variables

CVP/RAP	PAP	PAOP	Interpretation
Low/normal	Low/normal	Low/normal	Normal
Low/normal	High	High	Left heart failure (good right heart function)
Normal/high	High	Low	Pulmonary hypertension (e.g., COPD, ARDS, pulmonary embolism)
High	High	High	Hypervolemia (high CO) Global heart failure (low CO) Tamponade (low CO)

ARDS, Acute respiratory distress syndrome; *CO,* cardiac output; *COPD,* chronic obstructive pulmonary disease; *CVP,* central venous pressure; *PAOP,* pulmonary artery occlusion pressure; *PAP,* pulmonary artery pressure.

- Rare
  - Pulmonary infarction caused by catheter-related thromboembolism, obstruction of the pulmonary blood flow by the catheter tip, or prolonged inflation of the balloon. It is usually without consequences.
  - Endocarditis.
  - PA rupture occurs in less than 0.1% of cases but is associated with a mortality of greater than 30%. Warning signs include hemoptysis, with shadowing on the chest radiograph. Diagnosis is confirmed by pulmonary angiography. Treatment consists of embolization or thoracotomy. Factors increasing the risk of rupture include pulmonary hypertension, advanced age, hypothermia, coagulation disorders, and distal positioning of the catheter.

KEY POINTS

- Benefits of bedside PAC remain controversial, and insertion of a PAC cannot, per se, improve patient survival.
- PACs should not be inserted routinely but only in patients in whom the data collected will help in the patient's management and the same measurements cannot be obtained by a less invasive method.
- To be beneficial, data from the PAC must be collected, interpreted, and applied correctly.

Cardioversion and Defibrillation

Raúl J. Gazmuri

BEFORE THE PROCEDURE

Indications

- Emergency re-establishment of an organized electrical rhythm
  - Hemodynamically unstable polymorphic ventricular tachycardia
  - Ventricular fibrillation
  - Pulseless ventricular tachycardia
  - Narrow or wide QRS complex tachycardia (ventricular rate >150) associated with hemodynamic instability, chest pain, or pulmonary edema
- Elective reestablishment of sinus rhythm
  - Atrial fibrillation
  - Atrial flutter
  - Hemodynamically stable ventricular tachycardia unresponsive to medical treatment
  - Others

Contraindications

- Specific advance directives (e.g., do not attempt resuscitation for cases of ventricular fibrillation)
- Digitalis toxicity–associated tachycardia
- Sinus tachycardia caused by various clinical conditions
- Rhythms not responsive to electric shock (e.g., multifocal atrial tachycardia)
- Atrial fibrillation or atrial flutter without proper anticoagulation or exclusion of atrial thrombi

Equipment

- Automated external defibrillator or manual defibrillator
- Proper age-adjusted pads or paddles

ANATOMY

The heart is located behind the sternum. Its base is at the level of the third intercostal space immediately to the right of the sternum, and its apex is at the level of the fifth intercostal space inferior and usually just medial to the nipple. External cardioversion or defibrillation is attempted by delivering one or more electric shocks through the chest cavity for the purpose of passing an electric current of sufficient energy through the heart muscle to fully depolarize the atria (e.g., atrial fibrillation or atrial flutter) or the ventricles (e.g., ventricular fibrillation or ventricular tachycardia). Cardioversion should enable the natural or artificial cardiac pacemaker to resume control of the cardiac rhythm. Electrodes (paddles or pads) can be positioned on the anterior chest wall, with one electrode below the right clavicle lateral to the sternum and the other electrode below the breast tissue along the midaxillary line. Electrodes (e.g., pads or paddles that are more difficult) can also be positioned in an anteroposterior position, with the anterior electrode placed over the precordium and the posterior electrode at the left infrascapular location. For internal cardioversion or defibrillation, specially designed paddles are applied directly to the epicardial surface of the ventricles.

PROCEDURE

See Videos E6.1 and E6.2.

For external elective cardioversion, many of the following steps may have to be shortened or circumvented in hemodynamically unstable patients (especially if unconscious), requiring rapid termination of life-threatening arrhythmia (e.g., ventricular fibrillation or pulse ventricular tachycardia as part of cardiopulmonary resuscitation).

- Admit the patient to an appropriately equipped hospital area with the capability for monitoring cardiac rhythm, oxygenation, and vital signs, along with airway management and cardiopulmonary resuscitation.
- Fast the patient overnight or for at least 6–8 hours.
- Establish vascular access.
- Obtain an electrocardiogram.
- For sedation, consider using a short-acting anesthetic agent (e.g., midazolam, propofol, or etomidate) under the care of an anesthesiologist or similarly privileged anesthesia provider and adequate supportive personnel. An alternative to anesthesia is moderate sedation, in which the patient maintains consciousness but in a somnolent state. This has the advantage that it can be given by trained physicians without an anesthesiologist present.
- Attach monitor leads to the patient, and ensure proper display of the patient's rhythm.
- Place electrodes properly separated (as described under "Anatomy"). Apply coupling gel if using paddles; avoid smearing the gel over the chest wall to prevent current traversing superficially through the chest. In patients with permanent pacemakers or implantable cardioverter-defibrillators, place electrodes away from the device generator to avoid device malfunction. Consider reevaluating pacing thresholds in patients with permanent pacemakers and interrogation of implantable cardioverter-defibrillator function after cardioversion.
- Engage the synchronization mode, and identify markers on the R waves indicating adequate R-wave recognition. If necessary, adjust the gain of the monitor until markers appear on each R wave.
- Select the energy level to deliver the necessary current based on the patient's waveform, age, and arrhythmia. Organized rhythms with a simple reentry circuit (e.g., atrial flutter and monomorphic ventricular tachycardia) usually require less current than more complex rhythms (e.g., atrial and ventricular fibrillation).
- Press the charge button on the unit or paddles.

- If using paddles, apply approximately 12 kg pressure to each paddle.
- Press the discharge button on the unit or paddles simultaneously.
- Check the monitor. If the arrhythmia persists, increase the energy level according to the protocol for the specific rhythm.
- Reset the synchronization. Most units default to the unsynchronized mode, allowing immediate defibrillation if ventricular fibrillation ensues.
- Repeat the shock until the conversion of the arrhythmia or completion of the protocol.
- Deliver unsynchronized shocks only for ventricular fibrillation or pulseless ventricular tachycardia.

AFTER THE PROCEDURE

Postprocedure Care

- Obtain an electrocardiogram.
- Assess hemodynamic and respiratory status.
- Observe the patient until the recovery from anesthesia or sedation is complete.
- Consider hospital discharge if the procedure was elective.

Complications

- Cardioversion and defibrillation are relatively safe procedures with infrequent complications that may include:
  - Induction of ventricular fibrillation if the electric shock is improperly synchronized
  - Transient conduction abnormalities
  - Myocardial dysfunction (after high-energy and repetitive delivery of electric shocks)
  - Release of cardiac enzymes
  - Pulmonary edema
  - Embolization of thrombi formed within the cardiac chambers (e.g., atrial fibrillation and flutter)
  - Respiratory depression associated with anesthesia or sedation

KEY POINTS

- Sinus rhythm will be restored in a high percentage of patients.
- Underlying conditions may predispose certain patients to a recurrence of arrhythmias.
- Early defibrillation of ventricular fibrillation is associated with improved survival.

Transvenous and Transcutaneous Cardiac Pacing

Raúl J. Gazmuri

BEFORE THE PROCEDURE

Indications

- Treatment of symptomatic bradycardia
  - Sinus bradycardia
  - Second-degree or third-degree atrioventricular block
- Prophylaxis
  - Bradycardia-induced ventricular tachyarrhythmias (e.g., torsades de pointes)
  - Increased risk of advanced atrioventricular block (e.g., acute myocardial infarction, infective endocarditis, surgery in patients with underlying conduction defects)
- Overdrive pacing for termination of tachyarrhythmias
  - Supraventricular tachycardia
  - Ventricular tachycardia
- Improving hemodynamic function
  - Sequential atrioventricular pacing

Contraindications

- Specific advance directives (e.g., do not attempt resuscitation for cases of pulseless electrical activity)
- Asymptomatic bradycardia
- Severe hypothermia (risk of ventricular fibrillation)

Equipment

- Pacing catheter with pulse generator
- Transcutaneous electrodes with pacing unit (integrated with current cardioverter-defibrillators)

ANATOMY

The heart is located behind the sternum. Its base is at the level of the third intercostal space immediately to the right of the sternum, and its apex is at the level of the fifth intercostal space inferior, usually just medial to the nipple. Transcutaneous pacing can be performed by delivering electric impulses through the chest cavity to "capture" and drive the electrical activity of the heart. Electrodes can be placed on the anterior chest wall, with one electrode below the right clavicle lateral to the sternum and the other electrode below the breast tissue along the midaxillary line. Electrodes can also be placed in an anteroposterior configuration, with the anterior electrode placed over the precordium and the posterior electrode at the right infrascapular location. For transvenous pacing, the pacing catheter can be advanced through the brachial (antecubital), femoral, internal jugular (preferably right), subclavian (preferably left), or the right subclavian via supraclavicular access (experienced practitioner).

PROCEDURE

Transvenous Temporary Pacing

See Video E7.1.

- Admit the patient to an appropriately equipped hospital area with the capability for monitoring cardiac rhythm, oxygenation, and vital signs, along with airway management and cardiopulmonary resuscitation.
- Obtain a 12-lead electrocardiogram (ECG).
- Attach monitor leads to the patient, and ensure proper display of the patient's rhythm.
- Perform the procedure under fluoroscopy, if available and time permits; otherwise, use the ECG and rhythm to guide placement.
- Establish vascular access under local anesthesia and full sterility, advancing a proper-size introducer sheath.
- Select a pacing catheter contingent on approach. Catheters for use under fluoroscopy are semirigid (usually made of woven polyester) to facilitate maneuvering into position. Catheters designed for blind placement have a balloon at the tip to be floated into position. Transvenous pacing can also be accomplished using multipurpose pulmonary artery catheters built with up to five electrodes for right atrial and right ventricular pacing.
- Blind placement using a balloon-tipped catheter can be guided by the ECG. A V_1 lead of a conventional ECG is connected to the distal pole (cathode) of the pacing catheter and used to monitor a unipolar intracavitary electrogram. The catheter is floated, seeking the display of a right ventricular intracavitary electrogram point at which the balloon can be deflated, and the catheter advanced a few centimeters to position its tip in the right ventricular apex. Endocardial contact is confirmed by the development of an "injury" current characterized by prominent ST-segment elevation. The pacing electrode is connected to the pulse generator and used in the unipolar or bipolar configuration.
- Another, more practical, approach (which is preferred in emergency situations) is to advance the pacing electrode into the right ventricle and turn the pulse generator on in the asynchronous mode at a rate that exceeds the native rate. The pacing current is set between the default and maximum output, and the pacing electrode is maneuvered until capture occurs.
- A defibrillator should be available during insertion and afterward because life-threatening ventricular tachyarrhythmias may develop, especially if the pacing lead moves within the ventricular cavity.
- Leave a sterile sleeve around the catheter (available with most introducer kits) to facilitate subsequent repositioning if required.
- Obtain an anteroposterior and lateral chest x-ray to verify proper placement and exclude complications.

- Set pacing options as follows:
  - Determine the pacing threshold, and set the pacing output. For this purpose, set the pacemaker rate to exceed the spontaneous heart rate by 10–20 beats/min and the output to a level expected to capture 100% of the beats (i.e., 6 mA). Capture is verified on the ECG by identifying the presence of a spike (pulse) followed by a wide QRS complex. The output is reduced gradually until beats are no longer captured and then increased again to identify the minimal level at which 100% of the beats are paced; this is the threshold output. This threshold level should be less than 1 mA for ventricular pacing and less than 2 mA for atrial pacing in the unipolar and bipolar configurations; otherwise, the lead must be repositioned. The output is set at about three times the threshold level for reliable capture.
  - Set sensitivity (range: 0.5–20 mV), allowing the native R wave to inhibit the pacemaker impulse when the generator is set in synchronous mode. The output is first set to its minimal level (e.g., 0.1 mA) and the pacing rate to a value below the spontaneous heart rate. Starting from the maximal sensitivity (the lowest value; i.e., 0.5 mV), gradually decrease the sensitivity (increasing its value) until the unit stops sensing the R wave. For reliable inhibition, the sensitivity is set at about three times the sensitivity threshold (e.g., if the threshold is 3 mV, the level is set at 1 mV).
  - The pacing rate for bradyarrhythmias is set according to physiologic needs, usually between 60 and 75 beats/min. Higher rates (800 beats/min) are available for overriding the pacing of ventricular or supraventricular tachyarrhythmias.
  - Sequential atrioventricular pacing requires the placement of an additional lead or the use of a multipurpose pulmonary artery catheter along with a dual-chamber pulse generator. The individual chamber specifications for dual-chamber generators are similar, with the option of setting the AV pacing interval between 20 and 300 msec.

Transcutaneous Temporary Pacing

See Video E7.2.

- Transcutaneous pacing is noninvasive and can be used in emergency settings with ease and minimal delay while preparing for more definitive therapy. Alternatively, it can be used prophylactically.
- Pacing is limited to the ventricles (with minimal capability for atrial pacing), capture is not always attained, and tolerability may be poor.
- Place electrodes on the anterior chest wall or in an anteroposterior configuration, as described under "Anatomy." Place the negative electrode (i.e., cathode) anteriorly, close to the heart (typically over the palpable cardiac impulse or centered on a V_3 lead) to minimize the capture threshold. Place the positive electrode (i.e., anode) over the upper right region of the chest or the posterior chest wall between the bony spine and the inferior border of either the left or right scapula.
- Determine the pacing threshold as for transvenous pacing (described earlier), bearing in mind that the pacing threshold is much higher (20–140 mA), particularly in patients with emphysema and pericardial effusion and in patients undergoing positive pressure ventilation. The pacing output is set 5–10 mA above the threshold. Pulse generators are designed to deliver high current levels (200 mA) with a longer pulse duration (20–40 msec) to facilitate capture and minimize patient discomfort.
- Ensure that capture occurs by demonstrating coincident pulse generation; do not rely on the ECG capturing artifacts from the skeletal muscle activity.

AFTER THE PROCEDURE

Postprocedure Care

- Obtain an ECG.
- Assess hemodynamic status.
- Monitor native and paced rhythms.
- Establish etiology, and institute definitive treatment.

Complications

- Pacemaker malfunction, defined as the failure to sense, capture, or both
- Ventricular dysrhythmias at the time of insertion
- Myocardial perforation with risk of cardiac tamponade
- Diaphragmatic stimulation
- Complications related to the vascular access (e.g., phlebitis, pneumothorax, arterial puncture, brachial plexus injury, pulmonary embolism, and sepsis)

KEY POINTS

- Effective in pacing at the desired heart rate
- Transvenous pacing is more effective than transcutaneous pacing (lower capture rate)
- Lack of effectiveness for treatment of cardiac arrest caused by asystole or pulseless electrical activity
- Temporary measures pending the resolution of the rhythm abnormality or permanent definitive pacemaker placement

Ventricular Assist Device Implantation

Robert L. Kormos

BEFORE THE PROCEDURE

Indications

- Postcardiotomy failure (left ventricular assist device [LVAD])
  - Elevated left atrial pressure (LAP) and cardiogenic shock despite inotropic support and intraaortic balloon pump (IABP)
    - LAP >25 mm Hg
    - Cardiac index (CI) <2 L/min/m^2
    - Severe left ventricular (LV) dysfunction on echocardiogram
    - Intractable ventricular arrhythmias
    - Ongoing myocardial ischemia despite revascularization
- Postcardiotomy failure (bilateral ventricular assist device [BiVAD])
  - Evidence of an elevated central venous pressure (CVP; >9 mm Hg) despite pulmonary afterload reduction
  - Evidence of severe right ventricular (RV) dysfunction on echocardiogram
  - Inability to provide adequate blood flow to fill the LVAD (if an LVAD is in place)
- Bridge to cardiac transplantation
  - Failure of optimal medical therapy that increases the risk of compromised life or end-organ function while awaiting cardiac transplantation
    - CI <2 L/min/m^2
    - Mixed venous oxygen saturation <50% on optimal medical therapy
    - Ventricular arrhythmias
    - Severe symptoms at rest
    - Need for multiple inotropic agents
    - Lack of response to diuretic medications, with a rising creatinine
    - Pulmonary artery hypertension
    - Cool and constricted extremities reflective of poor perfusion
    - Low blood pressure, resting tachycardia, rales, and/or distended neck veins
    - Laboratory evidence of prerenal azotemia, hepatic dysfunction, or coagulopathy
    - Requirement for supplemental oxygen
- Bridge to bridge: in conditions of cardiogenic shock when indications for cardiac transplantation are not yet met but are potentially attainable
- LVAD versus BiVAD
  - BiVADs should be considered for:
    - Intractable ventricular tachycardia or fibrillation
    - Cardiogenic shock requiring resuscitation with extracorporeal membrane oxygenation (ECMO)
    - Cardiogenic shock with multiorgan failure
    - Pulmonary edema despite maximal medical therapy
    - Chronic RV failure with ascites, low pulmonary artery pressure, severe hepatic or renal dysfunction, and tricuspid insufficiency
    - Severe acute respiratory distress syndrome
    - Giant cell myocarditis
    - Large anterolateral myocardial infarction with involvement of the anterior right ventricle
    - RV infarction
- Destination therapy
  - Indicated for patients who meet the previous criteria for bridge to transplantation (BTT) LVAD candidacy but who are not eligible for transplantation based upon age, obesity, renal dysfunction that will not tolerate immunosuppressive agents, or other comorbidities suggesting that the risk of transplantation is unacceptable
  - Patients with advanced heart failure (HF) symptoms (New York Heart Association [NYHA] class IIIB or IV) who meet at least one of these criteria:
    - Continued failure despite optimal medical management for at least 45 of 60 days
    - NYHA class III or IV status for at least 14 days and dependent on IABP for 7 days and/or inotropes for 14 days
    - Treated with angiotensin-converting enzyme (ACE) inhibitors or beta-blockers for at least 30 days and found to be intolerant of these medications
    - Maximal oxygen consumption (VO_2 max) ≤14 mL/kg/min or ≤50% predicted VO_2 max with exercise testing (unless testing is contraindicated because of class IV status)

Contraindications

- Postcardiotomy failure
  - Sepsis
  - "Stone heart," or lack of any innate cardiac function
  - Age >70 years
  - Condition in which recovery is not anticipated and the patient is not a candidate for cardiac transplantation
- BTT
  - Patient is not a candidate for cardiac transplantation
  - Sepsis
  - End-organ damage is not likely to recover
  - Severe impairment of neurologic function
  - Severe chronic obstructive pulmonary disease
  - Procoagulation abnormalities, with previous venous or arterial thrombosis despite anticoagulation therapy
  - Pregnancy
  - Inability or refusal to receive blood transfusions
  - Technical obstacles that pose an inordinately high surgical risk

- Destination therapy
  - Same as for transplantation, other than the requirement for cardiac transplantation candidacy
  - Lack of social or family support that allows for home discharge
  - Inability to comprehend plans for postoperative LVAD training
  - Expected need for prolonged biventricular support
  - Severe symptomatic peripheral vascular disease
  - Intolerance to anticoagulant or antiplatelet therapies or any other perioperative or postoperative therapy the patient will require based upon his or her health status
  - Psychiatric disease, irreversible cognitive dysfunction, or psychosocial issues likely to impair compliance with protocols and LVAD management

Equipment

- Postcardiotomy
  - IABP
  - ABIOMED AB/BVS 5000 (LVAD and BiVAD)
  - Tandem Heart
  - Thoratec CentriMag (LVAD and BiVAD)
  - Thoratec PVAD (LVAD and BiVAD)
- BTT
  - Thoratec PVAD (LVAD and BiVAD)
  - Heartmate II
  - Heartware HVAD
  - DuraHeart
  - Levacor
  - CardioWest Total Artificial Heart
- Destination therapy
  - Heartmate II
  - Heartware HVAD

PROCEDURE

- Intraoperative preparation and evaluation
  - Lines: arterial, venous, Swan-Ganz (continuous cardiac output type for continuous-flow LVADs)
  - Preoperative echocardiogram assessment
    - LV thrombus
    - Interatrial septal defect or patent foramen ovale (PFO)
    - Aortic insufficiency
    - Tricuspid insufficiency
    - RV function
  - Hemodynamic control
    - Management and preservation of perfusion pressure for RV and coronary arteries using alpha-agonists
    - Preoperative thromboelastogram to assess coagulopathy and the need for transfusion products
    - Cautious volume management
  - Cannulation for cardiopulmonary bypass
    - Distal ascending aortic site for inflow
    - Standard two-stage venous cannula for drainage (for standard LVAD)
    - Biatrial cannulation for BiVAD or if tricuspid repair or PFO closure is required
  - Apical LV cannulation achieved for LVAD
    - Apical cannulation performed according to protocol dictated by each individual VAD brand
    - Preperitoneal pocket required for some LVADs; otherwise, a subcostal tunnel is created as needed
  - Aortic outflow graft sewn end-to-side for outflow
  - RVAD cannulation via the right atrial appendage
  - RVAD return to the pulmonary artery via arterial cannula
  - Closure of pericardium preferred
  - Adequate chest tube drainage from mediastinum and pleural spaces

AFTER THE PROCEDURE

Postprocedure Care

- Hemodynamic and volume control
  - Blood pressure maintenance is critical for RV function.
  - Adequate inotropic support is needed for the RV.
  - Appropriate blood product replacement should be given, guided by thromboelastogram.
  - Adequate blood pump flow is determined by adequate CI (at least 2.4 L/min/m^2).
  - In most cases, decompression of the LV should not be so great as to cause right-to-left interventricular septal shift. Mitral regurgitation should be reduced and the aortic valve open occasionally.
  - CVP should be maintained between 8 and 12 mm Hg.
- Intensive care unit management
  - Maintain positive-pressure ventilation until mental status and pulmonary function allow for extubation.
  - Remove chest tubes as soon as possible.
  - Begin anticoagulation for the ventricular assist device (VAD) with heparin after 24 hours (if bleeding is less than 50 mL/hr), and convert to warfarin when the patient is taking oral fluids.
  - Broad-spectrum antibiotics should be continued for 4–5 days.
  - Active physiotherapy should be carried out, with an emphasis on pulmonary toilet and incentive spirometry.

Complications

- Common
  - Bleeding: mediastinal, wounds, driveline sites, gastrointestinal
  - RV dysfunction
  - Infection: driveline-associated (especially at exit site), pulmonary, urinary tract
- Infrequent
  - Neurologic events
  - Arrhythmias
  - Hemolysis
  - Psychiatric
- Serious, rare complications
  - Device malfunction

OUTCOMES AND EVIDENCE

Successful clinical evaluation of the Thoratec PVAD led to U.S. Food and Drug Administration (FDA) approval for BTT indication in 1992. Twenty-four patients (62%) required support with an LVAD alone, and 15 (38%) required BiVAD support. Survival from support to successful outcomes was 70% for BTT and 67% for postcardiotomy recovery.

The HeartMate II (Thoratec Corporation, Pleasanton, California) is a continuous-flow rotary pump with an axial design, which is representative of the second generation of LVAD technology in clinical use in the United States. Successful clinical evaluation of the Thoratec pVAD led to FDA approval for BTT indication in 1992. Of the 133 patients receiving support with the HeartMate II device, the principal efficacy outcomes were observed in 100 patients (75%). The median duration of support was 126 days (range, 1–600). The survival rate during support was 75% at 6 months and 68% at 12 months. There was significant improvement in distance walked between baseline and

6 months, with over 50% of patients experiencing an improvement in the 6-minute walk distance to over 200 meters.

In 1998, the National Heart, Lung, and Blood Institute funded the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial. REMATCH was a pivotal trial designed to assess morbidity, mortality, and functional outcomes in a homogeneous cohort of patients with advanced HF ineligible for cardiac transplantation. Survival rates at 1 year (52% vs. 25%, $P = 0.002$) and 2 years (23% vs. 8%, $P = 0.09$) were superior (significantly) in the VAD patients compared with the survival rates in those patients randomized to medical therapy.

After the original REMATCH publication, Park and colleagues analyzed the outcomes of the trial, based upon the era of enrollment. Despite more high-risk characteristics, patients enrolled in the latter half of the study had significantly higher 1- and 2-year survival rates than those enrolled during early experience with the VAD. A similar improvement in survival outcomes was seen in the postapproval registry, with a 56% 1-year survival rate. Improved outcome with VAD use and experience is a consistent observation, which was also evident in the continued access protocol cohort versus primary cohort in the HeartMate II BTT trial. Demonstration of improved survival outcomes in patients with preimplant risk profiles similar to or worse than those enrolled in the initial randomized trial suggests that refinement of preoperative and postoperative management and greater experience with mechanical circulatory support are important factors in determining survival and functional improvements after VAD implantation.

The HeartMate II DT Pivotal Trial evaluated 200 patients with NYHA class IIIb–IV symptoms, ejection fraction (EF) <25%, and VO_2 max ≤14 mL/kg/min or treatment with intravenous inotropic agents for at least 14 days or an IABP for 7 days. The patients were randomized to receive a HeartMate II ($n = 134$) or a HeartMate XVE ($n = 66$). There was a greater than fourfold increase in the percentage of HeartMate II patients who successfully reached the primary endpoint (46% vs. 11%, $P < 0.001$). Patients randomized to the HeartMate II had 1- and 2-year survival rates of 68% and 58%, compared with 55% and 24% in patients who received the HeartMate XVE.

Pericardiocentesis

Stefano Maggiolini and Felice Achilli

PREPROCEDURE

Indications

- Pericardial tamponade
  - Pericardiocentesis is the first treatment option in patients with overt tamponade because only the removal of fluid allows normal ventricular filling and restores adequate cardiac output.
  - If the patient is hemodynamically stable, the procedure should be performed within 12–24 hours from diagnosis, after obtaining laboratory results including the blood counts. A scoring index has been proposed in patients with a suspicion of tamponade for deciding whether to perform urgent pericardiocentesis or drainage later in the subsequent hours. It consists of three components obtained during the initial presentation: etiology, clinical presentation, and echocardiographic findings.
- Pericardial effusion without hemodynamic compromise
  - Chronic asymptomatic large pericardial effusion (>20 mm evaluated as the largest telediastolic echo-free space in two-dimensional mode). In this case there are not mandatory indications. We think that a close clinical and echocardiographic monitoring, with the need to resort to pericardiocentesis in the case of symptoms or progression of the effusion, is very important.
  - Suspected bacterial or tuberculous pericarditis
    - Elective pericardiocentesis is warranted in patients with suspicion of purulent pericarditis.
    - Purulent pericarditis should be managed aggressively, as death is inevitable if untreated, whereas with comprehensive therapy, 85% of cases have been reported to survive the episode and have a good long-term outcome.
    - Treatment consists of systemic antibiotic therapy and complete evacuation of the effusion. Surgical drainage usually is required, because percutaneous drainage alone is not able to completely evacuate the effusion, which is often rich in fibrin and can be loculated and associated with dense adhesions. An alternative and less invasive method, which can be used to completely evacuate purulent effusions, thus controlling sepsis and avoiding the evolution to constrictive pericarditis, consists of pericardial drainage associated with intrapericardial infusion of streptokinase. Fibrinolytic therapy can enhance the removal of material that would otherwise be too viscous or particulate to be removed by tube drainage. This treatment should be considered before undertaking surgery.
  - Suspected neoplastic effusion
  - Pericardiocentesis for diagnostic purpose in mild or moderate effusions (<20 mm) should be confined to selected cases.
    - Pericardiocentesis with a diagnostic purpose (except in cases of suspected neoplastic, tuberculous, or purulent pericarditis) is not justified in the majority of cases for the following reasons: (1) low diagnostic power; (2) the underlying pathology is often already known or identifiable by different noninvasive tests; (3) viral pericarditis is usually self-limiting, and it only requires an antiinflammatory treatment; and (4) high procedural risk.

Contraindications

- Urgent pericardiocentesis or drainage of pericardial effusion is indicated for each patient with an established diagnosis of cardiac tamponade and hemodynamic shock.
- Aortic dissection and postinfarction rupture of the free wall are contraindications to pericardiocentesis and indications for urgent surgical drainage. When surgical management is not immediately available or the patient is too unstable, pericardiocentesis and controlled pericardial drainage of very small amounts of the hemopericardium can be attempted to temporarily stabilize the patient in order to maintain blood pressure at ~90 mm Hg.
- Relative contraindications include uncorrected coagulopathy, anticoagulant therapy, and thrombocytopenia (PLTc <50,000/mm^3) and small, posterior, and loculated effusions.
  - The alterations of coagulation can be corrected using:
    - Fresh frozen plasma or platelets (may be time consuming)
    - Recombinant human factor VIIa, which may be effective in a shorter time.
    - For patients on warfarin: vitamin K + prothrombin complex concentrate (PCC 50 U/kg)
  - In case of patients receiving novel oral anticoagulants (NOACs) (non–vitamin K antagonist oral anticoagulants), it is necessary to use different strategies depending on the type of NOAC. A specific reversal agent for dabigatran (idarucizumab) has shown a nearly complete reversal of the anticoagulant effects within minutes.
  - A similar reversal agent, Andexanet alfa, a recombinant modified human factor Xa decoy protein that reverses the inhibition of factor Xa, has been recently introduce for patients treated with apixaban, rivaroxaban or edoxaban. If the reversal agent is not available the interventional strategy is similar to patients on warfarin with administration of PCC 50 U/kg or activated PCC 50 U/kg. The efficacy of PCC or aPCC has not been firmly established to neutralize the anticoagulant effect of these drugs. The administration of PCC or aPCC can be considered if immediate hemostatic support is required.

Equipment

- Echocardiography
- Multiangle bracket, to be assembled on the probe
- Needle-guide kit with sterile sheath and sterile echo-gel (Ultra Pro II needle guide [CIVCO USA, Kalona, IA])

- 14- to 16-gauge Teflon-sheathed needle (technique A)
- 18-gauge, 9-cm needle on a syringe for apical approach (technique B)
- 18-gauge, 15-cm needle, included in the PeriVac set (Boston Scientific USA, Marlborough, MA) for subxiphoid approach
- J-tipped guidewire
- 6F–8F dilator
- Drainage catheter: pigtail angiocatheter 6F–8F or pericardiocentesis set (PeriVac)
- Disposable flushing system to maintain the patency of the system

ANATOMY

The pericardium is a fibroserous sac that contains the heart and the origin of the main vessels. The pericardium is composed of two layers: the visceral pericardium, a monolayer membrane of mesothelial cells that is adherent to the epicardial surface of the heart, and the fibrous parietal layer that surrounds most of the heart. The pericardial space normally contains 25–50 mL of fluid in adults. If the amount of fluid increases, the pericardium is not immediately distensible, even though stress relaxation may occur within minutes from the beginning of the increase in pericardial pressure. If the fluid accumulates slowly, over weeks or months, the pericardium can increase in size to a maximum capacity of 1–2 L. The heart, and therefore the pericardium, is located at the center of the mediastinum, partially covered by the lungs; by the sternum and by the costal cartilages of the third, fourth, and fifth ribs; and by intercostal muscles. About two-thirds of the heart is located on the left side of the chest. The heart rests on the diaphragm. The pericardium is innervated by the vagus nerve, by the left recurrent laryngeal nerve, and by the esophageal plexus, and it also has rich sympathetic innervation from the stellate and first dorsal ganglia and the cardiac, aortic, and diaphragmatic plexuses. When performing pericardiocentesis, close attention should be paid to avoid damaging the internal thoracic artery, which runs behind the sternal end of the costal cartilages, and the vascular bundle at the inferior margin of each rib (Fig. E9.1).

PROCEDURE

Echo-Guided Technique (A)

- Perform a two-dimensional and Doppler study to assess the size, distribution, and hemodynamic effect of the effusion.

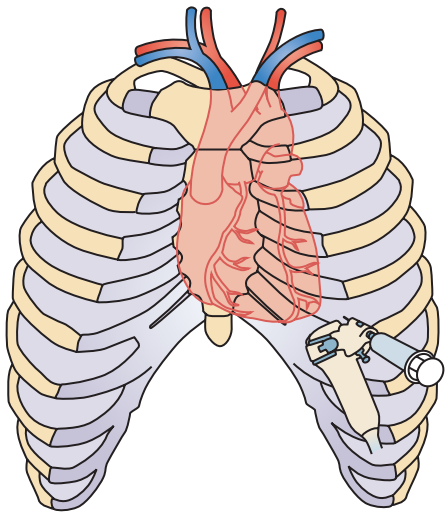

Fig. E9.1 Projection of cardiac area on the anterior thoracic wall.

- Place the patient in a semireclining position, at an angle of about 30 degrees, and slightly rotated leftward to enhance fluid collection in the inferoanterior part of the chest.
- Ensure that a central venous catheter is in place. The catheter is essential for monitoring right atrial pressure and permitting the rapid infusion of fluids and drugs as indicated.
- Continuous arterial pressure monitoring is indicated to detect the presence of pulsus paradoxus and to rapidly detect and correct sudden hemodynamic instability.
- Medical management:
  - In the unstable patient with hypotension and tachycardia, during preparation for pericardiocentesis, measures aimed at stabilizing the patient should be instituted. Intravenous fluid administration is the best treatment option before and during drainage. In stable patients without low systolic blood pressure (>100 mm Hg), this treatment is not useful, and it could be dangerous in terms of reducing the cardiac output.
  - Intravenous administration of diuretics is contraindicated and could be fatal in patients on the edge of their compensatory mechanism in tamponade.
  - Both dopamine and dobutamine improved hemodynamics in cardiac tamponade; dobutamine has greater beta activity, and therefore it may be considered preferable. However, the usefulness of inotropes is generally limited because endogenous adrenergic stimulation is already enhanced under tamponade conditions, and ejection fraction is preserved, but stroke volume is critically depressed.
  - Packed red cell units should be readily available before starting nonemergency procedures.
- Respiratory management
  - Pulse oximetry and supplemental O_2 should be warranted.
  - Influence of respiratory parameters: spontaneous versus mechanical ventilation and $PaCO_2$ levels significantly influence the evolution of pericardial tamponade. Pericardial pressure decreases 3–6 mm Hg when $PaCO_2$ decreases to 24 mm Hg; conversely, pericardial pressures increase 2–4 mm Hg when $PaCO_2$ reaches 57 mm Hg. Increased intrathoracic pressures during the inspiratory phase of mechanical ventilation can decrease cardiac output up to 25% in patients with tamponade. To avoid further hemodynamic compromise, patients with suspected cardiac tamponade should not receive positive-pressure ventilation unless absolutely necessary.
- After appropriate disinfection of the operative field, local anesthesia of the skin is obtained by injecting with 2% lidocaine subcutaneously.
- The trajectory of the needle is defined by the angle between the probe and the chest wall. Ultrasound does not cross aerial spaces. Therefore, if cardiac structures are identified, there is no lung tissue interposed between the probe and the pericardium.
- The proper landmark for needle insertion corresponds to the area where the pericardial space is closest to the probe and the fluid accumulation is maximal; this site is para-apical more often than subxiphoid. The subcostal route is less frequently used because it requires a longer path to reach the fluid. It passes anterior to the liver capsule and is directed toward the right chamber of the heart.
- The optimal needle trajectory should be transfixed in the operator's mind and then a 14- to 16-gauge Teflon-sheathed needle with an attached saline-filled syringe is advanced in the direction of the fluid-filled space.
- Para-apical approach: Insert the needle at 3–5 cm from the parasternal border (to avoid the internal thoracic artery) and close to the superior edge of the rib (to avoid the intercostal artery).

- Subxiphoid approach: Direct the needle posteriorly until the tip passes posterior to the bony cage. Press the hub of the needle toward the diaphragm and advance the needle with a 15-degree posterior tilt, either directly toward the patient's head or toward the right or left shoulder.
- When fluid is aspirated, the needle should be advanced approximately 2 mm farther. The sheath should be advanced over the needle and the steel core withdrawn.
- If bloody fluid has been aspirated or if the position of the sheath is questionable, the position of the catheter can be confirmed by injecting 5 mL of agitated saline through the sheath. The bubbles in the solution provide a contrast effect that can be observed by two-dimensional echocardiography. Thus if contrast agent appears in the pericardial space, the procedure can be continued.
- A guidewire should be advanced through the sheath, and then the sheath should be removed over the guidewire.
- A small incision should be made at the entry site, followed by introduction of a dilator (6F–8F) over the guidewire. Predilatation of the chest wall passage facilitates subsequent insertion of the introducer sheath-dilator (6F–8F).
- The guidewire and the dilator should be removed and only the sheath left in the pericardial sac. A pigtail angiocatheter should be inserted through the introducer sheath and the fluid aspirated.

Real-Time Echo-Monitored Procedure (B)

(This is the technique preferred by the authors.) See Video E9.1.

- A different approach uses a needle carrier mounted on the transducer to advance the needle to the pericardial space under continuous visualization.
- Patient preparation and supportive management are the same as those described earlier.
- Mount the bracket on the probe to support the needle-guide kit and to allow a real-time echo-monitored procedure. The bracket supports the needle with different angles, and the operator can choose between a closer angle for the subcostal approach and a wider angle for the apical approach (Fig. E9.2).
- Cover the probe with the sterile sheath and mount the needle-guide kit on the sheathed probe (Fig. E9.3).
- Once the optimal position is found and the pericardiocentesis procedure is started, the echocardiography probe should not be more mobilized to avoid tearing the tissue. The execution of the technique with two operators can be useful to minimize this risk; one can firmly hold the probe, and the other can advance the needle. The needle (SDN 18-gauge, 9-cm Cook for apical approach, or the needle included in the PeriVac set for subxiphoid approach) is connected to a syringe for constant gentle aspiration and is slowly introduced through the tissues until there is echographic visualization of the tip (Fig. E9.4A–C).
- When the needle tip is observed on the echo screen in the pericardial space and fluid is freely aspirated, the syringe is disconnected and a J-tipped guide is inserted (see Fig. E9.4D).
- The technique is summarized in Fig. E9.5.
- Remove the needle and make a small incision at the site of insertion.
- The drainage catheter (a pigtail angiocatheter 6F–8F or pericardiocentesis set [PeriVac]) is subsequently introduced along the guidewire, according to the Seldinger technique, after introducing a 6F–8F dilator over the guidewire.
- Completely aspirate the pericardial effusion by syringe suction if the pericardial sac contains <1 L.

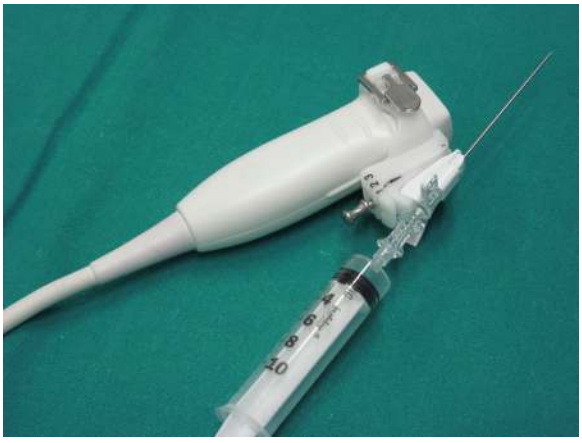

Fig. E9.2 Echocardiographic probe with bracket, needle guide, and syringe.

Fig. E9.3 After the bracket is mounted, the probe is protected by sterile wrap.

AFTER THE PROCEDURE

Postprocedure Care

- After the procedure, perform a chest radiography to exclude the presence of pneumothorax or pneumopericardium.
- Repeat aspiration by syringe every 4–6 hours. In order to optimize catheter patency, it could be useful to use a disposable continuous flushing system between aspirations.
- Remove the catheter once the drainage has decreased to less than 25–30 mL in 24 hours.
- It is important to empty the pericardial sac as completely as possible to reduce the risk of recurrence, leaving the catheter in place up to 72 hours (or more) if the fluid has a rate of accumulation greater than 30 mL in 24 hours. The removal of the liquid must take place gradually (max 1 liter during the first phase), and the removal must be completed in the following hours. This is to avoid a potentially serious complication: pericardial decompression. Pericardial decompression is a rare, potentially life-threatening syndrome characterized by wide clinical scenarios (from pulmonary edema to cardiogenic shock) that can develop after a successful pericardial drainage.
- The omission of extended catheter drainage is an important independent predictor of recurrence.
- Reaccumulation of pericardial fluid is common in patients with malignant pericardial effusions (40%–70% recurrence rate without

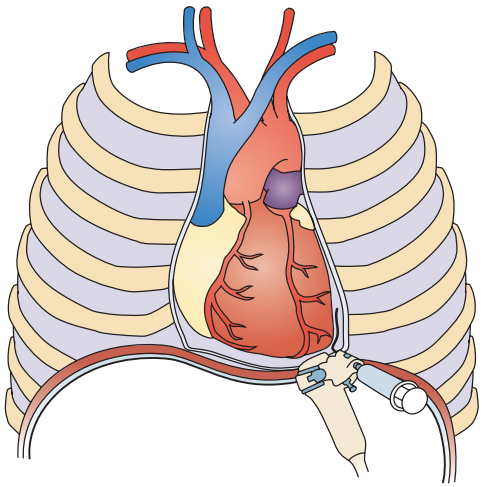

Fig. E9.5 Representation of pericardiocentesis using the apical approach. The pericardial needle is continuously monitored by apical four-chamber echocardiographic view while entering the pericardial space. When the pericardial effusion is reached, a guidewire is introduced in the pericardial space.

specific treatment). In these patients, several measures have been suggested to prevent recurrence of tamponade. These approaches include (1) complete evacuation of the fluid, (2) prolonged pericardial drainage, and (3) systemic antineoplastic treatment as baseline therapy. Other suggested measures are intrapericardial instillation of sclerosing and cytotoxic agents tailored to the type of tumor, radiation therapy in patients with radiosensitive tumors (i.e., lymphomas and leukemias), and pericardiotomy.

- Perform a complete echocardiographic study in all patients before removing the catheter and before discharge from the intensive care unit (ICU) or coronary care unit.

Complications

- Common
  - Puncture of cardiac chambers (1.5%)
  - Pneumothorax (1%)
  - Pleuropericardial fistulas (0.8%)
  - Arrhythmias (usually vasovagal bradycardia)
- Infrequent
  - Laceration of coronary arteries or intercostal vessels
  - Bacteremia
  - Pneumopericardium
- Serious, rare complications
  - Death (0.1%–0.5%)
  - Chamber laceration requiring surgery
  - Pericardial decompression

In a series of 161 pericardiocenteses performed under continuous echocardiographic visualization (technique B), two major complications occurred (1.2%), no deaths, no perforations or ruptures of cardiac chambers were reported, and the incidence of minor complications was 4.3%.

In the case of the most frequent complication, some suggestions can be given: Puncture of the cardiac chambers with the needle can be solved in most cases with the needle retraction and the insertion of the catheter into the pericardium. If the perforation is carried out by the catheter, it must be left in place and a new pericardiocentesis must be carried out by placing another catheter in the pericardium before removing the previous one; then the perforating catheter can be withdrawn. If the controlled drainage resolves the tamponade, also with eventual autotransfusion of pericardial blood, surgery can be avoided.

OUTCOMES AND EVIDENCE

- Randomized studies comparing different techniques do not presently exist.
- Pericardiocentesis-related mortality and serious complications are low when the procedure is performed by trained professionals following consolidated techniques.
- Percutaneous pericardiocentesis has been performed for many years using the blind subxiphoid approach. This technique is associated with a high incidence of morbidity and mortality, and using electrocardiographic needle monitoring does not lead to significantly better outcomes. Accordingly, blind approaches are no longer justified.

Paracentesis and Diagnostic Peritoneal Lavage

Louis H. Alarcon

PARACENTESIS: BEFORE THE PROCEDURE

Indications

- Paracentesis is the insertion of a needle or catheter into the peritoneal cavity for the purpose of aspirating peritoneal fluid. It is most often indicated for diagnostic or therapeutic evacuation of ascites.
- Diagnostic indications
  - New-onset ascites: fluid evaluation to help determine etiology, differentiate transudate versus exudate, detect the presence of cancerous cells, or address other considerations
  - Differentiate between suspected spontaneous or secondary bacterial peritonitis
- Therapeutic indications
  - Respiratory compromise secondary to ascites
  - Abdominal pain or pressure secondary to ascites (including abdominal compartment syndrome)

Contraindications

- Absolute contraindication
  - Acute abdomen that requires surgery
- Relative contraindications
  - Inadequate volume of ascites on imaging (e.g., ultrasound)
  - Uncorrected hypovolemia
  - Severe uncorrected thrombocytopenia (platelet count <20,000/μL) or coagulopathy (international normalized ratio [INR] >2.0)
  - Pregnancy
  - Distended urinary bladder
  - Abdominal wall cellulitis
  - Distended bowel
  - Intraabdominal adhesions

Equipment

- Ultrasound machine
- Local anesthetic
- Chlorhexidine prep
- Sterile towels, gloves
- 18- or 20-gauge, 2- to 3-inch needle
- 20- to 50-mL syringe
- 14- to 16-gauge cannula-over-needle
- 8.5F 40-cm polyurethane pigtail catheter with guide wire
- 2-0 polypropylene suture

ANATOMY

The site for paracentesis is in the abdomen, lateral to the rectus muscle in the lower quadrant midway between the umbilicus and the anterior superior iliac spine, avoiding prior surgical incisions. Ultrasound guidance is recommended to identify the site of the largest volume of ascites and reduce the chance of injury to the intestines.

PROCEDURE

See Video E10.1.

- The patient should be supine. Bedside ultrasonography can be a valuable aid for localizing the largest collection of ascites and avoiding injury to the bowel and should be employed routinely. The patient should void or have a urinary bladder drainage tube inserted before the procedure. The area is cleansed, draped, and anesthetized.
- When a small volume of ascitic fluid is needed for diagnostic studies, an 18- or 20-gauge, 2- to 3-inch needle attached to a 20- to 50-mL syringe is inserted into the abdomen lateral to the rectus muscle in the lower quadrant, midway between the umbilicus and the anterior superior iliac spine, avoiding prior surgical incisions. The skin is retracted caudad while inserting the needle. When fluid is aspirated, the needle is stabilized, and the fluid sample is obtained by syringe. After removal of the needle, the skin is released, causing the entrance and exit needle sites to form a "Z-track" that reduces the chance of ascitic fluid leakage.
- For large-volume paracentesis, a 14- to 16-gauge cannula-over-needle is employed. Once the fluid is aspirated into the syringe, the needle is removed, leaving the plastic catheter in place, which is attached to plastic tubing and a vacuum canister. Usually, 4–6 L of ascites can be safely removed, although larger volumes have also been obtained.
- If it is necessary to place a catheter into the peritoneal cavity, a guide wire should be inserted into the peritoneal cavity through the needle; an 8.5F 40-cm polyurethane pigtail catheter should be guided into the peritoneal cavity over the wire and sutured in place.
- The aspirated fluid should be submitted for a cell count, absolute polymorphonuclear neutrophil count, albumin, total protein concentration, Gram stain, and cultures. Optional studies, based on clinical suspicion, may include glucose concentration, amylase concentration, lactate dehydrogenase concentration, bilirubin concentration, and cytology.

AFTER THE PROCEDURE

Postprocedure Care

- The patient should be closely monitored for complications (see later), especially bleeding and peritonitis.
- If a pigtail catheter is left in place, it should be attached to a collection bag and monitored for bleeding or the drainage of succus.

Complications

- Common
  - Hypotension
    - Hypotension after paracentesis in cirrhotic patients can be associated with a worsening of arteriolar vasodilation.[1] In the first few hours after large-volume paracentesis, there is a reduction in the plasma levels of renin and aldosterone, an increase in the atrial natriuretic peptide concentration, a reduction in the cardiac filling pressures, and an increase in the cardiac index.
    - However, after 12–24 hours, these changes reverse, reflecting effective hypovolemia. Infusion of intravenous colloids, specifically albumin, has been shown to attenuate the hemodynamic consequences of paracentesis and the associated neurohumoral alterations.[2] However, no large, randomized study has shown that routine expansion of plasma volume with a colloid solution confers a survival advantage.
- Infrequent
  - Bleeding
    - The incidence of significant hemorrhage from this procedure is about 1%, despite the fact that over 70% of patients have clotting parameter abnormalities.[3] Therefore it is usually unnecessary to normalize the prothrombin time before proceeding.[4]
- Serious complications (e.g., bowel perforation) are rare (0.1%)[3]
  - Peritonitis
  - Bowel injury
  - Injury to the bladder
  - Injury to the epigastric vessels

OUTCOMES AND EVIDENCE

- Determining the etiology of ascites is based on the patient's history, physical examination, liver function tests, ultrasonography, and ascitic fluid analysis. Abdominal paracentesis and ascitic fluid analysis should be an early step in the workup of patients with new-onset ascites. Paracentesis is also important to diagnose infection of the ascitic fluid (i.e., peritonitis).
- Development of ascites is a common complication of cirrhosis, being more frequent than either encephalopathy and variceal hemorrhage in these patients. The median survival of cirrhotic patients with ascites is 2 years.[5] Other causes of ascites besides cirrhosis include malignancy, heart failure, tuberculosis, renal failure, and pancreatic disease.
- The mainstays of treatment of ascites secondary to cirrhosis involve dietary sodium restriction (2 g/day) and oral diuretics (e.g., spironolactone and furosemide).
  - The underlying etiology of liver disease should be corrected when possible, and ethanol consumption should be strongly discouraged. Abstinence from ethanol can normalize portal venous pressures in some patients with early ethanol-induced liver disease.[6]
  - Patients with early cirrhosis and diuretic-responsive ascites should not be managed by serial paracentesis; rather, medical management should be employed. In the majority of patients, ascites can be controlled with medical management.
  - In 5%–10% of patients, ascites becomes resistant to medical treatment. The standard of care for the management of refractory ascites is therapeutic paracentesis. This can be performed as often as every 2 weeks to control symptomatic ascites.
  - Other options for managing refractory ascites include transjugular intrahepatic portosystemic shunt (TIPS) and liver transplantation. In a randomized trial of 60 patients comparing TIPS with repeated therapeutic paracentesis, the probability of survival without liver transplantation at 2 years was 58% in the TIPS patients as compared with 32% in the paracentesis patients.[7] A smaller study of 25 patients randomized to TIPS or paracentesis demonstrated the opposite: mortality was higher in the TIPS group.[8]
  - Surgical portosystemic and peritoneovenous shunts have fallen out of favor because of the high incidence of morbidity and mortality and the development of hepatic encephalopathy.
  - For patients with tense ascites, large-volume paracentesis rapidly relieves intraabdominal pressure. A single 4- to 6-L paracentesis can be performed safely and often does not require an infusion of colloids.[9] However, paracentesis does nothing to correct the etiology of the ascites, and ascites will recur if sodium restriction and diuretics are not instituted or fail. Referral for liver transplant evaluation should be considered for eligible patients with cirrhosis and refractory ascites.
  - Infection of ascitic fluid often occurs in cirrhotic patients. When there is no surgically correctable etiology (e.g., perforated viscus), the term *spontaneous bacterial peritonitis* is used. This diagnosis is made when there is a positive ascitic fluid culture or an ascitic fluid polymorphonuclear (PMN) cell count greater than 250 cells/mm^3 in the correct clinical scenario without any evidence for an intraabdominal, surgically correctable etiology. The infection is usually monomicrobial. Polymicrobial infection suggests secondary peritonitis. Consideration of the diagnosis mandates paracentesis and evaluation of the ascitic fluid; a clinical diagnosis without paracentesis is inadequate.

DIAGNOSTIC PERITONEAL LAVAGE: BEFORE THE PROCEDURE

Indications

- With the widespread use of focused abdominal sonography for trauma (FAST), the indications for diagnostic peritoneal lavage (DPL) are decreasing
- Patients who have sustained blunt trauma and have no overt signs of acute abdominal injury or bleeding but require an evaluation to rule out intraabdominal hemorrhage or hollow viscus injury
- Patients who are not candidates for computed tomography (CT) (e.g., because of hemodynamic instability) or when FAST is unavailable or yields equivocal results

Contraindications

- The only absolute contraindication to performing a DPL is the clinical condition of the patient mandating immediate laparotomy.
- Relative contraindications include previous abdominal surgery, cirrhosis, obesity, and coagulopathy.
- In patients with pelvic fractures or pregnancy, a supraumbilical incision should be performed.

Equipment

- Local anesthetic
- Chlorhexidine prep
- Sterile towels, gloves
- 10-mL syringe
- 8F–9F 25-cm lavage catheter
- 2-0 polypropylene suture

ANATOMY

DPL should be performed in the midline of the abdomen immediately below the umbilicus, or above the umbilicus in patients with a pelvic

fracture, suspected pelvic hematoma, or pregnancy. Prior surgical incisions should be avoided if possible.

PROCEDURE

- The patient should be in the supine position. Gastric and bladder decompression tubes should be inserted to minimize the risk of injury to these organs. The periumbilical skin should be prepped and draped sterilely. Local anesthesia is injected into the site.
- DPL can be performed with an open, semiopen, or closed technique.
  - The open technique employs a midline infraumbilical abdominal incision 2–5 cm in length; the incision should be supraumbilical if the patient has a pelvic fracture or is pregnant. A small incision is made in the midline abdominal fascia and peritoneum. An 8F–9F 25-cm lavage catheter with side holes is inserted under direct visualization toward the pelvis.
  - The closed method uses a Seldinger technique. A 16-gauge, 3-inch needle is inserted through a skin puncture and into the peritoneal cavity. A guide wire is passed through the needle into the peritoneal cavity. The lavage catheter is inserted over the wire.
  - The semiopen technique involves incising the skin and fascia and then using a guide wire technique for inserting the catheter into the peritoneal cavity.
- Once the catheter is placed, aspiration should be attempted with a syringe.
- If 10 mL of blood is aspirated, the DPL is considered positive, and appropriate surgical intervention should be undertaken.
- Otherwise, 1 L of crystalloid solution is infused (10 mL/kg in pediatric patients) and then retrieved by gravity and sent to the laboratory for analysis.
- In general, the DPL is considered positive in blunt-trauma patients if:
  - Red blood cell (RBC) count is greater than 100,000/mm^3
  - White blood cell (WBC) count is greater than 500/mm^3
  - Amylase concentration is greater than 100 IU/L
- Other positive findings include the presence of bile or food particles or the drainage of lavage fluid from the bladder drainage catheter, gastric tube, or thoracostomy tube.
- The sensitivity and specificity of the test are dependent on the threshold criteria for determining a positive test result.
- If the lavage is negative but there is a high index of suspicion for intraabdominal pathology, the DPL catheter can be left in place for repeat lavage to rule out delayed hemoperitoneum or intestinal perforation.

AFTER THE PROCEDURE

Complications

- Infrequent
  - Bowel or vascular injury occurs in less than 1%[10]
  - Bladder injury
  - Bleeding (cause for a false-positive DPL result)
  - Wound infection

OUTCOMES AND EVIDENCE

- Evaluation of the abdomen is a critical component in the assessment of injured patients. Failure to identify intraabdominal injury results in preventable morbidity and mortality in trauma patients. The physical examination for abdominal injury is often hampered by alterations of the sensorium by substances (e.g., ethanol and illicit drugs), injury to the central nervous system, or pain from other injuries. Moreover, a significant amount of blood can be present in the peritoneal cavity without obvious abdominal distention or peritoneal signs.
- DPL, CT, and ultrasonography have emerged as the main diagnostic modalities to evaluate trauma patients and currently have complementary roles. DPL was introduced by Root and colleagues in 1965 for the evaluation of abdominal trauma.[11]
  - In the era before CT and ultrasonography, DPL was the first well-established method to identify hemoperitoneum in trauma patients.
  - DPL is primarily useful in diagnosing hemoperitoneum from blunt, solid-organ injury, but it can also be helpful for the diagnosis of hollow viscus injury.
- For *hemodynamically stable* patients with an equivocal abdominal examination, associated neurologic injury, or painful injuries, abdominal CT is recommended as the diagnostic modality of choice and has all but eliminated the need for DPL in these patients.
  - CT is also the preferred diagnostic method for determining whether nonoperative management of a solid-organ injury is appropriate.
  - Furthermore, in stable patients with a positive DPL, a follow-up abdominal CT should be considered. Thus CT and DPL play complementary roles in evaluating stable patients after blunt abdominal trauma.
- For *hemodynamically unstable* patients, FAST and DPL are the preferred tests, with FAST rapidly gaining acceptance over DPL in many trauma centers as the preferred initial diagnostic modality.
  - FAST and DPL are used to rule out hemoperitoneum as the cause of hemodynamic instability.
  - In contrast to DPL, FAST can be used to identify pericardial tamponade.
  - These tests can be performed expeditiously, and ongoing efforts at resuscitation and evaluation can occur simultaneously with the performance of the test.
  - Because resuscitation is difficult during CT, CT is contraindicated when patients are hypotensive or hemodynamically unstable.
  - DPL is also useful in certain clinical scenarios. Consider, for example, a head-injured patient needing an emergency craniotomy: DPL can be performed in the operating room at the same time as the craniotomy without interfering with the neurosurgical procedure.
- Controversy exists regarding the best way to manage blunt trauma patients with isolated evidence of free intraabdominal fluid by CT but without evidence of solid-organ injury.
  - In a review of the literature, isolated free fluid was observed in 2.8% of over 16,000 blunt trauma patients studied with CT.[12] Of these, only 27% underwent a therapeutic laparotomy, so some experts recommend serial abdominal examinations, whereas others recommend surgical exploration to rule out hollow viscous injury.
  - DPL can be useful in the evaluation of patients with suspected perforated viscus. Very early after bowel perforation, the WBC count in the lavage fluid may be low; however, within a few hours after injury, the degree of inflammation is usually sufficient to increase the WBC count in the lavage fluid to greater than 500 cells/mm^3. The presence of bile, amylase, bacteria, or food particles in the lavage fluid also confirms intestinal perforation.
- The use of DPL in the evaluation of hemodynamically stable patients with penetrating abdominal wounds remains controversial.

  - A significant number of missed injuries remain undetected by this method. For example, Kelemen and colleagues[13] reported a 21% false-negative rate for stable patients with abdominal gunshot wounds. Using a low RBC threshold (1000/mm^3) has been described in an attempt to overcome this shortfall.[14]
- False-positive DPL leading to unnecessary laparotomy may occur in as many as 30% of cases.[10,15] This problem can be reduced by using CT as a complementary test in stable patients. The false-negative rate (i.e., failure to diagnose hemoperitoneum) is low. However, DPL is unable to detect retroperitoneal injuries (CT is the preferred test to detect retroperitoneal injuries for the stable patient) and is insensitive for detecting early hollow viscous and diaphragmatic injuries.
- One of the major problems with DPL is that the test is too sensitive. Only about 30 mL of the blood in the peritoneal cavity is necessary to produce a positive DPL. In this era of selective management of solid-organ injuries, a significant number of nontherapeutic laparotomies would be performed on the basis of these DPL results unless the diagnostic evaluation includes other modalities as well.
- Proponents of the open technique argue that it is safer, whereas proponents of the closed and semiopen methods argue that these approaches are more expeditious and can be safely performed by appropriately trained individuals.
- A large meta-analysis that aggregated the results from 1126 patient trials showed that the incidence of major complications is not different for the diverse DPL techniques.[16]
- Failure to properly place the catheter and technical difficulties were more likely to occur with the closed method, whereas the procedure time was shorter with the open method (17.8 vs. 26.8 minutes, respectively).
- Sensitivity, specificity, and accuracy were not different between the various methods of catheter insertion.

Thoracentesis

J. Terrill Huggins, Amit Chopra, and Peter Doelken

BEFORE THE PROCEDURE

Indications

- Pleural effusion is not explained by the clinical presentation
- Massive pleural effusion with impending respiratory failure
- Suspected pleural space infection
- Suspected complication of pneumonia (empyema)
- Suspected hemothorax

Contraindications

- Absolute
  - Lack of expertise
  - Severe uncorrectable coagulopathy (platelet count <25,000 cells/μL; international normalized ratio [INR] >2.0)
  - Azotemia (creatinine >6 mg/dL)
  - Uncooperative patient
- Relative
  - Operator-dependent and of technical nature
  - Lack of image guidance to determine the safety of the puncture site

Equipment

- Diagnostic thoracentesis
  - Iodophor- and chlorhexidine-containing antiseptic
  - 10- and 30-mL sterile syringes
  - 21-gauge needle
  - 21-gauge spinal needle may be needed for obese patients
  - 1% lidocaine for use as local anesthetic
- Therapeutic thoracentesis
  - Commercially available catheter-over-needle system

ANATOMY

The pleura is a serous membrane that covers the lung parenchyma, mediastinum, diaphragm, and rib cage. The pleura is divided into the visceral and parietal pleura. The visceral pleura covers the lung parenchyma and the interlobar fissures. The parietal pleura lines the inside of the chest wall and the diaphragm. As pleural fluid forms, separation of the visceral and parietal pleura occurs, creating a space for a needle to be placed safely. Free-flowing pleural fluid will collect through gravitational effects in dependent areas. Thus if a patient is sitting upright, pleural fluid will collect along the diaphragm and the costophrenic and cardiophrenic angles. In contrast, in a supine patient, pleural fluid will collect along the posterior aspects of the lung.

The parietal pleura receives its blood supply from the systemic capillaries of the intercostal arteries supplying the costal pleura, whereas the mediastinal pleura is supplied by the pericardiacophrenic artery. The diaphragmatic pleura is supplied by the superior phrenic and musculophrenic arteries. The bronchial arteries likely supply the visceral pleura. The intercostal artery, vein, and nerve travel below the ribs. It is important to understand that the neurovascular bundle is not protected by the phalange of the rib within the first 8–10 cm from the origin of the vessels and nerves from the spine. Performing a thoracentesis near the spine increases the risk of intercostal artery laceration and hemothorax.

PROCEDURE

See Video E11.1.

- Obtain informed consent.
- Place patient in a sitting position if hemodynamically stable, or move the patient to the edge of the bed, with the head of the bed elevated to a 30- to 45-degree angle.
- Perform thoracic ultrasonography, and mark the puncture site.
- The upper margin of the rib immediately below the access area should be defined by palpation (may be impossible with obesity).
- The area should be disinfected with an iodophor- or chlorhexidine-containing antiseptic.
- Use 1% lidocaine without epinephrine for local anesthesia.
- Perform the procedure under sterile conditions at this point.
- Inject lidocaine subcutaneously into the periosteum of the rib and the parietal pleura, ensuring that the upper margin of the rib is identified and anesthetized.
- The upper margin of the rib should be identified with a 21-gauge needle before placing a thoracentesis catheter for a therapeutic procedure.
- Accessing the pleural space over the upper margin of the rib (this should be identified) places the needle at a greater distance from the intercostal vessels and nerves.
- Always maintain the needle angle perpendicular to the patient.
- Once the pleural fluid is aspirated, retract the needle outside the pleural space.
- Place a 30- to 60-mL syringe onto the needle, and advance into the pleural space to collect the specimen.
- If therapeutic thoracentesis is desired, withdraw the needle after the pleural fluid is clearly aspirated.
- If fluid cannot be obtained with a small-gauge needle, no attempts at placing a thoracentesis catheter should be made.
- Insert the catheter-over-needle system under continuous application of suction until the pleural fluid is aspirated.
- Once the pleural fluid is obtained, advance the catheter system another 1 cm to place the catheter with its maximum diameter in the pleural space.
- Without advancing the needle, strip the catheter into the pleural space, and remove the needle.
- To prevent air entry into the pleural space, turn the thoracentesis stopcock off as related to the patient.

- Finally, connect the drainage tubing and collection bag to the thoracentesis catheter.
- To prevent the development of excessively negative pleural pressures in ventilated patients, draining large amounts of pleural fluid is not recommended unless pleural manometry is performed.

AFTER THE PROCEDURE

Postprocedure Care

- A postprocedure chest radiograph should be performed on all ventilated patients.
- Monitor for signs of tension pneumothorax and hemothorax
  - Hypotension
  - Worsening lung compliance in ventilated patients
  - Tube thoracostomy is required for all patients who develop a pneumothorax on mechanical ventilation

Complications

- Common
  - A cough caused by lung reinflation
  - Anterior chest pain in the setting of an unexpandable lung
  - Pain at the puncture site
  - Seroma or hematoma at the puncture site
  - Pneumothorax (up to 30% for non–image-guided procedures)
- Infrequent
  - Pneumothorax with image guidance reported between 0% and 3%
  - Inadvertent puncture of subdiaphragmatic structures (e.g., liver and spleen)
  - Hemothorax
- Serious, rare complications
  - Pneumothorax
  - Tension pneumothorax
  - Intercostal artery laceration
  - Hemothorax
  - Reexpansion pulmonary edema
  - Hypotension

OUTCOMES AND EVIDENCE

- Feasibility and safety of ultrasound-guided thoracentesis in mechanically ventilated patients are strongly supported by the literature.
- Clinically directed thoracentesis should not be performed in mechanically ventilated patients.
- Bedside ultrasonography is the preferred modality for the diagnosis of pleural effusion in the critically ill patient.

Chest Tube Placement, Care, and Removal

Gregory A. Watson and Brian G. Harbrecht

BEFORE THE PROCEDURE

Indications

- Most commonly undertaken to treat one of the following conditions:
  - Pneumothorax
  - Pleural fluid collection
    - Hemothorax
    - Simple effusion
    - Empyema
- Can be both a diagnostic and a therapeutic maneuver

Contraindications

- In an emergent situation (i.e., tension pneumothorax), there are no contraindications
- In a nonurgent situation, caution should be exercised in the presence of:
  - Known or suspected adhesions
    - Prior chest surgery or trauma
    - History of pleural space infection
    - Intrinsic parenchymal disease
  - Complex, loculated air or fluid collection(s)
    - Typically noted on imaging studies
- In situations where insertion is not emergent and is anticipated to be difficult, consideration is recommended for placement by a skilled operator (surgeon) or under image guidance (computed tomography [CT], ultrasound)

Equipment

- Chest tube of appropriate size and configuration (Fig. E12.1)
  - In general, larger tubes are required to drain blood, pus, or viscous fluid, and smaller tubes (i.e., pigtail catheter) may suffice for a simple effusion or pneumothorax.
    - Non-pigtail sizes range from 20F to 40F for adults and from 6F to 26F for pediatric patients.
  - Straight tubes are most commonly placed in the emergency department or intensive care unit.
    - Right-angled tubes are available but typically are placed by surgeons in the operating room.
- Commercially available collection system (Fig. E12.2)
  - Includes the following components:
    - Plastic connector of at least 0.25-inch diameter to connect the chest tube to the accessory tubing. (A Y-connector may be used in the case of multiple chest tubes, but caution is advised because these are prone to occlusion and subsequent drainage failure.)
    - Accessory tubing (generally 0.5 inch in diameter and 6 feet long).
    - Drainage system (composed of a trap, water seal, and manometer compartments).
- Wall vacuum source with connection tubing
- Prepackaged chest tray
  - At a minimum, should contain a scalpel and a clamp (large Kelly clamp or hemostat)
- Skin antiseptic
- Sterile drapes
- Sterile gown and gloves, mask, and cap
- Local anesthetic
- Intravenous narcotic and/or sedative
- Suture material (commonly 0 silk)
- Gauze
- Tape

ANATOMY

Entry into the pleural space should generally be gained via a location based on ease of access, safety, and avoidance of complications. The American College of Surgeons Committee on Trauma recommends drain insertion between the anterior and posterior axillary lines at a level with or just above the fifth intercostal space (nipple level). In this location, the chest wall is thinnest, and the operator can avoid the pectoralis major muscle and breast parenchyma (anteriorly), the latissimus dorsi muscle (posteriorly), the axillary vessels/brachial plexus (superiorly), and the diaphragm/intraabdominal contents (inferiorly). Within the intercostal space, coursing along the inferior surface of each rib is the neurovascular bundle. Insertion of the tube over the superior aspect of the rib is recommended so that injury to these structures can be avoided (Fig. E12.3). From superficial to deep, one will first encounter skin, followed by a variable amount of subcutaneous tissue, the superior surface of the rib, the intercostal space with its musculature, and finally the parietal pleura. The pulmonary parenchyma and mediastinal structures are just beyond to the parietal pleura, so it is important to avoid overzealous insertion of the chest tube. Tubes placed into an interlobar fissure (e.g., right-sided minor fissure) may slide in easily but not drain effectively. In some instances (e.g., a loculated collection), specialized placement may be required, and the assistance of a surgeon or insertion under image guidance is encouraged.

PROCEDURE

See Video E12.1.

- Confirm the correct patient and laterality. If drainage is nonemergent, perform a "time-out" to verify the indication(s) and review the relevant imaging and coagulation studies.
  - A procedural checklist may be helpful and has been shown to reduce errors and decrease complications.
- Obtain necessary equipment (see earlier) and fill the water seal compartment of the collection system with the indicated amount of water.

Fig. E12.1 Standard chest tube *(top)* with trocar *(middle)* and angled chest tube *(bottom)* without trocar.

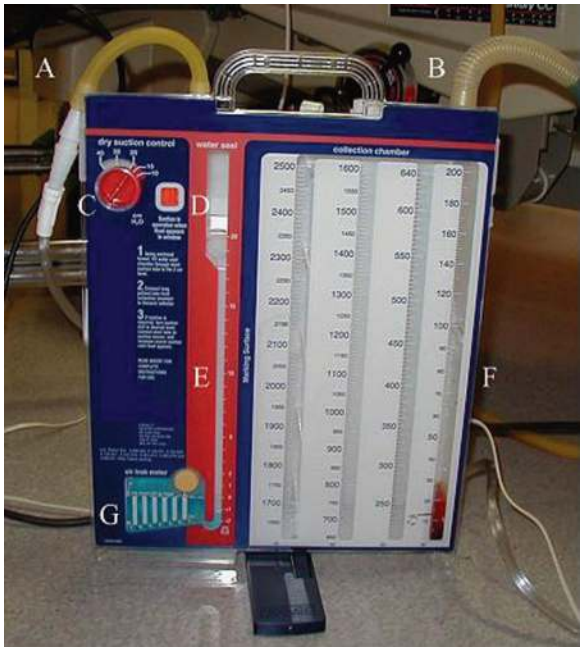

Fig. E12.2 Modern chest drainage system. **A,** Accessory tubing to wall suction. **B,** Accessory tubing to chest tube/patient. **C,** Suction control. **D,** Float indicating suction is operative. **E,** Water seal chamber. **F,** Collection chamber. **G,** Air leak meter.

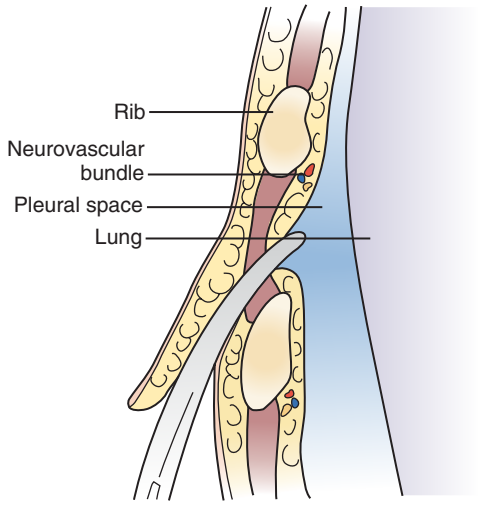

Fig. E12.3 Use of Kelly clamp to enter pleural space.

- Position as follows:
  - Supine or slight elevation of the head of the bed
  - Ipsilateral arm behind the head or abducted
  - Bed at comfortable height for the operator
  - Ensure adequate lighting
- Practice aseptic technique and observe universal precautions.
- Prep the area broadly with skin antiseptic.
- Drape widely such that anatomic landmarks (e.g., the nipple) are visible.
- Plan the skin incision to overlie the rib just inferior to the chosen intercostal space. (For example, if entering the fifth interspace, place the incision along the superior aspect of the sixth rib.)
- Consider premedication with a narcotic or anxiolytic.
- Inject local anesthetic (apply gentle syringe aspiration at all times).
  - First anesthetize the skin.
  - Then angle the needle slightly cephalad to anesthetize the periosteum of the rib and the deeper tissues.
  - Several passes may be required to cover an area 1–2 cm in diameter.
  - If air or fluid is aspirated, retract the needle while aspirating it until it ceases and then inject additional local anesthetic to anesthetize the parietal pleura.
- Make an incision large enough to accommodate the operator's index finger and chest tube at the same time.
- Bluntly dissect (with index finger and/or Kelly clamp) along an oblique path angled superiorly to the chosen intercostal space, with care taken to remain on the superior border of the rib (see Fig. E12.3).
- If the patient is on a ventilator, hold respirations temporarily.
- Gently enter the pleural space with the tip of the clamp.
  - Avoid excessive advancement of the clamp to minimize injury to deeper structures.
  - Typically will feel a pop and get return of air and/or fluid.
- Open the clamp slightly to sufficiently enlarge the opening into the pleural space.
- Insert index finger to confirm entry into the pleural space.
  - Should be able to palpate parietal pleura and, at times, the lung.
  - Note the presence of any adhesions (seen in up to 15% of cases).
- We recommend discarding the chest tube trocar and grasping the tip of the tube with the Kelly clamp to facilitate safer insertion.
- Insert index finger alongside the chest tube and guide the tube into the pleural space away from the lung parenchyma.
  - Though it is recommended to direct the tube anteroapically for a pneumothorax and posterobasally for fluid, the exact location within the pleural space is probably not important in most cases.
  - Ensure that the last drainage hole is well within the pleural space.
- Connect the tube immediately to the collecting system.
- If suction is desired, adjust the wall vacuum source to provide slow, consistent bubbling in its regulation chamber and, when air is being removed, from the pleural space.
  - Typically, the collection system is set initially to pull with −20 cm H_2O suction pressure.
- Secure the tube to the skin at the exit site with sutures (avoid a purse-string stitch).
- Cover the wound with dry gauze and tape.
- Obtain a chest x-ray to document proper placement, evaluate expansion of the lung, and assess for residual pleural fluid or air.

AFTER THE PROCEDURE

Postprocedure Care

- Daily assessment
  - System must remain upright and should be kept below chest level.

- The accessory tubing should be in a straight or coiled position and not kinked.
- Be certain the water level in the system is maintained.
- If suction is being used, verify the proper setting and confirm that it is functional (the float should be visible in the window).
- Note the amount of drainage, presence of bubbling, and respiratory variation.
  - Without suction applied, very large respiratory variations often indicate undrained air that separates the lung from the chest wall.

- Troubleshooting
  - Observation of synchronous water seal and motion with respiration suggests the tube is still functioning in the pleural space and that all connections are tight.
  - If the tube is not functioning and occlusion of the drainage holes is suspected:
    - Disconnect and flush with normal saline
    - Consider fibrinolytics (particularly if a parapneumonic effusion is present)
- If an air leak within the system is suspected:
  - Sequentially clamp the accessory tubing with distal suction applied. The leak will cease when a clamp is placed proximal to the site, and the problem can then be addressed.
  - If the accessory tubing or the connections are not the problem, check the insertion site. If the skin incision is too large, the leak may be audible and can readily be addressed with an additional stitch. Also, be certain the last drainage hole has not migrated out of the pleural space.
  - If neither of these identifies the problem, a major airway injury or bronchopleural fistula may be to blame.
- Removal
  - Should be performed once the indication for tube thoracostomy has resolved
    - Will vary somewhat according to the patient population and the indication for insertion
  - For a simple pneumothorax, hemothorax, or pleural effusion, we recommend:
    - Placement of the tube on -20 cm H_2O suction initially to facilitate lung reexpansion and/or evacuation of fluid
  - Suction may not be required in some patients (i.e., those without underlying lung disease or who do not require mechanical ventilation)
    - Continue suction until the lung is re-expanded and there is no air leak. Then convert to water seal.
    - Obtain a radiograph on water seal to confirm lung expansion.
    - Remove when drainage is negligible ($<$150–200 mL per day).
  - For empyema, the infectious process must be resolved, there should be no residual empyema cavity on imaging studies, and drainage must be scant before removal
    - It is common for empyema tubes to remain in place for weeks
  - In lung resection patients, management is more complex because the routine use of suction may potentiate air leaks. We recommend consultation with the patient's surgeon regarding management of the tube(s)
  - The timing of chest tube removal relative to the respiratory cycle (i.e., end inspiration or end expiration) does not appear to be important, even in ventilator-dependent patients
  - Although routine chest radiography after removal is not a universal practice, we recommend obtaining one within 4 hours of removal to confirm lung expansion.
    - Some leaks may be very slow and require many minutes to be detected by chest films.
  - Routine clamping of chest tubes should generally be avoided.

Complications

- Reported to be as low as 2% and as high as 30%
- Improper insertion technique, operator inexperience, and forceful use of sharp trocars are avoidable errors that account for many of the complications
- Common
  - Malpositioning
    - Generally low; however, a recent study of critically ill patients who underwent CT after tube thoracostomy reported an incidence of 30%
    - Clinically more important that the tube reside in the pleural space rather than a specific location relative to the chest wall or lung parenchyma
  - Infectious
    - Insertion site (wound) infection
    - Pleural space infection (empyema) rates vary from 1% to 11%
  - Unresolved pneumothorax
  - Persistent pleural fluid collection
- Infrequent
  - Injury to the lung
    - May manifest as hemothorax, persistent air leak, residual pneumothorax, or subcutaneous emphysema
  - Injury to the intercostal vessels
    - May manifest as hemothorax and occasionally requires surgery to achieve hemostasis
  - Chylothorax
  - Long thoracic nerve injury (winging of the scapula)
  - Intercostal neuralgia
  - Horner syndrome
  - Phrenic nerve palsy
- Serious rare complications
  - Reexpansion pulmonary edema
    - Manifests as dyspnea (in the absence of lung collapse) after drainage of a large pneumothorax or hemothorax
    - Ipsilateral edema seen on chest radiograph
    - Treatment is supportive
    - Some recommend slow removal of large effusions ($<$1 L in the first 30 minutes) to minimize the risk
  - Esophageal rupture
  - Perforation of the heart or great vessels
  - Laceration of the subclavian vessels
  - Injury to the diaphragm and/or upper abdominal structures (liver, spleen, stomach, colon)
  - Puncture of silicone breast implants (intrathoracic silicosis)

KEY POINTS

- Few aspects of chest tube management have been subjected to rigorous study or are standardized.
- Patient outcomes after tube thoracostomy are related to their underlying condition(s).
  - Deaths caused by the procedure itself are infrequent.
- No clear consensus exists regarding the role of prophylactic antibiotics for tube thoracostomy, but they may be of some benefit.
  - Recent meta-analysis of studies performed in trauma patients revealed a reduction in the risk of posttraumatic empyema and pneumonia.
  - If one elects to administer antibiotics, coverage against *Staphylococcus* should be included.

Fiber-Optic Bronchoscopy

Massimo Antonelli, Giuseppe Bello, and Francesca Di Muzio

SPECIALTY AND CATEGORY WITHIN SPECIALTY

- Intensive care medicine:
  - Diseases of the respiratory system
  - Airway management

CPT CODES

- Bronchoscopy

ICD-9 CODES

33.2 Diagnostic procedures on lung and bronchus
33.22 Fiber-optic bronchoscopy
33.24 Closed [endoscopic] biopsy of bronchus
33.27 Closed endoscopic biopsy of lung

PREPROCEDURE

Indications

- Diagnostic uses
  - To assess the patency and anatomy of the upper airway
  - To evaluate problems associated with endotracheal tubes and airway stents, such as tracheal damage, device malposition, or airway obstruction
  - To investigate lung abnormalities of unclear etiology on the chest x-ray
  - To investigate unexplained hemoptysis, cough, and localized wheeze or stridor
  - To obtain lower respiratory tract specimens by bronchoalveolar lavage (BAL) or protected specimen brushing (PSB) for cytologic or microbiologic analyses
  - To investigate the etiology of positive sputum cytology results
  - To determine the location and extent of respiratory tract injury after toxic inhalation or aspiration of gastric contents
  - To evaluate the airways for suspected tracheobronchial injury after thoracic trauma
  - To evaluate a suspected tracheoesophageal fistula
  - To perform endobronchial or transbronchial lung biopsies (TBLBs) and transbronchial needle aspirations (TBNAs) for histologic, cytologic, or microbiologic analyses
- Therapeutic uses
  - To remove retained secretions or mucus plugs not mobilized by physiotherapy
  - To retrieve foreign bodies (Videos E13.1 and E13.2)
  - To perform difficult tracheal intubations
  - To aid in performing percutaneous tracheostomy (Video E13.3)
  - To perform selective intubation of the mainstem bronchus
  - To place airway stents
  - To perform airway balloon dilatation for the treatment of tracheobronchial stenosis
  - To remove abnormal endoluminal tissue from the trachea or bronchi through the use of forceps or laser techniques

Contraindications

- Absolute contraindications
  - Absence of consent from the patient unless a medical emergency warrants the procedure
  - Lack of trained personnel to perform or directly supervise the procedure
  - Lack of adequate personnel and facilities to manage possible life-threatening emergencies
  - Inability to adequately oxygenate the patient
  - Inability to achieve adequate platelet count and coagulation status if biopsy is anticipated
  - Unstable hemodynamic status
  - Active uncontrolled bronchospasm
- Relative contraindications
  - Lack of patient cooperation
  - Unstable angina or recent myocardial infarction (within 6 weeks)
  - Acute hypercapnia
  - Acute brain injury (risk for increased intracranial pressure)
  - Severe pulmonary hypertension and uremia (increased risk for serious hemorrhage after biopsy)

Equipment

- Fiber-optic bronchoscope, comprising components that are incorporated into a functional unit (see Figs. E13.1 and E13.2)
- Control handle with the following:
  - Body that fits into the hand
  - Eyepiece, to which video or photographic devices may be attached; just under the lens, a diopter adjustment ring for image focusing
  - On some bronchoscopes, the top of the endoscopic view is marked by an indent or black triangle to assist in orientation.
  - Tip bending lever; located on the back of the handle and used to activate the up and down movement of the last 2–3 cm of the insertion cord
  - Suction control valve
  - Suction connector
  - Access port to the working channel
  - Insertion cord: it is the flexible bronchoscopic element connected to the control handle that is introduced into the airway; within it are the viewing bundle, one to three light bundles, the working channel, and two wires that control the distal tip of the scope.

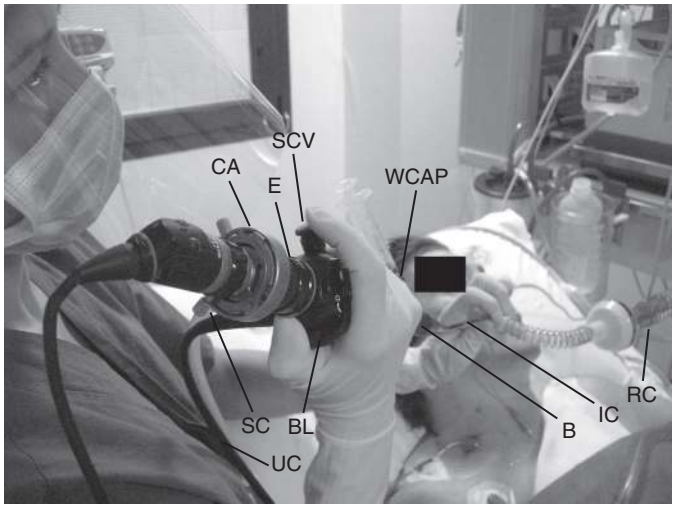

Fig. E13.1 Fiber-optic bronchoscopy in a patient under mechanical ventilation. Note how the operator uses her right hand to hold the handle of the instrument, with her thumb over the bending lever and her index finger over the suction control valve. *B,* Body; *BL,* bending lever; *CA,* camera attachment; *CH,* control handle; *E,* eyepiece; *IC,* insertion cord; *RC,* respiratory circuit; *SC,* suction connector; *SCV,* suction control valve; *UC,* universal cord; *WCAP,* working channel access port.

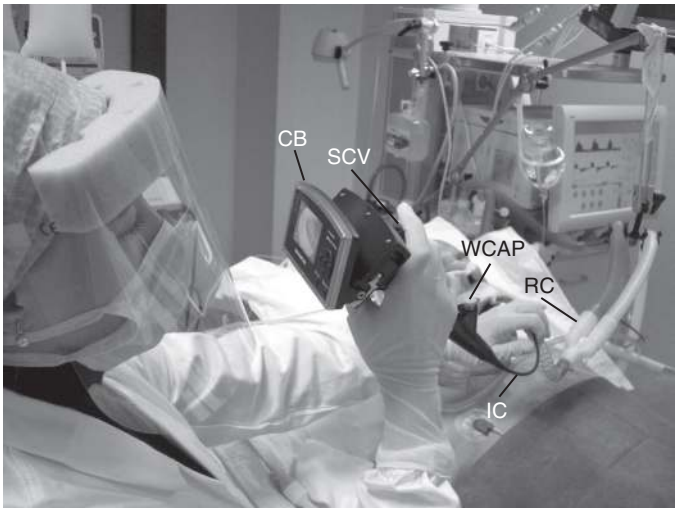

Fig. E13.2 Fiber-optic bronchoscopy in a patient under mechanical ventilation. The operator uses a recent model, battery-driven bronchoscope incorporating a video camera, light source, and recording unit. The camera body of this bronchoscope can be rotated to the right and the left side by 90 degrees to either side, and the liquid crystal display panel can be tilted from 0 to 120 degrees. *CB,* Camera body; *IC,* insertion cord; *RC,* respiratory circuit; *SCV,* suction control valve; *WCAP,* working channel access port.

- Universal cord arises from the side of the control handle and transmits the light from the light source to the bronchoscope, illuminating the field of view. The light source is the free-standing apparatus into which the universal cord attaches. In some types of bronchoscopes (portable scopes), the universal cord is not needed, as the light source is built into the control handle of the instrument and power is provided by a battery system. Modern digital flexible endoscopic systems use a charge-coupled device chip located at the end of the scope to relay digitized information to a monitor via a processor. The venting connector is a component of the bronchoscope usually located on the universal cord. The ethylene oxide sterilization venting cap and leakage tester are attached to this connector. The ethylene oxide cap must be installed when the endoscope is subjected to gas sterilization and during transportation by air. It must be removed before immersion or when the instrument is in use.
- Ancillary technical materials
  - Venous access equipment
  - Oxygen and related delivery equipment
  - Wall or portable vacuum systems and related suction supplies
  - Laser equipment, if applicable
  - Bite block, to be used in transoral procedures in awake patients
  - Sterile gauze, for clearing the tip of the bronchoscope during the procedure
  - Water-soluble lubricant
  - Antifogging systems, including warm water (max 60°C), weak soap solutions, and commercially available antifogging solutions; when fogging occurs during the procedure, bringing the tip of the scope into contact with the mucosal surface; may clarify the image.
  - Microbiology and cytology brushes, flexible forceps, retrieval valves, transbronchial aspiration needles, fixatives
  - Specimen-collection traps, syringes for medication delivery, physiologic (0.9%) saline solution for BAL
  - Laryngoscope
  - Endotracheal tubes in various sizes
  - Oral intubating airway that maintains an open passage into the oropharynx and protects the endoscope from being bitten; it is useful if the oral route is chosen in patients under general anesthesia
  - Endoscopy masks to assist fiber-optic intubation in patients being ventilated by a face mask provided with a rubber diaphragm that permits the passage of either the bronchoscope or the tracheal tube into the airways and prevents air leakage
  - Endotracheal tube introducers of various sizes
  - Cricothyroidotomy kit
  - Laryngeal mask airway or other extraglottic devices of various sizes for ventilator support in emergency situations; laryngeal mask airway may also be used to aid the passage of the bronchoscope into the trachea
  - An adapter to facilitate insertion of the bronchoscope while preventing loss of the respiratory gases and maintaining ventilation and positive end-expiratory pressure throughout the procedure during either invasive or noninvasive ventilation (NIV)
  - Self-inflating or anesthesia bag attached to a face mask by a T-adapter; used for bag-mask ventilation in nonintubated, sedated patients undergoing bronchoscopy
  - Resuscitation equipment
- Medications
  - Lidocaine (1%–2%) for topical anesthesia; the minimum amount of lidocaine necessary should be used when installing through the endoscope; the total dose of lidocaine should be limited to 8.2 mg/kg in adults; particular care is needed when administering lidocaine to patients with liver or cardiac failure
  - Sedative agents (e.g., benzodiazepine and propofol)
  - Synthetic narcotics (e.g., fentanyl or remifentanil) to provide sedation and analgesia and to suppress the cough reflex
  - Benzodiazepine and/or narcotic antagonists
  - Epinephrine (usually 1:10,000 dilution) for bleeding control
  - Nasal decongestants
  - Emergency and resuscitation drugs

- Monitoring devices
  - Pulse oximeter
  - Continuous electrocardiogram
  - Continuous intraarterial blood pressure or intermittent cuff blood pressure measurement at least every 5 minutes
  - Intracranial pressure, essential in patients with serious brain injury
  - End-tidal carbon dioxide, useful in patients with brain injuries
  - Respiratory function monitoring of patients under mechanical ventilation for following ventilation parameters, such as exhaled tidal volume and peak inspiratory pressure
  - Chest x-ray 1 hour after transbronchial biopsy to exclude pneumothorax
- Cleaning and sterilization equipment
  - Dedicated room for cleaning and manual or automated sterilization; automated washer disinfectors are recommended to minimize staff contact with disinfectant and their fumes
  - Soft nonabrasive cleaning cloth to gently wipe the external surfaces and components of the endoscope immediately after use
  - Water or neutral detergent solution to irrigate all accessible channels of the endoscope at the end of the procedure
  - Leak testing system
  - Cleaning brushes and neutral detergent solution for a thorough cleaning of the internal and external surfaces of the endoscope: cleaning brushes are passed through the working channel access port, the suction port opening, and the suction connector. They are also used carefully to clean the distal end of the instrument.
  - Protease enzymatic agent for cleaning and the removal of blood and protein residues
  - High-level disinfection or sterilization agents (e.g., peracetic acid, glutaraldehyde, or ethylene oxide)
  - Sterile water for rinsing the endoscope
  - 70% ethyl or isopropyl alcohol to flush the external surfaces and inner channels of the endoscope. This is used when the quality of the rinse water is in doubt or to assist in the drying process.
  - Cupboard to hang the endoscope

ANATOMY

- See Video E13.4
  - The trachea passes from the larynx to the level of the fourth or fifth thoracic vertebra, where it bifurcates into the two main bronchi (i.e., the left and the right) at the anatomic point known as the *main carina*. The trachea has an inner diameter of about 21–27 mm and a length of about 10–16 cm. About 15–20 incomplete C-shaped cartilaginous rings reinforce the anterior and lateral sides of the trachea and main bronchi. The posterior wall, or membranous trachea, is free of cartilage and contains bundles of muscle fibers that insert into the posterior ends of the cartilage plates. The anterior (ventral) and posterior (dorsal) directions can be identified by noting the relative flattening and flexibility of the posterior wall of the lumen.
- Bronchi
  - The right main bronchus is wider, shorter, and closer to the midline than the left main bronchus. The cartilage and mucous membrane of the main bronchi are similar to those of the trachea. At the level where the main bronchi enter the lungs, the membranous region disappears, and the cartilage plates are no longer C-shaped but are smaller, more irregular, and arranged to surround the circumference of the airway. At this level, the muscular coat no longer inserts into the cartilage, but forms a separate layer of interlacing bundles. Consequently, the airway lumen can be occluded by the contraction or flaccidity of the muscle.
  - The right main bronchus subdivides into three lobar bronchi, whereas the left main bronchus divides into two. The lingula of the left lung, nominally a part of the left upper lobe, is analogous to the right middle lobe. The lobar bronchi divide into segmental bronchi, each of which supplies a bronchopulmonary segment. The bronchopulmonary segments are the topographic units of the lung, and they are used to identify regions of the lung either radiologically or surgically. There are 10 bronchopulmonary segments per lung, but because of anatomic development, some of the segments in the left lung fuse, giving rise to 8 segments. For counting orders or generations of airways, the main bronchi are usually counted as the first generation, the lobar bronchi as the second generation, and so on peripherally. Generally, in adult subjects, a bronchoscope with an outer diameter of 5 mm cannot be advanced farther than the fourth- or fifth-order bronchi.
- Bronchioles
  - As the branching continues through the bronchial tree, the amount of hyaline cartilage in the walls decreases until it is absent in the bronchioles, which lie distal to the bronchi, beyond the last plate of cartilage. When any airway is pursued to its limit, the terminal bronchiole is reached. Each terminal bronchiole then gives rise to several respiratory bronchioles, which lead to the alveolar ducts and sacs. The alveolus is the basic anatomic unit of gas exchange in the lung.
- Nomenclature of peripheral bronchi
  - The nomenclature commonly used for the bronchial anatomy is that of Jackson and Huber. Subdivisions of the bronchial tree correspond to the anatomic segments and are named accordingly.
  - The right main bronchus gives rise to three lobar bronchi: upper, middle, and lower. The portion of the right main bronchus between the upper lobe bronchus and the origin of the middle and inferior lobe bronchi is known as the lower part of the right main bronchus, or bronchus intermedius. The right upper lobe bronchus is subdivided into three segmental bronchi: the apical, posterior, and anterior. The right middle lobe bronchus branches into two segmental bronchi: the lateral and medial. The right lower lobe bronchus gives rise to five segmental bronchi: the superior segmental bronchus, posteriorly directed and situated just below the orifice of the middle lobe bronchus, and more distally, four basal segmental bronchi: the medial, anterior, lateral, and posterior; occasionally, the medial basal bronchus is partially separated from the other basal segments by an extra fissure.
  - The left main bronchus subdivides into two lobar bronchi: the upper and lower. The left upper lobe bronchus subdivides into a superior division bronchus and a lingular division bronchus. The superior division has two segmental bronchi: the apicalposterior and anterior. The lingular division has two segmental bronchi: the superior and inferior. The anatomy of the left lower lobe bronchus is similar to that of the right lower lobe bronchus, except that there are usually only three basal segmental bronchi on the left: the anteromedial, lateral, and posterior. Compared with the right side, the superior segment of the left lower lobe bronchus arises more proximally than the orifices serving the basal pyramid.
  - With the advent of fiber-optic bronchoscopy, Dr. Shigeto Ikeda introduced additional nomenclature for the fourth, fifth, and

sixth divisions. According to this nomenclature, the segmental bronchi are numbered from 1 to 10 on each side and are identified with the capital letter "B" for bronchus and prefixed by the capital letter "R" for right or "L" for left. This way, LB6 identifies the superior segmental bronchus of the left lower lobe. Subsegmental, or fourth-order bronchi, are designated by the lowercase letter "a" for posterior and "b" for anterior; the letter "c" may be used for additional bronchi. Fifth-order bronchi are identified by the Roman numerals "i" (posterior) and "ii" (anterior). Finally, "α" and "β" are used for sixth-order bronchi.

- Variations of the bronchial anatomy are not infrequent.
- Key bronchoscopic anatomic features
  - Right lung. The orifice of the bronchus to the right upper lobe is in the 3 o'clock position, and its distance from the carina is quite variable. The arrangement of the three segmental bronchi of the right upper lobe bronchus is nearly symmetric. Just beyond the lower section of the right main bronchus, or bronchus intermedius, the typical anatomic configuration consists of the orifice of the middle lobe bronchus, anteriorly directed, in the 12–2 o'clock position; the orifice of the bronchus to the superior segment of the lower lobe, at the same level but in the 6–7 o'clock position; and, directly in front, the basal segmental bronchi of the right lower lobe.
  - Left lung. After entering the left main bronchus, the orifices of the upper and lower lobe bronchi generally lie in the top left and bottom right, respectively, of the bronchoscopic image field. Within the orifice of the left upper lobe bronchus, the lingular division bronchus lies (clockwise) to the right of the superior division bronchus. Inside the entrance of the left lower lobe bronchus, the orifice of the superior segmental bronchus is in the 6–7 o'clock position, just as in the right lung.

PROCEDURE

- Define the indication for fiber-optic bronchoscopy.
- Choose the size of the bronchoscope as indicated by the intended procedure, the patient size, and the size of the endotracheal tube; a large bronchoscope with a wide working channel provides excellent suction performance and permits the passage of large bronchoscopic tools. In adult patients with tracheal intubation, an outer diameter of the bronchoscope at least 1.5 mm narrower than the lumen of the endotracheal tube can prevent excessive increases in airflow resistance, gas trapping, and airway pressure that decrease delivered tidal volume.
- Assure the bronchoscope is in proper working order.
- Check any cameras and/or video equipment that may be used.
- Assess the patient's medical, physiologic, and psychologic status.
- Reassure the patient, if conscious.
- Prescribe appropriate premedication, if needed.
- Establish intravenous access.
- Connect the bronchoscope to the light source when it is present, turn on the light, adjust the focus (e.g., by looking at written material until a clear view is obtained), and obtain the white balance.
- Connect the suction catheter to the suction connector.
- Place the distal end of the insertion cord of the bronchoscope into warm water.
- Apply or check the monitoring.
- Place the patient in a supine, semirecumbent, or even sitting position, depending on the type of procedure.
- Start topical anesthesia, general anesthesia, or intravenous sedation, based on the needs of the patient.
- Stand behind or to the left or right side of the patient. If you stand to the side, you can approach the patient either from behind or the front; in the latter situation, once the bronchoscope has passed into the pharynx, the superior part of the endoscopic view will correspond to the inferior region of the patient. The endoluminal landmarks described earlier guide the operator's orientation.
- Lubricate the bronchoscope.
- Handling the bronchoscope. Right-handed users will find it easier to hold the handle of the instrument with their right hand, with the index finger over the suction valve and the thumb actuating the bending lever, and to use their left hand to hold the insertion cord. The black cursor in the viewfinder, when present, describes the plane of movement of the tip of the endoscope.
- The bronchoscopic procedure requires only three movements: (1) flexion of the tip of the bronchoscope along the plane of the cursor; (2) rotation of the entire endoscope to the left or right; and (3) the advancement or withdrawal of the instrument. The goal is to keep the point of interest (e.g., vocal cords, bronchial orifice, etc.) in the center of the field. When the bending lever is depressed, the tip rises, whereas when the lever is elevated, the tip is directed in the opposite direction. The insertion cord should be kept as straight as possible to either prevent accidental damage to the bronchoscope or improve the control over the tip of the instrument. To look right, the tip of the bronchoscope may be turned upward while the control handle is twisted clockwise. Alternatively, the insertion cord may be rotated anticlockwise with the tip turned downward. To look left, the insertion cord is rotated clockwise or anticlockwise with the tip deflected downward or upward, respectively. The operator will decide which maneuvers to perform depending on the ease of obtaining the desired movements.
- The insertion cord should be able to rotate throughout its length when the handle is rotated axially to avoid distortion of the image orientation. This orientation distortion resulting from the axial rotation usually occurs when the distal end of the bronchoscope is blocked by the airtight rubber seal at the entrance of the endotracheal tube or even by the inside walls of the endotracheal tube. In these circumstances, the tip of the bronchoscope fails to rotate synchronously with the proximal end of the instrument.
- When a camera attachment is used with the bronchoscope, the camera position relative to the bronchoscope needs to be calibrated by rotating the bronchoscope camera system until a certain movement inside the patient's airway corresponds with the proper motion on the monitor.
- The bronchoscope may be inserted into the airway through the nose or the mouth in spontaneously breathing patients or through the endotracheal tube in intubated patients. During NIV, the bronchoscope is passed through the NIV interface (Videos E13.5 and E13.6).
- The application of NIV during bronchoscopy may be useful either in at-risk hypoxemic patients who are initially breathing spontaneously and who start NIV to assist bronchoscopy or in patients who are already receiving NIV and scheduled to undergo bronchoscopy during NIV. When NIV is administered through a face mask, a T-adapter with a sealing connector is attached to the mask for insertion of the bronchoscope through the nose or the mouth.
- Fiber-optic intubation. The endoscope may be passed transnasally or transorally through the vocal cords into the trachea. Then the endotracheal tube is slipped over the instrument.
- Sampling techniques. Samples from the lower airways are commonly obtained by BAL, PSB, TBLB, and TBNA. When BAL or PSB is performed, the sampling area is selected based on the location of the new or progressive infiltrate on a chest x-ray or the segment visualized during bronchoscopy as having purulent secretions. Data are lacking for the optimal sampling site in patients with diffuse lung infiltrates.

- BAL. The tip of the bronchoscope is wedged as far as possible into a distal airway (generally a fourth- or fifth-order bronchus), and a sterile saline solution is instilled through the bronchoscope and then aspirated into a sterile trap. Minimal injecting pressure is advisable so as to avoid inadvertent alveolar rupture. Aliquots of 20–60 mL are injected and aspirated back after each instillation. The total amount of fluid used to perform BAL ranges from 140 to 240 mL. In the supine patient, BAL fluid recovery is best from the right middle lobe or lingula. At least 5 mL of retrieved fluid are needed for adequate microbiologic analysis. The first aliquot of aspirated fluid is likely to contain a large amount of material from the proximal airway and must be analyzed separately from the rest. The recovery of more than 5% squamous epithelial cells in the BAL specimen indicates proximal tracheobronchial contamination. Because lidocaine has bacteriostatic properties, the use of this local anesthetic could alter the microbiologic results.
- PSB. This technique is performed using a retractable brush within a double-sheathed catheter having a distal dissolvable plug that initially occludes the outer catheter. First, the tip of the bronchoscope is positioned close to the sampling area. Next, the catheter is inserted through the working channel and advanced 1–3 cm beyond the distal end of the bronchoscope to avoid the collection of pooled secretions around the distal tip of the instrument. The inner catheter containing the brush is advanced to eject the distal plug into a large airway, and the brush is advanced under direct vision into the desired subsegment. Once the sample is obtained, the brush is retracted into the catheter, which is then withdrawn and removed from the bronchoscope. The brush is then advanced beyond the catheter, cut with sterile scissors, and placed into 1 mL of transport medium to avoid drying.
- TBLB. Histologic samples of the bronchial mucosa, bronchial wall, lung parenchyma, and alveoli may be obtained using TBLB. In diffuse lung disease, the biopsy specimen should be taken from a peripheral airway, preferably the lower lobe. In this way, the danger of significant bleeding may be reduced, owing to the smaller caliber of the distal bronchial vessels. The number of biopsies needed for TBLB is not standardized. However, seven to eight biopsy specimens have been proposed for localized lung lesions, whereas five TBLB samples from one lung seem to ensure a high diagnostic yield for most diffuse lung diseases.
- TBNA. TBNA may be used to obtain tissue samples from paratracheal, hilar, and peribronchial areas. For visible tumors, the yields of TBNA and forceps biopsy are similar. A protected transbronchial needle is passed through the working channel of the bronchoscope and positioned with the needle perpendicular to the endobronchial wall. The tracheal wall, carina, mainstem bronchus, or major spur is pierced with a quick thrust. Suction is then applied to the proximal end of the needle sheath with a 20-mL syringe containing 2 mL of saline solution. The needle and sheath are removed from the bronchoscope, and the specimen is ejected into a suitable container for cytologic analysis. If a dry syringe is used, the specimen is smeared on a glass slide before the examination. At each biopsy site, two or three punctures are commonly made, employing a new needle for each location.
- Recommendations for bronchoscopy during mechanical ventilation through the endotracheal tube include the following:
  - Insert a connector between the endotracheal tube and the ventilator tubing through which to slide the bronchoscope. Volume-controlled ventilation is usually preferred. Set the fraction of inspired oxygen (FiO_2) at 100%, and remove or reduce positive end-expiratory pressure, except in very severe respiratory failure. Increase respiratory frequency and decrease tidal volume; increase percent inspiratory time. Set the peak pressure alarm to a level that allows adequate ventilation. After the procedure, return all ventilator parameters to their initial values. Over the first 30 minutes after the termination of bronchoscopy, gradually reduce the applied FiO_2 to the prebronchoscopy requirements, provided that the patient can maintain an arterial oxygen saturation of hemoglobin measured by a pulse oximeter (SpO_2) at >92%.
  - Other procedural considerations. Enteral feeding or oral food intake should be suspended for at least 4 hours before the procedure. Asthmatic subjects should be premedicated with a bronchodilator before the procedure. Platelet count and coagulation times should be checked before performing bronchoscopy in patients in whom a biopsy is anticipated.

AFTER THE PROCEDURE

Postprocedure Care

- Monitoring
  - Level of consciousness
  - Medications administered
  - Subjective responses (e.g., pain, discomfort, and dyspnea)
  - Blood pressure, heart rate, rhythm, and changes in cardiac status
  - SpO_2 and supplemental oxygen use
- Close surveillance to promptly detect and treat any new findings presenting over the first hours after the end of the procedure (see "Complications")
- Nothing by mouth for 2 hours

Complications

- Common:
  - Hypoxemia commonly occurs during bronchoscopy; the insertion of a bronchoscope into the airways reduces the cross sectional area available for airflow, thus increasing the airway resistance and the work of breathing. Continuous suctioning through the instrument evacuates gas from the airway and decreases the residual functional capacity, often leading to the development of hypoxemia. Hypoxemia may be more severe after BAL, owing to ventilation-perfusion abnormalities induced by the instillation of a saline solution; the decrease in arterial oxygen partial pressure resulting from bronchoscopy may last a few minutes to several hours after the removal of the bronchoscope
  - Mild hypercapnia
  - Increased airway resistance
  - Modest alterations in systolic blood pressure, consisting of either a decrease (generally related to sedation) or an increase from the baseline
  - Slight increase in heart rate
- Infrequent:
  - Periprocedural adverse drug reactions
  - Bronchospasm or laryngospasm, particularly in patients with preexisting reactive airway disease
  - Major cardiac rhythm abnormalities; the risk of arrhythmias is the greatest during the passage of the bronchoscope through the vocal cords in nonintubated patients, especially if hypoxemia is present
  - Bradycardia or other vagally mediated phenomena
  - Epistaxis, in transnasal procedures
  - Pneumothorax; it is very uncommon after bronchoscopy, but has an increased incidence in patients undergoing TBLB

  - Significant bleeding, defined as more than 50 mL of blood loss; the likelihood of hemorrhage from bronchoscopy increases when biopsy or brushing procedures are performed; patients at a higher risk of bleeding include those with uremia, immunosuppression, pulmonary hypertension, liver disease, coagulation disorders, or thrombocytopenia
  - Fever and chills; fever rarely occurs after bronchoscopy (1.2%), but occurs more commonly (10%–30% of cases) after BAL; fever is thought to be generally caused by the release of proinflammatory cytokines from alveolar macrophages and does not itself indicate a developing infection related to the procedure
  - Nausea, vomiting
  - Cross-contamination of bronchoscopes
- Serious, rare complications:
  - Death

OUTCOMES AND EVIDENCE

- Outcome after bronchoscopy depends on the patient's coexisting condition; flexible bronchoscopy is associated with a 0.3% incidence of major complications and a mortality rate of 0.02%; major complications requiring resuscitative measures are significantly more likely with rigid bronchoscopy as compared with flexible bronchoscopy.
- The most frequent life-threatening complications leading to death after bronchoscopy include airway problems, cardiovascular events, and bleeding.

Bronchoalveolar Lavage and Protected Specimen Bronchial Brushing

Lillian L. Emlet

BEFORE THE PROCEDURE

Indications

- Diagnosis of pneumonia
  - Viral, bacterial, fungal, pneumonias
  - Quantitative cultures for ventilator-associated pneumonias
  - Infiltrates in an immunocompromised host
- Evaluation of diffuse lung infiltrates and evaluation of interstitial lung disease
- Suspected pulmonary hemorrhage
- Suspected malignancies
- Both bronchoalveolar lavage (BAL) and protected specimen bronchial brushing (PSB) use quantitative culture techniques to differentiate between airway colonization and true pulmonary infections.[1–4]

Contraindications

- Acute respiratory distress syndrome with hypoxemia
  - May cause derecruitment in noncompliant severe air space disease
  - Cardiac arrhythmias, hypoxemia, bronchospasm
- Bronchopleural fistula
  - May not be able to return adequate specimen for analysis

Equipment

- Flexible fiberoptic bronchoscope
- Sterile saline
- Vacuum suction source
- Suction tubing
- Syringes: 10 mL, 20 mL, or 60 mL slip-tip
- Sterile collection trap
- Lidocaine, 1%–2% for topical anesthesia, if needed
- Medications for procedural conscious sedation, if needed
- Burman airway or oral airway
- Supplemental oxygen
- Endotracheal bronchoscope attachment

ANATOMY

- If performed on native airways, the first structures to be identified are the epiglottis and the vocal cords.
  - Topical anesthesia using 1%–2% lidocaine is administered through a bronchoscope to the vocal cords.
- The next landmark to be located is the trachea and the identification of the carina.
  - Additional administration of 1%–2% lidocaine to the carina.
- Right and left main bronchi are identified, and the location of the desired BAL specimen is obtained at the site where purulent material is present or where infiltrate is visible on the chest x-ray.[5]
- If unsure as to which lobe needs to be sampled, the posterior portion of the right lower lobe should be sampled first. Autopsy studies indicate that pneumonias in intensive care unit (ICU) patients often involve this lobe.[6–9]
- To obtain the BAL, the bronchoscope is advanced to the farthest segment of the affected bronchus until it cannot be advanced any farther.

PROCEDURE: BRONCHOALVEOLAR LAVAGE

See Video E14.1.

- Obtain informed consent, including for topical anesthesia of airways and/or conscious sedation.
- Prepare for conscious sedation, and use telemetry devices to monitor continuous pulse oximetry, intermittent blood pressure cuff measurement, and supplemental oxygen (via nasal cannula or nonrebreather mask or ventilator).
- For patients at risk of bronchospasm, premedicate with bronchodilators, and treat airways with 2% lidocaine via an atomizer.
- Review the chest radiograph to identify the ideal location for BAL. The right middle lobe or lingula is preferred in supine patients, with the right lower lobe also serving as a possible direct path for aspiration.
- Prepare the bronchoscope, collection trap, tubing, and sterile saline.
- Anesthetize vocal cords in nonintubated patients and the carina in intubated patients with 2% lidocaine (5 mg/kg maximum).
- Avoid suctioning before obtaining the BAL specimen to avoid specimen contamination.
- Advance the bronchoscope until wedged in the desired subsegmental bronchus.
- Flush 20 mL sterile saline through the wedged bronchoscope, watching for the flow of saline into distal airways and for the blanching of tissues.
- Obtain the sample immediately after the wash, ensuring the return of the lavage specimen into the collection trap.
- Slight repositioning of bronchoscope tip can allow for better fluid return.
- Intermittent pulsing of suctioning can reduce distal airway collapse.
- Repeat 20-mL sterile saline washes as necessary to obtain an adequate sample (usually a total of 30–50 mL, which is usually 40%–70% recovery of total instilled volume).
- Larger-volume aliquots for lavage can be used (as much as 50 mL per lavage, with total volume of 120 mL in 3–6 aliquots).[5,10]

  - Estimated alveolar surface area distal to the wedged bronchoscope is 100 times greater than the peripheral airway.
- Fluid return of the BAL can affect the validity of results, and small returns may contain only diluted material from the bronchus rather than the alveoli, resulting in false negatives.[11]
  - In patients with highly collapsible airways, including patients with chronic obstructive pulmonary disease (COPD), the amount of negative pressure applied via the bronchoscope to aspirate the sample can limit the amount of sample returned and may give rise to a false-negative result.
- Sensitivity of BAL is 71% and specificity is 80% (95% confidence interval [CI], 66%-86%) in the diagnosis of pneumonia.[12–23,33]

PROCEDURE: PROTECTED SPECIMEN BRONCHIAL BRUSHING

- Same procedure as BLA, except for the use of an endobronchial catheter wedged in the tracheobronchial tree.
- The brush is rubbed against areas of suspected infection and then removed from the procedure port of the bronchoscope.
- The brush is then aseptically cut into a measured volume of sterile diluent (usually 1 mL of preservative-free sterile saline).[10,24]
- Double-lumen catheter brush systems with single-sheathed or telescoping plugged catheter tips with distal occluding plugs are used.[24–26]
- Quantitative cutoff is 10^3 colony-forming units per milliliter (CFU/mL).
- Sensitivity of protected specimen bronchial brushing for pneumonia is 61% (95% confidence interval [CI], 44%–77%) and specificity is 76% (95% CI, 92%–97%).[13,27–33]

AFTER THE PROCEDURE

Postprocedure Care

- Patients are continuously monitored until full recovery from conscious sedation.
- Ventilated patients are placed on 100% fraction of inspired oxygen (FiO_2) during the procedure and weaned back to previous FiO_2 levels, as tolerated. Derecruitment is possible and may require recruitment maneuvers.
- Specimen handling
  - For PSB, the brush should be aseptically cut into 1 mL of preservative-free sterile saline.[10,24]
  - For BAL, the specimen container should be sent for analysis within 30 minutes, although refrigeration can prolong transport and analysis.[34,35]
- The specimen should be obtained before new antibiotics are administered.
  - Even a few doses of antibiotics can result in negative microbiologic cultures.[36]
  - Quantitative culture techniques of distal pulmonary secretions with minimal or no upper airway contamination.[1,2]
  - BAL and PSB culture sensitivities are lowered if antibiotic therapy has already been initiated.[37–39]
- These techniques do not retrospectively identify resolving pneumonia or assess the adequacy of therapy.[9,40–43]

Complications

- Common
  - Cough
  - Transient infiltrates that typically resolve in 24 hours
  - Transient decrease in partial pressure of oxygen (PaO_2)
- Infrequent
  - Transient fever, chills, myalgias[44]
- Serious, rare complications
  - Derecruitment and hypoxemia resulting in intubation and positive-pressure ventilation or increase in ventilator requirements[45–48]
  - Pneumothorax

KEY POINTS

- Quantitative culture techniques are necessary to differentiate, infecting organisms from pharyngeal contaminants.[49–53]
  - Significant BAL culture concentrates are at least 10^5–10^6 CFU/mL.[2,6,54–57]
  - Significant PSB culture concentrates are at least 10^3 bacteria.[10]
- A small number of false-positive BAL and PSB results can be seen even when using strict criteria to distinguish between airway colonization and deep lung infections of 10^3–10^4 CFU/mL.[58]
- False-negative BAL and PSB results occur when:
  - Bronchoscopy is performed at an early stage of infection and bacterial load is not high enough to reach diagnostic significance.
  - Specimens are obtained from unaffected segments of lung.
  - Specimen processing errors occur.
  - Specimens are obtained after initiation of a new class of antibiotics.
  - Consider repeat sampling for persistently symptomatic patients with initial negative quantitative concentrations.[59]

Percutaneous Dilatational Tracheostomy

Cherisse Berry and Daniel R. Margulies

BEFORE THE PROCEDURE

Indications

- Requirement of a temporary or long-term artificial airway for prolonged mechanical ventilation
- Management of secretions
- Nonemergency airway obstruction

Contraindications

- Inability to clearly palpate and identify tracheal landmarks
- Enlarged thyroid or other neck mass
- Active infection at the site
- Emergency need for airway
- High ventilatory requirements (FiO_2 ≥70%, positive end-expiratory pressure [PEEP] greater than 15 cm H_2O)
- Bleeding
- Increased intracranial pressure
- Clinically significant coagulopathy or supratherapeutic international normalized ratio (INR) or partial thromboplastin time (PTT)
- Documented tracheomalacia
- Cervical irradiation
- Morbid obesity
- Maxillofacial or neck trauma
- Lack of cervical spine clearance
- Inability to extend the neck because of a cervical spine fracture
- In addition, we do not perform the procedure in patients younger than 16 years of age because of the scarcity of experience reported in pediatric patients

Equipment

- Equipment required at the bedside to perform the percutaneous dilatational tracheostomy (PDT) procedure should include
  - PDT introducer set (Ciaglia Blue Rhino Percutaneous Tracheostomy Introducer Set #C-PTIS-100-HC, Cook Critical Care, Bloomington, Indiana)
  - Bronchoscope with video monitor display and bronchoscopy endotracheal tube adapter
  - Continuous electrocardiographic (ECG) monitor
  - Blood pressure monitoring device
  - Pulse oximeter
  - Free-flowing intravenous catheter
  - Mechanical ventilator
  - Suction
  - Resuscitation ("crash") cart
  - Open tracheostomy instrument tray (unopened)
- Supplies required at the bedside include:
  - ChloraPrep or other solution for skin preparation
  - 4 × 4-inch bandages
  - Syringes and needles
  - Sterile gowns and gloves
  - Shiley Percutaneous Dual Cannula Cuffed Tracheostomy Tube
  - Kelly clamp
  - Sterile saline solution
- Medications required at the bedside include:
  - 1% xylocaine with epinephrine 1:100,000.
  - Midazolam, 1 mg/mL injectable or other appropriate sedative.
  - Morphine, 10 mg injectable or another appropriate narcotic.
  - Vecuronium, injectable, or other appropriate paralyzing agent.
  - Sterile normal saline flush solution.
  - Other medications at the discretion of the PDT operator.
  - The choice of a PDT introducer set may vary by institution; ours includes the set listed only because we have significant experience with it. However, it is critical that only one type of PDT introducer set be in use in an institution at any given time. To ensure maximum safety, every aspect of this procedure must be standardized, especially the equipment used.

ANATOMY

The thyroid notch and cartilage are palpated, followed by the cricothyroid membrane and cartilage and the tracheal rings. It is essential that the tracheal puncture be made inferior to the cricoid cartilage landmark. If the second and third tracheal rings cannot be distinctly identified, the procedure is aborted, and an open tracheostomy is performed.

ULTRASOUND

Although not required, the use of real-time ultrasound guidance can help to identify pretracheal vessels and high-risk vascular anatomy overlying the PDT site. Identification of these vessels before proceeding with PDT can help reduce bleeding risk, the risk of air embolism, and the risk of surgical intervention for hemostasis.

PROCEDURE

See Video E15.1.

- A single tapered PDT dilator and kit with simultaneous intraoperative bronchoscopy is used.
- Two teams are used simultaneously. One team manages the endotracheal tube, and the other manages the placement of the tracheostomy tube.
- The patient's physiologic parameters, including arterial oxygen saturation, are monitored continuously throughout the procedure by the intensive care unit (ICU) nurses and a respiratory therapist.
- Intravenous sedation and paralytic agents are administered as required, and the patient is fully ventilated via an endotracheal tube.

- The patient is positioned with the neck slightly extended and a pillow under the shoulders.
- Under sterile conditions, the PDT dilators and tracheostomy tube must be prepared.
- The Blue Rhino tracheal dilator is water activated, so it is dipped in sterile saline or water to enhance its lubricant coating.
- The Shiley Percutaneous Dual Cannula Cuffed Tracheostomy Tube is designed specifically to be used with the Cook Percutaneous Tracheostomy Introducer Set. Depending on the size of the patient, it is prepared by inflating the balloon to ensure the integrity and then collapsing the balloon by withdrawing all air.
- The tracheostomy tube, with the cuff, completely deflated, is inserted over the introducer dilator as one unit, placed 2 cm from the tip of the dilator, and then lubricated with sterile gel. The Shiley's tapered distal tip and inverted cuff shoulder are specifically designed for easier insertion. It is important that the tracheostomy tube be placed exactly 2 cm from the tip. If it is placed more than 2 cm from the tip, it will likely not enter the trachea. If it is advanced too far and placed less than 2 cm from the tip, the trachea may be damaged upon insertion.
- The neck is prepared with ChloroPrep.
- The dermis and subcutaneous tissues are infiltrated with 1% lidocaine with epinephrine.
- The upper airway endoscopist will then introduce the bronchoscope into the endotracheal tube.
- The endotracheal tube is untaped, the cuff deflated, and the tube is then withdrawn until the tip lies just below the vocal cords. The utmost care is taken to avoid withdrawing the endotracheal tube too far, which could result in extubation of the patient. We recommend that the bronchoscope remain near the tip of the endotracheal tube but entirely within it to prevent inadvertent puncture or spearing of the bronchoscope by the puncture needle.
- The PDT operator verifies the patient's neck anatomy, starting with palpation of the thyroid notch and cartilage and then moving down to the cricothyroid membrane and cartilage and the tracheal rings.
- The anatomy is reconfirmed with digital palpation of the cricoid cartilage because it is essential that the tracheal puncture is made inferior to this landmark. If the second and third tracheal rings cannot be distinctly identified, the procedure is aborted, and an open tracheostomy is performed.
- A 2-cm horizontal or vertical skin incision centered between the second and third tracheal rings is made, and the midline subcutaneous tissues are dissected bluntly with a hemostat until the pretracheal fascia is exposed. Before tracheostomy, the trachea is approximately 2–2.5 cm deep from the skin at the suggested insertion site.
- The PDT operator reconfirms the tracheal anatomy by direct palpation through the incision. The trachea is then punctured between the second and third tracheal rings with a 14-gauge cannula-over-needle from the PDT kit.
- Tracheal penetration is confirmed by visualization with the bronchoscope, in addition to aspiration of air from the needle.
- The needle is removed, and a J-tip guide wire is then introduced into the trachea through the cannula and visualized with the bronchoscope. The puncturing cannula is then withdrawn.
- A small 14F dilator is then introduced over the guide wire to widen the tracheal opening. The dilator is then withdrawn.
- An 8F guiding catheter is introduced over the guide wire to the skin level mark on the guide wire. The guiding catheter and guide wire are introduced as a unit into the trachea until the safety ridge on the guiding catheter is at the level of the skin. The positioning of the guiding catheter is confirmed by aligning the proximal end of the catheter with the proximal gray mark on the guide wire. This positioning is critical to prevent displacement of the J-tip guide wire and possible trauma to the posterior tracheal wall during subsequent dilatations.
- The lubricated Blue Rhino tracheal dilator is then passed over the cannula and guide wire and into the trachea to dilate the tract fully. This requires forceful pressure to accomplish smoothly.
- The tracheal dilator is then withdrawn, but the guiding catheter and guide wire remain in place.
- The tracheostomy tube and introducer dilator are threaded over the guide cannula and guide wire as one unit and inserted into the trachea under direct bronchoscopic visualization.
- The introducer dilator, guiding catheter, and guide wire are then withdrawn, leaving the tracheostomy tube in place.
- The inner cannula is then inserted, and the cuff is inflated.
- The PDT operator continues to hold the tracheostomy in place with one hand and never removes it until the tracheostomy tube is sutured in all four corners to ensure the tube is not inadvertently displaced.
- The bronchoscope is then inserted into the tracheostomy tube to confirm placement within the trachea.
- The ventilator tubing is then connected to the tracheostomy. The appropriate tidal volume and oxygen saturation are confirmed.
- The tracheostomy tube is sutured to the neck with 4-0 gauge nylon sutures placed in each corner.
- Once the tracheostomy tube is sutured in all four corners and also secured around the neck with umbilical tape, the endotracheal tube is removed. Make sure that the umbilical tape is not placed too tightly, as skin breakdown can result. At least one finger should be able to fit between the umbilical tape and the skin.

AFTER THE PROCEDURE

Postprocedure Care

- A simple 4 × 4-inch gauze dressing is partially slit and placed between the tracheostomy wings and the skin.
- A chest radiograph is not indicated unless the procedure was complicated.
- Close observation by the nursing staff is required to detect bleeding externally at the tracheostomy site or internally into the airway. The bleeding must be immediately reported to the PDT operator and the ICU physician and must be carefully evaluated and controlled.
- Bleeding into the airway can lead to the formation of an obstructing clot at the carina, with fatal consequences (Table E15.1).

OUTCOMES AND EVIDENCE

- PDT is a safe procedure, with morbidity and mortality rates equivalent to or lower than those of an open tracheostomy.
- Numerous early studies reported the morbidity of PDT to be between 3% and 19%, compared with a complication rate of 26%–63% for open tracheostomy.
- Recent studies have found the overall mortality for a tracheostomy to be 37%, with no statistically significant difference in mortality for PDT compared with an open tracheostomy.
- The incidence of wound infection has been reported to be 6.6%.
- One study compared PDT with surgical tracheostomy (ST) and found that PDT was associated with a significantly reduced risk of wound infection (odds ratio [OR], 0.28; 95% confidence interval [CI], 0.16–0.49; $P < 0.0005$).
- One report found the overall incidence of bleeding to be 5.7%, with no significant difference in incidence when comparing PDT with ST.

TABLE E15.1 Complications of Percutaneous Dilatational Tracheostomy

Immediate	Early	Late
Bleeding (minor venous oozing)	Pneumothorax	Stomal infection
Puncture or laceration of the posterior tracheal wall	Subcutaneous emphysema	Tracheo-inncominate fistula
Tracheal ring fracture	Pneumomediastinum from an esophageal injury	Tracheo-esophageal fistula
Brief episodes of hypoxia or desaturations	Unplanned decannulation	Tracheal stenosis
Serious hemorrhage from a severed blood vessel	Tracheostomy tube occlusion from secretions/mucus plugs	Unplanned decannulation
Loss of airway	Cuff leak	Voice changes
Paratracheal cannulation	Stomal infection	Tracheomalacia
Conversion to open tracheostomy		Pneumonia
Death		Dysphagia

Esophageal Balloon Tamponade

Jin H. Ra and Marie L. Crandall

BEFORE PROCEDURE

Indications

- Short-term hemostasis and stabilization of patients until definitive therapy can be arranged
- Failure to achieve hemostasis after endoscopic treatment of bleeding esophageal varices
- As a temporizing measure when endoscopic treatment is not immediately available or emergency transcutaneous intrahepatic portosystemic shunt is being arranged

Contraindications

- Known or suspected esophageal tear
- Recent esophageal surgery
- Known esophageal stricture
- Use with caution with those patients with a hiatal hernia

Equipment

- Minnesota tube (a modified Sengstaken-Blakemore tube with esophageal suction port above esophageal balloon)
- Sengstaken-Blackmore tube (has 250 cc gastric balloon and esophageal balloon and a single gastric suction port)
- Linton-Nachlas tube (has a single gastric 600 cc balloon)

PROCEDURE

- See Video E16.1
- Admit patient to an intensive care unit
- If not already done, proceed with endotracheal intubation for airway protection
- Ensure all equipment is available and ready
  - Tube of choice
  - Large-volume syringe
  - A traction pulley system
  - Adequate suction
- Test the integrity of the gastric and esophageal balloon(s) of the tube by inflating fully. Deflate the balloon(s), making sure all the air is out.
- Insert tube transnasally and advance it into the esophagus its full length. If the transnasal route cannot be used, transoral insertion is also acceptable. Avoid transnasal placement in coagulopathic patients if possible.
- Put 30 to 50 mL of air through the gastric port, clamp it, and check for correct placement. The partially inflated gastric balloon must be clearly seen below the diaphragm on a chest x-ray. Do not overinflate the gastric balloon during this step, as accidental full balloon inflation in the esophagus would likely lead to esophageal rupture.
- Once placement is confirmed, inflate gastric balloon fully (500–700 mL).
- Pull the tube back slowly until meeting with resistance. Traction can then be applied in a number of ways: with an overhead frame-pulley system—such as the one used for skeletal traction—or by securely taping the tube to the nose. More creatively, the patient can be fitted with a football helmet or a catcher's mask, which is then used to stabilize the tube. The frame-pulley system has the advantage that the degree of traction can be accurately measured. A 1-kg weight is enough (a 1-L bag of a crystalloid solution can be conveniently used).
- Connect the suction ports to suction; if the tube has gastric and esophageal suction ports, connect them to suction separately and monitor the output. If blood continues to come out of the esophageal port, inflate the esophageal balloon to 25–35 mm Hg (this is best done by attaching a three-way stopcock to the inflation port, with one of the limbs connected to a transducer for continuous pressure monitoring).

AFTER PROCEDURE

Postprocedure Care

- If inflated, monitor the pressure of the esophageal balloon at least once a day, but preferably continuously.
- Monitor the angle of the tube with respect to the nose and adjust accordingly to prevent pressure necrosis.
- The tube should be removed as early as possible. It is not known how long a tube can safely remain in place, but it can be left in place 24–48 hours, and the gastric balloon should be deflated every 12 hours to check for rebleeding.
- To remove the tube, the steps are reversed. First, deflate the esophageal balloon (if using a tube that has one), keeping the gastric balloon on traction. If bleeding does not resume, one can proceed to discontinue the traction while keeping the gastric balloon fully inflated for an additional 24–48 hours. If there is no rebleeding, then the gastric balloon is deflated, and the tube is removed.
- If bleeding continues, reinflate the appropriate balloon.

Complications

Severe, life-threatening complications arise in 20%–60% of cases. Complication rates increase with prolonged use.

- Common:
  - Esophageal and fundal mucosal ulcerations
  - Pressure necrosis of the alae nasae
  - Nasopharyngeal bleeding
- Serious but infrequent:
  - Aspiration pneumonia

- Serious, rare complications:
  - Esophageal perforation
  - Airway obstruction
  - Tube migration with laryngeal obstruction or tracheal rupture
  - Impaction of the balloon requiring surgery for removal

OUTCOMES AND EVIDENCE

- Primary hemostasis can be achieved in about 30%–90% of cases.
- The variability in success rates is due to patient selection, concomitant use of other therapies, and experience of staff using the tubes.
- The evidence is weak because most studies are at least 2 decades old, employed different types of tubes (e.g., Sengstaken-Blakemore, Linton, or Minnesota), and were not randomized. This situation is unlikely to change, as balloon tamponade is seldom needed nowadays.
- There was a recent multicenter randomized control trial by Escorsell et al. in 2017 comparing esophageal balloon tamponade with esophageal stenting to control acute refractory variceal bleeding. There were a total of 28 randomized patients. Control of bleeding occurred in 66% of stented patients versus 20% of balloon tamponade group. The study concluded that the stent group demonstrated better efficacy than balloon tamponade against refractory esophageal variceal bleeding.

Nasoenteric Feeding Tube Insertion

Ibrahim I. Jabbour, Albert T. Hsu, and Marie L. Crandall

BEFORE PROCEDURE

Indications

- Inability to maintain volitional intake (in the setting of a functional gastrointestinal tract) *and*:
- Critical illness expected to require an intensive care unit (ICU) stay of more than 2 days
- Poor nutritional status
- Weight loss and nutrient depletion
- Multiple comorbid conditions
- Failure to eat for more than 7 days

Contraindications

- Inability to tolerate enteral nutrition:
- Mechanical bowel obstruction
- Peritonitis
- Hemodynamic compromise (e.g., starting or escalating dose of vasopressor[s] in a previously stable patient)
- Short gut (relative contraindication)
- Severe cranial or facial fracture(s) or deformity
- Esophageal obstruction or recent surgery
- Esophageal or gastric varices
- Coagulopathy (relative contraindication)

Equipment

- Tube:
  - Nasogastric sump tube (14F–18F)
  - Nasoenteric feeding tube with stylet and/or metal weighted tip
- Lubricant
- Gloves
- Gown with long sleeves
- Eye protection
- Emesis basin
- Syringe:
  - 60-mL Toomey syringe if inserting sump tube
  - 10-mL Luer-Lok syringe if inserting nasoenteric feeding tube
- Stethoscope
- Adhesive device:
  - Tape
  - Bridle
- Optional:
  - Lidocaine jelly
  - Pro-motility agent (e.g., metoclopramide, erythromycin)
  - End-tidal CO_2 detector

ANATOMY

- Successful placement of the nasogastric tube requires that it pass through the nasal cavity, pharynx, and esophagus, into the stomach. The nasal cavity consists of the nares, septum, lateral nasal wall, and roof. The pharynx consists of a space that extends from the nares down to the inferior border of the cricoid cartilage. At this level, it divides into the esophagus and larynx. The esophagus continues until it terminates in a smooth-muscle sphincter that separates the lower esophagus from the stomach. Typically the lower esophageal sphincter lies 38–40 cm from the incisors in adults. The pylorus lies approximately 60–65 cm from the incisors.

PROCEDURE

- See Video E17.1
- Position patient:
  - If awake, place in sitting position.
  - If intubated or unable to comply with instructions, place supine and elevate head of bed to 45 degrees.
- Coat tube with lubricant.
- Consider applying lidocaine jelly to back of nares.
- Insert tube into nares.
- As tube enters the hypopharynx, ask patient to tilt head forward and swallow.
- Once inserted to 35 cm, tape tube in place and confirm intraesophageal position:
  - Obtain chest x-ray (CXR) *or*
  - Attach end-tidal CO_2 detector to end of the tube. If indicator turns yellow (positive for CO_2), remove tube and reposition. If indicator remains purple (negative for CO_2), proceed.
- Advance feeding tube to 55 cm and tape in place if intending to initiate gastric feeding.
- If intending to initiate gastric feeding:
  - Check position of the tube.
  - Use stethoscope to auscultate left upper quadrant.
  - Insufflate air into tube using syringe.
  - If passage of air into stomach is heard (this distinct gurgling sound is called borborygmi), tape tube in place and confirm its position with CXR. If unable to hear passage of air, reposition tube.
- If intending to initiate postpyloric feeding:
  - Place patient into right lateral decubitus position.
  - Administer pro-motility agent.
  - Advance tube to 80–100 cm.
  - Check distal position of tube with x-ray.

- Other adjuncts for assistance with positioning of tube:
  - Electromagnetic stylet (e.g., Cortrak Enteral Access System)
  - Endoscopy
  - Bedside fluoroscopy
  - Bedside ultrasound
  - pH value of gastric aspirate (e.g., Flocare NGT)

AFTER PROCEDURE

Postprocedure Care

- Obtain CXR and/or upper abdominal x-ray to confirm position of tube.
- Remove stylet if present.
- Attach tube securely to nose using tape.
- Consider placing bridle to help prevent displacement.

Complications

- Common:
  - Unplanned removal of feeding tube
- Infrequent:
  - Trauma from insertion of tube
  - Bleeding from nasal turbinates
  - Retropharyngeal hematoma
- Serious and rare:
  - Inadvertent placement into cranium, trachea/bronchus
  - Perforation of bronchus (pneumothorax), esophagus, stomach

KEY POINTS

- Early nutrition support therapy, especially using the enteral route, may improve patient outcomes by reducing complications, length of ICU stay, and improving caloric intake.
- Placement of nasoenteric feeding tubes results in complications in approximately 2%–5% of cases. Experienced practitioners who verify placement of the tube before initiating feeding can reduce the incidence of adverse sequelae resulting from malpositioned feeding tubes.
- The decision to initiate gastric versus postpyloric feeding remains controversial. Evidence of aspiration or intolerance to gastric feeding should prompt physicians to consider placing a postpyloric feeding tube.
- In patients at risk of tube displacement, securing the tube via bridle significantly decreases tube removal rates

Lumbar Puncture

Sarice L. Bassin and Thomas P. Bleck

BEFORE PROCEDURE

Indications

- Suspicion of a central nervous system (CNS) infection
- Suspicion of a subarachnoid hemorrhage
- The need to obtain cerebrospinal fluid to diagnose other inflammatory or degenerative CNS diseases
- Reduction of cerebrospinal fluid (CSF) pressure in pseudotumor cerebri

Contraindications

- Absolute
  - Intracranial or spinous (especially intramedullary) mass (e.g., tumor, abscess). If there is a concern, an imaging study should be performed before the procedure. A rapid decrease in intracranial pressure from the withdrawal of CSF could precipitate herniation or worsening of spinal cord function if a mass lesion is present.
  - Overlying skin infection
  - Lumbar spine disease
- Relative
  - Coagulopathy and/or thrombocytopenia, because an epidural hematoma can develop at the puncture site. Fresh frozen plasma and platelets should be infused to correct hematologic abnormalities before the procedure. If a coagulopathy is discovered after the procedure, therapy should still be administered, because bleeding can occur for many hours.
  - If a lumbar puncture is being performed to evaluate a patient with an aneurysmal subarachnoid hemorrhage, withdraw the smallest possible amount of CSF to obtain the necessary laboratory tests. Reducing the CSF pressure could precipitate rebleeding.
  - Uncooperative patient

Equipment

- Lumbar puncture tray or individual components (see later)
- Chlorhexidine or povidone-iodine prepping solution
- Sterile drape with a central opening
- 1% Lidocaine and a syringe with 25- and 22-gauge needles for local anesthesia
- 20- or 22-gauge spinal needle
- Manometer
- Tubes for CSF collection

ANATOMY

The site of the intended puncture is either the L4-5 or the L5-S1 interspace. These can be determined as follows. The L3-4 interspace can be located by drawing an imaginary line between the posterior iliac crests. This is usually the most rostral space employed because the adult spinal cord ends at L2. Walk the fingers down the spinous processes to identify the L4-5 and L5-S1 interspaces, and mark them on the skin. Note that during lumbar spine disease, the question of a spinal mass or an overlying skin infection prevents the lumbar approach; a lateral cervical approach can be performed by a physician trained in this technique. In cases of a difficult lumbar puncture in obese patients, a bedside ultrasound can be helpful.

PROCEDURE

- See Video E18.1.
- Place the patient in the lateral decubitus position with knees flexed to the abdomen and head flexed with the chin toward the chest.
- Position the patient's back as close as possible to the edge of the bed nearest the examiner.
- Before preparing the skin, locate the L4-5 and L5-S1 interspaces and mark them.
- The skin should then be prepared with chlorhexidine or povidone-iodine. The preparation should proceed outward in a spiral and cover several interspaces in case multiple attempts are necessary.
- Drape the patient's back with a sterile sheet with an opening to the prepared area so that it covers the posterior iliac crest.
- Anesthetize the skin with 1% lidocaine using a 25-gauge needle, which may be exchanged for a longer 22-gauge needle to reach deeper tissues.
- Using a 20- or 22-gauge spinal needle, advance it with the stylet in place to avoid the introduction of epidermal cells into the subarachnoid space.
- Direct the bevel of the needle upward to separate the fibers of the ligamentum flavum. The angle of the needle 15 degrees cephalad and slightly downward toward the bed.
- When the dura is punctured, and a slight "pop" is felt, the stylet should be withdrawn.
- If a free flow of CSF does not occur, the needle can be rotated or may have to be advanced (after replacing the stylet).
- Once the free flow of CSF is obtained, attach a manometer to the spinal needle, usually by way of a stopcock. CSF should rise steadily in the manometer until the opening pressure is reached and respiratory fluctuation can be visualized in the fluid column.
- The patient's legs should be carefully extended and relaxed for an accurate pressure reading.
- Collect four tubes of CSF (3 mL of fluid in each) and send them for appropriate studies.

- In cases of pseudotumor cerebri in which a lumbar puncture has been chosen as a therapeutic modality to reduce the raised intracranial pressure, after quantifying the opening pressure, the removal of 20 mL of CSF, with the closing pressure documented, is generally recommended.
- Replace the stylet to minimize the possibility of pulling a nerve root through the dura as the needle is removed.
- Withdraw the needle and apply pressure to the puncture site.
- If the subarachnoid space cannot be entered with this technique or the patient cannot lie in the lateral decubitus position, a lumbar puncture can be performed with the patient sitting on the side of the bed leaning forward over a bedside table. However, once free CSF flow occurs, the patient should be returned to the recumbent position for accurate pressure measurements.
- If a patient is unable to bend one leg (e.g., after an angiographic procedure), a lumbar puncture can be attempted in the lateral position with the bottom leg held straight, and the top leg bent into the abdomen and supported with a pillow.

AFTER PROCEDURE

Postprocedure Care

- Allow the patient to lie flat for 1–3 hours after the procedure to minimize the risk of post–lumbar puncture headache. Argument persists regarding the value of prone versus supine positioning on the incidence of a headache and about the use of varying sizes and types of needles.

Complications

- Common
  - Headache
  - Bleeding from the puncture site
- Infrequent
  - CSF leak
  - Infection
  - Subarachnoid cyst
- Serious, rare complications
  - Epidural hematoma formation
  - Cerebral herniation
  - Aneurysmal rebleeding
  - Nerve root injury

OUTCOMES AND EVIDENCE

- To ensure an optimal diagnostic outcome when performing a lumbar puncture, it is wise to check with the laboratory before the procedure to learn if any unusual tests are being performed, because an additional tube or larger volumes or special handling of CSF may be required. Regarding optimal patient outcomes, if a diagnostic lumbar puncture is delayed for imaging in a suspected case of bacterial meningitis, blood cultures should be obtained, and empiric antibiotics should be administered, as CSF cultures can be obtained up to 4 hours after starting treatment.

Jugular Venous and Brain Tissue Oxygen Tension Monitoring

Jovany Cruz Navarro, Sandeep Markan, and Claudia S. Robertson

ULTRASOUND-GUIDED INTERNAL JUGULAR VEIN OXYGEN SATURATION ($SjvO_2$) CATHETER PLACEMENT: BEFORE THE PROCEDURE

Indications

- Severe traumatic brain injury
- Subarachnoid hemorrhage
- During neurosurgical and cardiovascular procedures in which cerebral blood flow may be reduced
- Detection of arteriovenous fistulas
- To titrate hyperventilation in patients with increased intracranial pressure (ICP)

Contraindications

- Absolute
  - Infection of the placement site
  - Suspected pathologic conditions affecting the internal jugular vein or superior vena cava
  - Severe coagulopathy
- Relative
  - Cervical spine injury
  - Tracheostomy
  - Recurrent sepsis
  - Hypercoagulable state
  - Hypersensitivity to heparin if a heparin-coated catheter is used
  - Distorted anatomic landmarks

Equipment

- Sterile gowns
- Sterile gloves
- Mask
- Betadine or chlorhexidine solution
- Commercially packaged catheterization kits are available, which may include:
  - Drapes
  - Disinfectant sponges
  - Gauze pads
  - Sutures with needles
  - Guide wire
  - Scalpel
  - Vein dilator
  - Penetration device, guide, and anesthetic syringe, in addition to a 1% or 2% lidocaine anesthetic solution
- Ultrasound machines with high-resolution vascular transducers are preferred for this procedure
- Sterile transduction gel, acoustically transparent sterile transducer sheath, and sterile rubber bands or clips to secure sheath around transducer
- 5.5F fiberoptic intravascular catheter (Opticath catheter)
  - The catheter contains the fiberoptics for light transmission; a distal lumen for pressure reading, sampling, or infusion; and a thermistor for temperature measurement
- Optical module (to link to bedside monitor)
- Introducer kit

ANATOMY

The cerebral venous sinuses drain out of the skull through the jugular foramina and into the internal jugular veins. Immediately distal to the jugular foramen, the vein dilates, forming the jugular venous bulb. The cerebral and cerebellar veins and the veins of the brainstem all open into major sinuses (e.g., superior sagittal; inferior sagittal; straight, right, and left transverse; and occipital sinuses); these terminate in the right and left sigmoid sinuses, which curve downward into a deep groove on the mastoid part of the temporal bone. Finally, they turn forward in the posterior aspect of the jugular foramen to become the jugular bulb of the internal jugular vein.

The trachea is in the midline descending to the sternal notch. The two heads of the sternocleidomastoid muscle and the clavicle form a triangle at the anterior neck. The internal jugular vein may be accessed through this triangle, approximately 2–3 cm above the clavicle. Performing a venous puncture higher in the triangle reduces the risk of pneumothorax and allows for better arterial compression in the case of an inadvertent puncture of the carotid artery.

PROCEDURE

See Video E19.1.

- Continuous electrocardiography (ECG), blood pressure measurement, and pulse oximetry
- Place the patient in the Trendelenburg position to increase jugular filling and reduce the possibility of an air embolism. (Note: Trendelenburg positioning should be minimized as much as possible to avoid undesired elevations of ICP.)
- Rotate the patient's head slightly to the contralateral side of the chosen site if there is no evidence of cervical spine injury.
- Perform an ultrasound survey to assess the location and patency of the jugular vein and to determine whether one side has dominant flow (i.e., larger jugular vein). Catheter placement is easier, and continuous oxygen saturation measurements will usually be better on the side with the greater blood flow.

- The common carotid artery and the internal jugular vein should be easily identified. The common carotid artery is seen as a pulsating, noncompressible, rounded structure. The internal jugular vein is larger, easily compressible, and nonpulsatile. Ensure that the internal jugular vein is patent by gently compressing the vein with the transducer (Note: slight pressure is sufficient to collapse the lumen of the internal jugular vein). Orienting the transducer in a cross-sectional plane during the ultrasound examination facilitates interpretation of the resulting images. Usually, ultrasound probes have a marker on one side that corresponds to the same side of the image on the screen. This helps the operator identify the correct orientation of the image.
- After identification of an acceptable site for cannulation, recruit an assistant.
- Follow universal precautions when placing a jugular venous line.
- Prepare the skin using a chlorhexidine-based antiseptic, and cover the area with a sterile fenestrated drape. Iodine can be used in patients with hypersensitivity to chlorhexidine.
- To prepare the ultrasound probe, have the assistant dispense enough acoustic gel onto a sterile transducer sheath to cover the transducer surface inside the sheath.
- The assistant carefully feeds the probe into the sheath and through the gel while extending the sterile sheath away from the operator over the length of the probe wire. Eliminate any wrinkles in the sheath and any air bubbles between the transducer and the sheath. Place the rubber bands to secure the cover sheath in place. To complete the acoustic coupling, apply a small amount of sterile ultrasound gel to the covered ultrasound probe or the patient's skin.
- Identify a convenient sterile area on which the probe can be placed when not in use.
- Position the transducer perpendicular to the skin so that the internal jugular vein is centered in the resulting ultrasound image and between the two heads of the sternocleidomastoid muscle. The ultrasound probe should be held in the nondominant hand.
- Gently palpate the skin to confirm that the puncture will occur between the muscle heads and not through one of the heads.
- Using an 18-gauge needle, puncture the skin just below the transducer, being careful not to damage the sterile sheath.
- Slowly advance the needle at a 30- to 45-degree angle in an upward direction (cephalad) while watching the ultrasound screen. As the needle is advanced, negative pressure is maintained in the syringe until the vein is punctured and blood return is obtained. The needle will appear as a hyperechogenic shadow.
- If you do not aspirate blood as the needle is advanced, slowly withdraw the needle while gently maintaining negative pressure. The venous puncture may become evident upon needle withdrawal. Occasionally, pressure from the ultrasound probe may compress the vein, making it difficult to enter the vessel.
- As soon as the blood is freely aspirated, place the probe in the predetermined sterile area, stabilize the needle, and disconnect the syringe.
- Confirm that the blood flow is nonpulsatile. If possible, transduce blood pressure with the transducer line that is usually provided with the catheter kit.

Introducer Insertion

- Using the Seldinger technique, introduce a flexible guide wire through the needle and into the internal jugular vein. Direct the guide wire in an upward direction toward the jugular bulb.
- While holding the guide wire in place, remove the needle. The guide wire can be visualized in both cross-sectional and longitudinal views within the lumen of the internal jugular vein in the ultrasound screen.
- Use the scalpel to make a small incision in the skin to widen the opening.
- Thread the guide wire through the distal opening of the dilator until it exits through the proximal end of the dilator.
- Confirm that it has reached the proximal end of the dilator, hold the wire in place, and advance the dilator through the skin and into the vessel.
- Once the proper placement is achieved, remove the guide wire and the green dilator.
- Hold the proximal end of the guide wire at all times when advancing the dilator or catheter. This avoids complications from the unintended advancement of the guide wire.
- Bleeding frequently occurs after the dilator is withdrawn; minimize it by applying pressure until the bleeding subsides.

Opticath Intravascular Catheter Insertion

- Inspect the sterile package first; if visibly damaged, DO NOT USE!
- Have an assistant remove the outer wrapping, and leave the catheter covered by the inner covering.
- Pass the optical connector to the assistant, who will connect it to the optical module and proceed with the preinsertion calibration. PLEASE NOTE that only *after* verifying with your assistant that the preinsertion calibration was successful should one proceed to the next step. Failure to do so will result in inaccurate readings.
- After a successful preinsertion calibration, the oximetry system is now ready for use. Prepare for the catheter insertion.
- Pull off the remaining inner catheter covering, and pull the red retainer tab to release the catheter.
- Grasp the catheter near the entrance of the black reference assembly, and gently pull it straight out. Care should be taken in removing the catheter, as the fiberoptics may be damaged if the catheter is withdrawn improperly.
- Flush the catheter with sterile solution, using the distal lumen to remove the remaining air.
- The catheter tip should be illuminated with a red-light emission before insertion.
- The catheter should then be advanced until resistance is felt; this distance is usually about 13–15 cm and indicates positioning within the jugular bulb.
- The catheter is then pulled back 0.5–1 cm to minimize cephalic vascular impact with head movement.
- Connect the distal lumen to a pressure monitoring line.
- When the catheter is in position and blood is flowing, the system will immediately provide oxygen saturation (SO_2) readings.
- At this time, ask the assistant to perform a light intensity calibration.
- Verify the position of the catheter tip, and secure the catheter to the patient. The optical module should be secured to or near the patient to avoid strain or tension on the catheter.
- Apply the dressing as per hospital protocol.

Postprocedure Care

- A lateral cervical spine x-ray should be used to confirm adequate catheter tip placement, which should be above the C1–C2 level to minimize contamination with blood coming from the facial vein.
- The Opticath intravascular catheter is removed by a physician. It is usually removed when ICP has been normal for 24 hours without specific treatment.
- When removing the catheter, the patient must be in the Trendelenburg position to avoid inadvertent air embolism.
- Remove the sutures securing the catheter to the skin.
- Carefully withdraw the Opticath intravascular catheter.
- Apply pressure to the site for a few minutes to prevent bleeding.

- Apply a sterile dressing.
- Assess for bleeding or signs of infection.
- Dispose of the Opticath intravascular catheter per hospital protocol.
- Clean the optical module and cable for storage.

Complications

- Carotid artery puncture
- Skin hematoma
- Pneumothorax
- Hemothorax
- Jugular vein thrombosis
- Nerve injury
- Catheter misplacement
- Infection

OUTCOMES AND EVIDENCE

- Normal jugular bulb oxygen saturation values are between 55% and 75%.
- <55% indicates relative cerebral hypoperfusion.
- >75% suggests luxuriant perfusion.
- Please refer to the standard critical care guidelines for management.

BRAIN TISSUE OXYGEN PROBE PLACEMENT: BEFORE THE PROCEDURE

Indications

- Severe traumatic brain injury
- Aneurysmal subarachnoid hemorrhage
- Malignant stroke
- Vasogenic edema
- To assess brain tissue oxygenation, detect brain hypoxia, and for continuous monitoring of brain tissue chemistry (e.g., metabolites and drugs)

Contraindications

- Absolute
  - Infection and/or lack of skin covering the site of planned insertion
  - Coagulopathy
- Relative
  - Incompatibility with available magnetic resonance imaging (MRI) system, if an MRI of the brain will be needed

Equipment

- Sterile gown pack.
- Sterile gloves.
- Sterile linen pack.
- Sterile 4 × 4 gauze bandages.
- Mask.
- Shave prep kit.
- Betadine bottle.
- 16-gauge (orange) angiocatheter to tunnel the probe.
- Cranial access tray.
- One refrigerated combined LICOX probe box.
- "Smart card" (enclosed in the sterile LICOX probe container).
- Note: Do not discard the probe packaging before the probe smart card has been removed from the packaging. Use only the smart card supplied with the probe (the serial number on the probe should match the number on the smart card). Use of the wrong smart card can cause measurement errors. If the serial numbers do not match, use another LICOX probe box, and return the first one to the vendor.
- #11 blade.
- Nylon 3-0 suture.
- Surgeon's head light.
- Standard surgical suction.
- LICOX monitor with a complete set of cables.
- Module box and link box and cable (to attach LICOX monitor to bedside monitor).

ANATOMY

Ideally, the probe should be placed into the region at risk for brain hypoxia, avoiding areas of cerebral contusion of hemorrhage. However, if a computed tomography (CT) scan reveals no areas at risk for hypoxia, the probe should be placed on the right frontal lobe. The probe may be placed 2–4 cm off the midline just anterior to the coronal suture and at least 1 cm from any other probe when possible. Preparation must include shaving the patient's head to a disc diameter of approximately 2–4 cm off the midline, just anterior to the coronal suture.

PROCEDURE

- Because these patients are critically ill, vital signs (e.g., invasive blood pressure, central venous pressure, ECG, pulse oximetry, and core temperature) must be continuously monitored.
- The patient must be under adequate sedation throughout the procedure and have intravenous access and mechanical ventilatory support.
- Wash hands. All staff involved in the procedure should wear a surgical mask and gloves throughout the entire procedure.
- After reviewing the patient's CT head scan, the physician will determine the anatomic area for catheter placement.
- As noted earlier, the probe is placed in the area at risk for brain hypoxia, but if the CT scan does not show areas at risk for hypoxia (i.e., diffuse axonal injury), place the probe at least 1 cm from the ICP probe.
- The catheter insertion area will be prepped with Betadine. Strict sterile field and sterile technique must be maintained throughout the procedure.
- Place sterile drape.
- Place the patient in a semi-Fowler position, raising the head of the bed to the level of the physician's preference.
- If a ventriculostomy was previously placed, the same incision may be used for probe placement. If no incision exists, make a 3-cm linear incision, carrying it down to the bone.
- Infiltrate the incision with local anesthetic and epinephrine to help control the bleeding from the scalp incision.
- A self-retaining retractor is then inserted to provide good bone exposure.
- The blunt end of the forceps can be used to remove the periosteum.
- Drill the burr hole in the skull at the desired catheter insertion site, using a hand drill.
- Remove the drill, and rinse the hole with a sterile isotonic solution.
- Incise the dura carefully with a stylet or a #11 blade, securing hemostasis as necessary.
- Insert the sharp end of the 16-gauge angiocatheter needle from the inside out through the scalp, 5 cm distant from the burr hole.
- Remove only the needle, leaving the angiocatheter.
- Remove the LICOX catheter from its sterile package.
- Remove the probe from the humidity protection chamber.
- Insert the LICOX probe's distal tip into the angiocatheter, and tunnel it below the scalp toward the burr hole.
- Pull the angiocatheter completely out of the scalp.

- Using forceps, insert the distal end of the probe into the brain parenchyma. Ensure that the catheter body is not damaged during insertion.
- If necessary, adjust the position of the probe to allow the distal tip of the catheter to be positioned correctly with respect to the insertion site.
- Use a single suture to secure the probe to the scalp near the insertion; this must be done carefully to avoid damaging or dislodging the catheter.
- Carefully remove the retractor.
- Make sure the $PbtO_2$ probe remains in place.
- At the burr hole site, close the scalp incision using standard closure techniques; this must be done with extreme caution to avoid damaging the probe.
- Apply an extra transparent and soft-cloth adhesive dressing or any appropriate dry sterile occlusive dressing.
- Date and initial the dressing.
- Change the LICOX dressing every 48 hours or whenever saturated, using sterile technique that includes mask and sterile gloves. Cleanse the insertion site with Betadine swabs from the central line dressing kit.

AFTER THE PROCEDURE

Postprocedure Care

- Securing of the LICOX cables
  - The cables should be taped to an arm board and then pinned to the patient's gown, allowing enough slack to accommodate movement of the patient for turning and transferring.
  - Plug in the connecting cable to the proximal end of the probe.
  - Connect both ends of the Y cable to the LICOX monitor. Insert the smart card in the card slot.
  - Power on the LICOX monitor.
  - Wait a few seconds for a stable reading; it may take up to 2 hours for reliable readings.
  - Connect the LICOX monitor to the bedside monitor, using the link box and cable.
  - A CT scan of the head should be obtained after the procedure is completed to confirm the location of the probe and rule out possible intracranial hemorrhage.
- Discontinuation of the LICOX CMP system
  - It is recommended that the LICOX probe not be left in tissue for more than 5 days.
  - The probe should be removed by a qualified provider, and is usually removed after ICP has been normal for 24–48 hours without intervention.
  - Remove the sutures securing the probe to the scalp.
  - Carefully pull out the $PbtO_2$ probe.
  - Suture the insertion site in the scalp with a single stitch.
  - Assess for bleeding, cerebrospinal fluid (CSF) leak, and signs of infection.
  - Clean the skin and apply a sterile dressing.
  - Dispose of the $PbtO_2$ probe per hospital protocol.
  - Clean the cables and attach to the monitor for storage. Blood and debris may be removed from the cables with a towel and aqueous soap solution that also may contain formaldehyde. Disinfectants containing a high percentage of alcohol or phenol will damage the cables.

Complications

- Common
  - Generally, there are no common complications.
- Infrequent
  - Infection and contusion in $<2\%$
- Serious, rare complications
  - Thrombosis and hemorrhage

OUTCOMES AND EVIDENCE

- Normal brain tissue PO_2 values are between 25 and 50 mm Hg.
  - <20 mm Hg suggests impending cerebral hypoxia.
  - <10 mm Hg suggests critical hypoxia.
- Please refer to the standard critical care guidelines for the management of cerebral hypoxia.

Intracranial Pressure Monitoring

Mauro Oddo and Fabio Taccone

BEFORE PROCEDURE

Indications

- Common
  - Traumatic brain injury (TBI)
  - Subarachnoid hemorrhage
  - Intracranial hemorrhage (ICH)
  - Hydrocephalus
- Uncommon
  - Meningitis/encephalitis/brain abscess
  - Acute liver failure
  - Pseudotumor cerebri
  - Postoperative

Contraindications

- Absolute
  - Anticoagulation
  - Bleeding diathesis
- Relative
  - Scalp infection
  - Lack of specialized healthcare personnel

Equipment

- Flexible catheter or fiberoptic transducer
- Surgical scalpel
- Spinal needle
- Neurosurgical drill/saw
- Surgical scissors
- Retractors
- 14-gauge catheter

ANATOMY

- For brain monitoring, the entry point is located in the superiorly directed midpupillary line, 3 cm lateral to the sagittal suture and 2 cm anterior to the coronal suture on the right (frontal approach). This is the most commonly chosen site because it sits anterior to the motor strip, is lateral to both the superior sagittal sinus and the large bridging veins, and is on the nondominant hemisphere in most patients. If using a posterior approach, the entry point is 6 cm from the inion and 3 cm lateral to the midline. For lumbar monitoring, the L3-4 space is preferred.
- There are four main ways to monitor ICP
  1. Using an external flexible catheter inserted into the lateral cerebral ventricles (i.e., ventriculostomy) is generally considered as the gold standard method.
  2. Using a catheter (fluid-coupled) or fiberoptic transducer (fluid-uncoupled) placed into the brain parenchyma (i.e., intraparenchymal catheter) is a valid and comparable alternative method to intra-ventricular catheter.
     - 1 and 2 are recommended (see Fig. e20.1).
  3. Using a screw or bolt placed through the skull into the subarachnoid space.
  4. Using a sensor positioned in the epidural/subdural space beneath the skull.
     - 3 and 4, although feasible, are not usually recommended.
- A lumbar drain can also be used to measure ICP and control the CSF outflow if zeroed at the level of the third ventricle (not recommended as standard practice).

PROCEDURE

- Ventriculostomy
  - Place the patient in a supine position with the head of the bed elevated to approximately 20 degrees.
  - Shave areas (frontal or posterior) bilaterally.
  - Prepare with a chlorhexidine-alcohol solution and cover with a sterile drape.
  - Inject lidocaine solution (1%) into the skin and subcutaneous tissue.
  - Make a 1-cm incision with the scalpel and extend down to the bone. Hold the twist drill perpendicular to the skull to make a burr hole, avoiding the brain parenchyma.
  - Once the burr hole is irrigated, insert a spinal needle through the dura to verify that the incision is large enough to accommodate the catheter.
  - Advance the ventricular catheter through the burr hole perpendicular to the brain parenchyma, toward the inner canthus of the ipsilateral eye. Insert the catheter to a depth of approximately 6 cm to enter the frontal horn of the lateral ventricle. If the cerebrospinal fluid (CSF) is encountered before a depth of 6 cm, withdraw the stylet and advance the catheter the remaining distance. If CSF flow is not obtained at 6 cm, additional attempts should be made with the catheter tip directed more medially (i.e., toward the bridge of the nose or the inner canthus of the contralateral eye).
  - Tunnel the external end of the catheter under the scalp to exit through a separate incision approximately 5–6 cm from the entry point. Connect the distal end of the catheter to a pressure transducer and/or drainage system. Close the incision wound with sutures, and secure the catheter to the scalp with nylon suture. Apply a sterile nonocclusive dressing to minimize the risk of infection.

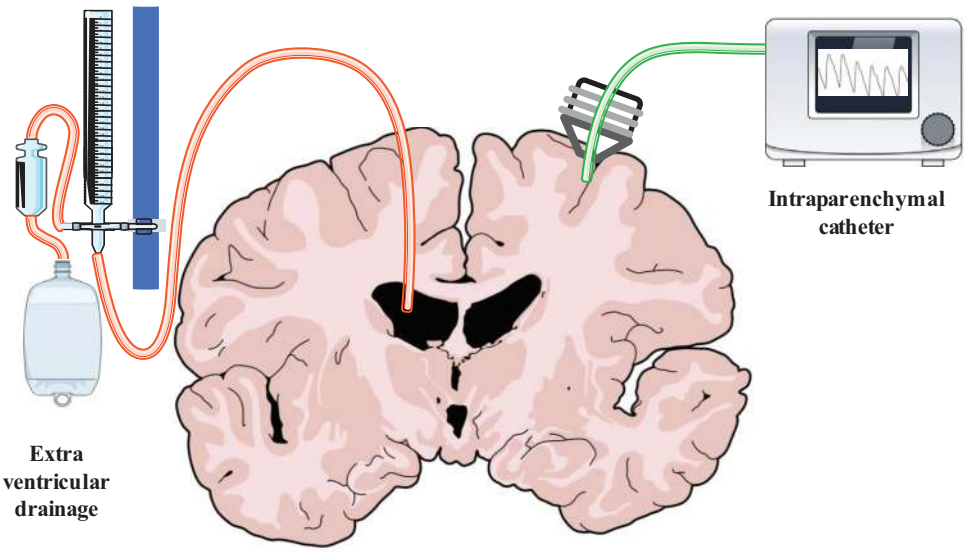

Fig. E20.1 Intraparenchymal probe and external ventricular drainage catheter to measure intracranial pressure.

- Zero the pressure transducer (fluid-coupled) at the level of the external auditory meatus.
- Intraparenchymal
  - The placement and tunneling of the device are similar to that of a ventriculostomy, but the depth of insertion depends on the compartment being monitored (e.g., subdural space, parenchyma, or ventricular system).
- Subarachnoid screw or bolt
  - The device is inserted using the same location and technique described earlier for burr hole placement. Once the burr hole is drilled, the dura and arachnoid are opened, and the threaded bolt is placed into the skull abutting the dura. Continuous fluid coupling between the subarachnoid space and an external pressure transducer are recorded through rigid tubing attached to the top of the bolt.
- Epidural/subdural sensor
  - This is inserted via the burr hole into the space between the skull and the epidural lining.
- Lumbar drain
  - Ensure that the patient has a functioning ventriculostomy in place and open cisterns on head CT scan
  - Place the patient in lateral decubitus.
  - Use the same preparation as for brain monitoring.
  - Insert a 14-gauge needle with 10–15 degrees of angulation in the cephalic direction, and once the lumber cistern is entered, rotate the needle 90 degrees, remove the obturator from the needle, and measure an opening pressure.
  - Insert the catheter with a guide wire until the 15-cm mark on the catheter is reached. Remove the needle while maintaining the catheter in the same position. Remove the guide wire from the lumbar drain catheter and connect the drain to the CSF collecting system.

AFTER PROCEDURE

Postprocedure Care

- If fluid-coupled systems are used, the pressure transducer must be adjusted to the head position to avoid errors in measurement.
- Check for air bubbles, blood clots, or other material occluding the tubing.
- Inspect the drain insertion site to ensure no leakage of CSF around the exit site.
- Sample the CSF daily to detect infection early.
- Normal ICP values are between 0 and 10 mm Hg (under resting conditions).
- *Intracranial hypertension* is defined as a sustained elevation of ICP above 20–25 mm Hg for more than 5 minutes.

Complications

- Common
  - Malpositioning
  - Erroneous values (subarachnoid catheters in case of swollen parenchyma and dural flap; epidural catheters when ICP exceeds 30 mm Hg)
  - Erroneous zeroing (intraparenchymal if monitoring more than 5–7 days)
- Infrequent
  - Overdrainage (lumbar drain)
  - Radiculopathy (lumbar drain)
- Serious, rare complications
  - Infections (ventriculitis, seen with intra-ventricular probes, extremely rare with intra-parenchymal probes)
  - Hemorrhage: 0.5% to 10% (more frequent with intra-ventricular probes)
  - Brain herniation (lumbar drain)

OUTCOMES AND EVIDENCE

- Monitoring ICP is recommended in critically ill patients with coma (defined by a GCS < 9) after acute brain injury (e.g., trauma, intracranial hemorrhage, encephalitis) with abnormal noncontrast head CT scan (defined by the presence of intracerebral lesions and/or signs of brain edema, such as sulci or cisternal effacement) who are at risk for intracranial hypertension
- Monitoring ICP is useful in critically ill patients to manage intracranial hypertension, to guide ICP-targeted therapies, to calculate and monitor cerebral perfusion pressure, and to drain CSF.

- Intraventricular and intraparenchymal probes are equally effective in measuring ICP. Ventriculostomy must be continuously zeroed. Fiber-optic monitors are zeroed before insertion and are not affected by the patient position or bed height. The drift of measurements over time can be a problem, and intraparenchymal probes do not allow CSF drainage. ICP can also be measured via subarachnoid, epidural/subdural, or lumbar drains. Compared with intraventricular or intraparenchymal catheters, subarachnoid and subdural/epidural probes do not guarantee a reliable measure of ICP.
- The risk of hemorrhagic complications from the placement of an ICP monitor ranges from approximately 0.5%–10%. The risk of a hemorrhage increases dramatically when coagulation abnormalities are present. The placement of intraparenchymal probes is easier than with intraventricular catheters, particularly in conditions of brain edema and ventricular effacement.
- The rate of infection associated with ICP monitors correlates with duration of placement, presence of a CSF leak, frequency of CSF sampling, presence of intraventricular hemorrhage, and concurrent systemic infection. The utility of prophylactic antibiotics and daily surveillance of CSF cultures is highly controversial. The rate of catheter-related infection is clearly higher with intraventricular than with intraparenchymal catheters.
- Noninvasive tools for ICP monitoring (transcranial Doppler, optic nerve sheath diameter, infrared pupillometry) may be used as a complement to invasive ICP or in patients in which invasive ICP is contraindicated

Indirect Calorimetry

Pierre Singer and Guy Fishman

BEFORE THE PROCEDURE

Indications

- A need for estimating energy expenditure (EE) in critically ill patients in whom the EE is highly variable and difficult to predict by simple equations, such as:
  - Patients with liver disease
  - Obese patients
  - Trauma patients
  - Patients with comorbidities
  - Patients under sedation

Contraindications

Absolute Contraindications

- Situations preventing a complete collection of expired gases
- Leaks of gas from the ventilator circuit
- Leaks around endotracheal tubes or through chest tubes
- Instability of delivered oxygen concentration
- Oxygen concentration above 65%

Relative Contraindications

- Hemodynamically unstable patient
- Large bias flow
- Extreme circuit flow rates

Equipment

- Indirect calorimeter

PROCEDURE

See Videos E21.1 and E21.2

- Select the patient.
- Connect the inspiratory sampling line tube to the water trap container.
- Switch on the monitor.
- Warm up according to the recommendations.
- Choose the correct respiratory mode.
- Perform gas calibration if required.
- Insert patient data.
- Connect the mixing chamber inlet to the expiratory outlet of the respirator.
- Place the inspiratory sampling line in the inspiratory tube of the respirator.
  Or connect the connector after the humidifier.
- Press start.
- Measure for 5–30 minutes, according to the device and the percentage of variability (5 minutes if variability 5%, 30 minutes if variability 10%).
- Get a report.

AFTER THE PROCEDURE

- Adjust metabolic nutritional care according to the metabolic measurements to avoid undernutrition and overnutrition.

COMPLICATIONS

- Common
  - Inaccurate measurements caused by equipment malfunction and methodological problems
- Infrequent
  - Infection crossover

Extracorporeal Membrane Oxygenation Cannulation

Penny Lynn Sappington

SPECIALTY AND CATEGORY WITHIN SPECIALTY

Critical care medicine
- Mechanical support for refractory respiratory and cardiac failure

BEFORE PROCEDURE

Indications

- Venovenous extracorporeal membrane oxygenation (ECMO)
  - Acute severe respiratory failure with high mortality risk, reversible and nonresponsive to optimal conventional therapy. ECMO is considered when there is approximately at 50% mortality (PaO_2/FiO_2 <150 on FiO_2 <90% and Murray score 2–3) and indicated at 80% (PaO_2/FiO_2 <100 on FiO_2 100% and Murray score 3–4 despite optimal care for ≥6 hours) using ARDSNET criteria with low tidal volume ≤6 cc/kg and high positive end-expiratory pressure (PEEP) ≥10 cm H_2O; maintaining P_{LAT} >30 cm H_2O.
    - Trial of diuresis
    - Trial of sedation/paralytics
    - Trial of prone positioning
- See Table E22.1 for respiratory etiologies.
- Venoarterial ECMO: indication for ECMO in adult cardiac failure is cardiogenic shock: Inadequate tissue perfusion manifests as hypotension and low cardiac output
  - Shock persists despite the following therapies:
    - Volume administration
    - Inotropes and vasoconstrictors
    - Mechanical support with intraaortic balloon counterpulsation or Impella if appropriate

See Table E22.2 for cardiac etiologies.Contraindications

- Absolute contraindications
  - Significant life-limiting disease
  - Significant baseline lung disease, including home O_2 dependence or heart disease
  - Not a transplant candidate
  - Multiple organ failure
  - Significant immunosuppression, bone marrow with absolute neutrophil count (ANC) <500
  - Cancer survival <2 years
  - Cirrhosis
  - AIDS or untreated HIV disease
  - Recent stroke/intracranial hemorrhage
  - Suspicion of anoxic brain injury
  - Specific to venoarterial (VA) ECMO:
    - Aortic regurgitation
    - Aortic dissection
    - Severe peripheral vascular disease
- Relative contraindications
  - Age
  - Bleeding diathesis
  - Gastrointestinal bleed
  - Greater than 14 days of mechanical ventilation
  - Encephalopathy
  - Morbid obesity

Equipment

Permanent equipment:
- Centrifugal pump
- Marquet Cardiohelp
  - Integrated pump and oxygenator
  - Provides real-time arterial and venous pressures, hemoglobin and SVO_2
- Thoratec Centrimag
  - Magnetically levitated pump Impella—contract free for less hemolysis
  - No hand crank, must have backup console
  - ROTOFLOW
  - Inexpensive pump
- ECMO cart (including instrument tray)
- Oxygenator bracket (Quadrox D)
- Pump external drive
- Heater/cooler with appropriate water lines and connectors (BioCal or Sarns) or heating blanket
- Oxygen/medical air blender with appropriate-length (20 ft each) gas lines and connectors for all operating rooms and intensive care areas
- Cardiotomy reservoir holder
- Manifold for pressure readings on the BioPump 540 transducer, Medtronic DLP pressure display
- Tubing clamps and scissors
- Hand crank
- Bed plate with two long poles
- 3/8″ Keck roller clamp for an additional outflow or inflow cannula
- Full 100% oxygen E cylinders with a tubing adapter
- Set of each: four types of gas connectors
  - Possible accessory equipment
  - Hemoconcentrator bracket

Disposable supplies:
- ECMO CarMeda-bonded (CB) Medtronic custom tubing pack or a Maquet custom tubing pack–Quadrox Bioline or Levitronix pump head

TABLE E22.1 Respiratory Etiologies for Venovenous ECMO

Acute Respiratory Injury	Trauma
Pneumonectomy	Pulmonary contusion
Lobectomy	Pre–lung transplantation
ARDS	Chronic respiratory failure
Pneumonia	Post–lung transplantation
Viral illness – H1N1	Severe primary graft dysfunction
Aspiration	Severe rejection – cellular and/or humoral
Sepsis	Chronic respiratory disease
Inhalation injury	Asthma
	COPD

ARDS, Acute respiratory distress syndrome; *COPD,* chronic obstructive pulmonary disease.

TABLE E22.2 Cardiac Etiologies for Venoarterial ECMO

Cardiogenic Shock	Other Indications
Acute cardiotomy	Severe septic shock
Myocarditis	Severe hypothermia – rewarming
Peripartum cardiomyopathy	Pre–lung transplant – end-stage lung disease with PH and RV failure
Pulmonary embolism	Post–lung transplant – Severe primary graft dysfunction with RV failure*
Decompensated chronic heart failure	Cardiac arrest – ECPR
Heart Transplantation	
Severe primary graft dysfunction	
Severe rejection – cellular and/or humoral	

ECPR; PH, pulmonary hypertension; *RV,* right ventricle.
*Blood supply to the transplanted lungs depends on pulsatility in pulmonary artery pressure. No bronchial arterial supply can increase the risk of bronchial dehiscence.

- Cardiotomy reservoir
- Walrus extension connectors with high-flow stopcocks
- Terumo extensions high flow (one positive and one negative for kidney)
- Pressure veil and isolator tubings or DLP pressure display set
- 3/16″ to male connectors
- Extra 3/8″ CB straight connectors with a Luer-Lok
- 3/8″ non-Carmeda bonded connector
- 3/8″ perfusion adapter
- PlasmaLyte-A pH 7.4—2000 mL (prime the circuit)
- Sterile water for irrigation for BioCal or Sarns water heater (approximately 3–4 L)
  - Syringes: 3 mL, 10 mL, and 60 mL
  - Blood filter
  - Extra supplies for ECMO site
- BioMedicus Medtronic NextGen cannulae
- Multistage cannula for venous insertion: 21F, 23F, 25F, 27F
- Arterial: 25F (for venous insertion as an outflow cannula), 15F, 17F, 19F, and 21F
- CB Medtronic DLP malleable venous cannulae: 32F, 36F, and 40F
- CB EOPA cannulae: 20F, 22F, 24F
- CB/non-CB right angle venous: 40F
- CB Edwards RMI 36F RA
- CB two-stage 36/46
- Avalon cannulae dual lumen cannula: 23F, 27F, and 31F
- Crescent dual-lumen cannulae: 24F, 26F, 28F, 30F, 32F
- Insertion kits for cannulae (LivaNova Vascular dilator kit)
- Extra oxygenator Quadrox D
- Fresenius hemoconcentration (with Terumo tubing assembly)
- SCUF custom tubing pack
- IV tubing for hemofiltration
- Extra CB VAD/liver pack
- Extra length CB 6-ft. 3/8″ × 3/32″ tubing (sterile) and {1/4} × 3/32″ sterile tubing
- CB 3/8″ connectors with Luer-Lok
- 8F pediatric arterial CB cannula with {1/4}″ × {3/8}″ connector and {1/4}″ tubing CB (for distal femoral artery perfusion)
- Walrus large-bore stopcock and extension assemblies
- Terumo high-flow extension stopcocks
- Isolator (pressure veils), {3/16}″ male connectors, and stopcocks
- 3-mL, 10-mL, and 60-mL syringes
- 18-gauge needles and sterile safety blades or sterile scissors
- PlasmaLyte-A (pH 7.4)
- Blood filter (40 microns)
- Heparin (1:1000 units/mL)
- 210-cm guide wire
- 100-cm guide wire
- 145- and 260-cm Amplatz Super Stiff PTFE-coated guide wires
- Small biohazard bags
- Panduit ties and gun
- Appropriate charts, ECMO pre-bypass checklist, ECMO shift schedule, and a shift checklist

ANATOMY

For femoral cannulation, locate the femoral triangle of the patient. The femoral triangle is the name given to an area of the anterior aspect of the thigh formed as different muscles and ligaments cross each other producing an inverted triangular shape. Contained within this area, placed medially to laterally, are the femoral vein, artery, and nerve (remember "van"). The boarders of the triangle are composed of the medial border of the sartorius that forms the lateral border of the triangle; the inguinal ligament forms the superior border, and the medial border is formed by the medial border of the adductor longus. Within the triangle, the femoral artery lies at the midinguinal point, which is the midway point between the pubic symphysis and the anterior iliac spine. This midway point is an important landmark in locating the femoral artery. It is also an important landmark within the leg because medial to the femoral artery is the femoral vein. Thus, in effect, you can locate the femoral vein by palpating the femoral pulse and moving your needle medially.

The internal jugular vein lies within the triangle that is made up by the lateral head of the sternocleidomastoid muscle, the medial head of the sternocleidomastoid muscle, and the clavicle inferiorly. Locate the apex of the triangle and move inferiorly to the center to locate the internal jugular vein. The apex of this triangle is a good landmark in locating the internal jugular vein. The carotid artery lies lateral and inferior to the internal jugular vein.

Although anatomy is important to know, it recommended to use ultrasound real-time imaging for vasculature access for peripheral ECMO cannulation to minimize complications in these extreme critically ill patients.

In the anatomy for central ECMO cannulation, the ascending aorta located within the mediastinum is cannulated with the arterial cannula, and the right atrium is cannulated with the venous cannula in venoarterial ECMO. In central venovenous ECMO, cannulas are placed in the right atrium (venous cannula) and pulmonary artery (arterial cannula).

PROCEDURE

Venovenous Percutaneous

See Video E22.1. Cannulation is usually performed at the patient's bedside with the assistance of nursing staff, respiratory therapy, and perfusion. Percutaneous venous cannulation for ECMO is achieved with the use of a modified Seldinger technique. The right neck and the appropriate groin region are prepared and draped in a sterile fashion, and anesthesia is achieved with a local anesthetic. Unless contraindicated by immediate postoperative status, all patients receive a bolus of 3000–5000 units of Heparin (or 50-100 units/kg) for the cannulation procedure (percutaneous or open). Anticoagulation is given immediately after vasculature access with the guide wires. Use ultrasound guidance to access the veins (e.g., femoral or jugular). Use an angle of approximately 30 degrees with the skin to access the vein; then the guide wire is passed through the needle. As for any percutaneous technique, the guide wire should pass unimpeded. Occasionally, the onset of cardiac ectopy provides evidence regarding the location of the wire's tip. We commonly temporarily replace the wire with an Angiocath or small dilator to verify that the access achieved is venous and not arterial. The wire is then replaced, and, using it as a guide, sequentially larger dilators are passed. Manual compression of the insertion site is used to prevent excessive bleeding as the dilators are sequentially removed and reinserted. It is very important to ensure that the wire moves freely during both dilatation and cannula insertion. Free movement of the guide wire indicates that the dilator or cannulae is following the path of the wire and not kinking and taking an alternative path, such as through the vessel wall. Kinking can be prevented by gentle traction on the wire applied by an assistant as the dilator or cannula is passed. Creation of a skin incision slightly smaller than the cannula being inserted facilitates passage of the cannulae while still providing good hemostasis. Occasionally, difficulty is encountered with the passage of the cannula under the inguinal ligament or through the dilated opening in the vessel wall. Redilatation with a smaller dilator can facilitate passage. The preferred drainage site is the femoral vein, and the cannulae is advanced to just below the caval-atrial junction. The flows are usually the maximum capable with consideration to negative inlet pressures, RPMs in venovenous ECMO or positive resistance in venoarterial ECMO. Inflow to the patient is usually the right internal jugular vein, using a CB arterial BioMedicus cannulae (usually 17F, 19F, or 21F NextGen BioMedicus).

If a secondary site is needed, the femoral and internal jugular may be used and "Y'd" to either the venous or arterial cannulae depending on the desired ECMO configuration (e.g., VAV, VVA or VVV).

The dual-lumen cannulae (Avalon and Crescent) can be inserted into the internal jugular vein. This cannulae allows drainage from the cannulae holes sitting in the inferior vena cava (IVC) and superior vena cava (SVC) and return blood to the right atrium (RA). A baffle in the cannulae separates inflow from outflow.

After cannulation, it is important to assess the cannulae positions by obtaining a radiograph of the chest and abdomen.

Venoarterial Percutaneous

The preferred site is the femoral artery. Surgical (and percutaneous) insertion of arterial cannulae in the femoral artery can be complicated by malperfusion of the distal extremity. This complication may be addressed in several fashions, but should be dealt with expeditiously to avoid severe injury. We prefer either the insertion of a sheath in the superficial femoral artery (antegrade) or posterior femoral artery (retrograde) of the affected limb. This can be achieved in the open wound just distal to the reinfusion cannula insertion site or, in the case of a percutaneous cannula, via an incision at a separate site. The tubing is connected to a CB {3/8 } × {3/8}-inch connector with a Luer-Lok between the arterial cannulae and the ECMO arterial pump tubing. If decreased heparinization and low flow in this system are concerns, heparin 0.5–2 U/kg/hr may be infused by a pressure pump into this system for anticoagulation.

Venovenous/Venoarterial Surgical Cutdown

Using the same cannulas, when there is difficulty with percutaneous cannulation or the body habitus is not conducible, surgical cutdown to gain access to the femoral vessels can be done either at the bedside or, if time allows, in the operating room. The cannulation can be performed either using open cutdown, open cutdown with Seldinger technique to access vessels, or open cutdown with end-to-side graft (Dacron) to the artery for venoarterial (VA) cannulation.

Central Cannulation

Central ECMO cannulation is generally used as the first-choice modality for cardiorespiratory support postcardiotomy shock or as an upgrade from peripheral cannulation when there are not adequate flows to provide good end-organ perfusion or overcome problems inherent to peripheral ECMO: left ventricular (LV) distention and differential hypoxia of the heart and/or the brain. The main advantages of this type of ECMO are good venous drainage and reliable arterial return to the proximal aorta in antegrade fashion. If the LV is not fully decompressed, a vent, via the right superior pulmonary vein, left atrium (LA), or LV apex can be placed. The size of the cannulae is defined by body surface area and the calculated ECMO flow necessary to achieve the metabolic requirements of the patient. ECMO may be performed with central cannulation with a CB Medtronic 35-cm DLP 32F, 36F, or 40F malleable venous; CB Medtronic DLP 2 stage 34/46; or DII 40F RA for right or left atrial cannulation. Inflow to the patient may be accomplished with Carmeda EOPA 22F or 24F or other appropriately coated cannula for a pulmonary artery (PA) or aorta. The median sternotomy is the least favored, as this site is associated with more bleeding complications. The cannulae may be tunneled inferior to the sternum and the chest then closed for hemostasis.

AFTER THE PROCEDURE

Postprocedure Care

- Daily patient and circuit management on ECMO, including:
  - Patient
  - Fluid
  - Electrolytes
  - Nutrition
  - Respiratory support
  - Neurologic
  - Infection control
  - Sedation and pain control
  - Hematology/transfusions
  - Cardiovascular support
  - Physical therapy
  - Psychosocial
- Circuit
  - Aseptic technique

- Pump/gas flow pressure monitoring
- Blood product infusion techniques
- Circuit infusions
- Management of anticoagulation
- Circuit checks
- Hemofiltration setup
- Bedside care of the ECMO patient

Weaning from venovenous ECMO is done by turning off the gases after placing the patient on ARDSNET ventilator settings (6 cc/kg with P_{LAT} >30 cm H_2O on 50% and 10 PEEP), ensure Respiratory Rate (RR) is increased to ensure an acceptable minute ventilation, and closely monitor arterial saturations. Check an arterial blood gas (ABG) 1 hour after gases are off to ensure acceptable CO_2 clearance. The patient is decannulated after being maintained off of gases for 24 hours.

Weaning trial from the venoarterial ECMO system is very different from venovenous weaning because the circuit is taking blood flow from the cardiopulmonary system. The patient should be on minimal inotropic support before initiation of the weaning trial. The ventilator is set at the optimal setting. Additional heparin is given to achieve an activated clotting time (ACT) of 300 seconds. ECMO flows may be reduced by 1 L/min at intervals, and observation of the patient's hemodynamics and arterial saturation is critical. Echocardiogram imaging is also useful in determining when the patient may be ready to be decannulated. If cardiac function is acceptable on minimal support, usually decannulation occurs in the operating room the next morning.

Complications

- Medical
  - Intracranial and another hemorrhage
  - Pneumothorax/pneumopericardium
  - Cardiac arrest
  - Hypotension/hypovolemia
  - Severe coagulopathy/thrombocytopenia
  - Seizures
  - Hemothorax/hemopericardium
  - Uncontrolled bleeding
  - Thrombosis
- Mechanical
  - Circuit disruption
  - System or component alarm/failure (e.g., pump, bladder, venous return monitor oxygenator, or heater)
  - Air embolus
  - Inadvertent decannulation
  - Clots

OUTCOMES AND EVIDENCE

- Patient outcomes after ECMO cannulation are very much dependent on the coexisting condition at the time of cannulation and the clinical state of the patient on ECMO support.
- Comorbidities pre-cannulation
- Cardiopulmonary resuscitation (CPR)
- Organ dysfunction
  - Liver and renal failure
- Length of cannulation time
- Lactate level
- Type of ECMO support
  - Venovenous vs. venoarterial
- Outcomes trial
  - CESAR Trial
    - Of patients assigned to consideration for treatment by ECMO, 63% (57/90) survived to 6 months without disability vs. 47% (41/87) of those assigned to conventional management (relative risk: 0.69; 95% confidence interval [CI]: 0.05–0.97; $P = 0.03$).
  - ECMO in Influenza H1N1 Epidemic
    - The median duration of ECMO support was 10 days (range: 7–15). At the time of reporting, 48 of the 68 patients (71%; 95% CI: 60%–82%) had survived to intensive care unit (ICU) discharge, of whom 32 had survived to hospital discharge and 16 remained as hospital inpatients. Fourteen patients (21%; 95% CI: 11%–30%) had died and 6 remained in the ICU, 2 of whom were still receiving ECMO.
    - Survival outcomes after the use of ECMO in patients with acute respiratory failure during the H1N1 influenza pandemic have validated the role of ECMO as an important management strategy in adults with severe respiratory failure.
- EOLIA Trial (ECMO to Rescue Lung Injury in Severe ARDS)
  - Primary aim
    - VV ECMO + conventional mechanical ventilation (MV) is better than MV alone
  - Entry criteria
    - Severe hypoxemia (PaO_2 <60 or 80 mm Hg for 3 or 6 hours, respectively) or hypercapnia ($PaCO_2$ >60 mm Hg or pH <7.35 for at least 6 hours)
    - Crossover from control arm to ECMO allowed for prolonged periods of arterial oxygen desaturation to <80%
  - The study was terminated for futility after 67 months
    - During this period, 249 patients had been enrolled in 64 units
    - Fewer than one patient/unit/year
  - There was an 11% reduction in absolute 60-day mortality in favor of ECMO (35% vs. 46%)
    - Failed to reach statistical significance ($P = 0.07$)
  - The patients on ECMO had a significantly higher incidence of bleeding events requiring transfusion (46% vs. 28%) and severe thrombocytopenia (27% vs. 16%)
  - Emergency ECMO improves outcome by "buying time" in extremely hypoxemic patients
    - Thirty-five patients (28%) of the control group required emergency cross over to ECMO
    - Median SaO_2 77% and nine cardiac arrest events
    - Fifteen survived
    - ECMO improves outcome by reducing the invasiveness of MV
  - During ECMO
    - Tidal volume was reduced by 43%
    - Respiratory rate was reduced by 23%
    - PEEP remained essentially unchanged
      - This represents an estimated 66% reduction in the mechanical power applied to the lungs (from 28 J/min to 10 J/min)
      - This reduction was associated with a higher survival rate (81/124 patients) in the ECMO group (vs. 68/125 controls)
  - Limitations of the EOLIA:
    - Underpowered to answer the trial question
    - Trial was stopped early at 249/331 (75% of recruitment)
    - Implausible power calculation
      - Initial power calculation was based on a 60% mortality in the control group, which became clear that it was inflated compared with the actual mortality rate in the controls of 46%
  - High crossover rate of controls
    - The 28% crossover rate resulted a reduction of separation between the two arms and diluted the ECMO treatment effect

    - The cross over complicates the interpretation of the two arms in an intention-to-treat analysis
    - Introduces a potential bias against the ECMO group in the secondary risk of treatment failure analysis because ECMO was initiated much later and in sicker patients than the rest of the controls
  - Lack of blinding of clinicians and patients/families
  - Slow recruitment of 249 patients over 6 years leading to potential trial fatigue and/or change of practice
- There is a lack of quality randomized controlled trials (RCTs) of ECMO outcomes in the adult population, especially venoarterial ECMO.
