PREFACE

The *Textbook of Critical Care* is an established and trusted source of information in the field of intensive care medicine, focused on presenting current understanding of core physiologic principles and the fundamentals for clinical, evidence-based, and practice-related decision making. A reference book that successfully bridges the gap between medical and surgical intensive care practice and covers topics relevant to adult and pediatric populations, the *Textbook of Critical Care* offers chapters that address common problems with concise, easily understood descriptions of the underlying pathophysiology, evidence-based interventions, and state-of-the-art chapters for diagnosis, monitoring, and management of commonly encountered organ dysfunctions. System-based chapters with tables, figures, images, algorithms, and key points organize complex information concerning specific topics in an easily understood format for quick reference. The accompanying e-book, included with the book purchase, provides ready access to procedural videos, a powerful search engine, hyperlinked references, and downloadable images. Importantly, it is optimized for convenient use on all devices, providing a real-time, point-of-care reference.

This eighth edition has been fully updated to take into account new developments in intensive care medicine since the last edition, with chapters authored by leading experts in critical care, anesthesia, surgery, pulmonary medicine, and pediatrics from around the world. There is a continued emphasis on the importance of a multidisciplinary approach to the care of critically ill patients, with special attention to rapidly evolving areas that include imaging and monitoring, advanced respiratory modalities, extracorporeal gas exchange, and renal replacement therapy. We are sure that all those with an interest in critical care medicine, from student to expert, will find this eighth edition of the *Textbook of Critical Care* a valuable source of information.

Sudden Deterioration in Neurologic Status

Alexis Steinberg and Joseph M. Darby

Patients admitted to the intensive care unit (ICU) with critical illness or injury are at risk for neurologic complications.[1–5] A sudden or unexpected change in the neurologic condition of a critically ill patient often heralds a complication that may cause direct injury to the central nervous system (CNS). Alternatively, such changes may simply be neurologic manifestations of the underlying critical illness or treatment that necessitated ICU admission (e.g., sepsis). These complications can occur in patients admitted to the ICU without neurologic disease and in those admitted for management of primary CNS problems (e.g., stroke). Neurologic complications can also occur as a result of invasive procedures and therapeutic interventions. Commonly, recognition of neurologic complications is delayed or missed entirely because therapeutic interventions such as intubation and sedatives interfere with the physical examination or otherwise confound the clinical picture. In other cases, neurologic complications are not recognized because of a lack of sensitive methods to detect the problem (e.g., delirium). Morbidity and mortality are increased among patients who develop neurologic complications; therefore the intensivist must be vigilant in evaluating all critically ill patients for changes in neurologic status.

As the complexity of ICU care has increased over the course of time, so has the risk of neurologic complications. In studies of medical and surgical ICU patients, the incidence of neurologic complications has ranged from 12.3% to 54%[1,6] and is associated with increased morbidity, mortality, and ICU length of stay.

Sepsis is the most common clinical problem associated with development of neurologic complications (sepsis-associated encephalopathy). In addition to encephalopathy, other common neurologic complications include seizures and stroke. Neuromuscular disorders are now recognized as a major source of morbidity in severely ill patients.[7] Recognized neurologic complications occurring in selected medical, surgical, and neurologic ICU populations are shown in Table 1.1.[8–35]

IMPAIRMENT IN CONSCIOUSNESS

Global changes in CNS function, best described in terms of impairment in consciousness, are generally referred to as *encephalopathy* or *altered mental status*. An acute change in the level of consciousness, undoubtedly, is the most common neurologic complication that occurs after ICU admission. *Consciousness* is defined as a state of awareness (arousal or wakefulness) and the ability to respond appropriately to changes in environment.[36] For consciousness to be impaired, global hemispheric dysfunction or dysfunction of the brainstem reticular activating system must be present.[37] The degree of impairment in consciousness may range from a sleeplike state (coma) to states characterized primarily by confusion and agitation (delirium). States and descriptions of acutely altered consciousness are listed in Table 1.2.

When an acute change in consciousness is observed, the patient should be evaluated in the clinical context with consideration of the age, presence or absence of coexisting organ system dysfunction, metabolic status, medications, and presence or absence of infection. In patients with a primary CNS disorder, deterioration in the level of consciousness frequently represents the development of brain edema, increasing intracranial pressure, new or worsening intracranial hemorrhage, hydrocephalus, CNS infection, or cerebral vasospasm. In patients without a primary CNS diagnosis, an acute change in consciousness is often the result of the development of infectious complications (i.e., sepsis-associated encephalopathy), drug toxicities, or the development or exacerbation of organ system failure. Nonconvulsive status epilepticus (NCSE) is increasingly being recognized as a cause of impaired consciousness in critically ill patients (Box 1.1).[38–43]

Altered consciousness manifesting as impairment in wakefulness or arousal (i.e., coma and stupor) and their causes are well defined.[36–39] Substantial confusion remains, however, regarding the diagnosis and management of delirium. When dedicated instruments are used, delirium can be diagnosed in between 50% and 75% of critically ill patients, making this condition the most common neurologic complication of critical illness.[40–44] Difficulty in establishing the diagnosis of delirium stems primarily from prior beliefs that agitation and confusion in the critically ill are expected consequences of the unique environmental factors and sleep deprivation that characterize the ICU experience.

Currently accepted criteria for the diagnosis of delirium include impaired cognition that has a fluctuating course and is not explained by an underlying neurocognitive disorder.[45] Delirium is considered a direct physiologic consequence of another medical condition. Subtypes of delirium include hyperactive (agitated) delirium and the more common hypoactive or quiet delirium.[44] Impaired consciousness may be apparent as a reduction in awareness, psychomotor retardation, agitation, or impairment in attention (increased distractibility or vigilance). Cognitive impairment can include disorientation, impaired memory, and perceptual aberrations (hallucinations or illusions).[46] Autonomic hyperactivity and sleep disturbances may be features of delirium in some patients (e.g., those with drug withdrawal syndromes

TABLE 1.1 Neurologic Complications in Selected Specialty Populations

Medical	
Bone marrow transplantation[8,9]	CNS infection, stroke, subdural hematoma, brainstem ischemia, hyperammonemia, Wernicke encephalopathy
Cancer[10,11]	Stroke, intracranial hemorrhage, CNS infection, neurotoxicity from chimeric antigen receptor T-cell therapy (CAR T-cell)
Fulminant hepatic failure[12]	Encephalopathy, coma, brain edema, increased ICP
HIV/AIDS[13,14]	Opportunistic CNS infection, stroke, vasculitis, delirium, seizures, progressive multifocal leukoencephalopathy
Pregnancy[15,16]	Seizures, ischemic stroke, cerebral vasospasm, intracranial hemorrhage, cerebral venous thrombosis, hypertensive encephalopathy, pituitary apoplexy
Surgical	
Cardiac surgery[17,18]	Stroke, delirium, brachial plexus injury, phrenic nerve injury
Vascular surgery[19,20]	
Carotid	Stroke, cranial nerve injuries (recurrent laryngeal, glossopharyngeal, hypoglossal, facial), seizures
Aortic	Stroke, paraplegia
Peripheral	Delirium
Transplantation[12,21–23]	
Heart	Stroke
Liver	Encephalopathy, seizures, opportunistic CNS infection, intracranial hemorrhage, Guillain-Barré syndrome, central pontine myelinolysis
Renal	Stroke, opportunistic CNS infection, femoral neuropathy
Urologic surgery (TURP)[24]	Seizures and coma (hyponatremia)
Otolaryngologic surgery[25,26]	Recurrent laryngeal nerve injury, stroke, delirium
Orthopedic surgery[27]	
Spine	Myelopathy, radiculopathy, epidural abscess, meningitis
Knee and hip replacement	Delirium (fat embolism)
Long-bone fracture/nailing	Delirium (fat embolism)
Neurologic	
Stroke[28–30]	Stroke progression or extension, reocclusion after thrombolysis, bleeding, seizures, delirium, brain edema, herniation
Intracranial surgery[31]	Bleeding, edema, seizures, CNS infection
Subarachnoid hemorrhage[32,33]	Rebleeding, vasospasm, hydrocephalus, seizures
Traumatic brain injury[34]	Intracranial hypertension, bleeding, seizures, stroke (cerebrovascular injury), CNS infection
Cervical spinal cord injury[35]	Ascension of injury, stroke (vertebral artery injury)

CNS, Central nervous system; *HIV/AIDS,* human immunodeficiency virus/acquired immunodeficiency syndrome; *ICP,* intracranial pressure; *TURP,* transurethral prostatic resection.

TABLE 1.2 States of Acutely Altered Consciousness

State	Description
Coma	Closed eyes, sleeplike state with no response to external stimuli (pain)
Stupor	Responsive only to vigorous or painful stimuli
Lethargy	Drowsy, arouses easily and appropriately to stimuli
Delirium	Acute state of confusion with or without behavioral disturbance
Catatonia	Eyes open, unblinking, unresponsive

or delirium tremens). Delirium in critically ill patients is associated with increased morbidity, mortality, and ICU length of stay.[47–49] Both vulnerability factors (e.g., age, comorbidities) and precipitating hospital factors (e.g., acute illness and medications) are recognized risk factors for delirium.[50,51] Other major risk factors include psychoactive medications (benzodiazepines),[52,53] drug-induced coma, sleep alterations,[54] metabolic disturbances, and sepsis.

As has been noted, NCSE is increasingly recognized as an important cause of impaired consciousness in critically ill patients and is characterized by electrographic seizure activity without clear clinical convulsive activity.[55,56] Several electroencephalographic (EEG) criteria exist for classification of NCSE.[57] Nonconvulsive seizures make up around 90% of seizures detected in critically ill patients undergoing continuous EEG out of concern for subclinical seizures or unexplained altered mental status.[58,59] The frequency of NCSE in general ICU patients varies from between 8% and 20%.[58–61] Approximately 48% of patients remaining comatose after convulsive status epilepticus were found to be in NCSE.[62,63] Other predisposing factors for NCSE in the ICU include traumatic brain injury, subarachnoid hemorrhage, global brain ischemia or anoxia, stroke, sepsis, multiple organ failure, and medication intoxication or withdrawal. Substantial mortality and morbidity are associated with NCSE, with the underlying etiology affecting the outcome.[64] Early recognition of NCSE can prevent the development of refractory status epilepticus and allow for timely

BOX 1.1 General Causes of Acutely Impaired Consciousness in the Critically Ill

Infection
Sepsis encephalopathy
CNS infection

Drugs
Narcotics
Benzodiazepines
Anticholinergics
Anticonvulsants
Tricyclic antidepressants
Selective serotonin uptake inhibitors
Phenothiazines
Steroids
Immunosuppressants (cyclosporine, FK506, OKT3)
Anesthetics

Electrolyte and Acid-Base Disturbances
Hyponatremia
Hypernatremia
Hypercalcemia
Hypermagnesemia
Severe acidemia and alkalemia

Organ System Failure
Shock (if severe)
Renal failure
Hepatic failure
Pancreatitis
Respiratory failure (hypoxia, hypercapnia)

Endocrine Disorders
Hypoglycemia
Hyperglycemia
Hypothyroidism
Hyperthyroidism
Pituitary apoplexy

Drug Withdrawal
Alcohol
Opiates
Barbiturates
Benzodiazepines

Vascular Causes
Shock
Hypotension
Hypertensive encephalopathy
CNS vasculitis
Cerebral venous sinus thrombosis

CNS Disorders
Hemorrhage
Stroke
Brain edema
Hydrocephalus
Increased intracranial pressure
Meningitis
Ventriculitis
Brain abscess
Subdural empyema
Seizures
Vasculitis

Seizures
Convulsive and nonconvulsive status epilepticus

Miscellaneous
Fat embolism syndrome
Neuroleptic malignant syndrome
Thiamine deficiency (Wernicke encephalopathy)
Psychogenic unresponsiveness

CNS, Central nervous system.

treatment to be initiated. Currently, no clear guidelines exist for the management of NCSE.[65]

STROKE AND OTHER FOCAL NEUROLOGIC DEFICITS

The new onset of a major neurologic deficit that manifests as a focal impairment in motor or sensory function (e.g., hemiparesis) or one that results in focal seizures usually indicates a primary problem referable to the cerebrovascular circulation. In a study evaluating the value of computed tomography (CT) in medical ICU patients, ischemic stroke and intracranial bleeding were the most common abnormalities associated with the new onset of a neurologic deficit or seizures.[66] Even though the majority of strokes present through the emergency room, 7%–15% of all strokes occur in the hospital, with unique mechanisms including paradoxical embolism in immobile patients, cerebral hypoperfusion causing watershed infarcts, and extracorporeal membrane oxygenation.[67] In-hospital strokes can either be ischemic infarcts or intracerebral hemorrhage (ICH). Overall, the frequency of new-onset stroke is between 1% and 4% in medical ICU patients.[1,68] Among general surgical patients, the frequency of perioperative stroke ranges from 0.3% to 3.5%.[69] Patients undergoing cardiac or vascular surgery and surgical patients with underlying cerebrovascular disease can be expected to have an increased risk of perioperative stroke.[18] Around 7%–15% of patients requiring extracorporeal membrane oxygenation have neurologic complications, including ischemic and hemorrhage stroke and seizures.[70,71] In view of the preexisting complexity in critically ill patients, an in-hospital rapid-response stroke protocol can lead to significant reductions in time to evaluation and treatment of patients with new focal neurologic deficits.[72]

The frequency of new or worsening focal neurologic deficits in patients admitted with a primary neurologic or neurosurgical disorder is variable. Patients admitted with stroke can develop worsening or new symptoms as a result of stroke progression, bleeding, or reocclusion of vessels previously opened with interventional therapy. In patients who have undergone elective intracranial surgery, postsurgical bleeding or infectious complications are the main causes of new focal deficits. In trauma patients, unrecognized injuries to the cerebrovascular circulation can cause new deficits. Delayed cerebral ischemia related to vasospasm frequently occurs in patients presenting with aneurysmal subarachnoid hemorrhage. Patients presenting with traumatic spinal

cord injury and those who have undergone surgery of the spine or of the thoracic or abdominal aorta can develop new or worsening symptoms of spinal cord injury. Early deterioration of CNS function after spinal cord injury usually occurs as a consequence of medical interventions to stabilize the spine, whereas late deterioration is usually the result of hypotension and impaired cord perfusion. Occasionally, focal weakness or sensory symptoms in the extremities occur as a result of occult brachial plexus injury or compression neuropathy. New cranial nerve deficits in patients without primary neurologic problems can occur after neck surgery or carotid endarterectomy.

SEIZURES

New-onset seizures in general medical-surgical ICU patients are typically caused by narcotic withdrawal, hyponatremia, drug toxicities, or previously unrecognized structural abnormalities.[3,73] New stroke, intracranial bleeding, and CNS infection are other potential causes of seizures after ICU admission. The frequency of seizures is higher in patients admitted to the ICU with a primary neurologic problem such as traumatic brain injury, aneurysmal subarachnoid hemorrhage, stroke, or CNS infection.[74] Because NCSE is more common than was previously appreciated, NCSE should also be considered in the differential diagnosis of patients developing new, unexplained, or prolonged alterations in consciousness.

GENERALIZED WEAKNESS AND NEUROMUSCULAR DISORDERS

Generalized muscle weakness often becomes apparent in ICU patients as previous impairments in arousal are resolving or sedative and neuromuscular blocking agents are being discontinued or tapered. Polyneuropathy and myopathy associated with critical illness are now well recognized as the principal causes of new-onset generalized weakness among ICU patients being treated for nonneuromuscular disorders.[7,75–77] These disorders also may be responsible for prolonged ventilator dependency in some patients. Patients at increased risk for these complications include those with sepsis, systemic inflammatory response syndrome, and multiple organ dysfunction syndrome, in addition to those who require prolonged mechanical ventilation. Other risk factors include treatment with corticosteroids or neuromuscular blocking agents. In contrast to demyelinating neuropathies (e.g., Guillain-Barré syndrome), critical illness polyneuropathy is primarily a condition in which there is axonal degeneration. Critical illness polyneuropathy is diagnosed in a high percentage of patients undergoing careful evaluation for weakness acquired while in the ICU. Because primary myopathy coexists in a large number of patients with critical illness polyneuropathy, *ICU-acquired paresis*[77] or *ICU-acquired weakness*[7] may be better terms to describe this problem. Although acute Guillain-Barré syndrome and myasthenia gravis are rare complications of critical illness, these diagnoses should also be considered in patients who develop generalized weakness in the ICU.

NEUROLOGIC COMPLICATIONS OF PROCEDURES AND TREATMENTS

Routine procedures performed in the ICU or in association with evaluation and treatment of critical illness can result in neurologic complications.[78] The most obvious neurologic complications are those associated with intracranial bleeding secondary to the treatment of stroke and other disorders with thrombolytic agents or anticoagulants. Other notable complications are listed in Table 1.3.

EVALUATION OF SUDDEN NEUROLOGIC CHANGE

A new or sudden change in the neurologic condition of a critically ill patient necessitates a focused neurologic examination, review of the

TABLE 1.3 Neurologic Complications Associated With ICU Procedures and Treatments

Procedure	Complication
Angiography	Cerebral cholesterol emboli syndrome
Anticoagulants/antiplatelet agents	Intracranial bleeding
Arterial catheterization	Cerebral embolism
Bronchoscopy	Increased ICP
Central venous catheterization	Cerebral air embolism, carotid dissection, Horner syndrome, phrenic nerve injury, brachial plexus injury, cranial nerve injury
DC cardioversion	Embolic stroke, seizures
Dialysis	Seizures, increased ICP (dialysis disequilibrium syndrome)
Endovascular procedures (CNS)	Vessel rupture, thrombosis, reperfusion bleeding
Epidural catheter	Spinal epidural hematoma, epidural abscess
ICP monitoring	CNS infection (ventriculitis), hemorrhage
Intraaortic balloon pump	Lower extremity paralysis
Intubation	Spinal cord injury
Left ventricular assist devices	Stroke, seizures
Extracorporeal membrane oxygenation	Stroke, seizures
Lumbar puncture or drain	Meningitis, herniation
Mechanical ventilation	Cerebral air embolism, increased ICP (high PEEP and hypercapnia), seizures (hypocapnia)
Nasogastric intubation	Intracranial placement

CNS, Central nervous system; *DC,* direct current; *ICP,* intracranial pressure; *ICU,* intensive care unit; *PEEP,* positive end-expiratory pressure.

clinical course, medications, laboratory data, and appropriate imaging or neurophysiologic studies when indicated. The type and extent of the evaluation depend on the clinical context and the general category of neurologic change occurring. The history and physical examination should lead the clinician to the diagnostic approach best suited to the individual patient.

Essential elements of the neurologic examination include an assessment of the level and content of consciousness, pupillary size and reactivity, and motor function. Additional evaluation of the cranial nerves and peripheral reflexes and a sensory examination are conducted as indicated by the clinical circumstances. If the patient is comatose on initial evaluation, a more detailed coma examination should be performed to help differentiate structural from metabolic causes of coma.[37,38] When the evaluation reveals only a change in arousal without evidence of a localizing lesion in the CNS, a search for infection, discontinuation or modification of drug therapy, and a general metabolic evaluation may be indicated. Lumbar puncture to aid in the diagnosis of CNS infection may be warranted in selected neurosurgical patients and immunocompromised individuals. Lumbar puncture to rule out nosocomial meningitis in other patients is generally not rewarding.[79] EEG should be performed in patients with clear evidence of seizures and when the diagnosis of NCSE is being considered. Continuous EEG should be performed when the index of suspicion for NCSE remains high despite an unrevealing initial EEG examination.[58,80]

CT is indicated for nonneurologic patients with new focal deficits, seizures, or otherwise unexplained impairments in arousal.[66] In patients with primary neurologic disorders, CT is indicated if worsening brain edema, herniation, bleeding, and hydrocephalus are considerations when new deficits or worsening neurologic status occurs. In some cases, when the basis for a change in neurologic condition remains elusive, magnetic resonance imaging (MRI) may be helpful. In particular, the diffusion-weighted MRI technique can reveal structural abnormalities such as hypoxic brain injury, fat embolism, vasculitis, cerebral venous thrombosis, or multiple infarcts after cardiopulmonary bypass that are not apparent by standard CT.[81–86] MRI may be the imaging modality of choice in patients with human immunodeficiency virus (HIV) and new CNS complications.[81] For patients who develop signs and symptoms of spinal cord injury complicating critical illness, MRI can be used to further delineate the nature and severity of the injury. For patients who develop generalized muscle weakness or unexplained ventilator dependency, electromyography and nerve conduction studies can confirm the presence of critical illness polyneuropathy or myopathy.

MONITORING FOR NEUROLOGIC CHANGES

The common occurrence of neurologic changes in critically ill patients emphasizes the need for vigilant monitoring. A variety of clinical techniques such as the Glasgow Coma Scale, FOUR score,[87] National Institutes of Health (NIH) Stroke Scale, Ramsay Sedation Scale, Richmond Agitation-Sedation Scale, and Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) can be used to monitor clinical neurologic status.[40,41,43,88–90] For patients admitted to the ICU with a primary neurologic disorder, a variety of monitoring techniques, including measurements of intracranial pressure, brain tissue Po_2, cerebral metabolism, cerebral blood flow, cerebral perfusion pressure, autoregulation, and electrographic measurements, can be used.[91,92] Monitors can be invasive or noninvasive. More commonly used noninvasive measures are pupillometry,[93,94] near-infrared spectroscopy, bispectral index, transcranial Doppler, and EEG.

KEY POINTS

- An abrupt change in neurologic status is a common problem in critically ill patients that may be either a manifestation of the underlying critical illness and treatment or result from an acute unanticipated insult or injury to the nervous system. Neurologic changes in the critically ill are associated with increased morbidity and mortality.
- Impairment in consciousness manifesting as delirium is the most common neurologic complication occurring after ICU admission.
- NCSE is characterized by an alteration in consciousness or behavior associated with EEG changes without clear convulsive motor activity and is increasingly recognized as a cause for impaired consciousness in critically ill patients.
- Critical illness polyneuropathy and myopathy are now well recognized as the principal causes for the new onset of generalized weakness in critically ill patients and may contribute to prolonged ventilator dependency.
- An abrupt change in the neurologic condition of a critically ill patient necessitates a focused neurologic examination, review of medications, laboratory assessment and neuroimaging, and/or neurophysiologic studies when indicated.
- In-hospital stroke (ischemic or hemorrhagic) manifesting as a focal impairment in motor/sensory function or seizures is not uncommon and requires urgent workup and treatment.
- The Glasgow Coma Score, FOUR score, NIH Stroke Scale, Ramsay Sedation Scale, Richmond Agitation-Sedation Scale, and CAM-ICU are clinical assessment tools that are potentially useful in evaluating and monitoring neurologic status. A wide variety of invasive and noninvasive monitors exist for measuring specific brain physiology.

Claassen J, Mayer SA, Kowalski RG, Emerson RG, & Hirsch LJ. Detection of electrographic seizures with continuous EEG monitoring in critically ill patients. *Neurology*. 2004;62(10): 1743–1748.
A retrospective single-center study of patients undergoing continuous EEG in all ICUs to assess the frequency of seizures on contininous EEG and patients that require more prolonged EEG recording. Around 20% of patients on continuous EEG had seizures, and 90% of them were nonconvulsive seizures. Coma patients required >24 hours of recording to detect the first seizure.

De Jonghe B, Sharshar T, Lefaucheur JP, Authier FJ, Durand-Zaleski I, Boussarsar M, et al. Paresis acquired in the intensive care unit: a prospective multicenter study. *JAMA*. 2002; 288(22):2859–2867.
This prospective multicenter study of critically ill patients was the first to assess the clinical incidence, risk factors, and outcomes of mechanically ventilated patients developing ICU-acquired weakness, emphasizing a central role for corticosteroid use in its genesis and prolonged mechanical ventilation as a relevant ICU outcome.

Ely EW, Shintani A, Truman B, Speroff T, Gordon SM, Harrell FE Jr, et al. Delirium as a predictor of mortality in mechanically ventilated patients in the intensive care unit. *JAMA*. 2004;*291*(14):1753–1762.
This was a prospective cohort multicenter study of mechnically ventilated patients to determine if delirium was an independent predictor of outcome. Of 275 patients, delirium was found to be an independent predictor of 6-month mortality and ICU length of stay, even when covariates such as coma, sedatives, and analgesia were adjusted for.

Girard TD, Thompson JL, Pandharipande PP, Brummel NE, Jackson JC, Patel MB, et al. Clinical phenotypes of delirium during critical illness and severity of subsequent long-term cognitive impairment: a prospective cohort study. *Lancet. Respiratory Medicine*. 2018;6(3):213-222. doi:10.1016/S2213-2600(18)30062-6.
A multicenter, prospective cohort study of critically ill patients in medical and surgical ICUs with respiratory failure, shock, or both that assessed the prevelance of risk factors of delirium and their effects on long-term cognitive

outcomes. Sedative-associated, hypoxic, and septic delirium were common risk factors and frequently co-occurred. These are all indicators of acute brain injury and were identified as potential risk factors for long-term cognitive impairment, noting that some are not modifiable such as sedation.

Le Roux P, Menon DK, Citerio G, et al. Consensus summary statement of the International Multidisciplinary Consensus Conference on Multimodality Monitoring in Neurocritical Care: a statement for healthcare professionals from the Neurocritical Care Society and the European Society of Intensive Care Medicine. *Intensive Care Medicine*. 2014;40(9):1189-1209. doi:10.1007/s00134-014-3369-6.

A collaboration of multiple societies to address the evidence for multimodality monitoring, including invasive and noninvasive measures. A systematic literature review was done to develop specific recommendations about physiologic processes that may be important to the care of patients with neurologic complications.

Agitation and Delirium

Christina Boncyk, E. Wesley Ely, and Arna Banerjee

Agitation and delirium are commonly encountered in the intensive care unit (ICU). Although frequently underrecognized, delirium is present in up to 80% of critically ill adults on mechanical ventilation when routinely assessed.[1] Delirium and agitation are more than just an inconvenience; these conditions can have deleterious effects on patient and staff safety and contribute to poor outcomes, including increased duration of mechanical ventilation, increased ICU length of stay, increased risk of death, physical disability, and long-term cognitive impairment.[2–5] It is therefore important for clinicians to be able to recognize agitation and delirium and to have an organized approach for its evaluation and management.

AGITATION

Agitation is a psychomotor disturbance characterized by excessive motor activity associated with a feeling of inner tension.[6,7] The activity is usually nonproductive and repetitious, consisting of behaviors such as pacing, fidgeting, wringing of hands, pulling of clothes, and an inability to sit still. Careful observation of the patient may reveal the underlying intent. In the ICU, agitation is frequently related to anxiety or delirium. Agitation may be caused by various factors: metabolic disorders (hyponatremia and hypernatremia), hyperthermia, hypoxia, hypotension, use of sedative drugs and/or analgesics, sepsis, alcohol withdrawal, and long-term psychoactive drug use, to name a few.[8,9] It can also be caused by external factors such as noise, discomfort, and pain.[10] Agitation is important to manage, as it is associated with a longer length of stay in the ICU and higher costs.[8] Symptoms can be mild, characterized by increased movements and an apparent inability to get comfortable, or severe. Severe agitation can be life threatening, leading to higher rates of self-extubation, self-removal of catheters and medical devices, nosocomial infections,[8] hypoxia, barotrauma, and/or hypotension because of patient/ventilator asynchrony. Indeed, recent studies have shown that agitation contributes to ventilator asynchrony, increased oxygen consumption, and increased production of carbon dioxide (CO_2) and lactic acid; these effects can lead to life-threatening respiratory and metabolic acidosis.[9]

DELIRIUM

Delirium can be defined as follows: (1) A disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention. (2) A change in cognition (e.g., memory deficit, disorientation, language disturbance) or development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia. (3) The disturbance develops over a short period (usually hours to days) and tends to fluctuate during the course of the day. (4) There is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiologic consequence of a general medical condition, an intoxicating substance, medication use, or more than one cause (Fig. 2.1).[7] Delirium is commonly underdiagnosed in the ICU and has a reported prevalence of 20%–80%, depending on the severity of the illness and the need for mechanical ventilation.[2,4,11–13] Recent investigations have shown that the presence of delirium is a strong predictor of longer hospital stay, higher costs, and increased risk of death.[2,3,14] Each additional day with delirium increases a patient's risk of dying by 10%.[15] Longer periods of delirium are also associated with greater degrees of cognitive decline when patients are evaluated after 1 year.[3] Thus delirium can adversely affect the quality of life in survivors of critical illnesses and may serve as an intermediate recognizable step for targeting therapies to prevent poor outcomes in survivors of critical illness, including depression, posttraumatic stress disorder, and functional disability.[3,16]

Unfortunately, the true prevalence and magnitude of delirium have been poorly documented because myriad terms, including *acute confusional state, ICU psychosis, acute brain dysfunction,* and *encephalopathy,* have been used to describe this condition.[17] Delirium can be classified according to psychomotor behavior into hypoactive delirium, hyperactive delirium, or a mixed subtype. Hypoactive delirium, which is the most prevalent form of delirium, is characterized by decreased physical and mental activity and inattention. In contrast, hyperactive delirium is characterized by combativeness and agitation. Patients with both features have mixed delirium.[18,19] Hyperactive delirium puts both patients and caregivers at risk of serious injury but fortunately only occurs in a minority of critically ill patients.[18,19] Hypoactive delirium might actually be associated with a worse prognosis.[20,21] The Delirium Motor Subtype Scale may assist in making this diagnosis.[22]

Although healthcare professionals realize the importance of recognizing delirium, it frequently goes unrecognized in the ICU when not routinely screened for.[23–25] Even when ICU delirium is recognized, most clinicians consider it an expected event that is often iatrogenic and without consequence.[26] However, delirium needs to be viewed as a form of organic brain dysfunction that has consequences if left undiagnosed and untreated. Given the limited pharmacologic treatment options available, the most effective strategy for reducing its prevalence lies in prevention with nonpharmacologic treatment bundles, the cornerstone of which include routine patient assessments.[27,28]

Risk Factors for Delirium

The risk factors for agitation and delirium are many and overlap to a large extent (Table 2.1). Fortunately, several mnemonics can aid clinicians in recalling the list; three common ones are IWATCHDEATH, DELIRIUM, and THINK (Table 2.2). In practical terms, risk factors can be divided into three categories: the acute illness itself, patient factors, and iatrogenic or environmental factors. Importantly, a number of medications that are commonly used in the ICU are associated with the development of

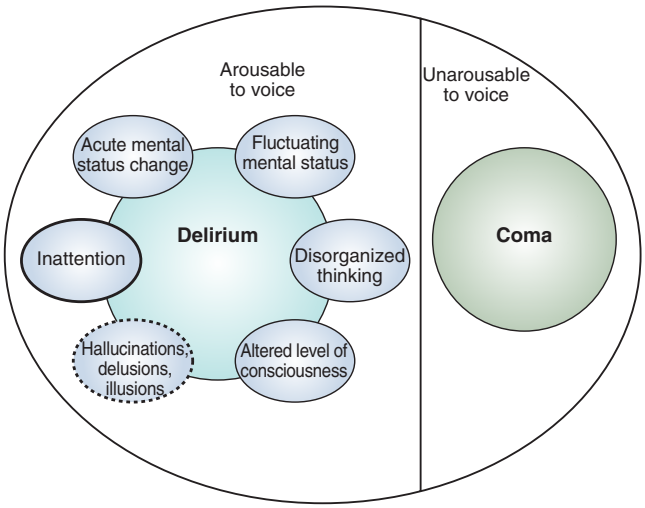

Fig. 2.1 Acute Brain Dysfunction. Patients who are unresponsive to voice are considered to be in a coma. Patients who respond to voice can be further evaluated for delirium using validated delirium monitoring instruments. Inattention is a cardinal feature of delirium. Other pivotal features include a change in mental status that fluctuates over hours to days, disorganized thinking, and altered levels of consciousness. Although hallucinations, delusions, and illusions may be part of the perceptual disturbances seen in delirium, they on their own are not synonymous with delirium, a diagnosis of which requires the presence of inattention and other pivotal features outlined earlier. (With permission from E. Wesley Ely and A. Morandi) (www.icudelirium.org).

TABLE 2.1 Risk Factors for Agitation and Delirium

Age >70 years	BUN/creatinine ratio ≥18
Transfer from a nursing home	Renal failure, creatinine >2.0 mg/dL
History of depression	Liver disease
History of dementia, stroke, or epilepsy	CHF
Alcohol abuse within past month	Cardiogenic or septic shock
Tobacco use	Myocardial infarction
Drug overdose or illicit drug use	Infection
HIV infection	CNS pathology
Psychoactive medications	Urinary retention or fecal impaction
Hyponatremia or hypernatremia	Tube feeding
Hypoglycemia or hyperglycemia	Rectal or bladder catheters
Hypothyroidism or hyperthyroidism	Physical restraints
Hypothermia or fever	Central line catheters
Hypertension	Malnutrition or vitamin deficiencies
Hypoxia	Procedural complications
Acidosis or alkalosis	Visual or hearing impairment
Pain	Sleep disruption
Fear and anxiety	

BUN, Blood urea nitrogen; *CHF,* congestive heart failure; *CNS,* central nervous system; *HIV,* human immunodeficiency virus.

agitation and delirium (Box 2.1). A thorough approach to the treatment and support of the acute illness (e.g., controlling sources of sepsis and giving appropriate antibiotics; correcting hypoxia, metabolic disturbances, dehydration, and hyperthermia; normalizing sleep/wake cycles), in addition to minimizing iatrogenic factors (e.g., excessive sedation), can

Opiates (especially meperidine)	Antibiotics
Anticholinergics	Corticosteroids
Antihistamines	Metoclopramide

reduce the incidence and/or severity of delirium and its attendant complications. A retrospective study conducted on postoperative delirium, specifically in patients undergoing cardiopulmonary bypass, has alluded to a decreased incidence of delirium in patients pretreated with statins.[29] Furthermore, ICU statins have been associated with decreased delirium, most significantly in the early stages of sepsis; in contrast to this, discontinuation of statins has been shown to be associated with increased delirium.[30] Randomized controlled trials, however, have yet to show a reduction in delirium outcomes with the use of statins versus no statins.[31,32]

PATHOPHYSIOLOGY

The pathophysiology of delirium is poorly understood, although there are a number of hypotheses.[33] It is likely that that the delirium is a result of the interaction of multiple pathophysiologic hypotheses rather than the result of one prevailing hypothesis. There are primary hypotheses:

- **Monoamine Axis Hypothesis.** Multiple neurotransmitters have been implicated, including dopamine (excess), acetylcholine (relative depletion), γ-aminobutyric acid (GABA), serotonin, endorphins, norepinephrine, and glutamate.[34–36] Elevated norepinephrine levels have been found in hyperactive delirium patients and,

when measured after traumatic brain injury, they are associated with poor neurologic status.[37]

- **Neuroinflammatory Hypothesis.** Inflammatory mediators, such as tumor necrosis factor alpha (TNF-α), interleukin-1 (IL-1), and other cytokines and chemokines, have been implicated in the pathogenesis of endothelial damage, thrombin formation, and microvascular dysfunction in the central nervous system (CNS), contributing to delirium.[36,38,39] Studies in the ICU have strengthened the evidence of a role for endothelial dysfunction in increasing the prevalence and duration of delirium.[40]
- **Cholinergic Deficiency Hypothesis.** Impaired oxygen metabolism contributes to cholinergic deficiency in the brain. According to this hypothesis, delirium is a result of cerebral insufficiency secondary to a global failure in oxidative metabolism.[41,42] In postoperative cardiac surgery patients, oxidative damage is associated with increased neuronal injury and postoperative delirium.[43]
- **Amino Acid Hypothesis.** Increased cerebral uptake of tryptophan and tyrosine can lead to elevated levels of serotonin, dopamine, and norepinephrine in the CNS. Altered availability of these amino acids is associated with increased risk of development of delirium.[44,45]

ASSESSMENT

The Society of Critical Care Medicine (SCCM) has recently updated guidelines for the use of sedatives and analgesics in the ICU.[46] The SCCM has recommended the routine monitoring of pain, anxiety, and delirium and the documentation of responses to therapy for these conditions.[46] These updated guidelines further include immobility and sleep disruption to emphasize the importance of mobility and adequate sleep hygiene in the acute care setting.

Many scales are available for the assessment of agitation and sedation, including the Ramsay Scale,[47] the Riker Sedation-Agitation Scale (SAS),[48] the Motor Activity Assessment Scale (MAAS),[49] the Richmond Agitation-Sedation Scale (RASS),[50] the Adaptation to Intensive Care Environment (ATICE)[51] scale, and the Minnesota Sedation Assessment Tool (MSAT).[51] Most of these scales have good reliability and validity among adult ICU patients and can be used to set targets for goal-directed sedative administration. The SAS, which scores agitation and sedation using a 7-point system, has excellent inter-rater reliability (kappa = 0.92) and is highly correlated (r^2 = 0.83–0.86) with other scales. The RASS (Table 2.3), however, is the only method shown to detect variations in the level of consciousness over time or in response to changes in sedative and analgesic drug use.[52] The 10-point RASS scale has discrete criteria to distinguish levels of agitation and sedation. The evaluation of patients consists of a three-step process. First, the patient is observed to determine whether he or she is alert, restless, or agitated (0 to +4). Second, if the patient is not alert and does not show positive motoric characteristics, the patient's name is called and his or her sedation level scored based on the duration of eye contact (−1 to −3). Third, if there is no eye opening on verbal stimulation, the patient's shoulder is shaken or pressure applied over the sternum by rubbing and the response noted (−4 or −5). This assessment takes less than 20 seconds in total and correlates well with other measures of sedation (e.g., Glasgow Coma Scale [GCS], bispectral electroencephalography, and neuropsychiatric ratings).[50]

Until recently, there was no valid and reliable way to assess delirium in critically ill patients, many of whom are nonverbal because of sedation or mechanical ventilation.[53,54] A number of tools have been developed to aid in the detection of delirium in the ICU. These tools have been validated for use in both intubated and nonintubated patients and measured against a "gold standard," the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) criteria. The tools are the Confusion Assessment Method for the ICU (CAM-ICU)[53,55–58] and the Intensive Care Delirium Screening Checklist (ICDSC).[11] Although there was initial hesitance about their ability to detect delirium in neurologically injured patients, delirium screening has shown to be possible, with delirious features remaining an important predictor for clinical outcomes.[59]

The CAM-ICU (Fig. 2.2) is a delirium measurement tool developed by a team of specialists in critical care, psychiatry, neurology,

TABLE 2.3 Richmond Agitation-Sedation Scale

+4	Combative	Combative, violent, immediate danger to staff
+3	Very agitated	Pulls or removes tube(s) or catheter(s); aggressive
+2	Agitated	Frequent nonpurposeful movement; fights ventilator
+1	Restless	Anxious, apprehensive, but movements not aggressive or vigorous
0	Alert and calm	
−1	Drowsy	Not fully alert but has sustained (>10 sec) awakening (eye opening/contact) to voice
−2	Light sedation	Drowsy; briefly (<10 sec) awakens to voice or physical stimulation
−3	Moderate sedation	Movement or eye opening (but no eye contact) to voice
−4	Deep sedation	No response to voice, but movement or eye opening to physical stimulation
−5	Unarousable	No response to voice or physical stimulation

Procedure For Assessment

1. Observe patient. Is patient alert, restless, or agitated?	(Score 0 to +4)
2. If not alert, state patient's name and tell him or her to open eyes and look at speaker. Patient awakens, with sustained eye opening and eye contact.	(Score −1)
3. Patient awakens, with eye opening and eye contact, but not sustained.	(Score −2)
4. Patient does not awaken (no eye contact) but has eye opening or movement in response to voice.	(Score −3)
3. Physically stimulate patient by shaking shoulder and/or rubbing sternum. No response to voice, but response (movement) to physical stimulation.	(Score −4)
4. No response to voice or physical stimulation.	(Score −5)

From Sessler CN, Gosnell MS, Grap MJ, et al. The Richmond Agitation-Sedation Scale: Validity and reliability in adult intensive care unit patients. *Am J Respir Crit Care Med* 2002;166(10):1338–1344.

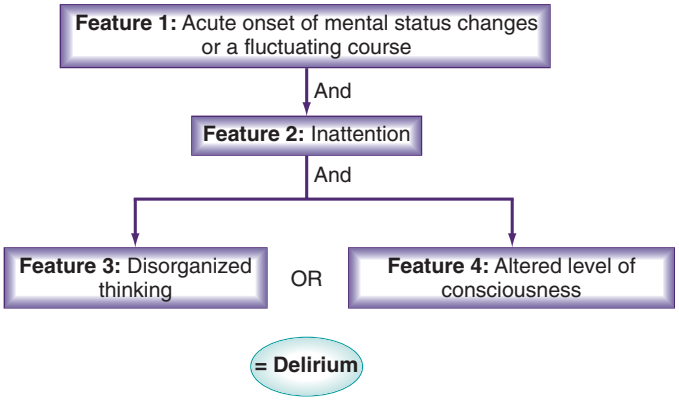

Fig. 2.2 Confusion Assessment Method for the Intensive Care Unit (CAM-ICU).

and geriatrics.[53,54] Administered by a nurse, the evaluation takes only 1–2 minutes to conduct and is 98% accurate in detecting delirium as compared with a full DSM-V assessment by a geriatric psychiatrist.[53,55] To perform the CAM-ICU, patients are first evaluated for level of consciousness; patients who respond to verbal commands (a RASS score of −3 or higher level of arousal) can then be assessed for delirium. The CAM-ICU comprises four features: (1) a change in mental status from baseline or a fluctuation in mental status, (2) inattention, (3) disorganized thinking, and (4) altered level of consciousness. Delirium is diagnosed if patients have features 1 and 2 and either feature 3 or 4 is positive (see Fig. 2.2).

The ICDSC[11] (Table 2.4) is a checklist-based assessment tool that evaluates inattention, disorientation, hallucination, delusion or psychosis, psychomotor agitation or retardation, inappropriate speech or mood, sleep/wake cycle disturbances, and fluctuations in these symptoms. Each of the eight items is scored as absent or present (0 or 1), respectively, and summed. A score of 4 or above indicates delirium, and 0 indicates no delirium. Patients with scores between 1 and 3 are considered to have subsyndromal delirium,[60] which has worse prognostic implications than the absence of delirium but a better prognosis than clearly present delirium.

Previous studies have called into question the usefulness of delirium evaluations for patients under sedation.[61,62] A small subset of patients (approximately 10%) were noted to have rapidly reversible sedation-related delirium, but unfortunately in this study the majority of patients continued to have persistent delirium even after interruption of sedation. Thus when feasible, delirium evaluation should be performed after interruption of sedation; however, delirium evaluations should not be forgone just because a patient is under sedation because the omission of the diagnosis would be far worse than overdiagnosing delirium in a handful of patients.

MANAGEMENT

The development of effective evidence-based strategies and protocols for prevention and treatment of delirium awaits data from ongoing randomized clinical trials of both nonpharmacologic and pharmacologic strategies. A brief overview is provided here.

When agitation or delirium develops in a previously comfortable patient, a search for the underlying cause should be undertaken before attempting pharmacologic intervention. A rapid assessment should be performed, including assessment of vital signs and physical examination to rule out life-threatening problems (e.g., hypoxia, self-extubation, pneumothorax, hypotension), or other acutely reversible physiologic causes (e.g., hypoglycemia, metabolic acidosis, stroke, seizure, pain). The previously mentioned IWATCHDEATH and DELIRIUM mnemonics can be particularly helpful in guiding this initial evaluation.

Once life-threatening causes are ruled out as possible etiologies, aspects of good patient care such as reorienting patients, improving sleep and hygiene, providing visual and hearing aids if previously used, removing medications that can provoke delirium, and decreasing the use of invasive devices if not required (e.g., bladder catheters, restraints), should be undertaken.

The use of the ABCDEF Bundle (**A**ssess, prevent, and manage pain; **B**oth spontaneous awakening and breathing trials; **C**hoice of appropriate sedation; **D**elirium monitoring and management; **E**arly mobility and exercise; and **F**amily engagement and empowerment) has been shown to decrease the incidence of delirium and improve patient outcome (Fig. 2.3).[27,28] This algorithm, building on the PADIS 2018 guidelines,[46] involves the following: (1) Routine *assessment* of agitation, depth and quality of sedation, and delirium using appropriate scales (RASS and SAS for agitation and sedation and CAM-ICU or ICDSC for delirium). They recommend using protocol target-based sedation and

TABLE 2.4 Intensive Care Delirium Screening Checklist

Patient Evaluation	
Altered level of consciousness	(A–E)*
Inattention	Difficulty in following a conversation or instructions. Easily distracted by external stimuli. Difficulty in shifting focus. Any of these scores 1 point.
Disorientation	Any obvious mistake in time, place, or person scores 1 point.
Hallucinations-delusions-psychosis	The unequivocal clinical manifestation of hallucination or behavior probably attributable to hallucination or delusion. Gross impairment in reality testing. Any of these scores 1 point.
Psychomotor agitation or retardation	Hyperactivity requiring the use of additional sedative drugs or restraints to control potential danger to self or others. Hypoactivity or clinically noticeable psychomotor slowing.
Inappropriate speech or mood	Inappropriate, disorganized, or incoherent speech. Inappropriate display of emotion related to events or situation. Any of these scores 1 point.
Sleep/wake cycle disturbance	Sleeping less than 4 h or waking frequently at night (do not consider wakefulness initiated by medical staff or loud environment). Sleeping during most of the day. Any of these scores 1 point.
Symptom fluctuation	Fluctuation of the manifestation of any item or symptom over 24 h scores 1 point.
Total Score (0–8)	

*Level of consciousness:
A—No response: score 0.
B—Response to intense and repeated stimulation (loud voice and pain): score 0.
C—Response to mild or moderate stimulation: score 1.
D—Normal wakefulness: score 0.
E—Exaggerated response to normal stimulation: score 1.

1. Dr. DRE:
   Diseases: Sepsis, CHF, COPD
   Drug **R**emoval: SATs and stopping benzodiazepines/narcotics
   Environment: Immobilization, sleep and day/night orientation, hearing aids, eye glasses, noise
   THINK:
   Toxic Situations – CHF, shock, dehydration – Deliriogenic meds (tight titration) – New organ failure (liver, kidney, etc.)
   Hypoxemia
   Infection/sepsis (nosocomial), immobilization
   Nonpharmacologic interventions[3]
   K$^+$ or electrolyte problems
2. Consider stoppinig or substituting deliriogenic medications such as benzodiazepines, anticholinergic medications (metoclopramide, H_2 blockers, promethazine, diphenhydramine), steroids, etc.
3. See nonpharmacologic protocol – see below.
4. If patient is nonverbal, assess via CPOT, or if patient is verbal assess via visual analog scale.
5. Analgesia – Adequate pain control may decrease delirium. Consider opiates, non-steroidals, acetaminophen, or gabapentin (neuropathic pain).
6. Typical or atypical antipsychotics. Discontinue if high fever, QTc prolongation, or drug-induced rigidity.
7. Consider non-benzodiazepine sedation strategies (propofol or dexmedetomidine)
8. Spontaneous Awakening Trial (SAT) – If meets safety criteria (no active seizures, no alcohol withdrawal, no agitation, no paralytics, no myocardial ischemia, normal intracranial pressure, $FiO_2 \leq 70\%$)
9. Spontaneous Breathing Trial (SBT) – If meets safety criteria (no agitation, no myocardial ischemia, $FiO_2 \leq 50\%$, adequate inspiratory efforts, O_2 saturation $\geq 88\%$, no vasopressor use, PEEP ≤ 7.5 cm)

Nonpharmacologic protocol[3]

Orientation
- Provide visual and hearing aids
- Encourage communication and reorient patient repetitively. Have familiar objects from patient's home in the room
- Attempt consistency in nursing staff
- Family engagement and empowerment

Environment
- Sleep hygiene: Lights off at night, on during day.
- Control excess noise (staff, equipment), earplugs
- Early mobilization and exercise
- Music

Clinical parameters
- Maintain systolic blood pressure > 90 mm Hg
- Maintain oxygen saturations >90%

Treat underlying metabolic derangements and infections

Fig. 2.3 Delirium protocol as a part of the ABCDEF Bundle.

targeting the lightest possible sedation, thus exposing the patient to lower cumulative doses of sedatives[63] and/or daily awakening trials[64] and spontaneous breathing trials[65] to reduce the total time spent on mechanical ventilation. Coordination of daily awakening and daily breathing was associated with shorter durations of mechanical ventilation, reduction in length of hospital stay, and no long-term neuropsychologic consequences of waking patients during critical illness.[66,67] (2) *Treatment* should start with treating analgesia first. Choosing the right sedative regimen in critically ill patients is important. Numerous studies have confirmed that benzodiazepines are associated with poor clinical outcomes.[68,69] The guidelines also recommend avoiding rivastigmine and antipsychotics if there is an increased risk of torsades de pointes. (3) *Prevention* also plays an important role. Risk factors for delirium need to be identified and eliminated, particularly with noise and immobility. Exercise and early mobility in ICU patients is associated with decreased length of both ICU and hospital polypharmacy.[70,71] Promoting day/night cycles within the ICU with minimization of noise and disturbance overnight to optimize sleep should be initiated.

Data from the Maximizing Efficacy of Targeted Sedation and Reducing Neurological Dysfunction (MENDS)[68] study and the Safety and Efficacy of Dexmedetomidine Compared with Midazolam (SEDCOM) trial[69] also support the view that dexmedetomidine can decrease the duration and prevalence of delirium when compared with lorazepam or midazolam. A recent large, randomized, multicentered, placebo-controlled trial failed to show benefit for use of haloperidol or ziprasidone in the treatment of delirium.[72] Routine use of antipsychotic medications for the treatment of delirium is not recommended.[46] Pharmacologic therapy should be attempted only after

correcting any contributing factors or underlying physiologic abnormalities. Although these agents are intended to improve cognition, they all have psychoactive effects that can further cloud the sensorium and promote a longer overall duration of cognitive impairment.

Benzodiazepines are not recommended for the management of delirium because they can paradoxically exacerbate delirium. These drugs can also promote oversedation and respiratory suppression. However, they remain the drugs of choice for the treatment of delirium tremens (and other withdrawal syndromes) and seizures.

At times, mechanical restraints may be needed to ensure the safety of patients and staff while waiting for medications to take effect. It is important to keep in mind, however, that restraints can increase agitation and delirium, and their use may have adverse consequences, including strangulation, nerve injury, skin breakdown, and other complications of immobilization.

SUMMARY

Agitation and delirium are very common in the ICU, where their occurrence puts patients at risk of self-injury and poor clinical outcomes. Available sedation and delirium monitoring instruments allow clinicians to recognize these forms of brain dysfunction. Through a systematic approach, life-threatening problems and other acutely reversible physiologic causes can be rapidly identified and remedied. A strategy that focuses on early liberation from mechanical ventilation and early mobilization can help reduce the burden of delirium. Use of antipsychotics should be reserved for patients who pose an imminent risk to themselves or staff.

KEY POINTS

- Delirium and agitation are prevalent within the ICU and unless routinely assessed are frequently overlooked.
- Clinicians should be aware of modifiable and nonmodifiable risk factors for delirium and agitation and work to decrease those risk factors when able.
- Once detected, investigation into the cause of agitation and delirium is necessary, as they may be a harbinger of metabolic, pharmacologic, or physical derangements (i.e., pain, sepsis, withdrawal, hypoxia).
- Several pathophysiologic hypotheses have been proposed to describe the etiology of delirium. It is likely that the presentation of delirium is a result of a combination of these mechanisms.
- Nonpharmacologic treatment bundles are successful in decreasing the incidence of delirium; however, once it occurs, there is limited evidence for the use of pharmacologic medications in decreasing delirium severity or duration.
- Identifying delirium and agitation within the ICU is important. Lack of identification can result in prolonged symptom duration, which is associated with worse survival and functional patient outcomes years after hospital discharge.

Management of Acute Pain in the Intensive Care Unit

Lauren Coleman, Jin Lee, and Christine Cocanour

INTRODUCTION

Pain management in the critically ill patient is complex. Each patient brings a unique set of sociodemographic, pharmacokinetic, and pharmacogenomic variables that are coupled with underlying psychosocial and medical comorbidities. These not only influence a patient's response to painful stimuli but also to treatment. We know that critically ill patients experience pain at rest, during routine intensive care unit (ICU) care, and during procedures.[1,2] Pain can originate from multiple sources, including somatic, visceral, and neuropathic. Pain may be acute, chronic, or acute on chronic in nature. Comorbidities such as depression and anxiety can exacerbate pain.[3,4] Patients that are younger, female, and of nonwhite ethnicity are more likely to experience more intense pain.[4–8] Aging patients experience many physiologic changes that may decrease their perception of pain and increase their vulnerability to the adverse effects of pain medications.[9–11]

It is imperative to adequately treat pain in the ICU patient. Pain during a procedure is not only influenced by the type of procedure (including routine care such as turning) but also by preprocedural pain intensity.[2,5,8,12,13] Adequate assessment of pain and preemptive analgesia are essential.[14] Inadequate pain control contributes to the development of delirium, and severe pain may lead to cardiac instability (tachycardia, bradycardia, hypertension, and/or hypotension), respiratory distress (desaturation, bradypnea, and/or ventilator distress), and immunosuppression.[14,15]

To optimize an analgesic regimen, it is important to obtain a thorough past medical history that includes a complete list of medications and whether alcohol, tobacco, or opioid dependence is present. Managing drug withdrawal in addition to achieving satisfactory analgesia requires a multimodal approach.

Multimodal analgesia combines two or more drug classes or techniques, employing different mechanisms of action that may target multiple pain pathways in order to achieve a synergistic or additive effect. This results in lower opioid consumption with the same or improved level of comfort.[16] Multimodal analgesia may include opioids, nonopioid analgesics such as nonsteroidal antiinflammatory drugs (NSAIDs) or gabapentinoids, regional or neuraxial blocks, and nonpharmacologic therapies. Each patient's medical history, allergies, age, injuries, and comorbidities will dictate the optimum regimen. Pain management protocols that mandate the use of validated pain and sedation scales consistently decrease the consumption of opioids and sedatives in ICU patients.[17,18]

ASSESSMENT

An assessment-driven and standardized pain management protocol improves ICU patient outcomes, but assessment of pain in the critically ill patient can be challenging. Many ICU patients are ventilated, cognitively impaired, and/or unable to self-report pain. Consequently, these patients are at risk for undertreatment of their pain. Valid assessment tools help guide analgesia while avoiding excess medication administration in those patients with adequate pain control.[16,19–22] A number of assessment tools are available for use in the ICU patient.[14]

For those patients able to self-report pain, the Numeric Rating Scale (NRS) in a visual format had the best sensitivity, negative predictive value, and accuracy in ICU patients.[14] More recently, the Defense and Veterans Pain Rating Scale (DVPRS) has become increasingly popular.[23] It combines a 1–10 pain scale with facial expressions and colors to express pain intensity. The DVPRS also includes supplementary questions to measure the degree to which pain interferes with a patient's usual activity, sleep, mood, and stress (Fig. 3.1).

The Behavioral Pain Scale (BPS) and the Critical Care Pain Observation Tool (CPOT) (Fig. 3.2) have the greatest validity and reliability for monitoring pain in those unable to self-report.[14] BPS is a three-domain assessment tool with four possible scores in each domain. Scores range from 3 to 12, with scores above 6 indicating an unacceptable level of pain.[14,24–26] CPOT is similar, with four domains and scores ranging from 0 to 2 in each domain. The possible score ranges from 0 to 8, with 3 or above indicating the presence of pain.[27–32]

Vital signs (heart rate, blood pressure, respiratory rate, oxygen saturation, and end tidal carbon dioxide) are not considered valid indicators for pain in critically ill patients and should only be used as cues to initiate further evaluation using one of the validated assessment measures.[14] In unresponsive or paralyzed patients in which the validated scales are impossible to use, no current assessment methods are available. Promising technology under development for this patient population includes measuring heart rate variability (Analgesia Nociception Index), incorporating several physiologic parameters (Nociception Level Index), and examining pupillary reflex dilation using video pupillometry.[33–38]

OPIOIDS

Historically, opioids were considered the mainstay of treatment for non-neuropathic pain in the critically ill patient population because of their high potency and efficacy.[14,39,40] Opioids act at specific G-protein–coupled receptors designated delta, kappa, and mu. These exist predominantly in the central nervous system, but also peripherally and in certain organs (notably the gastrointestinal tract and heart).[41] By acting at these receptors, opioids decrease the perception of pain without inducing loss of consciousness. All clinically relevant opioids are active at the mu receptor, and some have additional activity at other receptors.[41]

The decision regarding which opioid to prescribe is highly dependent on specific patient comorbidities and circumstances. When titrated appropriately, all intravenous opioids are considered equally

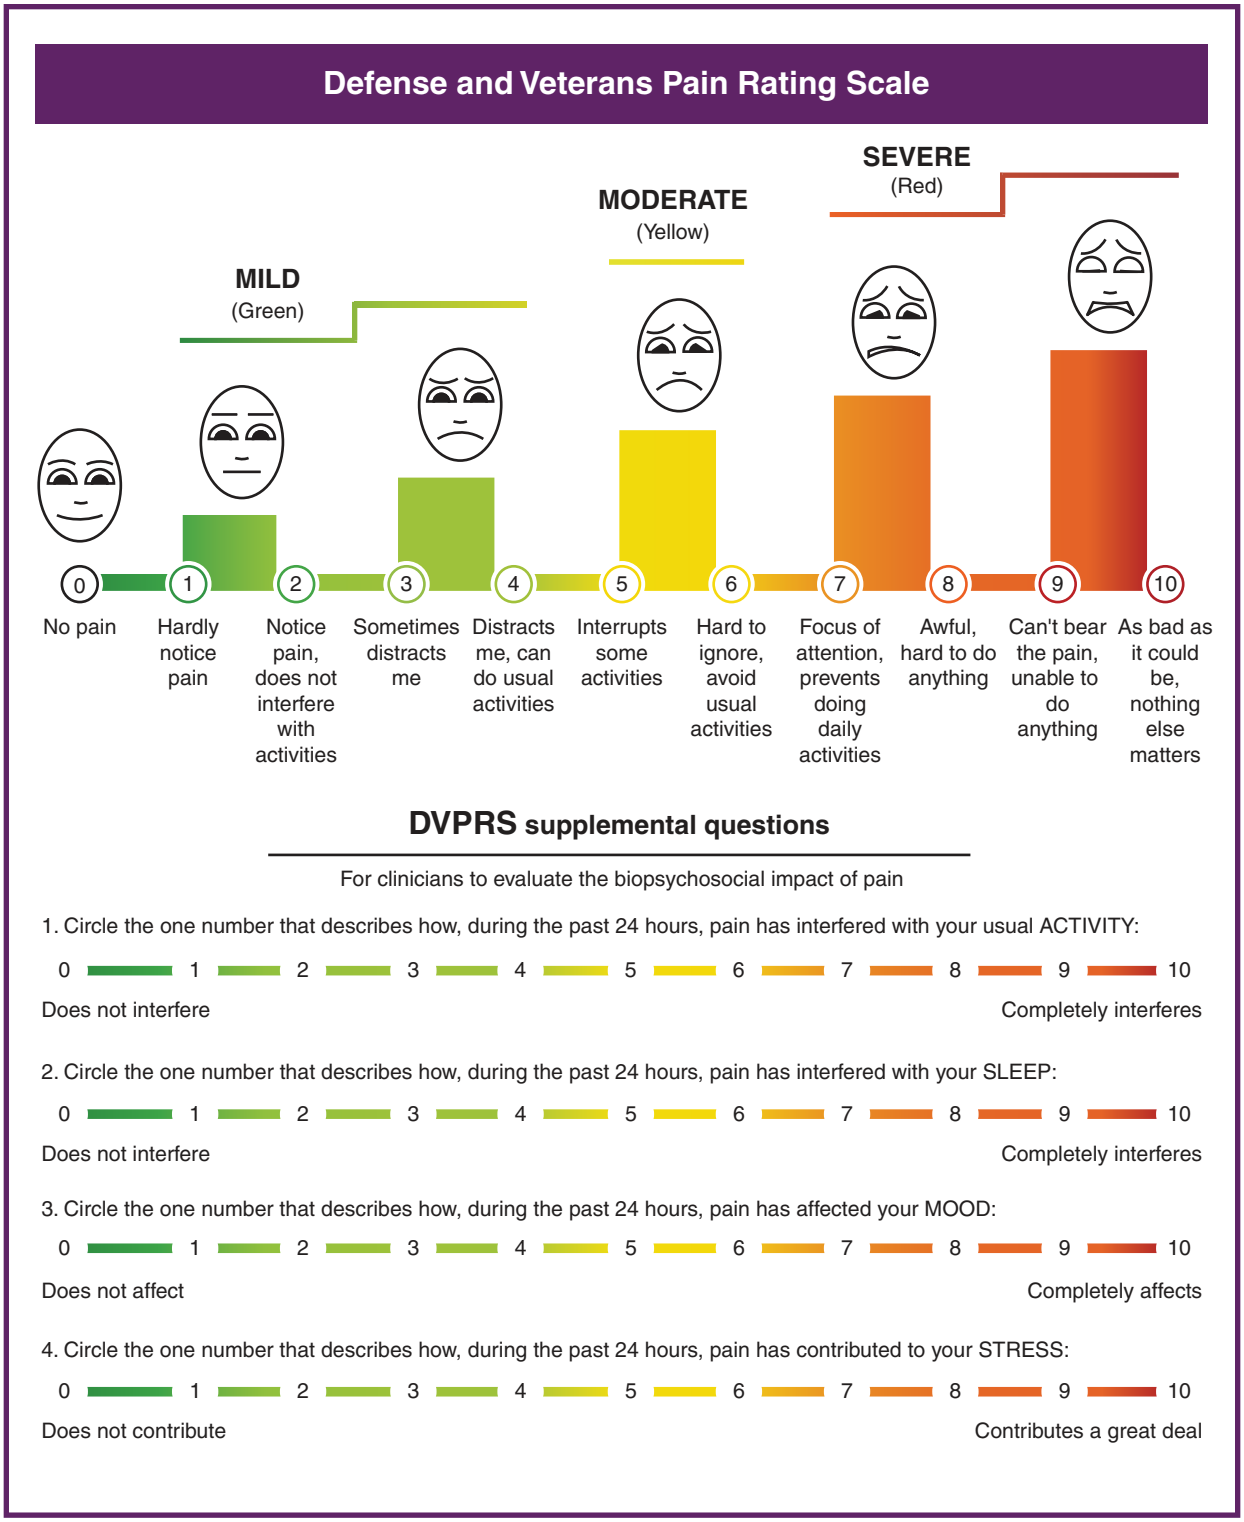

Fig. 3.1 The DVPRS is a graphic pain reporting tool for patients that can self-report. (From https://www.dvcipm.org/site/assets/files/1084/dvprs_single_page.pdf.)

Critical Care Pain Observation Tool

Indicator	Description	Score	
Facial expression	No muscular tension observed	Relaxed, neutral	0
	Presence of frowning, brow lowering, orbit tightening, and levator contraction	Tense	1
	All of the above facial movements plus eyelid tightly closed	Grimacing	2
Body movements	Does not move at all	Absence of movements	0
	Slow, cautious movements, touching or rubbing the pain site, seeking attention through movements	Protection	1
	Pulling tube, attempting to sit up, moving limbs/thrashing, not following commands, striking at staff, trying to climb out of bed	Restlessness	2
Muscle tension Evaluation by passive flexion and extension of upper extremities	No resistance to passive movements	Relaxed	0
	Resistance to passive movements	Tense, rigid	1
	Strong resistance to passive movements, inability to complete them	Very tense or rigid	2
Compliance with the ventilator (intubated patients)	Alarms not activated, easy ventilation	Tolerating ventilator or movement	0
	Alarms stop spontaneously	Coughing but tolerating	1
	Asynchrony: blocking ventilation, alarms frequently activated	Fighting ventilator	2
OR Vocalization (extubated patients)	Talking in normal tone or no sound	Talking in normal tone or no sound	0
	Sighing, moaning	Sighing, moaning	1
	Crying out, sobbing	Crying out, sobbing	2
Total, range			0–8

Behavioral Pain Scale

Item	Description	Score
Facial expression	Relaxed	1
	Partially tightened (e.g., brow lowering)	2
	Fully tightened (e.g. eyelid closing)	3
	Grimacing	4
Upper limbs	No movement	1
	Partially bent	2
	Fully bent with finger flexion	3
	Permanently retracted	4
Compliance with ventilation	Tolerating movement	1
	Coughing but tolerating ventilation for most of the time	2
	Fighting ventilator	3
	Unable to control ventilation	4

Fig. 3.2 Critical Care Pain Observation Tool (CPOT) and Behavioral Pain Scale (BPS) are two commonly used tools for monitoring pain in those patients that are unable to self-report. (Adapted from Gelinas C, Fillion L, Puntillo KA, et al. Validation of the critical-care pain observation tool in adult patients. *Am J Crit Care*. 2006;15(4):420–427 and Payen JF, Bru O, Bosson JL, et al. Assessing pain in critically ill sedated patients by using a behavioral pain scale. *Crit Care Med*. 2001;29(12):2258–2263.)

TABLE 3.1 Opioid Agents and Considerations for Use

Opioid	Dosage Forms	Onset	Pharmacokinetics	Considerations
Fentanyl	IV, IM, intranasal, transdermal, transmucosal	1–2 min	• Metabolized by the liver • No active metabolites	• Very potent (100 times the potency of morphine) • Rapid onset and short duration • Prolonged use leads to accumulation in peripheral compartments • Less association with histamine release
Hydromorphone	PO, IV, IM, SQ	5–15 min (IV) 30 min (PO)	• Metabolized by the liver into weak metabolites • Excreted renally	• Potent (7–10 times the potency of morphine) • Improved safety profile over morphine in renal impairment • Less association with histamine release
Morphine	PO, IV, IM, SQ, transdermal, transmucosal	5–10 min (IV) 15–60 min (PO)	• Metabolized by the liver into potent metabolites • Excreted renally	• Use with extreme caution in renal impairment • Use with caution in hepatic impairment • High association with histamine release (can lead to bronchospasm and hypotension)
Oxycodone	PO	10–30 min	• Metabolized by the liver to multiple metabolites (oxymorphone)	• Available in combination or alone
Hydrocodone	PO	15–30 min	• Metabolized by the liver to multiple metabolites (hydromorphone)	• Only available as a combination currently • Use with caution in those with severe asthma
Methadone	PO	30–60 min	• Metabolized by the liver • No active metabolites • Excreted in feces	• Plasma levels and risk of death peak 5 days after start • Respiratory depressant effect occurs later than analgesic effect • Watch for QTc prolongation • Inhibits serotonin reuptake and can also produce analgesia via NMDA receptor antagonism
*Tramadol**	PO	60 min	• Metabolized by the liver into O-desmethyl tramadol • Excreted renally	• Also modulates serotonin and norepinephrine uptake (can lead to seizures) • Less respiratory depression and fewer GI side effects than pure opioids

*Although not a typical opioid, tramadol is structurally related to morphine and has effects at opioid receptors
GI, Gastrointestinal; *IM,* intramuscular; *IV,* intravenous; *NMDA,* N-methyl-D-aspartate; *PO,* oral; *SQ,* subcutaneous.

effective with regard to analgesic efficacy and clinical outcomes.[39] However, studies have shown patients may demonstrate variability in opioid pharmacodynamics and pharmacokinetics, resulting in more favorable reactions to one opioid over another.[42] Thus providers must be comfortable with many different opioids, depending on the patient's reaction and clinical course. Common parenteral and oral opioids are summarized in Table 3.1.

Though opioids remain a cornerstone of pain management, considerable attention is now focused on limiting the opioids required through the use of multimodal therapy. This is primarily because of the many side effects of opioid-centered analgesia. Short term, these can include physical dependence, ileus, constipation, nausea and vomiting, respiratory depression, sedation, pruritus, and urinary retention.[43] Opioids may increase ICU length of stay and worsen post-ICU patient outcomes. Long-term sequelae of opioid use include addiction, immunosuppression, and opioid-induced hyperalgesia. These complications are prevalent, regardless of the specific opioid used or the route of administration.

Particular attention should be paid to bowel dysfunction associated with opioids secondary to binding of mu receptors in the enteric nervous system.[44] Opioids often induce constipation or worsen preexisting constipation; prevalence of these conditions with opioid use vary in the literature from 22% to 81% of patients.[44] Thus prevention via a robust bowel regimen that includes laxatives and/or bulking agents is an essential consideration when prescribing opioids.

ACETAMINOPHEN

Despite being a commonly used analgesic and antipyretic, acetaminophen's exact mechanism of action remains unknown. It has consistently been shown to reduce opioid requirements when used as an adjunct; furthermore, acetaminophen has minimal side effects. For the critically ill patient, acetaminophen offers an advantage in that it can be administered via multiple routes of administration (intravenous [IV], orally [PO], nasogastric [NG], per rectum [PR]). Although the IV formulation has a slightly faster onset when used as a first dose, there is minimal difference between the IV and enteral/rectal formulations when administered in a scheduled manner.[45] Acetaminophen carries a risk of hepatotoxicity, though this is more commonly noted when high doses are used for chronic pain rather than short-term acute pain. In 2011, the Food and Drug Administration (FDA) released a recommendation to reduce the maximum daily dose of acetaminophen from 4000 mg/day to 3000 mg/day; however, it is important to note that this recommendation was aimed at consumers exposed to numerous over-the-counter acetaminophen-containing combination products. In the inpatient setting, the maximum daily dose should remain 4000 mg/day.[46]

NSAIDs

NSAIDs work as analgesics and antipyretics by inhibiting cyclooxygenase (COX) enzymes, thereby reducing the formation of prostaglandins.

A wide variety of NSAIDs are available with numerous routes of administration (IV, PO, NG, PR, topical) and varying degrees of selectivity to COX-1 and COX-2.

Historically, there has been a reluctance to use NSAIDs in the acute pain setting because of their adverse effects, including increased risk of gastrointestinal bleeding, nephrotoxicity, impaired platelet function, and impaired wound healing. NSAIDs have long been avoided in the setting of fractures because of the risk of nonunion; however, more recent literature reviews have shown that this does not appear to be a long-term issue, particularly with early postinjury or postoperative administration.[47–49] Thus the most recent guidelines support their use in this setting.[50]

Platelet inhibition is primarily associated with inhibition of COX-1 and can be avoided with the use of COX-2 selective agents such as celecoxib. Unfortunately, COX-2 selective agents are not without risk—they are contraindicated after coronary artery bypass graft surgery and carry a risk of cardiovascular thrombotic events, such as myocardial infarction and stroke. Despite their known risks, NSAIDs can be beneficial in mitigating opioid exposure in select patient populations.

GABAPENTINOIDS

Opioids and other medications that often work well for nociceptive pain offer minimal benefit for neuropathic pain. For patients who suffer from diabetic neuropathy, spinal cord injury, burn pain, phantom limb, post-stroke central pain, postherpetic neuralgia, or other forms of neuropathic pain, gabapentinoids should be considered.[51–53] Gabapentin and its prodrug, pregabalin, work by inhibiting presynaptic calcium channels. Originally developed as antiepileptic medications, these agents have shown to be effective in the management of chronic neuropathic pain.[54] Although less data are available regarding their use for acute pain, gabapentinoids should be considered when a source of neuropathic pain is suspected. Caution should be exercised when initiating gabapentin or pregabalin in the elderly, as these agents are known to cause somnolence and dizziness. In patients with renal dysfunction, doses should be adjusted accordingly.

MUSCLE RELAXANTS

Patients who experience pain secondary to muscle spasm may find benefit from antispasmodic agents such as methocarbamol, cyclobenzaprine, baclofen, or diazepam. However, literature regarding their efficacy is scant, particularly in the acute pain setting. Careful consideration must be given before using these agents, given the associated risk of sedation. This is especially a concern in the older adult patient.

KETAMINE

Ketamine is a phencyclidine derivative that acts as an N-methyl-D-aspartate (NMDA) antagonist and has been used in the perioperative and procedural setting for its anesthetic and analgesic effects. More recently, subanesthetic doses of ketamine have been used in a continuous fashion to provide analgesia without eliciting hallucinations or other psychomimetic effects. Benefits of ketamine in the critically ill setting include its neutral hemodynamic effects and its lack of respiratory suppression. Traditionally, ketamine has been avoided in patients with cardiovascular comorbidities and patients with elevated intracranial pressure (ICP); however, recent literature suggests that ketamine may be used safely in patients with ICP concerns.[55]

At higher steady-state levels, magnesium has been shown to exhibit similar anti-NMDA activity in the perioperative setting.[56] Although this effect has not yet been demonstrated in the ICU setting, studies are currently ongoing.

LIDOCAINE

Topical lidocaine patches can be used for localized pain to avoid systemic effects, but their efficacy remains unclear, and caution should be exercised near open wounds. Lidocaine drips have been used in the perioperative setting to reduce opioid requirements and ileus recovery time, but its role in the critical care setting remains largely unknown.[57,58]

α_2 AGONISTS

Centrally acting α_2 agonists, such as dexmedetomidine and clonidine, may offer analgesic effects while avoiding respiratory depression. However, data regarding their use for acute pain in the critically ill population are minimal, and cardiovascular effects such as hypotension and bradycardia limit their use in hemodynamically unstable patients.

A summary of the previously discussed nonopioid analgesics can be found in Table 3.2.

REGIONAL ANESTHESIA

Regional anesthesia techniques include neuraxial blocks (such as spinal and epidural catheters), paravertebral blocks, intercostal nerve blocks, transversus abdominis plane blocks, and peripheral nerve blocks of the extremities. The use of regional anesthesia is associated with improved analgesia in many patient populations, including postoperative and polytrauma patients. Many studies have also shown that the use of regional anesthesia leads to decreases in opioid-related side effects.[43] Of special interest within the critically ill population is the association between epidural analgesia and improved global pulmonary outcomes.[59]

Despite the many benefits of regional anesthesia documented in the literature, it remains generally underused in the critically ill population for a multitude of reasons. Hemodynamic instability and sepsis are considered relative contraindications to neuraxial techniques.[60] Critically ill patients may also require anticoagulation or develop coagulopathy, both of which may limit the ability of providers to perform neuraxial techniques safely. Finally, caution must be exercised in patients at risk for developing compartment syndrome because of the potential masking of symptoms. Of note, however, this can also be a concern with systemic analgesia.

MUSIC MODALITIES

Music modalities for pain management can broadly be separated into music medicine and music therapy. Music medicine uses music to promote relaxation, provide distraction, and/or alleviate tension.[61] Music therapy is instead a holistic approach involving a music therapist that focuses on the healing process of music via personal interaction.

Within the critically ill population, three small studies have found minimal to moderate improvements in self-reported and assumed pain scores through various forms of music medicine.[62–64] Two of these studies even found temporary improvement in pain scores for mechanically ventilated patients undergoing music medicine.[63,64] In postoperative patients, a recent meta-analysis of 97 studies found that music medicine had a small to moderate effect on reducing opioid usage, and music therapy was found to decrease patient perception of pain intensity.[61] Music interventions generally had a stronger impact

TABLE 3.2 Nonopioid Agents and Considerations for Use

Class	Medication	Dosage Forms	Considerations
Acetaminophen	Acetaminophen	PO, IV, rectal	• Caution in hepatic dysfunction • IV formulation associated with hypotension
NSAIDs	Nonselective Ibuprofen	PO, IV, topical, rectal	• Caution in patients with gastrointestinal bleeding, acute kidney injury, and cardiovascular events • Ketorolac carries a black box warning cautioning against more than 5 days of use to mitigate these risks
	(COX-1 selective) Ketorolac Naproxen		
	(COX-2 selective) Celecoxib	PO	
Gabapentinoids	Gabapentin	PO	• Consider for neuropathic pain • Caution in elderly patients and renal dysfunction • Monitor for dizziness and drowsiness
	Pregabalin		
	Venlafaxine		
Muscle relaxants	Baclofen	PO	• Caution in elderly patients and renal dysfunction • Tolerance/dependence may develop with prolonged use of baclofen
	Methocarbamol		
	Cyclobenzaprine		
	Diazepam	PO, IV	• Associated with sedation and respiratory depression
NMDA antagonists	Ketamine	IV, IM, PO	• Contraindicated in history of CVA, severe cardiac decompensation, or conditions in which an increase in blood pressure may be harmful • Increased risk of laryngospasm (procedural doses) • Potential for tolerance with long-term use • Monitor for emergence reactions
	Magnesium (high dose)	IV, PO	• Contraindicated in patients with bradycardia • IV bolus can be associated with hypotension • Caution in patients with renal dysfunction and neuromuscular disease
Sodium channel blockers	Lidocaine	IV, topical	• IV product contraindicated in heart block • Monitor for neurologic and cardiac toxicity
α_2 agonists	Dexmedetomidine	IV	• Associated bradycardia and hypotension • Potential for tachyphylaxis to develop with long-term use
	Clonidine	PO	• Associated hypotension and sedation

COX, Cyclooxygenase; *CVA*, cerebrovascular accident; *IM*, intramuscular; *IV*, intravenous; *NSAID*, nonsteroidal antiinflammatory drug; *PO*, oral.

on acute or procedural pain versus chronic or cancer pain. Given these results, and the fact that music modalities are inexpensive and safe, consideration should be given to employing these modalities in the ICU, pending availability and institutional logistics.

COGNITIVE BEHAVIORAL MODALITIES

Cognitive behavioral modalities include hypnosis, guided imagery, and relaxation methods. Although these modalities have been extensively studied as an adjunct for both acute and chronic pain management, there is unfortunately a paucity of evidence within the critically ill population. Examining the postoperative literature, cognitive behavioral modalities frequently are found to improve postoperative pain and analgesic use.[65] Thus clinical practice guidelines from several prominent medical societies recommend cognitive behavioral therapy as adjunctive treatments in the postoperative patient.[65] As these modalities are noninvasive and associated with minimal harm, the critical care provider may consider incorporating these techniques into pain management.

AROMATHERAPY

Aromatherapy involves the inhalation, topical application, or injection of plant oils with pleasant smells. Common fragrances include bergamot, rose, orange, and mint, though lavender essential oil is one of the most frequently discussed in the literature. Although evidence examining aromatherapy for pain management in the ICU is lacking, a systematic review of randomized controlled trials found that aromatherapy reduces anxiety and improves sleep in critically ill patients.[66] This effect has also been noted in the mechanically ventilated subpopulation.[67]

PHYSICAL MODALITIES

Physical modalities include techniques such as acupuncture, cold or heat therapy, and massage. Although these interventions are generally safe and inexpensive, there is scant scientific literature in the critically ill population. One small study found acupuncture in the ICU to be feasible and safe, but effectiveness of the technique in this setting has not been studied.[68] Furthermore, the impact of physical modalities for

pain management in other patient populations is highly variable. As such, clinical practice guidelines neither recommend nor discourage the use of these techniques for postoperative pain management.[65] Whether the critically ill patient would benefit from these physical modalities is currently unknown.

KEY POINTS

- Pain management in the ICU patient is complex because of unique sociodemographic, pharmacokinetic, and pharmacogenomic variables that are coupled with underlying psychosocial and medical comorbidities.
- The costs of inadequate pain control are high and include the development of delirium, cardiac instability, respiratory distress, and immunosuppression.
- Valid pain assessment tools are important, as they help guide analgesia while avoiding excess medication administration in those patients with adequately controlled pain.
- Multimodal analgesia regimens are highly recommended because of their improved efficacy and an associated decrease in opioid consumption, with resultant reduction in opioid-related side effects.
- Nonpharmacologic modalities for pain control should not be underestimated and may have a role in a well-rounded regimen for pain management.

Fever and Hyperthermia

Paul Young

> "*Humanity has but three great enemies: fever, famine and war; of these by far the greatest, by far the most terrible, is fever.*"
>
> ***William Osler, from his address to the 47th annual meeting of the American Medical Association, 1896***

Fever is defined as an increase in body temperature as a result of a pathophysiologic response that increases the body's normal thermoregulatory set point. This set point varies with age, gender, the time of the day, and other factors.[1] Although there is no universally agreed-upon definition of what constitutes a febrile temperature,[1] a threshold of ≥38.3°C is perhaps the most commonly applied.[2] Whatever threshold is used, it is important to remember that body temperature varies depending on the route by which it is measured.[3] Because peripheral temperature measurements such as via the axilla or elsewhere on the skin can underestimate core temperature by 1°C or more,[3] continuous monitoring of core temperature is recommended in patients at risk of life-threatening temperature elevations and when precise control of temperature is desirable.

In clinical practice, fever is not always readily distinguishable from hyperthermia. Hyperthermia occurs when the body temperature is elevated but the thermoregulatory set point is normal. It is the result of environmental exposure to heat, increased heat generation, impaired heat loss, or a combination of these, and it implies that normal homeostatic thermoregulatory mechanisms have been overwhelmed. Elevated body temperature, caused by either fever or hyperthermia, is commonly encountered in patients who are in the intensive care unit (ICU). Although infection must always be at the front of one's mind when an elevated body temperature is encountered, there is also a broad differential diagnosis of noninfectious etiologies to consider (Box 4.1). Although many patients develop a fever during the course of an ICU admission, persistent fever is uncommon,[4] except in patients with neurologic conditions. In patients who do not have such conditions, fever typically abates within a day or two unless there is an undrained collection of pus. There are exceptions, and a few of these are notable. High fevers that persist for days or weeks are often a feature of influenza pneumonitis and are almost invariably encountered in patients with severe necrotizing pancreatitis. Among patients with a range of neurologic conditions, including subarachnoid hemorrhage, stroke, and traumatic brain injury, fever is particularly common and often persistent. In young patients with severe traumatic brain injury, persistent high fevers, tachycardia, and hypertension sometimes present a difficult management problem in the weeks after the primary brain injury. One uncommon neurologic condition where persistently elevated body temperature is routinely encountered is anti–N-methyl-D-aspartate (NMDA) receptor autoantibody encephalitis.[5] This condition warrants specific mention because patients with it often need prolonged intensive care, and potentially life-threatening body temperature elevation is sometimes a feature of the disease.[5]

An elevated body temperature in an ICU patient should prompt a clinical assessment undertaken with the differential diagnosis in mind (Box 4.2). Although fever is seen in patients with large myocardial infarctions and thromboembolic disease, the occurrence of fever alone is insufficient reason to undertake diagnostic testing for these because the presence of fever has a low specificity for these conditions. Because fever is a cardinal sign of infection and sepsis is a frequent and often lethal complication of critical illness, particular care should be taken to note new or worsening organ dysfunction and potential sites of infection. Although other diagnostic possibilities should always be considered, in practical terms, the occurrence of elevated body temperature in a critically ill patient is a key trigger for investigation for sepsis. In this regard, the threshold temperature value to trigger such investigation should be reduced as the clinician's view as to the likelihood of infection rises. If the probability of infection is judged to be sufficiently high, investigations for possible sepsis should occur irrespective of the body temperature, and antibiotics should be commenced promptly.

Beyond endeavoring to establish and treat the cause of an elevated body temperature, a key consideration for clinicians is whether to intervene to reduce the temperature.[6] Here the clinician should consider both the degree of temperature elevation and the strength of the evidence to intervene for the particular condition in question (Fig. 4.1).

A diagnosis of hyperthermia indicates that normal thermoregulation has been overwhelmed. Intervention with physical cooling should be initiated. The higher the elevation in body temperature in a patient with hyperthermia, the more rapidly and aggressively one should intervene. If malignant hyperthermia is the diagnosis, dantrolene should be administered promptly.[7]

If the elevation of body temperature is caused by a fever, one needs to consider the possibility that the fever might be beneficial for the patient. In the setting of infection, there is a substantial body of evidence that supports the notion that fever can be adaptive. Fever is a broadly conserved biologic response to infection that is seen in almost all animals. The conservation of a metabolically costly response like fever across biology suggests that it confers some evolutionary advantage. In ICU patients, in keeping with the hypothesis that fever might be of benefit in the setting of infection, increasing fever in the first 24 hours in the ICU is generally associated with reducing mortality risk after adjusting for illness severity in patients.[8] This is the case even for patients with brain infections.[9] In comparison, in the absence of infection, increasing fever is associated with increasing mortality risk.[8,9] Reassuringly, administration of the antipyretic acetaminophen (paracetamol) to febrile patients with known or suspected infection in the ICU in a randomized placebo-controlled trial appeared to be

BOX 4.1 Noninfectious Causes of Elevated Body Temperature

Central Nervous System
Subarachnoid hemorrhage
Intracerebral hemorrhage
Infarction
Hypoxic ischemic encephalopathy
Anti-NMDA receptor autoantibody encephalitis

Cardiac
Myocardial infarction
Pericarditis

Pulmonary
Atelectasis
Pulmonary embolism
Fibroproliferative phase of acute respiratory distress syndrome

Hepatobiliary and Gastrointestinal
Acalculous cholecystitis
Acute pancreatitis
Active Crohn disease
Toxic megacolon
Alcoholic hepatitis

Rheumatologic Syndromes
Vasculitides (e.g., polyarteritis nodosa, temporal arteritis, granulomatosis with polyangiitis)
Systemic lupus erythematosus
Rheumatoid arthritis
Goodpasture syndrome

Endocrine
Hyperthyroidism
Adrenal insufficiency
Pheochromocytoma

Other
Drug reactions ("drug fever")
Transfusion reactions
Neoplasms (especially lymphoma, hepatoma, and renal cell carcinoma)
Malignant hyperthermia
Neuroleptic malignant syndrome
Serotonin syndrome
Opioid withdrawal syndrome
Ethanol withdrawal syndrome
Transient endotoxemia or bacteremia associated with procedures
Devitalized tissue secondary to trauma
Hematoma

NMDA, N-methyl-D-aspartate.

BOX 4.2 Evaluation of New-Onset Fever/Hyperthermia in ICU Patients

History
Is the patient known to have a condition that causes fever?
Are there features in the history that suggest a particular diagnosis?
Is there a change in volume or purulence of respiratory secretions?
Is this a long-stay patient at particular risk of nosocomial infection and/or multidrug-resistant organisms?
Has the patient had a recent exposure to a drug that might be causing fever?

Infusions
Is the patient receiving blood? Consider a transfusion reaction.
Is the patient receiving vasopressors? New vasopressors or escalating vasopressors should prompt consideration of urgent administration of antibiotics.

Ventilator
What is the current level of support in terms of inspired oxygen and PEEP? What is the respiratory system compliance? Has there been a deterioration in pulmonary function that might point to a pulmonary cause for fever?

Monitor
Is the core temperature being continuously monitored? Does the clinical situation warrant consideration of such monitoring? How high is the temperature?
Is there tachycardia? Is the degree of tachycardia of clinical concern?
Is the blood pressure stable? A fall in blood pressure may indicate septic shock.

Equipment
Does the patient have venous or arterial lines? How long have they been in situ? Are there signs of infection like redness or discharge?
Note the amount and appearance of fluid from abdominal drains and intercostal catheters.
If the patient has an external ventricular drain, review recent cell counts and culture results and collect a new sample (unless one was taken recently).
Is there a rectal tube? If the patient has diarrhea, send a specimen to evaluate for *Clostridioides difficile*.
If the patient has an epidural catheter, inspect the insertion site, and examine the patient's lower limb neurology while considering the possibility of an epidural abscess.
If there is a urine catheter, examine urine for both volume and appearance. Oliguria may be a sign of impending sepsis; myoglobinuria may indicate rhabdomyolysis, which can complicate severe hyperthermia.

Key Elements of the Patient Examination
Perform a focused cardiorespiratory and abdominal examination, looking for causes and consequences of fever.
Look for signs of pneumonia.
Look for organomegaly and lymphadenopathy.
Look for signs of endocarditis.
Look at surgical and traumatic wounds (if necessary, remove bandages or dressings).
Note any areas of tenderness. Bony tenderness and joint pain in a patient with *Staphylococcus aureus* bacteremia generally indicates seeding of the infection to that site.
Examine the limbs for signs of deep vein thrombosis.
Perform a vaginal examination to exclude a retained tampon if appropriate.

Investigations
Will vary based on the clinical situation, but most often will include blood cultures, sputum cultures, urine cultures, a full blood count, and a chest x-ray.

ICU, Intensive care unit; *PEEP,* positive end-expiratory pressure.

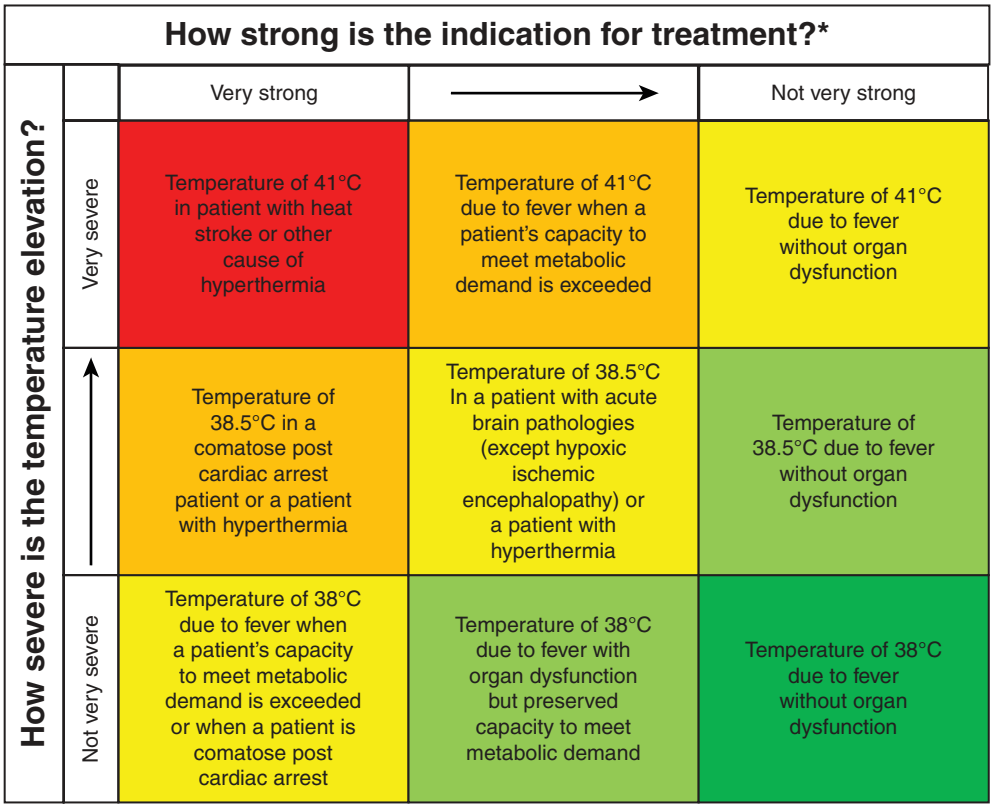

Fig. 4.1 When to Initiate Active Management of Elevated Body Temperature in the Critically Ill. *A strong indication for treatment combined with a severely elevated temperature is reflected by *red shading,* which corresponds to a situation where active management of elevated body temperature is reasonable; *dark green shading* indicates situations where active temperature management may be less desirable; *other shades* indicate different degrees of certainty about the appropriateness of treatment. (Reproduced from Young PJ & Prescott HC. When less is more in the active management of elevated body temperature of ICU patients. *Intensive Care Medicine*. 2019;45[9]:1275–1278.)

safe and was well-tolerated.[10] Such use of acetaminophen neither increased nor decreased days alive and free from intensive care.[10] Mortality rates were similar for patients who received acetaminophen to treat fever and for patients who did not.[10] Although these data do not provide a strong impetus for clinicians to give acetaminophen, they provide a degree of reassurance that if acetaminophen is administered to treat fever in the setting of an infection or given for another reason to a patient who happens to have fever and infection, such as for analgesia, harm is unlikely to result. Despite the considerations outlined earlier, there is an argument for treating fever in the ICU, even in patients with infections.[11] Patients in the ICU are supported beyond the limits of normal homeostasis. As fever increases metabolic demand, its presence may increase physiologic demands beyond the limits of supportive care. This is particularly true for patients who are the most unwell and for those who have limited reserves. Treating fever significantly reduces heart rate.[4] In patients who have limited cardiovascular reserves, such as those who have recently had a myocardial infarction, treatment of fever is reasonable, although evidence to support temperature control measures in this specific clinical setting is lacking.

For patients with infections, the authors of the SEPSIS-COOL trial reported that cooling patients with septic shock who were ventilated and sedated to normothermia might improve outcomes compared with not treating fever at all.[12] However, these findings were not reproduced in a subsequent similar trial, the REACTOR trial,[4] which randomized patients to normothermia or usual care. Overall, in patients without brain diseases, aggressive treatment of fever does not appear to alter outcomes compared with less aggressive approaches to temperature control.[4,13] For critically ill patients who have infections, a reasonable, albeit somewhat nebulous, approach is to treat fever routinely when it exceeds, say, 39°C core temperature and to treat fever at a lower level when it is judged to be of clinical concern. A more aggressive approach to fever control may be warranted in patients without infection, but this is not certain.[13]

Given the evidence supporting its safety,[3,10] acetaminophen is a reasonable first-line therapy to treat fever. Although aspirin is an effective antipyretic,[14] its use for this indication in the ICU has not been studied in randomized controlled trials. Of the nonsteroidal antiinflammatory drugs, ibuprofen has been most extensively studied in ICU patients. In patients with sepsis, ibuprofen decreases fever, tachycardia, oxygen consumption, and lactic acidosis but does not appear to improve survival.[15] Overall, irrespective of the antipyretic used, evidence suggests that physical cooling methods are more effective at reducing body temperature than antipyretic drugs.[16] That said, if fever is treated with physical cooling in an attempt to reduce physiologic demand, it is important that shivering, which markedly increases metabolic demand, is treated aggressively with opioids and/or sedatives. Neuromuscular paralysis may even be required. Because of the need to control shivering, physical cooling devices like cooling blankets are most useful in patients who are sedated.

In patients with traumatic brain injuries, acetaminophen alone is insufficient to prevent fever.[3] Strict avoidance of fever in such patients necessitates physical cooling. In the early period of management, this can be achieved because patients are often heavily sedated. However, during the recovery phase, the desire to control body temperature to attempt to prevent secondary brain injury often competes with the desire to reduce sedation and assess the patient's brain function. In this setting, nonsteroidal antiinflammatory drugs occasionally result in prompt abatement of fever, allowing physical cooling and associated sedation to be ceased. Interestingly, despite the fact that most clinicians consider temperature control to be desirable in patients who have traumatic brain injuries, fever of up to 38.5°C in the first 24 hours in the ICU is not associated with increased mortality risk after adjustment for illness severity.[9] A reasonable approach for patients with traumatic brain injuries is to seek to avoid both fever and hyperthermia whenever possible. Continuous monitoring of core body temperature is desirable in this setting. One approach is to administer acetaminophen regularly to reduce the burden of fever and to initiate physical cooling early if the body temperature exceeds 38°C.

In patients with subarachnoid hemorrhage, fever is particularly common, and the most appropriate way to treat it is not known. acetaminophen is an appropriate first-line therapy and can reasonably be administered regularly, given its favorable safety profile. Fever is common in patients with subarachnoid hemorrhage who are awake and, in the absence of high-quality evidence demonstrating that control of such fever improves neurologic outcomes, intervening in a manner that is likely to prolong mechanical ventilation time and associated complications is undesirable. Thus, although physical cooling to control fever in an effort to prevent secondary brain injury is appropriate for patients who are sedated for other reasons, it is undesirable to sedate patients with subarachnoid hemorrhage simply to control their body temperature. Fever is somewhat less common in patients with hemorrhagic and ischemic stroke, but in both of these conditions, the principles outlined in relation to subarachnoid hemorrhage apply.

For patients who have hypoxic ischemic encephalopathy, strict avoidance of fever is recommended. Routine use of therapeutic hypothermia does not appear to improve patient outcomes compared to early treatment of fever.[19]

KEY POINTS

- There is no universally agreed-upon definition of what constitutes a febrile temperature.
- Continuous monitoring of core temperature is recommended in patients at risk of life-threatening temperature elevations and when precise control of temperature is desirable.

KEY POINTS—cont'd

- Because fever is a cardinal sign of infection and sepsis is a frequent and often lethal complication of critical illness, particular care should be taken to note new or worsening organ dysfunction and potential sites of infection when a fever is present.
- A diagnosis of hyperthermia indicates that normal thermoregulation has been overwhelmed. Intervention with physical cooling should be initiated. The higher the elevation in body temperature in a patient with hyperthermia, the more rapidly and aggressively one should intervene.
- If the elevation of body temperature is caused by a fever, one needs to consider the possibility that the fever might be beneficial for the patient.
- Treating fever significantly reduces heart rate. In patients who have limited cardiovascular reserves, such as those who have recently had a myocardial infarction, treatment of fever is reasonable, although evidence to support temperature control measures in this specific clinical setting is lacking.
- Evidence supports the safety of using acetaminophen to treat fever in the critically ill. However, available evidence also suggests that physical cooling methods are more effective at reducing body temperature than antipyretic drugs.
- In patients with traumatic brain injuries, a reasonable approach is to administer acetaminophen regularly to reduce the burden of fever and to initiate physical cooling early if the body temperature exceeds 38°C.
- For patients who have hypoxic ischemic encephalopathy early treatment of fever is recommended.

This editorial provides a framework and evidence-based summary to aid clinicians in deciding when to treat an elevated body temperature.

Young P, Saxena M, Bellomo R, Freebairn R, Hammond N, van Haren F, et al. Acetaminophen for fever in critically ill patients with suspected infection. *New England Journal of Medicine*. 2015;373(23):2215–2224.
This randomized controlled trial tested the hypothesis that using acetaminophen to treat fever in ICU patients with known or suspected infections would decrease days alive and free from the ICU (i.e., worsen patient outcomes). Early administration of acetaminophen to treat fever resulting from probable infection did not affect the number of ICU-free days. A total of 55 of 345 patients in the acetaminophen group (15.9%) and 57 of 344 patients in the placebo group (16.6%) had died by day 90 (relative risk, 0.96; 95% confidence interval [CI], 0.66 to 1.39; P = 0.84).

Very High Systemic Arterial Blood Pressure

Michael Donahoe

Hypertensive emergency (HE) is a severe elevation in systemic blood pressure combined with new or progressive end-organ damage most frequently in the cardiac, renal, and central nervous systems. HE is an infrequent clinical presentation of acute hypertension that requires immediate, titrated blood pressure reduction.[1] Although HE is often associated with a blood pressure elevation >180/110 mm Hg, the diagnosis of HE is based upon the patient's clinical signs and symptoms rather than a specific blood pressure measurement. Clinical conditions associated with HE include hypertensive encephalopathy, intracranial hemorrhage (IH), acute coronary syndrome, acute pulmonary edema, aortic dissection, acute renal failure, and eclampsia.

The term *hypertensive urgency* (HU) has been historically used to describe critically elevated blood pressure (>180/110 mm Hg) without evidence for acute and progressive dysfunction of target organs. In HU, a more gradual reduction of blood pressure over several hours to days is the therapeutic target. A rapid decrease in blood pressure in HU has no proven benefit, and cerebral or myocardial ischemia can be induced by aggressive antihypertensive therapy if the blood pressure falls below a level needed to maintain adequate tissue perfusion. HU can progress to end-organ damage if blood pressure remains uncontrolled over a sustained interval. As urgent, titrated therapy is indicated only in patients with end-organ damage (i.e., HE), some groups divide high systemic arterial blood pressure into the two categories of HE and uncontrolled hypertension.[2] The majority of hospitalized patients with an elevation in systemic arterial blood pressure have uncontrolled hypertension.

A 25-institution US analysis of patients with HE reported a hospital mortality rate of 6.9%, with an aggregate 90-day mortality rate of 11% and a 90-day readmission rate of 37%.[3] Although the frequency of hospitalization for HE might be increasing, the all-cause hospital mortality for these patients continues to decrease.

Malignant hypertension refers to HE with advanced retinopathy, defined as flame-shaped hemorrhages, cotton wool spots, or papilledema. *Thrombotic microangiopathy* is an HE with active Coombs-negative hemolysis and thrombocytopenia in the absence of another cause, that improves with the lowering of the blood pressure.

PATHOPHYSIOLOGY

An acute elevation in systemic arterial blood pressure fundamentally involves an increase in systemic vascular resistance. This increase in vascular resistance results from a complex interaction of vascular mediators with a triggering factor in the setting of preexisting hypertension. Vasoconstriction can be promoted by circulating catecholamines, angiotensin II (ATII), vasopressin, thromboxane (TxA_2), and endothelin 1 (ET1). In contrast, compensatory production of local counter-regulatory vasodilators, including nitric oxide (NO) and prostacyclin (PGI_2), is inadequate to maintain homeostatic balance. The early stage of HE is associated with a pressure-induced natriuresis that further stimulates the release of vasoconstrictor substances from the kidney.

Specific cellular mechanisms of vascular injury in HE involve proinflammatory responses incorporating cytokine secretion, monocyte activation, and upregulation of endothelial adhesion molecules.[4] These proinflammatory factors extend the endothelial injury by promoting endothelial permeability and activating the coagulation cascade.

This cascade of intravascular events leads to the characteristic pathologic findings of obliterative vascular lesions. The vascular changes, evident to the clinician during an examination of the retina, are mirrored by similar changes in the kidney, leading to proliferative arteritis and, in advanced stages of the process, fibrinoid necrosis. A state of relative ischemia results in the affected organs, leading to end-organ dysfunction. The thrombotic microangiopathy (TMA) that characterizes the advanced stages of HE is a prothrombotic state characterized by endothelial dysfunction, platelet activation, and thrombin generation, with enhanced fibrinolytic activity.[3]

The potential adverse effects of aggressive blood pressure control have been most carefully studied in the cerebral circulation. The cerebrovascular arteriolar tone is adjusted over a range of cerebral perfusion pressures (CPPs) to maintain constant cerebral blood flow (CBF). Increases in CPP promote an increase in vascular resistance, whereas decreases in CPP act to vasodilate the cerebral vasculature. Steady flow is therefore maintained over a range of mean arterial pressure (MAP) from approximately 60 mm Hg to 150 mm Hg.[5] As MAP increases to values >180 mm Hg or above the upper limit of autoregulation, cerebral hyperperfusion, can occur, resulting in cerebral edema. Conversely, when CPP falls below the lower limit of autoregulation, CBF decreases, and tissue ischemia may occur. In patients with long-standing hypertension, a rightward shift of the CPP–CBF relationship occurs such that the lower limit of autoregulation occurs at a value higher than that in normal subjects. Comparative studies in hypertensive and normotensive patients suggest that the lower limit of autoregulation is about 20% below the resting MAP for both, although the absolute value is higher for the hypertensive patient. These data support the standard recommendation that a safe level of blood pressure reduction in HE is a 10% to 20% reduction of MAP from the highest values on clinical presentation, or a diastolic blood pressure typically in the 100 to 110 mm Hg range.

CLINICAL PRESENTATION

The history and physical examination in the patient with an acute elevation in systemic arterial blood pressure will focus on signs and symptoms of acute organ dysfunction. No specific blood pressure

threshold defines an HE. At identical blood pressure levels, end-organ damage may be present or absent.

According to the Studying the Treatment of Acute Hypertension (STAT) registry, the most common presenting symptoms in HE include shortness of breath (29%), chest pain (26%), headache (23%), altered mental status (20%), and a focal neurologic deficit (11%).[3] The most common admitting diagnoses are severe hypertension (27%), subarachnoid hemorrhage (11%), acute coronary syndrome (10%), and heart failure (8%). In approximately 25% of patients with HE, there is a history of either chronic or current medication nonadherence, and 11% of patients are current drug abusers. The mean systolic blood pressure in the STAT registry was 200 mm Hg (interquartile range [IQR], 186–220), and the median diastolic blood pressure was 110 mm Hg (IQR, 93–123).[3]

The patient evaluation must include a detailed medication history with attention to medications associated with blood pressure elevation (e.g., nonsteroidal antiinflammatory drugs [NSAIDs], calcineurin inhibitors, sympathomimetics). For patients with preexisting hypertension, the possibility of hypertensive medication nonadherence and withdrawal is considered.[6]

HEs may develop as secondary hypertension in association with such diverse etiologies as renal vascular disease, sleep apnea, hyperaldosteronism, pheochromocytoma, and pregnancy (preeclampsia). Also, illicit drug use is a significant risk factor for the development of HEs.

Blood pressure should be measured in both arms using an appropriately sized cuff and in a lower limb to detect differences associated with aortic dissection. Repeated blood pressure measurements are indicated, as a significant fraction of patients will resolve hypertension with bed rest and initial observation. Physical examination, including a fundoscopic examination, should focus on the identification of signs suggesting end-organ dysfunction.

HYPERTENSION AND CEREBROVASCULAR DISEASE

Hypertensive Encephalopathy

Acute elevations in systemic arterial blood pressure can lead to hypertensive encephalopathy (HEN). The clinical manifestations of HEN include headache, confusion, or a depressed level of consciousness; nausea and vomiting; visual disturbances (cortical blindness); or seizures (generalized or focal). Patients may present with focal neurologic deficits, although this finding is more common in cerebrovascular accidents. Rarely, HEN can show brainstem involvement manifesting as ataxia and diplopia.[7] If left untreated, the condition can progress to coma and death. Retinal findings, including arteriolar spasm, exudates or hemorrhages, and papilledema, may be present but are not a requirement. Magnetic resonance imaging (MRI) studies show edema involving the subcortical white matter of the parieto-occipital regions best seen on T2 and fluid-attenuated inversion recovery (FLAIR) imaging; a finding termed *posterior leukoencephalopathy*. Approximately two-thirds of patients will also have hyperintense lesions on T2 and FLAIR imaging in the frontal and temporal lobes, and one-third will have brainstem, cerebellum, or basal ganglia involvement.[8] The imaging findings are typically bilateral but can be asymmetric. HEN is the most common cause of reversible posterior leukoencephalopathy syndrome (RPLS).[6] Improvement or resolution of the radiographic findings is often delayed in comparison with clinical improvement.

The diagnosis of HEN is confirmed by the absence of other conditions and the prompt resolution of symptoms and neuroimaging abnormalities with effective blood pressure control. The failure of a patient to improve within 6–12 hours of blood pressure reduction should suggest an alternative cause of the encephalopathy. The condition is typically reversible with no observable adverse outcomes.

Acute Stroke

As blood pressure management differs significantly between acute ischemic stroke and acute hemorrhagic stroke, early imaging is required to guide treatment. The majority of patients with acute ischemic stroke have elevated systolic blood pressure on presentation to the hospital that declines to normal within 48 hours of presentation. Current data are contradictory whether hypertension in the early phase of acute stroke contributes to a worse patient outcome or is a surrogate marker of stroke severity.

During an acute stroke, cerebral autoregulation may be compromised in ischemic tissue, and lowering of blood pressure may further compromise CBF and extend ischemic injury. Medications used to treat hypertension may lead to cerebral vasodilation, augmenting CBF and leading to progression in cerebral edema. Ideally, a "correct" level of MAP should be maintained in each stroke patient to maintain CPP without worsening cerebral edema or progression of the lesion. Still, the clinical determination of this ideal value is often difficult.

Consensus guidelines recommend that blood pressure not be treated acutely in the patient with ischemic stroke unless the hypertension is extreme (systolic blood pressure >220 mm Hg or diastolic blood pressure >120 mm Hg) or the patient has active end-organ dysfunction in other organ systems.[1,2] When treatment is indicated, cautious lowering of blood pressure by approximately 15% during the first 24 hours after stroke onset is suggested. Antihypertensive medications can be restarted at around 24–48 hours after stroke onset in patients with preexisting hypertension who are neurologically stable unless a specific contraindication to restarting treatment exists. Special considerations are patients with extracranial or intracranial stenosis and candidates for thrombolytic therapy. The former group may be critically dependent on perfusion pressure so that blood pressure therapy may be further delayed. In contrast, treatment is recommended before lytic treatment is started, so that systolic blood pressure is ≤185 mm Hg and diastolic blood pressure is ≤110 mm Hg before lytic therapy administration.[1,2] The blood pressure should be stabilized and maintained below 180/105 mm Hg for at least 24 hours after intravenous (IV) lytic therapy.

Blood pressure is frequently elevated in patients with acute IH, often to a greater degree than seen in ischemic stroke. Theoretically, severe elevations in blood pressure may worsen IH by creating a continued force for bleeding. However, the increased arterial pressure may also be necessary to maintain cerebral perfusion in this setting, and aggressive blood pressure management could lead to worsening cerebral ischemia. For patients with suspected elevated intracranial pressure (ICP), ICP monitoring may be indicated to help maintain CPP during therapeutic interventions. American Heart Association guidelines, admittedly arbitrary and not evidence-based, suggest a target MAP of less than 110 mm Hg or a blood pressure of less than 160/90 mm Hg while maintaining a reasonable CPP in patients with suspected elevated ICP.[9] Based upon the results of INTERACT 1 and 2—which showed a decreasing trend in the primary outcome of death or severe disability, significant improvements in secondary functional outcomes, and reassuring safety data—many investigators advocate acute blood pressure reduction to a target systolic blood pressure of ~140 mm Hg for patients with spontaneous IH.[10]

HYPERTENSION AND CARDIOVASCULAR DISEASE

Acute Coronary Syndrome

Patients presenting with acute myocardial ischemia or infarction frequently suffer from an elevated MAP. The increased afterload raises the myocardial oxygen demand. Decreasing the heart rate and blood pressure in these patients will favorably reduce the myocardial oxygen demand and infarct size. However, a reduction in arterial pressure in this

setting should be made cautiously. Potent systemic vasodilation without coronary vasodilation can lead to a decrease in coronary artery perfusion pressure and infarct extension. For this reason, nitroglycerin (NTG), a robust coronary vasodilator, is often the antihypertensive agent of choice in acute coronary syndromes. In combination with beta-blocker therapy, this approach can reduce cardiac workload significantly in the setting of ischemia.

Acute Left Ventricular Dysfunction

Hypertension in acute left ventricular dysfunction (LVD) may be the inciting event with secondary myocardial dysfunction, or a secondary component of acute pulmonary edema resulting from the sympathoadrenal response to hypoxemia, increased work of breathing, and anxiety. Regardless, efforts to control hypertension in LVD are essential to resolve increased myocardial workload and diastolic dysfunction. However, the use of vasodilators in patients with LVD and normal to low blood pressure can lead to hemodynamic instability, impaired organ perfusion, and, potentially, shock.

IV vasodilators, including NTG and calcium channel antagonists, which permit rapid titration of blood pressure, are generally preferred in the setting of acute LVD. The dihydropyridine calcium antagonists nicardipine (NIC) and clevidipine (CLV) have been associated with reduced systemic arterial pressure, with the preservation of coronary blood flow. Patients with LVD may initially be hypertensive secondary to high initial catecholamine levels. With effective treatment or control of hypoxemia and anxiety, blood pressure may fall rapidly, especially in the setting of concomitant diuresis. Thus longer-acting medications such as angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blocker (ARB) therapy are avoided early in the treatment period. Noninvasive continuous positive pressure therapy will increase intrathoracic pressure and acutely reduce venous return and left ventricular afterload. This form of positive airway pressure can offer immediate benefit in the patient with acute pulmonary edema and elevated left ventricular filling pressures.

Patients with HE, in particular, may have suffered a natriuresis resulting in elevated levels of renin production by the kidney and, hence, increased circulating levels of the potent endogenous vasoconstrictor AII. Further reductions in intravascular volume and renal perfusion can lead to further increases in circulating AII levels. Therefore aggressive diuresis before blood pressure control is not advised. Medications that increase cardiac work (e.g., hydralazine) or impair cardiac contractility (e.g., labetalol) are contraindicated as primary therapy for hypertension in the setting of LVD.

Acute Aortic Dissection

Aortic dissection results from an intimal tear in the aortic wall. The primary morbidity and mortality result from the extension of that tear. The extension is promoted by factors that increase the rate of change of aortic pressure (dp/dt), including elevation in blood pressure, heart rate, and myocardial stroke volume. A high clinical suspicion is required, as the classic triad of chest pain, arm–leg blood pressure differential, and a widened mediastinum is present in only one-quarter of cases.

Heart rate and blood pressure in aortic dissection should be promptly reduced. Titratable combined modality therapy to promote vasodilation (NIC or nitroprusside) and control cardiac contractility (esmolol) is advocated for this disorder, with initial aggressive control of the heart rate and blood pressure (~60 beats per min and <120 mm Hg systolic pressure). Isolated treatment with a vasodilator alone could precipitate a reflex tachycardia, increasing dp/dt. Therefore initiate therapy first directed at heart rate control with the addition of vasodilator therapy as needed to achieve the blood pressure target. Effective pain control can also aid with patients achieving specific hemodynamic targets.

HYPERTENSION AND RENOVASCULAR DISEASE

The kidney is both a source of mediators that promote hypertension (i.e., AII) and a target of high systemic arterial pressure. Chronic hypertension is second to diabetes mellitus as a primary cause of renal insufficiency. Elevated systemic arterial pressure should be regulated in patients with underlying renal insufficiency, and a comprehensive workup initiated to determine the cause and effect relationship. Restrict the evaluation of patients for a renovascular cause of hypertension to patients likely to benefit from a correction procedure. Traditional vasodilator medications are preferred to ACE inhibitors for blood pressure control in the setting of renovascular disease, as ACE inhibitors can further compromise renal function.

Scleroderma Renal Crisis

Scleroderma renal crisis (SRC) is characterized by acute renal failure associated with the abrupt onset of moderate to severe hypertension, elevated plasma renin activity, and a normal to minimally abnormal urine sediment. Significant risk factors for SRC are the presence of diffuse scleroderma skin involvement and recent treatment with high-dose corticosteroids.[11] SRC results in a marked activation of the renin–angiotensin system. Aggressive control of blood pressure using ACE inhibitors, particularly early in the disease process, controls blood pressure in up to 90% of patients and promotes recovery in renal function.[11]

HYPERTENSION IN EXCESS CATECHOLAMINE STATES

Pheochromocytoma

Pheochromocytoma is frequently suspected in the setting of acute paroxysmal hypertension, although, in reality, the condition is quite rare. Pheochromocytoma results in the production of circulating catecholamines, which causes hypertension, diaphoresis, tachycardia, and paresthesias of the hands and feet. The classic triad of pheochromocytoma includes headaches, palpitations, and diaphoresis. These attacks can last from minutes to days and occur as frequently as several times a day or as infrequently as once per month. Operative manipulation of the tumor can result in perioperative hypertension. Hypertension therapy in this disorder must avoid the use of isolated treatment with a beta-blocker. This strategy can lead to unopposed alpha-adrenergic stimulation with the risk of further vasoconstriction and blood pressure elevation. The preferred agents for the treatment of hypertension resulting from pheochromocytoma are nitroprusside, NIC, and phentolamine, a potent alpha-adrenergic antagonist. If necessary, phentolamine can be combined with a beta-blocker.

PHARMACOLOGICALLY MEDIATED HYPERTENSION

The administration of exogenous substances (medications or illicit drugs) or abrupt withdrawal of substances can be associated with a hypertensive crisis. Rapid withdrawal or tapering of clonidine has been associated with a hyperadrenergic state characterized by hypertension, diaphoresis, headache, and anxiety. The syndrome is best treated by restarting the clonidine. If the symptoms are extreme, treatment is similar to that for the patient with pheochromocytoma. Hypertension can also occur during the withdrawal phase of alcohol abuse.

Monoamine oxidase (MAO) inhibitors can be associated with hypertension if the patient consumes foods or medications containing tyramine or other sympathomimetic amines. MAO inhibitors interfere with the degradation of tyramine in the intestine, leading to excess absorption and tyramine-induced catecholamine activity in the circulation.

Other medications—including metoclopramide; calcineurin inhibitors; cyclosporine; tacrolimus; and drugs of abuse, such as cocaine,

phenylpropanolamine, phencyclidine, and methamphetamine—must all be considered as possible factors in the intensive care patient with elevated systemic arterial pressure.

Hypertensive states may occur after spinal cord injury, particularly with stimulation of dermatomes and muscles below the level of the injury. The blood pressure elevation is believed to result from excess stimulation of sympathetic neurons. The hypertension is accompanied by bradycardia through stimulation of the baroreceptor reflex. Treatment is focused on minimizing stimulation and providing medical therapy as necessary. Patients with Guillain-Barré can manifest a similar syndrome.

HYPERTENSION AND MISCELLANEOUS CONDITIONS

Preeclampsia/Eclampsia

Hypertension can occur in pregnant women or women in the postpartum period. Acute severe hypertension in the second half of gestation may occur in preeclampsia, gestational hypertension, or HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome. Hypertension occurs as one manifestation of preeclampsia in the pregnant patient; the other key feature is evidence for end-organ dysfunction. Severe hypertension, particularly systolic hypertension in pregnancy, can be associated with central nervous system injury, including cerebral infarction and hemorrhage.

The optimal treatment of preeclampsia is delivery of the fetus, an approach that prevents progression to eclampsia. However, blood pressure should be regulated to avoid end-organ damage. The treatment goal is to achieve a range of 140–150/90–100 mm Hg.[12] IV labetalol, methyldopa, and hydralazine have been considered the first-line medications for the management of severe hypertension in pregnant and postpartum women. However, more recent guidelines have included nifedipine.[12] Magnesium sulfate is not considered an antihypertensive agent, but rather is administered for seizure prophylaxis in severe preeclampsia and eclampsia. Sodium nitroprusside (SNP) (fetal defects), ACE inhibitors (renal dysfunction in the fetus), and trimethaphan (meconium ileus) should be avoided.

Postoperative Hypertension

Postoperative hypertension most often occurs after vascular surgery procedures in patients with a background history of hypertension. The duration of postoperative hypertensive crisis is often brief (2–6 hours) but has been linked to postoperative cardiac and renal complications, including bleeding from suture lines, intracerebral hemorrhage, stroke, and LVD.[13]

Factors such as pain, anxiety, hypervolemia, hypoxemia, hypercarbia, and nausea are reversible factors that can contribute to postoperative hypertension and should be addressed. Postoperative hypertension is often limited in duration (2–12 hours), and aggressive attempts to lower blood pressure acutely can lead to delayed hypotension.

ANTIHYPERTENSIVE MEDICATIONS

A summary of the medications available for the treatment of elevated systemic arterial pressure is outlined in Table 5.1. Currently, the

TABLE 5.1 Intravenous Antihypertensive Therapy

Medication (Route)	Pharmacology	Dosing	Indication	Contraindication
Nitric Oxide Vasodilators				
Nitroprusside (IV infusion)	Onset: 2–3 min Duration: 2–3 min	Init: 0.25–0.5 mcg/kg/min Titrate: 0.5 mcg/kg/min Max: 2 mcg/kg/min	Most hypertensive emergencies	Contraindication in pregnancy. Use with caution in the settings of cerebral edema, acute coronary syndrome, or azotemia. Cyanide toxicity with prolonged use.
Nitroglycerin (IV infusion)	Onset: 2–5 min Duration: 5–10 min	Init: 5 mcg/min Titrate: 5 mcg/min q3–5min Max: 200 mcg/min	Acute coronary syndromes	Contraindication in pregnancy. Caution with use in a volume-contracted patient.
Calcium Channel Blockers				
Nicardipine (IV infusion)	Onset: 5–15 min Duration: 4–6 h	Init: 5 mg/h Titrate: 2.5 mg/h q5min Max: 15 mg/h	Most hypertensive emergencies	Contraindicated in advanced aortic stenosis.
Clevidipine (IV infusion)	Onset: 2–4 min Duration: 5–15 min	Init: 1–2 mg/h Titrate: 2× infusion rate every 90 sec Max: 32 mg/h	Most hypertensive emergencies	Contraindicated with allergy to soybean or egg products. Contraindicated with defective lipid metabolism. Contraindicated with advanced aortic stenosis.
Miscellaneous Medications				
Labetalol (IV infusion, oral)	Onset: 2–5 min Duration: 2–4 h	Init: IV bolus 20 mg Repeat bolus 20–80 mg q10min Infusion: 0.5–2 mg/min	Most hypertensive emergencies	Contraindication in airflow obstruction, acute heart failure, heart block, or in patients nontolerant of beta-blockers.
Phentolamine (IV)	Onset: 1–2 min Duration: 10–30 min	Test dose: 1 mg Repeat 5-mg boluses or continuous infusion may be provided	Pheochromocytoma Catecholamine withdrawal Catecholamine excess	Contraindicated with coronary artery disease.
Enalapril (oral)	Onset: 15 min Duration: 12–24 h	1.25–5 mg q6h	Scleroderma renal crisis	Use with caution in acute coronary syndrome. Not titratable.
Hydralazine (IV, oral)	Onset: 10–20 min Duration: 2–4 h	Init: 10 mg IV q20min Max: 20-mg dose Repeat q4–6h as needed	Pregnancy	Hydralazine is not recommended for hypertensive emergency in the general population due to an unpredictable effect duration

clinician has minimal comparative data to guide initial therapy for the patient with hypertension. Patients without end-organ dysfunction (HU) are best treated with oral agents, allowing a gradual reduction in blood pressure over 24–48 hours. In contrast, for patients with an HE, short-acting titratable medications provided in a monitored environment are preferred, as hypotension and compromised organ perfusion must be avoided. The sublingual and intramuscular routes should be avoided because of unpredictable pharmacokinetics. The conversion to oral therapy is timed to stable blood pressure readings and no further progression in end-organ dysfunction.

Patients with specific conditions (i.e., aortic dissection, severe preeclampsia, pheochromocytoma crisis) should have their systolic blood pressure reduced to <140 mm Hg during the first hour of treatment and to <120 mm Hg for aortic dissection. For the majority of adults without a specific condition, systolic blood pressure should be reduced by no more than 25% within the first hour; then, if stable, to 160/100 mm Hg within the next 2–6 hours; and then cautiously to normal during the following 24–48 hours.[1] Blood pressure–lowering medication is often withheld in the acute phase of patients with ischemic stroke.

Patients receiving NIC were more likely to have their blood pressure controlled to prospectively defined target ranges at 30 minutes compared with those receiving labetalol in one of the few comparative effectiveness trials of NIC versus IV labetalol in the emergency department management of acute hypertension.[14]

CLV was compared with three commonly employed medications for the treatment of postoperative hypertension (NTG, SNP, and NIC.[15] The primary endpoint was safety, as assessed by the incidence of death, stroke, myocardial infarction (MI), and renal dysfunction from the initiation of study drug infusion through postoperative day 30. There was no difference in the CLV-treated patients compared with the other treatment groups. However, mortality was significantly higher for SNP-treated patients compared with CLV-treated patients.

Nitric Oxide Vasodilators

SNP is a potent arterial and venous vasodilator that reduces preload and afterload. SNP was once the gold standard for the treatment of HE because of its short duration of action, allowing careful titration. The blood pressure response to SNP is rapid and mandates its use in a well-monitored environment with frequent blood pressure monitoring. The arteriolar and venous vasodilating activity of SNP may not be uniform, however. Redistribution of oxygenated blood flow from nonresponsive ischemic regions to vasodilated nonischemic coronary arteries can reduce CPP, resulting in a "coronary steal" syndrome. A similar "cerebral steal" syndrome has been suggested with the use of SNP because of preferential vasodilation in systemic vascular beds versus cerebral vessels. Through the dilation of large-capacitance vessels, SNP can increase cerebral blood volume, leading to an increase in ICP that raises additional concerns in patients with increased ICP. SNP is rarely associated with cyanide or thiocyanate toxicity, occurring primarily in patients receiving infusions for greater than 24–48 hours, in the setting of underlying renal insufficiency, or the use of doses that exceed the capacity of the body to detoxify cyanide (more than 2 μg/kg per min). Despite the marked potency and rapidly titratable characteristics of SNP, the recognized adverse effects on cerebral and coronary blood flow combined with the potential toxicities have made newer alternative agents favored over SNP for the treatment of HE.

NTG is a coronary vascular dilator and a systemic venodilator that reduces myocardial preload. NTG demonstrates arterial smooth muscle effects only at higher-dose infusions. The drug is contraindicated in patients with significant volume depletion, as venodilation in these patients will further lower preload, reduce cardiac output, and compromise overall systemic perfusion. When administered by the IV route, the medication has a relatively short duration of action. The drug has favorable effects for patients with acute coronary syndromes, including reducing myocardial oxygen demand via its effects on preload and afterload and augmenting myocardial oxygen delivery through its impact on the coronary circulation. Headache is the most common adverse effect of NTG, and methemoglobinemia is a rare complication of prolonged NTG therapy.

Calcium Channel Blockers

Calcium channel blockers (CCBs) are a heterogeneous class of medications used in the treatment of HE. Dihydropyridines, a specific class of CCB (e.g., NIC and CLV), are selective for vascular smooth muscle over the myocardium, with little, if any, activity in cardiac muscle or the sinoatrial node; thus they have little effect on heart rate and no effect on myocardial contractility.[16] The vascular smooth muscle relaxation without associated cardiac effects makes this class favorable for the treatment of HEs.

NIC is a dihydropyridine CBB that acts primarily as a systemic, cerebral, and coronary artery vasodilator. The greater water solubility of this drug compared with other CCBs (e.g., nifedipine) allows IV administration with a short onset (5–15 minutes) and short duration of action; therefore titration to a therapeutic effect is easy. NIC readily crosses the blood–brain barrier and relaxes vascular smooth muscle, especially in regions of ischemic tissue. The medication acts as a vasodilator of small-resistance cerebral arterioles but does not change intracranial volume or ICP with the preservation of cerebral oxygenation.[17] In comparison with SNP, NIC appears to offer equal efficacy with the advantage of avoiding the toxic metabolites of SNP, less frequent dose adjustments, and a decreased risk of increased ICP as reported with SNP. NIC has been shown to increase coronary blood flow with a favorable effect on myocardial oxygen demand.[18] NIC is metabolized by the liver, and excretion can be impaired in patients with liver disease.

CLV is a third-generation dihydropyridine CCB available as a racemic mixture with poor water solubility, so the drug is administered by continuous IV infusion in a lipid emulsion. A new formulation of CLV has been available in the United States since 2011 and contains a retardant (0.005% disodium edetate) that inhibits microbial growth for up to 12 hours. CLV reduces afterload without adversely affecting cardiac filling pressures or causing reflex tachycardia.[19] It has a rapid onset (~2–4 minutes) and offset of action (~5–15 minutes). It undergoes rapid ester hydrolysis by arterial blood esterases to form inactive metabolites, making medication clearance independent of renal or hepatic functional status.

CLV is contraindicated in patients with allergies to soybeans, soy products, eggs, or egg products and patients with defective lipid metabolism. Because of lipid-load restrictions, no more than 1000 mL, or an average of 21 mg/h of CLV infusion, is recommended per a 24-hour period.

CLV has shown favorable results in adult cardiac surgery patients with acute perioperative or postoperative hypertension, in acute hypertensive heart failure, and in patients with intracranial hemorrhage.[20,21] Elevated triglyceride levels have been reported in patients who received CLV, but these resolved with discontinuation of the medication.

Beta-Blockers

Esmolol is a short-acting, cardioselective beta-blocker with a rapid onset (<1 minutes) and short duration of action (10–20 minutes) that is only administered by continuous infusion. The short half-life requires bolus administration with each infusion titration. Esmolol reduces blood pressure, heart rate, and cardiac output and must be avoided in patients with bradycardia or impaired left ventricular function. Esmolol is optimally used in patients with tachycardia, hypertension, and normal to elevated

cardiac output. It is rapidly cleared by red blood cell esterases and is independent of renal or hepatic function.

Labetalol is an oral and parenteral agent that acts as an alpha- and nonselective beta-adrenergic blocker with an alpha-to-beta blocking ratio of 1:7.[22] The blood pressure–lowering effect is produced through a reduction in systemic vascular resistance without a compensatory increase in heart rate. In contrast to traditional beta-blockers, labetalol is associated with the preservation of cardiac output. The hypotensive effect of labetalol has an onset of 2–5 minutes, peak effect at 5–15 minutes, and duration of ~2–6 hours. Labetalol has minimal effect on cerebral circulation and is thus not associated with an increase in ICP in the normal brain. The drug has minimal placental transfer and has been used effectively in pregnancy-associated hypertension. It has been used effectively in patients with end-organ dysfunction in the setting of acute neurologic injury, pheochromocytoma, dissecting aneurysm, and eclampsia. The primary contraindication to the use of the medication relates to its nonselective beta-blocking properties. The drug should be used cautiously in patients with reactive airway disease and heart block.

Miscellaneous Medications

Enalapril is an intravenously administered ACE inhibitor. This medication reduces renin-dependent vasopressor activity, blocks the conversion of angiotensin I to AII, and blocks the degradation of bradykinin. ACE inhibitor administration is associated with a decrease in systemic vascular resistance, with minimal change in heart rate, cardiac output, or left ventricular filling pressure. Enalapril is effective in patients with low to normal renin levels and hypertension. The peak effect of enalapril may not be seen for up to 4 hours, with a duration of 12–24 hours. These pharmacokinetic parameters limit drug titration in the acute setting of an HE. ACE inhibitors are contraindicated in the setting of renal artery stenosis and pregnancy.

Phentolamine is a rapid-acting, alpha-adrenergic blocker. It is often considered the drug of choice for HEs secondary to pheochromocytoma, MAO–tyramine interactions, and clonidine rebound hypertension.

Hydralazine is a direct-acting vasodilator with a latent onset (5–15 minutes) and a prolonged effect (~12-hour half-life) that can be highly variable. Because of hydralazine's prolonged and unpredictable antihypertensive effects, this medication is best avoided in the management of an HE.

Diuretics should be avoided initially in the acute management of HE in the absence of pulmonary edema or renal parenchymal disease. Volume depletion is typical in HE patients, and these patients are susceptible to hypotension and compromised perfusion if vasodilators and diuretics are initiated together.

KEY POINTS

- Although HE is typically associated with a blood pressure elevation >180/110 mm Hg, the diagnosis is based on the patient's clinical signs and symptoms rather than a specific blood pressure level.
- Clinical conditions associated with HE include hypertensive encephalopathy, intracranial hemorrhage, acute coronary syndrome, acute pulmonary edema, aortic dissection, acute renal failure, and eclampsia.
- Patients with HU (without end-organ dysfunction) are best treated with oral agents, allowing a gradual reduction in the blood pressure over 24–48 hours.
- Patients with an HE should be treated with short-acting, titratable medications that are administered in a monitored environment, as hypotension and compromised organ perfusion must be avoided.

Low Systemic Arterial Blood Pressure

Joseph A. Hamera, Anna W. McLean, Lakhmir S. Chawla, and Kyle J. Gunnerson

INTRODUCTION

Assessment of hemodynamics is an important skill in the critical care setting. The goal of hemodynamic monitoring in a critically ill patient is to ensure adequate tissue oxygen delivery and end-organ perfusion. Low systemic arterial blood pressures are commonly encountered in the clinical setting, and a thoughtful, systematic approach should be used.

INITIAL EVALUATION

Initial evaluation usually begins with assessment of blood pressure (BP) readings. However, one should not rely solely on these readings, as there is no "normal" BP for all patients, and a BP value in the "normal" range does not always equate with adequate tissue perfusion. For example, a patient with a history of poorly controlled chronic hypertension may be normotensive, not yet in critical condition, but cannot meet his or her body's oxygen demand, resulting in evidence of significant anaerobic metabolism referred to as *cryptic shock*.[1] Conversely, a patient with cirrhosis or a pregnant patient may have adequate perfusion despite having a lower-than-normal BP.

Additionally, attention should be given to the mean arterial pressure (MAP). It is important to keep in mind that the MAP is the sum of two-thirds diastolic and one-third systolic pressure. The MAP is the main determinant of the perfusion pressure, or what pressure the organ sees. Safe levels of hypotension have historically been estimated to be anything greater than two-thirds of MAP.[2,3] Even more recently, it was found that an MAP less than 55 mm Hg during noncardiac surgery is independently associated with an increased risk of kidney and myocardial injury and has a moderate association with duration of surgery.[4] A good initial goal should be to restore the patient to an MAP of 65–70 mm Hg, but the level should be adjusted to restore tissue perfusion as assessed on the basis of mental status, appearance, urine output, etc.[5] Therefore hypotension triage needs to be quick and purposeful in order to prevent potentially damaging long-term sequelae.

An initial bedside assessment of tissue perfusion should include evaluation of mental status, urine output, and skin findings (e.g., temperature, diaphoresis, mottling, and capillary refill). If any of these parameters is abnormal, a more urgent approach to treatment must be taken. A focused cardiac and pulmonary examination is essential: presence of jugular venous distention; an S3 or S4 heart sound; new or worsening murmurs; or muffled heart sounds, crackles, or rales. Furthermore, a finding of absent breath sounds could be equally important, suggesting a pneumothorax.

All patients should have adequate intravenous (IV) access, preferably two patent 18-gauge or larger catheters. The patient should be monitored using a standard electrocardiogram (ECG) monitor and pulse oximetry. A 12-lead ECG should be performed, looking for evidence of myocardial ischemia. Chest radiography should be done, and supplemental oxygen should be given as needed. Complete blood counts, serum chemistry, lactate, arterial blood gas, random cortisol, coagulation panels, procalcitonin, and cardiac enzymes may be considered as part of the initial workup.

If equipment and a qualified operator are available, bedside ultrasound can form a useful part of the diagnostic workup of hypotension by demonstrating evidence of diminished cardiac contractility or pulmonary edema suggestive of cardiac failure, right ventricular findings consistent with pulmonary embolism, pneumothorax, or unexpected intraperitoneal fluid collections concerning for hemorrhage.[6] As with the physical examination, diligent attention must be paid to the proper performance of image acquisition and interpretation, as incorrect technique can lead to incorrect diagnosis and errors of commission or omission. A systematic approach to using ultrasound in hypotension is essential to avoid missed findings or misinterpretation. Multisystem examinations such as the Rapid Ultrasound in Shock and Hypotension (RUSH) protocol have been developed to aid in undifferentiated hypotension evaluation and, if possible, should be performed to completion to avoid premature closure.[7] As always, imaging findings do not stand alone and require interpretation in a clinical context to guide management decisions.[8]

WHAT IS THE CAUSE?

A review of cardiovascular physiology is essential in order to help focus the differential diagnosis of a hypotensive patient. A clinician's initial evaluation should be a global assessment (Fig. 6.1) of systemic vascular resistance (SVR) and cardiac output (CO). It is important to recall that *pressure = flow × resistance,* where flow is CO and resistance is SVR. Because CO is determined by stroke volume (SV) × heart rate (HR), the presence of hypotension means that at least one of these parameters (e.g., SV, SVR, or HR) is abnormal.[9] Assessment of HR is obvious by palpation of pulses or cardiac monitoring; however, assessing SV and SVR can be more challenging. Attention should be paid to systolic blood pressure (SBP) and diastolic blood pressure (DBP) in the context of pulse pressure (PP = SBP − DBP). DBP is a reasonable surrogate for SVR.

During systole, the SV is ejected into the proximal arterial conduits. Because more blood is being ejected than the peripheral circulation can accommodate in the arterioles, the arterial walls distend, increasing SBP in a way that is directly proportional to the SV and indirectly proportional to the capacitance (C) of the arterial wall. This relationship is represented by the following formula[9]:

$$SBP = SV \div C$$

That is, for a fixed SV, if capacitance is higher, the SBP is lower.

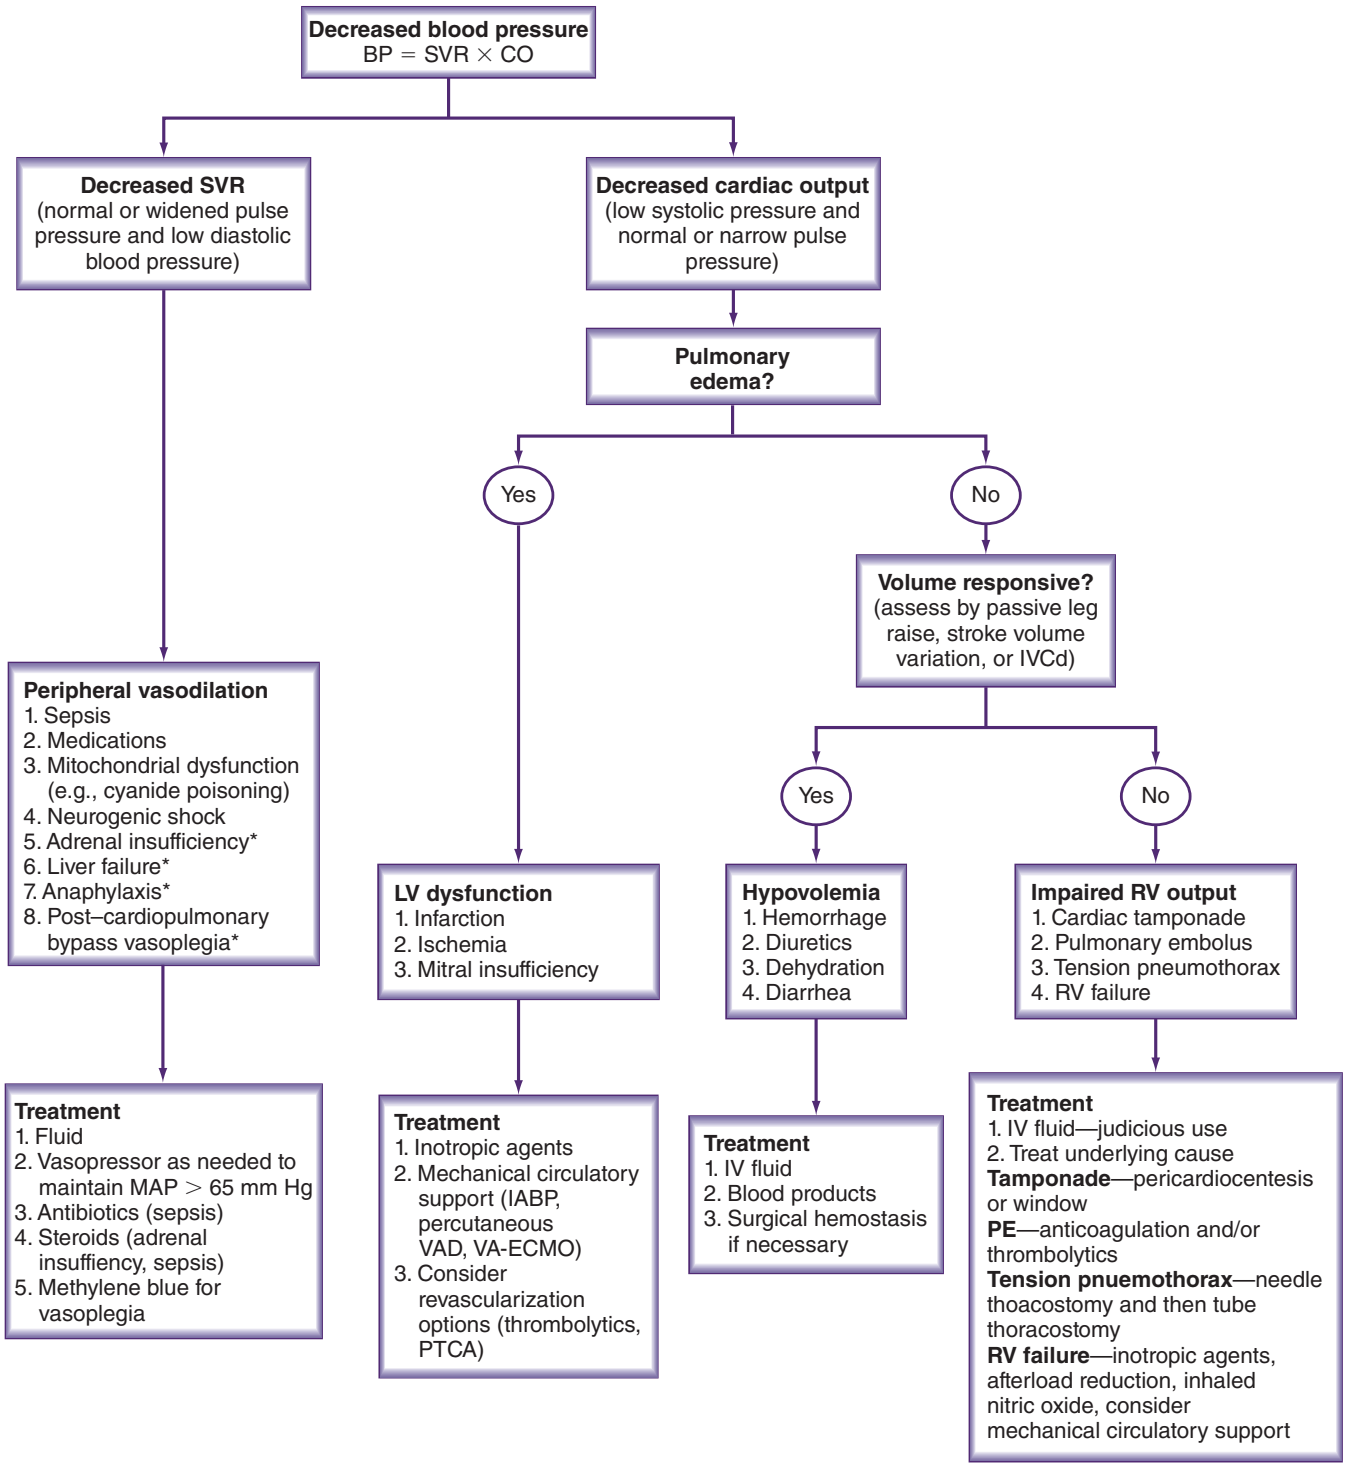

Fig. 6.1 Initial approach to a patient with low systemic arterial blood pressure. *Adrenal insufficiency, liver failure, post–cardiopulmonary bypass vasoplegia, and anaphylaxis are commonly listed as vasodilatory shock; however, data are inconclusive, and components of other types of shock (hypovolemic, cardiogenic) may also be present. *BP,* Blood pressure; *CO,* cardiac output; *IABP,* intraaortic balloon pump; *IV,* intravenous; *IVCd,* inferior vena cava diameter; *LV,* left ventricle; *MAP,* mean arterial pressure; *PE,* pulmonary embolism; *PTCA,* percutaneous transluminal coronary angioplasty; *RV,* right ventricle; *SVR,* systemic vascular resistance; *VAD,* ventricular assist device; *VA-ECMO,* venovenous extracorporeal membrane oxygenation.

During diastole, the portion of the SV that was "stored" by the distention of the arterial walls during systole fills the peripheral arterioles, leading to a progressive decrease in BP until the next systolic phase. This is the diastolic pressure, a parameter that is directly related to the SVR and capacitance (i.e., low diastolic pressure = low SVR and/or capacitance).[9] When using these basic cardiovascular principles to understand the cause of hypotension, it is important to remember the following: (1) capacitance does not change from heartbeat to heartbeat and (2) SV depends on preload, afterload, and contractility.

Low SVR is characteristic of a number of pathologic conditions, including sepsis, adrenal insufficiency, vasodilating medications, neurogenic shock, post–cardiopulmonary bypass (CPB) vasoplegia, and severe liver dysfunction. Decreased SVR (and aortic valve insufficiency) should be suspected in the presence of a widened PP and low DBP.[10,11]

Reduced SV can be the result of decreased preload, decreased contractility, or increased afterload. The most common cause of inadequate preload is hypovolemia. Other causes of inadequate preload include increased intrathoracic pressure caused by dynamic hyperinflation in mechanically ventilated patients[12,13] or tension pneumothorax, pulmonary embolism,[14] mitral valve stenosis,[15] cardiac tamponade,[16] and right ventricular failure.[17] Decreased contractility can be caused by myocardial ischemia or infarction, cardiomyopathy, myocarditis, negative inotropic drugs, myocardial stunning after CPB, and direct myocyte toxins such as chemotherapeutic agents and inflammatory mediators (e.g., tumor necrosis factor [TNF] and interleukin 1-beta [IL-1β]).[18] A reduction in SV can be identified by decreased SBP and normal or narrow PP.

Reduced HR is a relatively uncommon cause of low BP. Causes include structural damage to the conducting system; metabolic derangements such as hyperkalemia; autonomic dysregulation, as seen in central neurologic injury; and pharmacologic poisoning of the conduction system, as in the case of beta-blocker or calcium channel blocker overdose.[19] Shock states driven primarily by bradycardia, like other forms of cardiogenic shock, can initially manifest with relatively normal BP despite inadequate forward flow caused by the preservation of systemic vascular tone.

TREATMENT

Hypotension has been associated with higher morbidity and mortality in a variety of disease states, so until proven otherwise, hypotension should be considered synonymous with hypoperfusion and thus treated aggressively. A trial of at least 1.0 L of crystalloid should be infused to treat hypotension; the fear of pulmonary edema should not preclude the use of volume expanders in a patient who is not perfusing adequately.[1]

In a large series of intensive care unit (ICU) patients in shock, 78% were in either septic or hypovolemic shock.[20] Because treatment for both states requires intravascular volume resuscitation and clinical examination is unreliable for determining the need for and endpoint of volume resuscitation, several adjunctive tools have been developed to assist in decision making surrounding fluid administration.[21,22] The use of ultrasound at the bedside to evaluate inferior vena cava diameter (IVCd) has proven to be an accurate metric of volume responsiveness in mechanically ventilated and spontaneously breathing patients.[23] IVCd is measured subcostally, approximately 0.5–4.0 cm below the junction of the IVC and right atrium, in the longitudinal direction at a perpendicular angle to the IVC, and is calculated as "the change" in IVCd during inspiration as compared with expiration.[23] Patients with variation >50% will most likely respond to additional volume.[24]

Another method by which the clinician can evaluate volume responsiveness is the passive leg raise (PLR) test. In the nonintubated patient sitting with the head of the bed at 45 degrees, laying the patient flat and elevating the patient's legs at a 45-degree angle above the plane of the bed will cause a rapid temporary increase in venous return to the heart and an increase in CO, which has been shown to correlate with a 500-cc bolus of normal saline.[23] This maneuver increases PP in "responders." An increase in PP of more than 9% noted before and after the passive leg lifts will identify patients who are likely to respond to additional IV fluid administration.[25,26]

Although more invasive than the PLR, pulse contour analysis (PCA) has emerged as an accurate method for measuring cardiac performance (SV, CO, cardiiac index [CI]) and also measures PP or SV variation in the intubated and mechanically ventilated patient. By observing the undulation of the arterial line monitor for 30 seconds and the variability throughout the respiratory cycles, a decrease of 13% or more in SV during the inspiratory cycle correlates with preload responsiveness of SV. This variation represents a decrease in venous return in conjunction with the increased intrathoracic pressure during the inspiratory phase of ventilation. This measurement is only accurate when the heart rhythm is regular, so it is an unreliable index of preload responsiveness in patients with many kinds of arrhythmias, in the presence of an intraaortic balloon pump (IABP), or when there is loss of integrity in the arterial waveform. It is also only accurate in mechanically ventilated patients who are not experiencing large variations in intrathoracic pressures.[27,28]

In those patients where a low SVR is suspected as the primary cause of hypotension, the treatment is different. Large amounts of additional IV fluid alone will not adequately increase the BP to maintain tissue perfusion. Vasoconstrictor agents (e.g., norepinephrine, dopamine, phenylephrine, angiotensin II, and vasopressin) will be required in these patients. In certain specific cases, other pharmacologic adjuncts may be helpful. Low-dose hydrocortisone in vasoconstrictor-resistant septic shock[29] and methylene blue in post-CPB vasoplegia are two examples.[30]

In cases where hypotension is suspected to be caused by low SV, attention must be paid to the central cardiovascular system. These cases can be divided into failure of contractility or obstructive shock. In cases of primary left or right ventricular failure, steps must be taken to improve the performance of the heart either pharmacologically or mechanically. Optimization of a failing left ventricle involves reduction in preload and afterload with escalation to inotropic support if hypotension is present.[31] Management of primary right ventricular failure requires judicious optimization of preload, consideration of reduction in pulmonary arterial pressure, and inotropic support.[32] If pharmacologic means fail, escalation to mechanical circulatory support should be considered. Various forms of mechanical support are currently in use, including IABP, percutaneous ventricular support devices, and venous-arterial extracorporeal membrane oxygenation (VA-ECMO). The exact system required depends on which side of the heart requires support and the magnitude of support required.[31] Obstructive shock requires emergent disease-directed treatment. In cases of tension pneumothorax or cardiac tamponade, procedural decompression of the space is mandatory.[33,34] In cases of pulmonary embolism causing acute right ventricular failure, in addition to systemic anticoagulation, consideration of systemic thrombolysis or catheter-directed treatment should be made to offload the failing right ventricle.[35,36]

Hypotension mediated by bradycardia is typically managed by correction of the underlying cause. In metabolic causes, the underlying cause should be corrected. In pharmacologic cases, temporary management should include antidotes if available in addition to positive chronotropic agents such as atropine or beta-agonists. In cases caused by damage to the conduction system by ischemia or infiltrative disease, chronotropic agents are indicated temporarily, but clinicians should be prepared to start temporary pacing in the event these fail.

Many occurrences of hypotension may have some qualities of both decreased SV and decreased SVR. However, by using a systematic approach, the clinician can rapidly start diagnostic and therapeutic measures needed to treat tissue hypoperfusion.

KEY POINTS

- Assessment of any BP requires clinical consideration of the adequacy of tissue perfusion.
- BP goals in the ICU typically start around MAP 65–70 mm Hg, but must be individualized to patient needs using clinical markers of tissue perfusion.
- The assessment of hypotension should include making preparations for resuscitation, clinical examination, laboratory and radiographic testing, and the employment of bedside diagnostics where able to accelerate directed interventions.
- The physiology of hypotension necessarily involves derangement in HR, SV, or SVR. Diagnosing which perturbation(s) are present and for what reason can help focus management.
- Initial management of hypotension should usually involve a fluid challenge, with subsequent fluid administration directed by serial assessment of volume responsiveness. Early administration of pharmacologic vasopressors and/or inotropic support is indicated for inadequate response.

Tachycardia and Bradycardia

Bryan T. Romito and Joseph S. Meltzer

The resting adult heart rate normally ranges from 60 to 100 beats per minute (bpm). Heart rate and rhythm abnormalities occur frequently in critically ill patients, and the incidence of sustained arrhythmias can approach 40% in some intensive care unit (ICU) settings.[1,2] Common arrhythmia risk factors in the critically ill include advanced age, sepsis, myocardial ischemia, respiratory failure, renal insufficiency, acute brain injury, polypharmacy, metabolic disturbances, cancer, trauma, and burns.[2,3] Prompt recognition and treatment are essential, as the presence of tachyarrhythmias (characterized by heart rates >100 bpm) and bradyarrhythmias (characterized by heart rates <60 bpm) is associated with both significantly increased hospital length of stay and in-hospital mortality rates in the critically ill.[2]

TACHYARRHYTHMIAS

For classification purposes, tachyarrhythmias can be subdivided into those with a narrow QRS complex (≤120 milliseconds [ms]) and those with a wide QRS complex (>120 ms). In general, narrow QRS complex tachyarrhythmias are supraventricular tachycardias (SVTs), involving tissue from the His bundle or above.[4] Wide complex tachyarrhythmias typically represent ventricular tachycardias (VTs) or SVTs with abnormal conduction patterns.[5]

Sinus Tachycardia

Sinus tachycardia is an atrial supraventricular tachyarrhythmia with a narrow QRS complex. On the electrocardiogram (ECG), the P wave is positive in leads I, II, and aVF and biphasic/negative in lead V1.[4] The vast majority of sinus tachycardia is physiologic and associated with catecholaminergic triggers.[6] Sinus tachycardia may result from pain, physical activity, fever, or hyperthyroidism. Simulants, caffeine, anticholinergics, and beta-receptor agonists can all produce transient sinus tachycardia.[7] In critically ill patients, sinus tachycardia may signify a normal adaptive response to maintain cardiac output in the setting of decreased stroke volume, oxygen-carrying capacity, or arterial vascular tone. Although nonspecific, tachycardia can represent an early sign of impending cardiopulmonary instability, and it is an independent risk factor linked to several worse clinical outcomes in the ICU.[8] The development of sinus tachycardia in critically ill patients is often multifactorial, and appropriate management includes identification of risk factors, discontinuation of offending agents, and treatment of underlying causes (Table 7.1).[4]

Atrioventricular Nodal Reentrant Tachycardia

Atrioventricular nodal reentrant tachycardia (AVNRT) is the most common type of the "classical" SVTs.[5] It occurs as a result of a reentry circuit present either within or near the atrioventricular (AV) node. ECG findings of typical AVNRT include a regular tachycardia with indiscernible P waves and narrow QRS complexes.[4] The risk of developing AVNRT is almost twice as high in women as in men.[9] Vagal maneuvers (i.e., Valsalva and carotid sinus massage) in the supine position and/or intravenous (IV) adenosine are recommended for the acute treatment of patients with stable SVT.[7] If refractory, IV diltiazem, verapamil, or beta-blockers can be administered to hemodynamically stable patients. Calcium channel blockers are not appropriate for patients with suspected systolic heart failure. Synchronized direct current cardioversion (DCCV) is recommended for hemodynamically unstable patients with SVT or for stable patients when pharmacologic therapy is ineffective or contraindicated.[7]

Atrial Fibrillation

Atrial fibrillation (AF) is the most common sustained arrhythmia, with a lifetime risk of 25% in the general population.[10] ECG characteristics of AF include an irregularly irregular rhythm with no discernible P waves because of rapid atrial oscillations that vary in timing, amplitude, and shape.[5] Critically ill patients encounter multiple risk factors for developing new-onset AF. Inflammation; electrolyte abnormalities; hypervolemia; sepsis; excessive adrenergic stimulation; and receipt of beta-receptor agonists, vasopressors, and certain antiarrhythmics can all trigger AF in ICU patients.[10] Accelerated ventricular rates and loss of the normal atrial contribution to ventricular filling ("atrial kick") during AF may lead to rapid hemodynamic deterioration, especially in patients with diastolic dysfunction. The development of new-onset AF is associated with increased hospital mortality rates and long-term risks of ischemic stroke, heart failure, and death.[10]

New-onset AF in critical illness is often reversible. The majority of patients will spontaneously convert to sinus rhythm within 72 hours of treatment of the underlying causes or removal of the offending agent.[2] Otherwise, management of the hemodynamically stable patient with AF involves three treatment principles: rate control, rhythm control/cardioversion, and anticoagulation. Beta-receptor antagonists are particularly effective for rate control in the setting of increased sympathetic tone from critical illness, sepsis, or the postoperative state.[10,11] Nondihydropyridine calcium channel blockers may be used for rate control in patients intolerant of beta-receptor antagonists, and digoxin can be considered as third-line therapy.[2] Calcium channel blockers are contraindicated in patients with acute heart failure, and the use of digoxin in patients with AF has been associated with sudden cardiac death.[12] In patients with permanent AF, targeting a resting heart rate <110 bpm is as effective as targeting a resting heart rate <80 bpm.[13] Amiodarone is an effective rhythm control agent, and it offers the additional benefit of rate control if both beta-receptor antagonists and calcium channel blockers are contraindicated. Pulmonary and thyroid toxicity have been described after its administration. IV magnesium, either as monotherapy or in combination with other agents, may provide greater rate and

TABLE 7.1 Common Causes of Arrhythmias in the ICU

Tachyarrhythmias	Bradyarrhythmias
Advanced age	Advanced age
Myocardial ischemia	Myocardial ischemia
Respiratory failure	Respiratory failure
Kidney failure	Kidney failure
Postcardiac surgery	Postcardiac surgery
Heart failure	Heart failure
Electrolyte abnormalities	Electrolyte abnormalities
Increased catecholamines: pain, exercise, anxiety	Increased vagal tone
Hyperthyroidism	Hypothyroidism
Hyperthermia	Hypothermia
Hypovolemia	Increased intracranial pressure
Anemia	Hypertension
Sepsis	Obstructive sleep apnea
Cancer	Infiltrative diseases: cardiac amyloidosis, sarcoidosis, hemochromatosis, lymphoma
Trauma/burns	Inflammatory diseases: Lyme disease, Chagas disease, myocarditis, endocarditis
Intoxication: alcohol, cocaine, stimulants	Rheumatologic diseases: rheumatoid arthritis, scleroderma, systemic lupus erythematosus
Medications: anticholinergics, beta-receptor agonists, chemotherapy agents, antiarrhythmics, vasopressors, inotropes	Medications: beta-receptor antagonists, calcium channel blockers, digoxin, dexmedetomidine, antiarrhythmics, opioids, tricyclic antidepressants, clonidine, lithium, phenytoin

rhythm control.[10,14,15] In patients with heart failure, treatment of AF with catheter ablation may be associated with improved clinical outcomes.[16,17]

Hemodynamically unstable patients with AF should be treated with synchronized DCCV. Even with multiple attempts, the reported success rates for electrical cardioversion of AF during critical illness range from 30% to 37%.[2] Concurrent administration of rate or rhythm control agents should be considered, given the high likelihood of recurrence.[10] In patients with a recurrence of persistent AF after electrical cardioversion, rate control is not inferior to rhythm control.[18] For prevention of thromboembolism, anticoagulation should be considered for all patients with AF. The risk of stroke may be greater in patients with higher CHA_2DS_2-VASc scores and with AF duration ≥48 hours. Overall, the risk of thromboembolic events should be weighed against the risk of anticoagulant-related bleeding for the individual patient.[19]

Atrial Flutter

Typical atrial flutter (AFl) is a macroreentrant, narrow complex atrial tachycardia that is characterized by a regular sawtooth pattern on the ECG.[4] Atrial rates usually range from 250 to 330 bpm.[7] The acute management of AFl is largely similar to the management of AF; however, ventricular rate control may be more difficult to achieve in AFl.[2] Patients with AFl are thought to have the same risk of thromboembolism as patients with AF, so anticoagulation should be considered accordingly.[7] Finally, DCCV of AFl can often be accomplished with lower energies compared with AF.[2]

Ventricular Tachycardia

Ventricular tachycardia (VT) is characterized by ≥3 consecutive complexes originating in the ventricles at a rate >100 bpm.[20] It is the most common cause of wide QRS complex tachycardia. VT is classified as sustained when it lasts >30 seconds or requires termination because of hemodynamic compromise in <30 seconds. Conversely, nonsustained VT (NSVT) has a duration of <30 seconds and terminates spontaneously. VT can also be classified as monomorphic (i.e., stable single beat-to-beat QRS morphology) or polymorphic (i.e., changing or multiform beat-to-beat QRS morphology).[20]

Hemodynamically stable patients with asymptomatic NSVT usually do not require treatment other than correction of any precipitating cause. The in-hospital mortality rate for patients with sustained monomorphic VT is approximately 50%.[2] In patients with stable monomorphic VT, administration of IV procainamide, amiodarone, or sotalol can be used to terminate the rhythm.[20] Amiodarone is often better tolerated in patients with systolic dysfunction.[2] In addition to antiarrhythmic administration, correction of electrolyte abnormalities and discontinuation of offending agents should be performed concurrently. DCCV and catheter ablation can be undertaken in refractory cases of sustained monomorphic VT. Patients with unstable monomorphic VT should be treated with DCCV.[20]

Polymorphic VT can occur in the setting of a normal (<460 ms) or prolonged (>460 ms) QT interval. Unstable patients with normal QT interval–associated polymorphic VT require immediate defibrillation. Recurrent polymorphic VT can be caused by ongoing myocardial ischemia that resolves with coronary revascularization.[20] Polymorphic VT associated with QT interval prolongation is termed *torsades de pointes.* It is characterized by a waxing and waning QRS amplitude.[20] Treatment of torsades de pointes includes discontinuing QT-prolonging agents, correcting electrolyte derangements, administering magnesium, and increasing the ventricular rate with isoproterenol or temporary pacing.[2]

BRADYARRHYTHMIAS

Abnormalities of the sinus node, atrial tissue, AV nodal tissue, or conduction system can contribute to the development of bradyarrhythmias.[21] Bradyarrhythmias are more common in older patients because of age-related degeneration and fibrosis of the conduction system. Other risk factors for the development of bradyarrhythmias include hypertension, respiratory failure, and ischemic heart disease (see Table 7.1).[22]

Sinus node dysfunction (SND) can manifest with sinus bradycardia, sinus pauses, or tachycardia–bradycardia syndrome.[21] Asymptomatic sinus bradycardia has not been associated with adverse outcomes, and treatment is not recommended. Symptoms attributable to SND can range from mild fatigue to syncope.[21] Correction of reversible causes is key to the acute management of SND. If symptoms persist despite conservative treatment, medications with chronotropic effects such as atropine, dopamine, isoproterenol, or epinephrine can be administered. Severe refractory SND associated with hemodynamic instability should be treated with pacing.[21]

AV nodal disease presents as variable heart block with specific ECG patterns. In first-degree AV block, P waves are associated with 1:1 AV conduction and a prolonged PR interval of >200 ms.[22] Second-degree AV block is characterized by intermittent AV conduction and can be divided into two subtypes. Second-degree AV block Mobitz type 1 (Wenckebach) presents with progressive PR interval lengthening followed by a nonconducted P wave. Second-degree AV block Mobitz type

II presents with fixed PR intervals and periodic nonconducted P waves. Third-degree (complete) AV block presents with AV dissociation.[21,22]

The acute treatment of bradycardia attributed to AV block is similar to that of SND. In addition to addressing reversible causes, chronotropic agents such as atropine, isoproterenol, dopamine, dobutamine, and epinephrine can be administered. Temporary pacing may be needed in patients who are hemodynamically unstable or with refractory symptoms.[21,23] Depending on the scenario, this can be accomplished using transcutaneous, transvenous, or epicardial modalities. Irrespective of symptoms, permanent pacemaker implantation is indicated for patients with second-degree AV block Mobitz type II, high-grade AV block, or third-degree AV block.[22] Additionally, a transthoracic echocardiogram is recommended in order to evaluate for the presence of structural heart disease.[21]

KEY POINTS

- Tachyarrhythmias and bradyarrhythmias are both associated with increased in-hospital mortality rates in the critically ill.
- Sinus tachycardia may represent a normal adaptive response to maintain cardiac output in the setting of decreased stroke volume, oxygen-carrying capacity, or arterial vascular tone.
- Beta-receptor antagonists are particularly effective for AF rate control in the setting of increased sympathetic tone from critical illness, sepsis, or the postoperative state.
- Treatment of torsades de pointes includes correcting electrolyte abnormalities, administering magnesium, discontinuing QT-prolonging agents, and increasing the ventricular rate.
- Symptomatic SND and AV block can be treated with chronotropic agents.

Arterial Hypoxemia

Jean-Louis Vincent

Normal cell function requires an adequate oxygen supply. Lack of oxygen at the cellular level is called *hypoxia.* Oxygen delivery (DO_2) to the tissues is determined by cardiac output and the arterial oxygen content, which in turn is determined by the hemoglobin concentration and its oxygen saturation. *Hypoxemia* is defined by a significantly low partial pressure of oxygen (PaO_2; less than about 75 mm Hg), regardless of the inspiratory oxygen fraction (FiO_2). Hypoxemia can be compensated for by an increase in cardiac output, so that DO_2 may not be critically reduced by its presence. The increase in cardiac output that accompanies hypoxemia is mediated by an increase in sympathetic tone, resulting in combined increases in heart rate and contractility. Impaired O_2 delivery to the tissues is more often the result of decreased cardiac output or altered vascular tone than of a decrease in PaO_2. Tissue hypoxia is a hallmark of shock and is associated with altered cellular metabolism that results in increased blood lactate levels. To avoid confusion, the word *hypoxia* should not be used to characterize a low PaO_2.

Hypoxemia is almost always the result of respiratory failure, but it can also be the result of cardiac abnormalities. A low cardiac output can aggravate hypoxemia via a reduction in oxygen saturation of the mixed venous blood (SvO_2) (see later). Moderate hypoxemia must be compensated for by an increase in cardiac output, which may be poorly tolerated in frail patients. When that compensatory mechanism is exhausted or when there is concurrent anemia, hypoxia can develop and result in multiple organ failure and cardiac arrest.

The nonlinear relationship between SaO_2 and PaO_2 is affected by body temperature, partial pressure of carbon dioxide in arterial blood ($PaCO_2$), pH, and 2,3-diphosphoglycerate concentration (Fig. 8.1). As a result, patients can have a higher or lower SaO_2 for a given PaO_2, depending on the existing conditions. The critical PaO_2 value is approximately 60 mm Hg, because a further decline in PaO_2 results in a steep fall in SaO_2.

Although PaO_2 reflects pulmonary function, it must be related to FiO_2 when judging oxygenating efficiency. (The PaO_2/FiO_2 ratio is one indicator commonly employed for that purpose.) The SaO_2 is the primary determinant of oxygen content and strongly influences DO_2. (Dissolved oxygen is a negligible fraction of the total oxygen transported per milliliter of blood.) Thus, giving supplemental oxygen to increase PaO_2 to supranormal levels does not appreciably increase DO_2 and is generally inadvisable except in the context of life-threatening anemia. Nevertheless doing so may have marginal utility if used immediately before interventions that may result in hypoxemia, such as endotracheal intubation or bronchoscopy.

PaO_2 and SaO_2 are measured by arterial blood gas analysis, which requires invasive sampling and is not performed continuously. Capillary blood oxygen saturation (SpO_2) can serve as a surrogate measure of SaO_2 and can be measured noninvasively and continuously with a pulse oximeter. Pulse oximetry uses spectrophotometry to detect oxyhemoglobin (peak absorption at 940 nm) and deoxyhemoglobin (peak absorption at 660 nm) via a pulsatile optical signal directed through tissue, with their ratio reflecting the SpO_2 in that tissue (e.g., fingertip or earlobe). However, this measurement can be affected by various factors. The SpO_2 may give a falsely low indication of the SaO_2 if there is poor pulsatility of the waveform: for example, in the presence of altered cutaneous perfusion. Light transmission through the tissues of the fingertip can be decreased by dark nail polish, again affecting that measurement. Methemoglobinemia can also result in a falsely low SpO_2 reading, whereas carboxyhemoglobinemia can result in a falsely elevated SpO_2 reading.[1]

Another issue with pulse oximetry, notably in critically ill patients, is that it takes many seconds for the SpO_2 to reflect acute changes in PaO_2, including those occurring as a result of alterations of oxygen administration and/or positive end-expiratory pressure (PEEP). Response times are even more prolonged when there is reduced cardiac output.[2,3]

CAUSES OF ARTERIAL HYPOXEMIA

Causes of hypoxemia can be categorized into four groups (Fig. 8.2).

1. Decreased Alveolar Oxygen Content (PAO_2)

According to the alveolar gas equation, the alveolar PAO_2 is determined by:

$$PAO_2 = FiO_2(P_{atm} - PH_2O) - PaCO_2/RQ,$$

where FiO_2 is the concentration of inspired oxygen, P_{atm} is the atmospheric pressure, PH_2O is the partial pressure of water (typically 47 mm Hg at ambient temperature), and RQ is the respiratory quotient[4,5] (i.e., the amount of oxygen consumed relative to the amount of carbon dioxide produced when nutrients are metabolized). RQ is generally assumed to be 0.8, although it may vary. Under normal conditions at sea level,

$$PAO_2 = 0.21\ (760\ \text{mm Hg} - 47\ \text{mm Hg}) - (40\ \text{mm Hg}/0.8) \approx 100\ \text{mm Hg}.$$

The first part of the equation can be affected by altitude because P_{atm} decreases.[6] The second part of the equation is primarily affected by $PaCO_2$, which typically results from hypoventilation (e.g., central respiratory depression, neuromuscular weakness). Hence, unless there is an increase in the concentration of inspired oxygen, PAO_2 can decrease in the presence of an increased $PaCO_2$, which in turn is determined by the following equation:

$$PaCO_2 = CO_2\ \text{production} \div (\text{respiratory rate} \times [\text{tidal volume} - \text{dead space}]).$$

Thus $PaCO_2$ can rise with an increase in CO_2 production (increased metabolism), a decrease in minute ventilation (e.g., because of central respiratory depression or neuromuscular weakness), and/or an increase in dead space ventilation.

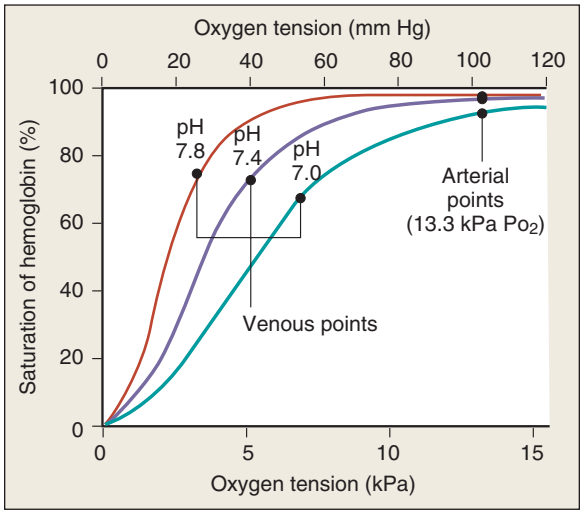

Fig. 8.1 Oxygen saturation varies with the PaO_2 in a nonlinear relationship and is affected by temperature, $PaCO_2$, pH, and 2,3-diphosphoglycerate (2,3-DPG) concentration.

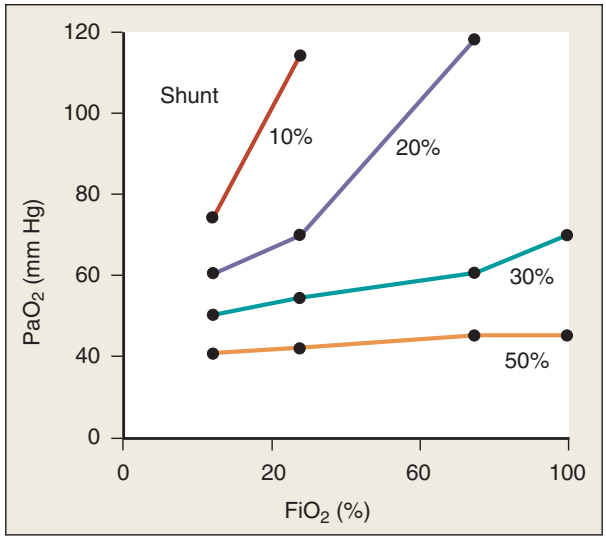

Fig. 8.3 Blunted response to increasing inspired oxygen concentration. A patient with a shunt greater than 50% has little response to increasing FiO_2.

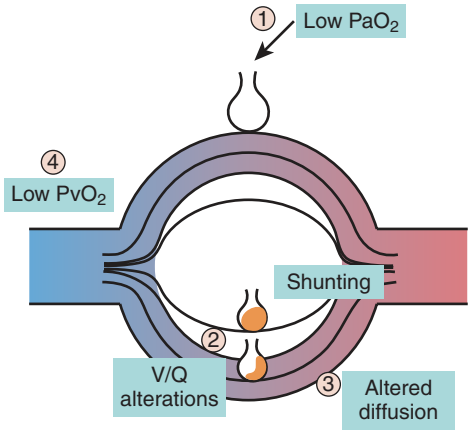

Fig. 8.2 The four mechanisms of hypoxemia. *V/Q,* Ventilation/perfusion.

2. Ventilation/Perfusion (V/Q) Mismatch and Presence of a Pulmonary Shunt

This is the most common cause of hypoxemia and arises when perfusion is maintained in regions that are no longer participating effectively in gas exchange: for example, atelectasis, pneumonia, or lung edema. Some therapeutic interventions may also contribute: in normal conditions, the presence of hypoxic pulmonary vasoconstriction reduces perfusion to underventilated areas of lung, but this mechanism can be altered by vasoactive medications (vasodilators in particular). Hence, a substantial fraction of the cardiac output will not participate in gas exchange and will be "shunted" to cause "venous admixture." The normal shunt fraction is approximately 3%–4% and arises primarily in the bronchial arterial circulation. Reduced ventilation of perfused alveoli increases the shunt fraction and thus decreases PaO_2. If V/Q alterations are partial, an increase in FiO_2 can largely correct this effect, but when the shunt is complete, an increase in FiO_2 will not improve PaO_2 (Fig. 8.3).

Right-to-left shunts can also be anatomic (e.g., intracardiac shunts and intrapulmonary shunts resulting from arteriovenous malformations). Anatomic shunting can also develop in end-stage liver disease.

Pulmonary perfusion is not homogeneous: dependent areas are preferentially perfused compared with nondependent ones. As a result, changes in the patient's position can alter arterial oxygenation, depending on the location and distribution of the underventilated lung areas or the regions of intrapulmonary shunt. If the patient is placed in a position in which the underventilated areas of the lung (often gravitationally dependent zones in the setting of lung injury) are also the ones receiving rich perfusion, hypoxemia will worsen. Placing a patient with severe acute respiratory distress syndrome (ARDS) in the prone position can therefore improve gas exchange.[7]

In the presence of severe respiratory failure, pulmonary hypertension resulting in elevated right heart pressures may reopen a patent foramen ovale, thereby creating an intracardiac right-to-left shunt. This possibility should be considered when an increase in PEEP therapy worsens gas exchange.

Of note, the opposite of shunt is increased dead space, where preserved alveolar ventilation is associated with reduced perfusion. This predisposes to increased $PaCO_2$, which can be compensated for by increasing minute ventilation. Massive pulmonary embolism and diffuse lung injury that reduces the capacity of the "baby lung" are typical causes of increased dead space. Hypoxemia commonly observed in this condition is not straightforward.

3. Impaired Diffusion

Acting alone, this is a rare cause of hypoxemia in the acutely ill. It can result from an increase in the diffusion distance between the alveolar space and the capillary lumen. A reduction in the capillary transit time can occur as a result of a dramatic increase in cardiac output during strenuous exercise. Combinations of rapid transit coupled with the innately impaired diffusing properties of injured tissue may accentuate hypoxemia.

4. A Decrease in the Oxygen Saturation of Mixed Venous Blood (SvO_2) Can Contribute to the Severity of Hypoxemia

This is usually because of inadequate cardiac output, anemia, or increased oxygen consumption by body tissues. However, in the absence of parenchymal damage or admixture/shunt from other causes, low

SvO_2 does not alter the effectiveness of oxygenating blood passing through the gas exchanger of the healthy lung.

MANAGEMENT OF ARTERIAL HYPOXEMIA

The first action to increase PaO_2 is to increase the FiO_2 If the response is unsatisfactory, one can consider increasing the flow rate of supplemental oxygen or using a mask with an oxygen reservoir (i.e., a "nonrebreather mask"). If the response is still poor, then the patient is likely to have severe V/Q mismatching or a true right-to-left shunt. The next step should be to try to reopen closed alveoli by repositioning and applying positive pressure ventilation using continuous positive airway pressure (CPAP) in the absence of endotracheal intubation, or PEEP if the patient is receiving mechanical ventilation (noninvasive or invasive). Relief of an excessive breathing workload and a high oxygen consumption often helps restore the balance, allowing effective O_2 delivery. Prone positioning improves arterial oxygenation in the majority of ARDS patients.

KEY POINTS

- PaO_2 (in relation to FiO_2) primarily reflects the lung function, and SaO_2 the amount of oxygen carried to the tissues.
- Hypoxemia is the result of four major mechanisms.
- The primary action to correct hypoxemia is to increase the FiO_2, increase the oxygen flux, or increase the intrathoracic pressure.

Acute Respiratory Failure

Igor Barjaktarevic, Roxana Cortes-Lopez, and Tisha Wang

Acute respiratory failure (ARF) is defined by the sudden onset of severe impairment of pulmonary gas exchange and is characterized by the inability of the lungs to meet the body's metabolic needs for the transport of oxygen (O_2) into the blood and/or removal of carbon dioxide (CO_2) from the blood. The diagnosis of ARF is based on the measurements of arterial blood gas (ABG) parameters (i.e., partial pressure of oxygen [PaO_2], partial pressure of carbon dioxide [$PaCO_2$], and pH), and these values must always be interpreted in relation to the patient's baseline status. As a final common pathway for a variety of illnesses, ARF is one of the most frequently encountered diagnoses in the intensive care unit (ICU), and its management represents one of the key challenges of critical care medicine. This chapter aims to tie the physiology of breathing to the pathologic processes that lead to ARF and will also discuss the clinical approach to the patient with ARF.

ARF is one of the most common reasons for admission to the ICU and accounts for ~2 million admissions per year in the United States.[1] More than half of all patients admitted to the medical ICU with stays >48 hours have ARF at some point during their hospitalization,[2] with overall mortality rates of >33%.[2–5] Mortality significantly increases with age, preexisting comorbidities, and the presence of shock or multisystem organ failure.[6] With the aging population in the United States, the incidence of patients with ARF is expected to increase by 80% over the next two decades.

COMPONENTS OF THE RESPIRATORY SYSTEM

Understanding the process of respiration is a key step in understanding and managing ARF. Respiratory control is established by the tight coordination of three groups of neurons in the medulla oblongata: a dorsal respiratory center that controls inspiration, a ventral respiratory group that controls expiration, and a pneumotaxic center that controls the rate and depth of breathing. In addition to neurons in the brainstem, a peripheral chemoreceptor system is located outside the brain in the form of carotid bodies and aortic bodies that detect subtle changes in PaO_2. The neural impulses from the central nervous system (CNS) traverse the spinal cord and motor neurons, reaching and activating the diaphragm and other respiratory muscles. Contraction of the inspiratory muscles creates negative pleural pressure by expanding the chest cavity and pushing the abdominal contents caudally. The negative pressure created in the thorax during inspiration leads to subatmospheric pressure in the alveoli, creating a gradient for the flow of inspired air toward the alveoli. Oxygen-rich inspired air allows the diffusion of O_2 from the alveoli to the blood through the alveolar–capillary membrane, where deoxygenated hemoglobin becomes saturated with O_2 to form oxyhemoglobin.

O_2 is consumed by all human tissues, and the ability to do so depends on gas exchange in the lungs. The average O_2 uptake of an adult is approximately 250 mL/min, although this rate depends on numerous factors.[7] Most (~98.5%) O_2 is carried to peripheral tissues via oxyhemoglobin, whereas the remainder is transported as O_2 dissolved in the fluid phase of blood. The total transport of O_2 by the arterial system is termed *oxygen delivery* (DO_2) and is normally several-fold higher than the O_2 demand of the peripheral tissues. However, O_2 utilization (VO_2) can become dependent on DO_2 in pathologic conditions such as ARF.[7–9] In these states, the normally balanced relationship between oxygen delivery and oxygen demand can be disrupted by decreased O_2 delivery or increased O_2 demand (Fig. 9.1).

DO_2 is the product of cardiac output and arterial oxygen content (CaO_2), a value determined by the concentration of hemoglobin (Hgb) and oxygen saturation (SaO_2) (Fig. 9.2). Adequate perfusion of capillaries in the peripheral tissues allows for the liberation of O_2 from oxyhemoglobin.

PATHOPHYSIOLOGIC PROCESSES LEADING TO ARF

ARF can be a consequence of a wide range of tissue defects, which can have both pulmonary and extrapulmonary etiologies. It is important to understand the mechanisms leading to hypoxemia, as the best therapeutic approach may require targeting the appropriate etiology. This, however, is often difficult in the early stages of managing a patient with acute hypoxemia. Considering a broad differential diagnosis for ARF is crucial to appropriate management of the underlying condition (Table 9.1).

CLASSIFICATION OF ARF

Respiratory failure can be classified as acute or chronic. The clinical presentation of ARF is typically dramatic and obvious, often with profound derangements in ABG values. "Acute on chronic" respiratory failure represents an acute deterioration in the presence of preexisting chronic pulmonary disease and chronic respiratory dysfunction. Chronic respiratory dysfunction may present with markers of chronic hypoxemia (e.g., polycythemia, or *cor pulmonale*) and may or may not require ICU care. Regardless of acuity, respiratory failure represents a potentially life-threatening group of disorders for which inadequate management may lead to rapid clinical deterioration.

ARF has been classically described as one of two types: hypoxemic or hypercarbic failure. More recent classifications categorize ARF into four different types, based on the mechanism of hypoxemia.[10] Table 9.2 describes differences among the four types of ARF with regard to the mechanism of hypoxemia, location of the abnormality, and most commonly seen clinical syndromes. Despite these categories, considerable overlap exists in the different types of ARF. Furthermore, a given patient can have multiple types of ARF contributing to their clinical presentation.

Type I or Classic "Hypoxemic" Respiratory Failure

Type I ARF is the most common form of respiratory failure and at sea level is defined by PaO_2 <60 mm Hg, with normal or decreased $PaCO_2$. The primary abnormality originates in one of three dysfunctions: (1) inadequately oxygenated alveoli (because of low fraction of inspired oxygen [FiO_2] and/or alveolar collapse and/or the presence of alveoli filled with fluid, cells, debris, or blood); (2) compromised transition of oxygen from the alveoli to the blood (because of interstitial processes or pulmonary vascular disease); or (3) compromised ability of the blood to oxygenate (because of obstructed blood flow, shunting, low Hgb concentration, or the presence of dysfunctional Hgb). The analysis of ABG values and calculation of the alveolar-arterial (A-a) gradient are important in the assessment of type I ARF.

Type II or "Hypercarbic" Respiratory Failure

Type II ARF ($PaCO_2$ >45 mm Hg) represents the failure of the lungs to remove a sufficient amount of CO_2 in a given time interval and is characterized by decreased alveolar minute ventilation. An increase in $PaCO_2$ leads to hypoxemia because CO_2 displaces O_2 and effectively reduces the alveolar partial pressure of oxygen (PAO_2). In contrast to some cases of type I ARF, hypoxemia in type II ARF is rather easily corrected with supplemental oxygen. This type of respiratory failure is frequently the result of acute or chronic neuromuscular dysfunction or

TABLE 9.1 Pathophysiologic Mechanisms That Lead to Hypoxia and Respiratory Insufficiency

1. Extrapulmonary processes, including chest wall and skeletal abnormalities (hypoxic hypoxia)
   a. Deficiency of oxygen in inspired air (high altitude, suffocation)
   b. Hypoactive hypoventilation (central nervous system trauma, drug toxicities, and neuromuscular and skeletal disorders)
   c. Upper airway obstruction leading to hypoventilation (trauma and angioedema)
2. Pulmonary etiologies (hypoxic hypoxia)
   a. Hypoventilation caused by increased airway resistance (chronic obstructive pulmonary disease and asthma)
   b. Abnormal alveolar ventilation–perfusion ratio (pulmonary embolism, pneumonia, aspiration, and emphysema)
   c. Diminished diffusing capacity via the alveolar–capillary membrane (interstitial lung disease and pulmonary vascular disease)
   d. Pulmonary shunting (atelectasis, pneumonia, hepatopulmonary syndrome, and arteriovenous malformations)
3. Cardiac right-to-left shunts (e.g., atrial septal defect [hypoxic hypoxia])
4. Inadequate capacity of blood to transport oxygen (anemic hypoxia)
   a. Anemia
   b. Hemoglobinopathies (methemoglobinemia and carbon monoxide poisoning)
5. Inadequate oxygen transport because of a circulatory defect (static hypoxia)
   a. General circulatory deficiency or collapse (shock or cardiac failure)
   b. Localized circulatory deficiency (peripheral, cerebral, and coronary vessels)
6. Abnormal tissue capability for using oxygen (histotoxic hypoxia)
   a. Late-stage irreversible shock
   b. Poisoning of cellular oxidation enzymes (cyanide or arsenic toxicity and heavy ethanol intoxication)
   c. Diminished cellular metabolic capacity for using oxygen

TABLE 9.2 Classification of Acute Respiratory Failure (Modified From[10])

	Type I	Type II	Type III	Type IV
Mechanism of hypoxemia	Low FiO_2 ventilation/perfusion (V/Q) mismatch Shunting Reduced diffusing capacity	Hypoventilation	Shunting Hypoventilation V/Q mismatch	Hypoperfusion or inadequate oxygenation of peripheral tissues
Location of pathologic process	Inhaled air composition Alveolar–capillary unit Oxygen-carrying capacity of blood	Airway Central nervous system (CNS) Neuromuscular system Chest wall	Alveolar–capillary unit collapse with regional hypoventilation	Cardiovascular system Peripheral tissues
Clinical syndromes	Cardiogenic pulmonary edema Acute respiratory distress syndrome (ARDS) Pneumonia Interstitial lung disease Pulmonary embolism Pulmonary hypertension Atelectasis Alveolar hemorrhage Carbon monoxide poisoning Anatomic shunts	Chronic obstructive pulmonary disease (COPD) Asthma CNS depression (intoxication) CNS trauma or injury Neuromuscular disorders Skeletal disorders Obesity–hypoventilation syndrome	ARDS Thoracic or upper abdominal surgery or trauma Inadequate postoperative analgesia Pleural tumor or inflammation Trapped lung Subdiaphragmatic tumor or inflammation Obesity	Septic (distributive) shock Hypovolemic shock Cardiogenic shock Compromised cellular oxidation Hypermetabolic states

FiO_2, Fraction of inspired oxygen.

the inability of the airways or lungs to ensure adequate ventilation and CO_2 exchange.

Type III or "Perioperative" Respiratory Failure

Type III respiratory failure is synonymous with perioperative respiratory failure and is related to atelectasis of the lung. It is often a consequence of abnormal abdominal and chest wall mechanics in the setting of surgery or trauma, especially those characterized by intrapleural or subdiaphragmatic pathologies. The patient usually splints the chest to limit involuntary movement of the injured region, leading to inadequate expansion of the dependent parts of the lungs, with resultant regional atelectasis and hypoventilation. As a result, type III ARF shares features with both type I (hypoxemic) and type II (hypercarbic) ARF. This type of ARF can be prevented or ameliorated by certain anesthetic strategies in addition to perioperative measures such as elevating the head of the bed, early ambulation, incentive spirometry, avoiding excessive sedation, and lowering intraabdominal pressure.

Type IV or "High-Demand" Respiratory Failure

Type IV respiratory failure is related to an inability of normal or relatively normal lungs to keep up with increased ventilatory demands associated with systemic hypermetabolism (e.g., secondary to sepsis). In other words, peripheral tissue demands cannot be satisfied by cardiorespiratory compensatory mechanisms. Under these conditions, respiratory muscle fatigue can lead to a requirement for mechanical ventilation (MV) to support adequate minute ventilation.

DIAGNOSTIC WORKUP

Obtaining a relevant history is crucial in narrowing down the etiology of ARF. A focused physical examination also helps assess the severity of respiratory failure and determine the need for immediate interventions. Common signs include tachypnea; the use of accessory respiratory muscles; nasal flaring; abdominal paradoxical breathing; and retractions in the intercostal, suprasternal, or supraclavicular areas. At times, irregular breathing patterns or poor chest wall excursion may be observed in addition to cough, wheezing, copious secretions, or cyanosis. A detailed examination of the upper airway and chest in addition to careful neurologic, cardiovascular, abdominal, skin, and musculoskeletal system examinations may also help narrow down the differential diagnosis. Table 9.3 lists common clues obtained from the history and physical examination of the patient, which can help diagnose the etiology of respiratory failure.

Before the comprehensive diagnostic workup, it is important to remember that establishing a diagnosis should not delay intervention in cases of severe ARF. ABG analysis should be obtained in all patients with suspected ARF. The ABG helps determine the chronicity of the respiratory failure and, more importantly, the extent and severity of the ARF. Fig. 9.3 schematically displays the changes in ABG parameters in acute and chronic respiratory disorders. Laboratory workup should also include complete blood count, basic metabolic profile, cardiac enzymes, and microbiologic evaluation. Chest imaging, including computed tomography (CT) when needed, can help with the diagnosis of a primary pulmonary pathology. Evaluating cardiac function with echocardiography can significantly narrow down the differential diagnosis in patients with systemic disease and shock. Increasing availability and accumulated evidence about the role of point-of-care ultrasound (POCUS) in the ICU has had a significant impact on the management of ARF. In addition to the broad cardiovascular assessment of critically ill patients with protocols such as Rapid Ultrasound for Shock and Hypotension (RUSH)[11] or Focused Assessment with Sonography in Trauma (FAST),[12] which are recommended aids to rapid recognition of the pathophysiologic processes leading to ARF, lung-centered POCUS techniques have also significantly evolved. The Bedside Lung Ultrasound Emergency (BLUE) protocol[13] for the immediate diagnosis of ARF has been widely implemented, and the ability of POCUS to facilitate more prompt and early management of ARF has become evident in recent years (Table 9.4).[14]

MANAGEMENT

Appropriate management of a patient with ARF usually requires admission to an ICU setting, where adequate support and close monitoring are available. Management should focus on stabilization of the patient's ventilatory and hemodynamic status in addition to

TABLE 9.3 Common Clues Obtained From the History, Symptoms, and Clinical Examination Findings That Can Help in the Initial Diagnostic Workup and Management of Acute Respiratory Failure

History and Symptoms	Signs on Physical Examination	Diagnosis
Cough, sputum, secretions	Rales or wheezing	Pneumonia, COPD exacerbation, bronchiectasis
Sudden onset of shortness of breath	Normal auscultation and percussion, possible signs of leg swelling to suggest deep vein thrombosis	Pulmonary embolism
History of heavy smoking	Wheezing, rhonchi	Emphysema, chronic bronchitis
Orthopnea, chest pain, paroxysmal nocturnal dyspnea	Arrhythmia, peripheral edema, jugular venous distention, peripheral hypoperfusion	Congestive heart failure or acute coronary syndrome
Trauma, aspiration, blood transfusions	Diffuse crackles	ARDS
History of allergies, wheezing or airway disease	Wheezing	Asthma, COPD
Exposure to heavy metals, handling of animals, dust, or other significant environmental exposures	"Velcro" rales, clubbing	Chronic interstitial lung disease
Choking, aspiration, vomiting, dental procedures	Inspiratory stridor, poor air entry	Foreign body
Drug abuse	Constricted or dilated pupils, altered mental status, skin marks, perforated nasal septum, hypersalivation, decreased respiratory frequency	CNS depression, intoxication
Exposure to a new drug/chemical or foods known to be allergenic	Swollen oral mucosa and tongue; stridor or wheezing	Angioedema, anaphylaxis
Progressive muscle weakness or immobility	Sensory abnormalities	Neuromuscular disorders
Trauma, procedures, inhalational injury	Absent breath sounds unilaterally, hypertympanic, tracheal deviation	Pneumothorax
Trauma, procedures	Absent breath sounds, dull on percussion, tracheal deviation	Hemothorax

ARDS, Acute respiratory distress syndrome; *CNS,* central nervous system; *COPD,* chronic pulmonary obstructive disease.

correction of the pathophysiologic process underlying the respiratory failure. Prioritizing airway patency, breathing, and circulation has long been a basic tenet in the management of ARF, or the so-called "ABC" of ARF management (not to be confused with the American Heart Association's guidelines for cardiac arrest management).[15]

TABLE 9.4 Ultrasound Findings of Common Etiologies of Acute Respiratory Failure

Clinical Finding	Ultrasound Finding
Pneumothorax	Absence of "lung sliding" "Lung point" Absence of "comet tail" artifact "Bar code" sign on M-mode
Pleural effusion	Hypoechoic space "Quad" sign "Sinusoid" sign on M-mode
Pneumonia	Consolidation Hepatization of lung Dynamic air bronchograms
Pulmonary embolism	Peripheral wedge-shaped consolidation RV dysfunction (RV dilation, >1:1 RV:LV ratio, bowing of interventricular septum into LV) Pleural effusion
Pulmonary edema	>3 B-lines per intercostal space
Interstitial lung disease	Irregular pleural line Subpleural cysts Decreased lung sliding B-lines

Airway Patency

Securing airway patency is the first step in the management of ARF. This usually requires interventions such as positioning, suctioning of secretions, treatment with bronchodilators, and/or placement of an oral airway. When physical obstruction of the upper airway by a foreign body or mass is suspected, advanced invasive procedures, such as laryngoscopy or bronchoscopy, may be necessary. In cases of severe respiratory compromise that require more invasive ventilatory management, endotracheal intubation is indicated. This can be achieved via orotracheal or nasotracheal intubation or, in difficult cases when an endotracheal tube cannot be advanced through the vocal cords, emergency cricothyroidotomy. The inability of a patient to protect their airway because of compromised mental status (usually with a Glasgow Coma Scale score <8) also warrants endotracheal intubation to secure the airway. The process of securing the airway in ARF requires an understanding of the ongoing pathologic process and an advanced knowledge of the anatomy of the upper airway. Appropriate monitoring and measures to maintain adequate oxygenation during the process should be undertaken.

Breathing

Breathing encompasses oxygenation and ventilation and is based on the movement of fresh, oxygenated air into and out of the lungs, enabling gas exchange by bringing in oxygen and flushing out carbon dioxide. Breathing assistance is required for both oxygenation and ventilation disorders. Treating hypoxemia should be the first step, which usually can be achieved with supplemental oxygen. Oxygen can be provided via nasal cannula, face mask, Venturi mask, nonrebreather mask, or high-flow oxygen delivery devices. When hypoxemia cannot be corrected with supplemental oxygen alone or ventilation is compromised, transition to MV may be necessary. MV may be provided via noninvasive ventilation (NIV) or via invasive MV through an endotracheal tube. Severe respiratory failure with an inability to oxygenate and/or ventilate despite MV may occasionally require assisted gas exchange by extracorporeal membrane oxygenation (ECMO).[16]

Circulation

Natural breathing without positive airway pressure not only provides gas exchange but also affects hemodynamics on a breath-to-breath basis, allowing unimpeded venous return and cardiac output. Circulation affects our respiratory patterns, and they are also affected by ventilatory mechanics. Treating hypotension or hypertension and optimizing cardiac output may help treat the underlying etiology of ARF and offset the potentially adverse effects of positive pressure ventilation on cardiac preload and afterload. Also, anesthetics and sedatives used for mechanically ventilated patients, in addition to paralytics used for intubation, often have significant hemodynamic effects that should be anticipated and aggressively corrected as necessary.

Further Management and Monitoring

Along with focusing on the "ABC" of ARF, the treatment of its underlying cause is of paramount importance to the patient's outcome. Antibiotics and source control for the management of infections, cardiac or inotropic medications, revascularization, air or fluid evacuation, anticoagulation or thrombolysis, fluid expansion, diuretics, vasodilators, bronchodilators, and glucocorticoids, in addition to many other medications and interventions, may be required to treat the underlying etiology.

The success and adequacy of the management of ARF should be continuously monitored. Multiple blood gas analyses may be required to ensure that both oxygenation and ventilation are maintained within desired limits. In general, PaO_2 should be maintained at >55–60 mm Hg, a range that represents a threshold for severe hypoxemia. Arterial blood oxygen saturation (SpO_2) can be tested and correlated to PaO_2 and can be used as a surrogate marker for the adequacy of oxygenation, with a general recommended goal of >88%. pH and arterial or central venous PCO_2 values reflect the adequacy of MV and are also useful in the setting of a metabolic acid-base disorder. ABG goals should in general be individualized. For example, permissive hypercapnia may be appropriate for some patients, whereas other patients may benefit from therapeutic hyperventilation.

Ventilatory/Oxygenation Support Strategies and Mechanical Ventilation

The purpose of MV is to improve oxygenation and ventilation to correct respiratory acidosis and hypoxemia, meet metabolic demands, rest respiratory muscles, and optimize cardiac function and blood circulation. MV allows for augmented or controlled minute ventilation and the provision of high concentrations of oxygen and positive end-expiratory pressure (PEEP). MV may therefore positively affect gas exchange and the regional distribution of lung aeration and ventilation.[17] MV can be *noninvasive,* involving a variety of interfaces such as nasal or face masks, or *invasive,* involving endotracheal intubation. General indications for intubation and invasive MV are described in Table 9.5.

NIV has been increasingly used in the past two decades as an alternative to endotracheal intubation and MV in appropriate clinical settings.[18] NIV with continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) modalities benefits selected cases of chronic obstructive pulmonary disease (COPD) exacerbation, cardiogenic pulmonary edema, obesity hypoventilation, decompensated obstructive sleep apnea, and neuromuscular disease.[18,19] It has also been used successfully for respiratory failure in postoperative patients,[20] immunocompromised patients,[21] or in patients with a do-not-intubate (DNI) code status.[22]

NIV requires the patient's cooperation and an anatomically preserved, functional upper airway. It is not a replacement for invasive MV, nor is it suitable for all patients with ARF. Significantly depressed mental status with an inability to protect the airway, copious secretions, massive hemoptysis or hematemesis, recent upper gastrointestinal and facial surgery, bowel obstruction, facial trauma or deformity, cardiopulmonary arrest, and severe arrhythmias are contraindications to its use.[19] NIV is not always prudent as the first step in advanced hypoxemic respiratory failure, as it may lead to a more difficult transition to MV in cases of NIV failure.[23] There is some evidence, however, that it can be of benefit in the setting of severe hypoxemia during the

TABLE 9.5 General Indications for Intubation and Mechanical Ventilation

Cardiopulmonary arrest or impending arrest
Respiratory distress/tachypnea with increased ventilatory demand and breathing effort leading to respiratory muscle fatigue
Severe hypercarbic respiratory failure with either poor candidacy for NIV or failure of NIV
Severe refractory hypoxemia with failure of noninvasive oxygen delivery devices
Severe refractory metabolic acid-base disorder
Inability to protect the airway
Inability to clear secretions
Need for therapeutic hyperventilation or hypoventilation
Upper airway obstruction with poor airway patency
Decreased respiratory drive with bradypnea
Coma with Glasgow Coma Scale score of <8
Severe trauma
Surgery requiring general anesthesia

NIV, Noninvasive ventilation.

process of *transitioning* to invasive MV.[24] In circulatory shock states that lead to type IV ARF, NIV may adversely affect venous return and pulmonary hemodynamics in volume-depleted patients.[25]

A recent alternative to NIV and perhaps to MV has been the use of high-flow nasal cannula (HFNC). This newer oxygen delivery system provides heated and humidified air at 21%–100% of FiO_2 with flow rates of up to 60 liters per minute (L/min). Oxygen-enriched gas is delivered through a large-bore nasal cannula that helps prevent entrainment of room air. Mechanisms by which HFNC helps improve oxygenation and ventilation include provision of heated, humidified gas that aids mucociliary clearance; delivery of gas at high-flow rates to match patient demand; generation of low-level PEEP; washout of dead space from the upper airway; minimization of oxygen dilution; and improved patient comfort when compared with other options for respiratory support.[26]

A prospective, multicenter, randomized controlled trial published in 2015 evaluated patients admitted to the ICU with acute hypoxemic respiratory failure and determined that HFNC as compared with NIV and standard oxygen therapy alone did not reduce intubation rates but did reduce ICU mortality at 90 days.[27] HFNC was especially beneficial in patients with severe hypoxemia, defined as PaO_2:FiO_2 ≤200 mm Hg, in whom HFNC also reduced the rate of intubation.

Retrospective studies have also investigated the use of HFNC in critically ill patients during hypercarbic respiratory failure, with possible benefits.[28] The use of HFNC in this population, however, is not well-established.

Invasive MV requires an endotracheal or tracheostomy tube to seal the interface between the patient and the ventilator. Before initiation of invasive MV, a careful assessment of risks and benefits needs to be undertaken, as both intubation and MV carry risks of potentially fatal complications. Although it is clearly a lifesaving measure when appropriately used, invasive MV may lead to significant hemodynamic compromise that results from the sedative effects of medications used for intubation and MV; abrogation of the patient's inspiratory drive; and changes in cardiac preload, afterload, and interventricular dependence.[29,30] MV also increases the risks of ventilation-associated lung injury, dynamic hyperinflation, and pneumonia, in addition to the discomfort of patient–ventilator asynchrony. Importantly, in situations involving terminal illnesses or irreversible etiologies of ARF, a discussion with the patient and family regarding the appropriateness and expectations of invasive MV is warranted.

Evaluation of the patient's anatomy, such as the presence of facial hair; oral cavity inspection, including dentition; neck shape and mobility; and the presence of secretions or obstruction, is helpful for predicting the odds of a difficult intubation and for planning the specific intubation approach. Before intubation, the operator needs to carefully choose sedatives and anesthetics, secure vascular access, prepare hemodynamic support, adequately preoxygenate the patient, and prepare for supportive manual bag–valve mask ventilation.[23] It is important to remember that every intubation in the setting of ARF may become a difficult intubation,[31] and experienced operators and rescue strategies for securing the airway need to be available. Upon endotracheal intubation, the tube position should be confirmed and secured to avoid accidental extubation.

While attached to a ventilator, the patient's comfort, gas exchange, mechanics, and ventilator waveforms need to be continuously monitored. Adequate analgesia must be provided while using the least sedation required to achieve comfort and ventilator synchrony.[32–34] Spontaneous breathing trials should be initiated daily once the patient's condition is stable.[34–36] With few exceptions, the upper body should be elevated to >30 degrees, and daily prophylaxis for deep venous thrombosis should be provided.

In patients with or at high risk for acute lung injury and acute respiratory distress syndrome (ARDS), a lung-protective ventilation strategy should be used. This entails using low tidal volumes (5–7 mL/kg of ideal body weight), permissive hypercapnia, PEEP of 5–15 cm H_2O to best compliance, and maintaining noninjurious inspiratory driving and plateau pressures (<15 and 30 cm H_2O, respectively).[37,38] In patients without ARDS but with respiratory failure, strict adherence to low tidal volumes may be less crucial, as recent data suggest that an intermediate tidal volume ventilation strategy may keep safe airway pressure targets and have similar outcomes in this patient population.[39] Early neuromuscular paralysis can be used in cases of severe ARDS or in patients experiencing ventilator dyssynchrony despite high doses of sedatives.[40] In cases of refractory hypoxemia, additional strategies,[41] including prone positioning,[42] pulmonary vasodilators (e.g., inhaled nitric oxide),[43] recruitment maneuvers,[44] high-frequency oscillatory ventilation,[45] or airway pressure release ventilation (APRV or bilevel ventilation),[46] have been used but with variable success rates.

In patients with severe ARDS, early use of paralytics for brief periods (,48 hours) had been previously accepted as the standard of care after the ACURASYS trial demonstrated a decrease in 90-day mortality.[32,40] The Prevention and Early Treatment of Acute Lung Injury (PETAL) network has since conducted the ROSE trial, a larger trial of ARDS patients examining paralysis versus usual care with lighter sedation. This more recently published trial did not confirm benefit of routinely initiating paralytics on mortality or other secondary outcomes.[47]

Prone positioning is another adjunctive therapy used in the treatment of hypoxic respiratory failure. Prone positioning recruits dependent lung regions, which helps improve ventilation–perfusion matching and may help gas exchange by more equally distributing tidal volumes and associated transpulmonary pressures. The latter reduces average tissue stress on the lung, helping in the "lung protective" strategy. In a large trial using prone positioning for ≥16 hours a day in patients with severe ARDS (PaO_2:FiO_2 ≤150 mm Hg), a significant reduction in 90-day mortality was observed.[42] However, in a subsequent Cochrane review of nine trials of varying quality that looked at the effects of prone positioning on outcomes, no consistent evidence of benefit or harm was found.[48] Differences in patient selection, duration, and severity of disease may help explain this apparent discord.

Patients with profound nonresolving ARF despite the previously mentioned strategies should be considered for ECMO if the underlying etiology is considered reversible.[49] Although no clear evidence of a mortality benefit exists for the early implementation of ECMO in patients with severe ARDS, the EOLIA trial showed increases in prone positioning–free days, renal failure–free days, and renal replacement–free days in patients with early referral to an ECMO center.[50]

CONCLUSION

ARF is one of the most common conditions encountered in critical care medicine and is associated with significant morbidity and mortality. Understanding the pathophysiology of ARF with regard to oxygen consumption, delivery, and transport; the etiologies of ARF (types I–IV); and the clinical presentation (acute or acute on chronic) is essential for the skilled management of these patients. The priority in the management of ARF is to focus on the "ABC" approach, with efficient and effective decision making regarding the use of HFNC, NIV, and/or invasive MV. Finally, therapies need to be directed at both the ARF itself and the underlying condition in order to optimize patient outcomes.

KEY POINTS

- ARF is one of the most common indications for admission to the ICU and carries a high morbidity and mortality.
- An understanding of the pathophysiology of respiratory failure and a focus on the stabilization of oxygenation, ventilation, and hemodynamics are essential in the management of ARF.
- Respiratory failure can be divided into four categories: hypoxemic, hypercarbic, perioperative, and high-demand respiratory failure, although in practice, it is often a combination of multiple categories.
- The use of HFNC can be considered a noninferior alternative to NIV for acute hypoxic respiratory failure and may have a survival benefit in patients with severe hypoxemia.
- NIV in select cases of acute hypercarbic respiratory failure has been shown to reduce dyspnea, ICU length of stay, need for mechanical intubation, and mortality.
- Adjunctive therapies for the treatment of moderate to severe ARDS include prone positioning, early paralytic use, and lung-protective ventilation.
- Although without clear evidence to support a mortality benefit, data suggest that the early implementation of ECMO for patients with severe ARDS may lead to improved outcomes.

Garland A, Dawson NV, Altmann I, Thomas CL, Phillips RS, Tsevat J, et al. Outcomes up to 5 years after severe, acute respiratory failure. *Chest*. 2004;126(6):1897–1904.
Investigators assessed the long-term prognosis of patients hospitalized for acute respiratory failure requiring mechanical ventilation using the SUPPORT study database, a prospective five-center study that included >1700 patients. Of those who survived hospitalization, ~37% of patients died during posthospital follow-up, with survival declining the most in the first year after discharge. Posthospital death was associated with older age, male gender, worse prehospitalization functional capacity, and being unable to return home after hospital discharge.

Leach RM & Treacher DF. The pulmonary physician in critical care 2: oxygen delivery and consumption in the critically ill. *Thorax*. 2002;57(2):170–177.
To best care for a critically ill patient, it is important to have a good understanding of the pathophysiology of the process ultimately leading to shock. This review article provides an explanation and review of oxygen transport, delivery, and consumption.

Organized jointly by the American Thoracic Society, the European Respiratory Society, the European Society of Intensive Care Medicine, and the Société de Réanimation de Langue Française, and approved by ATS Board of Directors. International Consensus Conferences in Intensive Care Medicine: noninvasive positive pressure ventilation in acute respiratory failure. *American Journal of Respiratory and Critical Care Medicine*. 2001;163(1):283–291.
This publication provides a detailed summary of the use of noninvasive positive pressure ventilation (NIV) for acute respiratory failure. It includes a detailed review of the different modes of NIV and the indications and contraindications to the use of NIV.

Roupie E, Lepage E, Wysocki M, Fagon JY, Chastre J, Dreyfuss D, et al. Prevalence, etiologies and outcome of the acute respiratory distress syndrome among hypoxemic ventilated patients. SRLF Collaborative Group on Mechanical Ventilation. Société de Réanimation de Langue Française. *Intensive Care Medicine*. 1999;25(9):920–929.
This prospective, multicenter cohort study of 36 French ICUs evaluated the prevalence and outcome of patients with ARDS requiring mechanical ventilation using the American-European Consensus Conference definition of ARDS. Patients were categorized into three groups depending on the severity of hypoxemia and whether they met ARDS criteria and were followed for 28 days. The prevalence of ARDS was 6.9% of all ICU admissions and accounted for 15.8% of mechanically ventilated patients. Mortality rate was highest among the group with hypoxemia who met ARDS criteria (60%) when compared with other hypoxemic, non-ARDS ventilated patients. Three variables were independently linked to mortality: SAPS II score at inclusion, septic shock, and immunosuppression.

Slutsky AS. Mechanical ventilation. American College of Chest Physicians' Consensus Conference. *Chest*. 1993;104(6):1833–1859.
This article summarizes key concepts of mechanical ventilation to provide recommendations on the management of mechanical ventilation in specific situations. These recommendations were a result of an international consensus committee meeting consisting of specialists within anesthesia, critical care, and pulmonary and respiratory therapy. This meeting provided the basis of some of the most important concepts of mechanical ventilation that are still used today.

The Acute Respiratory Distress Syndrome Network. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *New England Journal of Medicine*. 2000;342(18):1301–1308.
This multicenter, randomized controlled trial served to create a paradigm shift in the traditional approach to mechanical ventilation. It sought to compare ventilation with traditional lung volumes (10–15 mL/kg of predicted body weight) versus lower tidal volumes (4–6 mL/kg of predicted body weight) to determine if there was a difference in mortality and ventilator-free days. The trial was stopped early, as mortality was significantly lower in the low tidal volume ventilation group.

Hyperbaric Oxygen in Critical Care

Kinjal N. Sethuraman and Stephen R. Thom

Hyperbaric oxygen (HBO_2) treatment involves intermittent breathing of pure oxygen at greater than ambient pressure (>1.4 atmospheres absolute [ATA]). Over the past 20 years, HBO_2 has undergone refinement, with an increased understanding of the mechanisms of action and clinical applications.

APPLICATIONS

HBO_2 treatment is carried out in either a monoplace (single person) or multiplace (typically two or more) chamber. Pressures applied while in the chamber are usually 2–3 ATA, representing the sum of the atmospheric pressure plus additional hydrostatic pressure equivalent to 1 or 2 atmospheres. Treatments are usually for 2–8 hours, depending on the indication, and may be performed between 1 and 3 times daily. Monoplace chambers are usually compressed with pure oxygen. Multiplace chambers are pressurized with air, and patients breathe pure oxygen through a tight-fitting face mask, hood, or endotracheal tube. Multiplace chambers require an inside tender to manage the starting and stopping of supplemental oxygen. Patient selection is important when choosing a monoplace vs. multiplace chamber for treatment. During treatment, arterial oxygenation as indexed by the PaO_2, typically exceeds 2000 mm Hg and levels of 200–400 mm Hg occur in tissues.[1]

HBO_2 should be viewed as a drug and the hyperbaric chamber as a dosing device. Elevating tissue oxygen tension is a primary effect. Although this may alleviate physiologic stress in hypoxic tissues, lasting benefits of HBO_2 must relate to an abatement of the underlying pathophysiologic processes. As knowledge surrounding the biochemical effects of HBO_2 grows, there may be an increase in the list of indications for it. The current accepted indications comprise a heterogeneous group of disorders (Box 10.1), thus implying that there are several mechanisms of action for HBO_2 (Box 10.2).[1–3]

In this chapter, we discuss the most common emergent indications for HBO_2.

Arterial Gas Embolism and Decompression Sickness

Among the earliest applications of hyperbaric therapy was to treat disorders related to gas bubbles in the body. Compressed air construction work required exposure to elevated ambient pressure within compartments (caissons) for many hours to excavate tunnels or bridge foundations in muddy soil that otherwise would flood. In the 19th century, workers were noted to frequently experience joint pain, limb paralysis, or pulmonary compromise when they returned to ambient pressure. This condition—decompression sickness (DCS), caisson disease, or bends—was later attributed to nitrogen bubbles in the body, and recompression was found to relieve symptoms. Recompression to treat DCS, based purely on Boyle's law with a reduction of gas bubble volume caused by pressure, was later improved by adding supplemental oxygen. Doing so hastens inert gas diffusion out of the body and may exert beneficial effects by additional therapeutic mechanisms. Similar observations were made at later times for scuba divers who also are prone to DCS and may develop arterial gas embolism (AGE) caused by pulmonary overpressurization on decompression.

Iatrogenic AGE has been reported in association with different types of interventions that include cardiovascular, obstetric/gynecologic, neurosurgical, and orthopedic procedures. AGE can occur whenever disruption of a vascular wall separating blood from gas occurs. Nonsurgical processes reported to cause AGE include overexpansion during mechanical ventilation, hemodialysis, and after accidental opening of central venous catheters.[4]

Treatment of gas bubble disorders includes standard support of airway, ventilation, and circulation plus prompt application of HBO_2. Gas bubbles may persist for several days, and although delays should be avoided, HBO_2 may be beneficial even when begun after long delays.[5–9] Controlled animal trials support the efficacy of HBO_2, but randomized clinical trials have not been conducted.[10] Yet in their review of 27 case series, Moon and Gorman described the substantial benefit of HBO_2 treatment, in which 78% of 441 cases receiving HBO_2 fully recovered and 4.5% died, whereas only 26% of 74 cases not undergoing HBO_2 treatment fully recovered and 52% died.[4]

Mechanisms of action of HBO_2 in AGE and DCS treatment include the reduction of gas bubble size according to Boyle's law, hyperoxygenation to hasten inert gas diffusion, inhibition of leukocyte adherence to injured endothelium, and inhibition of inflammatory microparticle formation.[11] Endothelial dysfunction occurs in association with mechanical interactions of bubbles at vessel walls and lumen occlusion.[12–16] Neutrophil activation and perivascular adherence occur and are associated with functional deficits post decompression.[4,17,18] Animals depleted of leukocytes before experimental cerebral air embolism suffer less severe reduction in cerebral blood flow and better neurologic outcome.[19] HBO_2 has been shown to temporarily inhibit human beta-2-integrin adhesion function.[20] Inhibition of neutrophil beta-2-integrin adhesion by HBO_2 has been described in a number of animal models, including skeletal muscle ischemia-reperfusion, cerebral ischemia-reperfusion, pulmonary smoke inhalation injury, and brain injury after carbon monoxide (CO) poisoning.[21–24] The mechanism for this effect involves *S*-nitrosylation of cytoskeletal beta-actin, which impedes the coordinated cell-surface beta-2-integrin migration required for firm adherence.[25]

Carbon Monoxide Poisoning

CO is the leading cause of injury and death by poisoning in the world.[26] The affinity of CO for hemoglobin to form carboxyhemoglobin (COHb), is more than 200-fold greater than that of O_2. CO-mediated hypoxic stress is a primary insult, but COHb values correlate poorly with clinical outcome.[27–33] Pathologic mechanisms, in addition to elevations of COHb, include intravascular platelet-leukocyte aggregation,

BOX 10.1 Accepted Indications for Hyperbaric Oxygen Therapy

- Air or gas embolism
- Carbon monoxide poisoning
- Clostridial myositis and myonecrosis
- Crush injury, compartment syndrome, acute traumatic ischemia
- Decompression sickness
- Enhancement of healing in selected problem wounds
- Severe anemia
- Intracranial abscess
- Necrotizing fasciitis
- Refractory osteomyelitis
- Radiation necrosis
  - Delayed radiation injury
- Compromised skin grafts and flaps
- Thermal burns
- Central retinal artery occlusion
- Idiopathic sudden sensorineural hearing loss

Data from Weaver, LK, ed. *Hyperbaric Oxygen Therapy Indications*, 13th ed. Durham, NC: Undersea and Hyperbaric Medical Society; 2014.

BOX 10.2 Mechanisms of Action of Hyperbaric Oxygen

Related to Hyperoxygenation of Tissues

- Angiogenesis/neovascularization/osteogenesis/epithelization in ischemic tissues (mechanisms likely include O_2 behaving as an intracellular signal transducer, leading to augmentation of one or more growth factors and mobilization of vasculogenic stem cells)
- Bacteriostatic/bactericidal actions
- Carboxyhemoglobin dissociation hastened
- Inhibition of *Clostridium perfringens* alpha toxin synthesis
- Improved phagocytic bacterial killing
- Temporary inhibition of neutrophil beta-2-integrin adhesion
- Vasoconstriction
  - Induction of growth factors and growth factor receptors
  - Inhibition of neutrophil adhesion
  - Reduction of ischemia reperfusion injury
  - Reduction in inflammation and edema

Related to Pressurization

- Reduction of gas bubble volume (Boyle's law)

leukocyte-mediated oxidative injury to the brain, the excessive release of amino acids (e.g., glutamate), impaired mitochondrial oxidative phosphorylation, and possible myocardial calcium overload.[34–40]

Survivors of acute CO poisoning are at risk for developing delayed neurologic sequelae (DNS) that include cognitive deficits, memory loss, dementia, parkinsonism, paralysis, chorea, cortical blindness, psychosis, personality changes, and peripheral neuropathy. DNS typically occurs from 2 to 40 days after poisoning, and its incidence is from 25% to 50% after severe poisoning.

Administration of supplemental oxygen is the cornerstone of treatment for CO poisoning. Oxygen inhalation will hasten the dissociation of CO from hemoglobin and provide enhanced tissue oxygenation. HBO_2 causes COHb dissociation to occur at a rate greater than that achievable by breathing pure oxygen at sea level. Additionally, HBO_2, but not ambient pressure oxygen treatment, has several actions that have been demonstrated in animal models to be beneficial in ameliorating pathophysiologic events associated with central nervous system (CNS) injuries mediated by CO. These include an improvement in mitochondrial oxidative processes,[41] inhibition of lipid peroxidation,[42] and impairment of leukocyte adhesion to injured microvasculature.[23] Animals poisoned with CO and treated with HBO_2 have been found to have more rapid improvement in cardiovascular status,[43] lower mortality,[44] and diminished incidence of neurologic sequelae.[45] A large study from China comparing patients with carbon monoxide toxicity who received HBO_2 and those who did not showed decreased mortality.[46]

Despite criticisms of their analysis, a meta-analysis by the Cochrane Library concluded that it is unclear whether HBO_2 reduces the incidence of adverse CO-mediated neurologic outcomes.[47] Five prospective, randomized trials have assessed the clinical efficacy of HBO_2 for acute CO poisoning.[31–33,48,49] Several studies failed to find a benefit,[31,49] but methodologic weaknesses discussed by several authors[40,50] diminish their clinical impact. Only one clinical trial satisfies all characteristics deemed necessary for the highest quality of randomized controlled trials.[51] The variation in patient selection, hyperbaric oxygen dose, and methodology contribute to the skepticism that these studies create. Overall, patients who received 2.8 ATA of HBO_2 had better outcomes than those who received 2.0 ATA, implying a dose-dependent response to treatment. In patients exposed to smoke and fire, careful attention needs to be paid to the patient's airway, and early intubation should be strongly considered. Some patients being treated for CO toxicity become more alert during HBO_2 therapy, and therefore in ventilated patients, adequate sedation should be prioritized because of the risk of dislodging the endotracheal tube and patient safety. Some burn centers employ adjunctive HBO_2 for severe burns. Animal models have documented benefits with HBO_2 in reducing partial- to full-thickness skin loss, hastening epithelialization, and lowering mortality.[1] Randomized clinical trials, albeit with small patient numbers, have reported improved rates of healing of burns with shorter hospitalization stays and therefore reduced costs.[52–55] The rationale for treatment has been based on reducing tissue edema and increasing neovascularization. There is growing evidence that HBO_2 benefits patients with severe burns. A comparative study of patients with 20%–60% body surface area thermal burns showed that patients receiving 6–10 HBO_2 treatments over 2 weeks had lower levels of proinflammatory cytokines, reduced length of stay in the hospital, and fewer complications.[56]

Clostridial Myonecrosis (Gas Gangrene)

Successful treatment of gas gangrene depends on prompt recognition and aggressive intervention. Early treatment with HBO_2 is recommended to inhibit the production of alpha-toxin by *Clostridium perfringens*. Mortality rates with conventional therapy from 11% to 52% have been reported. Currently, there are five retrospective comparisons using HBO_2 and 13 case series in the literature. These have been discussed in several reviews.[1,57,58] Because of difficulties with comparison among patient groups, impartial assessment of HBO_2 efficacy based on mortality or "tissue salvage" rates is difficult. Most authors comment on clinical benefits associated with treatment. Temporal improvement of vital signs in patients with gangrene can be among the most dramatic observations in day-to-day practice.

Progressive Necrotizing Infections

The use of HBO_2 for treatment of necrotizing fasciitis and Fournier gangrene, which are mixed aerobic-anaerobic infections, has been reported in six nonrandomized comparisons and four case series.[59–68] As with gas gangrene, variations in time of diagnosis and clinical status on admission compromise assessment of the existing literature. Most studies have reported that when HBO_2 is added to surgery and antibiotic therapy,

mortality is reduced versus surgery and antibiotics alone. Animal trials have been difficult to assess because synergistic bacterial processes are difficult to establish and model. One report has found HBO_2 to potentiate antibiotics in streptococcal myositis,[69] and several animal models of polymicrobial bacteremia and sepsis have reported increased survival with HBO_2.[70–72] Mechanisms of action may include the suppressed growth of anaerobic microorganisms and improved bactericidal action of leukocytes (which function poorly in hypoxic conditions).[12,73–75]

CRITICAL CARE IN HYPERBARIC MEDICINE

Preparations for treatment begin while the patient is still in the intensive care unit (i.e., before transport to the hyperbaric chamber is initiated). Issues to be addressed include informed consent, a determination that all intravenous/arterial lines and nasogastric tubes/Foley catheters are secured, capping all unnecessary intravenous catheters, placing chest tubes to one-way Heimlich valves, and adequately sedating or paralyzing the patient as clinically indicated.

The environment of the hyperbaric chamber imposes limitations on equipment, including space restrictions, fire codes, and the effect of pressure on equipment function. Electrical components of equipment are located outside the hyperbaric chamber. Cables penetrate the chamber bulkhead to make a connection to the pneumatic portion of ventilators, internal cardiac pacer wires, electrocardiogram attachments, and arterial line transducers. The patient is attached to equipment at ambient pressure before treatment. Once the treatment pressure is achieved, all settings are verified and transducers recalibrated. It is especially important to remember to check the cuff pressure of endotracheal tubes. Many centers make it a practice to replace the air in these cuffs with an equivalent volume of sterile saline before treatment to avoid volume changes related to pressurization.

Several intravenous infusion pumps operate normally in the multiplace chamber environment. If glass bottles, pressure bags, or any other gas-filled equipment is used inside a hyperbaric chamber, it must be adequately vented and closely monitored during treatment. There are limited numbers of ventilator brands approved for the high-pressure environment, and pressure cycle modes function more reliably than do those targeting tidal volume. Furthermore, patients with severe lung disease and high mean airway pressures often cannot be treated under hyperbaric conditions until pulmonary function improves.

Bed type, size, and timing of treatment around other procedures and diagnostic testing can limit the number of HBO_2 treatments the patient receives. The recent trend to place very ill patients with elevated creatinine levels on continuous dialysis has also hindered the ability to treat patients at regular intervals.

ADVERSE EFFECTS

The inherent toxicity of O_2 and potential for injury caused by elevated ambient pressure must be addressed whenever HBO_2 is used therapeutically. Middle ear barotrauma is the most common adverse effect of HBO_2 treatment.[76] As the ambient pressure within the hyperbaric chamber is increased, a patient must be able to equalize the pressure within the middle ear by auto-insufflation. Standard protocols include the instruction of patients on auto-insufflation techniques and adding oral or topical decongestants when needed. When these interventions fail, tympanostomy tubes must be placed. Intubated patients have difficulty with equalization, and the tympanic membrane must be examined after each treatment. The incidence of tympanostomy tube placement has been reported to be approximately 4% in one series.[77] Others report an overall incidence of aural barotrauma to be between 1.2% and 7%.[78,79]

Pulmonary barotrauma during HBO_2 treatment is extremely rare but should be suspected when any significant chest or hemodynamic symptoms occur during or shortly after decompression. Because the offending gas in virtually all cases will be pure O_2, absorption within the body occurs rather quickly in most cases. If symptoms do develop, however, decompression should be prevented or interrupted and the patient carefully evaluated. If the pneumothorax is suspected, placement of a chest tube is appropriate. Preexisting pneumothorax should be treated with chest tube drainage before initiating therapy.

Biochemical toxicity resulting from O_2 can be manifested by injuries to the lungs, CNS, and eyes. Pulmonary insults can impair mechanics (elasticity), vital capacity, and gas exchange.[79] These changes are typically observed only when treatment duration and pressures exceed typical therapeutic protocols. CNS O_2 toxicity manifests as a grand mal seizure. This occurs at an incidence of approximately 1–4 in 10,000 patient treatments.[78,80,81] The risk is higher in hypercapnic patients and possibly those who are acidotic or compromised as a result of sepsis, because an incidence of 7% (23 in 322 patients) was reported in a case series of HBO_2 treatment of gas gangrene.[57] Anecdotally, intubated patients seem to be at higher risk of seizures because of the greater oxygen concentrations to which they are exposed. Seizures are managed by reducing the inspired O_2 tension while leaving the patient exposed to the same ambient pressure (to avoid pulmonary overexpansion injury when a patient is in the tonic convulsion phase).

Progressive myopia has been reported in patients who undergo prolonged daily therapy, but this typically reverses within 6 weeks after termination of treatments.[82] There is a risk for nuclear cataract development, most typically when treatments exceed a total of 150–200 hours, but cataracts may arise with less provocative exposures.[83,84] Although there is a theoretical risk of retrolental fibroplasia in neonates,[85] there are no reports of this having occurred. Currently, the experimental and clinical evidence does not indicate that typical HBO_2 therapy protocols have detrimental effects on neonates or the unborn fetus.[86] This apparent tolerance is likely caused by the relatively short duration of hyperoxia.

OTHER RISKS

Confinement anxiety for patients may occur and is typically managed with the use of sedating agents. Any environment with an elevated concentration of O_2 presents a risk for fire. Scrupulous attention to avoiding an ignition source is standard in HBO_2 therapy programs.[87]

The risk for acquiring respiratory diseases in a confined environment needs to be considered. Patients and their accompanying tenders should wear surgical masks at all times in a multiplace chamber. Patients using head tents, hoods, or fitted masks for oxygen delivery are in a closed circuit and offer reduced risk for transmitting disease; however, when a respiratory illness is suspected in a patient, N95 masks should be worn by staff. N95 mask fit should be tested under hyperbaric conditions to ascertain proper fit and protection.

KEY POINTS

- Several therapeutic mechanisms of action for HBO_2 therapy stem from hyperoxygenation of perfused tissues, reduction of gas bubble volumes, and decrease in proinflammatory processes.
- Safe treatment of critically ill patients can be accomplished in either one-person "monoplace" or larger multiple-person hyperbaric chambers.
- Efficacy of hyperbaric oxygen therapy has been documented by randomized clinical trials for a heterogeneous group of disorders.

ANNOTATED REFERENCES

Bennett MH, Feldmeier J, Hampson N, et al. Hyperbaric oxygen therapy for late radiation tissue injury. *Cochrane Database Syst Rev.* 2012;5:CD005005.
This meta-analysis surveyed 11 trials and concluded that for people with late radiation tissue injury affecting the head, neck, anus, and rectum, HBO_2 improved outcome.

Hampson NB, Piantadosi CA, Thom SR, et al. Practice recommendations in the diagnosis, management, and prevention of carbon monoxide poisoning. *Am J Respir Crit Care Med.* 2012;186(11):1095–1101.
The consensus opinion paper reviews current issues pertaining to acute CO poisoning. Based on data from the existing study with the best design that most closely addresses the actual practical handling of patients, it concludes that HBO_2 should at least be considered in all cases of serious acute CO poisoning and normobaric 100% oxygen continued until the time of HBO_2 administration.

Londahl M, Katzman P, Nilsson A, et al. Hyperbaric oxygen therapy facilitates healing of chronic foot ulcers in patients with diabetes. *Diabetes Care.* 2010;33(5):998–1003.
When clinicians discuss critical care, skin ulcers are rarely considered. However, the foot wound of a diabetic patient heightens the risk of cardiovascular and all-cause mortality beyond that associated with the metabolic derangements typically linked to diabetes. This blinded, prospective, randomized trial of 94 patients demonstrated that HBO_2 improved wound healing over twofold compared with placebo.

Pulmonary Edema

Sonal R. Pannu, John W. Christman, and Elliott D. Crouser

BACKGROUND AND EPIDEMIOLOGY OF PULMONARY EDEMA

Acute pulmonary edema is a commonly occurring emergency that demands immediate medical attention.[1,2] It is broadly classified into cardiogenic (increased hydrostatic pressure) or noncardiogenic (increased microvascular permeability) causes; however, it is common for critically ill patients to present with pulmonary edema arising from a combination of cardiogenic and noncardiogenic etiologies. It is a major health problem, accounting for ~10% of intensive care unit (ICU) admissions,[3] and is associated with an estimated acute hospital mortality of ~10%–25%[4–6] and 1-year mortality exceeding 40%.[5,7,8]

PATHOPHYSIOLOGY OF PULMONARY EDEMA

The alveolar-capillary microcirculation regulates the amount of fluid within the lung. Normal pulmonary physiology is governed by Starling forces that favor a small net extravasation of fluid from the alveolar capillaries into the lung interstitial space that is facilitated by hydrostatic forces and by the presence of microscopic gaps between the capillary endothelial cells.[9] The rate of fluid influx is mitigated by a protein osmotic pressure gradient favoring movement of fluid from the interstitial space back into the circulating plasma. The resulting relatively small physiologic fluid movement from the vasculature into the lungs is normally offset by fluid efflux via the pulmonary lymphatic system, which ultimately drains back into the systemic venous circulation. In normal adults, interstitial fluid volume is strictly controlled because the physiologic extravasation is exactly balanced by lymphatic clearance[10]; as fluid passes through the lung interstitium, it is excluded from the alveolar space (AS) by occlusive tight junctions between alveolar epithelial cells.[1,11] The Starling equation for filtration mathematically represents the fluid balance between the pulmonary vasculature and interstitium, which "depends on the net difference in hydrostatic and protein osmotic pressures and permeability of the capillary membrane."[12]

$$Q = K[(Pmv - Ppmv) - (\pi mv - \pi pmv)]^{9}$$

where:
Q = net transvascular filtration of fluid into the IS
K= filtration coefficient
Ppmv = hydrostatic pressure in perimicrovascular IS
Pmv = hydrostatic pressure within the capillaries (e.g., the pulmonary capillary wedge pressure [PCWP])
πmv = protein osmotic pressure in the circulation
πpmv = protein osmotic pressure in the perimicrovascular IS

Although the Starling equation is conceptually useful in understanding the mechanisms favoring pulmonary edema formation, it is impractical to accurately measure most of these parameters clinically. Among the four forces, only the pulmonary artery occlusion pressure (PAOP) can be measured clinically. It is derived from the pulmonary artery catheter balloon wedged into a pulmonary artery segment, is a reflection of left atrial filling pressure, and is thought to be a useful but imperfect estimate of the hydrostatic pressure of the lung microcirculation. In the absence of acute lung injury (e.g., capillary damage), changes in the rate of fluid flux through the lungs are dictated primarily by changes in hydrostatic pressure. Nonetheless, a basic understanding of this equation is needed to understand the mechanisms governing the development of pulmonary edema.

In the presence of factors altering the Starling equation, the surplus fluid in the capillaries results in interstitial edema, which is reflected in chest images as peribronchial and perivascular cuffing. Pathologically, dilation of lymphatics may be noted as the lymphatic capacitance increases and is eventually overwhelmed as it attempts to accommodate the additional interstitial fluid. Ongoing accumulation of excess fluid in the interstitium overcomes the tight junctions in the alveolar epithelium, and subsequent alveolar edema results. Alveolar edema results in marked changes in lung water that are clinically manifested as increased work of breathing and hypoxemia. Lack of ventilation in the flooded alveolar units results in variable degree of right-to-left shunting of the pulmonary arterial blood flow, which contributes to hypoxemia.

CARDIOGENIC PULMONARY EDEMA (INCREASED CAPILLARY HYDROSTATIC PRESSURE)

Increased hydrostatic pressure in the pulmonary capillaries increases transvascular fluid filtration and is most often caused by volume overload or impaired left ventricular function (elevated filling pressures) that elevates pulmonary vascular pressures. Mild elevations of left atrial pressure, reflected by a PAOP of 18–25 mm Hg, cause edema formation and engorgement of the perimicrovascular and peribronchovascular interstitial spaces. As left atrial pressure rises further (PAOP >25 mm Hg), the capacitance of the lymphatics and lung interstitium (estimated at ~500 mL fluid) is exceeded and fluid overwhelms the lung epithelial barrier, flooding the alveoli with protein-poor fluid.[13,14] The development of edema with increases in the hydrostatic pressure is also a function of the acuity of pressure elevation. In the setting of gradual pressure changes associated with valvular deformities, the gradually proliferating collaterals of the lymphatic system prevent rapid edema formation and prevent overt symptoms of pulmonary edema at even high PAOP. On the other hand, sudden impairment of left ventricular function or massive fluid overload may lead to rapid development of the pathophysiologic changes described earlier.

Light and electron microscopic changes in animal lung tissue with hydrostatic lung edema indicate statistically significant increase in nonparenchymal interstitium: that is, the interlobular septa and the connective tissue sleeves that surround conducting portions of the respiratory tree and extraalveolar pulmonary blood vessels.[15] The thickness of the air–blood barrier, which consists primarily of matrix or ground substance in the interstitium, is significantly greater in the edematous lungs. Interestingly in high-pressure edema, barrier lesions have also been noted in both endothelial and alveolar epithelial regions. Frank disruptions of the thin and thick sides of the blood-gas barrier suggest capillary stress fractures. In moderate-pressure edema, epithelial blebs may be noted. These findings imply that barrier leaks may result from hydrostatic pulmonary edema, based on the severity and chronicity of the disease.[16] Thus interstitial edema from capillary injury is an alternative mechanism, in addition to the hydrostatic and osmotic pressure variations, which may explain or contribute to edema formation in some cases of cardiogenic pulmonary edema.

Hypoxemia results clinically from the development of alveolar and interstitial fluid accumulation, destabilization of alveolar units (impaired surfactant function), and consequent ventilation–perfusion (V/Q) mismatching. Gas exchange is severely impaired as a result of alveolar flooding, and intrapulmonary shunting ensues. The presence of edema fluid reduces pulmonary distensibility and moves the lung's pressure–volume curve rightward. The loss of surfactant plays an important role in the reduction of the total lung volume and related alveolar ventilation because of the instability and collapse of alveoli. Airway resistance is associated with the development of hydrostatic pulmonary edema caused by peribronchiolar fluid accumulation.[17] Consequently, patients developing pulmonary edema have to breathe more rapidly and have to work harder to expand their lungs, leading to increased work of breathing.

Occasionally noncardiogenic causes, such as rapid resuscitation with fluids or administered blood products (specifically in the setting of renal failure), cardiac valvular diseases, or rarely, pulmonary veno-occlusive diseases may cause pulmonary edema by similar mechanisms; however, given that cardiac etiology is by far the most common, we broadly refer to high capillary pressure pulmonary edema as cardiogenic pulmonary edema.

NONCARDIOGENIC PULMONARY EDEMA (INCREASED VASCULAR PERMEABILITY)

This mechanism of pulmonary edema features an abnormal increase in the microvascular permeability of the lung, as opposed to elevated capillary pressures, thereby promoting greater fluid and protein flux into the interstitial and alveolar spaces. In terms of the Starling equation, pulmonary vascular damage results in an increase in the filtration coefficient and the leakage of larger solutes (proteins). This decompartmentalization increases the interstitial osmotic pressure, helping to favor lung edema formation. During permeability pulmonary edema, increasing interstitial hydrostatic pressures associated with proteinaceous fluid eventually disrupt tight junctions in the alveolar epithelial barrier.[18] However, increased interstitial hydrostatic pressure is not the only proponent of increasing extravascular lung water. Important synergy exists between increased vascular permeability and hydrostatic pressure in the lungs. In the presence of increased barrier permeability and absence of oncotic forces that resist transvascular fluid transfer, hydrostatic capillary pressure is relatively unopposed. This tendency for seepage at normal hydrostatic vascular pressure is further exacerbated by decreases in colloidal oncotic pressure (COP) that result from low albumin levels.[19,20]

ACUTE RESPIRATORY DISTRESS SYNDROME: A PROTOTYPICAL MANIFESTATION OF NONCARDIOGENIC PULMONARY EDEMA

Permeability pulmonary edema resulting from injury to the lung capillary endothelium and/or alveolar epithelium is a classical feature of the acute lung injury that characterizes acute respiratory distress syndrome (ARDS). The very first description of ARDS depicted areas of alveolar atelectasis, hyperemia, and alveolar and interstitial hemorrhage, with a striking presence of alveolar neutrophils along with hyaline membranes.[21] Consequences of disruption of the alveolar epithelial barrier include loss of surfactant and impairment of the endothelial lining, favoring alveolar collapse during normal tidal breathing.

Causes of direct injury to the alveolar epithelium include gastric aspiration, bacterial pneumonia, and the neutrophilic alveolitis that is characteristic of ARDS. Other conditions that promote acute lung capillary endothelial injury include systemic infections (sepsis), severe burns, polytrauma, and other systemic inflammatory conditions. Varied etiologic insults, individually or in combination, lead to represent a spectrum of progressive noncardiogenic lung injury associated with impaired gas exchange (shunting, V/Q mismatching) and reduced lung compliance (increased work of breathing).[13,14]

High-permeability pulmonary edema markedly affects gas exchange and lung mechanics. Decrease in static respiratory compliance is notable and may be attributable to loss of aerated units (alveolar atelectasis) and, to some extent, to surfactant reduction.[22] Both interstitial lung parenchymal and chest wall edema contribute to reduced thoracic compliance.[23] As noted previously, ventilation–perfusion mismatch with variable degrees of shunting and increased dead space is conspicuous and directly proportionate to the severity of lung injury.

Certain causes of noncardiogenic pulmonary edema deserve special consideration because of their unique clinical presentations.

TRANSFUSION-RELATED ACUTE LUNG INJURY

Transfusion-related acute lung injury (TRALI) is an adverse response to transfusion of blood products containing plasma that is characterized by the acute (within 6 hours) onset of dyspnea, hypoxemia, and bilateral pulmonary infiltrates. Injury is mediated mechanistically by anti–human leukocyte antigen (HLA) antibodies, neutrophil activation, and related endothelial barrier damage.[24,25] The diagnosis of TRALI is supported clinically and by the exclusion of cardiogenic edema or fluid overload. Thus a low brain natriuretic peptide (BNP) (<250 pg/mL) supports the diagnosis.[26] Treatment includes immediate discontinuation of any transfusing blood products, followed by supportive care, which often requires intubation and mechanical ventilation. Duration of symptoms is typically limited (48–96 hours).[25]

VAPING-ASSOCIATED LUNG INJURY

Use of vaping devices (electronic cigarettes) containing nicotine, cannabis, and other products rapidly increased after their introduction in 2007. By 2018 vaping had affected more than 3.6 million US youths, with a majority of these being school-age adolescents and children. As of February 18, 2020, a total of 2807 hospitalized vaping-associated lung injury (VALI) cases or deaths have been reported to the Centers for Disease Control and Prevention (CDC), with 68 confirmed deaths.[27] Lung tissue of patients with respiratory failure reveals diffuse alveolar damage, acute fibrinous pneumonitis, or organizing pneumonia.[28] Foamy macrophages and pneumocystis-like vacuolization have been seen consistently. The exact pathology of acute lung injury is yet

to be determined. It has been speculated, however, that noncardiogenic edema results from alveolar epithelial injury by inhaled toxic nanoparticles of diluents such as propylene glycol and vegetable glycerin. These may eventually decompose at the parenchymal level, generating potentially harmful carbonyl compounds.[29] Taking a thorough history of any use of vaping products in the 90 days before presentation is key. Hypoxemia is consistently present, with constitutional symptoms, cough, and dyspnea preceding it. Imaging findings on high-resolution computed tomography include ground-glass opacities and fluffy nodules centered on terminal airways.[30] Ruling out other differential diagnoses and providing supportive respiratory assistance is the recommended management approach, followed by absolute abstinence.

OTHER MECHANISMS RESULTING IN PULMONARY EDEMA

PULMONARY EDEMA ASSOCIATED WITH DECREASED INTERSTITIAL HYDROSTATIC PRESSURE

NEUROGENIC PULMONARY EDEMA

Neurogenic pulmonary edema may occur after a significant central nervous system insult[31] and is most often triggered by conditions associated with rapid and extreme elevations in intracranial pressure (ICP),[31,32] in addition to acute spinal cord injury, intracranial hemorrhage, or status epilepticus. Sympathetic nervous system activation and intense catecholamine release are thought to be the primary mechanisms.[33] The condition typically resolves within 48 hours of ICP normalization.[34]

RE-EXPANSION PULMONARY EDEMA

Rapid expansion of a collapsed lung after draining a large pleural effusion or pneumothorax may cause unilateral lung edema. The incidence of re-expansion pulmonary edema (RPE) is quite uncommon when appropriate precautions are taken.[35,36] We typically note RPE occurring within hours of draining a large pleural effusion in cases of sustained (>72 hours) lung collapse. It is seen more commonly after draining spontaneous pneumothorax and correlates to the pneumothorax size and prior symptom duration.[37] Associated symptoms range from mild to life-threatening, including dyspnea, cough with frothy sputum production, chest discomfort, and hypoxemic respiratory failure. A unilateral edema pattern of the re-expanded lung is typical on chest x-ray (CXR), but infiltrates occasionally occur in the contralateral lung or in both lungs.[38,39] Most patients completely recover with supportive care within a few days. Preventive strategies include discontinuing pleural fluid removal at the onset of any signs of chest discomfort, limiting volume removal to <1.5 L, and avoiding high negative pressure (less than −20 cm H_2O).[40]

NEGATIVE-PRESSURE PULMONARY EDEMA

Negative-pressure pulmonary edema (NPPE) may present in the immediate postextubation period after the acute development of negative intrathoracic pressure generated during respiratory efforts against an obstructed upper airway. NPPE occurs in less than 0.1% of all elective surgeries and is most common in young, healthy, and athletic patients during postextubation laryngospasm. Other causes of NPPE include strangulation (or hanging), severe sleep apnea, endotracheal tube occlusion, or epiglottitis.[41] As with RPE, the condition typically resolves within several days.

ESTABLISHING THE ETIOLOGY OF PULMONARY EDEMA IN THE CLINICAL SETTING

It is important for care providers to quickly establish the cause of acute pulmonary edema so that appropriate therapy can be rapidly initiated to avoid serious, life-threatening complications. For instance, a patient with an acute rupture of mitral valve chordea tendineae would benefit from afterload reduction (e.g., peripheral vasodilators, intraaortic balloon pump [IABP]) and immediate mitral valve surgery,[42] whereas a patient with ARDS related to sepsis would benefit from judicial use of supplemental inspired oxygen, positive-pressure ventilation, and treatment of infections with early antibiotics. Unfortunately, the cause of pulmonary edema can be difficult to establish in the critical care setting and requires a skilled clinician with appropriate diagnostic tools.

Common clinical manifestations of pulmonary edema (of any cause) include the acute onset of dyspnea, anxiety, orthopnea, and in some cases pink (blood-tinged) frothy sputum. On examination, patients have signs of increased sympathetic tone (tachycardia, hypertension), increased work of breathing (e.g., accessory muscle use and diaphoresis), inspiratory crackles of the lung, and peripheral cyanosis.

CLINICAL FEATURES FAVORING CARDIOGENIC PULMONARY EDEMA

Beyond the clinical features of pulmonary edema previously mentioned, historical information, such as a recent myocardial infarction; new onset of cardiac arrhythmias; and examination findings of elevated jugular venous pressures, a third heart sound (S3), new cardiac murmurs, and/or dependent edema would favor the diagnosis of cardiogenic over noncardiogenic pulmonary edema. CXR findings of cardiomegaly, centralized pattern of interstitial and alveolar opacities, Kerley lines, and/or the presence of pleural effusions further support the diagnosis of cardiogenic pulmonary edema (Fig. 11.1).[43] Other supporting evidence includes elevated BNP and NT-pro BNP (BNP >1200 pg/mL, NT-pro BNP levels >1800 pg/mL)[44] or troponin, a marker of acute myocardial injury. However, these biomarkers lack diagnostic specificity.[45] Factors such as age, obesity, and renal failure can affect BNP levels and should be taken into account.[46] Given the lack of specificity, BNP levels are most beneficial in dyspneic patients with at least an intermediate probability of cardiogenic pulmonary

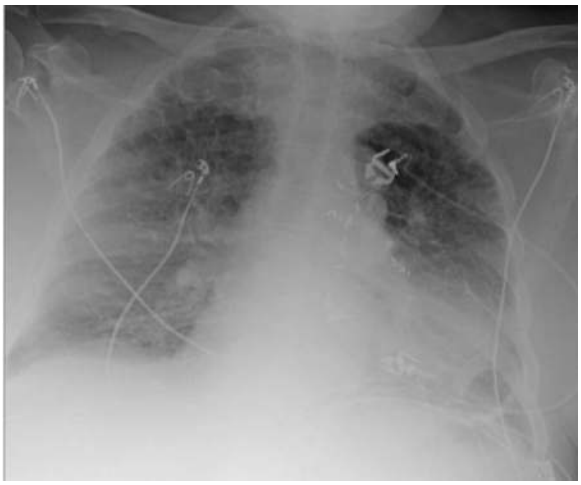

Fig. 11.1 This chest x-ray image is an anteroposterior (AP) view denoting bilaterally increased interstitial opacities with hilar prominence in the setting of cardiomegaly. Also Kerley lines, thin 1–2-cm hyperechoic lines indicating thickened interlobular septae, are noted.

edema. On the other hand, low levels (BNP <100 pg/mL;[47] NT-pro BNP <300 pg/mL) help to rule out a cardiogenic etiology of pulmonary edema. Cardiac imaging, particularly echocardiography, is very useful diagnostically and is shown to alter the management of a high percentage of critically ill patients presenting with acute pulmonary edema.[48,49] In recent years, bedside ultrasound (point-of-care ultrasound) has evolved significantly as an adjunct for diagnosing pulmonary edema when used by experienced operators. Thoracic bedside ultrasound relies on a combination of artifacts and related findings.[50] "B" lines are artifacts that run perpendicular to the pleura, and these "comet tails" obliterate the "A" lines that reverberate in diminishing fashion from the pleura and move in synchrony with pleural sliding. The presence of more than four B lines suggest thickened subpleural interlobular septae. A "B" profile, described as a bilateral anterior symmetrical B pattern with lung sliding that is present in at least two regions of the lung, suggests cardiogenic edema.[51,52] In noncardiogenic pulmonary edema, B lines are few and nonhomogeneous, and pleural sliding is affected (Video 11.1). Other features suggestive of noncardiogenic edema are discussed later. Bedside lung ultrasound not only has higher sensitivity (96%) compared with routine chest radiography (65%; P <.001) for detecting cardiogenic pulmonary edema but also its integration with clinical assessment may be more accurate than chest radiography and NT-pro BNP used together.[53]

CLINICAL FEATURES FAVORING NONCARDIOGENIC PULMONARY EDEMA

ARDS encompasses a spectrum of moderate to severe gas exchange abnormalities consequent to altered pulmonary vascular permeability, which often is further complicated by alveolar epithelial damage. Clinical features are based on the underlying etiology. The differential diagnosis of ARDS is broadly categorized as processes that cause direct versus indirect lung injury (Box 11.1). The most common direct causes are bacterial and viral pneumonia and aspiration pneumonitis, whereas nonpulmonary sources of sepsis, multiple transfusions, and trauma comprise the most common causes of indirect ARDS. Onset of symptoms (typically dyspnea, tachypnea, or related to their clinical insult) for not more than a week, presence of bilateral radiographic opacities, and exclusion of a primarily cardiogenic etiology of respiratory failure summarize the definition of ARDS. The Berlin definition (Box 11.2) categorizes ARDS into mild, moderate, and severe based on the arterial oxygen tension (PaO_2) and the fraction of inspired oxygen (FiO_2) while receiving positive end-expiratory pressure (PEEP) (Fig. 11.2 and Video 11.2).[54]

Highly specific diagnostic tests for ARDS are lacking, and the differentiation of ARDS from cardiogenic edema largely relies on the clinical acumen of the critical care providers. Details of the present illness as it relates to known risk factors for acute lung injury often provide important clues (see Box 11.1), as do certain test results (e.g., BNP <200 pg/mL)[45] (Table 11.1). On bedside ultrasound, findings such as limited pleural sliding, scattered or inhomogeneous B lines, pleural effusions, and

BOX 11.1 Common Causes of Cardiogenic and Noncardiogenic Pulmonary Edema

Cardiogenic Pulmonary Edema
- Acute exacerbation of heart failure
- Acute valve dysfunction (e.g., mitral valve chordae tendineae rupture)
- Arrhythmia/myocardial infarction
- Hypertensive crisis
- Fluid overload after aggressive volume resuscitation (e.g., postoperative)
- Ventricular septal rupture
- Pericardial tamponade

Noncardiogenic Pulmonary Edema
- Direct lung injury
  - Pneumonia
  - Gastric aspiration
  - Toxic inhalation
  - Negative pressure related (e.g., strangulation)
  - Vaping/electronic cigarette use
- Indirect causes of lung injury
  - Sepsis
  - Trauma
  - Pancreatitis
  - Multiple blood transfusions
  - Burn injury

BOX 11.2 Management of Cardiogenic Pulmonary Edema

Decrease Preload
- Diuretics (e.g., furosemide): decrease systemic venous tone and extracellular volume/volume overload[6]
- Opiates (e.g., morphine sulfate): reduce sympathetic tone
- Nitrates (e.g., nitroglycerin): venous and arterial vasodilator,[31] reduce myocardial oxygen demand[42]
- Nesiritide: recombinant BNP that results in vasodilation and diuresis[31]
- Ultrafiltration (volume removal)

Afterload Reduction
- ACE inhibitor/ARB: reduce preload and afterload[42,43]
- Nitroprusside (decreases venous return and afterload)
- Intraaortic balloon pump

Inotropic Support
- Dobutamine
- Dopamine
- Phosphodiesterase inhibitors (e.g., milrinone)
- Vasopressin (e.g., tolvaptan)

ACE, Angiotensin-converting enzyme; *ARB*, angiotensin receptor blocker; *BNP*, brain natriuretic peptide.

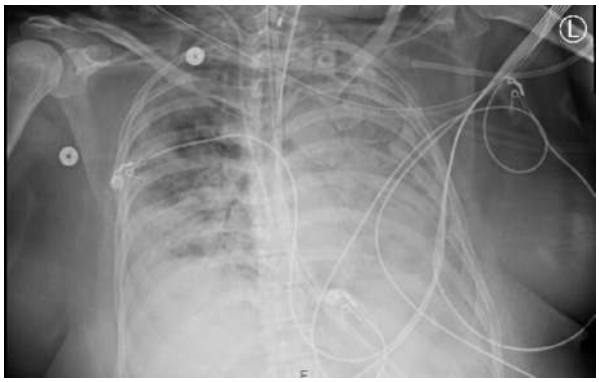

Fig. 11.2 This chest x-ray image is an anteroposterior (AP) view denoting bilateral interstitial and alveolar opacities, left side more prominent than the right side. Almost confluent alveolar opacities are noted on the left side with accompanying pleural effusion, suggestive of a left-sided pneumonia as the suggestive etiology for ARDS.

TABLE 11.1 Distinguishing Cardiogenic and Noncardiogenic Pulmonary Edema

	History	Examination	Laboratory Tests	Imaging	Pulmonary Artery Catheter
Cardiogenic	Heart disease Renal disease Uncontrolled HTN Edema Orthopnea Recent administration of IV fluids or blood products	Heart failure examination findings: Distended neck veins S3 heart sound Dependent edema Elevated blood pressure Cool extremities	*↑BNP >1200 pg/mL ↑Creatinine (in setting of volume overload) †↑Troponin	CXR: CMG pleural effusions ‡Kerley B lines Bedside USG: homogenous B lines and sliding pleura in at least two lung regions TEE: ↓LVEF Diastolic filling defect Severe mitral or aortic valvular disease Pericardial effusion with tamponade VSD	PCWP >18 mm Hg Prominent V waves (mitral regurgitation) Elevation and equilibration of right atrial pressure, pulmonary artery diastolic and PCWP (tamponade physiology) CVP >12 mm Hg
Noncardiogenic	Sepsis Aspiration event Trauma (long bone fractures) Burn injury Pancreatitis Multiple transfusions	Signs of active infection Extensive burn injury Evidence of trauma (absence of heart failure examination findings)	↑WBC *BNP <200 pg/mL	CXR: Diffuse central and peripheral infiltrates Normal heart size No or minimal pleural effusions Bedside USG: Presence of nonhomogeneous B lines, limited pleural sliding, and other patterns such as subpleural consolidations in at least two to three lung regions TEE: Normal LV and valvular function No evidence of volume overload	PCWP <18 mm Hg CVP <12 mm Hg

* Brain Natriuretic Peptide.

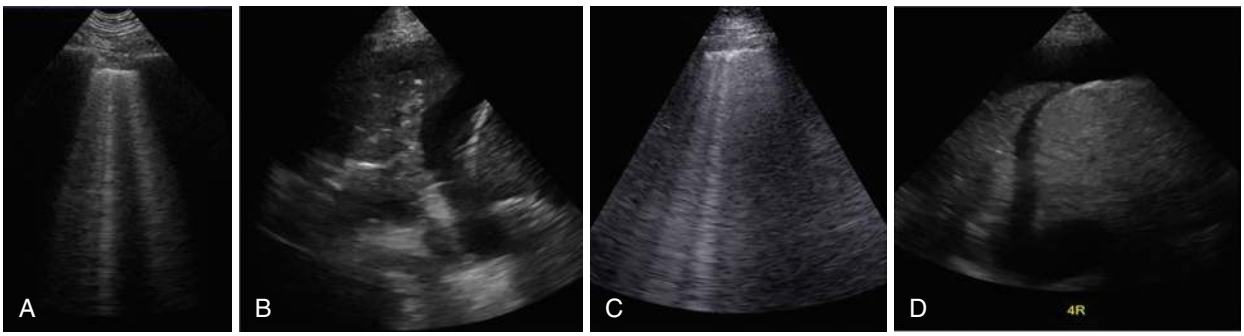

Fig. 11.3 Bedside Lung Ultrasound Images Suggestive of acute respiratory distress syndrome (ARDS). Lung ultrasound is an adjunct to the clinical examination for the diagnosis of ARDS. ARDS ultrasonic images reflect nonhomogeneous lung disease by combining normal A lines (spared areas) with the B pattern, and subpleural and translobar consolidation characterized by abolished lung sliding and irregular and thickened pleural lines in at least two regions. **(A)** Nonhomogeneous B lines; **(B)** thickened irregular pleura, **(C** and **D)** consolidative pattern ("C" profile).

presence of a consolidative or tissue-like pattern observed in more than one lung zone constitutes the "C" profile and provides a complementary diagnostic tool for clinicians at experienced centers (Fig. 11.3).[50,55]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF PULMONARY EDEMA

Table 11.1 summarizes the typical clinical findings that distinguish cardiogenic from noncardiogenic pulmonary edema. Ironically, pulmonary artery (PA) catheterization, the most definitive diagnostic modality, is no longer routinely used at the bedside because of the perceived incidence of complications (e.g., bleeding, pneumothorax, arrhythmias, infections, vessel trauma) and unreliability resulting from improper calibration or misinterpretation of the data.[56–58] Thus less-invasive techniques have largely replaced PA catheters for the routine evaluation of cardiogenic etiology for pulmonary edema in the ICU setting.

Echocardiography, both transthoracic (TTE) and transesophageal (TEE), is the most widely used tool for the definitive evaluation of critically ill patients with suspected cardiac disease. In the context of

PE, TEE can rapidly detect serious cardiac diseases associated with elevated left ventricular filling pressures, including impaired left ventricular ejection fraction (LVEF) caused by ischemic (typically causing regional wall motion abnormalities) or nonischemic (diffuse wall motion abnormalities) muscle disease, significant valvular disease, or pericardial effusions that cause tamponade physiology.[59]

Alternative modalities have evolved over the last decade to quantitatively diagnose pulmonary edema and differentiate cardiogenic from noncardiogenic forms. Determination of excessive extravascular lung water by the transpulmonary thermodilution (TPTD) technique may suggest the diagnosis of pulmonary edema. Several large case studies have shown the expected extravascular lung water (EVLW, 7.3–8.0 mL/kg predicted body weight) in lungs without pulmonary edema (area under the curve, 0.90; 95% confidence interval [CI], 0.88–0.91).[60,61] A national registry showed that >9.8 mL/kg represented the optimal threshold for distinguishing pulmonary edema, with an EVLW level of 14.6 mL/kg yielding a 99% positive predictive value.[60]

A pulmonary vascular permeability index may point toward ARDS if elevated, cardiogenic pulmonary edema if low, and a combination of both if the pulmonary vascular permeability index is within intermediate ranges.[62] Several limitations in the technology impede its deployment. These include the need for central venous and thermistor-tipped arterial catheters, accuracy and timing of evaluation, and the need for larger randomized clinical trials to prove benefit over current standard of care. In addition, limitations of the TPTD technique, such as vascular obstruction, focal injury, other contributors to extravascular water, and confounding are associated with the ranges and variations of tidal volume, PEEP, and so on.[63,64]

MANAGEMENT OF PULMONARY EDEMA

Therapeutic approaches are classified as either cardiovascular or pulmonary interventions. Cardiovascular interventions aim to reduce transcapillary fluid flux into the lung by reducing pulmonary capillary pressures. As shown in Fig. 11.4 and Box 11.2, such interventions aim to reduce preload (e.g., loop and proximal tubular diuretics, nitrates, or ultrafiltration in renal failure), reduce afterload (systemic vasodilating agents including nitrates and angiotensin-converting enzyme [ACE] inhibitors), or optimize cardiac contractility during impaired left ventricular function (catecholamines, phosphodiesterase [PDE] inhibitors, IABP). Although most effective in the setting of cardiogenic edema, pulmonary capillary hydrostatic pressure reduction can also mitigate the severity of noncardiogenic edema.

Pulmonary interventions are designed to optimize gas exchange, particularly oxygenation, by recruiting unstable, collapsed, or fluid-filled alveolar units, primarily through the administration of PEEP. PEEP, typically 5–15 cm H_2O, counteracts alveolar collapse during the ventilator cycle to enhance V/Q matching and consequently oxygen transfer from the alveoli to the blood. Alveolar stabilization also reduces the work of breathing by improving CO_2 exchange (i.e., lower ventilatory rates) and lung compliance. In addition to PEEP, it is often necessary to cautiously increase the fraction of inspired oxygen (FiO_2) to maintain adequate oxygenation (see Fig. 11.4). PEEP may be provided by a tight-fitting, occlusive face mask in the form of continuous positive airway pressure (CPAP) or noninvasive positive-pressure ventilation (NIPPV), wherein inspiratory support is added to PEEP (bilevel ventilation). Positive-pressure ventilation further mitigates cardiogenic pulmonary edema by decreasing both preload and afterload.[13] Early use of CPAP or NIPPV for respiratory distress in cardiogenic pulmonary edema should be strongly considered, as it provides support while awaiting the benefits of the aforementioned medical interventions. Based on the analysis of over 2900 patients, NIPPV has been shown to reduce both the need for endotracheal intubation and the likelihood of mortality.[65] The European Respiratory Society guidelines strongly recommend CPAP or NIPPV for cardiogenic edema[66]; however, it is unclear if bilevel NIPPV is superior to CPAP in improving dyspnea, work of breathing, oxygenation, and partial pressure of carbon dioxide ($PaCO_2$) retention.[67,68] Endotracheal intubation and sedation may be required for patients with intolerably high work of breathing or altered mental status.

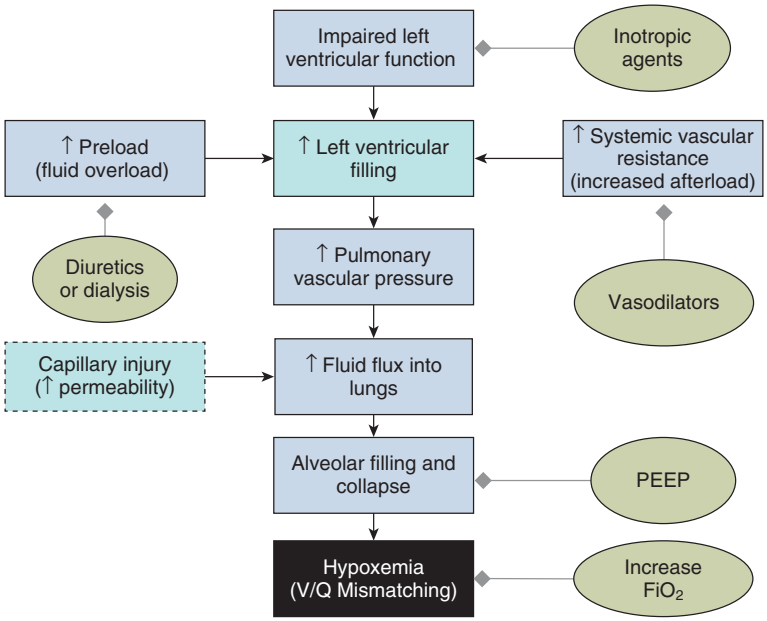

Fig. 11.4 Acute Management of Pulmonary Edema. This schematic represents basic mechanisms distinguishing cardiogenic and noncardiogenic pulmonary edema *(red boxes)* and the contributing factors *(blue boxes)* that ultimately lead to impaired gas exchange *(black box)*. The *green circles* represent treatments that are available in the intensive care unit setting to reduce pulmonary edema or to mitigate its adverse consequences. *FiO_2*, fraction of inspired oxygen; *PEEP*, positive end-expiratory pressure; *V/Q*, ventilation–perfusion.

A trial of high-flow nasal cannula or NIPPV may be given in the setting of noncardiogenic pulmonary edema. However, because of the etiologic heterogeneity, an individualized approach should be maintained with a low and early threshold for initiating mechanical ventilation.[69,70] When ventilator support is required, a lung-protective ventilation strategy that incorporates relatively low tidal volumes (4–8 mL/kg ideal body weight or less) is recommended to minimize ventilator-associated lung injury.[71]

KEY POINTS

- Pulmonary edema is broadly classified into cardiogenic (increased hydrostatic pressure) or noncardiogenic (increased microvascular permeability) causes; however, it is common for critically ill patients to present with pulmonary edema arising from a combination of cardiogenic and noncardiogenic etiologies.
- Common clinical manifestations of pulmonary edema (of any cause) include the acute onset of dyspnea, anxiety, orthopnea, and in some cases pink (blood-tinged) frothy sputum. On examination, patients have signs of increased sympathetic tone (tachycardia, hypertension), increased work of breathing (e.g., accessory muscle use and diaphoresis), inspiratory crackles of the lung, and peripheral cyanosis.
- In addition to the history and physical examination, laboratory testing (troponin, BNP) and imaging (CXR, bedside ultrasound, and echocardiogram) may be helpful in differentiating between cardiogenic and noncardiogenic causes of pulmonary edema.
- Management should be directed at the causes of the pulmonary edema. In addition, early use of NIPPV for respiratory distress in cardiogenic pulmonary edema should be strongly considered because it provides support while awaiting the benefits of the medical interventions described earlier.

Pleural Effusion in the Intensive Care Unit

Peter K. Moore, Hunter B. Moore, and Ernest E. Moore

EPIDEMIOLOGY

Pleural effusions are common in the intensive care unit (ICU). Estimated incidence depends on screening method and ranges from 8% by physical examination to 60% by ultrasound.[1,2] Transudative causes of effusion (heart failure, hypoalbuminemia) predominate in the medical ICU, whereas hemothorax and postsurgical effusions occur more frequently in trauma and cardiac ICUs.[3] In any setting, 83% of patients with acute respiratory distress syndrome have pleural effusions as assessed by computed tomography (CT) scan.[4]

PATHOPHYSIOLOGY

The pleural space is bound by the visceral pleural lining of the lung and the parietal pleura that covers the internal thoracic cavity. During health, a small amount of fluid within the pleural space is maintained by a balance between pleural fluid generation and removal. Approximately 0.01 mL/kg/hr of pleural fluid is generated per day (~16 mL/day in a 70-kg adult) from the vascular space.[5] Pleural fluid removal occurs via pores in the parietal pleura, which are large enough to allow egress of erythrocytes. Pleural fluid resorption has a remarkable capacity, with the ability to increase approximately 30 times the basal rate.[6] Because of the slow rate of fluid production and large capacitance for removal, pathologic pleural effusions usually result from both an increase in the production of fluid and a decrease in absorption.

Pleural effusions are best classified as transudates or exudates by Light's criteria (Table 12.1).[7] In general, etiologies that primarily affect hydrostatic pressure (e.g., heart failure) or intravascular oncotic pressure (e.g., nephrotic syndrome) will result in transudative effusions, whereas disease that causes increased vascular permeability and obstruction of parietal pleural lymphatics (e.g., infection, malignancy) will result in exudative effusions. Occasionally, an abnormal connection between the pleural space and an extrathoracic compartment will result in pleural effusion, such as seen in hepatic hydrothorax (Table 12.2).

Mechanical changes to the lung, chest wall, and diaphragm occur when fluid collects in the pleural space. Because of the outward recoil of the chest wall and inferior displacement of the diaphragm, the lung volume decreases approximately one third. In a healthy lung, the reduction in lung volume usually does not cause gas exchange derangements likely because ventilation and perfusion are reduced similarly in the areas of lung collapse.[8] Studies in patients with pleural effusions and normal underlying lungs have demonstrated that removal of pleural fluid can worsen gas exchange.[9] There is inconsistent evidence with regard to the benefit of evacuation of pleural effusion in mechanically ventilated patients. Several studies have demonstrated improvement in oxygenation and respiratory mechanics when effusions are drained in ventilated patients, but whether this translates to meaningful improvement in clinical outcomes is not clear.[10–12]

DIAGNOSTIC EVALUATION

Physical Examination

Physical examination findings of pleural effusion include reduced breath sounds, dullness to percussion, decreased tactile fremitus, and asymmetric chest expansion.[13] However, many physical examination maneuvers are difficult to perform accurately in critically ill patients because of many factors, including altered breath sounds from mechanical ventilation, difficulty with positioning, and presence of surgical drains and dressings.

Imaging

Chest x-ray has long been used to evaluate for suspected pleural effusions. Conventional upright x-rays can detect effusions of approximately 50 mL in the lateral view and 200 mL in the posteroanterior projection.[14] Lateral decubitus can detect even smaller volumes but is difficult to perform in most critically ill patients. On upright or semi-recumbent films, blunting of the costophrenic angles may be the only sign of small pleural effusion. Larger effusions can cause obliteration of the hemidiaphragm and mediastinal shift away from the effusion. The sensitivity of x-ray for diagnosing pleural effusion in the critically ill is lower because of the inability to position correctly, lung opacification from alternative causes, and lower quality of portable x-rays. Commonly, free-flowing pleural effusions will appear as hazy lower lobe opacities with indistinct diaphragm on portable anteroposterior semi-upright x-rays (Fig. 12.1A). Loculated effusions can appear as a "D" shape with the flat portion against the lateral edge of the pleura. Pleural fluid isolated to the fissure, so called "pseudotumor," can have the appearance of an intraparenchymal mass or consolidation on x-ray (see Fig. 12.1B).

Point-of-care ultrasound can be performed at the bedside in the ICU with ease and has increased sensitivity for pleural fluid. Ultrasound for pleural effusion can detect as little as 5 mL of fluid and has sensitivities similar to that of chest CT.[15] Ultrasound can differentiate consolidated or atelectatic lung from pleural fluid. In addition, features of pleural effusions, including debris, loculations, and pleural thickening on ultrasound, can assist with classifying collections as complex rather than simple effusion (Fig. 12.2).[16] Pleural thickening and nodularity on ultrasound are suggestive of cancer and should trigger further diagnostic evaluation with advanced imaging and/or pleural biopsy.[17]

Chest CT allows for the best visualization of size and characteristics of pleural effusions (Fig. 12.3). Contrast examination is not necessary in all pleural effusions but is useful to distinguish atelectatic or consolidated lung (which will enhance with pleural timed intravenous [IV] contrast) from pleural fluid.[18] Hounsfield units >15.6 in the pleural fluid is suggestive of hemothorax.[19]

TABLE 12.1 Light's Criteria for Exudative Pleural Effusion. Exudate If One or More Criteria Are Met

Exudative Pleural Effusion	Value
Pleural fluid-to-serum ratio of total protein	>0.5
Pleural fluid-to-serum ratio of LDH	>0.6
Pleural fluid LDH level	More than two-thirds upper limit of normal for serum

LDH, Lactate dehydrogenase.

TABLE 12.2 Causes of Pleural Effusions

Transudative	Exudative
Intrathoracic	
Congestive heart failure	Infection
Nephrotic syndrome	Bacterial
Cirrhosis	Tuberculosis
Iatrogenic volume overload	Fungal
Central venous occlusion	Viral
	Parasitic
	Malignancy
	Pulmonary embolism
	Rheumatologic disorder
	Post–cardiac injury or surgery
	Uremia
	Asbestos
	Drug-induced
	Radiation
	Yellow nail syndrome
	Hemothorax
	Chylothorax
	Esophageal rupture
Extrathoracic	
Hepatic hydrothorax	Pancreaticopleural fistula
Peritoneal dialysis	Feeding tube migration
Urinothorax	
Bilothorax	
Cerebrospinal fluid leak	
Central venous catheter migration	

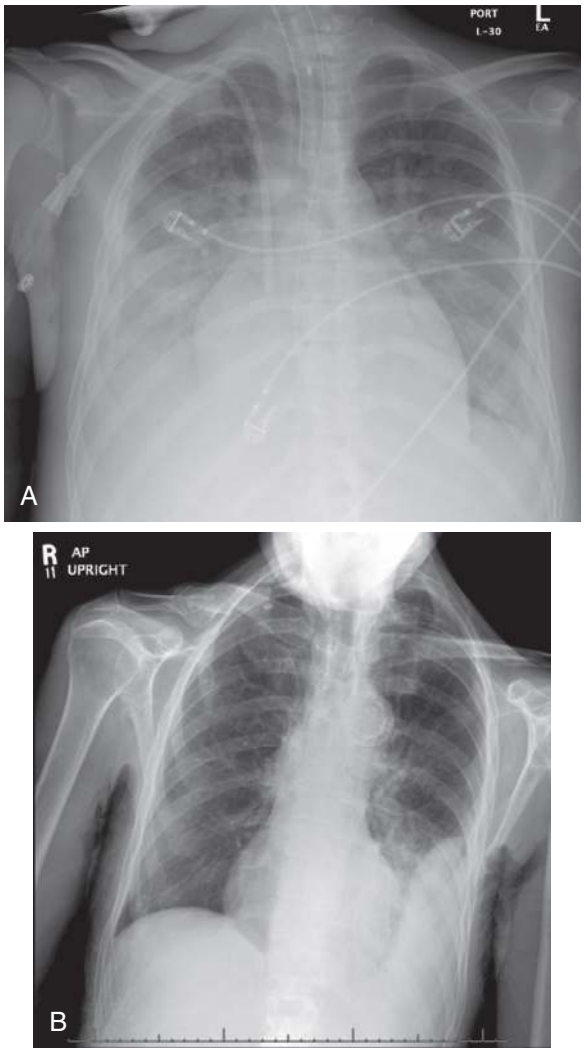

Fig. 12.1 A, Semi-recumbent portable chest x-ray demonstrates bilateral basilar hazy opacities silhouetting the diaphragm. Large bilateral pleural effusions were confirmed on bedside ultrasound. **B,** Loculated effusion with "D-sign."

Thoracentesis

Pleural fluid sampling through thoracentesis can be safely accomplished at the bedside in patients with >2 cm of pleural fluid between parietal and visceral pleura on bedside ultrasound. Fluid sampling can be deferred in patients with pleural effusions thought to be simply related to volume overload. However, if there is clinical concern for infection in the pleural space (i.e., ipsilateral pneumonia, unexplained fever, elevated white blood cell count) or hemothorax, prompt evaluation should be pursued. Ultrasound guidance is the preferred method for thoracentesis, as there are lower rates of pneumothorax with the use of ultrasound. Marking of the skin for thoracentesis location should be performed with bedside ultrasound while the patient is in the correct position for the procedure to ensure that the overlying skin does not shift with patient movement before sampling.[20] Although coagulopathy, thrombocytopenia, and use of antiplatelet agents previously were thought to increase the risk of bleeding, several recent studies have challenged that notion.[21,22]

PLEURAL FLUID EVALUATION

Pleural Fluid Gross Characteristics

At the time of thoracentesis characteristics of pleural fluid will often guide laboratory analysis and management. For example, purulent fluid with a putrid odor should be treated as an empyema with prompt chest tube drainage, bloody fluid should have its hematocrit analyzed (>50% of the blood hematocrit is diagnostic of hemothorax), milky appearance should prompt evaluation for chylothorax, and fluid that smells like ammonia should lead to evaluation for possible urinothorax. Pleural fluid is routinely sent for total protein and lactate dehydrogenase (LDH) levels to help classify as exudative vs. transudative (see Table 12.1), and cell count differential can further assist with

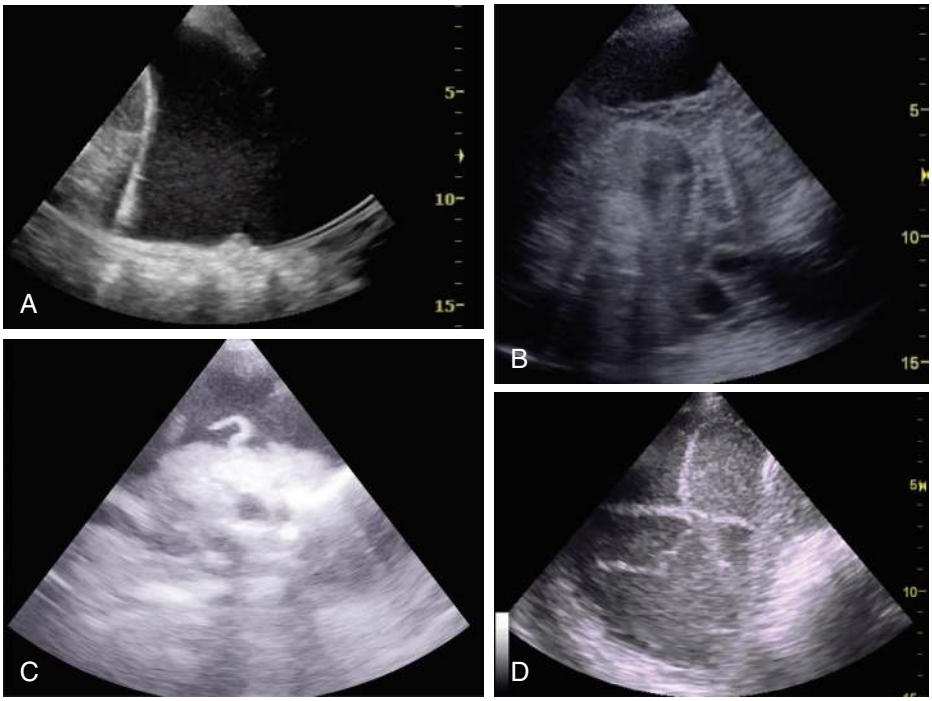

Fig. 12.2 Point-of-care ultrasound of pleural space shows **(A)** anechoic simple effusion, **(B)** complex effusion with multiple septations, **(C)** complex effusion with debris (blood clot in this example), and **(D)** empyema with septations and increased echogenicity of pleural fluid.

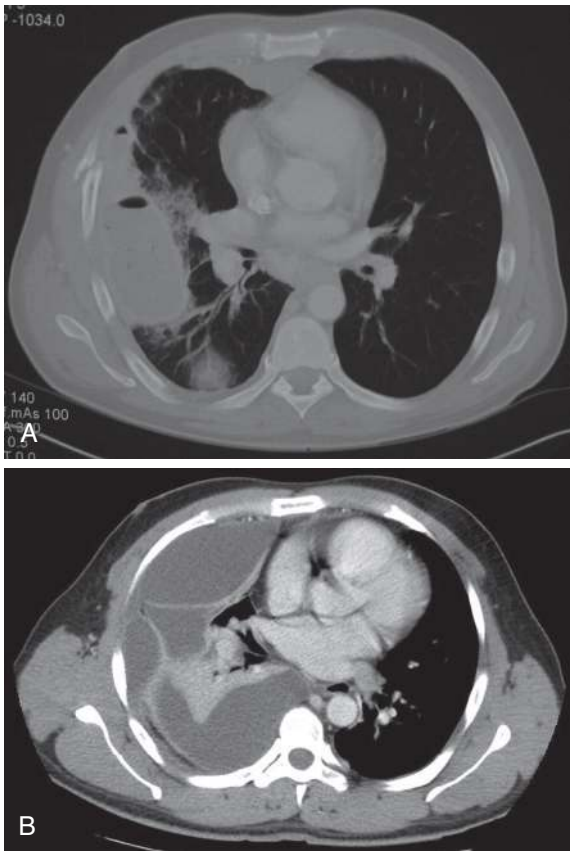

Fig. 12.3 Contrast-enhanced CT scan of the chest shows **(A)** simple loculated effusion and **(B)** organized multiloculated effusion. The multiloculated effusion is unlikely to resolve with tube thoracostomy and fibrinolytics; early VATS should be considered in these scenarios.

diagnostic evaluation of exudates. Any effusion that is sampled for concern for infection should have aerobic and anaerobic cultures, glucose, and pH evaluated to guide management.

Total Protein and Lactate Dehydrogenase

Elevation of pleural fluid total protein and LDH in relation to the serum is reflective of increased vascular permeability, which can be seen with inflammatory, infectious, or malignant conditions. In addition, as LDH is a marker of cellular breakdown, pleural LDH elevation can reflect increased inflammation within the pleural space.[23] Thus if LDH levels continue to rise on repeated pleural fluid sampling, there should be suspicion that inflammation is worsening within the pleural space.

Up to 25% of pleural effusions from transudative etiology can be misclassified as exudative using Light's criteria.[7] This is frequently encountered in the setting of heart failure when diuresis has concentrated the pleural space.[24] In this setting the patient's clinical symptoms and signs will usually lead to the correct diagnosis. Pleural N-terminal pro-brain natriutetic peptide (NT-ProBNP) has sensitivity and specificity of 94% for diagnosing heart failure–associated effusions. However, pleural levels of NT-proBNP correlate strongly with serum levels, and blood tests alone likely suffice in this scenario.[25] Pleural to serum albumin or protein gradient above 1.2 g/dL or 3.1 g/dL, respectively, in the setting of heart failure will correctly classify the effusion as transudative after diuresis.[26,27]

Leukocyte Count and Differential

At homeostasis, the leukocyte count is approximately 1700 WBC/μL with a macrophage and monocyte predominance.[28] Elevations in pleural fluid absolute leukocyte count are usually indicative of an exudative process but are otherwise nonspecific. Pleural fluid differential can be useful for differentiating causes of exudative effusions (Table 12.3). Neutrophil predominance is commonly seen in the setting of infection and infarction. Very high lymphocyte counts (>85%) are seen in tuberculosis and malignancy.[29] Eosinophilic pleural effusions

TABLE 12.3 Causes of Exudative Effusions by Pleural Leukocyte Differential

Neutrophil Predominant	Lymphocyte Predominant (>80%)	Eosinophil Predominant (>10%)
Parapneumonic effusion	Malignancy	Hemothorax
Acute inflammation of lung or pleura (e.g., ARDS)	Tuberculosis	Parasitic infection
Pulmonary embolism	Connective tissue disease	Fungal infection
	Chylothorax	Tuberculosis
	Yellow nail syndrome	Drug reaction
		Pulmonary embolism
		Eosinophilic polyangiitis with granulomatosis
		Malignancy

ARDS, Acute respiratory distress syndrome.

(eosinophils >10%) are less specific but can be seen 2 weeks after hemothorax or with drug reactions, pulmonary embolism, malignancy, parasitic infection, and eosinophilic granulomatosis with polyangiitis.[30,31]

pH and Glucose

In the absence of disease, the pleural space is basic, with a pH of approximately 7.6.[32] Pleural pH <7.3 is considered abnormal and is usually indicative of an exudative effusion, with the notable exception of the transudative urinothorax.[33] Low pleural pH has been shown to have negative prognostic value in the setting of parapneumonic effusions and malignancy-associated effusions.[34,35] Although parapneumonic effusions with pH <7.15 have a likelihood ratio of about 6 for requiring chest tube drainage, the relationship of pleural pH to the need for chest drainage is linear, and a strict cutoff for drainage based solely on pH may not be appropriate.[35–37] The exception is a pH >7.2 that can occur with *Proteus* infection because of ammonia production via urease.

Pleural glucose <60 mg/dL or pleural to serum glucose ratio of <0.5 is suggestive of a small number of inflammatory lung conditions. These include complicated parapneumonic effusion, esophageal rupture, malignancy, tuberculous pleuritis, or rheumatoid- or lupus-associated pleuritis. Pleural glucose <40 mg/dL in the setting of parapneumonic effusion predicts need for chest tube drainage but is less sensitive than pH.[37] Rheumatoid pleural effusions are notable for extremely low glucose levels and low pH and can imitate biochemical characteristics of an empyema.[38]

Culture

Pleural Gram stain and culture should be obtained in exudative effusions of unclear etiology. Fungal and mycobacterial samples should be sent in the appropriate clinical scenario. In the setting of pleural bacterial infection, inoculation of blood culture bottles with pleural fluid in addition to standard sterile bottles increased identification of bacterial pathogens from 38% to 59%.[39]

Cytology

Exudative pleural effusions of unclear etiology should undergo cytologic examination. Cytology has approximately 60% sensitivity for diagnosis of malignancy, but sensitivity varies significantly based on the type of cancer and location of metastasis (visceral versus parietal pleura).[40,41] Sending cytology on three separate samples increases sensitivity to approximately 90%.[23]

Triglycerides and Cholesterol

Triglycerides and cholesterol distinguish chylothorax from pseudochylothorax (also known as *cholesterol effusion*). Triglyceride levels >110 mg/dL are diagnostic of chylothorax, and levels <50 mg/dL effectively rule out the diagnosis. Levels between 50 and 110 mg/dL should be evaluated for chylomicrons by lipoprotein electrophoresis.[42] Cholesterol levels >200 mg/dL are consistent with pseudochylous effusions. Cholesterol/triglyceride ratio >1 is the most sensitive test for pseudochylous effusions, which result from chronic inflammation, most often from tuberculosis or rheumatoid arthritis.[43]

Other Pleural Fluid Tests

Adenosine deaminase (ADA) testing is most useful for distinguishing between tuberculosis and malignancy in lymphocytic effusions with negative mycobacterial cultures and cytology. ADA <35 U/L has a negative predictive value of approximately 95% in countries with low to intermediate rates of tuberculosis.[44] Although Xpert MTB/RIF PCR (GeneXpert) in the sputum is a highly sensitive test for active pulmonary tuberculosis, its sensitivity is only 50% for the diagnosis of tuberculous pleuritis when evaluated in the pleural fluid.[45]

Amylase from salivary or pancreatic sources will be in the pleural fluid in the setting of esophageal rupture or pancreaticopleural fistula. Pleural amylase to serum ratio >1 is generally considered positive. Malignancy can also result in amylase elevation.[46]

Pleural to serum creatinine ratio >1 is diagnostic of urinothorax, which is further supported by transudative fluid characteristics by Light's criteria with pH <7.4.[33]

There is interest in biomarkers of cancer (e.g., CEA, mesothelin) and infection (e.g., procalcitonin) in the pleural space, but at this time there have not been conclusive studies to support their routine clinical use.

Invasive Diagnostics

Pleural biopsy is often needed to diagnose tuberculous pleurisy and malignancy (either metastatic or primary pleural based). Methods of biopsy from least invasive to most invasive are closed (blind) needle pleural biopsy, image-guided needle biopsy, thoracoscopy/video-assisted thoracoscopic biopsy, and open pleural biopsy. In general, sensitivity for malignancy and tuberculosis increases with a more invasive diagnostic approach. Open pleural biopsy is only indicated with progressive pleural disease that cannot be approached thoracoscopically or with previous nondiagnostic thoracoscopic biopsy.

MANAGEMENT

Management of pleural fluid collections is targeted at the specific cause. For example, transudative effusions from congestive heart failure will resolve with diuresis, whereas moderate to large hemothoraces will require tube thoracostomy drainage. Extravascular causes of

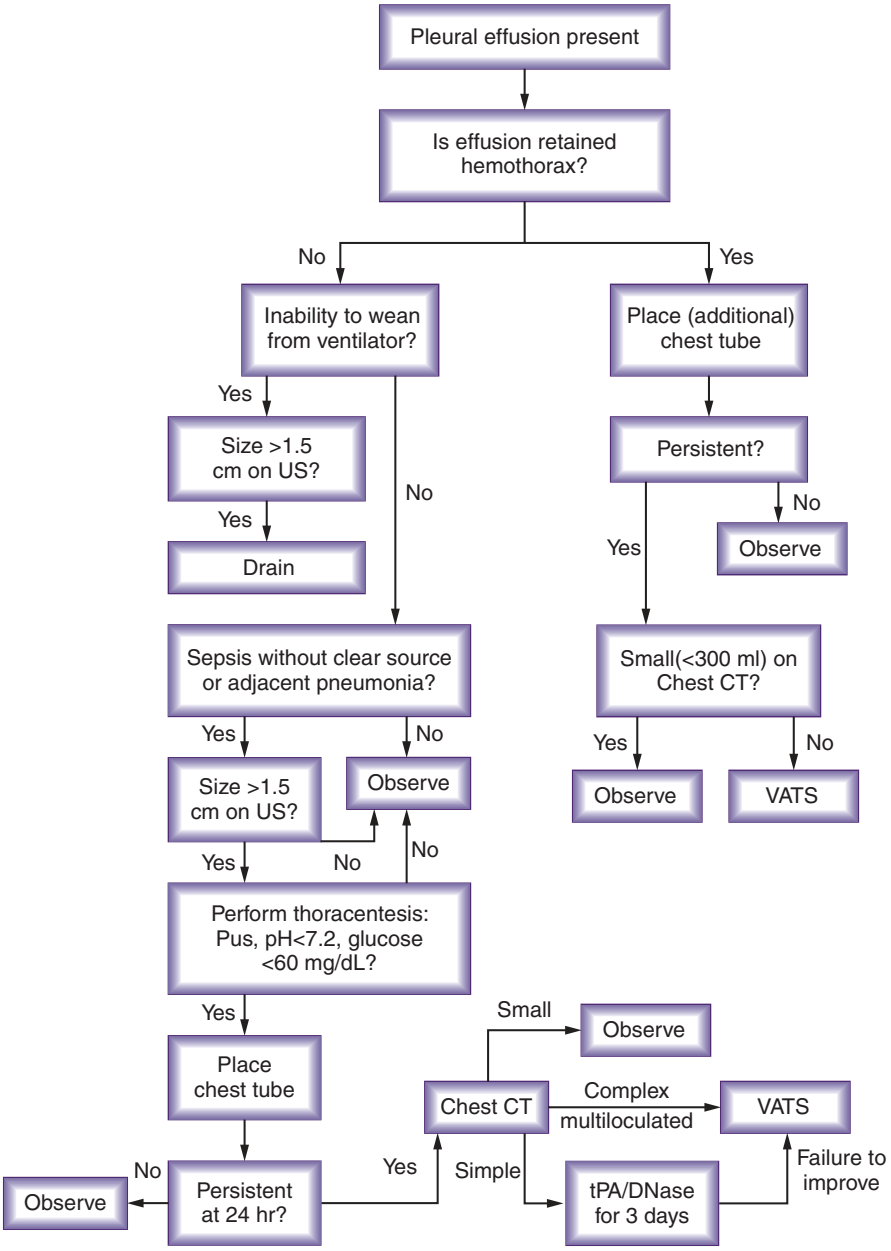

Fig. 12.4 General approach to pleural effusion in the ICU. This algorithm can serve as a general guide, but is not applicable to all clinical scenarios.

pleural effusions, such as those caused by esophageal rupture, pancreaticopleural fistula, and urinothoraces, often require endoscopic or surgical repair. A general approach to guide pleural space interventions in critically ill patients is outlined in Fig. 12.4. This chapter will focus on specifics of management of uncomplicated effusions in patients with refractory hypoxemia undergoing mechanical ventilation, parapneumonic effusion, hemothorax, and chylothorax.

Transudative and Uncomplicated Effusions in Mechanically Ventilated Patients

As accumulation of free-flowing fluid in the pleural space is accommodated by outward recoil of the chest and downward deflection of the diaphragm, the lung is only displaced by about one-third of the volume taken up by the effusion. In the setting of intact vasoregulatory mechanisms, ventilation/perfusion matching is maintained. Consequently, atelectasis from pleural effusion alone rarely causes significant hypoxemia, but does alter respiratory muscle mechanics.[8]

In the setting of mechanical ventilation, optimal treatment of uncomplicated effusion is controversial. In a recent prospective multicenter observational evaluation of patients weaning from mechanical ventilation, moderate to large pleural effusions were present in one-third of patients by ultrasound at the initiation of weaning. Moderate to large effusions were associated with increased rates of failure of first spontaneous breathing trials, increased weaning failures, and fewer ventilator-free days.[47] Although drainage of pleural effusions in the setting of mechanical ventilation has been demonstrated to improve oxygenation and respiratory mechanics, there have been no studies showing improvement in clinically significant outcomes such as duration of mechanical ventilation or mortality.[10–12] Prospective trials are needed to evaluate whether drainage of

pleural effusions in ventilated patients results in clinically meaningful outcomes.

Complicated Parapneumonic Effusion and Empyema

Close to half of patients admitted with bacterial pneumonia will develop a pleural effusion, with approximately 10% of these effusions becoming complicated (i.e., requiring chest tube drainage for resolution or having positive pleural fluid cultures).[48,49] Risk factors for development of complicated pleural space infections in the setting of pneumonia include diabetes, alcohol use, drug addiction, and poor dentition with aspiration.[49–51] Nosocomial pneumonias are more likely to result in complicated pleural effusions or empyema and have a high rate of requiring surgical decortication.[52] Retained hemothorax is the biggest risk factor for empyema, with an incidence of greater than 25%.[53]

Complicated parapneumonic effusions, and ultimately empyema, develop in three conceptual phases. The early exudative phase consists of sterile fluid accumulation from alterations in capillary permeability and reduced lymphatic clearance.[54] Most of these effusions resolve on their own if pneumonia is treated with appropriate antibiotics.[48] The second "fibropurulent" phase is initiated by bacterial invasion with resultant activation of the innate immune system and coagulation system. During this time, bacterial and neutrophil metabolism acidify the fluid, consume glucose, increase protein content, and release LDH from cellular apoptosis and necrosis. Because of the integrated responses of the innate immune and coagulation systems, hypercoagulability with resultant suppression of the fibrinolytic system occurs.[55] As this stage progresses, pleural effusions develop septations and loculations and become unlikely to resolve with antibiotics alone. If left untreated, the pleural effusion will go through an "organization" stage with formation of a fibrous rind that encases the lung, resulting in significant restriction of lung function and sequestration of bacteria within the pleural space.[56]

Parapneumonic effusions can be separated into three categories: uncomplicated parapneumonic effusion, complicated parapneumonic effusion, and empyema. Radiographic, biochemical, and microbiologic characteristics and risk of adverse outcome are described in Table 12.4.[57] Uncomplicated parapneumonic effusions are exudative effusions related to adjacent parenchymal inflammation will resolve with appropriate medical therapy. Approximately 90% of parapneumonic effusions are uncomplicated.[48] Of note persistent uncomplicated parapneumonic effusions can progress. Repeat pleural fluid sampling or advanced imaging should be pursued if a patient has enlarging effusion or sepsis with unclear source. Complicated parapneumonic effusions will either become infected (positive Gram stain/culture) or require drainage either with chest tube thoracostomy or thoracoscopic decortication. Empyema is defined by the presence of frank pus.

Gram stain and bacterial cultures of the pleural space at the time of thoracentesis can be helpful in guiding therapy for complicated parapneumonic effusions and empyemas. However, there will be no identifiable pathogen in up to 80% of cases.[58] As mentioned previously, direct inoculation of blood culture bottles with pleural fluid increases the yield of bacterial pathogens.[39] Empiric therapy should be initiated based on patient risk factors. In community-acquired pleural infections *Streptococcus* species are responsible for approximately 50% of infections. *Streptococcus anginosus* group (formerly *Streptococcus milleri*) is the most common pathogen (20%–30% of total cases) followed by other *Streptococcus* species, including *Streptococcus pneumoniae* and, less frequently, *Streptococcus pyogenes* and other *Streptococci (maskall, chen 2000)*.[50,59] The remaining cases are usually caused by *Staphylococcus aureus* (~10%), gram negatives (~10%), and anaerobes (~20%). Methicillin-resistant *S. aureus* (MRSA) is rare in the community-acquired empyema and was responsible for 2% of cases in one study.[50] Polymicrobial infections are frequent, especially when anaerobes are present. Hospital-acquired pleural infections have higher rates of MRSA (~25% of cases) and gram-negative organisms (~25%). The risk of death is approximately fourfold higher in nosocomial cases when compared with community-acquired cases.[50,58] Of note, although most antibiotics penetrate the pleura well, aminoglycosides may be inactivated at the lower pH present in pleural infections.[60]

Once complicated effusion or empyema is identified, pleural fluid must be evacuated from the pleural space for infection source control and prevention of fibrous rind formation. Historically, larger-bore chest tubes (>32 French) were used to treat pleural space infection, but clinical practice has shifted toward insertion of small-bore tubes. This is largely because of the relative ease of placement of smaller-bore tubes with less pain at the insertion site rather than results of a randomized clinical trial. The best current data for noninferiority of small-bore chest tubes come from post hoc analysis of 405 patients in the Multicenter Intrapleural Sepsis Trial I (MIST I) in which there were no differences in the rates of clinical failure in patients with small- versus large-bore chest tubes (size <10 36%; size 10–14F 36%; size 15–20F 40% and size >20F 44%, $P = 0.27$), but there was significantly less pain in the smaller-bore groups.[61]

After thoracostomy tube placement, output and radiologic assessment of the pleural space should be undertaken. If there is persistent pleural fluid after 24 hours, it is reasonable to initiate therapy with fibrinolytics/DNase to break down fibrin and clear cellular debris. Although initial trials with DNase or fibrinolytics had inconsistent evidence for benefit, they were limited by power or poor study design.[62] In 2011, the Multicenter Intrapleural Sepsis Trial II (MIST 2) randomized 210 patients with intrapleural infection to one of four therapies for 3 days: intrapleural tissue plasminogen activator (tPA) and placebo, intrapleural DNase and placebo, intrapleural tPA and DNase, or double placebo.[63] The primary outcome was the percentage of hemithorax occupied by pleural effusion at day 7 compared with day 1 (at randomization) as assessed by chest x-ray. The authors found that the tPA + DNase group had significantly reduced the size of pleural effusion when compared with the double-placebo group. tPA alone

TABLE 12.4 Radiographic and Biochemical Characteristics of Uncomplicated and Complicated Pleural Effusions

	Radiographic	pH	Glucose	Drainage Recommended
Uncomplicated small	<1 cm on bedside ultrasound	not assessed	not assessed	no
Uncomplicated moderate	>1 cm on ultrasound and less than half the hemithorax	>7.2	>60 mg/dL	no
Complicated	septation, debris, pleural thickening on ultrasound or volume more than one-half the hemithorax	<7.2	<60 mg/dL	yes
Empyema	similar to complicated	pus on aspiration		yes

or DNase alone did not significantly reduce the size of the pleural effusion when compared with placebo. Secondary outcomes of hospital length of stay and referral for thoracic surgery at 3 months were significantly lower in the tPA + DNase group when compared with double placebo. Notably, patients treated with DNase alone had a threefold increase in thoracic surgery referral at 3 months.

Surgical evacuation of pleural infections is often reserved for those who have failed tube thoracostomy with medical therapy or those who present late with multiloculated, organized empyemas. However, there have been six small randomized controlled trials of early video-assisted thoracoscopic surgery (VATS) decortication versus conventional tube thoracoscopy with fibrinolytics, mostly in children. A Cochrane review and meta-analysis of these studies concluded that early VATS was associated with significant reduction in hospital length of stay (−2.5 days) with no difference in mortality. The studies had significant heterogeneity and were limited by a relatively small sample size. A large randomized clinical trial of early VATS versus intrapleural fibrinolysis/DNase in adults fit for surgery should be pursued.[64]

When operative management of pleural infection is pursued, the preferred procedure is VATS decortication. The objectives of VATS are to unroof all loculated collections, including fissural loculations, and to free the lung from visceral pleural fibrous casing. After the procedure, the thorax is usually drained with three relatively large chest tubes (28F) to facilitate removal of debris and blood associated with the intervention. When a dense, fibrous peel prevents successful VATS decortication, a lateral muscle-sparing thoracotomy ("mini-thoracotomy") can be pursued. In the rare case of chronic empyema, standard posterolateral thoracotomy is often required. Occasionally patients with necrotic infections of the lung and pleural space require chronic open thoracic drainage with an Eloesser flap, in which marsupialization of the thoracic cavity is accomplished via segmental rib resection and ligation of skin to the underlying parietal pleura.[65] Alternatively, thoracostoma-mediated open drainage with suturing the skin margin to the chest wall and use of vacuum-assisted wound closure have been implemented with success.[66]

Hemothorax

Hemothorax in the surgical ICU (SICU) is predominantly the result of trauma. Blunt trauma–induced hemothorax is usually related to motor vehicle crashes, assaults, and falls. Falls in the elderly are becoming a more frequent cause of rib fractures because of the aging population. The dominant source of bleeding is the chest wall, and specifically rib fractures.[67] Sternal fractures, however, may be associated with internal mammary arterial transection, which can manifest as life-threatening delayed bleeding.[68] Delayed bleeding from a torn thoracic aorta is rare because routine whole-body CT scanning is done for major trauma evaluation before SICU admission.[69] Hemothorax after penetrating trauma is also frequently the result of rib fractures but may result from persistent lung parenchymal bleeding.[69] In the medical ICU, hemothoraces are rare, occur most often in patients with chronic kidney disease, and are usually iatrogenic from thoracentesis or chest thoracostomy.[70]

The first management decision is when to decompress a hemothorax. Traditionally, hemothoraces have been considered small if <500 mL, moderate at 500–1000 mL, and large at >1000 m:. But more recently the classification has been small <300, medium 300–900, and large >900.[71] A plain chest radiography usually requires >300 mL of blood to be recognized, although ultrasound is more sensitive.[72] CT scanning can assist in quantifying the size of the hemothorax if an intervention is considered (volume = $d^2 \times l$; d = depth, l = length).[73] The primary complication of a hemothorax is empyema, although a lung-restricting fibrothorax is a theoretical complication with larger collections. Experimentally,[74] and clinically,[75] it has been established that a normal pleural cavity can absorb a sizable hemothorax without adverse sequela. Factors that may impair resorption of a hemothorax include rib fractures, lung contusion, or diaphragm injury. Associated pneumothorax may also increase the risk of secondary infection. In general, most recommend that a hemothorax >300 mL should be evacuated by tube thoracostomy, but there are no randomized studies to indicate a limit for safe observation.

The second decision is the size of the tube for thoracostomy. For decades, a 36F chest tube was considered standard for any hemothorax to ensure rapid and complete evacuation. However, randomized trials have established a 28F tube is as effective and less traumatic to introduce.[76] In fact, recent studies suggest a 14F catheter may be sufficient.[77] Another contemporary issue has been the role of intrathoracic irrigation of the pleural space at the time of chest tube placement to minimize the risk of retained hemothorax.[78]

The third decision is the rare event of the need for operative intervention because of massive or ongoing pleural bleeding. The indications for emergent thoracotomy are based on data for initial presentation in the emergency department. In general, the indications for surgical intervention are an acute large-volume collection (>20 mL/kg, ~1500 mL), persistent bleeding (>3 mL/kg/hr for >3 hr, ~250 mL), or a caked hemothorax.[79] A caked hemothorax is the failure to evacuate a large blood collection with a second tube thoracostomy.

A more common problem in the ICU is a retained hemothorax (i.e., a persistent blood collection despite a well-positioned tube thoracostomy). Retained hemothoraces are often progressive blood collections, but may be a result of delayed bleeding, usually from displaced rib fractures. "Retained hemothorax" is often a misnomer in the setting of blunt trauma where ongoing inflammation causes collection of exudative fluid rather than true blood. Regardless, the scenario is compounded by a chest tube that may serve as a conduit for bacteria to infect the hematoma. Fibrinolytic therapy would appear optimal for a retained hemothorax, but the ability for tPA to enter a mature clot is limited. Unfortunately, most reported experience represents small, nonrandomized series, although some with compelling results.[80] In general, most intensivists will attempt tPA and DNase via the chest tube for simple collections. But large, persistent, or complex collections require VATS evacuation. Collective experience suggests early intervention (<day 4) is more successful in complete clot removal with less risk of pleural damage, so the "3-day rule for VATS" is widely accepted to prevent empyema or the theoretical restrictive fibrothorax.[81] The technical aspects of VATS are similar to those for any complicated pleural collection, although the dominant clot burden will usually exist in the dependent inferior pleural space.

Chylothorax

Chylothorax is the collection of chyle in the pleural space. Unlike chyle within the peritoneal space, which typically resolves without intervention, chyle in the chest is more persistent because of negative intrathoracic pressure. In the pleural cavity, the source of chyle is the thoracic duct, which extends from the cisterna chyli in the retroperitoneum via the mediastinum to empty into the venous system at the juncture of the left subclavian and jugular veins. Chyle consists of triglycerides in the form of chylomicrons, T lymphocytes, proteins, immunoglobulins, fat-soluble vitamins, and electrolytes; the predominant contents are derived from the intestine to be delivered to the bloodstream.[82] Chyle also contains constituents from the lymphatics of the other abdominal viscera, lung, and lower extremities. Total flow in the thoracic duct normally ranges from 1500 to 2500 mL/day and is augmented by dietary intake of fat.

The etiology of chylothorax can be broadly divided into trauma and nontrauma causes.[83–85] Trauma is usually the result of thoracic surgery, direct injury from penetrating wounds, or less commonly, blunt rupture. Iatrogenic injuries of the thoracic duct can occur with left-sided central venous access, and extravasation of lipid-containing total parenteral nutrition (TPN) can confuse the diagnosis. Nontraumatic etiology is most often malignancy, but there are a myriad of benign immune/inflammatory sources. Interestingly, an idiopathic cause is reported in 5%–15%. Consequently, the etiology of chylothorax varies considerably between medical intensive care units (MICUs) and SICUs.

The clinical manifestations of chylothorax are initially those resulting from a pleural effusion, as discussed previously. The side of the chylothorax is dependent on the location of the thoracic duct pathology. The thoracic duct traverses the mediastinum at approximately the fifth thoracic vertebra (i.e., lesions below T5 produce right pleural effusions and above T5 left effusions).[82] Chest pain and fever are unusual because there is a limited inflammatory response to the chyle that remains sterile as a result of the immunoglobulin content. On the other hand, chronic loss of immunoglobulins, T cells, and protein may produce immunosuppression and malnutrition, increasing the risk of infection in extrapleural locations and poor wound healing.[83–85] Tube thoracostomy output of a milky fluid is a hallmark of chylothorax, but is not clinically apparent in half of the patients. Furthermore, cholesterol pleural effusion and empyema may produce the same appearance.[86] The pleural volume output varies substantially depending on the etiology and size of the thoracic duct lesion. In patients with nontraumatic chylothorax, the course is often indolent, whereas postsurgical or postinjury chylothorax usually presents within the first week and the chest tube output often exceeds 500 mL/day.[87]

The diagnosis of chylothorax is established by analysis of the pleural fluid.[42] Triglyceride and cholesterol levels are determined in addition to the standard tests for pleural fluid, as discussed previously. The pH of a chylothorax exceeds 7.4, thus distinguishing it from an empyema (except for infections involving *Proteus* species). The LDH is low, and electrolytes and glucose levels reflect those in the plasma. However, the protein content of chylothoraces is usually elevated sufficiently to qualify as exudative. The white blood differential has a predominance of lymphocytes, which are largely polyclonal T cells. Lipid analysis is the most definitive for the diagnosis of chylothorax. Triglycerides generally exceed >110 mg/dL and cholesterol is <200 mg/dL. Triglycerides can be <110 mg/dL, but a cholesterol >200 mg/dL suggests a cholesterol effusion.[42,86] In the event of equivocal results, chylomicrons can be measured by lipoprotein electrophoresis.

With the diagnosis of chylothorax established, the next step is to identify the source. A chest CT scan is usually the first step for any chylothorax. The location of trauma-induced effusions is further pursued based on the side of injury—left-sided are usually the result of lesions above T5. Considering the innumerable causes of nontraumatic chylothorax, the evaluation is targeted sequentially to the most likely etiology. In the event of an unhelpful chest CT scan, alternative diagnostic tests include lymphangiography, lymphoscintigraphy, or magnetic resonance (MR) lymphangiography.[88]

The management of chylothorax varies substantially based on the etiology and rate of chyle accumulation. Low-output chylothorax is defined as <1000 mL/day. In general, the initial approach consists of continuous thoracostomy tube or catheter drainage, oral or enteral diet with high protein and low fat (<10 gm fat/day, minimizing long-chain triglycerols),[89] and somatostatin or octreotide.[90] For prolonged leaks, medium chain triglycerols can be added to the diet to avoid essential fatty acid deficiency because they are absorbed from the intestine and transported directly to the liver via the portal vein.[91] An essential component is treatment of an underlying medical disorder that is driving the chyle leak if present.

The management strategy for a high-volume chylothorax (>1000 mL /day) is more aggressive. Usually patients are placed immediately on TPN,[92] which has no fat restrictions, and administered octreotide.[90] Interventions are frequently done early for postoperative persistent high-volume leaks because of progressive morbidity from chyle content loss.[93] Percutaneous lymphatic interventions are usually attempted first where the capabilities exist.[94] The procedures include thoracic duct embolization or ablation and therapeutic lymphangiography.[95,96] For those who fail, an operative approach is needed, which usually consists of thoracic duct ligation and glue application and often combined with pleurodesis. VATS is an option for a clearly defined leak. For failures of this step-up approach or for high-risk patients, pleuroperitoneal or pleurovenous shunts are options.[97]

KEY POINTS

- Pleural effusions are classified as transudative or exudative by Light's criteria.
- Treatment of pleural effusion is targeted at the specific etiology of the effusion.
- Drainage of uncomplicated effusions in mechanically ventilated patients is controversial: It may improve oxygenation and respiratory mechanics, but it is unclear whether this facilitates liberation from the ventilator.
- Parapneumonic effusions with pH <7.2, glucose <60 mg/dL, and complex appearance on ultrasound or chest CT require drainage with tube thoracostomy.
- Community-acquired pleural space infections are usually caused by *Streptococcal* species.
- Hospital-acquired pleural space infections are often caused by methicillin-resistant *S. aureus* and resistant gram-negative rods.
- Moderate (>300 mL) and large hemothoraces should be drained with tube thoracostomy.
- Small-bore chest tubes appear to have similar efficacy to larger chest tubes in complicated parapneumonic effusion, empyema, and hemothorax.

Bauman ZM, Kulvatunyou N, Joseph B, et al. A prospective study of 7-year experience using percutaneous 14-French pigtail catheters for traumatic hemothorax/hemopneumothorax at a level-1 trauma center: Size still does not matter. *World J Surg*. 2018;42(1):107–113.
Bauman et al. prospectively evaluated the outcomes in patients who had small-bore (14F) pigtail catheters versus larger-bore chest thoracostomy tubes in the setting of traumatic hemothorax and hemopneumothorax at a single level-1 trauma center from 2008 to 2014. The authors found that although there were some baseline differences between patients who received pigtail catheters and chest thoracostomy tubes (pigtails were placed in older patients and more frequently with blunt trauma), there were no differences in procedure-related complications or failure rates.

Chakko SC, Caldwell SH, Sforza PP. Treatment of congestive heart failure. Its effect on pleural fluid chemistry. *Chest*. 1989;95(4):798–802.
Chakko et al. report a longitudinal study of pleural fluid biochemical characteristics in eight patients with congestive heart failure and pleural effusions. They demonstrated that treatment of heart failure with diuretics leads to an increase in pleural total protein and LDH levels. Three out of eight patients with heart failure–related pleural effusions were misclassified as exudative based on Light's criteria after diuresis.

Goligher EC, Leis JA, Fowler RA, et al. Utility and safety of draining pleural effusions in mechanically ventilated patients: A systematic review and meta-analysis. *Crit Care*. 2011;15(1):R46.

This systematic review identified 19 observational studies of drainage of pleural effusions in mechanically ventilated patients. The conclusion was that the PaO_2/FiO_2 ratio appeared to improve and the procedure was safe. However, there were insufficient data to suggest whether this translated to reduced duration of mechanical ventilation, ICU or hospital length of stay, or mortality.

Light RW, Macgregor MI, Luchsinger PC, et al. (1972). Pleural effusions: The diagnostic separation of transudates and exudates. *Ann Intern Med.* 1972;77(4):507–513.

Light et al. define criteria that separate transudative and exudative pleural effusions. Exudative effusions are defined by any of the following three criteria: ratio of protein in the pleural space to the serum >0.5, ratio of LDH in the pleural space to the serum >0.6, or LDH in the pleural space more than two-thirds the upper limit of normal LDH for the serum.

Rahman NM, Maskell NA, West A, et al. Intrapleural use of tissue plasminogen activator and DNase in pleural infection. *New Engl J Med.* 2011;365(6):518–526.

The MIST2 trial was a randomized, blinded, 2 × 2 factorial trial of a combination of intrapleural tPA and DNase, intrapleural tPA + placebo, intrapleural DNase + placebo, or double placebo in 210 patients with complicated parapneumonic effusion or empyema. The primary outcome of change in the area of pleural opacity on chest x-ray was significantly improved with use of the combination of intrapleural tPA and DNase when compared with placebo (−29.5% versus −17.2%). The rate of surgical referral at 3 months was lower in the combination tPA and DNase group than placebo (4% versus 16%), and hospital length of stay was shortened in the combination tPA and DNase group (−6.7 days). There were no significant differences in primary or secondary outcomes in the tPA- and DNase-alone groups with the exception of increase in surgical referral in the DNase-alone group (39%).

Polyuria

Ramesh Venkataraman and John A. Kellum

PATHOPHYSIOLOGY AND CLASSIFICATION

The daily urine output is determined predominantly by the daily intake of fluids, daily solute excretion, and the urine-concentrating ability of the nephrons. The average person excretes about 600–800 mOsm of solutes per day, and average urine output is about 1.5–2.5 L/day. Polyuria happens usually because of one or more of the following mechanisms:

- Increased fluid intake, necessitating excretion of a large volume of urine (primary polydipsia)
- Increased glomerular filtration rate (rare)
- Increased solute excretion (solute or osmotic diuresis)
- Inability of the kidney to reabsorb water (central or nephrogenic diabetes insipidus [DI])

Polyuria is hence broadly classified into *solute diuresis* or *water diuresis*. When increased solute excretion drives the polyuria, it is termed *solute diuresis.* Increased urine output secondary to increased water intake or impaired water reabsorption is termed *water diuresis.* However, some patients have mixed water and solute diuresis.

RECOGNITION OF POLYURIA

In critically ill patients, polyuria is usually easy to identify in patients with an indwelling urinary catheter. Careful measurement of urine volume passed or placement of a urinary catheter should be undertaken in patients who have increased urinary frequency; who are passing large volumes of urine; and who are severely hyperglycemic, hypercalcemic, or hypokalemic. Importantly, because intensive care unit (ICU) patients frequently receive in excess of 3 L a day in total input, urine output may exceed 3 L without pathology. Therefore clinical context and clinical judgement are required.[1,2]

SOLUTE DIURESIS

Total daily urinary solute excretion varies widely varies different ethnicities, cultures, and dietary habits. The average urinary solute excretion in a healthy American adult is between 500 and 1000 mOsm/d. Solute or osmotic diuresis causing polyuria is due to solute excretion in excess of the usual excretory rate.[3] The primary abnormality in such conditions is the inability for the kidney to reabsorb a large proportion of the solute filtered. Increased solute load can be secondary to excess solute intake or increased generation of solutes because of metabolism. Increased solute intake can occur after administration of intravenous fluids (saline, dextrose, or bicarbonate); enteral or parenteral nutrition; or ingestion of exogenous proteins, sugars, or alcohols. Increased solute generation from metabolism is seen in hyperglycemia and azotemia.

Solute excretion increases urine output in a linear fashion,[4] and solute diuresis impairs the ability of the kidney to concentrate the urine. Solute diuresis can be quite severe and can be caused by more than one solute concurrently. Unless there is an adequate replacement of solute and water, a persistent solute diuresis contracts extracellular volume, leading to severe dehydration and hypernatremia.

Multiplying urine osmolality by the 24-hour urine volume gives an estimate of total urine solute concentration. If urinary total solute concentration is abnormally large, a solute diuresis is present. Solute diuresis is caused by either excessive electrolyte excretion or excessive nonelectrolyte solute excretion. If the total urinary electrolyte excretion exceeds 600 mOsm/d, then an electrolyte diuresis is present. The total urinary electrolyte excretion (in mOsm/d) can be estimated as $2 \times (\text{urine } [Na^+] + \text{urine } [K^+]) \times \text{total urine volume}$.[5] Electrolyte diuresis is generally driven by a sodium salt, usually because of iatrogenic administration of excessive normal saline or sodium bicarbonate solutions, excessive salt ingestion, and repetitive administration of loop diuretics. However, salt-losing nephropathies usually do not cause polyuria because the increased delivery of chloride to the macula densa cells triggers tubuloglomerular feedback, causing afferent arteriolar constriction and resulting in decreased glomerular filtration rate (GFR) and an overall decrease in sodium excretion.

Cerebral salt wasting (CSW) is a clinical syndrome characterized by excess renal sodium excretion, polyuria, hypovolemia, and hyponatremia.[6] Although most often seen in patients with aneurysmal subarachnoid hemorrhage (SAH), it can occur in any primary neurologic illness, including central nervous system (CNS) tumors, infectious or carcinomatous meningoencephalitis, and after neurosurgical procedures. Normally, the sympathetic nervous system promotes reabsorption of sodium directly at the proximal tubule. During CSW, increased sodium excretion occurs possibly because of impaired sympathetic neural input to the kidney related to the brain injury. Another putative mechanism involves release of brain natriuretic peptide (BNP) leading to decreased sodium reabsorption and renin release. The resulting solute diuresis and polyuria cause hypovolemia, which then stimulates antidiuretic hormone (ADH) release via a baroreceptor-mediated mechanism, leading to water retention and hyponatremia. Often CSW and syndrome of inappropriate ADH secretion (SIADH) overlap and are difficult to distinguish biochemically. Clinical evidence of volume contraction suggests a diagnosis of CSW, whereas patients with SIADH are usually euvolemic.

A clearly excessive value for urine nonelectrolyte excretion (i.e., >600 mOsm/d) implies that nonelectrolytes are the predominant solutes contributing to the diuresis. The urinary nonelectrolyte excretion can be calculated by subtracting urine electrolyte excretion from the total urine solute excretion. The most common nonelectrolyte solute causing excessive diuresis is glucose, although its incidence is

decreasing in critically ill patients because of tighter glycemic control practices. Conditions associated with glucose-induced diuresis include diabetic ketoacidosis or hyperosmolar state.[7] Excessive excretion of urea is another important cause of solute diuresis. This problem can occur after relief of urinary tract obstruction, as a consequence of enteral nutrition using a high-protein tube feeding formula, or during recovery from acute tubular necrosis. Mannitol administration (e.g., as a therapy for intracranial hypertension) also can lead to significant solute diuresis. This issue is pertinent because mannitol is often administered to patients with head trauma, who are at risk for development of nephrogenic DI.

The correct diagnosis of solute diuresis depends on a clear systematic approach as discussed earlier. Management usually involves treatment of the underlying disorder and repletion of extracellular volume by hydration.

WATER DIURESIS

Definition and Pathophysiology

When polyuria occurs because of excess water intake or impaired water reabsorption, it is called *water diuresis.* The latter is usually secondary to impaired ADH release (central DI) or resistance to the action of ADH (nephrogenic DI). The usual hallmark is polyuria associated with a dilute urine (urine osmolality <300 mOsm/L). In general, diuresis is marked, and urine osmolality (Uosm) is often less than 100 mOsm/L.

A good understanding of water homeostasis is critical for recognizing and managing water diuresis. The normal plasma osmolality is 275–285 mOsm/L. To maintain this steady state while maintaining solute balance, water intake must equal water excretion. The primary stimulus for water ingestion is thirst, mediated either by an increase in effective osmolality or a decrease in blood pressure or effective circulating volume. Under normal circumstances, water intake generally exceeds physiologic requirements.

Unlike water intake, water excretion is very tightly regulated by multiple factors. The most dominant regulating factor affecting water excretion is arginine vasopressin (AVP) or ADH, a polypeptide synthesized in the hypothalamus and secreted by the posterior pituitary gland. The major stimulus for ADH release is plasma hypertonicity. ADH release is also affected by other nonosmotic factors, such as the effective circulating volume, hypoglycemia, and drugs. Once released, ADH binds to vasopressin-2 (V2) receptors located on the basolateral membranes of renal epithelial cells lining the collecting ducts. Binding of ADH to V2 receptors initiates a sequence of cellular events, ultimately resulting in the insertion of water channels called *aquaporins* into the luminal cell membrane. The presence of these water channels permits passive diffusion of water (hence its reabsorption) across the collecting duct. Any derangement in this process results in a lack of or inadequate water reabsorption by the collecting duct and will result in water diuresis.

In summary, water diuresis occurs either because of excessive water intake sufficient to overwhelm the renal excretory capacity (primary polydipsia) or the impairment of renal water reabsorption itself (DI). Impaired renal water reabsorptive capacity (leading to water diuresis) in turn can occur either as a result of failure of ADH release in response to normal physiologic stimuli (central or neurogenic DI) or failure of the kidney to respond to ADH (nephrogenic DI). In most patients, the degree of polyuria is primarily determined by the degree of ADH deficiency or AVP resistance.

Primary Polydipsia

Primary polydipsia, although rare in the ICU, can be clinically recognized based on the history of the patient. Usually there is a history of psychiatric illness, especially when phenothiazines are being used. Some patients with chronic psychiatric illnesses have a moderate to marked increase in water intake (up to 40 L/day).[8,9] It is presumed that a central defect in thirst regulation plays an important role in the pathogenesis of primary polydipsia. In some cases, the osmotic threshold for thirst is reduced below the threshold for the release of ADH. The mechanism responsible for abnormal thirst regulation in this setting is unclear. There is evidence that these patients have other defects in central neurohumoral control as well.[10] Hyponatremia, when present, also points to the diagnosis of primary polydipsia. The diagnosis of primary polydipsia is usually evident from low urine and plasma osmolalities in the face of polyuria. Hypothalamic diseases such as sarcoidosis, trauma, and certain drugs (e.g., phenothiazines) can lead to primary polydipsia (Table 13.1). There is no proven specific therapy for psychogenic polydipsia. Free water restriction is the mainstay of treatment.

Central Diabetes Insipidus

The osmotic threshold for ADH release is a serum osmolality of 280–290 mOsm/kg. Failure to maximally concentrate the urine (urine osmolality >1000 mOsm/kg) despite a serum osmolality above the osmotic threshold indicates DI. Central DI occurs when there is a defect in the secretion of ADH. Inadequate secretion of ADH (central DI) can be caused by a large number of disorders that act at one or more of the sites involved in ADH secretion, interfering with the physiologic chain of events that lead to the release of this hormone. However, the most common causes of central DI account for the vast majority of cases. Polyuria occurs when >80% of neurons secreting ADH are damaged.[11] These common causes include neurosurgery, head trauma, brain death, primary or secondary tumors of the hypothalamus, and infiltrative diseases such as Langerhans cell histiocytosis (see Table 13.1).

TABLE 13.1 Cause of Polyuria

1. Polyuria secondary to water diuresis
   - a. Excessive intake of water
     - i. Psychogenic polydipsia
     - ii. Drugs—anticholinergic drugs, thioridazine
     - iii. Hypothalamic diseases—trauma, sarcoidosis
   - b. Defective water reabsorption by the kidney
     - i. Central diabetes insipidus (vasopressin deficiency)
     - ii. Renal tubular resistance to AVP
2. Congenital nephrogenic diabetes insipidus
3. Acquired nephrogenic diabetes insipidus
   - a. Hypercalcemia
   - b. Hypokalemia
   - c. Drugs—lithium, demeclocycline
   - d. Chronic renal diseases—postobstructive diuresis, polyuric phase of ATN
   - e. Other systemic diseases—amyloidosis, sickle cell anemia
4. Polyuria secondary to solute diuresis
   - a. Electrolyte-induced solute diuresis
     - i. Iatrogenic—excessive sodium chloride load, loop diuretic use
     - ii. Salt-wasting nephropathy (rarely causes polyuria)
   - b. Nonelectrolyte solute–induced diuresis
     - i. Glucosuria—diabetic ketoacidosis, hyperosmolar coma
     - ii. Urea diuresis—high-protein diet, ATN
     - iii. Iatrogenic—mannito

ATN, Acute tubular necrosis; *AVP,* arginine vasopressin.

Nephrogenic Diabetes Insipidus

Nephrogenic DI refers to a decrease in urinary concentrating ability because of renal resistance to the action of ADH. In some cases, collecting duct cells fail to respond to ADH. Other factors that can cause renal resistance to ADH are problems that interfere with the renal countercurrent concentrating mechanism, such as medullary injury or decreased sodium chloride reabsorption in the medullary aspect of the thick ascending limb of the loop of Henle.

The most common cause of nephrogenic DI in adults is chronic lithium ingestion (see Table 13.1). Polyuria occurs in about 20%–30% of patients on chronic lithium therapy. The impairment in the nephrons' concentrating ability is thought to be the result of decreased density of V2 receptors or decreased expression of aquaporin-2, a water channel protein. Other secondary causes of nephrogenic DI include hypercalcemia, hypokalemia, sickle cell disease, and other drugs (see Table 13.1). Hypercalcemia-induced nephrogenic DI occurs when the plasma calcium concentration is persistently above 11 mg/dL (2.75 mmol/L). This defect is generally reversible with correction of hypercalcemia. The mechanism(s) responsible for hypercalcemia-induced nephrogenic DI remain incompletely understood. Compared with hypercalcemia-induced DI, hypokalemia-induced nephrogenic DI is less severe and often asymptomatic. Water diuresis can also follow relief of obstructive nephropathy. A rare form of nephrogenic DI can occur during the second half of pregnancy (gestational DI). This condition is thought to be caused by release of a vasopressinase from the placenta, leading to rapid degradation of endogenous or exogenous AVP.[12]

In children, nephrogenic DI is usually hereditary. Congenital or hereditary nephrogenic DI is an X-linked recessive disorder resulting from mutations in the V2 AVP receptor gene.[13] The X-linked inheritance pattern means that males tend to have marked polyuria. Female carriers are usually asymptomatic but occasionally have severe polyuria. In addition, different mutations are associated with different degrees of ADH resistance. Nephrogenic DI can also be inherited as an autosomal recessive disorder because of mutations in the aquaporin gene that result in absent or defective water channels, thereby causing resistance to the action of ADH.[14]

Approach to Polyuria (Fig.13.1)

Polyuria in a critically ill patient should be evaluated in a timely manner and the underlying cause determined and rectified. For all practical purposes, polyuria should be suspected in patients with urinary volume >200 mL/h for 2 or more consecutive hours in the absence of diuretic administration. A thorough review of patient history, medication list, and clinical and laboratory parameters often reveals the underlying cause of polyuria in a large proportion of critically ill patients. Common causes of solute diuresis, such as hyperglycemia, hypercalcemia, mannitol use or intravenous saline or bicarbonate use, and azotemia, are apparent by routine review of laboratory studies. History of an intervention to relieve bilateral urinary tract obstruction points toward solute diuresis because of increased sodium and urea excretion. Post-neurosurgery status, presence of traumatic brain injury, and clinical brain death suggest central DI as the likely cause of polyuria. History of a primary neurologic insult can suggest polyuria either because of CSW or central DI. The presence of severe hypothermia or hypokalemia and a history of lithium intake make nephrogenic DI the likely reason for polyuria. The rate of onset of polyuria can sometimes provide a clue about the diagnosis; when central DI is the problem, the onset of polyuria is generally abrupt, whereas when nephrogenic DI or primary polydipsia is the problem, the onset of polyuria tends to be more gradual.

When the cause of polyuria is not readily apparent, as a first step, spot urine osmolality should be measured. When urine osmolality is low (<300 mOsm/kg), it suggests a water diuresis from primary polydipsia or DI. On the other hand, when the urine osmolality is high (>600 mOsm/kg), it usually indicates the presence of solute diuresis. Urine osmolality values between 300 and 600 mOsm/kg could be the result of solute diuresis, water diuresis, or mixed diuresis. Plasma sodium concentration, along with urine osmolality, often helps in identifying the underlying pathophysiology. A low serum sodium with dilute urine indicates primary polydipsia. A normal plasma sodium may indicate solute or water diuresis. In such patients, if the urine osmolality is >600 mOsm, it usually indicates a solute diuresis and no further testing is necessary. If urine osmolality is indeterminate (300–600 mOsm/kg), total daily osmolar output can be calculated (Uosm × 24-hour urine volume) and if it is >1000 mOsm, solute diuresis can be diagnosed. A high plasma serum sodium in the presence of dilute urine indicates excretion of excess amounts of free water and favors a diagnosis of DI. In a patient with a neurologic disorder, it is important to differentiate polyuria caused by central DI from that caused by CSW (Table 13.2). Although both conditions lead to hypovolemia, CSW has increased urine osmolality from decreased sodium and urea reabsorption, whereas urine osmolality is very low because of water diuresis in central DI. CSW presents with hyponatremia, whereas patients with central DI often have hypernatremia.

When the diagnosis is unclear (plasma sodium is normal and urine osmolality is indeterminate), the diagnosis can be confirmed by determining the urinary response to an acute increase in plasma osmolality induced either by water restriction or, less commonly, by administration of hypertonic saline. When the patient is evaluated after water restriction, the urine osmolality, plasma osmolality, and plasma sodium should be measured. Achievement of a serum sodium >145 mEq/L and serum osmolality >295 mOsmol/kg ensures maximal ADH release and response in normal individuals with no additional effect with external ADH administration. Hence, if the urine osmolality reaches a normal value (>700 mOsmol/kg) after water restriction, this indicates that both ADH release and its action on collecting ducts are intact and the diagnosis is primary polydipsia. However, if urine osmolality is <700 mOsm despite a serum osmolality >295 mOsm/kg and serum sodium >145 mEq/dL, it denotes a blunted ADH release or ADH effect, and hence administration of exogenous ADH is recommended. Desmopressin nasal spray or as a subcutaneous or intravenous injection is preferred over aqueous vasopressin injections because of its shorter half-life. Urine volume and osmolality should be monitored every 30 minutes for the first 2 hours after exogenous ADH administration. Urine osmolality will be doubled after ADH administration in patients with central DI. In patients with complete nephrogenic DI, no significant change (<15%) in urine osmolality is seen after exogenous ADH administration. A small increase in urine osmolality (<45%) is seen in patients with partial nephrogenic DI. In contrast to patients with partial central DI, in patients with partial nephrogenic DI, urine remains dilute with osmolality not >300 mOsm/kg despite desmopressin administration. An alternative to performing a therapeutic trial of desmopressin is to measure plasma copeptin levels after infusing hypertonic saline to stimulate ADH release. However, copeptin assays are not yet widely available for clinical use. Copeptin is the C-terminal glycoprotein moiety of the ADH prohormone and therefore a surrogate marker of ADH.15 To distinguish central DI from primary polydipsia, hypertonic saline is infused to raise the serum sodium to >145 mEq/L, at which point plasma copeptin is measured. Copeptin levels ≤4.9 pmol/L indicate central DI, whereas higher levels suggest primary polydipsia.

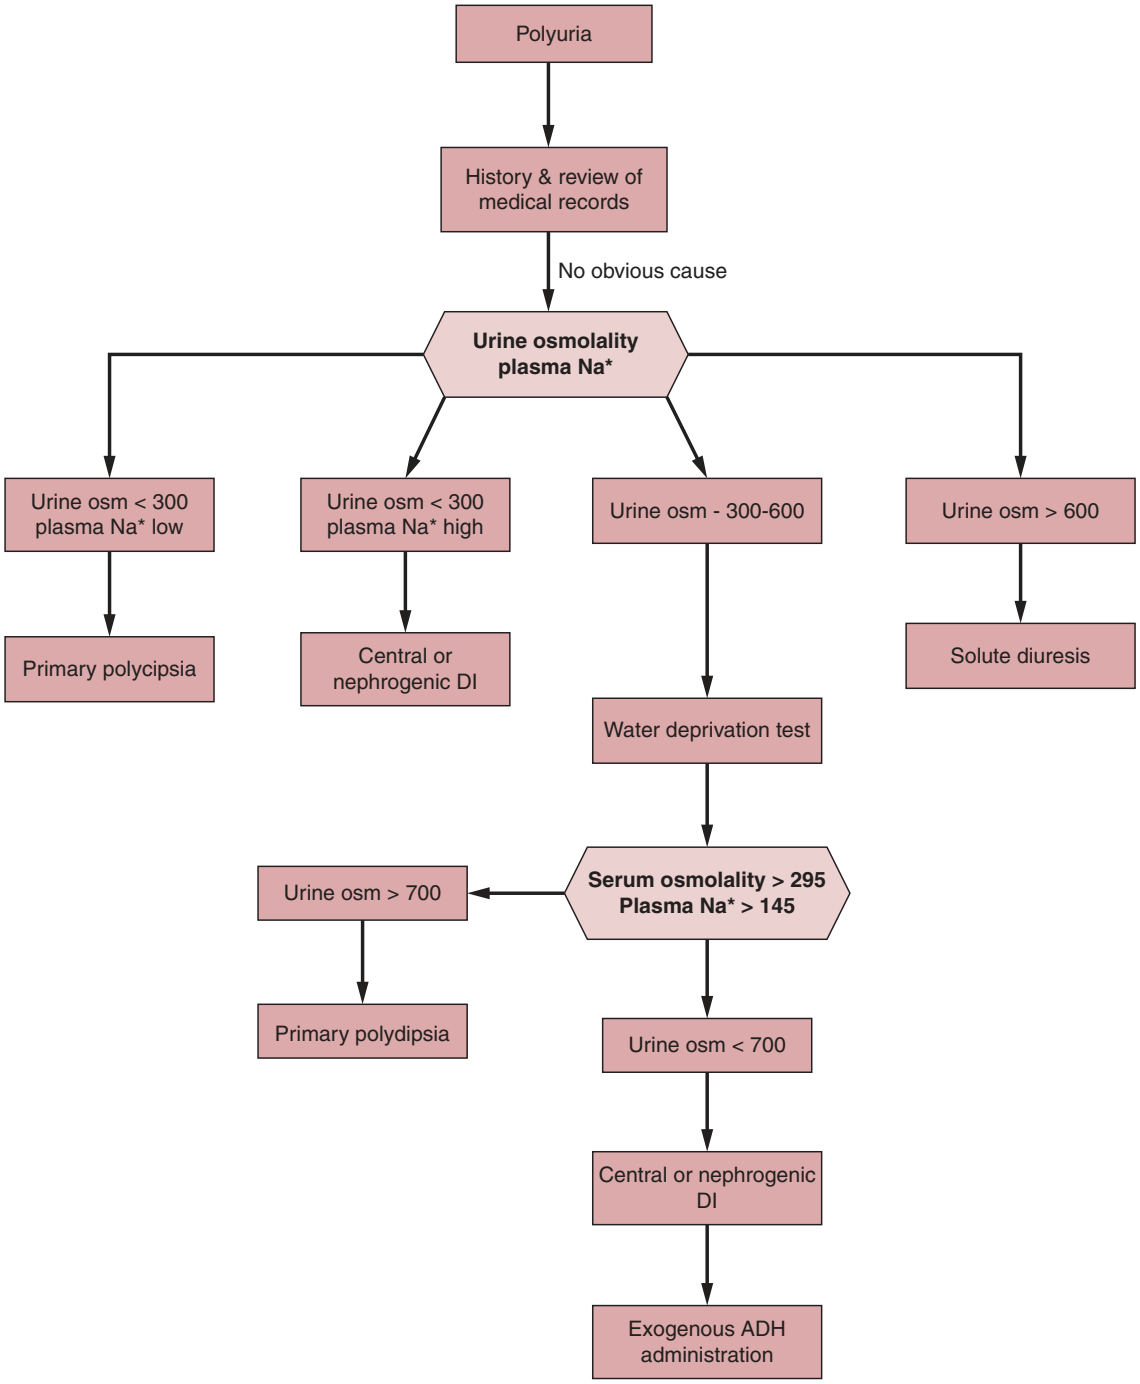

Fig. 13.1 Approach to polyuria.

TABLE 13.2 Differentiation of Cerebral Salt Wasting vs. Central DI

	Cerebral Salt Wasting	Central DI
Urine osmolality	High (>300 mOsm)	Low (<300 mOsm)
Serum osmolality	Low	High
Urine sodium	High (>40 mEq/L)	Low (<20 mEq/L)
Serum sodium	Low	High
Intravascular volume	Low	Low

DI, Diabetes insipidus.

Treatment of Polyuria

Primary polydipsia can only be treated by eliminating the underlying cause and by water restriction. In patients with schizophrenia and polydipsia, clozapine has been shown to have a beneficial effect. Treatment of the underlying cause will resolve polyuria in patients with solute diuresis. In patients with postobstructive diuresis, urine output is often very high because of combined sodium and urea diuresis. In such situations, attempting to replace the urine volume by intravenous infusion of isotonic saline to prevent hypovolemia will delay resolution of polyuria. A fluid infusion at a maintenance level, such as 75 mL of one-half isotonic saline per hour, is generally recommended and will

suffice to help resolve polyuria quickly without causing hypotension.[16] Because solute diuresis is often accompanied by hypernatremia, and very rapid correction of hypernatremia can have disastrous consequences (e.g., cerebral herniation), it is crucial to carefully monitor serum Na^+. The serum Na^+ should not be permitted to decrease more than 0.5–1 mEq/L per hour.

Central DI can be treated by replacing ADH. The agent of choice is desmopressin, because it has prolonged antidiuretic activity and a very minimal vasopressor effect. It is usually administered intranasally at doses of 10–20 μg once or twice a day. Patients with central DI with some residual releasable ADH can be treated with drugs, such as carbamazepine (100–300 mg twice daily), clofibrate (500 mg every 6 hours), or chlorpropamide (125–250 mg once or twice a day), that stimulate ADH release.

The mainstay of treatment of nephrogenic DI is solute restriction and diuretics. Thiazide diuretics in combination with a low-salt diet can diminish the degree of polyuria in patients with persistent and symptomatic nephrogenic DI. Thiazide diuretics (e.g., hydrochlorothiazide) act by inducing mild volume depletion. Hypovolemia induces an increase in proximal sodium and water reabsorption, thereby diminishing water delivery to ADH-sensitive sites in the collecting tubules and reducing the urine output. The potassium-sparing diuretic, amiloride, also may be helpful.[17] In patients with partial nephrogenic DI, exogenous administration of ADH can be attempted.

CONCLUSION

Polyuria is common in the ICU setting. Immediate recognition, determination of the underlying cause, and specific management will prevent significant hypotension and hypernatremia. A systematic approach based on pathophysiology is recommended to guide therapy.

KEY POINTS

- Urine output of > 3 L/day is defined as polyuria. However, any urine output >200 mL/h for 2 or more consecutive hours in the absence of diuretic administration warrants further evaluation and may require prompt treatment.
- Most causes of polyuria in the critically ill patient can be identified by a careful review of patient history and medical records, including medication list.
- When the cause of polyuria is unclear, urine osmolality along with plasma sodium should be performed.
- Very low urine osmolality (<300 mOsm/kg) indicates water diuresis, whereas urine osmolality >600 mOsm indicates solute diuresis.
- When untreated, polyuria leads to significant hypotension and hypernatremia.

Oliguria

Ramesh Venkataraman and John A. Kellum

Oliguria is one of the most common problems faced by clinicians in the intensive care unit (ICU). The goal of this chapter is to understand the reasons for oliguria and provide an evidence-based, practical, physiology-based approach to diagnosing and treating it.

DEFINITIONS AND EPIDEMIOLOGY

An average person excretes 600 mOsm of solute/day, and the maximal urinary concentration that can be achieved is 1200 mOsm/L. Hence a urine output of at least 500 mL per day is obligatory for excreting the average daily solute load. Therefore oliguria has generally been defined as urine output less than 500 mL per 24 hours.

The incidence of oliguria has been variedly reported in the literature, mainly because of the different definitions used. Some studies have estimated that up to 18% of medical and surgical ICU patients with intact renal function exhibit episodes of oliguria.[1] Furthermore, 88% of ICU patients who develop acute kidney injury (AKI) have a urine output of <0.5 mL/kg/h for 6 hours or more, and 18% have a urine output of <0.3 mL/kg/h for 24 hours or longer.[2]

To standardize the definition across different studies and populations, the Acute Dialysis Quality Initiative (ADQI) adopted a definition of *oliguria* as urine output of less than 0.3 mL/kg/h for at least 24 hours (www.ADQI.org). For all practical purposes, however, urine output under 0.5 mL/kg/h is usually considered inadequate for most critically ill patients. This is in part because fluid input resulting from medications, nutrition, and other reasons typically exceeds this threshold in critically ill patients, and fluid overload may result if urine output is inadequate to maintain fluid balance. Hence any urine output <0.5 mL/kg/h should immediately be evaluated and therapy initiated to reverse the inciting mechanism when feasible.

OLIGURIA IN ACUTE KIDNEY INJURY

Oliguria is often treated as an early marker of AKI. However, AKI need not manifest as oliguria in the intensive care setting, and oliguria is an insensitive and nonspecific clinical manifestation of AKI. Moreover, other factors, such as profound hypokalemia, hypothermia, hyperglycemia, and medications, can all lead to good urine output even in the presence of AKI, confounding the assessment of AKI severity. Although currently Kidney Disease: Improving Global Outcomes (KDIGO) definitions of AKI give equal weight to change in serum creatinine and reduction in urine output, these two measures differ significantly in terms of pathophysiology and their relationship to clinical outcomes. Although a rise in serum creatinine likely implies a true reduction in glomerular filtration, oliguria could just represent a stress response or imply an actual decrease in glomerular filtration. However, several studies have clearly demonstrated that even isolated oliguria (no creatinine criteria) is associated with significant short- and long-term adverse consequences, including death or permanent dialysis.[2] When associated with increased serum creatinine, oliguria seems to denote worse prognosis[2] and likely represents irreversible kidney injury. Ability of urine output to predict AKI also seems to vary across different patient cohorts, with better predictive ability in medical than surgical patients. When oliguria is prolonged, it almost always implies ongoing kidney injury, and the likelihood of reversibility of oliguria diminishes over time. Prowle et al. demonstrated that oliguria of longer than 12 hours' duration predicted stage 2 AKI better, and oliguria of lesser duration, although common, did not lead to biochemical AKI.[3] Hence although any oliguria (urine output <0.5 mL/kg/h) warrants a prompt assessment for risk of AKI, the presence of oliguria in itself does not imply occurrence of renal structural injury.

Pathophysiology of Oliguria

Oliguria can occur because of decreased glomerular filtration rate (GFR), increased tubular reabsorption of filtrate, or a combination of both. Factors that decrease GFR in ICU patients include overt hypovolemia related to fluid losses, hemorrhage, third-spacing, low cardiac output states, and systemic vasodilatation, as seen commonly in patients with sepsis or secondary to sedatives. In hypovolemic patients, release of antidiuretic hormone (ADH) and activation of the renin–angiotensin system lead to increased reabsorption of water and oliguria with a high urine osmolality. Similarly, other stressors such as surgery, pain, and trauma also release ADH and along with sympathetic stimulation can lead to oliguria as a physiologic response. Under these circumstances, oliguria can be easily reversed with the timely resolution of the inciting stress and/or volume replacement.

Although oliguria is simplistically perceived as a decline in glomerular filtration, multiple mechanisms have been implicated for oliguria in the critically ill patient with AKI, including overall reduction in renal blood flow, regional intrarenal variation in blood flow and redistribution, alteration in glomerular hemodynamics, direct glomerular injury, ischemia to the proximal tubule (S3 segment), renal interstitial edema, inflammatory insult, and tubular obstruction.[4] Not uncommonly, increased abdominal pressure decreases GFR by direct compression on the kidneys, leading to increased renal venous pressures. Fluid overload has been consistently shown to worsen renal functions in critically ill patients by increasing renal intracapsular and renal venous outflow pressures and is strongly associated with worsening of AKI and mortality.

Mechanical obstruction to urine flow is common and usually caused by obstruction or malposition of a urinary catheter, urethral or bladder neck obstruction from an enlarged prostate or malignancy, or tubuloureteral obstruction as seen in papillary necrosis.

DIAGNOSTIC APPROACH TO OLIGURIA

The diagnosis of oliguria necessitates an integrated approach as outlined in Fig. 14.1. Accurate monitoring of intake and output is required, usually with a urinary catheter in place. Intensive urine output monitoring has been shown to improve the detection of AKI and improve outcomes.[5] The risks of urinary catheter–associated urinary tract infections must be balanced against the benefit of hourly urine output monitoring in patients with high risk for the development of AKI. In general, patients in stage 1 KDIGO AKI or higher will benefit from accurate urine output monitoring and warrant a urinary catheter.[6] Transient oliguria is common and may not be an independent risk factor for morbidity and mortality in critically ill or injured patients, but sustained oliguria (at least 6 hours' duration) often indicates AKI and has been shown to be independently associated with hospital mortality. Oliguria mandates immediate evaluation for reversible causes and a risk assessment for AKI. The main goal of managing oliguria is to rapidly determine and correct the underlying cause(s), to halt the progression of kidney injury. Merely reacting to every oliguria with either fluid and/or diuretic therapy should be condemned, and efforts should be taken to understand and address the underlying pathophysiology. Targeted therapy to reverse the inciting events should be applied rapidly.

Clinical History and Examination

Evaluation of a patient with oliguria should start with a focused history taking, chart review, and clinical examination. A history suggestive of overt intravascular volume depletion such as history of vomiting and/or diarrhea, evidence of ongoing bleeding, perioperative fluid losses or deficits (e.g., gastric/ileostomy losses or vomiting), or extravascular fluid sequestration can point to a functional cause of oliguria with or without changes in serum creatinine or urea. History of patient comorbidities, prior or present myocardial infarction, or left ventricular systolic or diastolic dysfunction can provide clues to impaired cardiac output as a cause of oliguria. History of fever with localizing symptoms with or without hypotension makes septic AKI likely. A history of recent contrast administration for imaging, of intraoperative hypotension, or administration of nephrotoxic agents can suggest an intrarenal cause of oliguria in an adequately volume-resuscitated patient. Chart review should involve capturing of episodes of hypotension, duration of any hemodynamic instability, cumulative fluid balance, previous use of diuretics, use of nephrotoxic agents, and dosing of medications.

Routine clinical examination for volume status, including skin turgor, dry mucosa, and the presence of pedal or sacral edema, are insensitive and nonspecific and can be misleading. In critically ill patients, functional hemodynamic monitoring has become the standard for

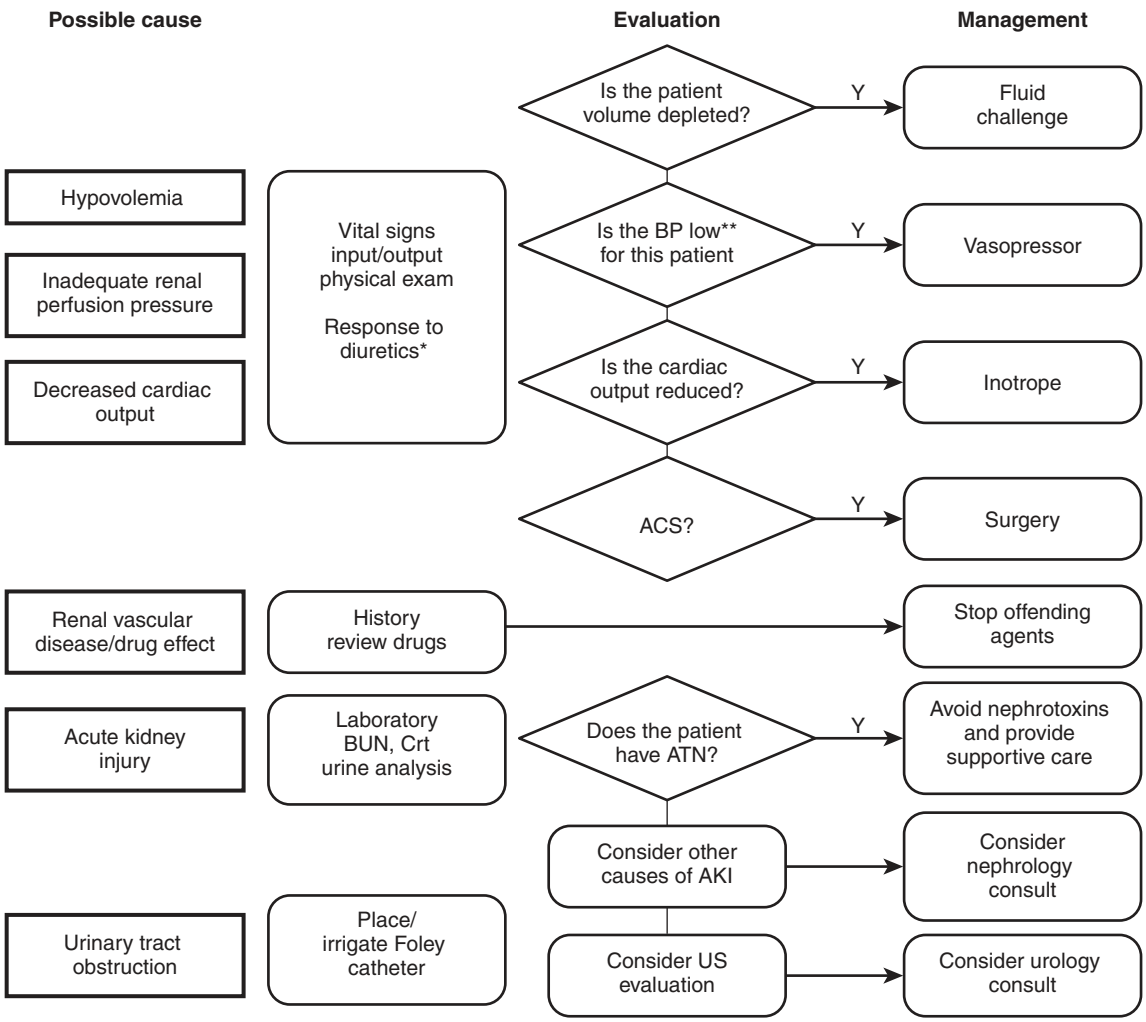

Fig. 14.1 Diagnostic Approach to Oliguria. *ACS,* Abdominal compartment syndrome; *AKI,* acute kidney injury; *ATN,* acute tubular necrosis or tubular injury; *BP,* blood pressure; *BUN,* blood urea nitrogen; *Crt,* creatinine; *US,* ultrasound.

assessment of fluid responsiveness (see later). A tense abdomen can be a very early and important clue for the onset of abdominal compartment syndrome (ACS) and should trigger frequent measurements of intraabdominal pressure (IAP) and hourly urine output monitoring.

Rule Out Urinary Obstruction

Acute oliguria in the ICU with no obvious inciting event should prompt an evaluation for postrenal obstruction. Elderly men with a prior history of prostatic hypertrophy/malignancy and elderly women with bladder neck obstruction are at high risk for such obstruction. Clinical palpation for a distended bladder and bladder ultrasound to determine residual urine volume should be immediately performed and the need for urinary catheterization decided. In critically ill patients with a urinary catheter already in place, obstruction of the urinary catheter by clots or sediments should be ruled out by flushing the catheter. Although uncommon in the acute setting, complete or severe partial bilateral ureteral obstruction may also lead to acute, "acute on chronic" failure.

Renal Imaging

An early diagnosis of urinary tract obstruction (UTO) with renal ultrasound and timely relief of obstruction will prevent further progression and secondary infections. Renal ultrasound also can be useful to assess for the presence of a chronic component to the kidney injury (decreased size of kidney and cortical thinning) and for detecting other causes of renal disease such as polycystic kidney disease (Table 14.1). In patients with severe hypovolemia and early obstruction, hydronephrosis may not be seen on the initial ultrasound examination but may appear later in the course of the disease. Computed tomography (CT) scanning should be performed if the ultrasound results are equivocal or if the kidneys are not well visualized.

Laboratory Parameters

Evaluation of new-onset oliguria not secondary to obstruction and obvious hypovolemia should start with the measurement of serum urea and creatinine concentrations. Often acute oliguria may not be accompanied by creatinine elevation and under these circumstances may be the earliest marker of impending AKI. When oliguria is associated with an elevation in serum creatinine, it implies ongoing AKI and a poorer outcome. Rate of rise of serum creatinine can also provide useful information regarding the severity and potential for reversibility of AKI. Elderly patients with less lean muscle mass, advanced liver disease, and fluid overload may have a falsely low serum creatinine for the degree of their renal injury, whereas patients with rhabdomyolysis may have a higher serum creatinine and a greater rate of rise disproportionate to the severity of their renal injury.

Although routine urine microscopy is generally recommended, the yield of urine microscopy in the ICU is very low. Urine sediment is typically bland or reveals hyaline and fine or coarse granular casts. However, the discrimination of these findings is limited and most often noncontributory in the management of oliguria. Rarely, urine microscopy reveals red cell casts indicating a primary glomerular pathology most commonly seen in patients with vasculitides. Eosinophilia, eosinophiluria, and hypocomplementemia, if present (although insensitive and nonspecific), point to the diagnosis of atheroembolic etiology of acute oliguria.[7] Urine eosinophilia is neither sensitive nor specific for acute interstitial nephritis and should not be relied on.

Urinary indices such as urinary sodium and fractional excretion of sodium (FE_{Na}) have been proposed to differentiate prerenal from intrinsic causes of AKI. Conventionally, an FE_{Na} of less than 1% has been used as a marker for a "prerenal" cause of oliguria, whereas a value of greater than 1% generally suggests a loss of tubular function and AKI. However, use of diuretics, agents interfering with the angiotensin–aldosterone axis, or osmotic agents such as mannitol interfere with sodium excretion and FE_{Na}. In patients who have received diuretics, fractional excretion of urea (FE_{urea}) may be useful. A low FE_{urea} ($\leq$35%) was a more sensitive and specific index than FE_{Na} in identifying intact tubular function, especially if diuretics were administered.[8] Urinary indices have not been validated in critically ill patients and have shown disparate results in patients with septic AKI. Systemic inflammation secondary to sepsis has been shown to cause conformational channels in the Na/H, chloride, and urea changes, thereby independently affecting their excretion. Recent studies have consistently demonstrated the limited diagnostic and prognostic utility of urine biochemistry in AKI,[9] and the routine use of these indices in patients with oliguria is not recommended.

Biomarkers

Several biomarkers have been evaluated in AKI and their utility in predicting progression of AKI in critically ill patients explored.[10] Biomarkers in AKI can be broadly stratified into those that primarily correspond to GFR (cystatin C) and those that reflect tubular damage (e.g., neutrophil gelatinase–associated lipocalcin [NGAL], kidney injury molecule-1 [KIM-1]) or stress (tissue inhibitor of metalloproteinases-2 [TIMP-2] and insulin-like growth factor binding protein-7 [IGFBP-7]). NGAL has been found to be a useful marker in predicting AKI onset and progression in varied populations.[11] A test using novel biomarkers, [TIMP-2]•[IGFBP-7], has been validated to predict moderate to severe (stage 2–3) AKI using both serum creatinine and urine output criteria and is Food and Drug Administration (FDA)–approved.[12]

TABLE 14.1. Diagnostic Tests and Their Utility in an Oliguric Patient

S. No.	Diagnostic Test	Comments
1	Urine microscopy	• Often noncontributory • RBC casts, when present, indicate glomerular pathology
2	Urine indices	• Very low utility in the ICU • Not recommended in the evaluation of oliguria
3	Renal ultrasound	• Should be routinely performed to rule out obstruction • Provides information on existence of chronic kidney disease
4	Biomarkers (NGAL, TIMP-2, and IGFBP-7)	• Consider when available • Elevation indicates structural kidney damage
5	Hemodynamic evaluation	• Mandatory to ensure fluid responsiveness and fluid tolerance
6	Measurement of intraabdominal pressure	• Suggested in patients with high risk for ACS

ACS, Abdominal compartment syndrome; *ICU,* intensive care unit; *IGFBP-7,* insulin-like growth factor binding protein-7; *NGAL,* neutrophil gelatinase–associated lipocalcin; *RBC,* red blood cell; *TIMP-2,* tissue inhibitor of metalloproteinases.

HEMODYNAMIC EVALUATION

Evaluation of hemodynamics and appropriate optimization is one of the logical important steps in the management of oliguria. Clinical

assessment of important hemodynamic variables such as preload, overall volume status, cardiac output, and tissue perfusion are all confounded by several factors, making them less useful in critically ill patients. Blood pressure and heart rate are affected by numerous physiologic and treatment variables and are unreliable measures of volume status. The presence or absence of jugular vein pressure (JVP) is not an accurate way to assess right ventricular or central venous pressures (CVPs) in the presence of positive pressure ventilation and positive end-expiratory pressure (PEEP). Similarly, peripheral edema is often the result of capillary leak and coexistent hypoalbuminemia and decreased oncotic pressure in critically ill patients. These patients can have an excessive volume of total body water and yet be intravascularly volume depleted.

It has been well established that measures such as CVP and pulmonary artery occlusion pressure (PAOP) do not provide reliable estimates of preload or preload responsiveness.[13] These static measures assume a linear pressure–volume relationship, which is often not the case in sick patients with comorbidities and are affected by the presence of atrioventricular valve abnormalities, compliance of the ventricle, and pericardial and abdominal pressures. Even when CVP is low, the value does not give any information on whether the patient will improve cardiac output in response to a fluid bolus (i.e., being preload responsive). The mixed venous oxygen saturation (SvO_2) or central venous oxygen saturation ($SCVO_2$) can serve as a surrogate for cardiac output, but again does not define optimal filling. Moreover, SvO_2 can be altered by the ability of tissues to extract and subsequently use delivered oxygen.

In patients on mechanical ventilation and without spontaneous triggering of the ventilator, an arterial pulse–pressure variation of >13% is strongly predictive of preload responsiveness.[14] However, the use of pulse contour analysis is limited in that it is applicable only in patients who receive >8 mL/kg tidal volume on the ventilator, who do not have arrhythmias, and in whom lung compliance is >30 cm of water. An easier and more applicable test of preload responsiveness in the ICU setting would be passive leg raising (PLR) and monitoring of change in cardiac index or pulse pressure.[15] This can be done in spontaneously breathing patients and in those with arrhythmias. However, any measurement of cardiac index, pulse pressure, or stroke volume variation warrants continuous cardiac output monitoring using one of the newer pulse contour techniques.

A bedside echocardiogram screening for inferior vena cava (IVC) size and respiratory variation in size, left and right ventricular size and function, and presence of pericardial tamponade can provide valuable information about preload and contractility and can rule out severe obstructive shock from massive pulmonary embolism and pericardial effusion. Ultrasound of the lungs looking for A profile vs. B profile along with extravascular lung water (EVLW) measurement, when available, will assist in determining fluid tolerance and should be routinely incorporated into the decision-making process before any empiric fluid bolus.

No one parameter individually can unequivocally predict fluid responsiveness, but when a combination of two or more are used, they can reliably predict fluid responsiveness. It is important to understand that improvement in cardiac output with a fluid bolus (fluid responsiveness) does not automatically predict improvement in urine output, and studies have shown little to no improvement in urine output when fluids were administered.

Evaluation for Intraabdominal Hypertension

An uncommon but often overlooked reason for acute oliguria is ACS. ACS should be suspected in any patient with a tensely distended abdomen, progressive oliguria, hypotension, and increased airway pressures (transmitted across the diaphragm). The mainstay of diagnosis is the measurement of IAP, and the most common way to assess IAP is to measure the pressure within the urinary bladder after transducing a fluid-filled urinary catheter.

ACS is defined as organ dysfunction that results from an increase in IAP. Normal IAP is 5–7 mm Hg. Abdominal perfusion pressure (APP) is the pressure difference between the mean arterial pressure (MAP) and IAP (APP = MAP − IAP). Sustained IAP >12 mm Hg is called *intraabdominal hypertension.* When the IAP is sustained >20 mm Hg with or without APP >60 mm Hg, it is called ACS.[16] ACS occurs in a wide variety of medical and surgical patients, including acute severe pancreatitis, major abdominal surgeries requiring large-volume resuscitation, emergent laparotomies with tight abdominal wall closures, or abdominal wall burns with edema. ACS leads to AKI and acute oliguria mainly by directly increasing renal outflow pressure and thus reducing renal perfusion. Other mechanisms include direct parenchymal compression and arterial vasoconstriction mediated by stimulation of the sympathetic nervous and renin–angiotensin systems. Cardiac output also can be compromised by impaired venous return.

TREATMENT OF OLIGURIA

Oliguria is a clinical sign that is often multifactorial in the critically ill patient, and no single therapeutic strategy can be universally applied to treat oliguric patients. A thorough evaluation and understanding of the underlying pathophysiologic processes responsible and specific strategies to attenuate and reverse them when possible should be employed.

Fluid Bolus

Oliguria is one of the most common indications for a fluid bolus in the ICU. However, routine empiric fluid therapy for every episode of oliguria should be strongly discouraged. Fluid bolus should be reserved only for oliguric patients with unequivocal evidence of hypovolemia and ongoing fluid losses (Table 14.2). In the absence of overt hypovolemia, fluid therapy should be considered only after careful hemodynamic evaluation and ensuring fluid responsiveness and fluid tolerance. A recent study that evaluated response to fluid bolus documented no change in cardiac output in most of the patients, with little or no improvement

TABLE 14.2 Effectiveness of Various Treatment Strategies in Oliguria

S. No.	Therapy	Indications
1	Fluid bolus	• Administer if overt hypovolemia and if fluid responsive and tolerant
2	Vasopressors	• In septic patients with MAP ≤65 mm Hg[1]
3	Inotropes	• If decreased LV and/or RV function with cardiorenal syndrome
4	Diuretics	• In fluid-overloaded patients • To prevent fluid overload • Once volume replete, consider FST[2] to assess response and risk stratify

FST, Furosemide stress test; *LV,* left ventricular; *MAP,* mean arterial pressure; *RV,* right ventricular.
1. In patients with known chronic hypertension, target MAP 70–75 mm Hg.

in urine output 1 hour after the fluid bolus.[17] Repeated fluid boluses for oliguria lead to fluid overload, which has been consistently shown to worsen AKI and mortality.[18] Fluid overload increases renal intracapsular and renal venous pressures, leading to renal hypoperfusion.

The type and volume of fluid administered have important therapeutic implications. When fluid therapy is indicated, 500 mL of a balanced crystalloid should be administered. Hyperchloremia induced by 0.9% saline has been shown to decrease renal blood flow and cause AKI[19,20] and hence should be avoided unless the patient is hyponatremic or hypochloremic. Starch preparations and hyperoncotic colloids such as 20% albumin have been shown to cause AKI, increase the need for renal replacement therapy (RRT), and increase mortality, and should not be administered.[21,22] Although 5% albumin has been shown to be equivalent to normal saline,[23] its relatively short intravascular half-life (only slightly longer than crystalloids) and higher cost make it the less preferred fluid compared with crystalloids.

Hemodynamic Manipulation

Autoregulatory mechanisms regulating renal blood flow are deranged in critical illness, making kidneys very sensitive to changes in MAP. In patients with vasodilatory shock, rapid restoration of perfusion pressure with vasoactive drugs is crucial to attenuate any renal injury. In critically ill patients, vasoactive drugs should be initiated early and concurrent volume expansion done to minimize the duration of hypotension. Norepinephrine is the drug of choice in sepsis-induced vasodilation and should be titrated to MAP >65 mm Hg. One multicenter randomized controlled study (SEPSISPAM study)[24] in septic patients demonstrated that higher MAP (70–75 mm Hg) may decrease the risk of renal injury in patients with chronic hypertension. Dopamine is ineffective in the prevention of AKI and should not be used to improve urine output or for renal protection.[25] Dopamine, being a weak diuretic, increases urine output without altering GFR and can lead to masking of the underlying pathology, causing worsening of AKI. Newer dopaminergic agonists (e.g., fenoldopam, dopexamine) increase renal blood flow without affecting medullary oxygenation and have not been shown to decrease the incidence of AKI.[26] They can induce significant hypotension, thereby further increasing the risk of renal injury, and hence these should not be used to treat oliguria. The renal-protective effect of vasopressin is debatable and hence not recommended as the primary or lone vasopressor in septic patients or for the sole purpose of improving renal function.

In patients with significant left and/or right ventricular dysfunction causing cardiorenal syndrome, inotropic support may improve renal perfusion and AKI. Dobutamine causes systemic vasodilatation and therefore should be initiated only after adequate volume repletion and in patients with vasodilatory shock after initiation of a vasopressor, preferably norepinephrine. In patients with cardiogenic shock, dopamine has been shown to worsen mortality and is not recommended for cardiorenal syndrome.[27]

Decompression of the abdomen with laparotomy, sometimes requiring that the abdomen be left open for a time, is the only definitive treatment for oliguria secondary to ACS.

Role of Diuretic Agents

The use of diuretic agents in oliguric renal failure is widespread despite the lack of convincing evidence supporting their efficacy. Traditionally, diuretics have been used in the early phases of oliguria to "jump start" the kidney and establish urine flow. Nonoliguric renal failure has a better prognosis than oliguric renal failure, and many clinicians believe that treating oliguria early also makes it easier to regulate intravascular volume status and avoid fluid overload imposed by the mandatory fluid requirements in the critically ill patient. Two large observational studies have evaluated outcomes related to diuretic use in AKI and have provided conflicting results. In the first cohort study (PICARD), patients were characterized based on exposure to diuretics on or before the day of nephrology consultation.[28] After adjustments of covariates and propensity scores, diuretic use was associated with increased risk of death and nonrecovery of renal function (odds ratio [OR], 1.77; 95% confidence interval, 1.14–2.76). A second large multicenter observational study (BEST kidney study) showed that the use of diuretics has no beneficial effect on clinical outcomes by three different multivariate models.[29] Furthermore, high doses of loop diuretics can be associated with ototoxicity.

There is a growing literature on the use of furosemide in the evaluation of oliguria and prediction of AKI progression. In a recent study, Koyner et al. employed a furosemide stress test (FST) to evaluate renal tubular functional integrity and its ability to predict progression of AKI and compared its performance with traditional biomarkers.[30] In this study, a standard intravenous dose of furosemide (1 mg/kg for furosemide-naïve patients and 1.5 mg/kg for furosemide-exposed patients) was administered to patients with stage 1 or 2 AKI, and the authors found a cutoff 2-hour urine output of <200 mL to be highly predictive of progression to stage 3 AKI (area under the curve [AUC], 0.87) and need for RRT (AUC, 0.86). In another study, FST nonresponse was used as a strategy to identify patients who might need RRT, and these patients were randomized to early vs. standard RRT.[31] FST seems to be a clinically applicable, functional marker of AKI that could potentially predict risk of progression of AKI and need for RRT. FST should not be attempted on hypovolemic patients, and ample care should be exercised when using it.

Renal Replacement Therapy

RRT should be considered when oliguric patients are unresponsive to optimization of volume status, hemodynamics, and a diuretic challenge. This will potentially avoid development of fluid overload and make management of volume status easier. There is no consensus on the timing of initiation of RRT in oliguric patients. One should consider the reasons for AKI, nature and severity of clinical and biochemical derangements, and underlying physiologic reserve of the patient to compensate for and tolerate homeostatic imbalances to decide on the timing of initiation of RRT. The elevation of biomarkers along with lack of response to FST may help identify patients who may benefit from early RRT.

CONCLUSION

The presence of oliguria should alert the clinician to undertake a diligent search for any correctable underlying causes and to assess the risk of AKI. Although oliguria is often multifactorial, reversible causes such as obstruction to the lower urinary tract or urinary catheter, hypovolemia, low cardiac output state, and increased IAP should be ruled out. Relieving urinary obstruction, optimization of fluid status, and hemodynamics remain the cornerstone in the management of oliguria. Instinctive use of fluid boluses and diuretics should be avoided. Use of isotonic-balanced crystalloids is recommended when fluid bolus is needed. Diuretics should be used in oliguric patients with fluid overload and in volume-replete patients to assess response and progression of AKI. When all these strategies fail, RRT should be considered.

KEY POINTS

- Oliguria in the ICU can be a physiologic response to stress or imply an impairment in glomerular function.
- Oliguria should prompt an immediate evaluation for reversible causes and a risk assessment for occurrence of AKI.
- Urinary biomarkers can help estimate structural damage and risk of progression of AKI.
- Empiric fluid boluses or diuretics for oliguria without comprehensive hemodynamic assessment should not be practiced.
- Balanced isotonic crystalloids are recommended when fluid bolus is indicated.
- Diuretics are indicated only in volume-replete patients to prevent and treat fluid overload and as a strategy for risk stratification.
- Early RRT may be considered in patients unresponsive to hemodynamic optimization and diuretic challenge.

Metabolic Acidosis and Alkalosis

Vinay Narasimha Krishna, Jared Cook, Keith M. Wille, and Ashita J. Tolwani

ACID-BASE DISORDERS

Acid-base disorders can be quantified by using the physiologic, base-excess, and physiochemical approaches (Stewart method).[1] The bicarbonate [HCO_3^-] buffer system plays a central role in the physiologic and base-excess methods. They share nearly common explanations while describing the types and mechanisms behind acid-base disturbances. However, Stewart's more recent (1980s) acid-base approach differs significantly from the other two approaches by not attributing a central role to [HCO_3^-], as HCO_3^- alone does not determine metabolic acid-base disorders. The Stewart approach adapts a method based on *charge differences between strong cations and anions.* According to Stewart, acid-base balance in the body is determined by "strong" and "weak" electrolytes that are present in body fluid compartments as cations and anions. Strong electrolytes are fully dissociated in aqueous solution, and weak electrolytes are partially dissociated. He proposed that changes in plasma [H^+] are related to water dissociation and not addition or removal of H^+ from the plasma.[2] Stewart derived six equations that, when solved simultaneously, yield the [H^+] of a solution, and these equations operate strictly under the physiochemical principles of electroneutrality (sum of cations is equal to sum of anions), conservation of mass (amount of substance in a solution is constant unless added or removed), and law of mass action (dissociation equiliriums of all incompletely dissociated substances must be met at all times).[2] Stewart proposed that [H^+] and HCO_3^- are dependent variables and that changes in hydrogen ion [H^+] and subsequently the pH are influenced by three independent variables: namely, partial pressure of carbon dioxide (pCO_2). When pCO_2 increases, [H^+] raises, and when it decreases, [H^+] decreases. Increases in pCO_2 define respiratory acidosis, and decreases in pCO_2 respiratory alkalosis.

Total concentration of weak acids [A_{TOT}]: weak acids are not completely dissociated in aqueous solution and are mainly represented by albumin and phosphate. Increase and decrease in [A_{TOT}] increases and decreases [H^+], respectively (e.g., hypoalbuminemia causes metabolic alkalosis and hyperphosphatemia results in metabolic acidosis).

Strong ion difference (SID): difference between the total concentration of strong cations (Na^+, K^+, Ca^{2+}, and Mg^{2+}) and strong anions (Cl^-, SO_4^-, and anions of organic acids). Concentrations of Na^+ and Cl^- are the main determinants of SID because of their magnitude, and normal values range from 39 to 42 mEq/L based on concentrations of Na^+ and Cl^- (SID = $Na^+ - Cl^-$ = 140 − 100 = 40 mEq/L). This simplest estimation is called *apparent SID* (SID_a). When other anions like plasma [HCO_3^-] and the anionic equivalence of albumin and phosphate are included in the calculation of SID, the estimation is called *effective SID* (SID_e). SID_e is difficult to calculate at the bedside and needs to be estimated from blood pH, pCO_2, and the plasma concentrations of albumin and phosphate using a formula or a nomogram. SID is always positive, as Na^+ concentration is greater than Cl^-. Because of the electroneutrality principle, SID is zero in healthy individuals, as the positivity is balanced by the negative charge present on HCO_3^-, albumin, and phosphate. Changes in SID result in metabolic acid-base disturbances. Metabolic acidosis develops because of a decrease in cations or increase in anions resulting in SID <39 mEq/L. Similarly, metabolic alkalosis develops when SID >42 mEq/L.

The difference between SID_a and SID_e is called strong anion gap (SIG) and represents unmeasured anions like ketones, SO_4^{2-}, and urate. SIG is similar to anion gap (AG) and ranges from 0 to 2 mEq/L. A SIG value >2 mEq/L reflects metabolic acidosis resulting from the presence of more anions than cations (e.g., ketones in diabetic ketoacidosis).[2]

The Stewart method describes six acid-base disorders based on variations in the three independent variables, as shown in Table 15.1.[1,2]

Stewart's methodology is mechanistic and useful in analyzing complex acid-base disorders, especially with SIG being superior to AG in detecting anions such as ketones. Compared with the traditional physiologic approach that is far more descriptive and widely adapted, the Stewart approach requires additional measurements of multiple ions and the use of complex calculations that hinder swift bedside clinical deployment. Interpreting SID with its two formulations, SID_a and SID_e, is cumbersome, and classification of metabolic acid-base disorders is unduly complex.[3] No quantitative assessment of the secondary compensatory responses to primary changes in SID_e, [A_{TOT}], and pCO_2 is offered by the Stewart approach. This is a major drawback and can risk misdiagnosis of the secondary responses as independent, simple acid-base disorders.[3] Hence this chapter focuses on the physiologic approach with the bicarbonate-carbonic acid buffer system that remains central in assessing acid-base disorders.

NORMAL ACID-BASE HOMEOSTASIS

On a daily basis, the body's metabolic processes generate 10,000–15,000 mEq of volatile acids and 1–2 mEq/kg of fixed acids that must be buffered and excreted to maintain the pH within a narrow range of 7.35–7.45. Chemical buffers and the pulmonary and renal systems operate interdependently to regulate and maintain acid-base balance. The most important buffer is the bicarbonate-carbonic acid (HCO_3^- and H_2CO_3) system, which acts immediately to buffer the extracellular fluid. The relationship between pH, HCO_3^-, and carbon dioxide (CO_2) is described by the Henderson-Hasselbalch equation:

$$pH = 6.10 + \log\left([HCO_3^-] \div [0.03 \times PaCO_2]\right)$$

The number 6.10 represents the dissociation constant for the reaction; 0.03 represents the solubility coefficient of CO_2 in blood. PCO_2 is the partial pressure of CO_2 in the blood.[4]

TABLE 15.1 Classification of Acid-Base Disorders Based on Three Independent Variables in Stewart's Method[1,2]

Independent Variable	Acidosis	Alkalosis
1. Respiratory pCO_2	↑pCO_2	↓pCO_2
2. Metabolic: abnormal SID		
Water excess	↓SID, [↓Na^+]	
Water deficit		↑SID [↑Na^+]
Hyperchloremia	↓SID	
Hypochloremia		↑SID
Lactic acidosis or ketoacidosis Unidentified anion excess	↓SID ↑SIG ↑ [XA]	
3. Nonvolatile weak acids: [A_{TOT}]		
Serum albumin	↑ [Alb]	↓ [Alb]
Inorganic phosphate	↑ [Pi]	↓[Pi]

[Alb], Albumin concentration; *[Pi],* inorganic phosphate concentration; *pCO_2,* partial pressure of carbon dioxide; *SID,* strong ion difference; *SIG,* strong ion gap; *[XA],* concentration of unidentified strong anion.

Normal acid-base status is maintained by pulmonary excretion of volatile acids and by renal excretion of fixed acids and the formation of bicarbonate. To maintain acid-base balance, the kidney must reabsorb all of the filtered bicarbonate (about 4000 mEq/day) and excrete the fixed daily acid load. Reabsorption occurs mostly in the proximal tubule (>90%) and, to a lesser degree, in the collecting tubule. Renal excretion of acid is achieved by combining hydrogen ions (H^+) with urinary buffers to be excreted as titratable acids, such as phosphate, urate, and creatinine, or with ammonia to form ammonium.[4] The ammonia buffering system is especially important because other buffers are filtered in fixed concentrations and can be depleted by high acid loads; by contrast, tubular cells actively regulate ammonia production in response to changes in acid load.

When acid-base derangements occur, the blood pH is returned toward normal, initially by chemical buffering, followed by pulmonary ventilation, and finally by renal regulation of acid-base excretion. The $PaCO_2$ is finely regulated by changes in tidal volume and minute ventilation. A decrease in pH is sensed by arterial chemoreceptors and leads to increases in tidal volume or respiratory rate. Pulmonary regulation occurs over minutes to hours. The kidney controls pH through the regulation of H^+ excretion, bicarbonate reabsorption, and the production of new bicarbonate. Reabsorption of bicarbonate is equivalent to removing free H^+. Changes in renal acid-base handling occur hours to days after changes in acid-base status.

ACID-BASE PATHOPHYSIOLOGY

Terminology and Classification

Acid-base disorders occur when a change in the normal value of the blood pH results from abnormal renal or pulmonary function or when an acid or base load overwhelms excretory capacity. *Acidemia* refers to a decrease in the blood pH below the normal range, whereas *alkalemia* refers to an increase in the blood pH above the normal range. *Acidosis* is a process that tends to decrease the blood pH and occurs by a fall in the plasma bicarbonate concentration and/or an elevation in $PaCO_2$. In contrast, *alkalosis* is a process that tends to raise the blood pH through an elevation in the plasma bicarbonate concentration and/or a fall in $PaCO_2$. Although acidemia cannot be present without acidosis and alkalemia cannot be present without alkalosis, acidosis or alkalosis can exist at any blood pH.

The four primary acid-base disorders are classified as respiratory or metabolic. A respiratory disturbance occurs when acidosis or alkalosis results from a primary change in the $PaCO_2$. Respiratory acidosis is a disorder that elevates the $PaCO_2$ and reduces the pH; respiratory alkalosis is a disorder that reduces the $PaCO_2$ and elevates the pH. A metabolic disturbance occurs when acidosis or alkalosis results from a primary change in the plasma bicarbonate concentration. Metabolic acidosis is a disorder that reduces the plasma bicarbonate concentration and pH; metabolic alkalosis is a disorder that elevates the plasma bicarbonate concentration and pH. Compensation refers to physiologic respiratory and renal changes by which the body attempts to return the pH toward normal in response to primary acidosis or alkalosis.[4,5] Compensation does not return the pH back to a completely normal value.

A simple acid-base disorder is a single primary acid-base disorder (respiratory acidosis, respiratory alkalosis, metabolic acidosis, or metabolic acidosis) with appropriate respiratory or renal compensation for that disorder. A mixed acid-base disorder is characterized as the simultaneous presence of two or more primary acid-base disorders and is frequently encountered in intensive care unit (ICU) patients. The arterial blood pH will depend on the direction and magnitude of disturbances. Mixed acid-base disorders can be suspected from the patient's history and whenever the measured compensatory values of either bicarbonate or $PaCO_2$ differ significantly from what is expected.

COMPENSATORY RESPONSES

Disturbances in acid-base balance lead to predictable responses that serve to limit the magnitude of change of the blood pH. The expected compensatory responses to primary acid-base disturbances are listed in Table 15.2.[5,6] The magnitude of the compensatory response is proportional to the severity of the primary acid-base disturbance. The Henderson-Hasselbalch equation shows that pH is determined by the ratio of the plasma HCO_3^- concentration and $PaCO_2$, not by either value in isolation.[6] In each acid-base disorder, compensatory renal or respiratory responses act to minimize the change in pH by minimizing alterations in the ratio. Metabolic disorders result in respiratory compensation (change in $PaCO_2$); respiratory acid-base disorders result in metabolic compensation (change in HCO_3^- concentration).

In metabolic acidosis, a low plasma HCO_3^- concentration decreases the pH, stimulating medullary chemoreceptors to increase ventilation and thereby decrease $PaCO_2$ and restore the pH toward normal. In general, for metabolic acidosis, respiratory compensation results in a 1.25 mm Hg decrease in $PaCO_2$ for every 1.0 mEq/L reduction in the plasma HCO_3^- concentration down to a minimum $PaCO_2$ of 10–15 mm Hg.[6] The expected $PaCO_2$ in a simple metabolic acidosis can be calculated by the Winters formula[5]:

$$PaCO_2 = 1.5 \times (HCO_3^-) + 8 \pm 2$$

This formula may be used in patients with metabolic acidosis to evaluate whether the observed $PaCO_2$ is an appropriate compensatory response or whether there is additional respiratory acidosis ($PaCO_2$ greater than predicted) or respiratory alkalosis ($PaCO_2$ less than predicted).[5]

Respiratory compensation to metabolic alkalosis should raise the PCO_2 by about 0.6–0.75 mm Hg for every 1 mEq/L increase in the plasma bicarbonate concentration.[6–8] The expected $PaCO_2$ may be estimated by the following formula:

$$PaCO_2 = 40 + ([\text{current } HCO_3^- - 24] \times 0.7)$$

TABLE 15.2 Acid-Base Abnormalities and Appropriate Compensatory Responses for Simple Disorders

Primary Acid-Base Disorders	Primary Defect	Effect on pH	Compensatory Response	Expected Range of Compensation	Limits of Compensation
Respiratory acidosis	Alveolar hypoventilation ($\uparrow P_{CO_2}$)	↓	↑ Renal HCO_3^- reabsorption (HCO_3^- ↑)	Acute: $\Delta[HCO_3^-] = +1$ mEq/L for each ↑ ΔP_{CO_2} of 10 mm Hg	$[HCO_3^-] = 38$ mEq/L
				Chronic: $\Delta [HCO_3^-] = +4$ mEq/L for each ↑ ΔP_{CO_2} of 10 mm Hg	$[HCO_3^-] = 45$ mEq/L
Respiratory alkalosis	Alveolar hyperventilation ($\downarrow P_{CO_2}$)	↑	↓ Renal HCO_3^- reabsorption (HCO_3^- ↓)	Acute: $\Delta [HCO_3^-] = -2$ mEq/L for each ↓ ΔP_{CO_2} of 10 mm Hg	$[HCO_3^-] = 18$ mEq/L
				Chronic: $\Delta [HCO_3^-] = -5$ mEq/L for each ↓ ΔP_{CO_2} of 10 mm Hg	$[HCO_3^-] = 15$ mEq/L
Metabolic acidosis	Loss of HCO_3^- or gain of H^+ ($\downarrow HCO_3^-$)	↓	Alveolar hyperventilation to ↑ pulmonary CO_2 excretion ($\downarrow P_{CO_2}$)	$P_{CO_2} = 1.5[HCO_3^-] + 8 \pm 2$ P_{CO_2} = last 2 digits of pH × 100 $P_{CO_2} = 15 + [HCO_3^-]$	$P_{CO_2} = 15$ mm Hg
Metabolic alkalosis	Gain of HCO_3^- or loss of H^+ ($\uparrow HCO_3^-$)	↑	Alveolar hypoventilation to ↓ pulmonary CO_2 excretion ($\uparrow P_{CO_2}$)	$P_{CO_2} = +0.6$ mm Hg for $\Delta [HCO_3^-]$ of 1 mEq/L $P_{CO_2} = 15 + [HCO_3^-]$	$P_{CO_2} = 55$ mm Hg

Adapted from Bidani A, Tauzon DM, Heming TA. Regulation of whole body acid-base balance. In: DuBose TD, Hamm LL, eds. *Acid Base and Electrolytes Disorders: A Companion to Brenner and Rector's The Kidney*. Philadelphia: Saunders; 2002:1–21.

In metabolic alkalosis, a high pH induces hypoventilation with a resultant rise in $PaCO_2$ and decrease in pH. However, hypoxemia induced by progressive hypoventilation eventually activates oxygen-sensitive chemoreceptors to stimulate ventilation and generally limits the compensatory pulmonary response to a $PaCO_2$ of <55 mm Hg.[7]

METABOLIC ACIDOSIS

Metabolic acidosis occurs via increased bicarbonate loss, decreased excretion of acid, an imbalance between production and consumption of endogenous acids, or administration of exogenous acid. The clinical significance of metabolic acidosis depends on the severity of the disorder. Without appropriate intervention, metabolic acidosis can progress to life-threatening changes in cardiac, neurologic, and metabolic function, as listed in Box 15.1.[9] Metabolic acidosis can be classified as high AG metabolic acidosis or non-AG (hyperchloremic) metabolic acidosis.

Serum Anion Gap

Calculation of the serum AG is a useful tool in the evaluation of metabolic acidosis. The serum AG represents the difference in the measured cations (mainly sodium) and the measured anions (chloride and bicarbonate). Mathematically, this is represented as follows:

$$AG = Na^+ - (Cl^- + HCO_3^-)$$

Based on the law of electroneutrality, the concentration of cations should be equal to the concentration of anions in the human body. Certain cations and anions are not measured on routine laboratory chemistry panels, and the serum AG quantifies these unmeasured anions. This can be represented as follows:

$$Na^+ + \text{Unmeasured Cations (UC)}$$
$$= Cl^- + HCO_3^- + \text{Unmeasured Anions (UA)}$$

Therefore:

$$AG = Na^+ - (Cl^- + HCO_3^-) = UA - UC$$

Box 15.1 Systemic Effects of Acidosis

Neurologic
- Obtundation and coma
- Hyperactivity of sympathetic nervous system
- Decreased cerebral metabolism
- Decreased response to catecholamines

Respiratory
- Increased minute ventilation
- Subjective dyspnea
- Respiratory muscle fatigue

Cardiovascular
- Decreased contractility of myocardium
- Core vasculature blood pooling (venoconstriction and arterial dilatation)
- Decreased cardiac response to catecholamines
- Tachyarrhythmias

Metabolic
- Hyperkalemia (inorganic acidemia)
- Hyperphosphatemia
- Increased protein catabolism

Adapted in part from Whitney GM, Szerlip HM. Acid-base disorder in critical care setting. In DuBose TD, Hamm LL, eds. *Acid-Base and Electrolytes Disorders: A Companion to Brenner and Rector's The Kidney.* Philadelphia: Saunders; 2002:165–183.

Calcium, magnesium, gamma globulins, and potassium are the major "unmeasured" cations and account for approximately 11 mEq/L under normal conditions (Fig. 15.1). Although potassium is routinely measured in chemistry panels, the concentration of potassium in the blood is negligible compared with that of sodium, chloride, and bicarbonate, so potassium is not typically included as a "measured" cation in the AG equation. Negatively charged plasma proteins (albumin), sulfates, phosphates, and other organic anions are the major "unmeasured" anions and account for 20–24 mEq/L. Thus the normal AG is

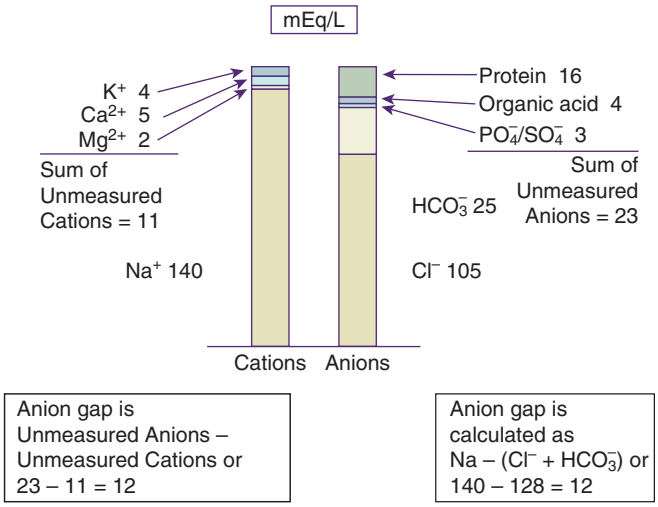

Fig. 15.1 Components of the serum anion gap.

about 12 mEq/L (23 − 11). Under normal circumstances, the serum AG is typically 12 ± 4 mEq/L but can vary depending on the laboratory method used.[10] Therefore the established normal range provided by the particular laboratory that performs the testing should be used.

The AG can be affected by increases or decreases in the UC or UA. The most important contributor to a normal serum AG is albumin, which has a negative charge at a physiologic pH. In patients with hypoalbuminemia, as commonly observed in critical illness or malnutrition, the AG must be corrected for low albumin. For each 1 g/dL fall in the plasma albumin concentration from a normal albumin concentration, the AG falls about 2.5 mEq/L.[10] This can be represented as follows:

$$\text{AG adjusted} = \text{AG} + 2.5 \times (\text{normal albumin} - \text{measured plasma albumin [g/dL]})$$

Other causes of a low or negative AG that may be important to consider for diagnostic and treatment purposes in ICU patients are listed in Table 15.3 and include hypercalcemia, hypermagnesemia, lithium intoxication, paraproteinemias such as multiple myeloma, and halide (bromide or iodide) intoxication.[11]

The contributors to serum AG in the normal physiologic state and in high AG and non-AG metabolic acidosis are depicted in Fig. 15.2.

HIGH–ANION GAP METABOLIC ACIDOSIS

High AG metabolic acidosis develops from excessive production, ingestion, or retention of a strong acid or a compound metabolized to a strong acid. These include negatively charged acids such as ketones, lactate, and sulfates, in addition to metabolites of methanol, ethylene glycol, or salicylate, which accumulate in place of the consumed HCO_3^- and cause a high AG. Other causes of an increased AG include hyperalbuminemia or uremia (increased anions) and hypocalcemia or hypomagnesemia (decreased cations)[11] (see Table 15.3).

The presence of a significantly elevated AG (AG >20 mEq/L) always represents metabolic acidosis, regardless of the pH or plasma bicarbonate concentration. In the event of a mixed acid-base disorder with a normal blood pH, a high AG points toward underlying metabolic acidosis, which otherwise may be missed. Therefore the serum AG should always be calculated when assessing acid-base disorders, especially in the ICU setting. The common causes of high AG acidosis in the ICU are lactic acidosis, ketoacidosis, toxin-induced acidosis, and renal failure (Box 15.2).

TABLE 15.3 Anion Gap in the Diagnosis of Metabolic Acidosis Anion Gap = $Na^+ - (Cl^- + HCO_3^-) = 9 + 3$ mEq/L

Decreased Anion Gap	Increased Anion Gap
Increased cations (not Na^+)	Increased anions (not Cl^- or HCO_3^-)
↑ Ca^{2+}, Mg^{2+}	↑ Albumin concentration
↑ Li^+	Alkalosis
↑ IgG	↑ Inorganic anions
Decreased anions:	Phosphate
(not Cl^- or HCO_3^-)	Sulfate
Hypoalbuminemia*	
Acidosis	↑ Organic anions
Laboratory error	L-Lactate
	D-Lactate
Hyperviscosity	Ketones
Bromism	Uremic
	↑ Exogenously supplied anions
	Toxins
	Salicylate
	Paraldehyde
	Ethylene glycol
	Methanol
	Toluene
	Pyroglutamic acid
	↑ Unidentified anions
	Uremic
	Hyperosmolar, nonketotic states
	Myoglobinuric acute renal failure
	Decreased cations (not Na^+)
	↓ Ca^{2+}, Mg^{2+}

Adapted from Emmett M, Narins RG. Clinical use of the anion gap. *Medicine.* 1997.56:38–54; Oh MS, Carroll HJ. The anion gap. *N Engl J Med.* 1977;297:814–817; Kraut JA, Madisa NE. Serum anion gap: its uses and limitations in clinical medicine. *Clin J Am Soc Nephrol.* 2007;2:162–174.

*Albumin is the major unmeasured anion. A decline in serum albumin of 1.0 g/dL from the normal value of 4.5 g/dL decreases the anion gap by 2.3–2.5 mEq/L. Correction is very important to diagnose anion gap acidosis in the setting of hypoalbuminemia.

Cambridge: Harvard University Press; 1954; Stewart PA. *How to Understand Acid-Base.* New York: Elsevier; 1981.)

Box 15.2 Clinical Causes of High Anion Gap and Normal Anion Gap Acidosis

High Anion Gap

Ketoacidosis

Diabetic ketoacidosis (acetoacetate)
Alcoholic (beta-hydroxybutyrate)
Starvation

Lactic Acid Acidosis (see Box 15.4)

L-Lactic acid acidosis (types A and B)
D-Lactic acid acidosis
Renal failure: sulfate, phosphate, urate, hippurate

Ingestions (Toxins and Their Metabolites)

Ethylene glycol → glycolate, oxalate
Methyl alcohol → formate
Salicylate → ketones, lactate, salicylate
Paraldehyde → organic anions
Toluene → hippurate (commonly presents with normal anion gap)
Propylene glycol → lactate
Pyroglutamic acidosis (acetaminophen use) → 5-oxoproline

Normal Anion Gap

Gastrointestinal Loss of HCO_3^- (Negative Urine Anion Gap)

Diarrhea
Fistula, external

Renal Loss of HCO_3^- or Failure to Excrete NH_4^+ (Positive Urine Anion Gap)

Proximal renal tubular acidosis (RTA type 2)
Acetazolamide
Classic distal renal tubular acidosis (low serum K^+) RTA type 1
Generalized distal renal tubular defect (high serum K^+) RTA type 4

Miscellaneous

NH_4Cl ingestion
Sulfur ingestion
Dilutional acidosis
Late stages in treatment of diabetic ketoacidosis

LACTIC ACIDOSIS

L-Lactic Acidosis

L-lactic acidosis is among the most frequent causes of elevated AG metabolic acidosis in the ICU and is associated with a high mortality.[12,13] L-lactate refers to the L (levo) enantiomer of lactic acid and is directly measured by the standard serum lactate assay. Lactic acid concentration should be measured directly if lactic acidosis is expected because the serum AG has a sensitivity and specificity of <80% in identifying elevated lactate levels.[14] Thus a normal AG does not rule out lactic acidosis. Jansen et al. have shown that lactate levels serve as a prognosis indicator that can signal underlying deterioration, prompt more aggressive management, and help avoid unnecessary treatment when the condition stabilizes.[15] Lactic acidosis occurs whenever production of lactate exceeds its utilization. In most cases of clinically significant lactic acidosis, there is evidence of defective utilization and increased production, depending on the etiology of lactic acidosis.

Pyruvate is the precursor of lactate and is produced in the cytoplasm from glucose metabolism via glycolysis in the Embden-Meyerhof pathway. Pyruvate normally undergoes oxidative decarboxylation by mitochondrial pyruvate dehydrogenase (PDH) to acetylcoenzyme A and then ultimately to CO_2 and H_2O. This process results in the synthesis of 36 moles of adenosine triphosphate (ATP) and requires oxidized nicotinamide adenine dinucleotide (NAD^+). Pyruvate can also enter the Cori cycle in the liver and renal cortex and be converted back to glucose. Oxidative phosphorylation, ATP synthesis, and reoxidation of NADH are inhibited during hypoxia. This anaerobic metabolism leads to an increased NADH/NAD^+ ratio, increased conversion of pyruvate to lactate, and synthesis of 2 molecules of ATP, rather than the 36 generated via the tricarboxylic acid cycle. The overall result of anaerobic metabolism is increased lactate levels, an elevated lactate/pyruvate ratio, greater glucose utilization, and lower energy production.

Traditionally, lactic acidosis has been categorized as type A or type B. Type A lactic acidosis is characterized by an impaired mitochondrial oxidative capacity in the setting of tissue hypoxia, whereas type B lactic acidosis is the result of dysregulation of cell metabolism rather than hypoxia (Box 15.3). Most cases of type A lactic acidosis are the result of reduced oxygen delivery because of reduced tissue perfusion from shock or cardiopulmonary arrest. Other causes are carbon monoxide poisoning and severe anemia. Type B lactic acidosis is classified as type B1 (related to underlying diseases like malignancies or liver disease), type B2 (related to the effect of drugs and toxins), and type B3 (associated with inborn errors of metabolism).[16] The most common drugs associated with type B2 lactic acidosis include biguanides (e.g., metformin), reverse transcriptase inhibitors, acetylsalicylic acid (ASA), propofol, and linezolid, among others (see Box 15.3). Sepsis is a common cause of lactic acidosis in the ICU. Lactate level predicts increased mortality in patients with and without sepsis, even at 1 year post-hospitalization.[17] Sepsis-induced lactic acidosis has been conventionally classified as type A lactic acidosis because of inadequate oxygen supply and augmented anaerobic metabolism. However, the lack of response to increased oxygen delivery, the absence of tissue hypoxia, and normal tissue ATP levels suggest that lactate formation during sepsis may be the result of dysregulation of cellular metabolism.[18,19] Decreased clearance of lactate, rather than increased production, has been demonstrated in sepsis.[20] In addition, increased pyruvate production, decreased PDH activity, regional differences in lactate production, and decreased clearance of lactate have been implicated as possible contributors to lactic acidosis.[21–23] Decreased muscle PDH activity has been shown in sepsis, and it can be restored by dichloroacetate, suggesting that lactic acidosis during sepsis is the result of functional inhibition of PDH, leading to enhanced conversion of pyruvate to lactate.[24,25]

Treatment of lactic acidosis requires identification and correction of the underlying cause. The therapeutic goal in type A lactic acidosis is restoration of tissue oxygen delivery through hemodynamic and/or respiratory support. The use of sodium bicarbonate in lactic acidosis is controversial and not supported by clinical studies.[9] Intravenous (IV) administration of sodium bicarbonate may increase lactate production, decrease portal vein flow, decrease ionized calcium levels, lower intracellular pH, and worsen cardiac output.[9,26,27] Bicarbonate increases extracellular pH only if ventilation removes the excess CO_2 generated; otherwise, hypercapnia can lower intracellular pH and impair cellular function.[9,26,27] Bicarbonate can worsen tissue oxygen delivery if the arterial pH increases more than the intracellular pH, with a leftward shift in the oxyhemoglobin dissociation curve. If tissue hypoxia is present, the use of bicarbonate can stimulate glycolysis mediated by the pH-sensitive rate-limiting enzyme phosphofructokinase and paradoxically increase lactate production.[28] Sodium bicarbonate should be administered cautiously when the arterial pH is less

than 7.15 because a pH below this value will promote the development of decreased responsiveness to catecholamines, arrhythmias, cardiac depression, and hemodynamic instability.[9]

Alternative buffering agents, such as tris-hydroxymethyl aminomethane (THAM), carbicarb, and dichloroacetate (DCA) have not shown any clinical benefit in patients with lactic acidosis. Carbicarb and DCA are unavailable in the United States.[29] THAM can bind to both CO_2 and metabolic acids. Protonated THAM is excreted by the kidney through glomerular filtration, together with bicarbonate or another anion. Thus THAM can increase the buffering capacity of blood without generating CO_2 but is less effective in patients with anuria. Reported toxicities of THAM include hyperkalemia, hypoglycemia, and respiratory depression.[9] THAM has not been specifically evaluated as a therapeutic agent for lactic acidosis in clinical trials. Carbicarb, an equimolecular mixture of sodium bicarbonate and sodium carbonate, has a buffering capacity similar to sodium bicarbonate but generates less CO_2. Animal studies have demonstrated inconsistent benefits of carbicarb in lactic acidosis, and one human study comparing the effects of sodium bicarbonate with carbicarb in metabolic acidosis found no benefit.[30,31] DCA stimulates the activity of the mitochondrial PDH enzyme complex indirectly through inhibition of the PDH kinase and hence decreases lactate production. Data from animal studies and one placebo-controlled double-blind clinical trial demonstrated that DCA improved acid-base status but not hemodynamics or survival.[28,32]

Dialysis can theoretically be used to treat lactic acidosis because it supplements bicarbonate, removes lactate, prevents decreased ionized calcium, avoids volume overload, and removes drugs associated with lactic acidosis such as metformin.[9,27] However, the same potential risks of worsening lactic acidosis with bicarbonate administration through the dialysate exist. Furthermore, in severe lactic acidosis, the quantity of lactate cleared by dialysis is much less than the quantity of lactate generated. Continuous dialysis modalities are preferred over intermittent dialysis in hemodynamically unstable patients and can deliver bicarbonate at a lower rate. Evidence supporting intermittent or continuous dialysis for treatment of lactic acidosis is anecdotal at best, and prospective controlled trials are warranted.[27]

D-Lactic Acidosis

D-lactate refers to the D (dextro) enantiomer of lactic acid. D-lactic acidosis is an uncommon form of lactic acidosis that occurs in patients with jejunoileal bypass, small bowel resection, or other causes of short bowel syndrome resulting from bacterial overgrowth. In these patients, abnormally large amounts of glucose and starch are metabolized to D-lactic acid by gram-positive intestinal anaerobes such as lactobacilli.[33,34] D-lactic acid is then absorbed into the systemic circulation and causes acidemia that tends to persist because D-lactate is not recognized by L-lactate dehydrogenase, the enzyme that converts L-lactate into pyruvate. Patients typically present with recurring episodes of metabolic acidosis after a carbohydrate meal in addition to neurologic abnormalities, including confusion, ataxia, slurred speech, and memory loss.[34] The diagnosis can be easily missed because the D-isomer responsible for the acidosis is not detected by the standard assay for lactate and requires a special assay for detection. Therapy for D-lactic acidosis includes administration of sodium bicarbonate to correct the acidosis, oral antibiotics to decrease gram-positive anaerobic colonic bacteria, and a low-carbohydrate diet to reduce carbohydrate delivery to the colon.[35] D-lactic acidosis has also been described in patients who have large amounts of propylene glycol and in those with diabetic ketoacidosis (DKA).[36,37]

KETOACIDOSIS

Ketoacidosis is a common complication in patients with insulin-dependent diabetes mellitus but can also be seen in chronic alcoholism and starvation (see Box 15.2). It results from the overproduction of ketone bodies, leading to accumulation of ketones in the plasma (ketonemia) and urine (ketonuria).

Diabetic Ketoacidosis

DKA occurs in patients with insulin-dependent diabetes mellitus and results from severe insulin deficiency in the setting of increased

metabolic demand, such as from a concurrent infection or myocardial infarction. It can also occur from poor compliance with insulin or missed injections. Insulin deficiency results in decreased glucose uptake, glycogen store depletion, lipolysis, and fatty acid oxidation leading to increased ketoacid production (acetoacetate and beta-hydroxybutyrate). Symptoms can progress from polydipsia, polyuria, nausea, vomiting, dyspnea, and diffuse abdominal pain to confusion, lethargy, and somnolence. Laboratory findings include hyperglycemia, increased serum AG, ketonemia, ketonuria, and increased plasma osmolality. The diagnosis is established by measuring plasma and urine ketone levels. However, clinicians must be aware that the nitroprusside reaction used in standard plasma and urine tests only measures acetone and acetoacetate levels and not beta-hydroxybutyrate levels, which is the predominant ketone in severe untreated DKA. Therefore laboratory analysis for ketones may be falsely negative. High plasma glucose levels can cause dilutional hyponatremia because the osmotic effect of hyperglycemia causes the movement of water into the intravascular space. For each 100 mg/dL of glucose over 100 mg/dL, the plasma sodium level is lowered by approximately 1.6 mEq/L. In spite of severely depleted total body potassium from osmotic diuresis, plasma potassium levels are initially elevated or within the normal range from insulin deficiency.[4,38]

The major goals of treatment are rapid volume expansion, correction of hyperglycemia, correction of acid-base and electrolyte disturbances, and identification and treatment of the precipitating cause. Adults should initially receive a rapid infusion of 1 L of isotonic saline with repeat boluses as necessary to prevent hemodynamic collapse. When the blood pressure and heart rate have stabilized and the patient is euvolemic, isotonic saline can be switched to 0.45% saline at a slower rate to replace the free water lost by osmotic diuresis. Insulin is typically administered as a 10- to 20-unit IV bolus (0.15 units/kg) followed by an infusion of 5–7 units/hour (0.1 unit/kg/hour). Insulin inhibits lipolysis and gluconeogenesis and allows for the conversion of ketones to bicarbonate. If the blood sugar falls below 250 mg/dL, the rate of insulin should be decreased to 0.03 u/kg/hour and 5%–10% dextrose should be added to the fluids. Once the AG normalizes, subcutaneous insulin should be administered while the insulin infusion is continued for another 1–2 hours. Potassium replacement should be administered at 10–20 mEq/hour if the plasma potassium level is less than 5.3 mEq/L and if renal failure is not present. Plasma potassium levels should be measured frequently, and the infusion should be stopped if hyperkalemia occurs. Small amounts of IV sodium bicarbonate should only be administered if the arterial pH is less than 6.9, with frequent monitoring of pH and serum AG. IV phosphate replacement can be given if the initial level is less than 1.0 mg/dL. Plasma phosphorus levels can be high initially because of the transcellular shift of phosphate out of the cell in the setting of acidosis and insulin deficiency.[38,39]

Hemodialysis-dependent patients with DKA are managed differently. Insulin administration is frequently the only treatment needed for DKA management in these patients. Anuric dialysis patients usually present with signs of extracellular volume (ECV) expansion rather than volume depletion because osmotic diuresis cannot occur in the absence of kidney function. Therefore dialysis patients do not require IV fluids unless they have evidence of extracellular fluid loss such as vomiting, diarrhea, or excessive insensible losses. If volume depletion is present, small amounts of isotonic saline should be carefully administered with close monitoring of respiratory and hemodynamic parameters. When volume overload is apparent, immediate hemodialysis is the therapy of choice. Hemodialysis will also help correct hyperglycemia resulting from diffusive clearance of glucose but must be performed in conjunction with insulin administration, as insulin is the only therapy that will halt lipolysis and gluconeogenesis. Dialysis-dependent patients with DKA should not receive routine potassium supplementation because total body potassium stores may be high and patients are unable to excrete a potassium load. Urgent dialysis is indicated if hyperkalemia is present with electrocardiographic findings. Similarly, significant metabolic acidosis can only be corrected with hemodialysis.[39,40]

Euglycemic DKA is an emerging entity that has been recognized in patients with both type 1 and type 2 diabetes mellitus who present with increased AG acidosis, ketosis, and relatively normal serum glucose <200 mg/dL.[41] The pathophysiology is thought to be related to decreased hepatic gluconeogenesis during fasting or enhanced urinary excretion of glucose. Common causes of euglycemic DKA include SGLT2 inhibitors, pregnancy, glycogen storage diseases, and chronic liver disease. Less common causes include pancreatitis, alcohol use, cocaine intoxication, gastroparesis, and Duchenne muscular dystrophy.[41]

Alcoholic Ketoacidosis

Alcoholic ketoacidosis (AKA) occurs in the setting of chronic alcoholism, recent binge drinking, minimal oral intake, and persistent vomiting. It is characterized by elevated plasma ketone levels, high AG, and normal or only slightly elevated plasma glucose level. Prolonged starvation results in decreased insulin activity, glycogen depletion, increased counterregulatory hormone production, dehydration, and increased lipolysis and fatty acid oxidation with accumulation of ketoacids. The metabolism of ethanol itself promotes ketoacidosis by leading to an accumulation in reduced NADH. Reduced NADH then results in impaired conversion of lactate to pyruvate, preferential conversion of pyruvate to lactate, and a shift toward beta-hydroxybutyrate production. Beta-hydroxybutyrate is the predominant ketone in AKA. As mentioned, the standard nitroprusside test for detecting ketones only detects acetoacetate and may be falsely negative or only minimally positive in AKA, leading to an underestimation of the degree of ketoacidosis.[42,43]

Patients with AKA frequently present with a mixed acid-base disturbance. They can have elevated AG metabolic acidosis from ketoacidosis and lactate, metabolic alkalosis from persistent vomiting, and chronic respiratory alkalosis from liver disease. Magnesium and phosphate levels may be low because of increased urinary excretion and poor nutrition.

The mainstay of treatment is hydration with 5% dextrose in isotonic saline. Before glucose administration, thiamine should be given to avoid precipitating Wernicke encephalopathy. Carbohydrate and fluid replacement reverse the pathophysiologic derangements that lead to AKA by increasing plasma insulin levels and suppressing the release of glucagon and other counterregulatory hormones. Dextrose stimulates the oxidation of NADH and aids in normalizing the $NADH/NAD^+$ ratio. Insulin should be avoided because it can lead to hypoglycemia, especially as the patient's endogenous insulin levels rise with carbohydrate and fluid repletion. Bicarbonate is only recommended if the plasma pH is less than 7.1 and the acidosis is not responding to IV fluids. Hypophosphatemia, hypokalemia, and hypomagnesemia should be corrected. Glucose infusion can exacerbate hypophosphatemia, resulting in rhabdomyolysis if not repleted.[44]

Starvation Ketoacidosis

Starvation, as mentioned earlier, results in ketoacidosis because of the increase in counterregulatory hormones and a decrease in insulin level, promoting fatty acid oxidation, gluconeogenesis, and ketone production. However, in comparison to the potentially severe ketoacidosis

that develops in uncontrolled diabetes and alcoholic states, ketoacid levels do not typically exceed 10 mEq/L with fasting. This is probably because of the insulin level, which, though lower, is still enough to limit the production of free fatty acids and thus ketoacidosis[45,46] (see Boxes 15.2 and 15.3).

TOXIC ALCOHOL INGESTIONS

Accumulation of the metabolites of methanol—ethylene glycol, diethylene glycol, and propylene glycol—causes a high AG and increased plasma osmolal gap. Intoxication should be suspected in any patient who presents with high AG metabolic acidosis, renal failure, and neurologic findings, and treatment should be initiated early.

The normal range of plasma osmolality is 285–290 mOsm/kg. Plasma osmolality (Posm) can be estimated from the following formula:

$$\text{Calculated Posm} = (2 \times \text{plasma [Na]}) + (\text{glucose mg/dL})/18 + (\text{BUN mg/dL})/2.8$$

The plasma osmolal gap represents the difference between the measured and calculated plasma osmolality. A difference of higher than 10 mOsm/kg is considered an osmolal gap. Accumulation of the noted alcohols will typically produce an osmolal gap of higher than 20 mOsm/kg. Methanol gives rise to the greatest increment in plasma osmolality, followed by ethylene glycol, propylene glycol, and finally diethylene glycol.[47] The absence of an osmolal gap does not exclude an alcohol-related intoxication. Furthermore, although the plasma osmolal gap may support the diagnosis of ingestion of a toxic alcohol, plasma toxicology screens specifically looking for the toxins are considered the gold standard.

Other causes of high AG metabolic acidosis that can be associated with an elevated plasma osmolal gap include lactic acidosis, ketoacidosis, advanced chronic kidney disease (CKD), formaldehyde ingestion, and paraldehyde ingestion. The plasma osmolal gap is usually less pronounced in these disorders (≤15–20 mOsm/kg), and plasma toxicology is not typically performed. Substances that can cause an osmolal gap without metabolic acidosis are ethanol, isopropyl alcohol ingestion, infusion of nonconductive glycine, sorbitol or mannitol solutions, severe hyperproteinemia, and severe hyperlipidemia.[47]

Methanol, used as a laboratory and industrial solvent, is commonly found in windshield wiper fluid, de-icing products, gas-line antifreeze, and various paint solvents and thinners. It is metabolized by alcohol dehydrogenase (ADH) to formaldehyde, which is further metabolized by aldehyde dehydrogenase (ALDH) to formic acid. The most common symptoms of methanol intoxication are abdominal pain and visual disturbances, including decreased visual acuity, photophobia, and blurred vision. Formic acid is the main toxic metabolite responsible for retinal, ophthalmic, and neural toxicity. Permanent blindness may occur because of optic nerve atrophy. High AG metabolic acidosis is the result of generation of formic acid and increased production of lactic acid. Lactic acidosis results from impaired cellular respiration by formate or increased generation of NADH during the metabolism of methanol.[47,48] Imaging findings in acute methanol intoxication include bilateral necrosis of the putamen, diffuse white matter necrosis, and subarachnoid hemorrhage on brain computed tomography (CT) and magnetic resonance imaging (MRI).[49]

Ethylene glycol is typically found in radiator antifreeze in addition to various solvents and paint formulations. It is metabolized by ADH to glycolaldehyde, then to glycolic acid by ALDH, which is further metabolized to glyoxylic acid and finally oxalic acid. The metabolites are responsible for neurologic, cardiopulmonary, and renal toxicity. Typically, neurologic abnormalities occur initially, followed by cardiopulmonary dysfunction, and finally renal dysfunction. Neurologic findings include coma, seizures, meningeal signs, external ocular paralysis, and delayed onset of cranial nerve deficits. Cardiopulmonary findings include tachycardia, hyperventilation, and heart failure. Oxalic acid combines with plasma calcium to form calcium oxalate, which leads to hypocalcemia, QTc prolongation, and risk of ventricular arrhythmias. Calcium oxalate crystals precipitate in the renal tubules, causing flank pain, oliguria, and renal failure. Calcium oxalate crystals are present in the urine 4–8 hours after ingestion of ethylene glycol and can be visualized by direct urine microscopy. High AG metabolic acidosis is the result of generation of glycolic, glyoxylic, and oxalic acids and increased production of lactic acid. Measurement of plasma ethylene glycol levels can confirm poisoning.[47,48]

Methanol and ethylene glycol poisoning are treated with fomepizole or ethanol, which inhibits ADH and prevents the formation of toxic metabolites. Fomepizole (15 mg/kg loading dose, then 10 mg/kg every 12 hours) is preferred over ethanol because of its easier dosing regimen and better side-effect profile. The indications for antidotal therapy are a plasma concentration of methanol or ethylene glycol higher than 20 mg/dL and two of the following: osmolal gap higher than 10 mOsm/kg, arterial pH lower than 7.3, plasma bicarbonate level lower than 20 mEq/L, and the presence of urinary oxalate crystals. Indications for hemodialysis are severe metabolic acidosis (pH <7.25), visual abnormalities, renal failure, electrolyte abnormalities not responsive to treatment, hemodynamic instability despite ICU treatment, and plasma concentration higher than 50 mg/dL. In ethylene glycol toxicity, pyridoxine and thiamine are administered to increase the metabolism of glycolic and glyoxylic acid to the less-toxic metabolites glycine and alpha-hydroxy-beta-ketoadipate. In methanol toxicity, folic acid or folinic acid increases the breakdown of formic acid to CO_2 and water.[47,48]

Diethylene glycol is present in brake fluid and is used as an illegal adulterant in ethanol spirits or in medication. Diethylene glycol is oxidized by ADH to 2-hydroxyethoxyacetaldehyde and then via ALDH to 2-hydroxyethoxyacetic acid. Acute oliguric and nonoliguric renal failure are frequent. Treatment consists of hemodialysis and fomepizole.[47]

Propylene glycol is a solvent for unstable drugs, including benzodiazepines, phenytoin, nitroglycerin, and some topical medications. The majority of intoxications have resulted from excessively large or rapidly infused IV injections of propylene glycol–containing medications such as benzodiazepines. Neurologic depression is the primary manifestation of acute propylene glycol poisoning. Metabolic acidosis is attributed to the generation of lactic acid during metabolism of propylene glycol. Discontinuation of propylene glycol–containing medication can lead to correction of the acidosis within 24 hours in most patients. In the face of extremely high blood concentrations, hemodialysis is extremely effective in rapidly reducing plasma propylene glycol levels.[47]

Use of isopropyl alcohol is the most common cause of toxic alcohol exposure in the United States; it is found in rubbing alcohol, hand sanitizer gels, and other antiseptic preparations. It is metabolized by ADH to acetone, without production of AG acidosis. Toxicity is mainly limited to gastrointestinal (GI) effects, such as hemorrhagic gastritis and neurologic depression. Isopropyl alcohol is the only toxic alcohol that causes ketosis without acidosis. In comparison to other toxic alcohols, isopropyl alcohol intoxication is usually managed supportively. Hemodialysis may increase the rate of elimination of both isopropyl alcohol and acetone and should be considered for patients with deteriorating mental status or hemodynamic instability.[47]

SALICYLATES

Salicylate toxicity may develop with either acute or chronic exposure to salicylates. Acute and chronic salicylate toxicity is associated with a high mortality if not recognized early and treated. Salicylates are found in over-the-counter medications such as aspirin, bismuth subsalicylate, effervescent antacids, ointments, liniments, and oil of wintergreen (methyl salicylate) and in numerous prescription medications. Patients with salicylate toxicity may present with neurologic symptoms (cerebral edema, coma, agitation, tinnitus, or seizures), pulmonary symptoms (hyperventilation/tachypnea or acute lung injury), and GI symptoms (nausea or vomiting). Nausea, vomiting, diaphoresis, and tinnitus are the earliest signs and symptoms of salicylate toxicity. Salicylates stimulate the respiratory center, leading to hyperventilation and respiratory alkalosis. They also uncouple oxidative phosphorylation and interfere with the Krebs cycle, leading to increased lactate production, ketosis, and high AG metabolic acidosis. Interference with aerobic respiration also causes hypoglycemia, fever, and fluid loss. Adult patients with acute poisoning usually present with mixed respiratory alkalosis and metabolic acidosis but can also present with primary respiratory alkalosis. In children, respiratory alkalosis may be transient, with metabolic acidosis occurring early in the course.[50]

The therapeutic range of salicylates is 10–30 mg/dL. Patients become symptomatic at concentrations higher than 40 mg/dL. Levels higher than 90–100 mg/dL usually have serious or life-threatening toxicity. In overdoses, the peak plasma concentration may not occur for 4–6 hours. Laboratory tests should be repeated every 4–6 hours until the level falls into the nontoxic range. Renal excretion of salicylic acid depends on urinary pH. Increasing the urine pH to 7.5 prevents reabsorption of salicylic acid from the urine. Because acidosis facilitates transfer of salicylate into tissues, especially in the brain, it must be treated aggressively by raising the blood pH higher than the brain pH, thereby shifting the equilibrium from the tissues to the plasma. Alkalinization with IV sodium bicarbonate is the mainstay of treatment in patients whose plasma pH is not already elevated (>7.5), and care should be taken not to raise plasma pH to inappropriately high levels (>7.55). Hypokalemia occurs commonly in salicylate-poisoned patients and prevents urinary excretion of salicylate unless corrected. Because intoxication can decrease cerebral glucose concentrations despite normal plasma glucose concentrations, adults who are hypoglycemic or have altered mental status, regardless of their plasma glucose concentration, should be treated with supplemental glucose. Indications for hemodialysis include a plasma level higher than 120 mg/dL (acutely) or higher than 100 mg/dL (6 hours post-ingestion), refractory acidosis, coma or seizures, noncardiogenic pulmonary edema, volume overload, and renal failure. In chronic overdose, hemodialysis may be required for a symptomatic patient with a plasma salicylate level higher than 60 mg/dL.[50,51]

PYROGLUTAMIC ACIDOSIS

Accumulation of 5-oxoproline (pyroglutamic acid), an organic acid intermediate of the gamma-glutamyl cycles, is a rare, but underdiagnosed, cause of severe, high AG metabolic acidosis in adults. The acidemia associated with pyroglutamic acid usually occurs in association with acetaminophen therapy and in the setting of severe sepsis, liver dysfunction, or renal dysfunction. Heterozygosity for glutathione synthase deficiency may also be an underlying risk factor for development. The etiology appears to be a drug-induced reversible inhibition of either glutathione synthetase or 5-oxoprolinase. Diagnosis is made by measuring urinary 5-oxoproline levels to demonstrate the presence of pyroglutamic acid. Treatment with methionine or *N*-acetylcysteine to replenish glutathione should be considered.[52–55]

RENAL FAILURE

Early CKD is associated with hyperchloremic normal AG metabolic acidosis, and advanced CKD is associated with elevated AG metabolic acidosis. In early CKD, acid excretion is initially maintained by increased ammonium excretion. When the GFR falls below 40–50 mL/min, tubular function decreases, leading to retention of H^+, an increase in the amount of bicarbonate excreted, and metabolic acidosis. To maintain electroneutrality, the kidneys retain chloride with each bicarbonate ion lost, causing hyperchloremic metabolic acidosis. Because glomerular function decreases at a much slower rate than the loss of tubular function, the excretion of sulfate and other organic and inorganic acid anions is not affected, as their filtration by the kidney is maintained. The AG remains in normal range because of the continued excretion of organic acids by the kidneys. In advanced CKD, when the GFR falls below 20 mL/min, the capacity of the kidneys to filter the anions of organic acids is significantly diminished, causing retention of phosphates, sulfates, urate, and hippurate anions in the plasma and development of elevated AG metabolic acidosis.[56,57]

Clinical consequences of chronic metabolic acidosis in CKD include osteopenia, worsening secondary hyperparathyroidism, CKD progression, and increased mortality. Recent clinical trials have suggested that correction or prevention of metabolic acidosis by alkali administration is able to slow the progression of CKD. As a result, to prevent CKD progression and bone loss, sodium bicarbonate supplementation (0.5–1 mEq/kg/day) is recommended for patients with CKD with plasma bicarbonate concentrations lower than 22 mEq/L.[57,58]

NON–ANION GAP (HYPERCHLOREMIC) METABOLIC ACIDOSIS

Normal or non-AG metabolic acidosis is also called *hyperchloremic metabolic acidosis* because the kidneys reabsorb chloride instead of bicarbonate, yielding no net change in the serum AG. Hyperchloremic metabolic acidosis may result from impaired renal acid excretion, increased renal or GI bicarbonate loss, H^+ gain, marked urinary excretion of organic acid anions with replacement with chloride, or administration of chloride-rich solutions during resuscitation (Box 15.4). In impaired renal acid excretion, the absence of sufficient ammonium excretion results in the acid anions being excreted with sodium and potassium. This results in a sodium deficit and avid renal retention of filtered sodium and chloride. The retained chloride replaces the lost bicarbonate. GI or urinary bicarbonate loss leads to a sodium deficit and a reduction in extracellular fluid volume. This stimulates renal retention of sodium and chloride, thereby replacing the lost bicarbonate by the retained chloride.[59]

URINARY ANION GAP

In assessing the cause of hyperchloremic metabolic acidosis, the urine AG (UAG) may be useful in differentiating renal causes from GI causes. The UAG is calculated as the difference between the measured urine cations (Na^+ and K^+) and urine Cl^-:

$$UAG = (Na^+) + (K^+) - (Cl^-)$$

In diarrhea and other nonrenal causes of hyperchloremic acidosis, the kidney should attempt to compensate by increasing net acid excretion. The major mechanism for this increase is a marked increase in urinary ammonium excretion. Because urinary ammonium measurements are not readily available, the UAG serves as a surrogate. Under normal circumstances, the sum of the excreted urine sodium and urine

Box 15.4 Differential Diagnosis of Hyperchloremic Metabolic Acidosis

Gastrointestinal Bicarbonate Loss
Diarrhea
External pancreatic or small bowel drainage
Ureterosigmoidostomy, jejunal loop

Drugs
Calcium chloride (acidifying agent)
Magnesium sulfate (diarrhea)
Cholestyramine (bile acid diarrhea)

Renal Acidosis
Hypokalemic
Proximal renal tubular acidosis (RTA) (type 2) (see Box 15.5)
Distal (classic) RTA (type 1)

Drug-Induced Hypokalemia
Acetazolamide (proximal RTA)
Amphotericin B (distal RTA)

Hyperkalemic
Generalized distal nephron dysfunction (type 4 RTA) (see Box 15.5)
Mineralocorticoid deficiency or resistance (pseudohypoaldosteronism type 1)
PHA-I, PHA-II
↓ Na^+ delivery to distal nephron
Tubulointerstitial disease
Ammonium excretion defect

Drug-Induced Hyperkalemia
Potassium-sparing diuretics (amiloride, triamterene, spironolactone)
Trimethoprim
Pentamidine
Angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers
Nonsteroidal antiinflammatory drugs
Cyclosporine, tacrolimus

Normocalcemic
Early renal insufficiency

Other
Acid loads (ammonium chloride, hyperalimentation)
Loss of potential bicarbonate: ketosis with ketone excretion
Dilution acidosis (rapid saline administration)
Hippurate
Cation-exchange resins

potassium is greater than the amount of excreted urine chloride and the UAG is positive. In patients with normal AG metabolic acidosis, the excretion of ammonium occurs with chloride, increasing the urine chloride concentration. In such settings, urine chloride usually exceeds the sum of urine sodium and urine potassium, resulting in a negative UAG; the UAG will be negative when ammonium is present and balanced by negatively charged urinary chloride. A negative UAG is consistent with increased ammonium excretion and occurs in patients who develop metabolic acidosis as a result of diarrhea. If little ammonium is present, the UAG will be zero or positive, similar to that in patients who have hyperchloremic metabolic acidosis associated with impaired ammonium excretion, as seen in renal tubular acidosis (RTA).

There are several limitations to the UAG. The UAG cannot be interpreted accurately in the setting of increased urinary excretion of unmeasured anions. Unmeasured anions may be excreted with sodium or potassium or with ammonium. Examples of unmeasured urinary anions include ketoacids, hippurate, D-lactate, and 5-oxoproline. As a result, the excretion of ammonium with these unmeasured anions will not reduce the UAG, which occurs when ammonium is excreted with chloride. In addition, the excretion of sodium or potassium with unmeasured anions leads to a positive UAG.[60] The UAG also cannot be interpreted in volume-depleted states with urine sodium levels less than 25 mEq/L because of impaired distal sodium delivery.[61]

The urine osmolal gap (UOG) can overcome some of the limitations of the UAG.[59,60] The UOG indirectly assesses urine ammonium concentration by comparing the difference of directly measured urine osmolality to the calculated urine osmolality. The formula for calculating urine osmolality is as follows:

$$\begin{aligned}&\text{Calculated urine osmolality (mOsm/kg)}\\&=(2\times[\text{Na}+\text{K}])+(\text{urea nitrogen in mg/dL})/2.8\\&\quad+(\text{glucose in mg/dL})/18\end{aligned}$$

Besides sodium, potassium, urea, and glucose (if present in the urine), the major urinary solute that contributes to urine osmolality is ammonium. Most of the UOG is therefore made up of ammonium in the form of ammonium chloride in addition to ammonium excreted with other unmeasured anions. Thus the UOG detects ammonium excretion regardless of the anion that is excreted along with it. The UOG must be divided by 2 in order to account for the anion being excreted with ammonium. In the setting of metabolic acidosis, urine ammonium levels should be higher than 200 mEq/L. An ammonium urine concentration of less than 75 mEq/L in a patient with metabolic acidosis indicates impaired renal ammonium excretion and correlates with a UOG of less than 150 mOsm/kg. In the setting of hyperchloremic metabolic acidosis from GI causes such as diarrhea, the UOG should be higher than 400 mOsm/kg.[59,60]

RENAL TUBULAR ACIDOSIS

RTA is characterized by impaired urinary acidification, resulting in retention of H^+, reduction in plasma bicarbonate levels, and hyperchloremic non-AG metabolic acidosis. RTA can be classified as proximal (type 2), distal (type 1), and hyperkalemic (type 4). The UAG is usually positive in RTA because of an inability to excrete H^+. Proximal (type 2) and distal (type 1) RTA are uncommon disorders (see Boxes 15.4 and 15.5).

Proximal Renal Tubular Acidosis (Type 2)

Proximal RTA is characterized by impaired proximal bicarbonate reabsorption with a lowered threshold for bicarbonate reclamation. This results in renal bicarbonate wasting whenever the bicarbonate concentration exceeds this lowered threshold. Below this threshold, bicarbonate is conserved and maximal urinary acidification (urine pH <5.5) occurs. Bicarbonate loss in the urine leads to increased H^+ concentration in the blood and a subsequent reduction in the arterial pH. Because of impaired proximal bicarbonate reabsorption, the distal nephrons become overwhelmed by an increase in bicarbonate delivery and cannot compensate for the loss in proximal function. However, as the plasma bicarbonate level decreases to 15–18 mEq/L, the amount of filtered bicarbonate decreases with reduced delivery of bicarbonate to the distal nephrons. At that point, the distal nephrons are able to function, leading to a reduction in bicarbonate loss and appropriate

Box 15.5 List of Select Disorders Associated With Renal Tubular Acidosis*

Renal Defect in Net Acid Excretion, Classic Distal Renal Tubular Acidosis (Type 1 RTA)

Systemic or Tubulointerstitial Disease

Medullary sponge kidney
Cryoglobulinemia
Balkan nephropathy
Nephrocalcinosis
Chronic pyelonephritis
HIV nephropathy
Renal transplant
Sjögren syndrome
Thyroiditis
Hyperparathyroidism

Drug or Toxin Induced

Ifosfamide
Amphotericin B
Foscarnet
Toluene
Mercury
Classic analgesic nephropathy

Renal Defect in HCO_3^- Reclamation, Proximal Renal Tubular Acidosis (Type 2 RTA)

Selective (Unassociated With Fanconi Syndrome)

Idiopathic

Carbonic anhydrase deficiency or inhibition
Drugs such as acetazolamide
Carbonic anhydrase II deficiency with osteopetrosis (Sly syndrome)

Generalized (Associated With Fanconi Syndrome)

Primary: inherited or sporadic
Genetically transmitted systemic diseases: cystinosis, Lowe syndrome, Wilson syndrome

Dysproteinemic States

Multiple myeloma
Monoclonal gammopathy

Secondary Hyperparathyroidism With Chronic Hypocalcemia

Vitamin D deficiency or resistance
Vitamin D dependency

Drugs or Toxins

Ifosfamide
Lead
Outdated tetracycline
Streptozotocin
Mercury
Amphotericin B (historic)

Tubulointerstitial Diseases

Sjögren syndrome
Medullary cystic disease
Renal transplantation

Generalized Defect of the Distal Nephron With Hyperkalemia (Type 4 RTA)

Mineralocorticoid Deficiency

Primary Aldosterone Deficiency

Adrenal disease (hemorrhage, destruction, infarction)
Heparin (low-molecular-weight [MW] or unfractionated)
Persistent hypotension in critically ill patient
Renin–angiotensin system modulating agents (angiotensin-converting enzyme inhibitor [ACEI], angiotensin receptor blocker [ARB])

Secondary Aldosterone Deficiency (Hyporeninemic Hypoaldosteronism)

Diabetic nephropathy
HIV disease
Tubulointerstitial nephropathy
NSAID use

Renal Tubular Dysfunction (Voltage Defect)

Drugs That Interfere With Sodium Channel or Na^+/K^+-ATPase

Amiloride
Pentamidine
Triamterene
Trimethoprim
Cyclosporine
Tacrolimus

Disorders Associated With Tubulointerstitial Disease

Renal failure
Lupus nephritis
Obstructive uropathy
Renal transplant rejection
Sickle cell disease

Adapted in part from DuBose TD Jr. Acid-base disorders. In Brenner BM, ed. *Brenner and Rector's The Kidney*. 8th ed. Philadelphia: Saunders; 2008:513–546.

* See source for complete list of disorders.

acidification of the urine to a pH less than 5.5. These patients also have hyperaldosteronism from salt wasting because of the defect in proximal reabsorption of filtered bicarbonate. Because of hyperaldosteronism, urinary potassium wasting and hypokalemia are common.[59,62]

Proximal RTA is suggested by a modestly low plasma bicarbonate level of 15–18 mEq/L with appropriate urinary acidification (urinary pH <5.5). This can be confirmed by measurement of the urine pH and fractional bicarbonate excretion during bicarbonate infusion, but this is not often done in practice. IV sodium bicarbonate is infused at a rate of 0.5–1.0 mEq/kg/hour to increase the plasma bicarbonate concentration toward normal (18–20 mEq/L). The urine pH, even if initially acidic, will rise rapidly once the reabsorptive threshold for bicarbonate is exceeded. As a result, the urine pH will increase to higher than 7.5 and the fractional excretion of bicarbonate will exceed 15%.[59,62]

In adults, proximal RTA is typically secondary to acquired proximal tubular damage such as heavy metal exposure and multiple myeloma,

whereas in children, it is associated with metabolic defects (see Box 15.5). Proximal RTA is often accompanied by other proximal tubular transport defects, including renal glycosuria, phosphate wasting, aminoaciduria, and hypouricemia (Fanconi syndrome). Medications such as carbonic anhydrase inhibitors (e.g., acetazolamide) and topiramate can cause proximal RTA by impairing proximal bicarbonate reabsorption without affecting the reabsorption of other proximal tubule solutes. The drugs tenofovir and ifosfamide can cause Fanconi syndrome.[59]

Complications include bone disease because of an increase in bone buffering of excess acid and acquired vitamin D deficiency from decreased calcitriol production. Defects in proximal transport may also result in phosphate wasting and hypophosphatemia, leading to rickets in children and osteomalacia or osteopenia in adults.[59,62]

Standard treatment is with oral alkali therapy. Because exogenous alkali is rapidly excreted in the urine, considerably higher doses of alkali are required compared with distal and type 4 RTA. About 10–15 mEq/kg/day of alkali is typically required to stay ahead of urinary excretion. Potassium citrate is the preferred form of alkali to ameliorate potassium losses. Thiazides are also sometimes used in conjunction with a low-salt diet to reduce the amount of alkali required. Thiazides induce volume contraction and enhance proximal bicarbonate reabsorption.[62]

Classic Distal Renal Tubular Acidosis (Type 1)

Classic distal RTA results from defective H^+ secretion in the distal tubule. Impaired H^+ secretion results in an inability to acidify the urine pH beyond 5.5 and reduced net acid excretion. The plasma bicarbonate may fall below 15 mEq/L. Hypokalemia occurs as a result of urinary potassium wasting from increased potassium secretion by distal tubular cells in the setting of diminished H^+ secretion. Hypercalciuria, alkaline urine, and low urinary citrate levels promote the precipitation of calcium phosphate stones and nephrocalcinosis. A diagnosis is made by the findings of hypokalemia, normal AG metabolic acidosis, inappropriately high urine pH (>5.5) regardless of the plasma bicarbonate concentration, and a positive UAG.[62]

The most common causes in adults are autoimmune disorders such as Sjögren syndrome. In children, RTA is most often a primary hereditary condition (see Box 15.5). Drugs such as ifosfamide and amphotericin cause distal RTA in adults and children. As in proximal RTA, complications include failure to thrive, rickets, and stunting of growth in children and osteomalacia or osteopenia in adults. Patients may otherwise be asymptomatic or may present with symptoms of severe acidosis or hypokalemia.[60]

Adults are generally treated with oral sodium bicarbonate or sodium citrate 1–2 mEq/kg/day. Patients with significant hypokalemia, nephrolithiasis, or nephrocalcinosis are treated with potassium citrate or Polycitra (potassium citrate plus sodium citrate).

Hyperkalemic Distal Renal Tubular Acidosis (Type 4)

Hyperkalemic distal RTA is characterized by hyperkalemia and hyperchloremic metabolic acidosis. It can occur in the setting of aldosterone deficiency or resistance or result from a voltage-dependent defect in H^+ secretion. In aldosterone deficiency or resistance, hyperkalemia is the primary disturbance, suppressing proximal tubular ammonium production and producing metabolic acidosis.[4] Urinary acidification is intact. The metabolic acidosis seen is generally mild, with the plasma bicarbonate level usually higher than 15 mEq/L. Despite impaired distal H^+ secretion, the urine pH is generally below 5.5. The ability to acidify the urine in this condition is the result of the inadequate amount of ammonia available for buffering of protons because the urinary pH falls in the absence of buffers. The findings of hyperkalemic, normal AG metabolic acidosis with an appropriately low urine pH (<5.5) and positive UAG confirm the diagnosis. The diagnosis is further supported by a bicarbonate fractional excretion of higher than 10% in the setting of bicarbonate infusion.[62]

Hyporeninemic hypoaldosteronism is the most common cause of type 4 RTA in patients with mild to moderate renal insufficiency resulting from diabetic nephropathy (see Box 15.5). Many drugs can cause type 4 RTA by affecting renin release, aldosterone production, or tubular potassium excretory capacity. Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit renin release. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), calcineurin inhibitors, and heparin can all reduce aldosterone production. Inhibitors of tubular potassium excretion include spironolactone, eplerenone, triamterene, and amiloride. The tubulointerstitial diseases commonly associated with type 4 RTA include sickle cell disease and obstructive nephropathy.[4,62]

Hyperkalemia from aldosterone deficiency or resistance can be diagnosed by measuring the transtubular potassium gradient (TTKG)[63]:

$$\text{TTKG} = (\text{urine } K^+ \times \text{plasma osmolality}) / (\text{plasma } K^+ \times \text{urine osmolality})$$

A TTKG higher than 8 indicates that aldosterone is present and that the collecting duct is responsive to it. A TTKG less than 5 in the presence of hyperkalemia indicates aldosterone deficiency or resistance. For the test to be accurate, the urine sodium concentration should be higher than 10 mEq/L and the urine osmolality should be greater than or equal to the plasma osmolality.[63]

Therapy is aimed at reducing the plasma potassium concentration and includes volume expansion, dietary potassium restriction, and potassium-wasting diuretics. Acidosis will usually improve once the hyperkalemic impedance of ammonium production is removed. Any drugs that suppress or block aldosterone should be discontinued. Mineralocorticoid replacement with fludrocortisone will improve hyperkalemia and acidosis but is not ideal in patients with uncontrolled hypertension or a history of heart failure. These patients are instead treated with a low-potassium diet and a loop diuretic.[4]

GASTROINTESTINAL TRACT LOSS

The secretions of the large and small bowel are mostly alkaline and have a bicarbonate level higher than that in the plasma. Significant loss of lower GI secretions results in non-AG metabolic acidosis (see Box 15.4). Diarrhea is the most common cause of external loss of bicarbonate, resulting in non-AG metabolic acidosis. Other causes include external drainage of pancreatic or biliary secretions, as from fistulas, ileus secondary to intestinal obstruction, and villous adenomas. Drugs that increase GI bicarbonate loss include calcium chloride, magnesium sulfate, and cholestyramine. Significant bicarbonate loss also occurs in patients who abuse laxatives. Urinary diversions, such as ureterosigmoidostomy or ureteroileostomy, can cause non-AG metabolic acidosis because of the absorption of chloride in exchange for bicarbonate across the bowel mucosa. Absorption of urinary ammonium in the sigmoid colon may also contribute to the development of acidosis, as metabolism of the ammonium in the liver results in the production of H^+.

Metabolic acidosis and hypokalemia from GI losses increase renal synthesis and ammonia excretion, thereby providing a urinary buffer that increases urine pH despite increased net acid excretion.[59] The urine pH is higher than 5.5 instead of an acid urine pH, as expected with systemic acidosis. Metabolic acidosis resulting from GI losses with a high urine pH can be differentiated from RTA by calculating the UAG.

OTHER CAUSES OF NON–ANION GAP ACIDOSIS

See Box 15.4.

Expansion of the extracellular fluid volume with non–bicarbonate-containing solutions, such as isotonic saline, causes metabolic acidosis by diluting the previous existing plasma bicarbonate (dilutional acidosis) and increasing the chloride load. This increased chloride load exceeds the renal capacity to generate equal amounts of HCO_3^-.[59,64]

Amino acids in total parenteral nutrition (TPN) are metabolized to HCl, which causes a transient non-AG metabolic acidosis. The decreased pH and decreased HCO_3^- stimulate renal reabsorption and generation of HCO_3^-. Metabolic acidosis occurs if the acid load overrides the ability of the renal tubules to secrete H^+ and generate ammonia for excretion in the urine, usually a short-lived process.[4]

In prolonged hypercapnia, renal tubules compensate for a prolonged respiratory alkalosis by decreasing reclamation and generation of HCO_3^- (which takes 12–24 hours for full effect). If the respiratory alkalosis resolves rapidly, reclamation and generation of HCO_3^- will return to normal over 1–2 days. During this period a resolving non-AG metabolic acidosis occurs.

In toluene intoxication or the treatment phase of DKA, metabolic acid production is markedly increased. Although ammonium excretion is also increased, the rate of urinary excretion of the acid anions (hippurate and keto-anions, respectively) exceeds the excretion of ammonium. The anions not excreted with ammonium are excreted with sodium and potassium, causing sodium deficits and avid retention of filtered sodium and chloride. The lost bicarbonate is replaced by the retained chloride. In addition, administration of large volumes of isotonic saline for resuscitation in patients with DKA promotes diuresis, with continued urinary loss of ketone bodies, with sodium as the cation while delivering chloride to replace the lost keto-anions.[59]

METABOLIC ALKALOSIS

Primary metabolic alkalosis is a subset of acid-base disorders characterized by an elevation in blood arterial pH, an increase in plasma HCO_3^- concentration, and a compensatory hypoventilation, resulting in a rise in $PaCO_2$. It is encountered relatively frequently in clinical practice as a result of the loss of H^+ from the GI tract or urine. This disorder is also often accompanied by hypochloremia and hypokalemia.[65]

In the presence of an increased serum bicarbonate concentration and low serum chloride (Cl^-) concentration, a patient may have either metabolic alkalosis or chronic respiratory acidosis. These disorders can be differentiated by the arterial pH, which is increased (>7.4) in metabolic alkalosis and decreased (<7.4) or normal in chronic respiratory acidosis. In primary metabolic alkalosis, the $PaCO_2$ generally increases approximately 6–7.5 mm Hg for every 10 mEq/L increase in HCO_3^- above normal.

Metabolic alkalosis may occur as a simple disorder or when associated with other disorders like respiratory acidosis, respiratory alkalosis, or metabolic acidosis, as a mixed disorder. An increase in the serum AG may be the only sign that metabolic acidosis coexists with metabolic alkalosis. Clinical examples of a mixed AG acidosis and metabolic alkalosis include patients with both DKA and vomiting or lactic acidosis with vomiting.[66]

Pathogenesis

Metabolic alkalosis can result from the loss of H^+, transcellular H^+ shift, exogenous alkali administration, or contraction alkalosis (Fig. 15.3). These factors may initiate systemic alkalosis, but under normal physiologic circumstances, alkalosis should never develop because the kidney is efficient at removing excess bicarbonate. However, in conditions where kidney function may be compromised, bicarbonate excretion may become impaired. Metabolic alkalosis is typically associated with impairment in kidney function, which is thought to maintain the alkalosis.

In effect, metabolic alkalosis results from impaired bicarbonate elimination from the kidney by its regular mechanisms (see Fig. 15.3). An increase in the plasma bicarbonate concentration results from either exogenous HCO_3^- administration or endogenous production. The kidneys will preserve rather than eliminate excess alkali and maintain alkalosis if either of the following conditions is present: (1) Cl^- deficiency (or ECV contraction), typically accompanied by potassium (K^+) depletion, which reduces effective renal perfusion and glomerular filtration and enhances bicarbonate reabsorption. Alkalosis in this setting can usually be corrected with saline infusion (saline-responsive) and K^+ repletion or (2) hypokalemia resulting from a mineralocorticoid excess, which is not responsive to ECV expansion.[67–69] This cause of alkalosis is not generally responsive to saline

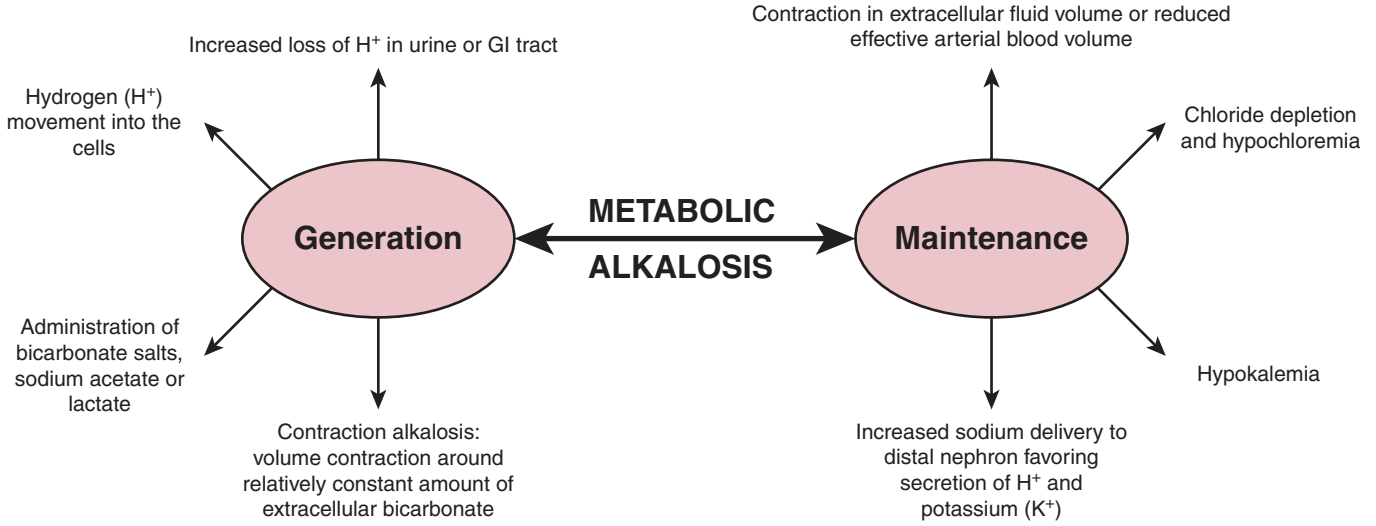

Fig. 15.3 Pathogenesis and Maintenance of Metabolic Alkalosis.

(saline-resistant), and treatment considerations include medications or surgical resection.

The most common factor maintaining metabolic alkalosis is a reduction in ECV, which leads to a reduction in GFR and a subsequent increase in sodium (Na^+), HCO_3^- reabsorption, and new bicarbonate generation.[70] Hypokalemia can both cause and maintain the presence of metabolic alkalosis. Mineralocorticoid excess is another factor that may trigger metabolic alkalosis, and, in those cases, hypokalemia is the factor that maintains the alkalosis.

Metabolic alkalosis associated with a reduction in volume responds well to repletion with normal (0.9%) saline and is known as *saline responsive.* However, mineralocorticoid or hypokalemia-induced alkalosis does not generally respond to volume administration and is said to be *saline-unresponsive.*

Symptoms of Metabolic Alkalosis

The symptoms of metabolic alkalosis vary according to the severity of the underlying acid-base abnormality. Presenting symptoms are often similar to those of hypocalcemia and may include mental confusion, decreased consciousness, seizures, muscle cramping, tetany, paresthesia, cardiac arrhythmias, and dyspnea. Common electrolyte abnormalities associated with alkalosis include hypokalemia and hypophosphatemia.[71]

Extracellular Fluid Volume Contraction, Hypokalemia, and Secondary Hyperaldosteronism

See Box 15.6.

Gastrointestinal Causes

GI hydrogen loss can result from the removal of gastric secretions (vomiting or nasogastric suction) or loss of intestinal secretions (congenital chloridorrhea, villous adenoma, laxative abuse). Loss of H^+ leading to metabolic alkalosis most commonly occurs through the GI tract by vomiting or nasogastric (NG) suction. Gastric fluid contains a high concentration of hydrochloric acid (HCl) and a lower concentration of potassium chloride (KCl). Each mEq of H^+ secreted generates 1 mEq of HCO_3^-, which is then absorbed into the plasma. Under normal physiologic conditions, the increase in plasma HCO_3^- concentration is only transient, as acid secretion into the duodenum stimulates an equal amount of pancreatic HCO_3^- secretion, which neutralizes the acid. However, if gastric fluid is removed by vomiting or NG suction, there is no stimulus for HCO_3^- secretion, because the HCl does not reach the duodenum. The net result is an increase in plasma HCO_3^- and subsequent metabolic alkalosis.

Under normal circumstances, any excess HCO_3^- generated would be excreted by the kidney in the urine, thereby correcting alkalosis.

Box 15.6 Causes of Metabolic Alkalosis

Exogenous HCO_3^- Loads
Acute alkali administration
Milk-alkali syndrome

Effective Extracellular Volume Contraction, Normotension, Hypokalemia, and Secondary Hyperreninemic Hyperaldosteronism
Gastrointestinal Origin
Vomiting
Gastric aspiration
Congenital chloridorrhea
Villous adenoma
Combined administration of sodium polystyrene sulfonate (Kayexalate and aluminum hydroxide)

Renal Origin
Diuretics (especially thiazides and loop diuretics)
Acute
Chronic
Edematous states
Posthypercapnic state
Hypercalcemia-hypoparathyroidism
Recovery from lactic acidosis or ketoacidosis
Nonreabsorbable anions such as penicillin, carbenicillin
Mg^{2+} deficiency
K^+ depletion
Bartter syndrome (loss-of-function mutation of Cl^- transport in thick ascending limb of loop of Henle)
Gitelman syndrome (loss-of-function mutation in Na^+/Cl^- cotransporter)
Carbohydrate refeeding after starvation

Other
Sweat loss in cystic fibrosis
Loss of fluid in third space

Extracellular Volume Expansion, Hypertension, K^+ Deficiency, and Hypermineralocorticoidism
Associated With High Renin
Renal artery stenosis
Accelerated hypertension
Renin-secreting tumor
Estrogen therapy

Associated With Low Renin
Primary aldosteronism
Adenoma
Hyperplasia
Carcinoma
Glucocorticoid suppressible

Adrenal Enzymatic Defects
11β-Hydroxylase deficiency
17α-Hydroxylase deficiency

Cushing Syndrome or Disease
Ectopic corticotropin
Adrenal carcinoma
Adrenal adenoma
Primary pituitary

Other
Licorice
Carbenoxolone
Chewing tobacco
Lydia Pinkham tablets

Gain-of-Function Mutation of Epithelial Sodium Channel (ENaC) With Extracellular Fluid Volume Expansion, Hypertension, K^+ Deficiency, and Hyporeninemic Hypoaldosteronism
Liddle syndrome

However, vomiting or NG suction also lowers the extracellular fluid compartment and effective circulating volume. The reduction in ECV leads to decreased GFR and less HCO_3^- filtered and also stimulates angiotensin and aldosterone production (secondary hyperaldosteronism), leading to increased Na^+ and HCO_3^- reabsorption by the proximal tubules.[72] Increased Na^+ reabsorption leads to increased HCO_3^- reabsorption because of the increase in H^+ secretion as Na^+ is exchanged for H^+ by the Na–H^+ transporter at the proximal tubule. Secreted H^+ ions combine with filtered HCO_3^-, causing reabsorption. Aldosterone primarily acts at the distal tubule to increase H^+ and K^+ secretion, resulting in greater acid and K^+ excretion. These processes lead to a hypokalemic metabolic alkalosis. Notably, the near-complete reabsorption of HCO_3^- in the setting of reduced ECV leads to the paradoxical finding of an acidic urine, despite the presence of extracellular alkalosis.

Renal Causes

See Box 15.6. Contraction alkalosis occurs when there is a relatively large loss of bodily fluid that does not contain HCO_3^-. In this setting, which is most commonly the result of diuretics, the ECV contracts around a fixed amount of HCO_3^-, resulting in a rise in HCO_3^- concentration.[73] Note that in this situation, total body bicarbonate remains the same despite the concentration change. Chronic diuretic use generates alkalosis by increasing salt delivery to the distal tubule, with resulting stimulation of H^+ and K^+ secretion. Loop and thiazide diuretics may effectively lower ECV without concomitant loss of HCO_3^-, resulting in a net increase in serum HCO_3^- and contraction alkalosis. Alkalosis is then maintained by one of several mechanisms, such as reduction of the ECV, hypokalemia, secondary hyperaldosteronism, or continued effect of the diuretic. Repletion of the extravascular fluid with 0.9% saline will typically improve the alkalosis in this setting.

Bartter syndrome is a disorder characterized by impaired Cl^- absorption, which then leads to salt wasting, volume contraction, and activation of the renin-angiotensin system. Five types of Bartter syndrome have been discovered, with four inherited in an autosomal recessive manner.[74] Bartter syndrome occurs more often in children, and the most common disorder results from a mutation of the gene encoding the bumetanide-sensitive $Na^+2Cl^-K^+$ cotransporter (*NKCC2* or *BSC1*) on the apical membrane; however, other mutations have been found involving different transporter channels. Elevated prostaglandin levels have been reported with this disorder, likely from volume contraction, hypokalemia, or high angiotensin II levels.[75] These defects lead to contraction of the ECV, hyperreninemic hyperaldosteronism, and increased Na^+ delivery to the distal nephron subsequent with K^+ wasting and alkalosis. The differential diagnosis of Bartter syndrome includes other causes of ECV contraction, such as emesis, diuretic use, or laxative abuse. Inhibition of the renin-angiotensin-aldosterone system or the prostaglandin-kinin system has been the goal of current treatment, with medications like spironolactone, prostaglandin inhibitors, propranolol, and ACE inhibitors, but the utility of such agents has been limited. K^+ and magnesium (Mg^+) repletion is also an important part of therapy.

Gitelman syndrome, like Bartter syndrome, is autosomal recessive and may manifest with hypokalemia, volume depletion with secondary hyperreninemic hyperaldosteronism, normotension, or even low blood pressure. Gitelman syndrome differs from Bartter syndrome in that it occurs more often in adulthood and is characterized by hypocalciuria, hypermagnesuria, and hypomagnesemia, similar to the effect of thiazide diuretics. Gitelman syndrome occurs as the result of missense mutations in the gene *SLC12A3,* responsible for encoding the thiazide-sensitive distal convoluted tubule Na^+/Cl^- cotransporter (NCCT).[74,76] Diminished activity of the Na^+/Cl^- cotransporter leads to calcium reabsorption and hypocalciuria. Reported symptoms include fatigue, cramping, nocturia, and salt craving. Treatment considerations include a sodium- and potassium-avid diet with magnesium supplementation. ACE inhibitors have also been advocated for this disorder.

Hypokalemia is a frequent finding in patients with metabolic alkalosis. It is an important contributor to both the development and maintenance of the alkalosis. The underlying causes of metabolic alkalosis (e.g., vomiting, mineralocorticoid excess, diuretic use) induce both H^+ and K^+ loss and thus cause hypokalemia. However, hypokalemia itself can be a primary cause of metabolic alkalosis. Hypokalemia causes metabolic alkalosis by several mechanisms. Initially, hypokalemia causes a transcellular shift, where K^+ leaves and H^+ enters cells, thereby increasing extracellular pH. Hypokalemia also causes a transcellular shift in proximal tubule cells, resulting in intracellular acidosis and ammonium (NH_4^+) production and excretion. Finally, H^+ secretion increases in the proximal and distal tubules with hypokalemia, leading to further HCO_3^- reabsorption. The net effect is an increase in acid excretion.

Magnesium deficiency promotes distal H^+ secretion and acidification of urine by stimulating renin and aldosterone secretion, which result in hypokalemic alkalosis.

Posthypercapnic alkalosis is frequently overlooked as a complication of mechanical ventilation. The normal physiologic response to respiratory acidosis is a compensatory increase in HCO_3^- reabsorption by the kidney, which increases plasma HCO_3^-. Use of mechanical ventilation for this disorder may rapidly lower the $PaCO_2$; however, plasma HCO_3^- will remain "inappropriately" elevated, resulting in development of metabolic alkalosis.[77] Additionally, spontaneous renal excretion of excess bicarbonate will be difficult if there is a concomitant presence of reduced GFR, chloride depletion, or reduced effective arterial blood volume (e.g., diuretic therapy) in critically ill patients. The duration of alkalosis in this setting, however, is unclear. Chronic respiratory acidosis is thought to be associated with urine Cl^- loss, leading to hypovolemia and hypochloremia. Repletion of Cl^- and restoration of volume (usually with 0.9% saline) typically corrects this disorder. In posthypercapnic alkalosis, the rapid fall in $PaCO_2$ may also lead to an acute increase in cerebral intracellular pH.[78,79] Complications including neurologic abnormalities and death have been reported with this effect, and as a result most experts have recommended a gradual reduction in $PaCO_2$ in patients with chronic hypercapnia.

Extracellular Volume Expansion and Mineralocorticoid Excess

The common causes of metabolic alkalosis maintain the alkalosis by hypovolemia-induced secondary hyperaldosteronism, which leads to increased acid excretion and hypokalemia. Disorders of mineralocorticoid excess, such as Conn syndrome, Cushing syndrome, and excess corticosteroid administration, produce a state of hyperaldosteronism, which also leads to hypokalemia and metabolic alkalosis (see Box 15.6).[80] In these disorders, the ECV increases, and hypertension may result. In these patients, metabolic alkalosis is perpetuated by the effects of hypokalemia, rather than hypovolemia, which leads to increased ammonium production, H^+ secretion, and HCO_3^- reabsorption.

Patients with secondary hyperaldosteronism from reduced arterial blood volume, as observed in conditions like congestive heart failure and cirrhosis, do not usually develop metabolic alkalosis unless treated with diuretics. In these patients, distal sodium delivery is reduced because of the expanded reabsorption of sodium in the proximal tubule. Without high distal sodium delivery, the effect of

aldosterone on sodium reabsorption and K^+ and H^+ excretion is diminished. High distal sodium delivery and elevated mineralocorticoid levels may occur together with primary mineralocorticoid secretory disorders or conditions like Liddle syndrome, which manifest as primary hyperaldosteronism.

Alkali Administration

In normal individuals and under most circumstances, chronic administration of sodium bicarbonate will only slightly alter the systemic pH because of the relatively rapid renal excretion of excess alkali and minimal rise in plasma bicarbonate levels. Alkalosis may occur, however, if large amounts of sodium bicarbonate or any substance metabolized to bicarbonate (like the sodium salts of citrate, acetate, or lactate) are administered more rapidly, such as in the use of sodium bicarbonate to treat lactic acidosis or administration of sodium citrate in the form of massive blood transfusions. Notably, other factors contributing to alkalosis, like hypovolemia, hypokalemia, or renal impairment, will often be present.

Citrate, the anticoagulant used in blood products, is being increasingly used as an anticoagulant for continuous renal replacement therapy (CRRT). Because 1 mmol of trisodium citrate is potentially metabolized to 3 mmol of sodium bicarbonate by the liver, metabolic alkalosis can occur from increased citrate. Metabolic alkalosis from citrate delivery in CRRT can be easily managed by decreasing the citrate infusion rate, increasing citrate and bicarbonate losses by increasing the dialysate/replacement fluid flow rate, or reducing the bicarbonate concentration in the dialysate/replacement fluid.[81]

Milk-alkali syndrome results from the ingestion of large quantities of calcium carbonate along with vitamin D and is characterized by hypercalcemia and metabolic alkalosis. Hypercalcemia causes impaired renal function through renal vasoconstriction, renal salt wasting, and volume depletion; the latter is exacerbated by vomiting. Hypovolemia and decreased renal function are responsible for maintaining systemic alkalosis. Alkalosis also increases renal reabsorption of calcium, thereby worsening hypercalcemia.

Diagnosis of Metabolic Alkalosis

When a diagnosis of metabolic alkalosis is established, the etiology can usually be determined from the patient's history. Otherwise, alkalosis is generally the result of one of three common causes: (1) emesis, (2) diuretic use, or (3) mineralocorticoid excess. Measurement of the urine chloride concentration usually helps differentiate among these conditions. When metabolic alkalosis is associated with a reduction in ECV, Na^+ and Cl^- reabsorption are enhanced to replenish ECV. In this setting, urinary Cl^- concentration should be very low, typically less than 25 mEq/L (Table 15.4 and Fig. 15.4).

Urinary Na^+ concentration is not a reliable measure of ECV status in the setting of metabolic alkalosis. If all of the filtered HCO_3^- cannot be reabsorbed, then some will be excreted with Na^+, and urinary Na^+ may be high. Thus the volume status may incorrectly appear to be euvolemic or hypervolemic.

If the urinary Cl^- is low, indicating a hypovolemic state, then 0.9% NaCl and water administration to replenish ECV should stop aldosterone production and lead to appropriate excretion of excess HCO_3^-, improvement of hypokalemia, and correction of metabolic alkalosis. These causes of metabolic alkalosis are considered saline-responsive.

Mineralocorticoid excess, by contrast, is associated with increased ECV and occasionally hypertension. Urinary Cl^- will be high, typically when higher than 40 mEq/L. Saline administration in such patients would further expand ECV and worsen hypertension. Alkalosis, which in this setting is primarily the result of hypokalemia, would not be corrected. These causes of metabolic alkalosis are considered saline-resistant.

TABLE 15.4 Diagnosis of Metabolic Alkalosis

Saline-Responsive Alkalosis	Saline-Unresponsive Alkalosis
Low Urinary [Cl^-]	High or Normal Urinary [Cl^-]
Normotensive	Hypertensive
Vomiting, nasogastric aspiration	Primary aldosteronism
Diuretics	Cushing syndrome
Posthypercapnia	Renal artery stenosis
Bicarbonate therapy of organic acidosis	Renal failure plus alkali therapy
K^+ deficiency	Normotensive
Hypertensive	Mg^{2+} deficiency
Liddle syndrome	Severe K^+ deficiency Bartter syndrome Gitelman syndrome Diuretics

The causes of saline-resistant metabolic alkalosis can be further distinguished according to whether hypertension is present. Hypertension tends to occur in mineralocorticoid excess states, whereas Bartter and Gitelman syndromes and exogenous alkali load are associated with normal blood pressure.

Treatment

The goals of the treatment of metabolic alkalosis are to reverse the cause of bicarbonate generation and address those factors that restrict secretion of excess bicarbonate from the kidneys. Diagnostic evaluation of metabolic alkalosis can be aided by measurement of the urine chloride concentration, systemic blood pressure, and estimated volume status of the patient. Other clinical findings that may assist with the evaluation include vomiting, NG suctioning, or alkali or diuretic use. Reversal of the underlying cause of alkalosis may include controlling emesis, addressing the removal of gastric secretions or lowering the gastric acid content removed, and discontinuing loop or thiazide diuretics. Medications that reduce gastric acid secretion, such as proton pump inhibitors or histamine-2 receptor blockers, have been administered to improve alkalosis in patients with persistent vomiting.[82,83] Any exogenous source of alkali, like bicarbonate, or substances that metabolize to bicarbonate (like citrate or lactate), should be discontinued if possible. Hypokalemia is common in metabolic alkalosis and should be corrected.

A reduction in renal excretion of excess bicarbonate is required to maintain metabolic alkalosis, so addressing factors that impair renal function and subsequent bicarbonate secretion will help correct alkalosis. Such conditions include reduced renal function, reduced arterial blood flow, K^+ depletion/hypokalemia, and Cl^- depletion/hypochloremia.

Treatment of metabolic alkalosis can be further divided on the basis of whether it responds to intravascular volume expansion. Patients with volume contraction as the cause of metabolic alkalosis are generally saline-responsive. On the other hand, patients with metabolic alkalosis because of mineralocorticoid excess, hypokalemia, or renal insufficiency are typically saline-resistant.

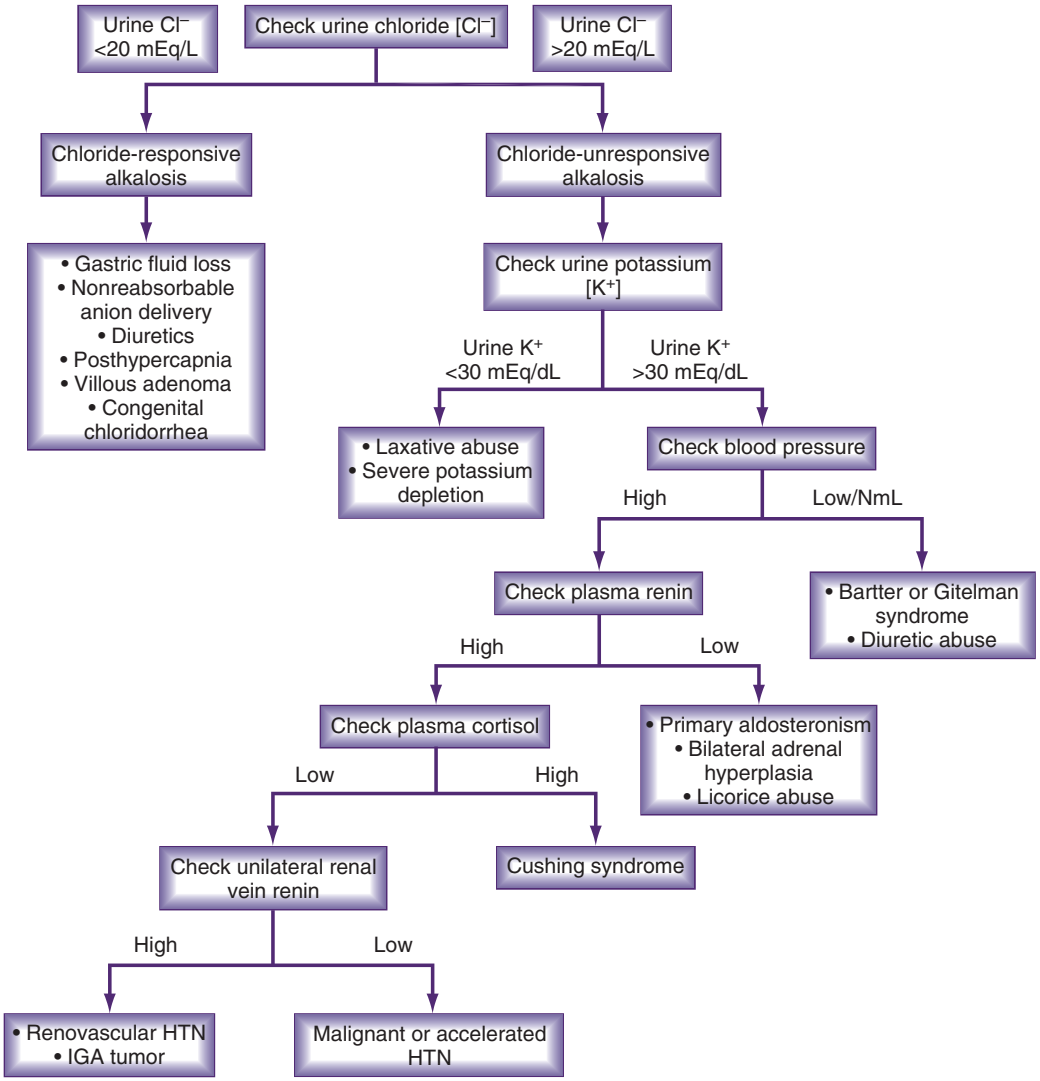

Fig. 15.4 Workup of metabolic alkalosis. (Data from DuBose TD Jr. Acid-base disorders. In Brenner BM, ed. *Brenner and Rector's The Kidney*. 8th ed. Philadelphia: Saunders; 2008:513.)

The treatment of metabolic alkalosis associated with volume contraction consists of volume expansion with 0.9% saline. Re-expansion of intravascular volume and correction of chloride deficiency lower proximal tubular bicarbonate reabsorption, enhance urine bicarbonate excretion, and lower plasma bicarbonate concentration. It is still a subject of ongoing debate whether the correction of metabolic alkalosis in response to saline infusion is from resolution of hypovolemia or secondary to repletion of the chloride deficit.[68]

Hypokalemia, if present, should be treated with potassium chloride. Metabolic alkalosis resulting from gastric acid loss, diuretics, and chloride depletion typically responds to 0.9% saline administration. Posthypercapnic metabolic alkalosis resulting from volume depletion also responds to 0.9% saline infusion.[79]

Saline-resistant metabolic alkalosis does not improve after administration of 0.9% saline. These patients are generally not volume depleted or chloride deficient, as shown by high concentrations of urinary chloride. In patients with excessive mineralocorticoid production, like in Conn syndrome, use of spironolactone to inhibit mineralocorticoid activity may be beneficial. Corticosteroid therapy may need to be discontinued, and ACE inhibitors may be helpful because of their potassium-sparing effect and control of hypertension. Surgical or chemical ablation of the adrenal glands may be necessary for definitive management.

Severe hypokalemia increases tubular H^+ excretion, ammonia production, and chloride wasting. Potassium repletion corrects this defect. As potassium wasting is a central finding in mineralocorticoid excess, Bartter syndrome, and Liddle syndrome, potassium-sparing diuretics like amiloride or triamterene are used in these patients.

Metabolic alkalosis may be observed in patients with edematous states, including heart failure, nephrotic syndrome, and cirrhosis. This often results from the use of diuretics; however, treatment with 0.9% saline is not usually helpful in these patients. Infusion of saline in this setting will increase fluid retention and edema and the alkalosis will not be corrected, as avid Na reabsorption will reduce excretion of any excess bicarbonate. These patients are often K^+ deficient, and potassium chloride administration may improve or correct the alkalosis by increasing the serum K^+ concentration. Use of potassium-sparing diuretics like amiloride and/or aldosterone antagonists like spironolactone for these patients may be indicated. Acetazolamide—a carbonic anhydrase inhibitor that inhibits proximal tubule sodium bicarbonate

reabsorption—can be administered in doses of 250–500 mg once or twice daily if additional diuresis is required in the volume-overloaded patient.[84]

Renal replacement therapy may be considered to correct metabolic alkalosis in situations where patients fail to respond to conventional therapies like volume expansion or K^+ repletion.[85] In such instances, dialysis with a lower bicarbonate bath concentration can quickly improve the alkalosis; however, even use of a standard bicarbonate bath concentration can be effective, as the patient's serum bicarbonate level is often higher than that of the standard bath concentration. CRRT can also be used to treat metabolic alkalosis, but attention to the CRRT fluid buffer composition is warranted because bases such as bicarbonate, citrate, or lactate may increase the serum bicarbonate concentration at high effluent/ultrafiltration rates.[86]

HCl for the treatment of metabolic alkalosis is usually reserved for patients with severe symptoms who do not respond to conventional therapy with IV fluids and for correction of electrolyte derangement. The arterial pH is usually higher than 7.55 and/or serum bicarbonate greater than 50 mEq/L, and there may be evidence of seizures, altered sensorium, or cardiovascular complications. Dilute HCl (0.1 *N*) should be given through a central IV catheter, and careful vigilance of catheter integrity and surrounding tissue should be maintained to avoid complications of acid extravasation, which may cause tissue necrosis.[87,88] Hemolysis can also complicate therapy with HCl. Titration of HCl can be challenging, and the goal of therapy is to lower the arterial pH to approximately 7.5, rather than to normalize the value. Alternatively, ammonium chloride (NH_4Cl), which is a precursor of HCl that is metabolized to urea and HCl, can be used in patients without severe renal insufficiency or liver failure.[89]

DIAGNOSIS OF ACID-BASE DISORDERS

A systematic approach is necessary for determining which acid-base disorder or disorders are present.[90] Accurate interpretation of acid-base balance requires simultaneous measurements of arterial pH and plasma electrolytes. The arterial blood gas (ABG) test directly measures arterial pH and $PaCO_2$. The bicarbonate concentration from the ABG test is calculated using the Henderson-Hasselbalch equation, and the bicarbonate concentration on venous chemistry panel is measured directly as "total CO_2" with an ion-selective electrode. The calculated value for HCO_3^- reported with the ABG test should be within 2 or 3 mEq/L of the measured HCO_3^- concentration obtained on the electrolyte panel. A discrepancy in the values suggests either the samples were not obtained simultaneously or that a laboratory error has occurred. The cause of acid-base disturbances is determined by examining the pH, PCO_2, and plasma electrolytes (primarily plasma bicarbonate) in the context of a given clinical situation. Analysis involves identification of the likely dominant acid-base disorder, followed by an assessment of the compensatory response. A stepwise approach to the diagnosis of acid-base disorders follows and is summarized in Box 15.7.[5,6]

The initial screening for an acid-base disorder entails obtaining a detailed history and performing a physical examination. The history and physical examination usually strongly suggest the acid-base disorder that is present. A history of diuretics or vomiting suggests metabolic alkalosis. A history of diarrhea, alcoholism, or diabetes suggests metabolic acidosis. Stigmata of liver disease on the physical examination may signify the presence of respiratory alkalosis, whereas findings of volume contraction suggest metabolic alkalosis. Kussmaul respiration is often associated with DKA and severe metabolic acidosis. Medications that can affect acid-base balance (e.g., laxatives, diuretics, topiramate, or metformin) should be considered in addition to signs of intoxication that may be associated with acid-base disturbances.

The first step in acid-base analysis is to determine whether the patient has acidemia or alkalemia by examining the arterial pH. If acidemia is present, then an acidosis must be present; similarly, if alkalemia is present, then alkalosis must be present. The second step is to determine whether the deviation in the pH (acidemia or alkalemia) is the result of a primary respiratory or metabolic derangement by examining the $PaCO_2$ and plasma bicarbonate concentration. In acidemia, a low plasma bicarbonate concentration denotes primary metabolic acidosis, whereas an elevated $PaCO_2$ points to primary respiratory acidosis. Likewise, in alkalemia, an elevated plasma bicarbonate concentration

Box 15.7 Stepwise Approach to Diagnosing Acid-Base Disorders

Initial Screening

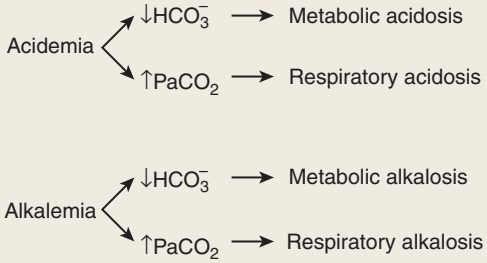
Consider the clinical setting by obtaining history and physical examination.

Obtain arterial blood gases (ABG) and electrolytes simultaneously.

Compare bicarbonate on ABG with venous electrolytes to ensure the calculated bicarbonate on ABG is within 2–3 mEq/L of measured bicarbonate on electrolyte panel.

Steps

1. Examine pH to determine if the patient has acidemia or alkalemia.
2. Look at PCO_2, HCO_3^- to determine if the primary process is metabolic or respiratory.



3. If a primary respiratory disorder is present in step 2, determine if it is acute or chronic.
4. Calculate the serum anion gap.
   a. Anion gap = $Na^+ - (Cl^- + HCO_3^-)$
5. If a metabolic disturbance is present from step 2 or high anion gap from step 4, determine if the respiratory system is adequately compensating.
   a. Expected $PaCO_2$ in acidosis: $PaCO_2 = (1.5 \times HCO_3^-) + 8 \pm 2$
   b. Expected $PaCO_2$ in alkalosis: $PaCO_2 = 40 + 0.7 \times (HCO_3^-{}_{meas.} - HCO_3^-{}_{normal}) \pm 5$
6. If anion gap is elevated, then calculate the Delta Delta Ratio (Δ/Δ) to assess for other simultaneous disorders.
   a. Δ/Δ compares the change in the anion gap with the change in bicarbonate.
   b. If ratio is between 1 and 2, then pure elevated anion gap acidosis is present.
   c. If <1, then a simultaneous normal anion gap acidosis is present.
   If >2, then a simultaneous metabolic alkalosis is present or a compensated chronic respiratory acidosis exists.

signifies primary metabolic alkalosis, whereas a low $PaCO_2$ is consistent with primary respiratory alkalosis. If a primary respiratory disturbance is present from step 2, the third step is to assess if it is acute or chronic by comparing pH and $PaCO_2$ by the formulas in Table 15.2.[6] If no primary respiratory disturbance is present, step 3 is skipped.

The fourth step is to calculate the serum AG. If primary metabolic acidosis is present from step 2, the serum AG is used to diagnose high AG metabolic acidosis. The AG should be adjusted for hypoalbuminemia. Even if metabolic acidosis is not present or the pH and $PaCO_2$ are within normal range, the serum AG should always be calculated because a **mixed acid-base** disorder can exist with a normal pH, $PaCO_2$, and plasma bicarbonate concentration, which is seen with high AG metabolic acidosis and concurrent metabolic alkalosis. If a high AG is present, ancillary tests to consider for differentiating the causes include plasma and urine ketones for ketoacidosis, plasma creatinine for renal failure, plasma L-lactate for lactic acidosis, plasma osmolality to calculate an osmolal gap and assess for toxic alcohol ingestion, and urine microscopy for crystals if ethylene glycol is suspected. If the primary metabolic acidosis is non-AG metabolic acidosis (plasma bicarbonate concentration is low without elevated AG), the UAG can help differentiate GI from renal causes.[91,92]

If a metabolic disturbance is present from step 2 or 4, the fifth step is to determine whether the respiratory system is adequately compensating. In metabolic acidosis, the Winters formula should be used to calculate the expected $PaCO_2$ for the degree of acidosis present. If the measured $PaCO_2$ is higher than the calculated expected $PaCO_2$, then concomitant respiratory acidosis is present. If the measured $PaCO_2$ is lower than the expected $PaCO_2$, then respiratory alkalosis is also present. In metabolic alkalosis, the normal respiratory response is less predictable. However, in general, the $PaCO_2$ should be between 40 and 50 mm Hg for appropriate compensation for metabolic alkalosis.[6]

If high AG metabolic acidosis is present from step 4, the last step is to determine the existence of any concurrent metabolic disturbances (such as non-AG metabolic acidosis or metabolic alkalosis) by comparing the degree of change in the serum AG with the change in the plasma bicarbonate level. This is done to assess the extent of contribution of the AG-producing process to the actual acidosis. This measurement is called Delta Delta Ratio[90]:

$$\text{Delta Delta Ratio} = \Delta AG/\Delta HCO_3^- = (AG - 12)/(24 - HCO_3^-)$$

If the metabolic disturbance is solely because of an elevated AG, the HCO_3^- should decrease by the same amount that the AG increases. A Delta Delta Ratio between 1 and 2 usually indicates uncomplicated high AG metabolic acidosis. A Delta Delta Ratio higher than 2 usually indicates a lesser fall in HCO_3^- than would be expected, given the change in the AG and the presence of concurrent metabolic alkalosis. An example of combined AG metabolic acidosis and metabolic alkalosis is volume contraction from vomiting in the setting of DKA. A Delta Delta Ratio less than 1 indicates a greater fall in HCO_3^- levels than would be expected, given the increase in the AG and therefore the presence of simultaneous non-AG metabolic acidosis. This might occur when lactic acidosis is superimposed on severe diarrhea. In this situation, the additional fall in HCO_3^- levels is the result of further buffering of an acid that does not contribute to the AG.[90]

Alternatively, an increase in anion gap can be interpreted as follows: A patient with an anion gap of 24 can be viewed as having 12 normal AG and 12 excess anions (A^-). With the assumption that the excess 12 A^- entered the body with 12 H^+ and that for every H^+, one HCO_3^- is consumed, then the expected $[HCO_3^-]$ will be 24 − 12 = 12 mEq/L. This is the expected $[HCO_3^-]$ based on the detected excess A^-. If the actual serum $[HCO_3^-]$ is equal to the expected $[HCO_3^-] \pm 2$ then there is no other acid-base disorder. If the actual serum $[HCO_3^-]$ is greater than expected $[HCO_3^-]$ then metabolic alkalosis is present. A non-AG metabolic acidosis indicating another process consuming $[HCO_3^-]$ is present if the actual serum $[HCO_3^-]$ is lesser than expected $[HCO_3^-]$.

SUMMARY

Acid-base disorders are common in the ICU and need to be anticipated in all critically ill patients. A clinician must be able to accurately monitor the acid-base status in order to promptly recognize derangements and implement appropriate interventions to prevent life-threatening complications as a result of the disturbance.

KEY POINTS

- Metabolic and mixed acid-base disorders are common in ICU patients and require early detection with a search for the underlying cause and initiation of appropriate treatment to prevent potentially fatal complications.
- Metabolic acidosis can be categorized as high or normal AG acidosis. High AG acidosis is frequently the result of lactic acidosis, ketoacidosis, toxic ingestions, or renal failure; non-AG acidosis is mostly the result of GI or renal bicarbonate loss. Diagnostic tests for differentiating causes of high AG acidosis include plasma and urine ketones, plasma creatinine, plasma L-lactate, plasma osmolality and osmolal gap, and urine microscopy for crystals. The urine AG can help differentiate causes of non-AG acidosis.
- The serum AG should always be calculated in the ICU because the presence of a significantly elevated serum AG represents metabolic acidosis, irrespective of pH or plasma bicarbonate. The serum AG must be adjusted for hypoalbuminemia.
- Compensation for primary metabolic acidosis is determined by the Winters formula. The Delta Delta gap is calculated to identify a concomitant metabolic disorder.
- Treatment for metabolic acidosis involves treating the underlying cause. Alkali therapy is often given for non-AG acidosis but is rarely indicated in high AG metabolic acidosis unless the arterial pH is less than 7.15 or for salicylate intoxication.
- Metabolic alkalosis may be initiated by acid loss or bicarbonate gain and maintained by renal mechanisms associated with bicarbonate resorption, including extracellular fluid volume contraction, chloride depletion, hypokalemia, and elevated mineralocorticoid activity.
- Metabolic alkalosis is most often caused by volume depletion with upper GI loss of hydrogen chloride (recurrent vomiting or NG suction) or by diuretic use with renal loss of H^+.
- The evaluation of metabolic alkalosis begins with measurement of the urine chloride and estimation of the ECV status. Metabolic alkalosis involving the loss or excess secretion of chloride is termed *chloride-responsive*.
- Compensation for primary metabolic alkalosis is estimated by the increase in $PaCO_2 = 0.75 \times \Delta\ HCO_3^-$.
- Treatment for metabolic alkalosis involves treating the underlying cause by administering IV 0.9% saline in chloride-responsive metabolic alkalosis and correcting mineralocorticoid excess and primary hyperaldosteronism in patients with a chloride-resistant metabolic alkalosis.

This review article defines euglycemic diabetic ketoacidosis, detailing common causes, diagnosis, and management. Interest in euglycemic DKA has risen

with the more widespread use of SGLT2 inhibitors for treatment of type 2 diabetes mellitus.

Cheungpasitporn W, Zand L, Dillon JJ, et al. Lactate clearance and metabolic aspects of continuous high-volume hemofiltration. *Clin Kidney J.* 2015;8(4):374–377.
This case report presents a patient with septic shock and lactic acidosis who was treated with high-dose CRRT with a hemofiltration rate of 7 L/h. The calculated clearance of lactic acid with CRRT was quite small compared with reported rates of lactic acid overproduction in septic shock. This suggests that elevated lactic acid alone is not a sufficient indication for CRRT.

Halperin ML, Hammeke M, Jose RG, et al. Metabolic acidosis in the alcoholic: a pathophysiologic approach. *Metabolism.* 1983;32:308.
Alcoholic ketoacidosis is underdiagnosed clinically. This disorder can not only result in life-threatening acidemia but also, as a result of malnutrition, cause life-threatening hypophosphatemia. This scholarly review explains the pathophysiology and provides a basis for appreciation of the clinical syndrome.

Luke RG, Galla JH. It is chloride depletion alkalosis, not contraction alkalosis. *J Am Soc Nephrol.* 2012;23:204–207.
This article discusses chloride depletion, which is the most common cause of metabolic alkalosis. It debates the underlying pathophysiology involved in chloride depletion alkalosis with evidence from human and rat nephron segment studies. The authors conclude that chloride administration without volume expansion is necessary and sufficient to correct chloride depletion alkalosis.

Mizock BA, Belyaev S, Mecher C. Unexplained metabolic acidosis in critically ill patients: the role of pyroglutamic acid. *Intensive Care Med.* 2004;30:502–505.
This paper identifies an important and recently realized cause of high AG acidosis in the critical care setting. This is an unsuspecting yet very common setting in which metabolic acidosis because of accumulation of this compound may develop; hence, this information is critical to the clinician when formulating diagnostic and therapeutic plans for high AG acidosis.

Seddik AA, Bashier A, Alhadari AK, et al. Challenges in management of diabetic ketoacidosis in hemodialysis patients, case presentation and review of literature. *Diabetes Metab Syndr.* 2019;13(4):2481–2487.
This review article seeks to define the nuances and challenges of managing diabetic ketoacidosis in anuric patients on hemodialysis. There are currently no guidelines for managing DKA in this population, but the authors make some recommendations in this regard.

Villar J, Short JH, Lighthall G. Lactate predicts both short- and long-term mortality in patients with and without sepsis. *Infect Dis.* 2019;12:1178633719862776.
This retrospective cohort study analyzed the association of serum lactic acid level with 3-day, 30-day, and 1-year mortality. Patients with a measured lactate level had increased mortality at 3 days, 30 days, and 1 year, even when lactic acid was within the normal range. There was a trend toward higher mortality with increasing lactic acid levels, and patients with sepsis had increased mortality irrespective of lactic acid level.

Hyperkalemia and Hypokalemia

Bryan T. Romito and Anahat Dhillon

Potassium (K^+) is the most abundant intracellular cation and is maintained within narrow physiologic limits.[1] Although reported values vary, the normal serum K^+ level in humans typically ranges from 3.5 to 5.0 mEq/L.[2] Alterations in electrolyte concentrations occur frequently in critically ill patients, likely the result of malnutrition, end-organ dysfunction, comorbid diseases, and polypharmacy. Early recognition and treatment of K^+ abnormalities are essential, as both hyperkalemia and hypokalemia are associated with an increased risk of mortality in intensive care unit (ICU) patients.[3,4]

OVERVIEW OF POTASSIUM HOMEOSTASIS

The kidney is the most important organ for regulating K^+ homeostasis. It maintains total body K^+ content by matching excretion with intake.[5] Hyperkalemia is rare in healthy individuals because of the kidneys' ability to readily filter K^+. With preserved renal function, most patients can consume up to 400 mEq per day or more of K^+ without developing clinically significant hyperkalemia.[1] More than 90% of the filtered K^+ is reabsorbed in the proximal tubule and ascending limb of the loop of Henle. This reabsorption is primarily mediated by changes in sodium concentration, activity of the sodium-potassium-chloride (Na^+-K^+-$2Cl^-$) cotransporter, and activity of the sodium/potassium–adenosine triphosphatase pump (Na^+-K^+-ATPase).[5]

The mineralocorticoid aldosterone plays an important role in renal K^+ handling. It increases intracellular K^+ concentration by stimulating the Na^+-K^+-ATPase in the basolateral membrane of proximal tubule cells. In the thick ascending limb, it promotes K^+ secretion by stimulating sodium reabsorption across the luminal membrane.[5] Overall, when hyperkalemia is present, aldosterone promotes renal K^+ secretion in order to normalize serum K^+ concentration. In addition to hyperkalemia, the release of aldosterone is stimulated by activation of the renin–angiotensin–aldosterone system (RAAS). Medications and disease states that interfere with the normal functioning of this pathway can significantly alter K^+ levels.

Approximately 2% of total body K^+ is in the extracellular fluid, and 98% of K^+ is in the intracellular compartment.[6] Because the changes in renal K^+ excretion described earlier can take hours to occur, the body has developed several physiologic mechanisms to quickly shift K^+ across cell membranes in order to prevent life-threatening deviations outside of the normal range. Under normal conditions, transcellular K^+ shifts are primarily affected by insulin, catecholamines, tonicity, and acid-base disorders.[5,6]

By increasing activity of the Na^+-K^+-ATPase, insulin decreases serum K^+ by shifting it intracellularly. Increased K^+ intake causes catecholamine secretion and beta-2-receptor stimulation. Like insulin, this sympathetic stimulation results in increased activity of the Na^+-K^+-ATPase and enhanced K^+ uptake into skeletal muscle cells.[6] Extracellular hypertonicity creates an osmotic gradient that promotes K^+ efflux out of cells, increasing serum levels. Nongap metabolic acidosis causes a K^+ shift into the extracellular compartment, likely mediated by the effects of acidosis on transporters that regulate skeletal muscle cell pH.[6] The changes in K^+ dynamics in response to high anion gap metabolic acidosis and respiratory acid-base disorders are minimal.

HYPERKALEMIA

Although no consistent definition exists, *hyperkalemia* is present when serum $K^+ > 5.0$ mEq/L. The severity of hyperkalemia can be further classified as mild ($K^+ = 5.1$–5.5 mEq/L), moderate ($K^+ = 5.6$–6.0 mEq/L), or severe ($K^+ > 6.0$ mEq/L).[7] Understanding the characteristics of the laboratory sampling site is important for ensuring an accurate diagnosis. Although serum, plasma, and whole blood are generally acceptable specimens for quantifying K^+ levels, the composition of the sample site will affect the reported concentration. For example, *pseudohyperkalemia* describes an in vitro process by which measured serum K^+ is elevated relative to plasma concentrations. This typically occurs in the setting of thrombocytosis as platelets release K^+ during the clotting process, and plasma samples are devoid of platelets.[8] In *reverse pseudohyperkalemia,* the in vitro concentration of plasma K^+ exceeds that of serum. This can occur in the setting of significant leukocytosis, with cell lysis causing a release of intracellular K^+. Both entities are preanalytical phenomena and do not represent clinically significant hyperkalemia.[8]

True hyperkalemia occurs as a result of increased extracellular K^+ or decreased K^+ excretion (Table 16.1). Major risk factors for hyperkalemia include renal failure, diabetes mellitus, and the use of medications that impair renal K^+ excretion.[9,10] Hyperkalemia rarely occurs in patients with normal kidney function, and both acute and chronic renal insufficiency decrease K^+ excretion. When the glomerular filtration rate (GFR) is <15 mL/min/1.73 m^2, even small increases in K^+ intake can cause severe hyperkalemia.[11] In patients with chronic kidney disease, the risk of hyperkalemia correlates strongly with estimated GFR (eGFR). The likelihood of developing hyperkalemia approximately doubles when eGFR <15 mL/min/1.73 m^2.[12] Patients with diabetes mellitus have a higher incidence of hyperkalemia than the general population. Contributing factors include insulin deficiency and reduced tubular secretion of K^+ because of hyporeninemic hypoaldosteronism.[13]

The administration of medications that impair the RAAS is a major risk factor for elevated serum K^+. Direct renin inhibitors, angiotensin-converting enzyme inhibitors (ACEIs), and angiotensin receptor blockers (ARBs) can all decrease renal K^+ excretion.[14,15] Beta-2-receptor blockers and nonsteroidal antiinflammatory drugs (NSAIDs) impair

TABLE 16.1 Causes of Abnormal Serum Potassium

HYPERKALEMIA	
Increased Extracellular Potassium	**Decreased Potassium Excretion**
Hypertonicity: hyperglycemia, sucrose, mannitol	Acute or chronic renal failure
Cell lysis: hemolysis, rhabdomyolysis, tumor lysis, tissue injury	Diabetes
Medications: succinylcholine, lysine, arginine, epsilon-aminocaproic acid, digoxin toxicity	Medications: beta-2-receptor blockers, NSAIDs, ACEIs, ARBs, direct renin inhibitors, potassium-sparing diuretics, ketoconazole, heparin, trimethoprim, pentamidine, calcineurin inhibitors
Hyperchloremic metabolic acidosis	Aldosterone deficiency or resistance
Hyperkalemic periodic paralysis	Type 4 renal tubular acidosis
HYPOKALEMIA	
Decreased Extracellular Potassium	**Increased Potassium Excretion**
Chronic decreased K^+ intake	Mineralocorticoid excess
Beta-2-receptor stimulation: catecholamines, stress	Bartter, Gitelman, and Liddle syndromes
Medications: insulin, toxicity from barium, thyroxine, risperidone, and quetiapine	Medications: loop diuretics, thiazide diuretics, glucocorticoids, penicillin derivatives, aminoglycosides, amphotericin B, cisplatin, tenofovir, foscarnet
Delirium tremens	GI losses: excessive diarrhea or vomiting
Hypokalemic periodic paralysis	Type 1 and type 2 renal tubular acidosis
	Magnesium deficiency

ACEI, Angiotensin-converting enzyme inhibitor; *ARB,* angiotensin receptor blocker; *GI,* gastrointestinal; *NSAID,* nonsteroidal antiinflammatory drug.

renin release.[9] Heparin and ketoconazole decrease aldosterone synthesis.[16,17] For most patients, RAAS blockade with only a single agent confers a low risk of hyperkalemia; however, the risk increases in the presence of other factors such as male sex, high baseline K^+, low eGFR, diabetes mellitus, heart failure, and coadministration of potassium-sparing diuretics.[9]

Pentamidine and trimethoprim can contribute to hyperkalemia by blocking the epithelial sodium channel (ENaC) in the distal nephron.[18] Compared with other antibiotics, trimethoprim administration is associated with an increased risk of acute kidney injury and hyperkalemia in patients aged 65 and over.[19] Calcineurin inhibitors cause downregulation of mineralocorticoid expression, leading to decreased mineralocorticoid function and aldosterone resistance.[18]

Hyperkalemia can develop as a result of transcellular K^+ dynamics, specifically the result of the release of intracellular K^+ or the prevention of extracellular-to-intracellular K^+ shifts. Given that K^+ is primarily located in the intracellular compartment, significant cell lysis from tissue injury, hemolysis, rhabdomyolysis, or tumor lysis can increase serum K^+ levels.[14] Succinylcholine is a depolarizing muscle relaxant that promotes K^+ efflux from skeletal muscle cells. The hyperkalemic response can be severe if given in the setting of burns, trauma, denervation, or prolonged immobility.[20] Administration of the positively charged amino acids L-lysine and L-arginine promote a transcellular shift of K^+ to the extracellular component to maintain electroneutrality.[21] Epsilon-aminocaproic acid is a lysine structural analogue and can produce hyperkalemia via a similar mechanism.[22] Familial hyperkalemic periodic paralysis is a rare autosomal dominant genetic disorder that results from a mutation in sodium channel function.[23]

Clinical Manifestations

Although some patients with hyperkalemia may present with paresthesias, diminished deep tendon reflexes, or weakness progressing to flaccid paralysis, most are asymptomatic. The most important effect of hyperkalemia is the impact on myocardial action potential.[14] Abnormalities in serum K^+ have electrophysiologic effects that can produce cardiac arrhythmias (Table 16.2). The electrocardiogram (ECG) abnormalities seen with hyperkalemia are often progressive and may follow a characteristic pattern. First the T wave becomes peaked, then the P wave broadens and decreases in amplitude, eventually disappearing.[24] Next the QRS complexes widen, producing a sine wave morphology as they merge with the T waves. As hyperkalemia progresses, the rhythm can degenerate into heart block, ventricular arrythmias, and asystole.[24] Although classically described, the correlation between the magnitude of K^+ elevation and ECG changes is poor. Severe hyperkalemia may present with minimal or atypical ECG findings.[14]

TABLE 16.2 Electrocardiogram Changes Caused by Abnormal Serum Potassium

Hyperkalemia	Hypokalemia
Peaked T waves	Flattened T waves
Broadening of P waves	U waves
Decrease in amplitude of P waves	ST segment depression
Loss of P waves	QT interval prolongation
Widening of QRS complexes (sine wave)	Ventricular arrhythmias
Heart block, ventricular arrhythmias, asystole	Asystole

Treatment

Treatment principles of hyperkalemia involve stabilizing the myocardial membrane, shifting K^+ to the intracellular compartment, and increasing K^+ excretion (Table 16.3). Although there is no consensus as to the level of hyperkalemia that requires intervention, it is recommended that patients with serum K^+ $\geq$6.0 mEq/L or those with ECG changes should be emergently treated.[10,14] Intravenous (IV) calcium salts (i.e., chloride and gluconate) are first-line treatment for hyperkalemia with ECG changes. Although they do not lower serum K^+, they stabilize the

TABLE 16.3 Treatment of Hyperkalemia

Treatment	Mechanism	Dose	Onset	Duration	Comments
Calcium	Stabilizes myocardial membrane	10 mL of 10% calcium chloride IV or 10-30 mL of 10% calcium gluconate IV	1–3 min	30–60 min	Dose can be repeated after 5 min if ECG changes persist
Sodium bicarbonate	Shifts K^+ into cells	50–100 mEq IV or 150 mEq IV over 3–4 h	Variable	Variable	Only effective with nongap metabolic acidosis; risk of fluid overload
Insulin	Shifts K^+ into cells	10 units IV regular insulin	15 min	4–6 h	Coadminister with 25 g of dextrose to prevent hypoglycemia
Albuterol	Shifts K^+ into cells	10 mg nebulized over 10 min	30 min	2–4 h	Risk of tachycardia
Loop diuretics	Increases renal K^+ excretion	40 mg IV furosemide or equivalent	Variable	Variable	Only administer to patients with symptomatic fluid overload
Sodium polystyrene sulfonate	Increases stool K^+ excretion	15 g 4× daily oral or 30 g 2× daily rectal	1–2 h	>4 h	Avoid in ileus or bowel obstruction; risk of intestinal necrosis
Dialysis	Removes K^+	Hemodialysis preferred over peritoneal in acute setting	Variable	Variable	Conventional hemodialysis causes most rapid fall in serum K^+

ECG, Electrocardiogram; *IV,* intravenous.

myocardial membrane and normalize ECG abnormalities. Insulin and beta-2-receptor agonists such as albuterol shift K^+ into cells, rapidly lowering serum levels. Both are effective when used as monotherapy; however, a synergistic effect occurs when they are coadministered.[25] Although efficacy data are mixed and standard dosing has not been established, sodium bicarbonate should be considered in hyperkalemic patients with a severe (pH <7.2) nongap metabolic acidosis.[14,25] Loop diuretics and cation exchange resins like sodium polystyrene sulfonate (Kayexalate) can increase K^+ excretion; however, their routine use is limited because of narrow efficacy windows, safety concerns, and delayed onset times.[26,27] Sodium zirconium cyclosilicate (ZS-9) and patiromer represent the newest generation of potassium-binding agents. Although they have been shown to be effective in treating hyperkalemia in the outpatient environment, there are limited data in the acute care setting.[27] Dialysis represents definitive treatment for hyperkalemia, but is usually reserved for cases refractory to medical management.

HYPOKALEMIA

Hypokalemia is present when serum K^+ <3.5 mEq/L.[28] Common causes of hypokalemia in critically ill patients include decreased extracellular K^+ and increased K^+ excretion. Both excessive diarrhea and vomiting can lead to hypokalemia. Large-volume emesis does not directly lower serum K^+ from gastric fluid losses; however, the reduction in hydrogen ions induces an extrarenal metabolic alkalosis that stimulates urinary K^+ wasting.[6] Although prolonged dietary restriction of K^+ can cause hypokalemia, it is more likely to exacerbate hypokalemia from other causes. Hypokalemic periodic paralysis, insulin, and beta-2-receptor stimulation from medications or stress shift K^+ into the intracellular compartment and lower serum K^+.[6,16,28] Toxicity from thyroxine, barium, risperidone, and quetiapine have all been associated with the development of hypokalemia.[16] The effect of alkalosis on lowering serum K^+ by transcellular shift is minimal.[6] There is a high prevalence of hypokalemia from increased renal K^+ excretion in patients taking loop and thiazide diuretics. Excessive mineralocorticoid activity from medications, adrenal disease, or tumor secretion will promote excessive renal K^+ losses.[28] Concomitant magnesium deficiency will exacerbate renal K^+ wasting and hypokalemia, potentially by downregulation of the sodium-chloride (Na^+-Cl^-) cotransporter in the distal tubule.[29] Other causes of hypokalemia from excessive renal losses include specific antimicrobials; antivirals; cytotoxic agents; Bartter, Liddle, and Gitelman syndromes; and some types of renal tubular acidosis (see Table 16-1).

Clinical Manifestations

Although as many as 20% of hospitalized patients develop hypokalemia, only 5% of these patients present with symptoms.[28] Common manifestations include muscle pain, cramping, and weakness of both smooth and skeletal muscle.[30] Hypokalemia is associated with an increased risk of arrhythmogenicity and potentiates the proarrhythmic effects of class III antiarrhythmics in patients with heart failure.[24] Like hyperkalemia, hypokalemia produces characteristic ECG changes (see Table 16.2). Common abnormalities include flattened T waves, prominent U waves, ST segment depression, and QT interval prolongation. Severe hypokalemia can produce malignant ventricular arrhythmias and cardiac arrest.[24,30]

Treatment

Appropriate management of hypokalemia involves treatment of underlying causes, discontinuation of offending agents, prevention of life-threatening arrhythmias, and repletion of total body K^+ stores. Every 1 mEq/L reduction in serum K^+ represents a total body deficit of 200–400 mEq.[28] In asymptomatic patients with mild to moderate hypokalemia, oral replacement with potassium chloride is recommended. Potassium bicarbonate is preferred in patients with a metabolic acidosis, and potassium phosphate is recommended in patients with hypophosphatemia.[31] Enterally administered K^+ is as effective as IV for increasing plasma concentration, and it minimizes the risk of rebound hyperkalemia.[32,33] IV repletion is recommended for patients with severe hypokalemia, those with ECG changes, or those unable to tolerate oral administration. IV correction using a peripheral route should not exceed 20 mEq/h because of the risk of phlebitis.[31] The use of infusion pumps and continuous cardiac monitoring are recommended, as inadvertent bolus administration can cause cardiac arrest. Combining IV and oral administration will result in the fastest correction of hypokalemia.[34] Treatment of coexisting hypomagnesemia is necessary to raise serum K^+ levels.[29] The use of computerized repletion protocols minimizes K^+ variability and time spent outside the physiologic range.[35]

KEY POINTS

- Hyperkalemia and hypokalemia have been associated with increased mortality in critically ill patients.
- Although classic ECG abnormalities are commonly described, severe hyperkalemia may present with minimal or atypical ECG findings.
- A synergistic hypokalemic response occurs when albuterol and insulin are coadministered.
- Severe hypokalemia can produce ventricular arrhythmias or cardiac arrest.
- IV K^+ repletion should be reserved for patients with severe hypokalemia, those with ECG changes, or those unable to tolerate oral administration.

Hyperphosphatemia and Hypophosphatemia

Marcus Ewert Broman

INTRODUCTION

Disturbances in the phosphate balance are common in critically ill patients, but are not always easy to relate to specific symptoms. Dysphosphatemia, however, may cause a significant increase in multiorgan failure. In a Swedish critical care cohort, more than half of the patients showed at least one serum phosphate concentration value outside the normal range (Fig. 17.1).[1] Serum phosphate levels should be measured repeatedly and at least once daily in the intensive care unit (ICU). Hypophosphatemia is multifactorial and independently associated with increased mortality, whereas hyperphosphatemia most often is secondary to renal failure. This chapter presents the etiologies, classifications of severity, clinical manifestations, and treatments of hypophosphatemia and hyperphosphatemia.

PHOSPHATE HOMEOSTASIS

Most phosphorus in the human body is complexed with oxygen as phosphate, which is a major intracellular anion. Approximately 85% of the total phosphorus amount (600 g = 20 mol) is contained in bone, where it is a constituent of crystalline hydroxyapatite. The rest (15%) is found in soft tissues, mostly intracellularly as a component of organic compounds, such as nucleic acids, cell membrane phospholipids, adenosine triphosphate, red blood cell 2,3-diphosphoglycerate, and phosphoproteins.

The normal serum phosphate concentration in adults ranges from 0.81 to 1.45 mmol/L (2.5–4.5 mg/dL). Phosphate concentration is 30% higher in children and 50% higher in infants, possibly because of an important role in growth. There is a circadian variation that is dependent on dietary intake in healthy subjects.

Serum laboratory analyses measure the free inorganic phosphate ions $H_2PO_4^-$ and HPO_4^{2-}—their ratio is pH dependent; at 7.4, the ratio is 1:4. Serum phosphate levels do not reflect total body phosphorus content. There is no common method in use to measure total body phosphorus stores. Only 55 % of the phosphate in serum is free, whereas 35% is complexed with sodium, calcium, and magnesium and 10% is bound to albumin.

The serum phosphate level may be low, although the total body phosphorus amount is normal, because of a shift into intracellular compartments or a negative intake/excretion balance. On the contrary, a total body phosphorus depletion can prevail in parallel to normal or high serum phosphate levels. Prolonged starvation and acidemia in ketoacidosis are clinical examples of situations that may deplete total body phosphorus amount.

Phosphate homeostasis relies on a complex interplay between the gastrointestinal, renal, parathyroid, and skeletal axis.

Under low serum calcium levels but also low phosphate levels, parathyroid hormone (PTH) is secreted and acts on the kidneys by enhancing hydroxylation of vitamin D to its active form, 1,25-dihydroxy vitamin D_3, which in turn augments both phosphate and calcium intestinal absorption.

Phosphate is freely filtered in the glomeruli, and up to ~90% is reabsorbed in the proximal tubules. PTH acts by reducing this tubular absorption.

A PTH release will result in a net drop in serum phosphate level. However, during steady state, the kidneys regulate phosphate homeostasis by matching urinary excretion with intake.

Tubular malfunction—for instance, because of rare genetic disorders—can lead to heavy phosphate urinary waste. The kidneys have a large capacity to excrete phosphate and thereby have a protective function against an ongoing phosphate load from nutritional intake and from metabolism.

Phosphatonins are regulatory peptides produced by osteoblasts and osteocytes in bone and secreted into the systemic circulation, where they decrease the renal tubular phosphate reabsorption, and thus increase the urinary phosphate excretion. Phosphatonins also participate in regulation of bone mineralisation. During baseline homeostasis about 200 mg of phosphate move in and out of the skeleton daily. Fibroblast growth factor-23 (FGF-23) is considered to be the key phosphatonin.[1–5]

HYPOPHOSPHATEMIA

Hypophosphatemia can be classified as moderate 0.4–0.81 mmol/L (1.25–2.5 mg/dL) or severe <0.4 mmol/L (<1.25 mg/dL).

The symptoms of hypophosphatemia are primarily a consequence of a declining 2,3-diphosphoglycerate level in erythrocytes, which increases the affinity of hemoglobin for oxygen and thereby reducing oxygen release in peripheral tissues. This in turn leads to decreased adenosine triphosphate levels in cells, slowing down all energy-dependent intracellular functions.

Critically ill patients with diabetic ketoacidosis and sepsis have a high incidence of hypophosphatemia. In particular, patients who have had cardiac surgery and major hepatic procedures tend to develop hypophosphatemia within the first week. Certain therapies instituted in the ICU, like establishing an aggressive diuresis, renal replacement therapy, and erythropoietin therapy, increase the risk of hypophosphatemia. Modern dialysis fluids contain phosphate, counteracting too high clearance. Frequently, patients present with initial hyperphosphatemia secondary to an acute kidney injury, which rapidly may turn into hypophosphatemia after renal replacement therapy has been initiated.

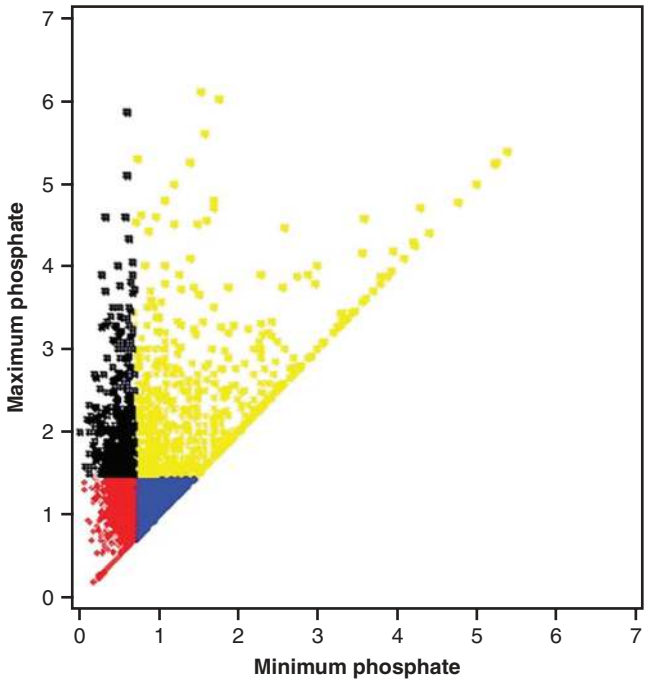

Fig. 17.1 Presentation of a large Swedish cohort consisting of 4656 patients with 19,467 phosphate measurements. Each *dot* in the plot represents the phosphate interval (defined by the lowest [x-axis] and the highest [y-axis] phosphate value) for one patient. Fifty-seven percent of the dots (*yellow,* hyper; *red,* hypo; and *black,* both hypo and hyper) are intervals with at least one value outside the normal range *(blue).* A phosphate deviation is a consequence of the critical illness itself, but also an independent parameter increasing the morbidity. The mean for all values was 1.18 mmol/L, with a standard deviation of ±0.52 mmol/L. (Modified from Broman M, Wilsson A, Hansson F, et al. Analysis of hypo- and hyperphosphatemia in an intensive care unit cohort. *Anesth Analg.* 2017;124:1897–1905.)

The phosphate homeostasis is dependent on an ongoing intestinal supply, and states with failing intestinal absorption or even losses, such as malnutrition, vomiting, diarrhea, and nasogastric suctioning, will cause hypophosphatemia (Box 17.1).

Hyperparathyroidism and proximal renal tubular disorders may impair phosphate resorption and cause hypophosphatemia. Rare genetic or acquired Fanconi syndrome results in renal tubular dysfunction and phosphaturia and subsequent hypophosphatemia.

In a fasting state the body first adapts by glycogenolysis of the liver stores, which will be depleted within 24 hours. Thereafter, insulin secretion decreases and a shift from glycogen to protein and fat catabolism takes place. Reintroduction of nutrition, especially a high-carbohydrate load, will increase insulin levels and reactivate anabolic pathways. A refeeding syndrome may follow from a combination of low phosphate supply with a sudden high anabolic demand, including an intracellular phosphate shift caused by insulin, resulting in low serum phosphate level. Identifying high-risk patients before initiating feeding and gradually increasing nutritional intake in combination with close monitoring of electrolytes and establishing timely repletion is mandatory to avoid this problem. Refeeding syndrome may appear with low levels of other electrolytes as well.

Total body phosphorus stores will be depleted in patients with ketoacidosis resulting from acidemia, which promotes phosphate shift from the cells to plasma and renal losses because of osmotic diuresis. Once insulin therapy is initiated and the acidemia is corrected, phosphate is reshifted from the serum back into the cells, resulting in severe hypophosphatemia.

Total body phosphorus depletion can also follow extreme catabolic states such as trauma, burns, and sepsis.

In hyperventilation, lowered carbon dioxide and respiratory alkalosis cause incorporation of phosphate into organic intermediates and a reduction in intracellular phosphate and a shift of phosphate from the extracellular compartment. Severe liver disease, sepsis, and salicylate intoxication can all induce hyperventilation and result in hypophosphatemia.

The severity of symptoms increases with more profound and longer-lasting hypophosphatemia.

Although moderate hypophosphatemia is often subclinical, it can be associated with significant morbidity.

Neurologic symptoms can be irritability, delirium, paresthesia, generalized seizures, and finally coma. Decreasing phosphate levels have been shown to decrease myocardial contractility and to predispose for ventricular rhythm disturbances, especially in conjunction with acute myocardial infarction. Several studies have indicated that ventilator dependence is prolonged in hypophosphatemic states and that weaning from the ventilator is more difficult. Reduced diaphragmatic strength, dysphagia, myopathy, and development of rhabdomyolysis have been reported in hypophosphatemia. Hematologic manifestations include hemolysis, thrombocytopenia, and affected phagocytosis and chemotaxis of leukocytes (Box 17.2).

In moderate or severe hypophosphatemia, 20–60 mmol phosphate (in some instances even more) can be administered intravenously over 24 hours. In addition, boluses of 20 mmol can be administered

BOX 17.1 Main Causes of Hypophosphatemia

Insufficient Intestinal Absorption
- Malnutrition
- Nasogastric suctioning
- Diarrhea
- Vomiting
- Vitamin D deficiency

Renal Excretion
- Diuretics
- Volume expansion
- Osmotic diuresis
- Primary or secondary parahyperthyroidism
- Renal tubular dysfunction
- Fanconi syndrome

Transcellular Shift
- Refeeding syndrome
- Ketoacidosis
- Insulin effect

Catabolic State
- Widely spread burns
- Multitrauma
- Sepsis

BOX 17.2 Principal Manifestations of Hypophosphatemia

Respiratory
- Worsened respiratory failure
- Dependence on ventilator

Cardiovascular
- Impaired myocardial contractility
- Cardiac rhythm disturbances

Muscular
- Muscular weakness
- Rhabdomyolysis

Neurologic
- Irritability
- Altered mental status
- Seizures

Hematologic
- Hemolysis
- Thrombocytopenia
- Affected phagocytosis and chemotaxis

BOX 17.3 Treatment of Hypophosphatemia

- Possible losses should be identified and stopped.
- Urgent correction should take place by infusing 20 mmol phosphate over 2–4 hours.
- The patient might also need a background administration of 20–60 mmol/24 hours, and in some instances even more.
- The phosphate concentration profile of the patient should be monitored with regular measurements, and the results should guide the correction.
- Phosphate content in ongoing intravenous infusions and in nutrition should be taken into account, and overcorrection should be avoided.
- If the hypophosphatemia turns out to be persistent or recurs, an evaluation of possible underlying mechanisms should take place.

over 2–4 hours (Box 17.3). Severe hypophosphatemia should be considered an emergency and corrected instantly under close surveillance and follow-up. Also, if the hypophosphatemic state is persistent or recurring, a careful evaluation of possible underlying mechanisms is mandatory.

A patient may have a disturbed phosphate regulation and be vulnerable to dysphosphatemia in both hypo- and hyper-directions. Frequent and individually well-reasoned phosphate level corrections should take place, keeping in mind that hyperphosphatemia from overcorrection might be a risk and difficult to manage in a renal failure setting.

Adverse effects of intravenous phosphate repletion are metastatic calcification, hypocalcemia, hyperkalemia associated with potassium-containing supplements, volume excess, hypernatremia associated with sodium-containing supplements, metabolic acidosis, and hyperphosphatemia. Therefore hypophosphatemia should be corrected gradually in most instances.

HYPERPHOSPHATEMIA

Hyperphosphatemia is defined as a serum phosphate level >1.45 mmol/L (>4.5 mg/dL).

Hyperphosphatemia will occur when phosphate entry into the extracellular fluid exceeds its excretion rate. There may be an endogenous or exogenous load or a shift from the intracellular compartment because of a disturbed homeostasis governing the phosphate turnover.

Patients with hyperphosphatemia are generally asymptomatic in a critical care setting, and the hyperphosphatemic state will in most cases be secondary to renal failure or to other severe multiorgan failure (Box 17.4).

Symptoms may arise from simultaneous hypocalcemia and can be life-threatening in their most severe forms. Hypotension, decreased myocardial performance, ventricular rhythm disturbances, increased vulnerability to seizures, and tetany have been described and are potentially fatal. Less severe symptoms comprise muscle cramps, perioral numbness, or tingling. Yet other symptoms may be bone and joint pain, pruritus, and rash. There can also be symptoms related to the underlying cause of hyperphosphatemia: for instance, uremic symptoms such as fatigue, shortness of breath, anorexia, nausea, vomiting, and sleep disturbances (Box 17.5).[13–17]

Diminished phosphate excretion may be caused by decreased renal excretion because of renal failure. There is a constant phosphate intake from nutrition and a phosphate burden from the metabolism. The kidneys have normally a very high capacity to excrete phosphate, and therefore the body is well protected against hyperphosphatemia. Urinary phosphate output cannot, however, match the intake anymore when glomerular filtration rate falls below ~20 mL/min/1.73 m^2.

Examples of endogenous loads are muscle breakdown in rhabdomyolysis, tumor lysis, and marked hemolysis.

BOX 17.4 Main Causes of Hyperphosphatemia

Renal
- Renal insufficiency
- Hypoparathyroidism

Cellular
- Rhabdomyolysis
- Tumor lysis

Medication Related or Iatrogenic
- Too large an ingestion
- Overcorrection with intravenous administration
- Laxatives
- Vitamin D intoxication
- Bisphosphonates
- Liposomal amphotericin B

BOX 17.5 Principal Manifestations of Hyperphosphatemia

Light Symptoms
- Can be hard to identify in a critical care setting; muscle cramps, pruritus

Severe Symptoms
- Come from simultaneous hypocalcemia; hypotension, ventricular arrhythmias, seizures

Examples of exogenous loads include ingestion of phosphate-rich compounds such as laxatives or intravenous overadministration of phosphate—for instance, too strenuous a correction of a hypophosphatemic state.

It has been shown that some critically ill patients have a tendency to vary in their phosphate concentration profile, with both hypophosphatemia and hyperphosphatemia, because of disturbed phosphate regulation during their stay in the critical care unit and are therefore prone to overcorrection. A stable phosphate concentration within the normal range should always be the goal.[1]

Other iatrogenic causes include bisphosphonate therapy in a setting of an existing renal insufficiency, use of liposomal amphotericin B in invasive fungal infections, and vitamin D toxicity.

Pathologies in the intestinal, renal, parathyroid, and bone systems may also lead to shifts that result in hyperphosphatemia.

Kidney injury over time disturbs adaptive bone mineralization processes by affecting hormonal and metabolic mechanisms. Bone hosts most of the body phosphorus as a reservoir, and bone resorption will result in increased phosphate shift to plasma and thus to hyperphosphatemia. This is defined as renal osteodystrophy.

Pseudohypoparathyroidism (renal resistance to PTH) results in increased renal phosphate reabsorption and leads to hyperphosphatemia and because of reflectory mechanisms to hypocalcemia.[18–21]

Managing hyperphosphatemia includes detecting and limiting the intake and enhancing urinary excretion. In the absence of severe renal failure or other conditions where administration of fluid is not tolerated, phosphate excretion can be optimized with saline infusion and diuretic administration enhancing a volume diuresis. Any patient with escalating, persistent, or treatment-resistant hyperphosphatemia should be considered for dialysis (Box 17.6). Oral phosphate binders do not have a role in acute dysphosphatemias in the critical care setting.

BOX 17.6 Treatment of Hyperphosphatemia

- Stop intake of phosphate
- Identify and eliminate iatrogenic causes
- Forced diuresis with saline infusion and diuretics
- Establishment of dialysis

KEY POINTS

- Phosphate has crucial functions in cell oxygen delivery, enzymatic processes, energy metabolism, and bone integrity.
- The phosphate concentration profile should be monitored and kept within the normal range 0.81–1.45 mmol/L (2.5–4.5 mg/dL).
- A moderate dysphosphatemia should be corrected without delay, and a severe dysphosphatemia should be considered an emergency.
- Hypophosphatemia is often multifactorial and may be transient without obvious symptoms and require only temporary phosphate substitution. However, should it persist, a careful evaluation of the underlying causes is compulsory for a successful resolution. Hypophosphatemia can cause significant worsening of multiorgan failure sequelae.
- Hyperphosphatemia is mostly a result of renal failure and of a multiorgan failure condition. Hyperphosphatemia in the absence of renal insufficiency is rare, because the kidney normally has a large capacity for excreting phosphate. Severe hyperphosphatemia can itself be life-threatening, and the only definitive treatment will be dialysis.

Hypomagnesemia

Vadim Gudzenko

Magnesium is an important ion that participates as a cofactor in over 300 enzymatic reactions, especially in those involving adenosine triphosphate (ATP). Hypomagnesemia is common in critically ill patients and is associated with increased mortality.[1,2]

CELLULAR PHYSIOLOGY AND METABOLISM OF MAGNESIUM

Magnesium is a divalent cation (Mg^{++}) that is predominantly localized to the intracellular compartment (99%). It is the second most abundant intracellular cation after potassium and plays an important role in cellular metabolism and homeostasis. At the cellular level, Mg^{++} influences membrane function by regulating ion transport; Mg^{++} is required for sodium/potassium–adenosine triphosphatase (Na^+/K^+-ATPase) activity, which maintains transmembrane gradients for Na^+ and K^+.[3,4] Mg^{++} also regulates intracellular calcium (Ca^{++}) flux by competing for Ca^{++} binding sites and influencing intracellular Ca^{++} transport.[3,4] It is also an essential cofactor for most ATP-requiring processes. Intracellular Mg^{++} is required for numerous critical biochemical processes, including DNA synthesis, activation of gene transcription, initiation of protein synthesis, and regulation of energy metabolism.[3,4]

Total body magnesium (21–28 g) is distributed in bone (53%), muscle (27%), soft tissue (19%), and blood (0.8%).[3] The normal concentration of total magnesium in serum is 1.5–2.3 mg/dL. Approximately 19% of circulating magnesium is bound to proteins, whereas 14% is complexed to plasma anions (citrate, phosphate, and bicarbonate). The majority of magnesium in plasma exists in its ionized form (67%), which represents the physiologically active species.[3] Consequently, the measurements of total serum magnesium may not accurately reflect the relative abundance of circulating Mg^{++}.[3,5]

Magnesium homeostasis is maintained by the small intestine, kidney, and bone.[3,6] Unlike calcium, there are no hormonal mechanisms for regulating Mg^{++}. Mg^{++} reabsorption in the loop of Henle is linked to sodium chloride (NaCl) transport and is inversely related to flow. Consequently, diuretic use and other conditions associated with increased tubular flow result in decreased Mg^{++} reabsorption.[3,6]

PREVALENCE AND ETIOLOGY OF HYPOMAGNESEMIA IN PATIENTS IN THE INTENSIVE CARE UNIT

The reported prevalence of hypomagnesemia in adult intensive care unit (ICU) admissions ranges from 15% to 60% of cases.[3,5] Most commonly, severe ionized hypomagnesemia in ICU settings is encountered after liver transplantation and in patients with severe sepsis,[5] but many conditions encountered in ICU patients can be associated with hypomagnesemia (Table 18.1). Hypomagnesemia is associated with an increased risk of mortality.[5]

CLINICAL SIGNS AND SYMPTOMS OF HYPOMAGNESEMIA

Hypomagnesemia is frequently asymptomatic in critically ill patients and is commonly identified through routine laboratory studies.[6,7] However, the relationship between hypomagnesemia and intracellular magnesium depletion is complex. Hypomagnesemia is most commonly seen in conjunction with hypokalemia, hypocalcemia, and/or other electrolyte abnormalities. In most instances, symptoms were attributed to Mg^{++} deficiency only after other electrolyte abnormalities had been corrected.[3,6,7] As summarized in Table 18.2, the clinical sequelae of Mg^{++} deficiency are most commonly related to the cardiovascular, metabolic, and neuromuscular systems.

Hypomagnesemia is associated with electrocardiogram (ECG) changes similar to those observed in patients with hypokalemia: flattened T waves, U waves, and a prolonged QT interval. Magnesium is a cofactor for Na^+/K^+-ATPase in cardiac tissue.[3,6,8] Hypomagnesemia is associated with a variety of dysrhythmias, including atrial fibrillation, multifocal atrial tachycardia, ventricular tachycardia, and torsades de pointes.[6,8] The administration of intravenous magnesium sulfate ($MgSO_4$) should be the initial therapy for torsades de pointes and should be considered as an adjunctive treatment for refractory ventricular dysrhythmias.[3,6,8] However, routine use of magnesium supplementation for the treatment of arrhythmia with the exception of torsades de pointes is not supported by high-quality evidence.[1] Magnesium administration during acute myocardial infarction is not recommended.[9–11]

Hypomagnesemia is commonly associated with both hypokalemia and hypocalcemia.[6] The medications and homeostatic changes that affect magnesium handling often affect K^+ handling as well. In addition, hypomagnesemia promotes the renal losses of K^+. Thus hypokalemia can be refractory to potassium supplementation unless magnesium is replaced first.[3,6] A somewhat similar condition is noted for hypocalcemia because hypomagnesemia suppresses parathyroid hormone release and activity.[12] Consequently, hypocalcemia can be refractory to Ca^{++} replacement unless Mg^{++} is replaced as well.[3,6] Hypomagnesemia has been shown to be associated with an increased incidence and degree of lactic acidosis.[13]

Magnesium produces a depressant effect on the nervous system through its ability to cause presynaptic inhibition.[3,6,8] It may also depress the seizure threshold by its ability to competitively inhibit *N*-methyl-D-aspartate receptors.[3,6,8] The neurologic and neuromuscular manifestations of hypomagnesemia include coma, seizures, weakness, and signs of muscular irritability. The supplementation of magnesium might provide neuroprotective properties in patients with traumatic brain injury and prevent cerebral vasospasm in patients with aneurysmal subarachnoid hemorrhage.[14,15] However, prehospital administration of magnesium for

TABLE 18.1 Etiology of Hypomagnesemia in the ICU[3,6,7]

Decreased GI intake	Magnesium-poor diet or total parenteral nutrition; malabsorption syndrome; short bowel syndrome
Increased GI losses	Chronic diarrhea; intestinal and biliary fistulae; nasogastric suctioning; vomiting
Intrinsic renal losses	Interstitial nephropathy; postrenal transplantation; postobstructive or postacute kidney injury diuresis
Drug-induced renal losses	Loop and thiazide diuretics; aminoglycosides; amphotericin B; cyclosporine; cisplatin; granulocyte colony-stimulating factor
Endocrine and metabolic causes	Hyperaldosteronemia; hyperparathyroidism; hyperthyroidism; SIADH; diabetic and alcoholic ketoacidosis; hypophosphatemia; hypercalcemia; hypoalbuminemia
Magnesium redistribution	Acute pancreatitis; administration of epinephrine, insulin; refeeding syndrome; massive blood transfusion
Other causes	CRRT; CPB; severe burns

CPB, Cardiopulmonary bypass; *CRRT,* continuous renal replacement therapy; *GI,* gastrointestinal; *SIADH,* syndrome of inappropriate antidiuretic hormone.

Hypertension	Athetoid movements	Muscle fasciculations	
Risk of digitalis toxicity			

ECG, Electrocardiogram.

patients with acute stroke did not reduce disability at 90 days.[16] In addition, the administration of Mg^{++} therapy is commonly used in pregnant patients with preeclampsia or eclampsia.[7,17]

Magnesium replacement has been used to treat bronchospasm in patients with asthma.[6] The proposed mechanism of action for the therapeutic benefit of Mg^{++} in bronchospasm involves its relaxant effects on smooth muscle and immunoregulatory actions that promote synthesis of prostacyclin and nitric oxide, leading to bronchodilation. Evidence to support the routine use of inhaled or intravenous magnesium for acute asthma attacks remains controversial; however, addition of intravenous $MgSO_4$ to nonresponders of standard therapy has been beneficial.[7]

TREATMENT OF HYPOMAGNESEMIA

The management of hypomagnesemia should include the identification and correction of underlying causes and the replacement of magnesium. The degree of hypomagnesemia, severity of clinical symptoms, associated electrolyte abnormalities, and renal function should be assessed before initiating Mg^{++} therapy.

In general, intravenous administration of Mg^{++} is preferred in symptomatic critically ill patients. Current recommendations for Mg^{++} replacement therapies are of somewhat limited value because of the lack of adequately controlled studies. Magnesium may be administered intravenously as $MgSO_4$ (1 g = 4 mmol) or $MgCl_2$ (1 g = 4.5 mmol) and orally as magnesium gluconate (500 mg = 1.2 mmol) or magnesium oxide (400 mg = 6 mmol). When intravenous Mg^{++} replacement is used, a bolus followed by continuous infusion or infusion alone is preferred, because renal filtration and excretion may limit Mg^{++} retention. For the management of torsades de pointes, 1–2 g of intravenous $MgSO_4$ over 5 minutes followed by infusion is recommended. For the urgent treatment of severe hypomagnesemia, an intravenous bolus of 4–8 mmol of Mg^{++} (1–2 g $MgSO_4$), followed by an infusion of 16–32 mmol Mg^{++} (4–8 g $MgSO_4$) over the next 6–12 hours should be considered. In cases of preeclampsia, an initial bolus of 4 g over 10–15 minutes followed by an infusion of 1 g/h should be used.[7]

KEY POINTS

- Hypomagnesemia is one of the most common electrolyte disturbances encountered in ICU patients.
- Hypomagnesemia is frequently asymptomatic; however, in ICU patients, it is associated with increased mortality.
- Hypomagnesemia in ICU patients manifests as disturbances in the cardiovascular, neuromuscular, and metabolic systems.
- Aggressive intravenous administration of magnesium is indicated in cardiac arrhythmias, including torsades de pointes, preeclampsia/eclampsia, and status asthmaticus refractory to conventional therapy.

Hypocalcemia and Hypercalcemia

Robert N. Cooney, Joan Dolinak, and William Marx

Abnormal serum calcium concentration is a common finding in critically ill patients. The prevalence of hypocalcemia in intensive care unit (ICU) patients ranges from 70% to 90% when total serum calcium is measured and from 15% to 50% when ionized calcium is measured.[1] Hypercalcemia occurs less frequently, with a reported incidence of <15% in critically ill patients.[2] Hypocalcemia is associated with injury severity and mortality in critically ill patients.[1,3–5] However, whether low serum calcium is protective, harmful, or simply prognostic in critical illness is unclear. Therefore in most instances, the management of hypocalcemia involves treating the underlying medical condition(s), except when patients are symptomatic or hemodynamically unstable.

CALCIUM PHYSIOLOGY AND METABOLISM

Calcium is a divalent ion (Ca^{2+}) involved in critical biologic processes like muscle contraction, blood coagulation, neuronal conduction, hormone secretion, and the activity of various enzymes.[3–5] Therefore it is not surprising that intracellular and extracellular calcium levels, like pH, are tightly regulated. A normal adult contains approximately 1–2 kg of total body calcium, which is primarily located in bone (99%) as hydroxyapatite.[1,3,5] Skeletal stores of calcium represent an unlimited reservoir that is predominantly regulated by extracellular Ca^{2+}, parathyroid hormone (PTH), and calcitonin. Extracellular concentrations of Ca^{2+} are typically 1–10,000 times greater than cytoplasmic Ca^{2+} levels.[1,3] Similarly, the majority of intracellular calcium (>90%) is found in subcellular organelles (e.g., mitochondria, microsomes, and endoplasmic or sarcoplasmic reticulum [ER/SR]) as opposed to in the cytoplasmic compartment. Ca^{2+}-mediated cell signaling involves rapid changes in cytoplasmic Ca^{2+} from both internal and external stores.[6,7] Cytoplasmic Ca^{2+} influx occurs through cell membranes by receptor-activated, G-protein–linked channels and the release of internal Ca^{2+} from ER/SR by second messengers.[6] The efflux of cytoplasmic Ca^{2+} involves the transport of Ca^{2+} across the cell membrane and into the ER/SR via specific transporters.[6–8] These tightly controlled pulsations of cytoplasmic Ca^{2+} thus regulate signal strength and frequency for calcium-mediated cellular functions. Alterations in Ca^{2+} signaling have been identified in myocytes, hepatocytes, neutrophils, and T lymphocytes during sepsis and may contribute to the development of organ dysfunction during catabolic illness (for a review see Ref. 7).

Extracellular calcium homeostasis is maintained by the coordinated actions of the gastrointestinal tract, kidneys, and bone.[1,3] Levels of extracellular Ca^{2+} are detected by calcium-sensing receptors on parathyroid cells.[8] In response to low serum Ca^{2+}, the parathyroid glands secrete PTH, which reduces the renal reabsorption of phosphate, increases renal calcium reabsorption, and stimulates renal hydroxylation of vitamin D.[1,3] PTH and 1,25-dihydroxy vitamin D (calcitriol) promote the release of calcium from bone by activating osteoclasts.[1,3] Calcitriol also stimulates intestinal absorption of dietary calcium and regulates PTH secretion by inhibiting PTH gene transcription. PTH secretion is also influenced by serum phosphate concentration. High circulating phosphate levels stimulate PTH secretion by lowering extracellular Ca^{2+}. Magnesium is required for the release of PTH from parathyroid cells and may explain the occurrence of hypocalcemia in patients with magnesium deficiency. Calcitonin is a calcium-regulating hormone secreted by the parafollicular C cells of the parathyroid gland during hypercalcemia. Although calcitonin inhibits bone resorption and stimulates the urinary excretion of calcium, this hormone does not appear to play a major role in calcium homeostasis in humans.[1,3]

The normal concentration of ionized calcium in the extracellular space (plasma and interstitium) is 1.2 mmol/L and represents 50% of the total extracellular calcium. The remaining 40% is bound to plasma proteins, and 10% is combined with citrate, phosphate, or other anions. Total serum calcium normally ranges from 9.4 to 10.0 mg/dL (2.4 mmol/L). The distribution of ionized and bound calcium may be altered in critically ill patients. Chelating substances like citrate and phosphate may influence the abundance of ionized Ca^{2+}. Increased free fatty acid levels caused by lipolysis or parenteral nutrition result in increased binding of calcium to albumin.[9] Protein-bound calcium is also increased during alkalosis and reduced during acidosis.[1,3] Correcting total serum calcium for albumin and pH does not accurately estimate ionized Ca^{2+}.[10,11] Therefore a direct measurement of ionized serum calcium has been found to be the most accurate way to determine the concentration of this cation, and hence this approach is indicated in critically ill patients.[12]

HYPOCALCEMIA IN CRITICALLY ILL PATIENTS

Ionized hypocalcemia is frequently seen in critically ill patients with sepsis, pancreatitis, severe traumatic injuries, or after major surgery. The incidence of hypocalcemia ranges from 15% to 50%.[3] The degree of hypocalcemia correlates with illness severity as measured by the Acute Physiology and Chronic Health Evaluation (APACHE) II score and is associated with increased mortality in critically ill patients.[4] In particular, the degree of systemic inflammation, as measured by cytokine, tumor necrosis factor (TNF)-alpha, and pro-calcitonin levels, appears to correlate with hypocalcemia in ICU patients.[11] Potential etiologies for the hypocalcemia of critical illness include impaired PTH secretion or action, vitamin D deficiency or resistance, calcium sequestration or chelation, or impaired mobilization of Ca^{2+} from bone (Table 19.1).

Hypocalcemia in the ICU is rarely caused by primary hypoparathyroidism. However, sepsis and systemic inflammatory response syndrome (SIRS) is commonly associated with hypocalcemia, which is caused in part by the impaired secretion and action of PTH and the failure to synthesize calcitriol.[1,3,11] Hypomagnesemia may contribute

to hypocalcemia during critical illness via inhibitory effects on PTH secretion and target organ responsiveness.[1,3,5] However, the presence of hypomagnesemia only weakly correlates with hypocalcemia in ICU patients.[4]

In many instances, the hypocalcemia of critical illness is multifactorial in etiology. Elderly patients are at an increased risk for vitamin D deficiency because of malnutrition, poor intestinal absorption, and hepatic or renal dysfunction.[3] In obese patients with previous gastric bypass, the intestinal absorption of calcium dramatically decreases despite reasonable vitamin D levels and recommended calcium intake.[13] Renal failure may precipitate hypocalcemia via the decreased formation of calcitriol and hyperphosphatemia and the chelation of ionized calcium.[1,3] The use of continuous renal replacement therapy in critically ill patients is associated with significant magnesium and calcium losses. This results in electrolyte replacement requirements that often exceed the calcium and magnesium supplementation provided in standard parenteral nutrition formulas.[14] Other potential causes of ionized hypocalcemia in critically ill patients include alkalosis (increased binding of Ca^{2+} to albumin), medications (anticonvulsants, antibiotics, diphosphonates, and radiocontrast agents), massive blood transfusion, sepsis, and pancreatitis.[1,3–5] More recently, the infusion of high doses of propofol have been shown to reduce circulating calcium concentrations by elevating serum PTH levels, but the physiologic significance of this phenomenon is unclear.[15] Ionized hypocalcemia (<1.0 mmol/L) is associated with prehospital hypotension and represents a better predictor of mortality in severely injured patients than does base deficit.[16] The exact reasons for this observation are unclear but potentially relate to head injury and/or the presence of hemorrhagic shock. Injured patients receiving blood transfusions may develop hypocalcemia as a consequence of Ca^{2+} chelation by citrate, which is used as an anticoagulant in banked blood.[17–19] The incidence of transfusion-related hypocalcemia is related to both the rate and volume of blood transfusion.[17,18] When blood transfusions are administered at a rate of 30 mL/kg/h (e.g., 2 L/h in a 70-kg patient) and hemodynamic stability is maintained, ionized Ca^{2+} levels are preserved by physiologic compensatory mechanisms.[19] Transient hypocalcemia may be observed with rapid transfusion and can be prolonged or exacerbated by hypothermia, renal failure, or hepatic failure.[17–19] Consequently, ionized calcium should be monitored and replaced when clinically indicated during massive transfusion. However, hypocalcemia tends to normalize within 4 days after ICU admission, and failure to normalize in severely hypocalcemic patients may be associated with increased mortality. Calcium replacement does not typically improve normalization or reduce mortality.[20]

HYPOCALCEMIA IN SEPSIS AND PANCREATITIS

Hypocalcemia is especially common in critically ill patients with systemic infection or pancreatitis.[1,3,4,7,11] In animal models, serum calcium concentrations decrease after endotoxin infusion.[7,11,21,22] When septic patients with hypocalcemia were compared with nonseptic controls, increased TNF-alpha and interleukin-6 levels correlated with ionized hypocalcemia.[23] Septic patients with hypocalcemia may demonstrate increased or decreased PTH levels; however, urinary excretion of calcium and bone resorption appear to be preserved when compared with controls.[11,21] Procalcitonin levels are increased during sepsis-induced hypocalcemia, but mature calcitonin only exerts a weak and transient effect on circulating calcium level.[23,24] Collectively, the results suggest that hypocalcemia during severe infection has a multifactorial etiology but that inflammatory cytokines, impaired activation of vitamin D, and elevated procalcitonin are contributory.

It remains unclear whether sepsis-induced hypocalcemia is pathologic or protective. Calcium administration in experimental sepsis has been shown to increase or have no effect on mortality.[21,22] Similarly, investigations on the effects of Ca^{2+} blockade on septic mortality demonstrate conflicting results.[23–25] Therefore although sepsis-induced hypocalcemia is commonly seen in critically ill patients, neither routine replacement of calcium nor the use of calcium channel blockers is supported by the existing literature. As with most situations, sepsis-induced hypocalcemia should be treated if patients are symptomatic.

Pancreatitis represents another inflammatory condition that is associated with hypocalcemia in critically ill patients.[1,3,25,26] Saponification of retroperitoneal fat contributes to the development of hypocalcemia in patients with pancreatitis.[3,25,26] In rats with experimental pancreatitis, injection of free fatty acids into the peritoneum induces hypocalcemia.[25] However, the amount of calcium chelated is relatively small compared with the calcium stores in the bone reservoir available for exchange. Interestingly, elevated levels of PTH seen in pancreatitis, like sepsis, do not result in normalized ionized calcium levels.[25–27] Although the resistance of bone and kidney to PTH may be a factor, it is likely that inflammatory pathways identical to those in sepsis are responsible. In pancreatitis, like sepsis, hypocalcemia is an indicator of disease severity. As with most clinical conditions, calcium replacement during pancreatitis should be reserved for the symptomatic or hemodynamically unstable patient.

HYPOCALCEMIA AND MASSIVE TRANSFUSION PROTOCOLS

Massive transfusion (more than 10 units of packed red blood cells [PRBCs] in a 24-hour period) is a commonly used technique in the resuscitation of trauma patients. Fresh frozen plasma (FFP) and PRBCs are stored with citrate as the preservative. Ca is a cofactor for

factors II, VII, IX, and X. Hypocalcemia occurs because of calcium chelation by citrate.[28] Low ionized calcium levels are associated with hypotension and poor outcome. Ionized calcium (iCa) levels (iCa <1) has been shown to be an independent predictor for the need for massive transfusion and mortality.[29] Monitoring serum calcium levels during massive transfusion protocols is a prudent practice.

SIGNS AND SYMPTOMS OF HYPOCALCEMIA

Hypocalcemia is frequently asymptomatic, and attributable signs or symptoms may be difficult to elucidate in critically ill patients. In general, the signs and symptoms of hypocalcemia correlate with both the magnitude and rapidity of onset of the condition. Neurologic (paresthesias, seizures, dementia) and cardiovascular (hypotension, impaired cardiac contractility, dysrhythmias) signs may be seen with ionized hypocalcemia Ca^{2+} <1.0 mmol/L.[3,5] Neuromuscular symptoms of profound hypocalcemia include muscle spasms and tetany. Psychiatric disturbances (dementia, psychosis, depression) also may be attributable to hypocalcemia.[3,5]

Classic signs of hypocalcemia include the Chvostek and Trousseau signs, which test for latent tetany. The Chvostek sign is an involuntary twitching of facial muscles in response to light tapping of the facial nerve. It is nonspecific and is present in 10% to 25% of normal adults and may be completely absent in chronic hypocalcemia. The Trousseau sign is a carpopedal spasm induced by reduced blood flow to the hand in the presence of hypocalcemia when a blood pressure cuff is inflated to 20 mm Hg for 3 minutes. The Trousseau sign is also nonspecific and may be absent in one-third of patients with hypocalcemia.

Cardiac dysrhythmias, such as ventricular tachycardia, prolonged QT interval, and heart block, are more serious complications of hypocalcemia.[3,5] In addition, decreased cardiac output and hypotension, especially where refractory to vasopressors and volume, should prompt calcium replacement when hypocalcemia is present.[3,5]

TREATMENT OF HYPOCALCEMIA

Critical thresholds for calcium replacement vary, but severe ionized hypocalcemia <0.8 mmol/L and symptomatic hypocalcemia should be replaced in critically ill patients.[1,3,5] Treatment of asymptomatic ionized hypocalcemia >0.8 mmol/L is usually unnecessary and may be harmful in conditions such as sepsis and cellular hypoxia.[1,3,5,27]

Treatment of hypocalcemia requires intravenous calcium replacement. The two solutions most commonly used are 10% calcium chloride and 10% calcium gluconate. Each solution contains 100 mg/mL of calcium salt and is provided in 10-mL ampules. Ten percent calcium chloride contains 27 mg/mL of elemental calcium (1.36 mEq/mL); 10% calcium gluconate contains 9 mg/mL (0.46 mEq/mL). Typically, 10 mL of 10% calcium gluconate solution is infused over 10 minutes. A total of 200 mg of elemental calcium may be necessary to raise the total serum calcium by 1 mg/dL. Because the effect of calcium infusion is usually brief, a continuous infusion may be necessary. Calcium chloride should not be infused peripherally if calcium gluconate is available, because the former can produce tissue necrosis and thrombophlebitis if extravasation occurs.

Hemodynamically unstable patients in the ICU who are hypocalcemic may show a transient increase in blood pressure and/or cardiac output with calcium administration. This is probably the result of increased cardiac performance.[27] However, in the presence of tissue hypoxia, calcium administration may aggravate the cellular injury.[9,24] Nonetheless, calcium administration is probably warranted in the hypocalcemic, hemodynamically unstable patient, especially those requiring adrenergic support.

Despite the prevalence of hypocalcemia in critically ill patients, there is a paucity of evidence on the benefit of calcium supplementation in this population. Other than elevating systemic ionized calcium, there is no clear evidence that calcium supplementation affects the outcome in critically ill ICU patients.[28] Collectively, these data suggest that hypocalcemia is a metabolic derangement associated with severe illness as opposed to a correctable condition resulting in a poor outcome.

HYPERCALCEMIA

Hypercalcemia is rare in critically ill patients, estimated to be present in between 1% and 15% of ICU patients.[2] Defined as an increase in serum calcium above 10.4 mg/dL (2.60 mmol/L), hypercalcemia usually is caused by excessive bone resorption. Hyperparathyroidism and humoral hypercalcemia of malignancy are the most common causes of hypercalcemia in hospitalized patients.[2,5,29] Less common causes of hypercalcemia include granulomatous disease, prolonged immobilization, and medications (e.g., thiazide diuretics or lithium) (Table 19.2).[35-43]

TABLE 19.2 Causes of Hypercalcemia

Parathyroid Hormone Mediated
Sporadic (adenoma, hyperplasia, or carcinoma)
Familial (MEN neoplasia 1, 2a, or 4; hyperparathyroid jaw tumor syndrome; familial isolated hyperparathyroidism)
Ectopic parathyroid hormone in malignancy
Tertiary hyperparathyroidism
Malignancy
Hypercalcemia of malignancy (PTHrP)
Local osteolysis
Ectopic parathyroid hormone
Calcitriol-related hypercalcemia
Vitamin D Related
Granulomatous disease (i.e., sarcoidosis, tuberculosis, berylliosis, coccidiomycosis, histoplasmosis, leprosy, inflammatory bowel disease, foreign body granuloma)
Vitamin D intoxication
Endocrine Disorders
Thyrotoxicosis
Adrenal insufficiency
Pheochromocytoma
VIPoma (Verner Morrison) syndrome
Drugs
Thiazide diuretics
Lithium
Milk-alkali syndrome
Hypervitaminosis A
Other
Immobilization in major burns with renal failure
Acute renal failure with rhabdomyolysis
Chronic renal failure treated with calcium and calcitriol or a vitamin D analogue
Renal transplant
Candidiasis in the setting of acute leukemia or immunosuppression
Genetic mutation of the *CYP24A1* gene

MEN, Multiple endocrine neoplasia; *PTHrP,* parathyroid-related protein.

Mild hypercalcemia is usually asymptomatic. However, patients with circulating Ca^{2+} above 12 mg/dL may manifest symptoms of confusion, delirium, psychosis, and coma.[2,5,29] Patients with hypercalcemia also may experience nausea, vomiting, constipation, abdominal pain, and ileus. Cardiovascular effects of hypercalcemia include hypotension, hypovolemia, and shortened QT interval. Profound skeletal muscle weakness may result. Seizures, however, are rare.

The treatment of hypercalcemia should be directed at the underlying medical condition. Saline infusion and diuresis are indicated in symptomatic patients and when the serum calcium level rises above 14 mg/dL (3.5 mmol/L). For patients with underlying malignancy, treatment with salmon calcitonin, pamidronate, or plicamycin may be necessary. These agents act to inhibit bone resorption. Hydrocortisone can also be used in combination with calcitonin to treat hypercalcemia associated with multiple myeloma.

Steroids are a principal therapeutic option produced by excessive production of calcitriol from calcidiol, independent of PTH, by the macrophages present in granulomas.[30] In foreign body granulomas with hypercalcemia, initial treatment may also include locally injecting steroids near the foreign body. The imidazole antifungals, primarily ketoconazole, inhibit the 1-alpha-hydroxylase from the macrophage and have been used to treat hypercalcemia in which steroids are not effective or their side effects cannot be tolerated.[31,32] Imidazoles can reduce calcium levels in other causes of hypercalcemia, though hepatic toxicity will limit their use.[33]

KEY POINTS

- Massive transfusion can cause hypocalcemia, in part because of the citrate used to store blood and chelation. Replacement is often necessary.
- The best test for hypocalcemia is an ionized calcium level, with replacement when values are <1.0 mmol/L.
- Hypocalcemia is frequently seen in ICU patients with sepsis or SIRS, pancreatitis, massive transfusions, and/or solid organ failure. It is often multifactorial and can be caused by vitamin D deficiency, inflammatory cytokines TNF-alpha and interleukin-6, and sequestering in the case of pancreatitis.
- Hypercalcemia is less likely to be encountered in the ICU. Most commonly, this is from an elevated PTH, but could be paraneoplastic, lytic, or caused by an infectious or granulomatous process.
- Initial treatment of hypercalcemia should be saline infusion and diuresis. Treatment should then be tailored to the cause and the patient's tolerance.

Disorders of Glucose Control or Blood Glucose Disorders

Roshni Sreedharan and Basem B. Abdelmalak

INTRODUCTION

Alterations in glucose metabolism are common in the intensive care unit (ICU). The adverse effects of uncontrolled hyperglycemia, especially in a critically ill patient, are fairly well described.[1–3] Management strategies for hyperglycemia in the critically ill patient have gone through substantial changes over the past two decades. Although hyperglycemia is associated with adverse clinical outcomes, trying to achieve euglycemia in all patients has not proven to be the solution. Although the initial landmark randomized controlled trial showed remarkable benefits to tight glycemic management in the ICU,[1] attempts by other investigators to replicate those findings were futile. On the contrary, it resulted in an increase in hypoglycemic episodes and consequently mortality, as evidenced by the largest multicenter randomized controlled trial to date.[4,5] It is worth noting that there is an exceedingly large body of evidence from observational and retrospective studies shedding light on the various glycemic domains that clinicians should keep in mind while managing hyperglycemia in both patients with and without diabetes.[6–8] The presence of a history of diabetes and the extent of a patient's chronic glycemic state would probably play a role in determining the glycemic target.[9,10] Furthermore, glycemic variability, regardless of the chosen target, may also have an impact on glycemic management outcomes.[11]

Hyperglycemia is associated with harm in the ICU, as is hypoglycemia, which is equally, if not even more, serious than hyperglycemia in its detrimental impact.[12,13] Hypoglycemia thus deserves much attention concerning its etiology, risk factors, and interventions aimed at prevention and timely treatment.

This chapter gives an overview of hyperglycemia, hypoglycemia, and their management strategies in the critically ill patient.

HYPERGLYCEMIA

Definition of Hyperglycemia

When a critically ill patient is hyperglycemic, it is important to delineate the clinical group to which the patient belongs. These include the following:

- A known diabetic
- Undiagnosed diabetic
- Nondiabetic with new-onset hyperglycemia (stress-induced)

The American Diabetes Association (ADA) has published criteria for the diagnosis of diabetes mellitus.[14] A diagnosis of diabetes is established when any one of the following criteria is met:

- Fasting plasma glucose >126 mg/dL (7 mmol/L)
- Postprandial plasma glucose >200 mg/dL (11.1 mmol/L) after 2 hours of a 75-g oral glucose tolerance test
- HbA_{1c} >6.5%
- Classic symptoms of hyperglycemic crisis with a random glucose >200 mg/dL (11.1 mmol/L)

Unfortunately, there is no set definition for hyperglycemia in the critically ill patient, as it is confounded by the presence of multiple variables, including the severity of illness, concurrent administration of glucose-containing medications such as antibiotics, feeding, and hyperglycemia-inducing medication, such as catecholamine infusions or glucocorticoids. When a patient presents with new-onset hyperglycemia (NOH), whether critically ill or not, it is prudent to rule out the presence of undiagnosed diabetes mellitus. The presence of an HbA_{1c} >6.5% might aid in making this diagnosis. The ADA/American Association of Clinical Endocrinologists (ACCE) in their consensus statement recommend that any blood glucose >180 mg/dL (10 mmol/L) be treated in patients who are critically ill in an attempt to reduce the adverse outcomes associated with hyperglycemia.[15]

Stress-Induced Hyperglycemia

Hyperglycemia was initially considered to be a normal adaptive response in a critically ill patient to survive a period of acute stress. An increase in the levels of catecholamines, growth hormone, exogenous and endogenous glucocorticoids, and glucagon, along with an increase in circulating cytokines and peripheral insulin resistance, may play an important role in the genesis of stress-induced hyperglycemia.[16,17] However, stress hyperglycemia in patients with previously normal glucose homeostasis has been associated with an increase in adverse outcomes in patients who are critically ill. These adverse outcomes were attributed to either hyperglycemia per se or free radical injury and its related adverse coronary and intracranial events.[18] Although hyperglycemia by itself during acute illness may not be the actual cause of the increase in mortality, it may indicate and correlate with the degree of underlying disease severity.

Diabetic versus Nondiabetic Blood Glucose Management in the ICU

Recent evidence indicates that glycemic targets in the ICU should probably vary based on the presence of a history of diabetes and the chronic glycemic state before ICU admission.[6,9,10,19,20] Furthermore, Abdelmalak and colleagues reported that 11% of patients presenting for noncardiac surgery have undiagnosed diabetes,[21] and there is no reason not to believe that many patients are probably admitted to ICU who are also undiagnosed diabetics. Diabetic patients who are chronically hyperglycemic can probably tolerate, or might even do better with, a higher-than-normal glycemic target and reduced glycemic variability. A retrospective study of 450 critically ill diabetic patients with a total of 9946 glucose measurements in the study cohort found that patients who had higher (>7%) preadmission HbA_{1c} levels had a lower mortality when the ICU time-weighted glucose concentration was higher (>180 mg/dL [10 mmol/L]), as compared with patients who had lower HbA_{1c} (<7%).[22] Similar findings were reported in

larger patient cohorts.[9,23,24] A meta-analysis of nine studies was conducted in 2012 with regard to hyperglycemia and in-hospital mortality associated with sepsis, measuring unadjusted ICU mortality in five of the nine studies. They observed an increase in ICU mortality and a 2.7-fold increase in hospital mortality in patients with NOH as opposed to diabetic patients with hyperglycemia.[25] This difference may be the result of the fact that in a previously chronically hyperglycemic diabetic, the organs and immune system may have been accustomed to higher blood glucose concentrations, and an acute attempt at euglycemia presents a state of relative hypoglycemia for them. Furthermore, if such an attempt at euglycemia is associated with moderate or severe hypoglycemia, as is the case with many tight glycemic control algorithms, such dangerously low concentrations are harmful by themselves[5,12] and contribute to a significant increase in glycemic variability.[11] One of the largest database studies evaluating the effect of diabetes on outcomes in critically ill patients found that hyperglycemia was more detrimental in nondiabetics and was potentially protective in diabetics. There was an increased risk of mortality exclusively in diabetic patients in the normoglycemic/hypoglycemic range, suggesting a relative intolerance to relative and absolute hypoglycemia in this subset of patients.[26] In light of these findings, we probably should seek different glycemic targets (and more robust insulin protocols to achieve such targets) that vary based on the presence of a diagnosis of diabetes and previous chronic glycemic states. Marik and Egi have proposed an example of such variable glycemic targets based on the patient's clinical condition, history of diabetes, and HbA_{1c}, signifying the extent of the long-term status of glycemic control.[27]

THE GLYCEMIC DOMAINS AND THE INFLUENCE OF PREEXISTING DIABETES DIAGNOSIS ON OUTCOMES IN THE ICU

The three domains of glycemic control are hyperglycemia, hypoglycemia, and glucose variability. Each of these has independently been shown to increase mortality in critically ill patients.[7,11,13,28,29] Two large studies evaluated these three domains and the approach to glycemic management in the ICU, in addition to the role of diabetes in this complex milieu. The results of both studies are strikingly similar. Hyperglycemia and an increase in glucose variability were associated with an increase in mortality in nondiabetic but not in diabetic patients. On the other hand, hypoglycemia was associated with an increase in mortality in both groups. Furthermore, in diabetic patients, premorbid glycemic control has been shown to play an important role in outcomes based on the glycemic goals. In patients with poor preadmission glycemic control, mortality was higher with lower ICU blood glucose levels than their own "normal" (i.e., relative hypoglycemia). Conversely, in patients with good preadmission glycemic control, survival was higher when ICU blood glucose levels were maintained closer to the normal range (which is also their own normal as well). In 2014 Plummer and colleagues[30] further substantiated previous observations by Egi and colleagues,[22] who observed an 18% increase in the risk of mortality for every 20 mg/dL (1.1 mmol/L) increase in maximum blood glucose in nondiabetic and diabetic patients with good preadmission glycemic control. The data from these studies further emphasize that having one glycemic goal for all critically ill patients is probably suboptimal.[8,20,22,30]

GLYCEMIC GOAL IN THE ICU

Based on the NICE-SUGAR trial, most centers target a blood glucose level of <180 mg/dL (10 mmol/L) for critically ill patients in an attempt to treat hyperglycemia while reducing the incidence of hypoglycemia[4] noticed with the application of tight glycemic control. The ADA also recommends a goal of 140–180 mg/dL (7.7–10 mmol/L) in ICU patients.[31]

GLUCOSE MONITORING IN THE ICU

In current-day practice, most ICUs use bedside glucometers for monitoring, reporting, and managing blood glucose in critically ill patients. Bedside glucometers were introduced in an attempt to improve outpatient diabetes control (i.e., for patient self-monitoring of blood glucose) and are probably not accurate for intensive monitoring and treatment of hyperglycemia in critically ill patients.[32–35] Several variables can affect the accuracy of a bedside glucometer, such as rapidly changing hematocrit, hypoxia, acidosis, use of vasopressors, and peripheral edema. This makes measuring capillary blood glucose using a bedside glucometer less than ideal in the monitoring of patients who need titration of insulin infusions. The Central Laboratory and Standards Institute (CLSI), and the Food and Drug Administration (FDA) require that 95% of the meter readings are within 20% of the reference value. Although such monitors may meet this standard, the issue remains that allowing even that much of a variation in a critically ill patient on an infusion can make insulin therapy risky.[35] Laboratory whole-blood glucose measurement is the gold standard in blood glucose measurement but is labor intensive and not very practical when hourly glucose measurements are required. Another option is to monitor blood glucose using a blood gas analyzer (BGA), which is close to laboratory standards.[34] Blood glucose measurement from arterial whole-blood samples drawn via an arterial line using a BGA is associated with fewer errors (1% outside the permitted 20% error zone) when compared with capillary samples (27% outside the 20% error zone) or arterial samples (12% outside the 20% error zone) using a glucometer.[36] Arterial blood samples have been recommended for the measurement of blood glucose using a BGA, and this has also been extended to point-of-care (POC) testing when used, as opposed to capillary blood samples. In critically ill patients who are dysglycemic, hourly blood glucose measurements are recommended.[29] Although POC testing has been largely used for this purpose, continuous glucose monitoring (CGM) techniques are being developed to consistently recognize dysglycemic episodes.[37] CGM techniques could be either subcutaneous or intravenous. Subcutaneous CGM devices have been studied extensively. The accuracy and reliability of these subcutaneous devices have been demonstrated in critically ill patients in circulatory shock and on vasopressor infusions.[38] In a randomized trial evaluating the impact of CGM on glycemic control and the occurrence of hypoglycemia in critically ill patients, CGM did not improve overall glycemic control but did reduce the occurrence of hypoglycemic events.[39] Another interesting extension of CGM is in the implementation of fully automated closed-loop glucose control. This system automatically modulates insulin (or dextrose) delivery based on glucose measurements using a CGM device without human input. An evaluation of the feasibility of an automated closed-loop glucose control system using continuous subcutaneous glucose measurements in critically ill patients demonstrated an increased duration of blood glucose within the target range without the occurrence of hypoglycemia.[40] CGM techniques are probably as effective and safe as POC testing. In addition, they reduce nursing burden and detect more dysglycemic/hypoglycemic episodes, especially during the night.[39,41,42] Although the technology seems very promising, routine use of CGM techniques in ICUs would need more trials demonstrating their safety and efficacy.[31]

The practical option of using a bedside glucometer might be an acceptable one in many situations when the gold standard is not available or feasible or poses much delay, provided that blood samples are

whole blood—either arterial or central venous vs. capillary samples—when feasible. When the glucometer-rendered glucose value is near the extremes, especially hypoglycemia, and/or showing a major difference compared with the prior value, a central laboratory confirmation might be in order.

Irrespective of the method of blood glucose monitoring or target blood glucose used, there is a requirement to implement a systematic algorithm for insulin infusion titration in the critically ill patient to reduce the occurrence of adverse incidents, primarily hypoglycemia and glucose variability.[43,44] Although Preiser and Devos made this suggestion at a time when tight glucose control was still in vogue, it still holds true when we target a more moderate blood glucose target as well. They suggested that ICUs should develop protocols in collaboration with nursing and medical staff, which are locally applicable. These systematic algorithms should suggest adaptation of the rate of insulin using a dynamic rather than a sliding scale (e.g., adapting the rate of infusion to nutritional support and to the delta change from the prior value vs. the absolute glucose value), the time for next glucose check, types of devices to be used for sampling, and sites of sampling. Once a protocol has been developed, all ICU healthcare providers should be educated on it. On implementation, the quality of this protocol can be evaluated by the incidence of hypoglycemia divided by the frequency of blood glucose checks, time to achieve target glucose, proportion of time in the target range, and blood glucose variability.[45] By implementing such robust algorithms and protocols, we can strive to achieve better glycemic control in critically ill patients and at the same time reduce glucose variability and the occurrence of hypoglycemia.

These issues led to the consensus recommendations on measurement of blood glucose and reporting glycemic control in critically ill adults[35] that has taken a more conservative approach. Here are a few excerpts from the Consensus Recommendations on Measurement of Blood Glucose and Reporting Glycemic Control in Critically Ill Patients:

- All patients whose severity of illness warrants an invasive vascular monitor should have blood glucose samples drawn from an arterial line. If not available, as a second option, samples can be drawn from a central venous line. Only when severity of illness does not warrant an invasive line should capillary blood be used for sampling.
- Samples taken from arterial or central lines should be analyzed either in the central laboratory or using a blood gas analyzer. If delay with the central laboratory is unacceptable, blood gas analyzers should be the default analyzer. A glucometer is acceptable only when a capillary sample is taken from a patient considered to be too well to need invasive vascular access.

ADA Recommendations for Management of Blood Glucose in Hospitalized Patients

In 2020 the ADA issued recommendations for the management of blood glucose in a critically ill adult based on the evidence available thus far[31]:

- Continuous intravenous insulin infusion is the best method for achieving glycemic targets in the critical care setting.
- Insulin therapy should be initiated for persistent hyperglycemia starting at a threshold greater than 180 mg/dL (10 mmol/L). Once insulin therapy is started, a target glucose range of 140–180 mg/dL (7.8–10.0 mmol/L) is recommended for the majority of critically ill and noncritically ill patients.
- More stringent goals such as 110–140 mg/dL (6.1–7.8 mmol/L) may be appropriate for selected critically ill patients, as long as this can be achieved without significant hypoglycemia.
- Intravenous insulin should be administered based on validated written or computerized protocols that allow for predefined adjustments in the infusion rate, accounting for glycemic fluctuations and insulin dose.
- A hypoglycemia management protocol should be adopted and implemented by each hospital. A plan for preventing and treating hypoglycemia should be established for every patient. Episodes of hypoglycemia in the hospital should be documented and tracked.
- The treatment regimen should be reviewed and changed if necessary to prevent further hypoglycemia when the blood glucose value is less than 70 mg/dL (3.9 mmol/L).

HYPOGLYCEMIA

Definition of Hypoglycemia

In 2013 the ADA and the Endocrine Society Workgroup defined hypoglycemia in five categories[46,47]:

- Severe hypoglycemia (symptoms requiring assistance from another person, neuroglycopenic symptoms, seizures or coma, and reversal of these symptoms with the administration of glucose). Glucose measurements may not be available, but neurologic recovery after glucose administration is diagnostic.
- Documented symptomatic hypoglycemia (with a measured plasma glucose of <70 mg/dL [3.9 mmol/L]).
- Asymptomatic hypoglycemia (no symptoms of hypoglycemia but measured plasma glucose is <70 mg/dL [3.9 mmol/L]).
- Probable symptomatic hypoglycemia (symptoms of hypoglycemia not accompanied by a plasma glucose measurement but are presumed to be caused by a plasma glucose concentration <70 mg/dL [3.9 mmol/L]).
- Pseudo-hypoglycemia (symptoms of hypoglycemia in a person with diabetes but with a measured plasma glucose concentration >70 mg/dL [3.9 mmol/L]).

The definition of hypoglycemia in a critically ill patient is challenging because of a lack of symptom reporting in sedated or critically ill patients. The definition and recognition of hypoglycemia in this group of patients are dependent on close monitoring of measured blood glucose. Landmark studies, which have resulted in current glucose management strategies in the ICU, have repeatedly used previously defined severe hypoglycemia values (blood glucose <40 mg/dL [2.2 mmol/L]) for the diagnosis of hypoglycemia in the ICU.[1,2,4]

In 2020 the ADA defined the levels of hypoglycemia severity as follows[48]:

Level 1: measurable glucose concentration <70 mg/dL (3.9 mmol/L) but ≥54 mg/dL (3.0 mmol/L)

Level 2: blood glucose concentration <54 mg/dL (3.0 mmol/L)

Level 3: severe event characterized by altered mental or physical functioning requiring assistance from another person for recovery

INCIDENCE OF HYPOGLYCEMIA IN THE CRITICALLY ILL

The reported incidence of hypoglycemia is variable and depends on the definition used, the glycemic target, and the admission diagnosis. In a retrospective study from the Australia and New Zealand Intensive Care Society adult patient database, the incidence of hypoglycemia (lowest blood sugar observed during the first 24 hours of ICU stay) ranged from 1.5% to 13.8% depending on the definition used (<44 mg/dL [2.4 mmol/L] versus <82 mg/dL [4.5 mmol/L]).[49]

An interesting study by Niven and colleagues examined the impact of two major landmark trials (Leuven 1 and NICE-SUGAR) on glycemic management in 195 adult ICUs over 80 hospitals from January 1, 2001, to December 31, 2012, using the APACHE database. At the start

of the study, the incidence of hypoglycemia was 3%. This increased to 5.8% after the Leuven study, which advocated tight glycemic control, was published and then slightly dropped to 5.2% after the NICE-SUGAR investigators published their results recommending a more liberal target.[50]

RISK FACTORS AND BARRIERS TO RECOGNITION OF HYPOGLYCEMIA IN THE ICU

Identified predictors of hypoglycemia in the ICU include female gender, APACHE 2 score, continuous venovenous hemodialysis (CVVHD), use of bicarbonate substitution solutions, diagnosis of sepsis, use of vasopressors/inotropes, prior diagnosis of diabetes mellitus, serum creatinine >3 mg/dL, insulin therapy, discontinuation of nutrition therapy without an adjustment in insulin therapy, mechanical ventilation, and ICU length of stay.[12,51,52] There are several barriers and risk factors to recognizing hypoglycemia in a critically ill patient—sedation, absence of symptoms, reduced oral intake, frequent change in rate of enteral or parenteral nutrition, and inappropriate timing of insulin. Even a single episode of severe hypoglycemia (<45 mg/dL [2.5 mmol/L]) has been associated with increased mortality.[12] Increased vigilance and relaxation of the glycemic target are warranted in patients with risk factors so as to reduce the incidence of hypoglycemia.

OUTCOMES OF HYPOGLYCEMIA IN THE CRITICALLY ILL

In a post hoc analysis of the NICE-SUGAR trial, severe hypoglycemia (<40 mg/dL [2.2 mmol/L]) and moderate hypoglycemia (41–70 mg/dL [2.3–3.9 mmol/L]) occurred in 3.7% and 45% of the studied patients, respectively. Although hypoglycemia was more common in the intensive insulin therapy group (93.3% severe hypoglycemia; 82.4% moderate hypoglycemia), the association of hypoglycemia with death was similar in both groups. Moderate hypoglycemia was associated with a 40% increase in the risk of death, and severe hypoglycemia doubled this risk. For both groups, the strongest association with death was from distributive shock. This was probably related to the impairment of autonomic function, white blood cell activation, and release of inflammatory mediators.[5] In a recent systematic review and meta-analysis of longitudinal follow-up cohort studies investigating the association between hypoglycemia and adverse outcomes, a dose-dependent relationship between the severity of hypoglycemia and adverse vascular events and mortality was recognized.[53] In some circumstances, hypoglycemia is a consequence of severe underlying disease and serves as a predictor of death and not necessarily the cause. From prospectively collected data from two observational cohorts, patients with hypoglycemia had a higher mortality in comparison with those without hypoglycemia, even after stratification by severity of illness, diagnostic category, diabetic status, mean blood glucose during ICU admission, and coefficient of variation as an index of glycemic variability.[13] In a retrospective cohort study from the Netherlands, despite adjustment for disease severity, the incidence of death in patients exposed to hypoglycemia (<45 mg/dL [2.5 mmol/L]) was 40 per 1000 ICU days compared with 17 per 1000 ICU days in patients without an exposure to hypoglycemia, indicating a possible causal relationship.[54]

PHYSIOLOGY AND SYMPTOMATOLOGY OF HYPOGLYCEMIA

During an episode of hypoglycemia, below a blood glucose concentration of 65 mg/dL (3.6 mmol/L), the secretion of counterregulatory hormones glucagon and epinephrine increases. Both glucagon and epinephrine increase blood glucose concentrations by increasing gluconeogenesis and glycogenolysis—glucagon to a much greater degree than epinephrine. Free fatty acids are mobilized from the adipose tissue and converted to ketone bodies to be used as an energy source when there is a decrease both in insulin and in the ratio of insulin to glucagon.[55] The brain and heart are two organs that are dependent on glucose for energy utilization and function. Consequently, most of the symptoms of hypoglycemia are related to these two organ systems.

The brain uses glucose and ketone bodies as fuel, especially during starvation.[56] Brain glucose concentrations drop close to zero when blood glucose concentration falls below 36 mg/dL (2 mmol/L).[57] This can result in irreversible brain injury in cases of severe and prolonged hypoglycemia. Patients experiencing hypoglycemia present with either adrenergic (tremors, palpitations, anxiety), cholinergic (sweating, paresthesias), or neuroglycopenic symptoms (cognitive, behavioral, psychomotor changes, seizures, coma).[58–60] Hypoglycemic coma may occur when glucose levels are below 40–50 mg/dL (2.2–2.3 mmol/L).[60] The neurons most sensitive to hypoglycemia are located in the superficial layers of the cortex, the hippocampus, the caudate nucleus, and the subiculum.[55,61,62] Even in the absence of cell death, mild recurrent hypoglycemia can cause dysfunction in the hippocampus.[63]

The myocardial cells can use either fatty acids or glucose as fuel. During episodes of hypoxia or ischemia, myocardial cells preferentially use glucose as a substrate for adenosine triphosphate (ATP) generation.[64] Hypoglycemic episodes stimulate the sympathoadrenal system, which can be proarrythmogenic.[65] Various rate and rhythm disturbances, including sinus tachycardia, sinus bradycardia, atrial and ventricular ectopies, and ventricular repolarization abnormalities, have been observed during acute hypoglycemic episodes.[66–68]

MANAGEMENT OF HYPOGLYCEMIA

The management of hypoglycemia involves recognition, immediate treatment, development of a differential diagnosis, evaluation, and long-term management.

Recognition of Hypoglycemia (Fig. 20.1)

Hypoglycemia is usually recognized using the Whipple triad:

- Symptoms of hypoglycemia
- Documented low blood glucose concentration
- Resolution of symptoms when plasma glucose is raised

This is not always possible in critically ill patients. The diagnosis of hypoglycemia is established when the measured plasma glucose is less than 70 mg/dL (3.9 mmol/L).

Treatment

- Depending on the extent of neurologic or neuroglycopenic symptoms, make sure that airway protection is ensured.
- Supplementing glucose is crucial once a diagnosis of hypoglycemia is established. Patients with mild to moderate symptoms of hypoglycemia are effectively treated with oral glucose tablets or carbohydrate-rich food supplements. A response is usually seen in 15–20 minutes. Continued monitoring and supplementation with glucose (as needed) is recommended, as the response to oral glucose may be transient.[69]
- In patients who have severe symptoms or are unable to take glucose orally, intravenous dextrose is supplemented. An initial dose of 25 g of 50% dextrose (50 mL) or a fraction of it is given. For example, if mild to moderate hypoglycemia is encountered, 6.25 g (12.5 mL) or 12.5 g (25 mL), respectively, is given and that can be repeated as needed. The rationale behind giving a smaller amount vs. the full dose in mild to moderate hypoglycemia is to avoid converting a

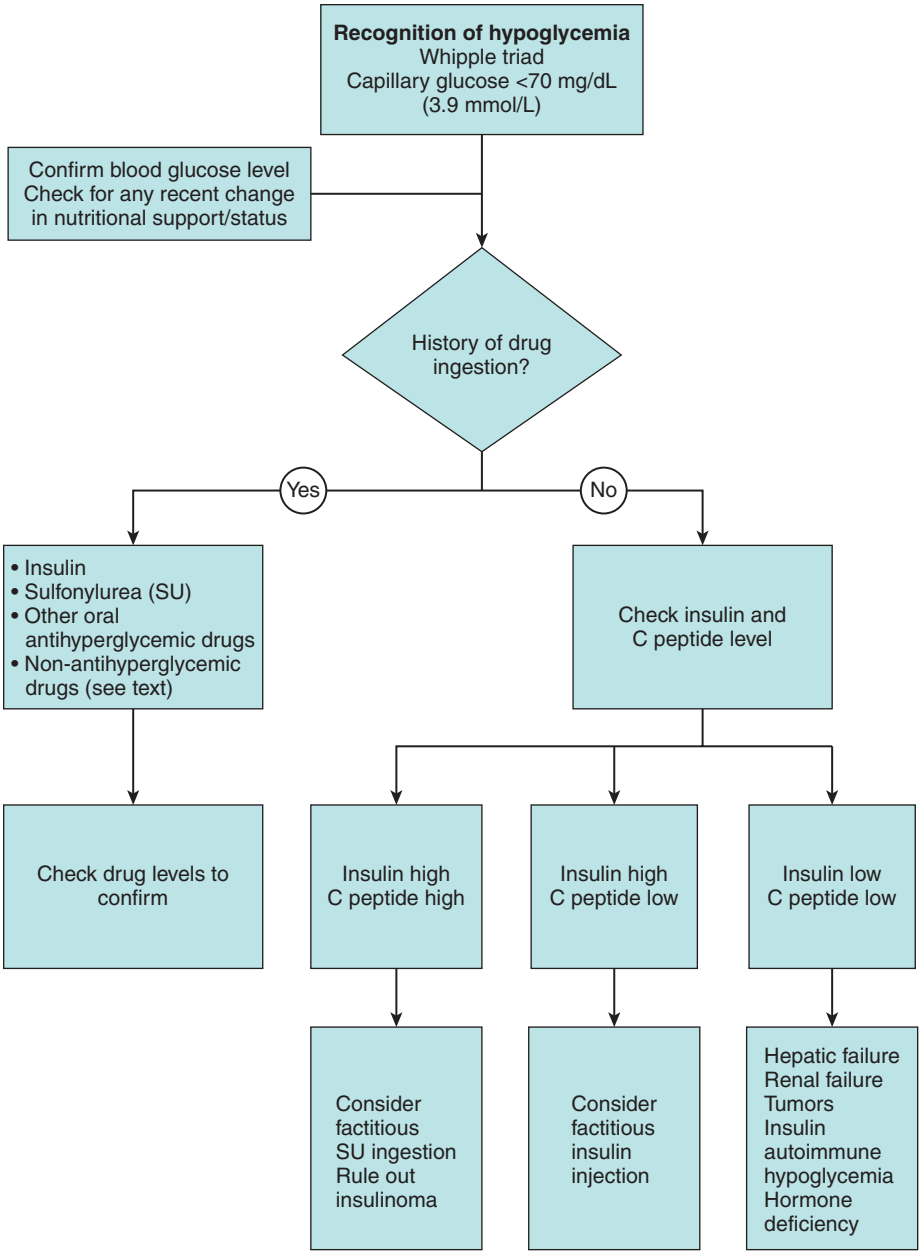

Fig. 20.1 Recognition and Evaluation of Hypoglycemia.

hypoglycemic episode to a hyperglycemic one. The full ampule of 25 g is usually needed to treat severe hypoglycemia (50 mL). A recheck of the blood glucose level would be indicated immediately in 5 minutes or so, after injecting the D50 intravenously. Similar to oral glucose, the effect is transient and may need a continuous dextrose infusion.

- Glucagon can either be given intravenously or subcutaneously at a dose of 1 mg in adults when hypoglycemia is severe or refractory. This can cause transient hyperglycemia.[70]

Differential Diagnosis

- In a critically ill patient, hypoglycemia may be a consequence of therapy with insulin for the management of hyperglycemia, especially when there is a change in nutritional support. Other insulin secretagogues, oral hypoglycemic agents, and several other non-antihyperglycemic agents[71] are frequent culprits as well. The commonly cited non-antihyperglycemic drugs responsible for inducing hypoglycemia include quinolones, pentamidine, quinine, beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, and insulin-like growth factor (IGF).[71] Critical illness or sepsis leading to hepatic, renal, and cardiac dysfunction in and of itself can cause hypoglycemia. Rarely, tumors (islet and nonislet cell), hormonal deficiencies, and development of antibodies to either insulin or the insulin receptor may be the cause of hypoglycemia in critically ill patients.[69]

Evaluation

- When blood glucose concentration is indicative of hypoglycemia, it should be corrected immediately and the cause should be investigated.
- If there is no obvious medication-related cause, measurement of insulin and C peptide levels can be helpful.

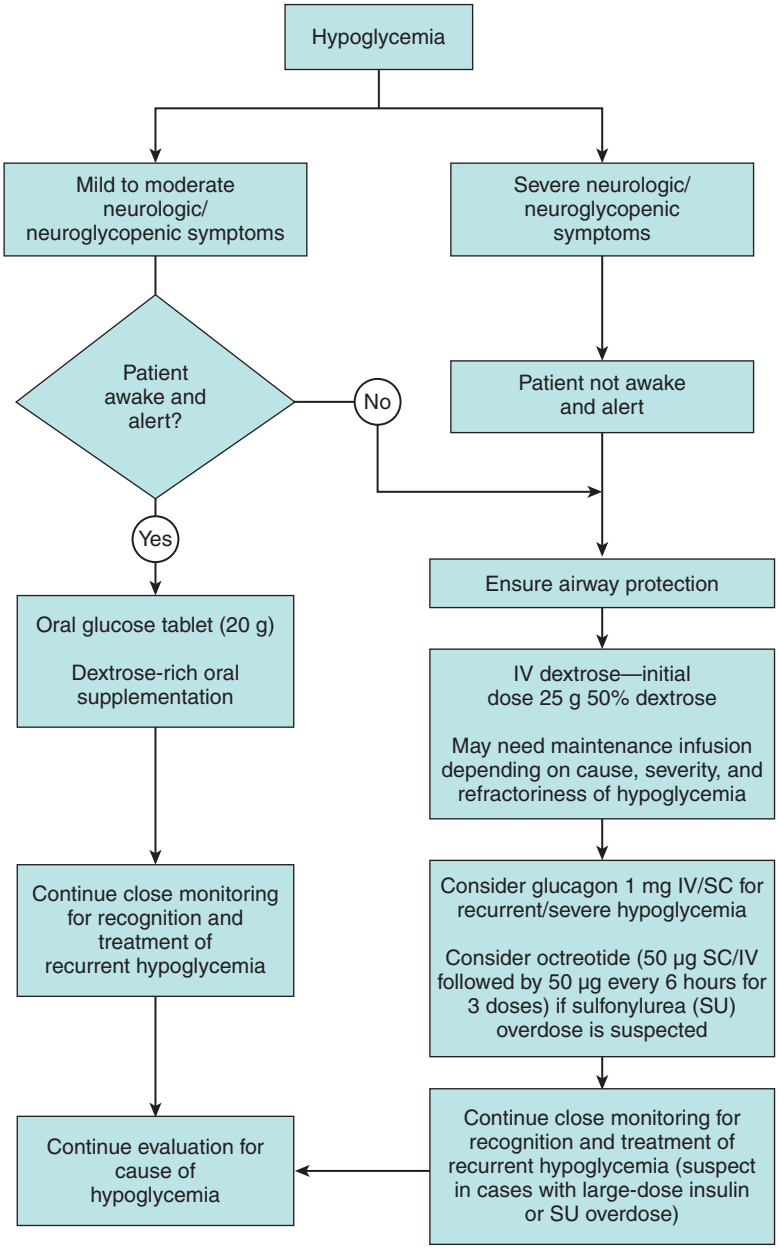

Fig. 20.2 Management of Hypoglycemia. *IV*, Intravenous; *SC*, subcutaneous.

- Make sure that no sudden change in nutritional status (nil per oral [NPO] status/change in rate of enteral/parenteral feed) and/or the insulin content in the feeding solution has been made.
- If sulfonylurea is suspected as the cause, radioimmunoassay can detect sulfonylurea levels.
- Check all medications to look for medication-induced hypoglycemia (non-antihyperglycemic).
- Evaluate for deterioration in renal or hepatic function.
- Evaluate for hormonal deficiencies: thyroid hormone, cortisol.
- Rule out medication error, wrong dose, or concentration of insulin (a common offending agent in medication error).

Management (Fig. 20.2)

- Treat the cause.
- Depending on the cause, an extended period of treatment may be necessary, such as in the case of sulfonylurea-induced hypoglycemia or inadvertent administration of a large dose of insulin.
- In cases of sulfonylurea-induced hypoglycemia, octreotide may be used.[72–74]

CONCLUSION

Several investigators have substantiated the existence of three domains that clinicians need to consider when managing hyperglycemia and setting glucose control targets in the ICU. In attempting to achieve a safe glycemic target, clinicians should consider the treatment of hyperglycemia, prevention of hypoglycemia, and reduction of glycemic variability.[6,9,10,24] Each one of these factors weighs in on improving outcomes in these patients. It is of paramount importance that we tailor insulin protocols based on the clinical picture of the patient to achieve an appropriate target glycemic control. Further research should be directed toward developing such protocols. Although labor intensive, this, coupled with a standardized method for glucose measurement in the ICU, could provide us with data for further clinical

research on the impact of glycemic control on outcomes in critically ill patients. Glycemic control and avoidance of hyperglycemia are important in critically ill patients, but close attention should be paid to prevent hypoglycemia and its related adverse outcomes. Even mild hypoglycemia in the critically ill is associated with increased mortality. Current evidence suggests moving toward more moderate targets that are associated with improved outcomes and fewer hypoglycemic episodes until further evidence emerges.

KEY POINTS

- An increase in the levels of catecholamines, growth hormone, exogenous and endogenous glucocorticoids, and glucagon, along with an increase in circulating cytokines and peripheral insulin resistance, may play an important role in the genesis of stress-induced hyperglycemia.
- In their consensus statement the ADA/ACCE recommend that any blood glucose >180 mg/dL (10 mmol/L) be treated in patients who are critically ill in an attempt to reduce the adverse outcomes associated with hyperglycemia.
- Continuous intravenous insulin infusion has been shown to be the best method for achieving glycemic targets in the critical care setting.
- Once insulin therapy is started, a target glucose range of 140–180 mg/dL (7.8–10.0 mmol/L) is recommended for the majority of the critically ill and non–critically ill patients.
- Just as "one size does not fit all," one glycemic target does not suit all ICU patients. We probably should seek different glycemic targets (and more robust insulin protocols to achieve such targets) that vary based on the presence of a diagnosis of diabetes and previous chronic glycemic state.
- There is a requirement to implement a systematic algorithm for insulin infusion titration in critically ill patients to reduce the occurrence of adverse incidents, primarily hypoglycemia and glucose variability. These systematic algorithms should suggest adaptation of the rate of insulin using a dynamic rather than a sliding scale, the time for next glucose check, type of devices to be used for sampling, and sites of sampling.
- Although laboratory blood glucose measurement is the gold standard, it is labor intensive and not practical for hourly blood glucose measurements. Blood glucose measurement from arterial whole-blood samples drawn via the arterial line using a BGA is associated with fewer errors when compared with capillary samples or arterial samples using a glucometer and hence recommended for POC testing in the ICU.
- The single largest factor limiting achievement of glycemic control in the ICU is the occurrence of hypoglycemia and subsequent increase in mortality.
- The ADA defines moderate hypoglycemia as a blood glucose level of 40–70 mg/dL (2.2–3.9 mmol/L) and severe hypoglycemia as a blood glucose <40 mg/dL (2.2 mmol/L). Mild, moderate, and severe hypoglycemia are associated with increased mortality in the critically ill, and any blood sugar less than 70 mg/dL (3.9 mmol/L) warrants aggressive evaluation and management.
- The ADA Standards of Medical Practice 2016 recommends a goal of 140–180 mg/dL (7.7 mmol/L) in critically ill patients, although the goal may vary from patient to patient based on the admission diagnosis, preadmission diagnosis of diabetes, and chronic glycemic state before admission to the ICU.
- Although laboratory whole-blood glucose is the gold standard for blood glucose measurement, it is time consuming, labor intensive, and not practical when hourly blood glucose measurements are required. Hence arterial blood samples are recommended for blood glucose measurement using a BGA as opposed to capillary samples or arterial samples using a glucometer.
- Identified predictors of hypoglycemia in the ICU include female gender, APACHE 2 score, CVVHD, use of bicarbonate substitution solutions, diagnosis of sepsis, use of vasopressors/inotropes, prior diagnosis of diabetes mellitus, serum creatinine >3 mg/dL, insulin therapy, discontinuation of nutrition therapy without an adjustment in insulin therapy, mechanical ventilation, and ICU length of stay.
- Patients experiencing hypoglycemia present with either adrenergic (tremors, palpitations, anxiety), cholinergic (sweating, paresthesias), or neuroglycopenic symptoms (cognitive, behavioral, psychomotor changes, seizures, coma). Hypoglycemic coma may occur when glucose levels are below 40–50 mg/dL (2.2–2.3 mmol/L). Various rate and rhythm disturbances, including sinus tachycardia, sinus bradycardia, atrial and ventricular ectopies, and ventricular repolarization abnormalities, have been observed during acute hypoglycemic episodes.
- Once hypoglycemia is recognized, various possible causes should be evaluated and management initiated. Depending on the severity of neurologic symptoms, treatment is initiated with oral or intravenous dextrose and glucagon. Depending on the cause, an extended duration of treatment may be required.

Anemia

Fahim Habib, Carl Schulman, and Alessia C. Cioci

INTRODUCTION

Anemia is defined as a reduction in the circulating red cell mass, the hemoglobin concentration, or both with an associated decrease in the oxygen-carrying capacity of blood.[1] It is among the most common clinical problems encountered among critically ill patients in the intensive care unit (ICU). Although a proportion are anemic on admission, the majority of the remainder become anemic during their ICU stay, and over 90% of ICU patients are anemic by day 3.[2] The likelihood of becoming anemic increases with each additional day in the ICU. Because of the association of anemia with worse clinical outcomes,[3] the traditional approach had been to transfuse packed red blood cells (PRBCs) in response to low hemoglobin (Hb) levels, with a Hb level of <10 g/dL being the most commonly used trigger for transfusion. As a result, 30%–50% of ICU patients were transfused an average of 5 units of PRBCs in response to a mean Hb concentration of 8.5 g/dL.[4] The Transfusion Requirements in Critical Care (TRICC) study was seminal in establishing the safety of a restrictive transfusion strategy.[5] Additionally, the increased recognition of transfusion-related complications, growing concerns about the scarcity of blood, and the economic impact of transfusion (approximately $270 per unit transfused in the United States) have prompted a major paradigm shift in the approach to the management of anemia in the ICU.[6,7] Current approaches include preventing blood loss, conserving blood, minimizing hemodilution resulting from the use of excess volumes of crystalloid for resuscitation, avoiding transfusions based on "transfusion triggers" alone, and accepting a lower Hb threshold in the majority of critically ill patients. Future efforts focus on improved conservation of blood, transfusion alternatives, and further advancements in blood substitutes.

EPIDEMIOLOGY

Clinically, anemia is defined by the hemoglobin concentration of blood. The World Health Organization defined anemia as a hemoglobin concentration of <14 g/dL for men and <12 g/dL for nonpregnant adult females.[8] Others have described the limits of a normal hemoglobin to range from 13.0 to 14.2 g/dL for men and from 11.6 to 12.3 g/dL for nonpregnant adult females.[9] Using these definitions, more than 60% of all critically ill patients are anemic at admission, and the majority of those with normal hemoglobin levels at admission will become anemic while in the ICU.[3,10] Over 90% will be anemic within 72 hours of ICU admission, and up to 25% of critically ill patients will have a hemoglobin concentration of <9 g/dL at some point in their ICU stay, especially when the ICU length of stay exceeds 7 days. Among patients who are not admitted for bleeding, have not been transfused, and do not have acute or chronic renal failure, there is an initial rapid decline in hemoglobin levels over the first 3 days by about 5 g/dL, followed by a slower rate of subsequent decline in hemoglobin concentration.[10,11] Each day spent in the ICU increases the chance of receiving a transfusion by 7%,[12] and 25%–53% of ICU patients will be transfused an average of 5 units of PRBCs per patient.[3,9,10,13–15] Among subgroups, patients admitted to the ICU for emergency surgery and trauma are transfused more often than medical ICU patients (57% and 48% vs. 32%). Patients with malignancies also have a higher prevalence of anemia at admission (68%), develop it during the ICU stay (47%), and have a need for transfusions.[16]

ETIOLOGY

The cause of anemia in critically ill ICU patients is often multifactorial.[17] The relative contribution of a particular etiologic factor varies from patient to patient and in the same patient from one time point to another. Key among these are (1) hemodilution, (2) blood loss, (3) impaired erythropoiesis, and (4) altered iron metabolism. Together the impairment in the development of mature red blood cells and alteration in metabolism of iron contribute to the development of the anemia of critical illness. Other concurrent derangements secondary to sepsis, hemolysis, use of antibiotics and chemotherapeutic agents, underlying hepatic or renal dysfunction, bone marrow suppression, and nutritional deficiencies further exacerbate anemia in the critically ill (Fig. 21.1).

Hemodilution

In the absence of bleeding, hemodilution is mostly responsible for the initial decrease in hemoglobin levels observed in the first 72 hours after admission to the ICU and results from the liberal use of crystalloids and, on occasion, colloids for the initial resuscitation of critically ill patients.[18,19] Limiting crystalloid use, earlier use of vasopressor therapy in patients who fail to respond to fluid resuscitation, and close monitoring of volume status are key to prevention of anemia caused by hemodilution.

Blood Loss

Blood loss can occur as a consequence of pathologic bleeding caused by the underlying disease process necessitating admission to the ICU, especially trauma and gastrointestinal (GI) hemorrhage, or from surgical interventions to treat the underlying or associated disorders. Stress gastritis, although rare since the advent of effective acid suppression therapy, remains a serious problem. The overwhelming majority of critically ill patients demonstrate some evidence of mucosal damage within the first 24 hours of admission. Overt anemia occurs in 5% of patients with stress-related GI bleeding, and clinically important bleeding necessitating transfusion is observed in 1%–4% of critically ill patients.[20] The risk for bleeding secondary to erosive gastritis is greatest in those on mechanical ventilation, those with coagulopathy, those with head injury, and those receiving corticosteroids.[21] Phlebotomy is an

Blood culture	10 mL
Drug levels	5 mL
Standard discard amount	2 mL

often unrecognized yet significant cause of hospital-acquired anemia in the ICU. Patients are on average phlebotomized 4.6 times a day with the removal of 40–60 mL of blood daily.[3,10] For every 50 mL of blood drawn, the risk of moderate to severe anemia increases by up to 18%.[22] The volume of blood required to be drawn varies with the test being ordered, but typical volumes required for the various common tests are presented in Table 21.1. Increasing severity of illness correlates with an increased number of laboratory studies ordered and thereby the blood volume drawn. The presence of an arterial line further increases the phlebotomized blood volume because of the need to "waste" before an appropriate sample can be obtained. Approximately half of all patients are transfused as a direct result of phlebotomy.[23]

Impaired Erythropoiesis

Under normal circumstances, in response to low arterial oxygen tension, the peritubular capillary endothelium of the kidney produces a glycoprotein hormone erythropoietin (EPO), which acts on bone marrow to stimulate the production of red blood cells. In critically ill patients, this erythropoietic response is blunted. It is believed to result from inappropriately low EPO levels compared with the degree of anemia.[24,25] EPO levels were reduced by up to 75% when compared with patients with iron-deficiency anemia not related to critical illness.[26] The blunted EPO production is likely mediated by proinflammatory cytokines such as interleukin (IL)-1, and IL-6, which downregulate the expression of the gene encoding EPO.[27] IL-6 also inhibits the renal production of EPO.[28] Subsequent studies, however, have questioned reduced EPO levels as the basis for impaired erythropoiesis.[28] A resistance to the effects of EPO, rather than its absolute level, may be the dominant mechanism behind the impaired erythropoiesis.

Altered Iron Metabolism

Under physiologic conditions, iron metabolism is tightly controlled. Approximately 10% of the 10–20 mg of iron contained in the diet is absorbed, primarily in the proximal duodenum (Fig. 21.2). The dietary iron may be in the heme or nonheme form. The heme form is absorbed via a heme carrier protein (HCP1), and the nonheme form is first converted from the ferric to the ferrous form by the enzyme

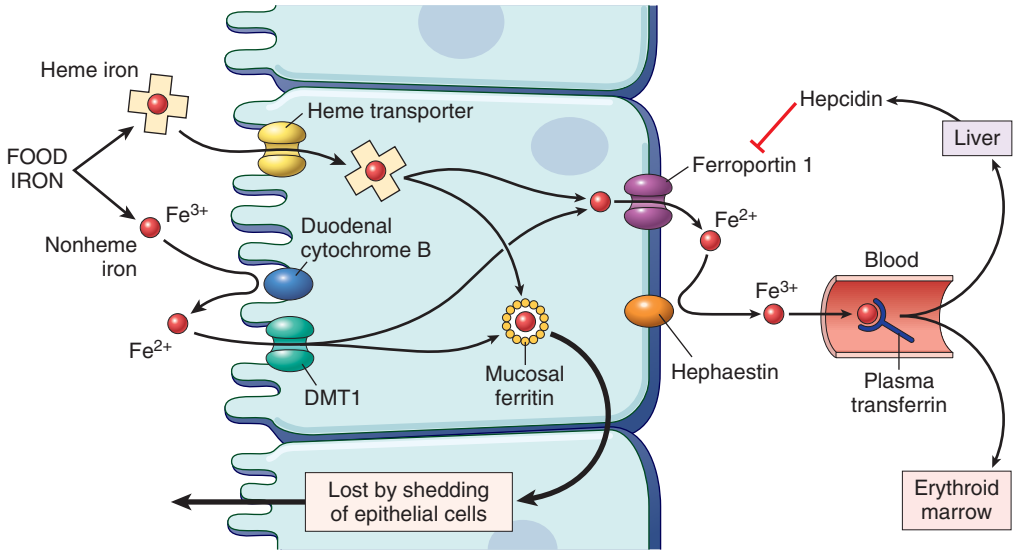

Fig. 21.2 Iron absorption in the duodenum. When the storage sites of the body are replete with iron and erythropoietic activity is normal, plasma hepcidin balances iron uptake and loss to and maintains iron homeostasis by downregulating ferroportin and limiting iron uptake. *DMT1,* Divalent metal iron transporter 1. (From Kumar V, Abbas AK, Aster JC, eds. *Robbins & Cotran Pathologic Basis of Disease,* 9th ed. Philadelphia, PA: Elsevier; 2015.)

duodenal cytochrome B (DcytB) and then transported across the apical membrane by the divalent metal iron transporter 1 (DMT1). The next step is determined by the iron needs of the body. If the iron stores are adequate and no additional iron is needed, the absorbed iron is stored in the enterocyte bound to ferritin and discarded when the enterocyte is shed. If there is a need for iron, the iron export protein ferroportin transports the iron across the basolateral membrane and into circulation, where it is transported bound to the glycoprotein transferrin, which maintains the iron in a soluble nontoxic form. At the cellular level it binds to the transferrin receptor (TfR1) facilitating the internalization of iron into cells. The principal determinant of whether the iron will be shed or absorbed is a 25-amino-acid peptide hepcidin, secreted by hepatocytes.[29] In conditions of adequate iron stores, there is an increase in hepcidin synthesis and release. It then circulates in plasma bound to an alpha-2-macroglobulin, ultimately binding to the iron export protein ferroportin on duodenal enterocytes, causing their internalization and degradation and preventing export of iron out of the cell. In conditions of iron need, increased erythropoietic demand, or hypoxia, hepcidin secretion decreases, allowing ferroportin to actively export iron from the enterocyte into circulation. In critical illness the associated inflammation results in the release of IL-6, which induces the synthesis of hepcidin, with resultant decreases in levels of serum iron and transferrin and decreased transferrin saturation despite adequate iron stores and results in the anemia observed in ICU patients. Additionally, the amount of iron lost as a result of blood loss from a variety of causes can reach up to 64 mg per day. This cannot be adequately compensated for by the 1–2 mg of iron absorbed daily, and a superimposed iron-deficiency anemia develops.[30]

Miscellaneous

Many of the drugs commonly used in the ICU have been implicated in the development of anemia, including antibiotics, angiotensin-converting enzyme inhibitors, calcium channel blockers, and beta-blockers. These medications may further suppress bone marrow function or lead to immunologically mediated hemolysis.[31]

LABORATORY EVALUATION OF ANEMIA IN THE ICU

The *complete blood count* (CBC) is the initial laboratory test performed in the evaluation of anemia. The hemoglobin, hematocrit, and red blood cell count are needed to establish the diagnosis and severity of the anemia. The absence of a uniform definition of anemia and the lack of a grading scale must, however, be recognized. The CBC also provides the red blood cell indices, including the mean cell volume (MCV), the mean cell hemoglobin, and the mean cell hemoglobin concentration (MCHC). Based on the MCV, the anemia can be classified into microcytic (MCV <80 fL), normocytic (MCV 80–100 fL), and macrocytic (MCV >100 fL).[32] The red blood cell distribution width (RDW), a measure of the variation in red blood cell size, is another parameter reported as part of the CBC and further aids in elucidating the cause. The various common causes of anemia based on these two indices are presented in Table 21.2.

The *reticulocyte count* is a measure of immature red blood cells present in circulation and is a marker of red blood cell production. It may be reported either as an absolute number or as a percentage. The normal absolute number of reticulocytes in the absence of anemia ranges from 25,000/μL to 75,000/μL. In the presence of anemia, a value of greater than 100,000 μL represents an appropriate response, whereas counts of less than 75,000 μL suggest a hypoproliferative process. When expressed as a percentage, normal values range from 1% to 2%. Values of 1.5% in men and 2.5% in women are considered elevated. In the anemic patient marrow response ramps up within 10 days of onset, increasing up to two to three times normal in order to combat the anemia. To account for these changes, the reticulocyte index is used, which estimates marrow production relative to normal. It is calculated using the formula:

$$\text{Reticulocyte index} = \text{Reticulocyte count (\%)} \times [\text{patient's hematocrit/normal hematocrit for age and gender}]/2.$$

A value of <2 denotes a hypoproliferation or maturation defect. For critically ill patients, there are several factors that may damage marrow response or lead to defects in erythrocyte maturation, including trauma,

TABLE 21.2 Diagnosis of Anemia Based on the Mean Corpuscular Volume and Red Blood Cell Distribution Width

	Low MCV (<80 fL)	Normal MCV (80–99 fL)	High MCV (≥100 fL)
Normal RDW	Anemia of chronic disease alpha- or beta-thalassemia trait	Acute blood loss Anemia of chronic disease	Aplastic anemia Chronic liver disease
	Hemoglobin E trait	Anemia of renal disease	Chemotherapy, antivirals, or alcohol
Elevated RDW	Iron deficiency Sickle cell beta-thalassemia	Early iron, folate, or vitamin B_{12} deficiency Dimorphic anemia (for example, iron + folate deficiency)	Folate or vitamin B_{12} deficiency Immune hemolytic anemia
		Sickle cell anemia	Cytotoxic chemotherapy
		Sickle cell disease	Chronic liver disease
		Chronic liver disease	Myelodysplasia
		Myelodysplasia	Hereditary spherocytosis, hereditary elliptocytosis, congenital hemoglobinopathies and RBC enzymopathies

inflammation, drugs/toxins, metabolic derangements, and sepsis, resulting in a low index value.[33]

Iron studies are needed to confirm the diagnosis of iron deficiency as a cause of microcytic anemia. These include the serum iron, ferritin, transferrin, and total iron-binding capacity. Given that both iron-deficiency anemia and anemia of critical illness frequently coexist in ICU patients, the characteristic pattern of iron studies reveals a low serum iron, low total iron-binding capacity, and low transferrin saturation. As ferritin is an acute-phase reactant, it is often normal or elevated.[2] However, in contrast to iron-deficiency anemia, in anemia of critical illness, EPO levels are only mildly elevated,[34] reticulocyte counts are disproportionately low, and hepcidin levels are elevated. There is, however, no commercial assay available to measure hepcidin levels.

Macrocytic anemias (MCV >100 fL) most commonly result from deficiencies of vitamin B_{12} or folate. Serum levels of both micronutrients are significantly affected by dietary modifications and are not reliable alone in making a diagnosis. *Methylmalonic acid and homocysteine levels* need to be obtained. Levels of both will be elevated in vitamin B_{12} deficiency, whereas in folate deficiency, methylmalonic acid levels are elevated and homocysteine levels are not. Other causes of macrocytic anemia include drugs and toxins, particularly chemotherapy agents, zidovudine, and alcohol. Rarely, especially in patients who have undergone significant gastric resections, pernicious anemia caused by deficiency of intrinsic factor can occur.

Elevated *lactate dehydrogenase* levels occur as a result of release from destruction of red blood cells in hemolytic anemias. Haptoglobin, an acute-phase reactant, binds the released free hemoglobin, and the complex is rapidly cleared from serum with a resultant decrease in serum *haptoglobin* levels. Elevated indirect *bilirubin* levels are also characteristic. In the presence of hemolysis, a positive *Coombs test* is suggestive of an autoimmune hemolytic anemia. A negative Coombs test should prompt evaluation for sickle cell diseases, thalassemia, glucose-6-phospahte dehydrogenase (G6PD) deficiency, hereditary spherocytosis, hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, and disseminated intravascular coagulation. A *peripheral smear* in addition to other clinical characteristics may help make the diagnosis.

PREVENTION OF ANEMIA IN THE ICU

The single most efficacious preventive measure is to avoid ordering daily screening laboratory tests, particularly CBCs and electrolyte/renal panels.[35] The average blood volumes needed for the more common tests are presented in Table 21.2. The absence of evidence in support for routine blood tests along with the potential for harm caused by such an approach has prompted several societies, including the Society of Critical Care Medicine (SCCM), to promote a philosophy of "Choosing Wisely," recommending against reflex routine testing.[36] The use of pediatric-sized blood collection tubes[37] and use of a blood-conserving arterial line system are other preventive approaches to blood loss.[38,39] Effective stress ulcer prophylaxis to reduce blood loss from the GI tract, correction of coagulopathy, and correction of nutritional deficiencies are other useful preventive measures.

MANAGEMENT OF ANEMIA IN THE ICU

Red Blood Cell Transfusion

Transfusion of PRBCs remains the standard approach for the management of anemia in critically ill patients. Approximately 40% of ICU patients receive blood transfusions.[40] Historically, transfusion was indicated for Hb concentrations below 10 g/dL. However, recent scientific evidence suggests that most critically ill patients safely tolerate lower Hb levels.[41] Additionally, PRBC transfusions are associated with numerous potential complications and are linked to worse outcomes. Finally, blood is a scarce and costly resource that may not always be available.[42] These considerations have led to a shift in transfusion guidelines, with recommendations that PRBCs be used for physiologic indications rather than an Hb-based transfusion trigger.

Liberal transfusion for Hb values less than 10 g/dL was based on historical observations that anemia was poorly tolerated in surgical patients.[43] However, subsequent studies have failed to validate this notion, and anemia below this threshold appears to be well tolerated. Clinical evidence to support this comes from studies in Jehovah's Witness patients who refuse to accept PRBC transfusions on religious grounds. In conscious healthy volunteers, isovolemic dilution can be tolerated until the Hb concentration decreases to 5 g/dL, without an increase in lactate concentration; however, significant cognitive changes were noted.[41,44] However, mortality increases significantly at Hb values below 5 g/dL, more so in individuals older than 50 years.[45]

Several studies have shown no benefit to liberal transfusion of PRBCs, while routinely showing an association with more ICU days and increased mortality. The ABC trial, a prospective observational study of 3534 patients from 146 Western European ICUs, found that mortality was significantly higher in the transfused than in the non-transfused group. The differences persisted even after the patients

were matched for the degree of organ dysfunction.[3] The CRIT study, a prospective, multicenter, observational study of 284 ICUs in 213 hospitals in the United States, found that transfusion was independently associated with longer ICU and hospital stays, in addition to increased mortality.[10] The multicenter trials group of the American Burn Association studied patients with more than or equal to 20% total body surface area burns at 21 burn centers in the United States and Canada. Overall, they found that nearly 75% of patients were transfused during their hospital stay, receiving a mean of 14 units. The number of units transfused correlated significantly with the number of infections and mortality.[46] In a prospective observational study by the North Thames Blood Interest Group, 53% of patients were transfused for a mean pretransfusion Hb level of 8.5 g/dL. About two-thirds were transfused for low Hb levels and only 25% for hemorrhage. ICU mortality in the transfused patients was significantly higher than that in the nontransfused patients.[13] Finally, Marik and Corwin analyzed outcomes in 272,596 patients, as reported in 45 studies. Blood transfusion was associated with an increased risk of death, infectious complications, and development of acute respiratory distress syndrome (ARDS).[47]

Most transfusions in the ICU are performed for the treatment of hemodynamically stable anemia. In the CRIT trial, over 90% of transfusions were given for this reason.[10] Perceived benefits of transfusion include increase in oxygen delivery to the tissues; increase in cell mass and blood volume; alleviation of symptoms of anemia, including dyspnea, fatigue, and diminished exercise tolerance; and relief of cardiac effects. The optimal Hb concentration can be influenced by the premorbid health status, disease process, and other factors.

The historical transfusion trigger of 10 g/dL was directly challenged in the TRICC trial.[48] Patients enrolled were randomized to either a restrictive transfusion strategy (transfusion for Hb below 7 g/dL, with a goal of maintaining circulating Hb between 7 and 9 g/dL) or a liberal transfusion strategy (transfusion for Hb levels less than 10 g/dL, with a goal of maintaining Hb between 10 and 12 g/dL). The restrictive transfusion strategy resulted in a 54% decrease in the average number of units transfused and avoidance of transfusion in 33% of patients, with no difference in 30-day mortality between the groups.

The use of a lower transfusion trigger of 7 g/dL is considered safe in critically ill patients, except in those with acute myocardial ischemia, who may benefit from a higher threshold of 8 g/dL. These guidelines have been adopted in most societal recommendations, although transfusions for Hb level alone are discouraged.[4,49] Additional indications for transfusion include hemorrhagic shock or evidence of inadequate tissue oxygenation.

Adverse Effects of Transfusion

A large proportion of ICU patients continue to receive PRBC transfusions for anemia, exposing them to serious risks, including transmission of infectious diseases, immune-mediated reactions (acute or delayed hemolytic reactions, febrile allergic reactions, anaphylaxis, and graft-versus-host disease), and non–immune-related complications (fluid overload, electrolyte toxicity, and iron overload). Transfusion-related complications are encountered in up to 4% of PRBC transfusions.[10] The risk of adverse outcomes increases incrementally with each unit of PRBC transfused.[50,51] In an observational cohort study of 5814 patients undergoing coronary artery bypass grafting, each unit of PRBC transfused resulted in more complications. Overall, there was a 73% increase in the odds of a major morbidity for each unit transfused (Table 21.3).[50]

With advances in screening and improvements in blood banking technology, transmission of infectious agents is less common. Current estimates of the risk of infection per unit of blood are approximately 1 in 2 million for human immunodeficiency virus, 1 in 1 million for hepatitis C virus, and 1 in 100,000 for hepatitis B virus.[52] The most common transfusion-related infections are secondary to bacterial contamination, which has an incidence of 12.6 events per 1 million units of allogeneic blood components transfused.[53] The risk of bacterial contamination is higher for PRBCs than for whole blood. Transfusion-related bacterial infections are most often caused by gram-positive organisms (e.g., staphylococcal spp., streptococcal spp., 58%) but may also be caused by gram-negative organisms (e.g., *Yersinia enterocolitica*, 32%). About 10% of these infections will result in a fatal outcome.[53] Increasing global travel has led to the emergence of infectious diseases not usually seen in the United States. Chagas disease, caused by the parasitic protozoan *Trypanosoma cruzi,* is endemic in much of South and Central America. Immigrants from these endemic areas now form an increasing proportion of the blood donor pool. This issue is especially relevant in regions with high immigrant populations. In two such cities, Los Angeles and Miami, seropositive rates among donors were 1 in 7500 and 1 in 9000, respectively, and have been increasing.[54] Once acquired, the parasitemia persists long after acquisition of the infection.[55] Novel therapies are being developed to mitigate the risk of transfusion contamination and infection. These include INTERCEPT, a photochemical treatment process that uses amotosalen and ultraviolet A (UVA) light to inactivate viruses, bacteria, parasites, and leukocytes that contaminate transfusion-ready blood products.[56]

The most common of all transfusion reactions are febrile nonhemolytic transfusion reactions (FNHTRs). These reactions are caused

TABLE 21.3 Potential Adverse Consequences Associated With Red Cell Transfusion

Infectious Complications	
Human immunodeficiency virus infection	1 in 2.3 million
Human T-lymphotropic virus infection	1 in 2 million
Hepatitis C virus infection	1 in 1.8 million
Hepatitis B virus infection	1 in 350,000
Parvovirus B19 virus infection	1 in 10,000
Bacterial infections (*Staphylococcus,* streptococci, *Yersinia enterocolitica,* etc.)	1 in 250,000
Parasitic infections (Chagas disease)	1 in 29,000 donors seropositive
Noninfectious Complications	
Hemolytic transfusion reactions	1 in 10,000 to 1 in 50,000
Delayed hemolytic transfusion reaction	1 in 1500
Febrile nonhemolytic transfusion reactions	1 in 100 to 35 in 100
Major allergic reactions	1 in 20,000 to 1 in 50,000
ABO mismatching	1 in 14,000 to 1 in 38,000
Transfusion-related acute lung injury (TRALI)	1 in 5000
Transfusion-related immunomodulation (TRIM)	1 in 100
Transfusion-associated circulatory overload (TACO)	Observed once two blood volumes replaced
Coagulopathy	Observed after transfusion of 10–15 units
Iron overload	
Hypothermia	
Hyperkalemia	
Thrombocytopenia	
Pulmonary hypertension	

by the accumulation of cytokines in stored blood components.[57–59] FNHTRs present within 1–6 hours after transfusion with fever, chills, occasionally severe rigors, and possibly mild dyspnea. Risk factors include young age, blood product type (highest with red blood cells and platelets), and whether the blood was leukoreduced or not.[60–62] Management includes termination of the transfusion and administration of antipyretics if necessary. Prevention is centered on prestorage leukoreduction, which involves removing white blood cells by passing the blood products through a specialized filter soon after it is collected.[63]

Major ABO blood type mismatching is estimated to occur in 1 of 138,673 PRBC units transfused and results in 1 death per 2 million units transfused.[53] Incompatibility may also result from antigens not routinely detected by current antibody assays. As a consequence, fatal acute hemolytic reactions still occur in 1 of every 250,000–1 million transfusions, and 1 patient per 1000 demonstrates the clinical manifestations of a delayed hemolytic transfusion reaction.[64,65]

Transfusion-related acute lung injury (TRALI) is a potentially serious pulmonary complication of transfusion. In severe cases, its clinical presentation is similar to that of ARDS.[66] Although initially described by Barnard in 1951 as noncardiogenic pulmonary edema related to transfusion, the term *TRALI* was coined by Popovsky and colleagues.[67,68] TRALI presents as hypoxic respiratory insufficiency of sudden onset within 6 hours of a transfusion, but usually starting within the first hours after transfusion.[69–71] Hypoxemia, fever, hypotension, tachycardia, and cyanosis may also occur. In 2019 the Delphi panel introduced new TRALI classification terminology. TRALI type I occurs in patients with no other risk factors for ARDS. TRALI type II occurs in patients who have risk factors for or have mild ARDS with marked respiratory deterioration after the transfusion event.[72] In these patients with risk factors for ARDS, recent studies have proposed a change of nomenclature from "possible TRALI" to "transfused ARDS."[73] Chest x-ray shows bilateral infiltrates, which may progress and cause whiteout of the entire lung field. Differential diagnosis includes transfusion-associated circulatory overload (TACO), cardiac diseases, allergic and anaphylactic transfusion reactions, and bacterial contamination of the blood. Although the exact incidence is unknown, TRALI is estimated to occur in 1 of every 5000 transfusions.[74] TRALI had been the leading cause of transfusion- related mortality in the United States until 2016, when it was surpassed by TACO.[75] Current evidence suggests two etiologies of TRALI: immune and nonimmune. Potential mediators include antileukocytic antibodies, lipid peroxidation products, and other as-yet unrecognized agents. Neutrophils are the key effector cells. Transfusions from multiparous female donors owing to exposure to paternal leukocytes are associated with the highest risk of the development of TRALI in the recipient.[76] Upon diagnosis or suspicion of TRALI, transfusions should be terminated and the blood bank notified. Treatment is centered on the correction of hypoxemia, with endotracheal intubation and mechanical ventilation being required in as many 80% of cases.[77–79]

Transfusion-related immunomodulation (TRIM) results in an increased incidence of bacterial infections, cancer recurrence, and organ dysfunction.[80,81] Opelz and colleagues first suggested clinical evidence of TRIM in 1973, when improved renal allograft survival was observed in patients transfused before transplantation.[82] Current evidence implicates transfusions in the development of nosocomial infections, including wound infections, pneumonia, and sepsis. In a prospective observational study, Taylor and colleagues found a significant association between transfusion and development of nosocomial infections (14.3% vs. 5.3%, $P <$,0001). In addition, mortality and length of stay were increased in the transfused group. The risk of infection increases 9.7% for each unit of PRBC transfused.[83] Development of these infectious complications results not only in increased length of stay but also in increased in-hospital deaths and increased costs as well.[84] These effects may be reduced by the use of prestorage leukocyte depletion.[85]

Other complications include TACO with the development of fluid overload and pulmonary edema and pulmonary hypertension with a decreased right ventricular ejection fraction.[85–87] The risk of TACO increases with the volume transfused—a transfusion of just two to four units carries an odds ratio (OR) of 2.00 for developing the complication.[88] The incidence of TACO is estimated to occur in 1%–4% of all transfusions given.[89,90] Management is centered around ventilatory support if needed and fluid mobilization.

Finally, the transfusion of PRBCs may not augment the oxygen-carrying capacity of blood. This results from development of the "storage lesion" caused by changes in red blood cells that occur during ex vivo storage. These changes are both structural and functional and include reduced deformability impeding microvascular flow, altered adhesiveness and aggregation, reduced intracellular levels of 2,3-diphosphoglycerate (which shifts the oxyhemoglobin dissociation curve to the left and reduces oxygen delivery to the tissues), reduced levels of nitric oxide and adenosine triphosphate, and accumulated bioactive compounds with proinflammatory activity.[91–96] The risk of complications increases with the duration of storage.[97,98] Koch and colleagues examined data from 6002 patients undergoing cardiac surgery. Patients given older blood had higher rates of in-hospital mortality and more complications.[99] Other recent studies have not found such an effect of storage.

The Role of Erythropoietin

Many factors contribute to the development of anemia in critically ill patients, but inappropriately low endogenous levels of EPO in response to anemia is a demonstrated phenomenon in critically ill patients.[24] Furthermore, there is a failure of circulating EPO to induce a response commensurate with the degree of anemia.[24] Recognition of these considerations has prompted the use of pharmacologic doses of EPO in an effort to reduce the need for and/or the amount of red blood cells transfused, but this approach has not been validated by scientific evidence. Corwin and colleagues conducted a prospective randomized, placebo-controlled trial (EPO3) on 1460 patients and found that epoetin alfa therapy did not decrease the number of PRBC units transfused and did not improve outcomes. Furthermore, a significant increase in thrombotic events was noted (hazard ratio, 1.41; 95% confidence interval [CI], 1.06–1.86).[100] Accordingly, routine use of EPO cannot be recommended. At our institutions, EPO use is limited to patients with chronic renal failure and Jehovah's Witnesses.

Current Recommendations

The decision to transfuse should be based on a patient's overall clinical picture and his or her individual demographics. Recommendations are summarized in Box 21.1.

Hemorrhage. Transfusion is indicated for patients with acute bleeding and hemodynamic instability or evidence of inadequate oxygen delivery, as demonstrated by elevated lactic acid or base deficit. Transfusion should be initiated without delay for laboratory analysis and should continue until bleeding is controlled and physiologic parameters have normalized.[107]

Critically ill. In hemodynamically stable patients with anemia, a restrictive strategy of transfusion should be employed. Transfusion with PRBCs should be instituted when the Hb level falls to less than 7 g/dL; however, the decision to transfuse should not be based on Hb level alone. Consideration should be given to the patient's intravascular volume status, evidence of shock, duration and extent of anemia, and cardiopulmonary physiologic parameters.[4]

BOX 21.1 Summary of Current Recommendations[4]

1. Packed red blood cell (PRBC) transfusion is indicated in patients with hemorrhagic shock (level 1).[19]
2. PRBC transfusion may be recommended for patients with acute hemorrhage after adequate fluid resuscitation if they have evidence of hemodynamic instability or evidence of inadequate systemic perfusion as demonstrated by elevated serum lactate or presence of a base deficit (level 1).[81]
3. A restrictive strategy of transfusion for hemoglobin (Hb) levels <7 g/dL is recommended for hemodynamically stable, critically ill patients, except for those with myocardial infarction or unstable angina.[101] This restrictive strategy is also recommended in critically ill trauma patients[102] and in those with stable cardiac disease (level 1).[101]
4. Transfuse patients with acute coronary syndromes who have admission Hb levels of <8 g/dL. Achieve posttransfusion hematocrit (Hct) of 30%–33% (level 3).[82,83,103]
5. Do not transfuse based on a transfusion trigger alone. Instead, individualize the decision based on the patient's intravascular volume status, evidence of shock, duration and extent of anemia, and cardiopulmonary status.
6. Transfuse as single units (level 5).[4]
7. Do not use transfusion as a means to wean patients off mechanical ventilation (level 2).[10]
8. Do not use transfusion as a stand-alone strategy to improve tissue oxygen delivery (level 2).[104]
9. In sepsis, transfusions can be recommended as part of a strategy of early goal-directed therapy during the initial resuscitation[86,105] (level 2).
10. Evidence for transfusion in patients with subarachnoid hemorrhage and traumatic brain injury should be individualized.[106]

Except in hemorrhage, patients should be re-evaluated after each unit of PRBCs to determine the need for additional transfusion.

Myocardial ischemia. Patients at risk of myocardial ischemia may benefit from a higher transfusion trigger of 8 g/dL. For patients with cardiac disease undergoing coronary artery bypass graft surgery, increased mortality is observed in patients with Hb levels below 8 g/dL on admission. Reduction in mortality can be achieved by transfusing to a hematocrit of 30%–33%. No mortality benefit is seen with hematocrits above 33%, and increased mortality is observed when hematocrits above 36% are achieved.[108–110]

Sepsis. There is no evidence to support routine transfusion of PRBCs in sepsis. Increased Hb has not been shown to yield improved tissue oxygenation.[111] Transfusion may be indicated for failure to achieve an adequate mixed venous saturation after adequate fluid resuscitation.[19]

Mechanical ventilation. No benefit in the weaning process or difference in duration of mechanical ventilation has been observed.[110]

NOVEL STRATEGIES

It is evident that hemodynamically stable patients can tolerate marked degrees of anemia. The understanding of the risks of receiving transfusions and the growing number of patients who do not accept blood products for personal or religious purposes has led to the recent shift to "bloodless medicine" at certain institutions. These "bloodless centers," particularly in surgical patients, are implementing strategies such as treating preoperative anemia, using erythropoiesis-stimulating agents, minimizing operative blood loss with hemostatic agents, and using autologous blood salvage during procedures in order to decrease the need for transfusions.[101,102] Other strategies include using low-volume adult or pediatric sampling tubes in the laboratory, reducing the number of laboratory tests ordered, and point-of-care microanalysis.[103,104] Additional approaches may include the development of newer methods of blood storage, use of advanced computing technologies to optimize the use of blood inventories, and development of blood substitutes.[105,112]

Blood substitutes are a novel strategy largely in response to concerns regarding the potential transmission of infectious agents and the impending shortage of blood in the face of increasing demands, and are also being implemented in bloodless centers across the country.[113] These innovations are specifically targeted as oxygen carriers (OCs) for delivery in the body, with huge strides being achieved over the last decade. They offer the distinct advantages of better shelf life without requirement of refrigeration, universal compatibility, clinically useful intravascular half-life (18–24 hours), and have freedom from the risk of infectious disease transmission (possibly with the exception of prion-mediated diseases). The two major types of OCs have been the Hb-based oxygen carriers (HBOCs) and perfluorocarbons (PFCs). Research of PFCs is mostly targeted toward diagnostic rather than clinical applications. HBOCs are derived from bovine and human blood and have initially showed promising results. HBOCs were not without complications, with one study of trauma patients having increased mortality over patients receiving saline infusion.[114] This increased mortality may have been a result of its nitric oxide scavenging properties leading to increased vasoconstriction effects.

To combat this, there was the creation of Sanguinate, a bovine pegylated carboxyhemoglobin that inhibits the previous vasoconstricting effects of HBOCs. It has shown promising results in Food and Drug Administration (FDA)–approved trials, even proving lifesaving in one case report, with no adverse events reported.[115,116] Another polymerized bovine hemoglobin, known as *Hemopure,* has had success in further case reports of Jehovah's Witnesses with hemolytic and sickle cell anemias.[117,118]

MacKenzie and colleagues recently described the outcome in 54 patients with severe life-threatening anemia (median Hb level, 4 g/dL) treated with the blood substitute HBOC-201; 23 (41.8%) of 54 patients survived to discharge. Survival was significantly more likely when the blood substitute was administered earlier (3.2 days in survivors vs. 4.4 days in nonsurvivors, $P = .027$).[119] Currently, most research is in its potential use for hemorrhagic shock and clinical situations where blood transfusion is not an option. Results so far have mostly been from small individual studies. Although promising, available data do not support the use of blood substitutes in their current form, and research is still ongoing.

KEY POINTS

- Anemia is exceedingly common in patients admitted to the ICU. Over 60% are anemic on admission, and more than 80% become anemic by day 3 of their ICU stay.
- Anemia in the critically ill patient is multifactorial in etiology. Iron-deficiency anemia and anemia of critical illness are the most frequent causes.
- Anemia of critical illness is cytokine mediated and results from decreased production of EPO, reduced response to EPO, and altered iron metabolism.
- Transfusion is clearly indicated for hemorrhagic shock and hemodynamic instability associated with blood loss after adequate fluid resuscitation.
- Transfusion of packed red blood cells is still employed by the majority of clinicians as the mainstay of therapy for anemia in critical illness. However, the optimal Hb concentration essential to maintain ideal tissue oxygen delivery remains unknown.
- A restrictive transfusion strategy is recommended for critically ill, hemodynamically stable patients without evidence of cardiac ischemia. Transfusion in these patients can often be avoided when the circulating Hb level is above 7 g/dL.
- Treatment with recombinant human EPO initially showed promise as a strategy for reducing exposure to allogeneic blood. More recent evidence, however, refutes these findings and points instead to an increase in thrombotic complications.
- Novel strategies to avoid the need for blood transfusion include use of blood conservation techniques, improved blood storage techniques, advanced inventory control, and evaluation of the efficacy of blood substitutes.

ANNOTATED REFERENCES

Corwin HL, Gettinger A, Fabian TC, et al. Efficacy and safety of epoetin alfa in critically ill patients. *N Engl J Med.* 2007;357:965–976.
In this prospective, randomized, placebo-controlled trial, 1460 anemic ICU patients received weekly recombinant human erythropoietin or placebo without benefit regarding 140-day mortality or transfusion requirements. EPO was associated with a significant increase in the incidence of thrombotic events. The purported benefits of EPO in the critically ill were clearly dispelled by this large multicenter trial.

Corwin HL, Gettinger A, Pearl RG, et al. The CRIT Study: anemia and blood transfusion in the critically ill—current clinical practice in the United States. *Crit Care Med.* 2004;32:39–52.
This prospective, multicenter, observational study described the transfusion experiences of ICU patients at 284 ICUs over a short period in the United States. Among subjects enrolled, 44% were transfused a mean of 4.6 ± 4.9 units; average ICU stay was 21 days. This study examined red blood cell transfusion practices in the critically ill in the United States.

Hébert PC, Wells G, Blajchman MA, et al. A multicenter, randomized, controlled clinical trial of transfusion requirements in critical care. *N Engl J Med.* 1999;340:409–417.
This Canadian study found no benefit of a liberal transfusion strategy when compared with a restrictive one when 838 anemic critically ill patients were compared for 30-day mortality or severity of organ dysfunction. This landmark trial demonstrated that a hemoglobin transfusion threshold of 7 g/dL was appropriate in critically ill patients without ongoing cardiac ischemia or GI bleeding.

Koch CG, Li L, Duncan AI, et al. Morbidity and mortality risk associated with red blood cell and blood-component transfusion in isolated coronary artery bypass grafting. *Crit Care Med.* 2006;34:1608–1616.
This study established the morbidity of transfusion in 11,963 patients who underwent isolated coronary artery bypass from 1995 through 2002, 5814 (48.6%) of whom were transfused. Transfusion of red blood cells was associated with a risk-adjusted increased risk of every postoperative morbid event: mortality, renal failure, prolonged ventilatory support, serious infection, cardiac complications, and neurologic events.

Koch CG, Li L, Sessler DI, et al. Duration of red-cell storage and complications after cardiac surgery. *N Engl J Med.* 2008;358:1229–1239.
This study examined the relationship between serious complications and mortality after cardiac surgery and transfusions of "older blood." Transfusion of red blood cells stored for more than 2 weeks was associated with a significantly increased risk of postoperative complications and reduced survival. Findings supported the notion that blood stored for prolonged periods may be deleterious.

Coagulopathy in the Intensive Care Unit

Hunter B. Moore, Peter K. Moore, and Ernest E. Moore

DIVERGENT PATIENT POPULATIONS: TRAUMA VERSUS SEPSIS

Noncardiac intensive care units (ICUs) predominantly manage coagulopathy in patients with trauma or sepsis. Although trauma is known as the third most frequent cause of death in the United States,[1] sepsis, which is not as well categorized, is believed to be the leading cause of death in hospitalized patients.[2] Both patient populations are at risk of developing coagulation abnormalities.[3] However, the drivers of pathology and timing are divergent. Trauma-induced coagulopathy (TIC) occurs within minutes to hours after injury,[4] whereas sepsis-induced coagulopathy (SIC) represents a spectrum of patients who have been ill days to weeks before progressing to coagulopathy associated with adverse outcomes[5] (Fig. 22.1). Attempting to assimilate the early drivers of coagulation changes between sepsis and trauma have highlighted discordances during the early phases of each disease process.[6] Therefore the approaches to the initial management of coagulopathy in trauma and sepsis are divergent. Whereas trauma research has focused on promoting coagulation, sepsis investigation has tested antithrombotic therapy such as activated protein C and antithrombin. However, the crosstalk between TIC and SIC shares a common historical origin with the term *disseminated intravascular coagulation (DIC).*

ORIGINS OF THE TERMINOLOGY OF DISSEMINATED INTRAVASCULAR COAGULATION

The early descriptions of coagulation changes during hemorrhagic shock date back to the 1770s. Hewson observed that the last blood drawn in sheep clotted first.[7] Almost 150 years later Cannon and Mendenhall validated this finding in which he observed clotting time in dogs was decreased with progressive hemorrhage.[8] This early onset of hypercoagulability led numerous investigators to attribute hypercoagulability as the driving mechanism for irreversible shock after hemorrhage.[9,10] Histologic evaluation of these animals demonstrated microvascular thrombi, and the term DIC was introduced to the literature.[11] Hardaway and colleagues had a long-term interest in DIC driving irreversible shock and demonstrated that pretreating animals with heparin before hemorrhage could effectively reverse DIC-attributable death.[12] They also demonstrated that a fibrinolytic agent could have the same effect of reversing lethal shock when delivered during resuscitation.[13] Hardaway's group later documented intravascular clots in patients with organ failure in 1965.[14]

In 1969 Cafferata and colleagues[15] provided the most compelling evidence of DIC in humans, with a observational postmortem examination of 12 patients who failed to resuscitate several days after injury, despite gaining surgical hemostasis. All 12 patients had clinical evidence of oozing and low-grade bleeding during the perimortem period; however, 8 of these patients had thrombi in their lungs. In the 1970s it was shown that endotoxin infusion could also drive organ failure associated with microvascular clots in animal models.[16] This was then appreciated in patients with cancer,[17] in which it was observed that treating patients with heparin had no effect on outcomes, as the underlying malignancy drove microthrombosis. These early studies set the foundation for decades of research in DIC driving coagulopathy in the critically ill. The laboratory diagnosis of DIC can be misleading, as intravascular microthrombi in a large autopsy series were evident in only 60%.[18]

A review of the interconnectivity of the inflammation and coagulation leading to excessive fibrin deposition and organ failure was published in the *New England Journal of Medicine* in 1999.[3] Twenty years later, as the COVID-19 pandemic overwhelms the healthcare system worldwide with concerns for a lethal cytokine storm, autopsy reports from these patients demonstrate thrombi deposition in multiple organ systems.[19] The most worrisome aspect of DIC is that it heralds the initiation of end-stage organ failure,[20] with no effective treatment, and remains a cause of irreversible shock, as reported by Hardaway and colleagues a half-century earlier.[12] Therefore the objective of ICU treatment is to address the critically ill patient's coagulopathy while treating the underlying clinical disease process to prevent progression to DIC.

IDENTIFICATION OF EARLY TRAUMA-INDUCED COAGULOPATHY

Coagulation changes after trauma are proposed to be broken down into early versus late changes.[21] Early coagulopathy in trauma is driven by shock and tissue injury[22] (Fig. 22.2) There is a spectrum of coagulation early after injury that appears to have divergent drivers.[23,24] These coagulation changes can range from hypocoagulable to hypercoagulable, including a mixed phenotype of one component of coagulation upregulated, whereas the other is inhibited[25] (Fig. 22.3). The majority of early deaths in trauma are related to bleeding and occur a median of 3 hours postinjury.[26] Most of these patients will not reach the ICU because of failure to obtain hemorrhage control in the prehospital setting, emergency department (ED), or operating room. This is often attributable to noncompressible truncal injuries in which the patient has bled to death because of structural problems[27] rather than coagulopathy. Of those patients who fail to generate a hemostatic response after injury and initial resuscitation, the question has been proposed if they are bleeding (coagulopathic) because they are dying or dying because they are bleeding.[28] Therefore attribution to death from coagulopathy becomes a challenge to decipher in critically injured patients. Regardless of the cause or effect, coagulation assessment is an important initial prognostic marker on trauma patients.

The fibrinolytic system appears to be the first component of coagulation activated after severe injury.[29] However, by hospital arrival, the

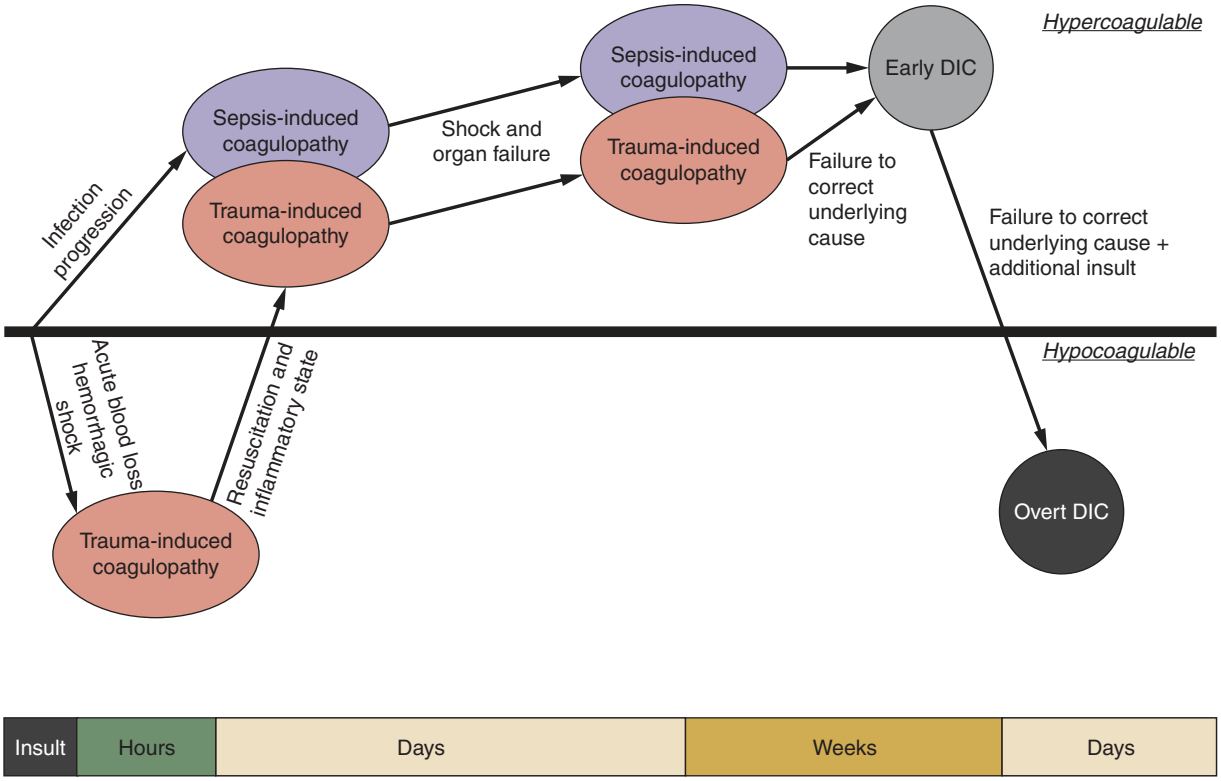

Fig. 22.1 Early trauma-induced coagulopathy (TIC) is distinct in mechanisms and clinical manifestations from disseminated intravascular coagulation (*DIC*), but later TIC and DIC have similar mechanisms and clinical consequences.

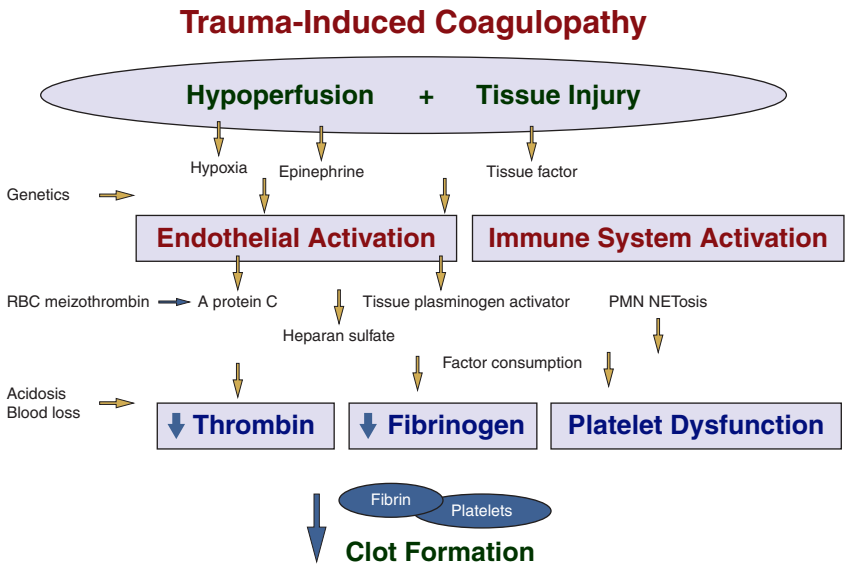

Fig. 22.2 Early trauma-induced coagulopathy (TIC) is driven by hypoperfusion and tissue injury, resulting in inadequate thrombin generation, fibrinogen depletion, and platelet dysfunction.

majority of patients have shut down fibrinolysis.[30,31] Typically, coagulopathic-injured patients have a prolonged international normalized ratio (INR) with elevated D-dimer levels in the ED.[4] There have been multiple proposed thresholds for INR levels to define patients as coagulopathic in trauma.[4,32,33] Although >1.2 has been proposed, an INR >1.5 is superior in predicting mortality and morbidity after trauma.[34] INR-defined coagulopathy in the acute setting has applicability to the patient who is resuscitated and transferred to the ICU, as this early coagulation change is also associated with organ failure and later thrombotic complications.[34,35] However, INR only represents the plasma contribution to clotting, ignoring the critical role of platelets. Moreover, INR does not reflect deficiency of clotting factors of the extrinsic system, which is what is presumed to account for a prolonged INR.[35]

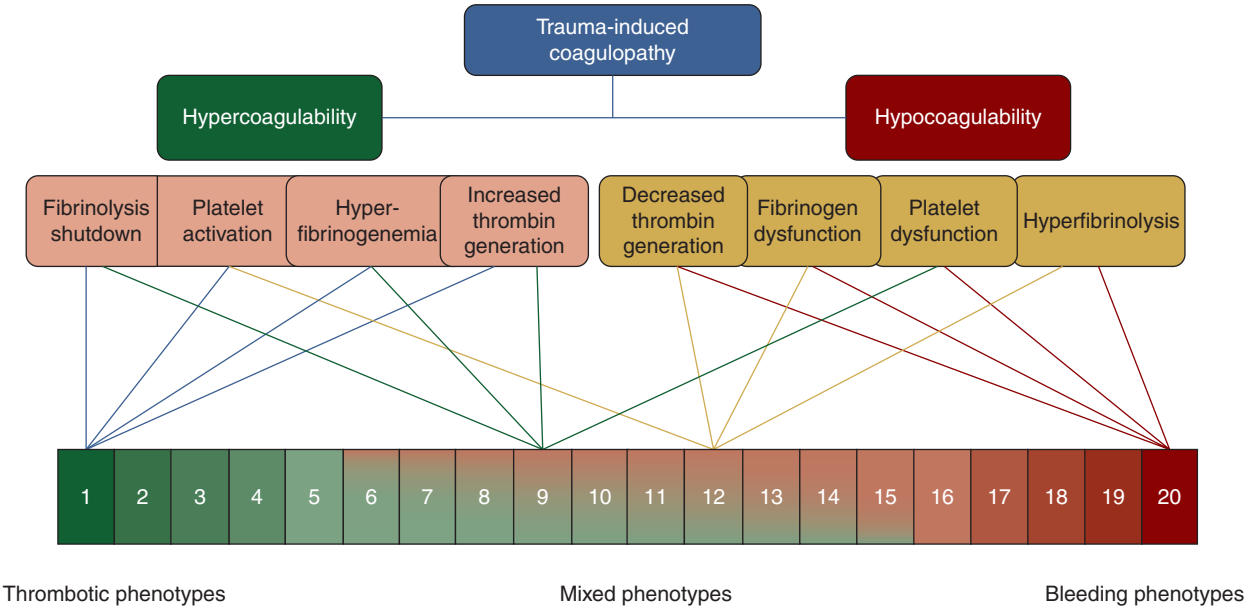

Fig. 22.3 Severe injury can provoke a myriad of trauma-induced coagulopathy (TIC) phenotypes that generally begin with uncontrolled bleeding and progress to thrombotic complications.

The more recent approach to identifying patients with early TIC is with viscoelastic hemostatic assays (VHAs).[36] This approach is able to replace a battery of conventional coagulation assays,[37] and transfusions based on the different coagulation measurements from VHA compared with conventional laboratory assessment have been demonstrated to reduce mortality.[38] Although there are multiple components of coagulation that may be deranged in VHA, a decrease in clot strength has repeatedly been associated with increased mortality.[39–42]

MECHANISMS OF EARLY TIC

The mechanisms driving early TIC are complex (see Fig. 22.2). The major components include impaired thrombin generation, fibrinogen dysfunction, platelet dysfunction, and alterations of the fibrinolytic system.[43] Although the exact mechanisms of each component are not clearly understood, some prevailing hypotheses have been generated. Decreased thrombin generation has been proposed to occur through activation of protein C[44] and shedding of the glycocalyx,[45] but the role of these mechanisms remains controversial. Fibrinogen dysfunction is believed to be related to metabolic abnormalities[46] and consumption at the site of injury.[47] Platelet dysfunction has been associated with damage-associated molecular pattern proteins such as histones[48] through binding Toll-like receptors.[49] Fibrinolysis activation is proposed to occur via tissue plasminogen activator (tPA) release from hemorrhagic shock,[50] whereas fibrinolysis suppression (shutdown) is associated with tissue injury.[51] There are numerous review articles on the topic of early TIC that describe the details of these hypotheses and others.[43,52–55]

Regardless of the underlying pathobiology, few early adjuncts in trauma resuscitation have been demonstrated to reduce mortality in trauma patients at risk of bleeding. The following are the three adjuncts in which clinical trials have resulted in positive outcomes: (1) tranexamic acid (TXA), which reduced bleeding mortality by 0.6% in a large multinational trial[56]; (2) prehospital plasma resuscitation in patients requiring helicopter transportation (9.8% reduction mortality)[57]; and (3) VHA-based resuscitation in patients in which the massive transfusion protocol (MTP) was activated (15.8% reduction mortality).[38] In each of these trials, total red blood cell transfusions were not reduced. The mechanisms by which these hemostatic adjuncts improve mortality remain unclear. Most trauma centers with adequate blood banks will use MTPs with an empiric ratio of red blood cell, plasma, and platelets to guide early resuscitation before coagulation test results become available. Many MTPs use a ratio of 1:1:1 despite lower ratios (2:1:1) having comparable outcomes.[58] The threshold for adding empiric blood components such as cryoprecipitate should start when patients have received more than 4 units of red blood cells.[59] In the future whole-blood resuscitation may become an alternative option for early hemostatic resuscitation in patients who are massively bleeding.[60] With these empiric transfusion strategies becoming more popular, the intensivist will take on a more important role in the de-escalation of hemostatic resuscitation, which will be discussed in the later section discussing late TIC.

IDENTIFICATION OF SEPSIS-INDUCED COAGULOPATHY

The onset of coagulation changes after sepsis is less well defined. A nonhuman primate model suggests this process begins to occur early[61–63] and appears to be variable based on the pathogen. The hallmark of sepsis driving coagulation changes includes a drop in platelet count, prolonged INR, and increase in fibrin degradation products.[64] When the International Society of Thrombosis and Hemostasis (ISTH) developed a DIC score, it was acknowledged that coagulation abnormalities in sepsis and other causes of DIC proceeded overtly apparent DIC.[65] This nonovert DIC group of patients was later simplified into a score to diagnosis SIC based on platelet count, INR, and Sequential Organ Failure Assessment (SOFA) score.[5] Prospective evaluation of the SIC score identified that this definition of coagulopathy in sepsis represented a broader spectrum of patients, some of whom were at risk of progression to overt DIC.[66] The prevalence of SIC appears to be comparable to TIC,[67] in which roughly a quarter of patients with sepsis meet this definition.[68] However, incorporation

of a SOFA score requires six variables that are calculated based on variables measured in the first 24 hours in the ICU. Unlike TIC, which can be determined within an hour of admission to the ED,[69] SIC is more challenging to diagnose and requires an ICU setting. Specifically, platelet counts and INR in the ED have not been found to predict mortality in sepsis.[70]

VHA testing in sepsis has gained popularity.[71–73] Several studies have demonstrated that a decreased angle,[71,72] decreased clot strength,[72] and lack of fibrinolysis[74] are associated with DIC and poor outcomes. However, septic patients without evidence of DIC have a tendency for hypercoagulability.[72] From the existing VHA data, it appears that patients with sepsis have a tendency towards hypercoagulability with fibrinolysis resistance,[72,75] and the reduction in clot strength/fibrinogen appears to be a later event in which patients have transitioned to DIC and organ failure.[72,73] Unlike early TIC, when there is clear evidence of pathology with ongoing bleeding from injured tissue caused by mechanical disruption and coagulation abnormalities, pathologic sequelae from early SIC are not clinically apparent, as these patients are not bleeding, and the progression to organ failure manifests in a time course measured by days rather than bleeding to death in minutes.

MECHANISM OF SIC/DIC AND TREATMENT

The drivers of DIC have been studied for decades without differentiation of the earlier stage of the disease process through SIC. Inflammation-provoked cytokine release is believed to be the initiator of coagulation changes in sepsis caused by endotoxin.[20] Cytokine production is believed to stimulate tissue factor production, resulting in systemic activation of coagulation.[76] Tissue factor expression is upregulated on macrophages and endothelial cells in response to elevated tumor necrosis factor-alpha (TNF-α), interleukin (IL)-6, and IL-1.[77] At the same time the cytokine storm damages the endothelium, reducing the antithrombic capacity of the systemic circulation via suppression of protein C, protein S, antithrombin, and tissue factor pathway inhibitor (TFPI).[78] VHA testing in healthy humans with endotoxin infusion has demonstrated activation of the fibrinolytic system within 2 hours after infusion, followed by a shutdown of fibrinolysis within an hour because of elevated plasminogen activator inhibitor-1 (PAI-1) levels.[79] Fibrinolysis activation with subsequent rapid suppression by PAI-1 was documented with endotoxin infusion in nonhuman primates, with concurrent increases in thrombin generation.[80] Pentoxifylline attenuates these fibrinolytic changes in this animal model, whereas IL-6 and TNF-α inhibitors have no effect.[81] These experiments were followed up with the hypothesis that an antifibrinolytic would prevent progression to DIC by blocking plasmin activation; however, TXA had no impact on the prothrombin component of endotoxin infusion in healthy subjects and did not alter cytokine production.[82] Regardless, the overwhelming majority of patients will have long passed the initial fibrinolytic activation phase of endotoxemia by the time sepsis is diagnosed.

An important component of DIC/SIC coagulopathy is thrombocytopenia. Declining platelet counts in DIC have been proposed to be largely attributable to consumption of platelets via fibrin accumulation in the intravascular space.[76] More recent animal data support that platelets bind lipopolysaccharide (LPS) via the Toll-like receptors and become activated, resulting in deposition in the lungs and increasing levels of TNF-α.[83] Inhibition of platelets has been proposed to be a potential therapy to attenuate the progression to DIC and organ failure.[84] Other causes of decreased platelet counts in the ICU associated with organ failure include thrombotic microangiopathy (TMA). TMA processes include hemolytic uremia syndrome (HUS), thrombotic thrombocytopenic purpura (TTP), and Shiga toxin–producing *Escherichia coli*. However, these occur at a much lower frequency (~150 times less frequent) than DIC-associated thrombocytopenia.[85]

Management of SIC/DIC has been focused on enhancement of the anticoagulation system. There are no randomized controlled trials treating septic patients with presumed SIC/DIC with heparin, antithrombin, protein C, thrombomodulin, or TFPI that have improved mortality. A summary of the clinical trials can be found at references that are predominantly targeted to patients with overt DIC.[86-88] The current management of SIC is to treat the underlying cause. This is most appropriately addressed by implementing the Surviving Sepsis Campaign recommendations of early sepsis diagnosis, administration of empiric broad-spectrum antibiotics (within 1 hour based on the presumed site of infection), 30 mL/kg crystalloid resuscitation in patients in shock or with high lactate levels (to be completed within 3 hours), addition of vasopressors in those whose blood pressure is not responding to initial crystalloid resuscitation (within 1 hour), and source control as soon as feasible (but within 6 hours).[89]

THE TRANSITION FROM EARLY TO LATE TIC: HYPOCOAGULABLE TO HYPERCOAGULABLE STATE

While the focus of early TIC is dominated by concerns for correcting underlying hypercoagulability to reduce bleeding, the focus of late TIC is transitions to treatment strategies to prevent thrombotic complications and organ failure.[21] Upon arrival in the ICU, severely injured trauma (with potential ongoing bleeding) requires a multimodality approach. Resuscitation should be optimized resuscitation while coagulopathy is corrected. Neglecting hypothermia and acidosis will exacerbate ongoing hemostatic dysfunction[90] and risk the patient getting stuck in the lethal triad of trauma. Obtaining baseline laboratory assessment of the patient's acid-base status and degree of anaerobic metabolism is an important first step in the management of a coagulopathic trauma patient. Hypocalcemia is another risk factor for ongoing coagulopathy. Patients receiving massive transfusions are at risk of hypocalcemia because of calcium binding to the citrate in the transfused blood.[91] Empiric calcium administration can be considered in patients with evidence of ongoing bleeding.

The timing from injury is also an important consideration in patient management. As previously mentioned, fibrinolysis activation is one of the earliest changes in coagulation after severe injury, and commonly is suppressed soon after.[29] This reperfusion fibrinolysis shutdown is associated with a massive increase in PAI-1 levels.[92] The timing of peak reperfusion fibrinolysis shutdown is between 2 and 4 hours after injury.[52] This has a similar time course to fibrinolysis shutdown induced by endotoxin in animal models.[80] Most severely bleeding trauma patients who survive to be admitted to the ICU will be in fibrinolysis shutdown[93] because those who have failed to correct hyperfibrinolysis (excessive systemic fibrinolysis) will have bled to death in the ED or in the operating room.[94] Therefore the use of antifibrinolytics upon ICU arrival of these patients is unlikely to have a benefit, and most will be past the 3-hour time from injury when TXA loses its survival benefit.[95]

Despite fibrinolysis shutdown being highly prevalent in this patient population, it does not equate to hemostasis. Patients in fibrinolysis shutdown who are undergoing massive transfusion will frequently have a prolonged INR, low fibrinogen, and platelet dysfunction.[96] TXA in this cohort does not improve fibrin clot strength (when assessed ex vivo) and has been associated with increased mortality.[97] Therefore all trauma patients on arrival to the ICU should have a global coagulation

assessment. By the time the patient arrives, initial coagulation laboratory values should have been obtained, which will also provide clinically relevant information. As previously mentioned, initial coagulation laboratory studies not only predict early mortality from bleeding but also are biomarkers for injury severity, the development of thrombotic complications, and organ failure.[34]

The hemostatic resuscitation of trauma patients in the ICU should be transitioned to goal-directed blood component administration. We have implemented a thromboelastography (TEG)-directed resuscitation approach based on an ongoing evaluation of blood product utilization at the Ernest E. Moore Shock Trauma Center.[98] The specific cutoffs for blood product transfusions based on VHA assessment are center-dependent. Manufacture normal limits do not necessarily reflect the hemostatic needs of actively bleeding trauma patients. We have used a rapid TEG-activated clotting time greater than 128 seconds as an indication for a plasma transfusion, a TEG angle of less than 65 degrees as an indication for cryoprecipitate transfusion, a TEG maximum amplitude (MA) less than 55 mm for a platelet transfusion, and LY30>5% for the antifibrinolytics (which is exceedingly rare in the ICU).

Rotational thromboelastometry (ROTEM) also provides comparable results to TEG in hemostatic resuscitation.[99] One advantage with the current ROTEM platform over TEG is the amplitude at 5 and 10 minutes. These results provide information to guide platelet- and fibrinogen-based products 20 minutes earlier than the current TEG parameters.[41] Without VHA testing, goal-directed resuscitation is based on standard laboratory assessment with a complete blood count, INR, and Clauss fibrinogen. Inflection points for transfusions with these assays require more estimating of what clotting parameter is dysfunctional. Regardless of coagulation assessment, the active bleeding patients should have a hemoglobin target of 10 to optimize platelet function.[100]

After the initial assessment of coagulation function and physiologic parameters of the ICU patient, the decision to transfuse should be based on clinical evidence of ongoing bleeding. Patients who are hemodynamically stable, have corrected their acidosis, and have stable hemoglobin levels do not necessarily warrant correction of an ongoing laboratory-detected coagulopathy. Each transfusion of blood incurs some risk to the patient. A high ratio of plasma to red blood cells has not been associated with an increased risk of acute respiratory distress syndrome (ARDS) in a patient undergoing a massive transfusion.[101] However, in patients requiring less blood products, high plasma utilization (>6 units) was significantly associated with ARDS,[102] particularly when a concomitant chest injury was present.[103] The same association has been appreciated with platelet transfusions.[104] Cryoprecipitate in trauma has not been associated with these adverse outcomes, but could be because of lower utilization. The combination of cryoprecipitate and TXA, however, has been associated with an increased risk of thrombotic complications.[105]

The transition to pathologic hypercoagulability resulting in thrombotic complications in trauma appears to become relevant with fibrinolysis resistance at 12 hours from injury[106] and with increased clot strength at 24–48 hours.[106,107] The inflection-point, VHA-detected risk of hypercoagulability appears to be a clot strength with an MA in the 70-mm range with TEG.[108–110] Management of late TIC hypercoagulability will be addressed in a later section. During this transition time from early to late TIC, patients will require ongoing evaluation for surgical bleeding. Patients who have a corrected coagulation profile and continue to be hypotensive or have surgical drains/chest tubes with high output should warrant consideration for taking the patient to the operating room.

Late TIC and SIC

Early TIC and SIC have completely different pathobiology. Trauma patients with early TIC are at high risk of bleeding to death, often present to the hospital in hemorrhagic shock, frequently undergo blood product resuscitation, and definitive care may require an operative intervention to control bleeding, whereas SIC patients present with distributive shock, undergo crystalloid resuscitation, are dependent on antibiotics to treat the underlying disease process, and may require an operative intervention to get source control of the infection. Assimilating these pathologies begins to occur after these patients have been resuscitated and are in the ICU. These critically ill patients begin to share similar coagulation features.

The proinflammatory immune response after trauma and sepsis resuscitation is referred to as the systemic inflammatory response (SIRS). When SIRS is severe and remitting, it can cause early multiple organ failure (MOF) and death.[111] The immune counterbalance to SIRS is called *compensatory antiinflammatory response syndrome (CARS)*.[112] CARS is associated with increased secondary infections, which can contribute to the development of late MOF and death.[113] Fortunately, with improved ICU care, both early and late MOF deaths have largely disappeared over the past decade. However, failure of SIRS and CARS to return to an immune homeostatic state can result in what has recently been coined persistent inflammation, immunosuppression, and catabolism syndrome, which is associated with chronic critical illness (CCI) with prolonged ICU stays and dismal long-term outcomes.[114] Similarity between trauma and sepsis coagulopathy during SIRS and CARS may persist and contribute to the underlying pathobiology of CCI. This is an unexplored area of research.

The transition to terminal coagulopathy represented as DIC is appreciated by a progressive decline in platelets and fibrinogen, which is presumed to occur from a consumption of these clotting components at the microvascular level.[76] Patients manifest an oozing coagulopathy but retain components of hypercoagulability via inhibited fibrinolysis.[115] Several scores are used to calculate the risk of DIC, with the International Society of Thrombosis and Haemostasis (ISTH) and Japanese Association for Acute Medicine (JAAM) having comparable performance.[116] Unfortunately, calculating DIC does not improve outcomes, and the treatment of these patients is supportive with the objective to treat the underlying pathology. A new definition of DIC based on quantifying thrombin generation to plasmin (fibrinolysis) ratios suggests that the majority of these patients have a disbalance of excessive thrombin generation and lack of plasmin generation driving coagulopathy.[117]

Trauma and sepsis drive a more rapid onset of DIC with a worse prognosis,[118] whereas malignancy-associated DIC tends to be more indolent and responsive to hemostatic adjuncts to address specific coagulation abnormalities.[119] This is an important patient management concept, as those patients with trauma and sepsis require vigilant efforts to determine if there is appropriate antibiotic coverage, source control, or need for procedure or operative intervention to prevent a vicious cycle of ongoing coagulopathy. Clinical trials are assessing if adjuncts to balance thrombin generation, such as soluble thrombomodulin[120–122] and antithrombin[123,124] or in combination,[123] are effective, but there is no definitive evidence for improvement in mortality with these treatment strategies at this time.[125] Additionally, prior work with activated protein C did not improve survival in DIC[126] despite promising early clinical observational studies. Ultimately the goal of management of DIC is treating the patient's underlying cause before they reach this level of critical illness.

KEY POINTS

- Early TIC is a distinct entity from DIC, but later TIC and DIC may share common features.
- Early TIC typically manifests as the inability to achieve hemostasis and is driven by a combination of inadequate thrombin generation, fibrinogen depletion, and platelet dysfunction.
- DIC is the result of inflammation-provoked hypercoagulability, resulting in increased tissue factor expression and widespread clot formation.
- Fibrinolysis shutdown can occur in both TIC and DIC, inhibiting the physiologic process of clot degradation.
- Viscoelastic hemostatic assays (TEG and ROTEM) provide the best assessment of the coagulation system.
- SIC is a new terminology based on platelet count, INR, and organ dysfunction and may progress to DIC.

Jaundice

Ryan Rodriguez and Marie Crandall

Bilirubin is a by-product of heme metabolism. Heme is largely derived from the hemoglobin in senescent red blood cells and is oxidized in the spleen, liver, and other organs by two isoforms of the enzyme heme oxygenase, in the presence of nicotinamide adenine dinucleotide phosphate (NADPH) and molecular oxygen, to form biliverdin, carbon monoxide, and iron.[1] Subsequently, biliverdin is converted into bilirubin by the phosphoprotein biliverdin reductase, which also uses NADPH as a cofactor. A visual representation of this pathway is shown in Fig. 23.1. Bilirubin is a lipophilic molecule. To be excreted, bilirubin that is produced in extrahepatic organs is bound to albumin and transported to the liver. The liver takes up the bilirubin – albumin complex through an albumin receptor. Bilirubin, but not albumin, is transferred across the hepatocyte membrane and transported through the cytoplasm to the smooth endoplasmic reticulum bound primarily to ligandin or Y protein, a member of the glutathione *S*-transferase gene family of proteins. Within hepatocytes, bilirubin is converted to water-soluble derivatives, bilirubin monoglucuronide and bilirubin diglucuronide, by the enzyme uridine diphosphate-glucuronosyl transferase. These conjugated forms of bilirubin are secreted across the canalicular membrane into the bile via an energy-dependent process. Conjugated bilirubin is excreted in the bile into the intestine, where it is broken down by the gut microflora into urobilinogen and stercobilin.

Total serum bilirubin consists of an unconjugated fraction and a conjugated fraction. The conjugated forms of bilirubin exist both freely in the serum and bound covalently to albumin. Conjugated bilirubin is water soluble and reacts directly to certain dyes added to the serum specimen. The unconjugated bilirubin does not react with the colorimetric reagents until a solvent is added. Accordingly, the conjugated and unconjugated forms of bilirubin are sometimes referred to as "direct" and "indirect" bilirubin. The sum of these two measurements is the "total" bilirubin. The normal total bilirubin concentration in adults is less than 18 μmol/L (1.0 mg/dL). Although any total bilirubin concentration higher than the upper limit of normal constitutes hyperbilirubinemia, jaundice (i.e., yellow discoloration of the sclerae, mucous membranes, and skin) is usually not clinically apparent unless the serum total bilirubin level is greater than 50 μmol/L (2.8 mg/dL). Unconjugated or indirect hyperbilirubinemia is present when the total serum bilirubin concentration is above the upper limit of normal and less than 15% of the total is in the direct or conjugated form.

DIFFERENTIAL DIAGNOSIS

The multitude of diagnoses depicted in Box 23.1 divides the causes of hyperbilirubinemia into two large groups according to whether the predominant abnormality is an increase in the circulating concentration of unconjugated (indirect) bilirubin or an increase in the concentration of conjugated (direct) bilirubin. Although this classification scheme is useful under some circumstances, many of the diagnoses listed in Box 23.1 are extremely rare and highly unlikely to be encountered by the intensivist caring for critically ill (adult) patients. A more useful classification scheme is depicted in Box 23.2. In this scheme, the causes of jaundice are grouped into three primary categories: extrahepatic obstruction to bile flow, increased bilirubin production, and impaired excretion secondary to hepatocellular necrosis and/or intrahepatic cholestasis and hepatitis. It is common for multiple mechanisms to be involved simultaneously.

Hyperbilirubinemia occurs frequently in critically ill patients and is an independent risk factor for an unfavorable outcome.[2,3] In a retrospective study of adult patients admitted to an intensive care unit (ICU) with severe sepsis or septic shock, the mortality rate was 12%, 24%, and 42% for individuals with a peak serum bilirubin concentration during the first 72 hours that was ≤1, 1.1–2, or >2 mg/dL, respectively.[4] In another retrospective study, hyperbilirubinemia was a significant risk factor for the development of acute respiratory distress syndrome (ARDS) among patients admitted to an ICU with sepsis.[5] In one widely cited study, hyperbilirubinemia occurred in 217 of 2857 trauma patients who had an Injury Severity Score greater than 14 and survived for longer than 48 hours after admission to the hospital.[6] In this study, hyperbilirubinemia was significantly associated with an increased length of stay in the ICU and death. Hyperbilirubinemia is also common in ICU patients who are recovering from cardiac surgery.[7,8] In this category of ICU patients, risk factors for the development of hyperbilirubinemia include prolonged cardiopulmonary bypass time, prolonged aortic cross-clamp time, and use of an intraaortic balloon pump.[8]

Determining the cause of new-onset hyperbilirubinemia is important when managing ICU patients because some problems can be corrected. Exclusion of a mechanical cause for jaundice (e.g., obstruction of the common bile duct because of choledocholithiasis or stricture) assumes the highest priority because failure to correct this type of problem in a timely fashion can lead to serious morbidity or even mortality. Fig. 23.2 shows an approach to handling new-onset hyperbilirubinemia in an adult patient. Hyperbilirubinemia is multifactorial, and although laboratory values evaluating the production and excretion of bilirubin can guide the workup, a liver biopsy or cholangiography is necessary when no other diagnosis can be confirmed.

Iatrogenic injuries to the common bile duct are fortunately quite rare. Damage to the biliary tree, stricture of biliary anastomoses, and retained stones after cholecystectomy or common bile duct exploration present as hyperbilirubinemia and elevated circulating levels of alkaline phosphatase or gamma-glutamyltransferase. Most often the diagnosis is made by detecting the dilation of intrahepatic and extrahepatic bile ducts using ultrasonography.

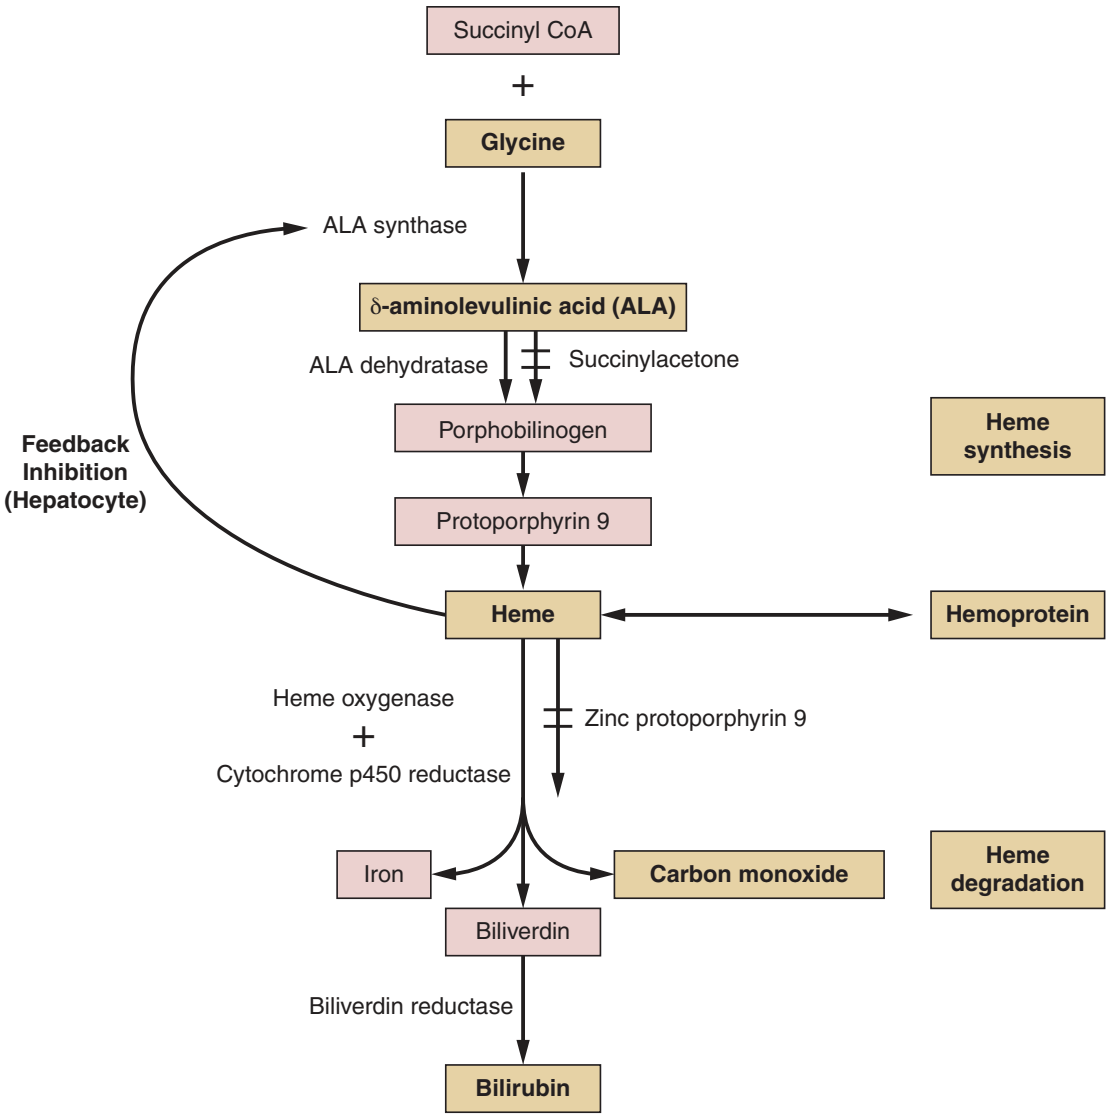

Fig. 23.1 Pathway, Regulation, and Inhibitors of Heme Metabolism. The first enzyme of the heme biosynthetic pathway, aminolevulinate (*ALA*) synthase (*ALAS*), is the rate-controlling enzyme of this pathway. Heme formation is subject to end-product regulation by negative feedback, but the exact point of metabolic control differs between hepatocytes and erythroid cells. In the liver, ALAS is regulated negatively by heme, the end product of the pathway. In contrast, in erythroid cells, ALAS is not under the same regulatory mechanism. Heme oxygenase (HO) is the rate-controlling enzyme of the heme degradation pathway. Succinylacetone (SA) is a potent inhibitor of ALA dehydratase activity. ZnPP9 is a potent inhibitor of HO activity. (From Tatsuya I, Chiang G, Ronnett GV. The regulation of heme turnover and carbon monoxide biosynthesis in cultured primary rat olfactory receptor neurons. *J Neurosci*. 1996;16:5621–5628, Fig. 3.)

By exceeding the capacity of the liver to conjugate and excrete bilirubin into the bile, hemolysis can result in jaundice. However, the liver can excrete approximately 300 mg/day of bilirubin,[9] and therefore clinically significant hyperbilirubinemia is only apparent if the rate of hemolysis (i.e., the number of red blood cells lysed per unit time) is fairly rapid. Approximately 10% of the erythrocytes in an appropriately cross-matched unit of packed red blood cells undergo rapid hemolysis, yielding about 250 mg of bilirubin.[10] Accordingly, transfusion of a single unit of packed red blood cells is not likely to increase the total serum bilirubin concentration. However, transfusion of multiple units of blood over a short period almost inevitably leads to some degree of hyperbilirubinemia, particularly if hepatic functionality is already impaired. Other common causes of acute hemolysis in ICU patients include sickle cell disease, immune-mediated hemolytic anemia, and disseminated intravascular coagulation.

Any condition that leads to extensive hepatocellular damage will increase the circulating total bilirubin concentration. Conditions in this category that are commonly encountered in ICU patients include viral hepatitis, "shock liver," alcoholic hepatitis, and hepatocellular injury induced by drugs, especially acetaminophen.[11] In most forms of jaundice resulting from hepatic inflammation or hepatocellular damage, circulating levels of transaminases are elevated to a greater extent than the total bilirubin concentration. Making a diagnosis of acetaminophen overdose early is extremely important because specific therapy using *N*-acetylcysteine can be lifesaving.[11]

BOX 23.1 Differential Diagnosis of Hyperbilirubinemia

A. Unconjugated hyperbilirubinemia
  1. Overproduction of bilirubin
    a. Hemolysis, intravascular: disseminated intravascular coagulation
    b. Hemolysis, extravascular
      i. Hemoglobinopathies
      ii. Enzyme deficiencies (e.g., glucose-6-phosphate dehydrogenase deficiency)
      iii. Autoimmune hemolytic anemias
    c. Ineffective erythropoiesis
    d. Resorption of hematoma
    e. Massive transfusion
  2. Hereditary unconjugated hyperbilirubinemia
    a. Gilbert syndrome (autosomal dominant)
    b. Crigler-Najjar syndrome type I (autosomal recessive)
    c. Crigler-Najjar syndrome type II (autosomal dominant)
  3. Drugs
    a. Chloramphenicol: neonatal hyperbilirubinemia
    b. Vitamin K: neonatal hyperbilirubinemia
    c. 5-Beta-pregnane-3 alpha, 20-alpha-diol: cause of breast milk jaundice
B. Conjugated hyperbilirubinemia
  1. Inherited disorders
    a. Dubin-Johnson syndrome (autosomal recessive)
    b. Rotor syndrome (autosomal recessive)
  2. Hepatocellular diseases and intrahepatic causes
    a. Viral hepatitis
    b. Alcoholic hepatitis
    c. Drug-induced hepatitis (e.g., because of isoniazid, nonsteroidal antiinflammatory drugs, and zidovudine)
    d. Cirrhosis
    e. Drug-induced cholestasis (e.g., because of prochlorperazine, haloperidol [Haldol], and estrogens)
    f. Sepsis
    g. Postoperative jaundice
    h. Infiltrative liver disease: tumors, abscesses (pyogenic, amebic), tuberculosis, parasites (e.g., *Toxoplasma*), *Pneumocystis jirovecii* pneumonia, *Echinococcus*
    i. Primary biliary cirrhosis
    j. Primary sclerosing cholangitis
  3. Extrahepatic causes
    a. Gallstone disease
    b. Pancreatitis-related stricture
    c. Pancreatic head tumor
    d. Cholangiocarcinoma
    e. Primary sclerosing cholangitis

BOX 23.2 Classification for Acute Jaundice Associated With Critical Illness

I. Extrahepatic bile duct obstruction
  A. Choledocholithiasis
  B. Common bile duct stricture
  C. Traumatic or iatrogenic common bile duct injury
  D. Acute pancreatitis
  E. Malignancy (e.g., ampullary carcinoma)
II. Increased bilirubin production
  A. Massive transfusion
  B. Resorption of blood collections (e.g., hematomas, hemoperitoneum)
  C. Acute hemolysis
    1. Disseminated intravascular coagulation
    2. Immune-mediated
III. Impaired excretion because of hepatocellular dysfunction, hepatitis, or intrahepatic cholestasis
  A. Drug- or alcohol-induced hepatitis
  B. Drug-induced intrahepatic cholestasis
  C. Drug-induced hepatocellular necrosis
  D. Gilbert syndrome
  E. Sepsis and other causes of systemic inflammation
  F. Total parenteral nutrition
  G. Viral hepatitis

Efforts to understand the pathophysiologic mechanisms responsible for cholestatic jaundice resulting from sepsis have largely focused on lipopolysaccharide (LPS)-induced alterations in the function and expression of various bile acid transporters.[12–14] Nevertheless, another factor that likely contributes to the development of intrahepatic cholestasis is the back-leakage of bile from the canalicular spaces into the sinusoids.[15]

SIDE EFFECTS OF TPN USAGE IN THE CRITICAL CARE SETTING

Malnutrition among hospitalized patients has been associated with increased morbidity, prolonged hospital stay, and increased costs to the healthcare system, but at times, an extended period of "nil per os (NPO)" status is one of the factors in current treatment algorithms for an extensive list of disease processes. Several studies have documented that "bowel rest" is associated with a disruption of the mucosal barrier structure and function, augmenting the inflammatory response to illness and resulting in greater infectious morbidity. Although this has been seen in some patient studies, total parenteral nutrition (TPN) as a temporary measure during these NPO periods has been shown to possibly reduce the complication rate in malnourished patients. As a consequence, nutritional support, most notably TPN, has become a standard of care for malnourished hospitalized patients.[16]

TPN has been shown to be associated with the development of hyperbilirubinemia.[17] The basis for TPN-induced cholestasis is thought to be multifactorial. Prolonged bowel rest and ileus may promote bacterial overgrowth and increased translocation of LPS into the portal vein on this basis. Phytosterols are present in the lipid emulsions used for TPN and have been associated with cholestasis, especially in premature infants.[18] Results from two retrospective studies suggest that the administration of more than 1 g/kg/day of lipid emulsion is associated with an increased incidence of hepatocellular dysfunction.[19,20] However, these data were derived from

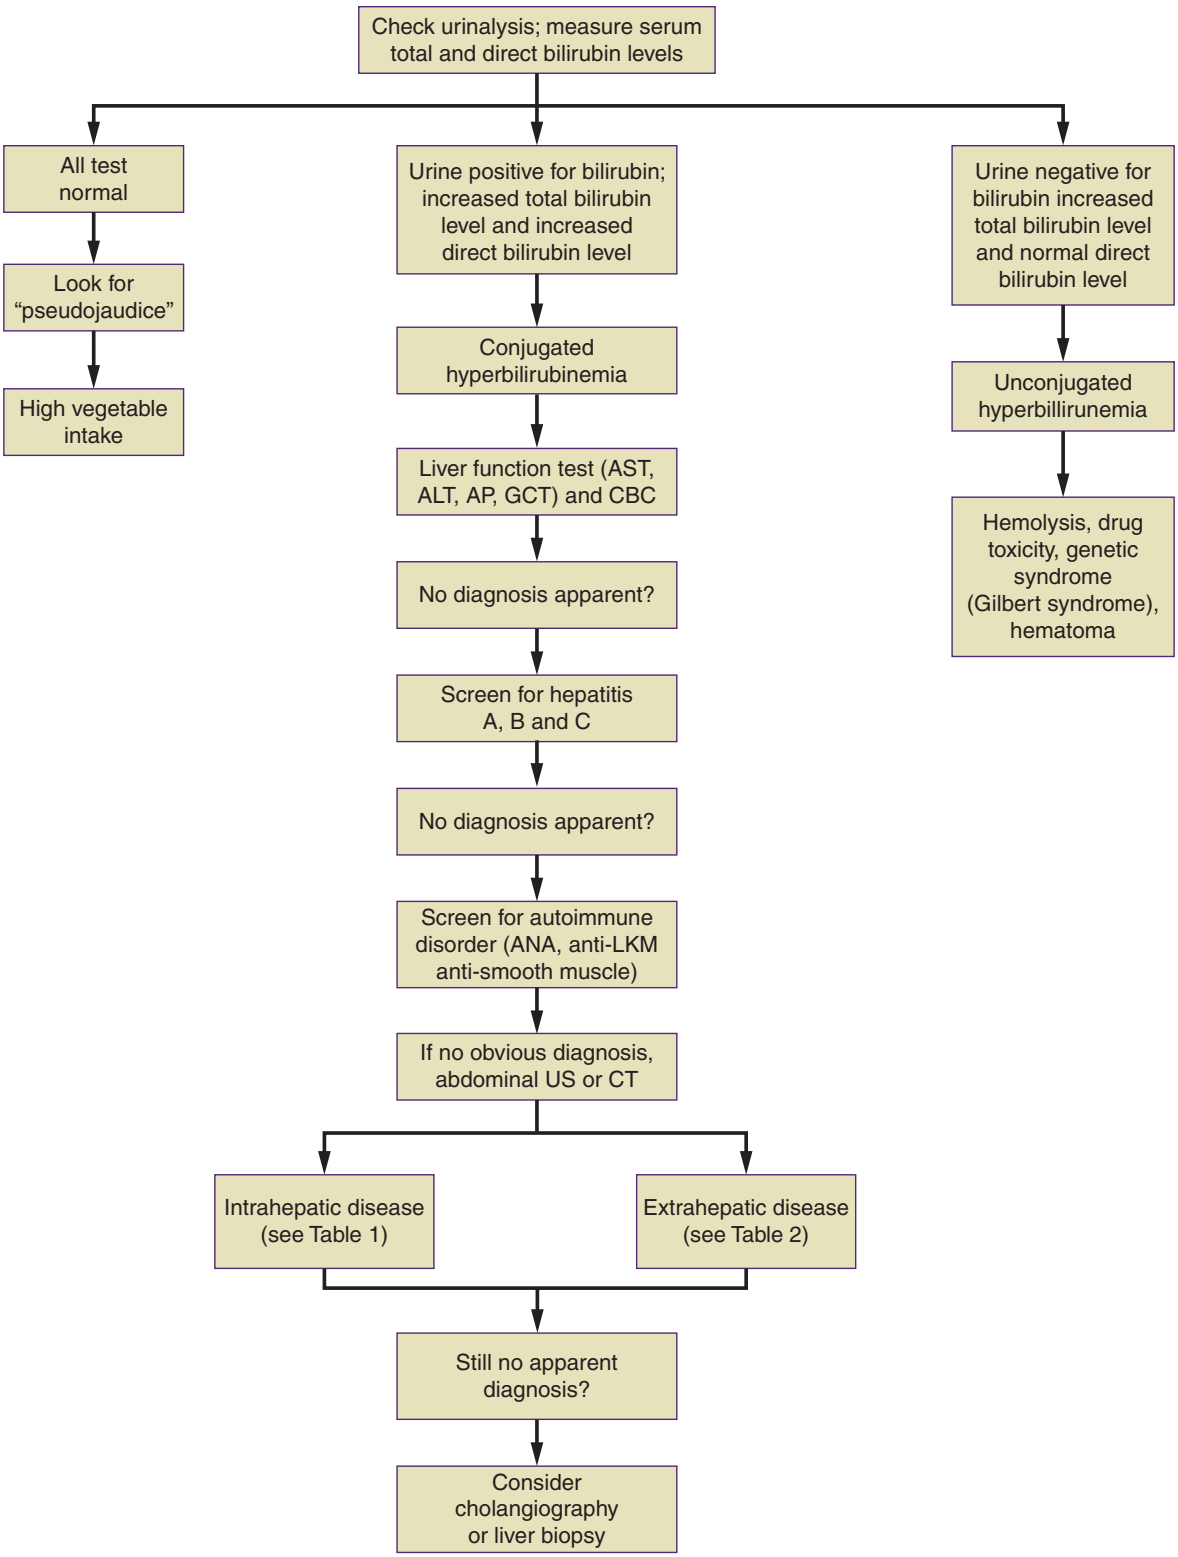

Fig. 23.2 Algorithm for a Systematic Approach to the Adult Patient with Jaundice. *ALT,* Alanine transaminase; *ANA,* antinuclear antibodies; *anti-LKM,* liver-kidney microsomal antibodies; *AP,* alkaline phosphatase; *AST,* aspartate transaminase; *CBC,* complete blood count; *CT,* computed tomography; *GGT,* gamma-glutamyltransferase; *US,* ultrasonography. (From Roche S, Kobos R. Jaundice in the adult patient. *Am Fam Physician*. 2004;69[2]:299–304, Fig. 1.)

studying patients receiving TPN at home for prolonged periods and may not apply to ICU patients. In any case, TPN is associated with the development of jaundice and hepatocellular damage. Accordingly, except in rare cases, the majority of ICU patients are better served by receiving enteral rather than parenteral nutrition.

KEY POINTS

- Heme is largely derived from the hemoglobin in aged red blood cells and oxidized in the spleen, liver, and other organs to produce bilirubin as a by-product.
- Total serum bilirubin consists of an unconjugated fraction and a conjugated fraction.
- Hyperbilirubinemia can be divided into unconjugated (hemoglobinopathies, enzyme deficiencies, autoimmune, certain drugs) vs. conjugated (viral hepatitis, alcoholic hepatitis, sepsis, postoperative, infiltrative liver disease).
- The normal total bilirubin concentration in adults is less than 18 mmol/L (1.0 mg/dL).
- Hyperbilirubinemia occurs frequently in critically ill patients and is an independent risk factor for an unfavorable outcome.
- The liver can excrete approximately 300 mg/day of bilirubin.
- TPN is associated with the development of hyperbilirubinemia.

ANNOTATED REFERENCES

Brienza N, Dalfino L, Cinnella G, et al. Jaundice in critical illness: promoting factors of a concealed reality. *Intensive Care Med.* 2006;32:267–274.
A study of jaundice in critically ill patients with severe shock, sepsis, and mechanical ventilation as risk factors for onset. There is no conclusive treatment, but supportive care and treatment of the underlying sepsis are thought to reduce the incidence and severity of critical care jaundice.

Cavicchi M, Beau P, Crenn P, et al. Prevalence of liver disease and contributing factors in patients receiving home parenteral nutrition for permanent intestinal failure. *Ann Intern Med.* 2000;132:525–532.
A study by Cavicchi et al. concluded that the prevalence of TPN-related liver disease increased with longer duration of parenteral nutrition, contributing highly to mortality in patients with permanent intestinal failure. However, parenteral intake of omega-6–rich, long-chain triglyceride lipid emulsions is recommended in these patients.

Chan S, McCowen KC, Bistrian BR, et al. Incidence, prognosis, and etiology of end-stage liver disease in patients receiving home total parenteral nutrition. *Surgery*. 1999;126:28–34.
There is increasing evidence demonstrating that chronic TPN-dependent patients have a higher incidence of severe liver disease. These patients require careful monitoring and may have minimal scope for long-term survival without transplantation of the liver or the small bowel.

Heyland DK, MacDonald S, Keefe L, et al. Total parenteral nutrition in the critically ill patient. *JAMA*. 1998;280(23):2013–2019.
The role of TPN in the critically ill patient is poorly understood. Daren et al. conclude that TPN does not influence the overall mortality rate of critically ill patients, though it may reduce the complication rate. This is especially true in malnourished patients.

Zhai R, Sheu CC, Su L, et al. Serum bilirubin levels on ICU admission are associated with ARDS development and mortality in sepsis. *Thorax.* 2009;64:784–790.
In a study of bilirubin levels in the ICU, it was noted that higher concentration of serum bilirubin is associated with subsequent development of ARDS and mortality in sepsis.

Ascites

Zarah D. Antongiorgi and Jennifer Nguyen-Lee

DEFINITION AND DIAGNOSIS

Whereas a normal peritoneal cavity contains only 25 mL of fluid, the peritoneum has the capacity to absorb 900 mL/day.[1] Ascites is the pathologic accumulation of peritoneal fluid, occurring most commonly in decompensated liver cirrhosis (85%), with malignancy, tuberculosis, heart failure, and pancreatitis accounting for the remainder.[2,3] The International Club of Ascites classifies ascites severity, with fluid detectable only on imaging (<100 mL) as grade 1, moderate symmetric abdominal distention with up to 1 L of fluid as grade 2, and tense distention associated with a large volume of fluid as grade 3.[4] Cirrhotic ascites can be uncomplicated or complicated, the latter involving concomitant development of spontaneous bacterial peritonitis (SBP), hepatorenal syndrome, or hepatic hydrothorax. Refractory ascites (5%–10% of cases) is persistent or rapidly recurring ascites despite maximal medical therapy.[4]

Symptoms of ascites include weight gain, abdominal pain, fullness, early satiety, and shortness of breath. History and physical examination looking for signs of liver disease or other underlying cause form the foundation of diagnostic evaluation. Detecting ascites on examination can prove difficult if <1500 mL is present. If flank dullness on percussion is not appreciated, there is a 90% chance no ascites is present.[5] Although computed tomography (CT) will identify ascites, ultrasound is the preferred imaging modality. It is a highly sensitive, low-cost, nonradiation-producing method that simultaneously allows evaluation of the liver and hepatic vasculature.

Patients with new-onset ascites should undergo diagnostic paracentesis, with removal of 20–30 mL for evaluation of fluid color, turbidity, and total protein and for calculation of the serum–ascites albumin gradient (SAAG).[6,7] A SAAG >1.1 g/dL is 97% accurate in identifying ascites resulting from portal hypertension (Table 24.1).[8] Infected ascites is a life-threatening complication, requiring timely assessment of the ascitic cell count and differential. A study of hospitalized patients with cirrhosis and SBP demonstrated a 3% increase in mortality for every hour that diagnostic paracentesis was delayed.[9] Fluid can be sent for triglyceride levels if chylous ascites is suspected, amylase for pancreatitis, cytology for malignancy, or *Mycobacterium* culture for tuberculosis.

PATHOPHYSIOLOGY

Portal hypertension from either increased hepatic resistance or increased portal blood flow is the key pathophysiologic event in the formation of ascites and is described in detail in Chapter 83. Normal portal venous pressure is <5 mm Hg. Once it is over 10 mm Hg, fluid from hepatic sinusoids and splanchnic capillaries overwhelms the peritoneal lymph drainage.[3,10,11] However, increased pressure is only one aspect of the pathophysiology, as fluid dysregulation and development of ascites results from a complex interplay of hemodynamic and hormonal responses.[7,12] In liver cirrhosis, hepatic sinusoidal congestion with progressive fibrotic transformation leads to endothelial cell dysfunction, causing nitric oxide–mediated vasodilation of splanchnic and peripheral arterial vascular beds. Initially, a hyperdynamic circulatory response compensates for the vasodilation to maintain adequate perfusion pressure. As vasodilation worsens and effective circulating volume decreases, however, compensatory activation of the sympathetic nervous and renin – angiotensin – aldosterone systems results in renal sodium and water retention, leading to fluid overload and hyponatremia (Fig. 24.1).[12–18] This process is hastened when infection from bacterial translocation causes endotoxin release, compounding vasodilation. Ultimately, tissue perfusion is compromised, leading to life-threatening organ dysfunction, the most salient being hepatorenal syndrome with decreasing glomerular filtration rate and severe renal vasoconstriction, as detailed in Chapter 84. In contrast to the mechanisms in cirrhosis, ascites in infection and malignancy is the result of inflammation and leakage of high-protein lymph.[3]

MANAGEMENT

After addressing underlying causes of cirrhosis, including alcohol cessation or hepatitis C treatment, ascites management is primarily focused on fluid removal. Initial treatment of cirrhotic ascites is salt restriction (no more than 2000 mg/day) and oral diuretics to promote natriuresis. The aldosterone antagonist spironolactone can be used alone, but the addition of the loop diuretic furosemide for patients with an inadequate response or moderate- to large-volume ascites is recommended.[19,20] Starting daily doses of 100 mg of spironolactone and 40 mg of furosemide achieve natriuresis without significant hypokalemia. Doses can be increased while maintaining the same ratio over 3–5 days to maximum daily doses of 400 mg of spironolactone and 160 mg of furosemide.[6,21] Initial goals of diuretic therapy are weight loss of 0.5 kg/day (or up to 1 kg/day in edematous patients) and a measured 24-hour sodium excretion of 78 mmol/day.[11,22] Side effects include intravascular volume depletion, renal insufficiency, and electrolyte abnormalities. If creatinine increases by more than 50% or more than 1.5 g/dL, or if sodium falls by more than 10 mEq/L, therapy should be adjusted.[22] Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided, not only because of the risk of renal injury but also because they impede diuretic-mediated sodium excretion.[23] Additionally, angiotensin-converting enzyme inhibitors and angiotensin receptor II antagonists should be used cautiously, given negative effects on arterial pressure and potential for worsening renal function.[6,21] Though more studies are needed, one small randomized controlled trial showed short term benefits of midodrine and adding midodrine 15-30 mg/day

TABLE 24.1 Causes of Ascites in the Normal or Diseased Peritoneum by Serum-to-Ascites Albumin Gradient (SAAG)

NORMAL PERITONEUM	
Portal Hypertension (SAAG >1.1 g/dL)	**Hypoalbuminemia (SAAG <1.1 g/dL)**
Hepatic congestion	Nephrotic syndrome
Congestive heart failure	Protein-losing enteropathy
Constrictive pericarditis	Severe malnutrition with anasarca
Tricuspid insufficiency	
Budd–Chiari syndrome	
Liver Disease	**Miscellaneous Conditions (SAAG <1.1 g/dL)**
Cirrhosis	Chylous ascites
Alcoholic hepatitis	Pancreatic ascites
Fulminant hepatic failure	Bile ascites
Massive hepatic metastases	Nephrogenic ascites
	Urine ascites
	Ovarian disease
DISEASED PERITONEUM (SAAG <1.1 g/dL)	
Infections	**Other Rare Conditions**
Bacterial peritonitis	Familial Mediterranean fever
Tuberculous peritonitis	Vasculitis
Fungal peritonitis	Granulomatous peritonitis
HIV-associated peritonitis	Eosinophilic peritonitis
Malignant Conditions	
Peritoneal carcinomatosis	
Primary mesothelioma	
Pseudomyxoma peritonei	
Hepatocellular carcinoma	

can be considered on a case-by-case basis, although no long term benefits have been shown to date.[6,24]

PARACENTESIS

Diuretics are started for initial control, but therapeutic paracentesis is indicated in settings of tense ascites to relieve abdominal pressure. The procedure is relatively safe when done under ultrasound guidance. Complications (<1%) include leakage of ascitic fluid, bleeding, infection, and bowel perforation.[25] Routine correction of thrombocytopenia or prolongation in the prothrombin time is not recommended, as paracentesis has been performed safely in patients with platelets <50,000/μL and international normalized ratio (INR) >2. In a retrospective study of 4729 procedures, the incidence of significant bleeding was relatively low (0.19%) despite coagulopathy in many patients.[26] The only real contraindication to paracentesis is disseminated intravascular coagulopathy, although other safety considerations include cooperation level of patient, pregnancy status, presence of bowel distention, and skin infection at insertion site.[21]

After removal of a large volume, paracentesis-induced circulatory dysfunction can result from effective hypovolemia with activation of the renin – angiotensin system, resulting in hyponatremia and renal impairment. When fluid removal exceeds 5 L, intravenous replacement of albumin is recommended (8 g/L of ascites removed), which is supported by data demonstrating improved survival.[27] Although large-volume paracentesis is time consuming and costly, benefits include improved patient comfort, shortened hospitalization, preserved hemodynamics, and a decreased risk of SBP and hepatic encephalopathy.[28]

PROGNOSIS AND COMPLICATIONS

Ascites signifies progression from compensated to decompensated liver failure and carries a 20% 1-year mortality.[29] Within the first decade of diagnosis, 50% of patients with cirrhosis will develop ascites.[30] Once complications such as refractory ascites or hepatorenal syndrome develop, yearly mortality increases to 75%.[31,32] Ascites features in a validated scoring system for liver failure, serving as one of five components of the Child-Turcotte-Pugh (CTP) score that also factors in encephalopathy, albumin, INR, and total bilirubin to predict mortality.[33] In a recent network meta-analysis of 49 randomized clinical trials with over 3500 patients investigating options for ascites management in decompensated liver cirrhosis, approximately one in three patients receiving a standard treatment of paracentesis followed by fluid replacement died within 11 months.[34] Though not a component of the current Model for End-Stage Liver Disease plus serum sodium score (MELD-Na) used in transplant allocation, the presence of moderate ascites correlates with a higher waitlist mortality for patients with MELD-Na scores <21 and is equivalent to an additional 3.5 MELD-Na unit points.[35] Given the poor prognosis, once ascites develops, patients should be evaluated for liver transplantation.

SPONTANEOUS BACTERIAL PERITONITIS

SBP occurs in 30% of patients with ascites, carries a 20% mortality rate, and is defined by[36]:

1. Positive bacterial culture (single organism)
2. Ascitic fluid polymorphonuclear cell count ≥250/mm^3
3. Absence of surgically treatable source of infection

SBP arises from translocation of intestinal bacteria, predominantly *Escherichia coli* and *Klebsiella*.[37] Common symptoms include fever, abdominal pain, nausea and vomiting, increasing encephalopathy, and decreased renal function. Prompt diagnostic paracentesis is indicated, with ascitic fluid sent for cell count, total protein, glucose, amylase, lactate dehydrogenase, Gram stain, and anaerobic and aerobic cultures. Cultures of ascitic fluid should be inoculated in blood culture bottles at the bedside to maximize chances of identifying a causative organism.[7,21] Patients with a low ascitic protein content (<1.5 g/L) are particularly at risk of developing SBP.[38] Treatment should start as soon as infection is suspected with a third-generation cephalosporin, such as ceftriaxone or cefotaxime, for a 5- to 7-day course.[6,21]

SBP should be differentiated from secondary bacterial peritonitis resulting from abscess or perforated viscus, as treatment is substantially different. Secondary bacterial peritonitis should be suspected if ascitic fluid analysis has a glucose <50 mg/dL, elevated lactate dehydrogenase, or polymicrobial culture results.[39] Further workup includes upright plain films, CT with water-soluble contrast, and surgery consultation.

After an initial SBP event, the chance of a repeat infection is 70%.[40] A meta-analysis of eight studies with 647 patients investigating antibiotic prophylaxis to prevent recurrent SBP demonstrated an overall mortality of 16% in the antibiotic group versus 25% for the control. Statistically significant improvements were seen in rates of reinfection and in a 3-month survival benefit.[41] Oral prophylaxis with norfloxacin

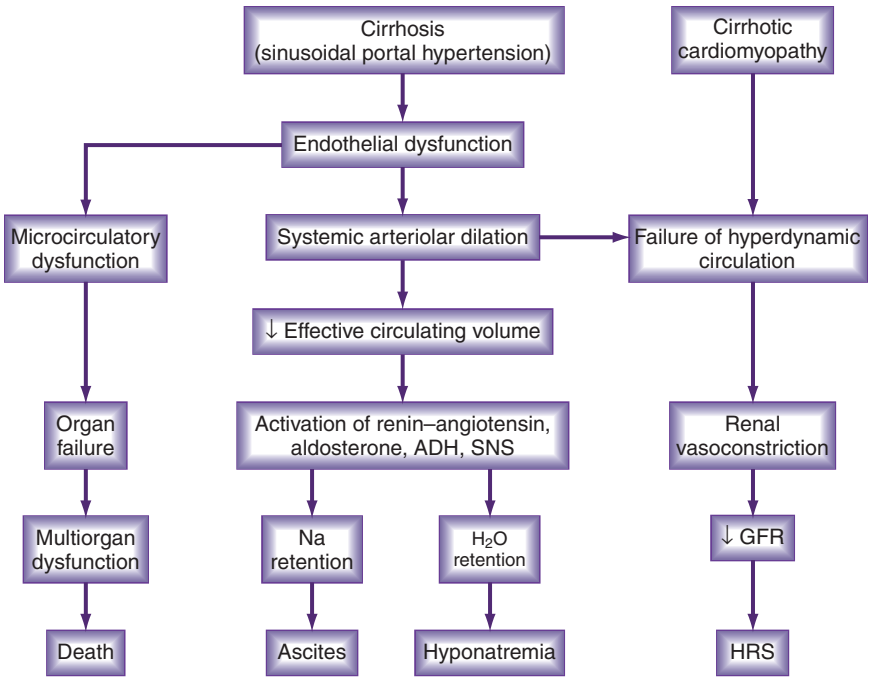

Fig. 24.1 Pathophysiology of Cirrhosis and Ascites. Cirrhosis is associated with splanchnic arterial vasodilation, leading to a decrease in effective circulating volume and a hyperdynamic circulation. The decrease in effective circulating volume causes the activation of renal sodium and water retentive pathways (e.g., RAAS, renal SNS, and ADH). Resulting sodium and water retention leads to ascites because of the spillage of excess sodium and water from hepatic lymph into the peritoneal cavity. As the disease progresses, a progressive decrease in effective circulating volume develops, causing severe renal vasoconstriction and a decrease in glomerular filtration rate (*GFR*). The onset of cirrhotic cardiomyopathy accentuates this problem and tips the patient over into hepatorenal syndrome (*HRS*). The accompanying circulatory disturbance leads to organ failure and death. Sepsis is frequently associated with this process. *ADH,* Antidiuretic hormone; *RAAS,* renin–angiotensin system; *SNS,* sympathetic nervous system. (From Salerno F, Camma C, Enea M, et al. Transjugular intrahepatic portosystemic shunt for refractory ascites: a meta-analysis of individual patient data. *Gastroenterology*. 2007;133:825–834.)

or trimethoprim/sulfamethoxazole is recommended for patients after one SBP episode and for those with active gastrointestinal bleeding, a low-protein ascitic fluid (<1.5 g/dL), impaired renal function (creatinine [Cr] ≥1.2 mg/dL), or liver failure (CTP score ≥9 and bilirubin ≥3).[6]

Refractory Ascites

Refractory ascites is diagnosed when maximal medical management for at least 1 week or repeated large-volume paracenteses within 4 weeks are insufficient to remove ascites.[15] Diuretic failure results from resistance to or complications from therapy, including renal impairment or electrolyte perturbations (hypokalemia or hyperkalemia, hyponatremia). Refractory ascites carries a mortality of 21% at 6 months and 70% at 2 years, so expedited evaluation for liver transplantation is indicated.[42] Treatment consists of serial therapeutic paracentesis, transjugular intrahepatic portosystemic shunt (TIPS), or liver transplantation (Table 24.2).

TIPS involves percutaneous placement of an expanding metal stent within an artificially created channel that diverts portal blood flow into the hepatic veins, thus decreasing portal hypertension and ascites. Consideration for TIPS occurs once patients require more than two large-volume paracenteses in a month. Complications include stent occlusion, worsened liver failure, heart failure, infection, renal failure, and increased hepatic encephalopathy. In a meta-analysis of TIPS versus repeated paracentesis aggregating six randomized controlled trials with a total of 390 patients, TIPS was shown to significantly improve liver transplant–free survival (hazard ratio [HR] = 0.61, 96% confidence interval [CI] 0.46–0.82, $P < .001$).[43] This is different from a previous Cochrane review of five randomized control trials dating from 1996 to 2004 comparing 162 patients who showed no difference in 30-day or 2-year mortality. However, patients who underwent TIPS showed a significant increase in hepatic encephalopathy (odds ratio [OR] 2.24, 95% CI 1.39, $P < .01$).[44] Selection of patients for TIPS is key. It is not recommended if bilirubin is >5 mg/dL, age >70 years old, MELD score >18, or CTP score >12.[45,46]

First tested in patients in 2010, the Automated Low-Flow Ascites Pump (ALFApump, Sequana Medical AG, Switzerland) is a surgically implanted device that drains ascites into the bladder. Ascites is directed from the abdominal cavity, out a peritoneal catheter, through a subcutaneous pump, and into a bladder catheter. Once in the bladder, the ascitic fluid can be eliminated out of the body through urination.[47] Between February 2010 and June 2011, 40 patients in multiple European centers underwent placement of an ALFApump for refractory ascites. Significant adverse events included infection, catheter dislodgement, and wound dehiscence leading to explantation of the device in 13 of the 40 patients.[48] In one single-center study of 21 patients, the ALFApump was successful in reducing the need for paracentesis, but was similarly limited because of the high rate of complications (15 of 21 patients), including catheter leakage, infection, and explantation.[49] The ALFApump is effective, and improvements in surgical technique could improve its safety profile. It could be a viable palliative treatment for patients with contraindications to TIPS or liver transplantation in select patient populations.

TABLE 24.2 Management of Refractory Ascites

Definitions	Ascites that is not eliminated even with maximum diuretic therapy Ascites that is not eliminated because maximum dosages of diuretics cannot be attained, given the development of diuretic-induced complications
Recommended therapy	Large-volume paracentesis + IV albumin (8 g/L of ascites), especially if more than 5 L ascites are removed Synthetic plasma volume expanders are not recommended Continue with salt restriction and diuretic therapy as tolerated to prevent ascites reaccumulation
Alternative therapy	TIPS for appropriately selected patients who require repeated paracenteses (>2 per month) or those in whom paracentesis is ineffective (i.e., loculated) ALFApump for patients who are not candidates for TIPS or liver transplant

Data from European Association for the Study of the Liver. EASL Clinical Practice Guidelines for the management of patients with decompensated cirrhosis. *J Hepatol.* 2018;69(2):406–460. Erratum in: *J Hepatol.* 2018;69(5):1207.
IV, Intravenous; *TIPS,* transjugular intrahepatic portosystemic shunt.

KEY POINTS

- Ascites is most commonly the result of liver disease and has a 20% yearly mortality.
- Diagnostic paracentesis should be performed in all patients with new ascites to differentiate between ascites secondary to portal hypertension (SAAG >1.1 g/dL) from other conditions.
- Medical management includes sodium restriction and oral diuretics, usually starting with spironolactone 100 mg and furosemide 40 mg daily.
- SBP is a life-threatening complication, and treatment should begin promptly with a third-generation cephalosporin as soon as infection is suspected.
- Treatment options for refractory ascites include serial paracentesis, TIPS, or ALFApump, but expedited evaluation for liver transplantation should also begin for appropriate candidates.

This updated meta-analysis of six randomized controlled trials with 390 patients showed a significant improvement of transplant-free survival of cirrhotic patients with refractory ascites, decreased ascites recurrence, and improved hepatorenal syndrome despite a significantly higher number of hepatic encephalopathy episodes in the TIPS group.

European Association for the Study of the Liver. EASL Clinical Practice Guidelines for the management of patients with decompensated cirrhosis. *J Hepatol.* 2018;69(2):406–460. Erratum in: *J Hepatol.* 2018;69(5):1207.
This comprehensive review provides evidence-based recommendations for management of the patient with decompensated cirrhosis, including management of ascites, refractory ascites, SBP, and other complications, including hepatorenal syndrome.

Saab S, Hernandez JC, Chi AC, et al. Oral antibiotic prophylaxis reduces spontaneous bacterial peritonitis occurrence and improves short-term survival in cirrhosis: a meta-analysis. *Am J Gastroenterol.* 2009;104:993–1001.
This meta-analysis of eight prospective clinical trials with a total of 647 patients randomized to oral antibiotic prophylaxis for SBP compared with placebo or no intervention documented an overall mortality benefit (RR = 0.65; 95% CI 0.48–0.88) for antibiotic treatment groups. The overall mortality rate was 16% for treated patients and 25% for the control cohort. Groups treated with prophylactic antibiotics also demonstrated a lower incidence of all infections (including SBP) of 6.2% compared with the control group rate of 22.2% (RR = 0.32; 95% CI 0.20–0.51).

Acute Abdominal Pain

Marcus K. Hoffman and S. Rob Todd

INTRODUCTION

Diagnosing acute abdominal pain in critically ill patients can be difficult if the clinician tries to work through a comprehensive list of differential diagnoses (Fig. 25.1). The most common etiologies seen outside of the intensive care unit (ICU) also occur within it, but other diagnoses must be considered. Certain patient populations to include trauma patients, postoperative patients, and those who are immunosuppressed, to name a few, should illicit even broader differential diagnoses. This chapter focuses on the difficulties in diagnosing acute abdominal pain in the critically ill patient, highlighting those diagnoses most relevant in this population.

INITIAL APPROACH

The top diagnoses on the differential list are rather different for patients who present to the hospital with acute abdominal pain and are critically ill than for those patients in an ICU who develop acute abdominal pain. Paramount to narrowing down the differential diagnosis for acute abdominal pain for either scenario is gathering as much information as reasonably possible. For patients presenting with abdominal pain, the history of the present illness with associated symptoms can be revealing. Providers should query the past medical history, current medications, prior surgical procedures, prior hospitalizations, and any recent courses of antibiotics. For those hospitalized critically ill patients who develop abdominal pain, a thorough understanding of their hospital course to date will help reorder a blind differential diagnosis. For patients in an ICU, the bedside nurse can be a wealth of knowledge, especially when patients are intubated or have altered sensorium. Events in the preceding 24 hours may likely be the trigger for acute abdominal pain.[1] For example, diffuse abdominal pain after paracentesis or drain placement by interventional radiology might be concerning for an unsterile procedure seeding the abdomen or for iatrogenic bowel perforation. Mesenteric artery embolism is a rare complication of percutaneous coronary angioplasty.

PHYSICAL EXAMINATION

In certain disease pathologies, the physical examination is not especially enlightening, but in others, the diagnosis might be made without further workup. For example, septic shock may develop from strangulated inguinal or incisional hernias with ischemic or necrotic bowel driving the underlying pathobiology. All surgical scars should be noted, as they may add or remove some of the diffferential diagnoses (internal hernia after gastric bypass surgery or acute cholecystitis after cholecystectomy as respective examples). Furthermore, pointing out surgical scars is sometimes the cue necessary for patients or family members to recall past surgical procedures not initially reported. Right upper quadrant (RUQ) tenderness may be indicative of biliary pathology. Suprapubic pain may be indicative of genitourinary causes of illness. All tubes, drains, and catheters present should be inspected for location and quality and quantity of output. Finally, an assessment of the patient's vital signs and any hemodynamic-altering medications are important.

DIAGNOSTIC ADJUNCTS

The evaluation of critically ill patients with abdominal pain almost universally entails obtaining laboratory and imaging studies based on the history and physical examination. Laboratory studies include, yet are not limited to, complete blood counts with leukocyte differentials, comprehensive metabolic panels including a liver function panel with conjugated bilirubin, coagulation studies, arterial or venous blood gases, and lactic acid measurements. Additional diagnostic studies to consider include urine analysis and cultures, blood cultures, stool cultures, and *Clostridium difficile* toxin assays if there is a concern for that infection.

Radiographic adjuncts include plain radiographs, ultrasonography, computed tomography (CT), and nuclear imaging studies. Plain radiographs may prove useful in diagnosing a perforated viscus (perforated ulcer or diverticulitis), cecal or sigmoid or volvulus, or toxic megacolon. Ultrasonography is the modality of choice if a biliary pathology or ovarian torsion is suspected. The mainstay of imaging modalities is the CT scan of the abdomen and pelvis, with intravenous (IV) contrast when possible. For critically ill patients being evaluated for acute abdominal pain, enteral contrast adds little in diagnostic value, but frequently delays the acquisition of images while exposing the patient to the risk for aspiration. Enteral contrast may be useful if the patient had an intraabdominal operation with anastomosis of gastrointestinal tract within the last 2–3 weeks and there is a concern for anastomotic leak or if there is a concern for esophageal perforation or peptic ulcer perforation.

DIFFERENTIAL DIAGNOSIS BASED ON PHYSICAL EXAMINATION FINDINGS

Peritonitis

Peritonitis is defined as inflammation of the peritoneal cavity at the mechanistic level, but, in clinical vernacular, peritonitis refers to abdominal pain on palpation that spans all quadrants. The overwhelming majority of cases of peritonitis are secondary to gastrointestinal (GI) tract perforation. Peritonitis with chest or abdominal radiographs demonstrating free air under the diaphragm may be sufficient to warrant surgical exploration. Critically ill patients presenting to the emergency center most commonly have a perforated gastroduodenal

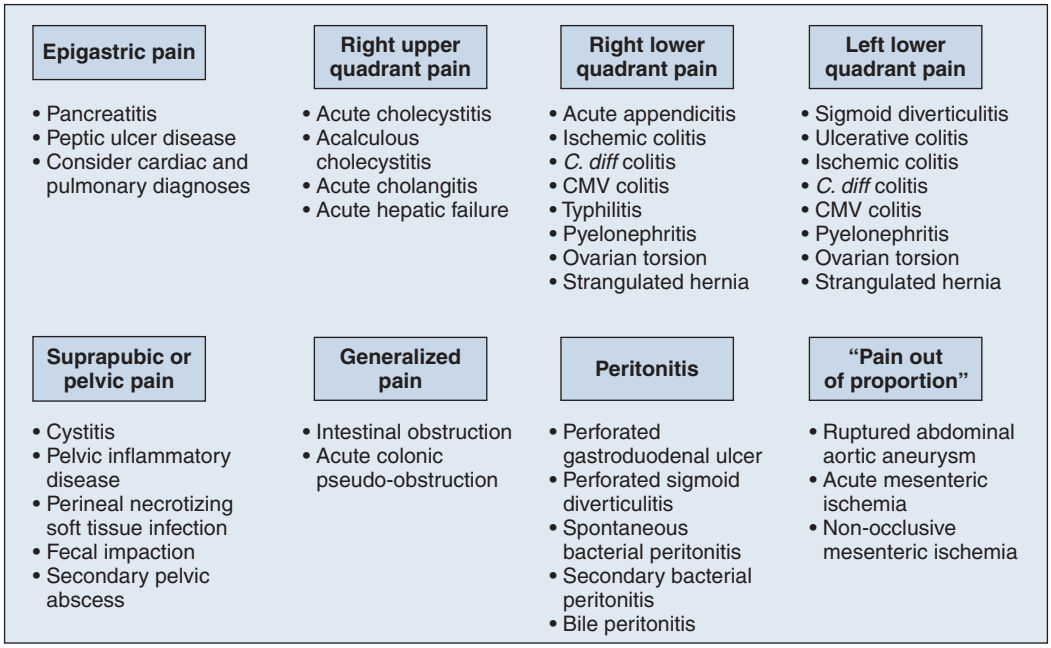

Fig. 25.1 Acute Abdominal Pain. Differential diagnosis based on physical examination findings. *C diff, Clostridium difficile; CMV,* cytomegalovirus.

ulcer or perforated sigmoid diverticulitis. Peritonitis and pneumoperitoneum in the ICU patient can be the result of perforation of any location in the GI tract.[2] It is frequently a late presentation of abdominal pain, especially if that pain cannot be communicated to medical staff for a variety of reasons, including intubation, sedation, and/or altered sensorium. If pneumoperitoneum is not present on the plain radiograph, the evaluation most typically proceeds to a CT of the abdomen and pelvis, where pneumoperitoneum or other stigmata of perforation are appreciated. Pneumoperitoneum can be seen for up to a week after laparotomy, laparoscopy, or percutaneous endoscopic gastrostomy (PEG) tube placement but frequently resolves within 3 days. Aside from expected pneumoperitoneum after PEG insertion or possibly attributed to barotrauma, any pneumoperitoneum with abdominal pain or clinical demise should prompt an urgent surgical consult.

In patients with cirrhosis and any degree of ascites, spontaneous bacterial peritonitis (SBP) must be considered and treated appropriately. A diagnostic paracentesis may aid in directing antimicrobial therapy. For patients with end-stage renal disease who undergo peritoneal dialysis, secondary bacterial peritonitis can occur because of unsterile dialysis technique or catheter damage. Intraperitoneal antibiotic treatment via catheter is a viable treatment option.[3] Finally, patients presenting after a cholecystectomy or liver biopsy can develop bile peritonitis from slow, progressive biliary leakage into the abdominal cavity, but are also at risk for iatrogenic intestinal injury during the aforementioned procedures.

"Pain Out of Proportion"

At the other end of the spectrum from peritonitis are patients who report severe pain, yet their physical examination does not elicit a significant response, classically referred to as "pain out of proportion." If this scenario arises and there is a palpable abdominal mass, the greatest diagnostic concern is a ruptured abdominal aortic aneurysm (AAA). Although an AAA can be diagnosed using ultrasonography, the imaging modality of choice remains CT.[4] This provides meaningful data that can be used to plan an endovascular repair. In the critically ill population, most cases of pain out of proportion are acute mesenteric ischemia, with the likely cause being embolic disease from atrial fibrillation. In such instances, laboratory studies may reveal a reactive leukocytosis and/or elevated lactic acid levels. A CT scan with IV contrast may reveal differences in bowel wall enhancement, a lack of IV contrast within the vasculature, or nonspecific findings such as intraperitoneal fluid. Early surgical consultation is warranted, as ischemia can be reversed if intervention occurs in a timely fashion.[5] Acute mesenteric ischemia from superior mesenteric artery occlusion can begin a sequence of ultimately fatal events if the entire small intestine is irreversibly ischemic at surgical exploration. Nonocclusive mesenteric ischemia is similar to acute mesenteric ischemia in that the bowel is not receiving adequate blood flow relative to what is being demanded. This supply-demand mismatch can be seen in cardiogenic shock or high-dose vasopressor use with enteral nutrition and seen in hemodialysis patients eating immediately after a dialysis session. A CT scan in this scenario may not show any of the findings noted earlier with acute mesenteric ischemia but may reveal pneumatosis intestinalis. First steps are to stop enteral feeds for heart failure and patients on high-dose vasopressors and to make sure dialysis patients are not hypotensive. Surgical exploration may not be warranted if abdominal pain has resolved and the patient is not clinically worsening, but pneumatosis intestinalis warrants surgical consultation.

Epigastric Pain

Epigastric pain in the critically ill patient can be the result of a wide variety of causes. Extraabdominal sources must be considered and evaluated, including pulmonary and cardiac pathologies. Epigastric pain and tenderness to palpation in the critically ill patient in the emergency setting without antecedent history should be evaluated for pancreatitis, to include a hepatic function panel, amylase and lipase, and a CT scan of the abdomen and pelvis.[6] The same presentation but with a recent history of pain that worsens is concerning for gastroduodenal ulceration, which may have perforated within the last few hours but has yet to result in peritonitis. A CT scan with oral contrast of the abdomen and pelvis may be useful in this latter scenario, as it can delineate the ulceration into the wall or demonstrate containment of a perforation.

Right Upper Quadrant Pain

As the primary occupant of the RUQ, the hepatobiliary system accounts for the most common causes of pain in this location. Any evaluation should begin with laboratory studies, including a hepatic function panel with total and direct bilirubin, in addition to gamma-glutamyl transpeptidase (GGTP). The imaging modality of choice is ultrasonography, looking for intrahepatic duct dilation, common bile duct diameter, gallbladder wall thickness or surrounding fluid, and biliary stones or sludge in the biliary system. Lack of findings on ultrasonography should prompt a CT scan of the abdomen and pelvis for further evaluation. Acute cholecystitis leads the differential list for critically ill patients in both the emergency center and ICU. Patients in the ICU setting receiving total parenteral nutrition (TPN) or vasopressors are especially at risk for acalculous cholecystitis.[7] Confirmation can be made by hepatobiliary iminodiacetic acid (HIDA) scan, but this imaging modality requires that the patient be stable enough to spend over 1–3 hours in the radiology department and has a high false-positive rate in the setting of prolonged bowel rest. Fevers, chills, and RUQ pain should raise concern for acute cholecystitis or cholangitis. Obligatory mention must be made of Charcot triad (jaundice, fevers, and RUQ pain) and Reynolds pentad (addition of hypotension and altered mental status), but note that although these are highly specific, they have extremely low sensitivities. Patients with significant physiologic reserve are candidates for endoscopic retrograde cholangiopancreatography (ERCP) and cholecystectomy for acute cholangitis and acute cholecystitis, respectively. For those patients who are too ill to undergo general endotracheal anesthesia, a cholecystostomy tube will temporize acute cholecystitis. The vast majority of patients with cholangitis respond to administration of antibiotics and resuscitation, but for those still too ill for ERCP, the intrahepatic biliary system can be decompressed via percutaneous transhepatic cholangiography (PTC) with tube placement for external drainage.[8]

Finally, patients with acute hepatic failure can develop RUQ pain as the liver swells from injury. This is commonly misdiagnosed as acute cholecystitis, as ultrasonography will demonstrate pericholecystic fluid and possibly wall thickening, but this is in the setting of the whole liver being edematous and swollen.[9] The distinguishing difference is that the patient is tender along the whole subcostal region of the liver, as opposed to only being tender at the location of the gallbladder. In acute hepatic failure or cirrhosis, HIDA scans are not especially helpful because of issues with initial hepatic uptake and thus should not be used for working up cholecystitis.

Right Lower Quadrant Pain

Discussions of right lower quadrant pain reflexively focus on appendicitis. Although appendicitis can cause severe illness if it festers for long enough untreated outside of the hospital, it is extremely rare in ICU patients. More commonly, the cecum and ascending colon develop various types of colitis. Ischemic colitis can result from embolic disease or low flow in the setting of high-dose vasopressors.[10] Not infrequently, these are diagnosed by either CT imaging with IV contrast or intraoperatively when patients continue to decompensate. Infectious colitis occurs secondary to a wide array of pathogens. *C. difficile* colitis results from prior antibiotic exposure, yet typically presents with more diarrheal complaints than abdominal pain. Cytomegalovirus (CMV) colitis is seen in immunosuppressed patients, specifically transplant patients. Neutropenic enterocolitis, also referred to as *typhlitis,* is almost exclusively described in the ascending colon of immunocompromised patients with profound neutropenia. The pathophysiology is thought to be bacterial invasion of the bowel wall. Treatment of the infectious colitis types listed begins with antibiotics specific to *C. difficile*, antiretrovirals active against CMV, and broad-spectrum antibiotics, respectively.[11]

Pyelonephritis, possibly with urosepsis, most commonly presents as right (or left) lower quadrant pain wrapping around to the back. In young females, lower quadrant pain is also concerning for ovarian torsion. Ultrasonography is the diagnostic modality of choice, as Doppler imaging can determine if arterial flow is present. Finally, strangulated hernias can present as lower quadrant pain causing critical illness, typically the result of physiologic effects of bowel necrosis. These may be clinically palpable and tender hernias, such as an inguinal hernia, or they may be more difficult or sometimes impossible to palpate, such as a femoral hernia, Spigelian hernia, or obturator hernia.

Left Lower Quadrant Pain

Left lower quadrant pain in the critically ill patient has an almost identical differential diagnosis as right lower quadrant pain, excluding appendicitis and neutropenic enterocolitis. Similar to appendicitis being the reflex thought in right lower quadrant pain, most providers reflexively think of diverticulitis with left lower quadrant pain. Patients may be critically ill upon presentation with diverticulitis, but this common presentation usually occurs with overall peritonitis on examination. Development of diverticulitis in ICU patients is a rare event, given that most patients are on enteral feeds and have bowel regimens. Although fulminant or toxic ulcerative colitis can present as right lower quadrant pain, it most commonly presents as left lower quadrant pain progressing to generalized abdominal pain as it advances from distal to proximal. For fulminant ulcerative colitis, emergent surgery is reserved for massive hemorrhage, perforation, or peritonitis; otherwise, high-dose IV steroids are the mainstay of initial therapy.[12]

Colonic ischemia resulting from endovascular or open AAA repairs most frequently presents as left lower quadrant pain. It is typically a crampy abdominal pain with loose bowel movements (with or without blood present). Abdominal tenderness in the left lower quadrant is especially concerning for transmural ischemia. Suspicion and prompt evaluation are of the utmost importance, as associated mortality is around 50% but increases up to 90% with delay in diagnosis.[4] Flexible sigmoidoscopy is employed to confirm the diagnosis. A worsening physical examination or overall status prompts surgical exploration to evaluate for transmural necrosis.

Suprapubic or Pelvic Pain

Suprapubic or pelvic pain most commonly occurs with cystitis or pelvic inflammatory disease; however, these do not frequently cause critical illness in otherwise healthy individuals. For patients presenting to an emergency center critically ill with suprapubic pain, patients must be examined for a possible necrotizing soft tissue infection of the perineum or genitals, which can extend up onto the abdominal wall.[13] In the ICU patient with suprapubic pain, cystitis and fecal impaction should be evaluated and treated appropriately. Finally, pelvic abscesses from other intraabdominal pathologies can occur.

Generalized, Nonspecific Abdominal Pain

Intestinal obstruction often presents with acute, diffuse, crampy abdominal pain coupled with nausea and vomiting, obstipation, distention, and tenderness to palpation. Obstruction can be partial or complete and can involve the small or large intestine. Obtaining an adequate history of previous surgeries and colonoscopies is important. Obstruction may be the result of adhesions or incisional hernias from prior surgical procedures. Fever, leukocytosis, and lactic acidosis are concerning for intestinal ischemia resulting from obstruction or herniation.[14] Plain radiographs will demonstrate air-fluid levels and dilated bowel (small or large). A CT scan of the abdomen and pelvis with oral contrast can often identify a transition point or other causes of obstruction like

volvulus or intussusception. Decreased intestinal wall enhancement on CT, peritoneal signs, and leukocytosis are predictive of intestinal ischemia in patients with small bowel obstructions and should prompt surgical exploration. Nonoperative management may be appropriate with nasogastric decompression and bowel rest. However, in bowel obstructions that do not resolve or have signs of ischemia present, surgical management is imperative.

Acute colonic pseudo-obstruction (Ogilvie syndrome) characteristically has significant dilation of the cecum and right colon without any anatomic obstruction. There is a strong association with opiate administration. Lower abdominal pain coupled with constipation, distention, nausea, vomiting, and paradoxical diarrhea are common. CT confirms the diagnosis by excluding evidence of mechanical obstruction or toxic megacolon resulting from colitis. Treatment consists of correcting any electrolyte abnormalities, decompressing the stomach, and avoiding narcotics. The anticholinesterase inhibitor neostigmine may be effective for colonic decompression but requires cardiac monitoring and should be used with caution in patients with asthma or cardiac abnormalities and the elderly.[15] Colonoscopic decompression should be attempted when supportive measures fail.[16] If decompression fails, worsening colonic distention can compromise bowel wall viability, seen as cecal ischemia and necrosis requiring colon resection.

Abdominal pain in the critically ill patient has a vast array of causes. A proper history and physical examination may give clues as to the specific cause. Aside from hepatobiliary pathology and ovarian torsion, CT is the mainstay of imaging. Oral contrast adds minimal additional information. Critically ill patients with abdominal pain warrant a prompt surgical consultation.

KEY POINTS

- The history of present illness, past medical history, physical examination, and antecedent hospital course can rapidly narrow down the differential diagnosis in acute abdominal pain in the critically ill patient.
- Laboratory values, plain radiographs, and CT scans are the mainstay of evaluating acute abdominal pain.
- Ultrasonography is most useful in evaluating pathologies of the hepatobiliary and genitourinary systems.
- Peritonitis is concerning for bowel perforation, and the radiographic evaluation should be initiated with an upright radiograph.
- "Pain out of proportion" is most concerning for acute mesenteric ischemia.
- Lower quadrant pain may be the result of genitourinary causes, but is most commonly the result of colonic pathologies.

Ileus in Critical Illness

Stephen A. McClave and Endashaw Omer

INTRODUCTION

Evidence of ileus, gastroparesis, or small bowel dysmotility is common in the setting of critical illness. Data on the incidence of ileus estimate an occurrence ranging from 50% to 80% in critically ill patients,[1] with an average incidence of 38%.[2] In the postoperative surgical intensive care unit (ICU), evidence of postoperative ileus ranges from 24% to 75%.[3] Ileus can affect the entire gastrointestinal (GI) tract or just a segment, from the proximal gut, to the small bowel, to the colon. Definitions are poorly standardized and can be vague and elusive. Usually, ileus is characterized clinically by hypoactive or absent bowel sounds, abdominal distention, and delayed passage of stool and gas, but the process may involve nausea, vomiting, and abdominal tenderness. Objective measurements are limited mostly to research tools such as measuring gastric emptying by acetaminophen absorption tests or passage of radiolabeled carbon compounds, or small intestinal manometry. When present, ileus in critical illness has been shown to be associated with nutritional deficits, greater risk of aspiration, sepsis, prolonged mechanical ventilation, and increased allocation of healthcare resources.[4–6] Although similarities exist between the ileus of critical illness and postoperative ileus in the surgical ICU patient, the precipitating factors are different. These entities share similar pathophysiologic patterns, and both are usually self-limited, tending to resolve spontaneously within days.

Many aspects of ileus are counterintuitive.[7] Bowel sounds are not needed or required to initiate nutritional therapy, as recommended by the societal guidelines.[8] A nasogastric tube placed for gastric decompression in postoperative ileus would be expected to benefit the surgical patient, but instead actually worsens outcome by increasing the incidence of pneumonia and atelectasis and leading to slower return of GI function.[9] Surprisingly, gastric feeding is well tolerated in over 90% of critically ill patients.[10–13] When the level of infusion of formula within the GI tract is diverted from the stomach to the small bowel, there is little change in outcome.[8] Although multiple findings of GI dysfunction do reflect gastroparesis or intestinal dysmotility, other signs and symptoms are often included in the definition, which may or may not be related, such as diarrhea, GI bleeding, or increased abdominal pressure.[7]

What continues to stoke interest in this entity is the correlation between ileus and adverse outcomes.[7] The link to adverse outcome is shown in studies where evidence of GI dysfunction has prognostic value and is associated with increased ICU length of stay, duration of mechanical ventilation, and even mortality.[7] Ileus is also linked to decreased delivery of enteral nutrition (EN), feeding intolerance, or feeding failure. The presence of ileus does identify a patient at high nutritional risk, a patient who may be more difficult to feed, whose risk of complications is increased, and whose delivery of EN should be provided with more caution.[7] Critically ill patients need the therapeutic advantage of early EN; however, resolution of the ileus is important to facilitate further delivery of the nutritional regimen.

DEFINING GASTROINTESTINAL DYSFUNCTION

Definitions for ileus and GI dysfunction in critical illness vary over a wide spectrum of signs and symptoms. GI dysfunction usually relates to disordered motility and is most often defined by a constellation of symptoms, including nausea, vomiting, regurgitation, abdominal distention, and hypoactive-to-absent bowel sounds.[2,14] Feeding intolerance is defined separately as a reduced delivery of EN for whatever reason.[2,14] Often, the definitions of GI dysfunction have an overreliance on gastric residual volumes (GRVs) to make the definition.[14] Additional factors are added to the definition in a somewhat haphazard manner, such as intraabdominal hypertension, overt GI bleeding, and diarrhea.[14–18]

There is a difference in the definitions of ileus between a static score of signs and symptoms seen on admission to the ICU and a more graded series of findings suggesting a spectrum of increasing severity.[7] GI dysfunction is more of a static definition and is a greater issue on admission to the ICU. GI dysfunction in the acute and immediate postacute phases of critical illness is often influenced by prolonged bed rest, increasing disease severity, comorbidities, the metabolic state, and use of opioid narcotics.[7,10] Feeding intolerance, on the other hand, is a more dynamic process and is a greater issue with initiation and advancement of early EN.[7,10] Feeding intolerance is more likely to be influenced by nursing care, the existence of protocols, the culture or leadership of the ICU, and whether GRVs are used. A component of "grading" implies the continuum of a process over a spectrum from mild to severe degree, a contrived definition where such a spectrum may not exist.[7,14,17,19] The designation of increasing grades of GI dysfunction has been defined by a greater number of GI signs and symptoms, by a reduction in the delivery of EN, or by the finding of additional complications such as organ failure (as measured by Sequential Organ Failure Assessment or SOFA score), the presence of overt GI bleeding, or the development of intraabdominal hypertension.[14,17–19] Other systems designated an increased grade by whether there was a positive response, a poor response, or no response to therapy.[14]

What sustains interest in GI dysfunction is its correlation with adverse outcomes. Multiple studies have shown that evidence of ileus or GI dysfunction upon admission to the ICU is associated with prolonged duration of mechanical ventilation, increased ICU length of stay, and greater mortality.[2,14–20] In those studies describing a spectrum of severity of GI dysfunction, increasing grades were shown to be associated with a demonstrated stepwise reduction in survival.[14,17,18] In

one study, increasing grades of an abdominal GI score correlated with greater 28-day and 90-day mortality.[18]

For the critically ill patient receiving early EN in the ICU, use of these signs and symptoms of ileus or GI dysfunction to define "intolerance" is problematic.[7] No standardization of the practice exists. There are over 40 definitions of feeding intolerance in the literature,[2] and 88% of them rely heavily on the use of GRVs. There is large interobserver variability,[2] such that hypoactive bowel sounds had to be removed from the definition in one study because of discrepancies between clinical participants.[20] Clinical conditions can change the interpretation of these signs and symptoms. Abdominal distention, reduced bowel sounds, and cramping may be interpreted differently in a patient with hemodynamic instability on vasosuppressive therapy compared with a patient who is hemodynamically stable and not requiring these agents. A change in symptoms as EN is initiated may be more important than the findings of ileus on admission to the ICU. Homeostatic proteins such as albumin, prealbumin, and transferrin have prognostic value on admission but provide no nutritional information and are not markers of nutritional status or adequacy of nutritional support. Feeding intolerance is often defined by the reduced delivery of EN as a percentage of goal requirements, but this parameter can only be measured retrospectively. Protocols in the ICU may affect the perceived incidence of feeding intolerance, as protocols that direct slow ramp-up and encourage reaching only 80% of goal requirements may be misinterpreted as feeding intolerance.

MECHANISM OF ILEUS IN CRITICAL ILLNESS

Gastric emptying is affected by both zero-order and first-order kinetics.[21,22] Liquids empty by first-order kinetics, which relate to increased fundic pressure, cause a rapid parabolic emptying of liquids, and the rate of emptying speeds up with increasing meal volume.[21] This pattern of gastric emptying may remain normal even with advanced gastric dysmotility.[22] Solids empty by zero-order kinetics, which is related to the steady antral grinding of solids and a fixed rate of emptying through the pylorus unaffected by meal volume.[21,22] Formulas may have a hybrid pattern, combining both first-order and zero-order kinetics. For example, the infusion of enteral formulas should follow the first-order kinetics of liquid emptying unless casein in the formula begins to curdle, at which point the pattern would switch more to zero-order kinetics of solid emptying.

A number of clinical factors affect gastric emptying and subsequent dysmotility. Osmolarity of the formula is a key factor, as duodenal osmoreceptors will slow gastric emptying until the luminal contents are isosmotic. Increasing fat content slows gastric emptying. Source of protein is also a factor in gastric emptying, as whey protein has been shown to empty faster than casein protein.[23] With the metabolic stress of critical illness, corticotropin-releasing factor (CRF) causes increased production of corticosteroids, which has the effect of reducing gastric emptying.[24] Other factors may delay gastric emptying, such as elevated intracranial pressure, increasing intraabdominal pressure, hyperglycemia, and electrolyte abnormalities (especially potassium or sodium).[6] Altered antropyloroduodenal (APD) activity is reported in the ICU.[25,26] Gastric emptying may be adversely affected by central input from the vagus nerve or from neurohormonal feedback loops.[6]

Small bowel intestinal dysmotility occurs commonly in both medical and surgical ICU patients. Nearly 100% of surgical patients undergoing abdominal aortic aneurysm repair were shown in one study to have small bowel dysmotility,[27] whereas up to 42% of critically ill patients on mechanical ventilation in a medical ICU were shown to have evidence of intestinal dysfunction.[28] The pathophysiologic mechanism of small bowel dysmotility differs slightly from the process affecting gastric function. Intestinal dysmotility is characterized by an altered pattern in the migrating motor complexes. A number of factors contribute to intestinal dysmotility.[6] Proinflammatory cytokines such as interleukin-2 and interleukin-6 cause increased leukocyte migration and inflammation in the muscularis propria of the smooth muscle in the intestinal wall, leading to an inhibitory effect on contractility.[29] Ionic channels are altered in structure and function, causing abnormalities in the contractility of intestinal smooth muscle.[30] Tachykinins (substance P and neurokinin) elevated as part of the stress response cause increased activation of NK2 receptors, leading to inhibition of intestinal motility.[26] Nitric oxide (NO) and vasoactive intestinal peptide (VIP) are released in sepsis and cause suppression of migrating motor complexes.[31] Neurohormonal dysregulation leads to increased sympathetic activity, which causes a consequent reduction in intestinal motility.[32] Increased activation of nociceptor reflexes in a severity-dependent fashion (from incision of the skin only, to entry into the peritoneum, to manipulation of bowel) inhibits motility in postoperative surgery patients.[33]

Clinical factors may play a large role in perpetuating ileus in critical illness.[6] Electrolyte abnormalities, opioid analgesia, and excessive fluid resuscitation may all reduce intestinal motility. The use of crystalloid has a more inhibitory effect than use of colloid for volume resuscitation.[6] Use of a nasogastric tube for decompression, bowel wall edema, bowel manipulation at the time of surgery, sepsis, and intestinal hypoperfusion all may worsen the ileus seen in critically ill patients or postoperative patients in the surgical ICU.[6,9] Prolonged bed rest can lead to intestinal stasis.[2] Activation of Toll-like receptors in sepsis-induced ileus occurs as a direct result of release of lipopolysaccharide (LPS) endotoxin.[34] Alteration in the gut flora with emergence of a pathobiome has been correlated with dysmotility and feeding intolerance,[35] and a reduction in biliary and pancreatic secretions lose their trophic effect on intestinal function and subsequent motility[6] (Fig. 26.1A–C).

IMPLICATIONS FOR DELIVERY OF ENTERAL NUTRITION

The foundation of feeding in the ICU is by intragastric feeding. Placing a 10–12 French nasogastric tube requires a low level of expertise and usually promotes faster time to initiation of EN. Diverting the level of feeding from the stomach to the small bowel has surprisingly little effect on outcome parameters.[8] Meta-analyses of multiple randomized controlled trials of gastric versus small bowel feedings show that the only difference is a reduction in the diagnosis of pneumonia with small bowel feeding compared with gastric feeding.[8] No other outcome parameter changes by diverting the level of feeding, including duration of mechanical ventilation, ICU or hospital length of stay, and mortality. In fact, the largest multicenter trial by Davies and colleagues showed no difference in any outcome parameter between gastric and small bowel feeding.[36]

Early initiation of feeding in the ICU helps prevent ileus from setting up. In two trials involving patients with severe acute pancreatitis, expeditious placement of enteral access and initiation of enteral feeding minimized the duration of ileus and increased the success of enteral feeding.[37,38] In a study by Cravo and colleagues, delays in initiation of enteral feeding from 0 to 6 days prolonged the duration of ileus, leading to reduced success of enteral feeding and increased need for total parenteral nutrition (TPN).[37] A second trial by Eatock and colleagues, comparing gastric with small bowel feeding in pancreatitis, showed equal success with gastric feeding in every parameter evaluated.[38] The success of gastric feeding was attributed to the fact that feedings were started within 48 hours of onset of symptoms, such that less ileus and gastric stasis was incurred.

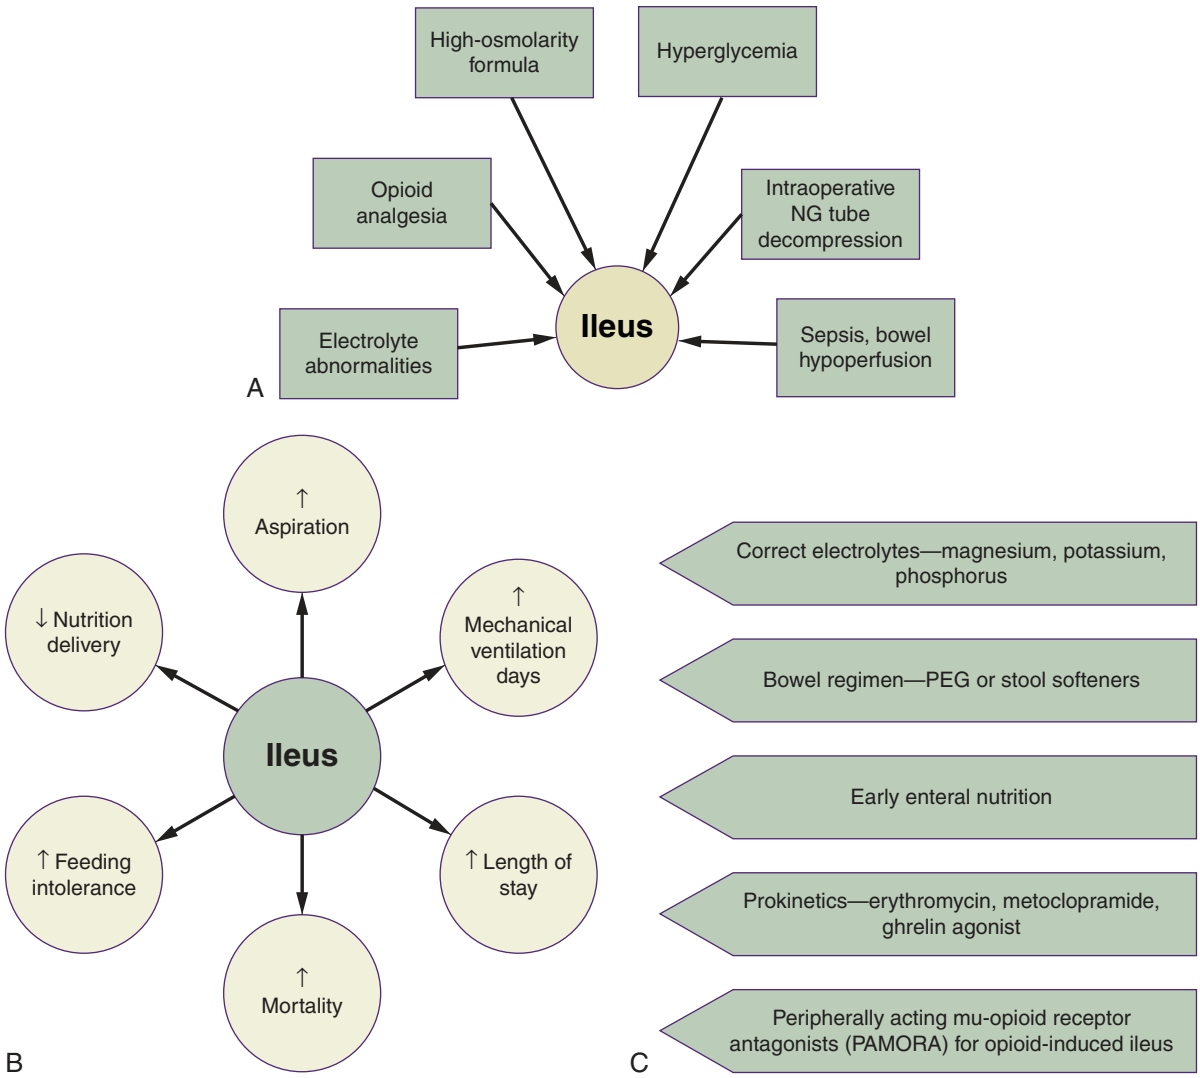

Fig. 26.1 Causes, Consequences, and Management Strategies of Ileus in Critical Illness. **A,** Causes. **B,** Consequences. **C,** Management strategy. *NG,* Nasogastric; *PEG,* percutaneous endoscopic gastrostomy.

Intermittent feeding may actually enhance tolerance and reduce GI dysmotility compared with continuous infusion.[39] Multiple studies in animal models show that intermittent feeding with 20- to 30-minute infusions repeated every 2 hours hastened the gastric emptying of liquids and increased mesenteric blood flow.[39] Protein synthesis was greater with intermittent feeding, and the components of the ileal brake (PYY and gastrointestinal inhibitory polypeptide) were increased, resulting in less diarrhea and more time for nutrients to be absorbed.[39]

When diarrhea or upper GI bleeding occurs, it should be evaluated independently and not lumped together with a number of other signs or symptoms attributed to GI dysmotility. In over 50% of cases, diarrhea is related to medications (especially sorbitol, which is a common mixing agent used by pharmacists to deliver medications by the enteral route).[40] Twenty percent of the time, diarrhea is related to *Clostridium difficile* or antibiotic-associated diarrhea. Most often, diarrhea is low-volume incontinence in the ICU and not related to GI dysfunction.[40] The workup of a GI bleed in the ICU again should not be attributed to GI dysfunction, but should be investigated independently. Minimal bleeding in a noncirrhotic ICU patient on mechanical ventilation may represent stress gastritis. Increased delivery of EN is effective in promoting mucosal blood flow and may be the best treatment in that setting. Clinicians should avoid the use of colorimetric cards to detect occult GI bleeding. Occult bleeding (as determined by such cards) should be differentiated from overt bleeding where there is obvious hematemesis, melena, or hematochezia. Cirrhotic patients should be differentiated from noncirrhotics, and a significant GI bleed where there is a drop in hemoglobin, volume contraction, and hemodynamic instability should be differentiated from insignificant bleeding.

A number of clinical strategies may be used in the ICU patient who shows evidence of ileus or significant GI dysmotility. Electrolytes should be corrected, minimizing subsequent alterations, particularly in potassium and magnesium. GRVs should not be used.[8] A bowel regimen that includes stool softeners or polyethylene glycol helps maintain the passage of stool and gas. Lubiprostone is an agent that actively increases water secretion by the intestine and helps promote bowel movements in the ICU.[6] Early enteral feeding should be promoted, and the use of protocols to direct delivery helps improve success. Prokinetic agents may play a role early on in the initiation of enteral feeding and include erythromycin, metoclopramide, and experimental ghrelin agonists. In patients on opioid narcotics, agents such as peripherally acting mu-opioid receptor antagonists may be

used, such as methylnaltrexone (Relistor), naldemedine (Symproic), or alvimopan (Entereg).[6]

Goal-directed fluid management is important to avoid bowel wall edema and increasing intraabdominal pressures. Small-peptide formulas with medium-chain triglycerides may stimulate peptide transporters and promote better gastric emptying.[6] Low-fat formulas likewise may enhance gastric emptying. Avoiding hyperglycemia with moderate to relatively stricter control of glucose levels is important, and variability in blood glucose may actually be more important than absolute levels.[6] Experimental agents that have been used in postoperative ileus include ceruletides (an analog to CCK), celecoxib (a cyclooxygenase inhibitor), and rosiglitazone (a PPAR-gamma activator), all of which have helped reduce ileus and promote early feeding.[6]

Certain findings on physical examination should cause the clinician to back off of enteral feeding if the ileus is sustained. Worsening of symptoms in the face of feeding, greater abdominal distention, vomiting, or sudden cessation in the passage of stool and gas should be interpreted with caution, as it may reflect intolerance, potential ischemic bowel, and a contraindication to further advancement. Increasing lactic acidosis or worsening radiographs showing pneumatosis intestinalis or a greater number of dilated loops of bowel can all reflect poor tolerance, intestinal dysmotility, and the increasing chance of intestinal ischemia.

CONCLUSIONS

Ileus should be expected in critical illness. The best use of signs, symptoms, or a scoring system for GI dysmotility may be that it differentiates patients at high nutritional risk from those at low risk.[7] Despite the common occurrence of gastroparesis and intestinal dysmotility, gastric feeding is tolerated well in the vast majority of critically ill patients.[12,13] Clinicians should avoid misinterpretation of findings. Evidence of intestinal dysmotility on admission should be interpreted in a similar fashion to that of other prognosticators such as reduced homeostatic proteins (albumin, prealbumin, transferrin) or elevated markers of inflammation (C-reactive protein and erythrocyte sedimentation rate).[7] Clinicians should stop using colorimetric cards to detect occult GI bleeding. Overt yet insignificant bleeding with no changes in hemoglobin in an ICU patient on mechanical ventilation should not deter delivery of EN.[7] Overt significant bleeding with a drop in hemoglobin and hemodynamic instability should lead to cessation of feeding until the source can be evaluated or determined.

Clinicians should monitor patients on enteral feeding by physical examination, intake and output records, and passage of stool and gas. GRVs are misleading and a poor sign of gastric emptying, aspiration risk, or intolerance. Use of GRVs invariably serves as an impedance to the delivery of EN.[8] With appropriate goal-directed fluid resuscitation, there may be little use for measuring intraabdominal pressure. Intraabdominal hypertension is disappearing with the strategy of conservative goal-directed fluid management. Mild increases in intraabdominal pressure may actually improve with the delivery of enteral feeding.[7] Physicians should be leery of a spectrum or gradation of findings where no spectrum exists.[7] Delivery of EN represents a challenge to the GI tract, and patients should be monitored closely, especially with initiation of enteral feeding.

Protocols help minimize the impact of ileus. Providing early EN helps stimulate motility and reverse the effects of ileus. Bowel regimens help reduce the signs or symptoms that might otherwise be interpreted as GI dysmotility. A change in response to initiation of enteral feeding may be more important than the static findings of GI dysmotility at the onset. The findings of ileus on admission provide prognostic information, but may be less useful or even counterproductive in directing subsequent nutritional therapy. Such findings should not dissuade the clinician from at least trying to feed the ICU patient and provide the clinical benefit of early enteral feeding.

KEY POINTS

- Gastroparesis and intestinal dysmotility are common, involving more than 75%–80% of critically ill patients in the ICU.
- Issues of ileus in critical illness are counterintuitive, as gastric feeding is tolerated in over 90% of ICU patients despite the frequent presentation of hypoactive bowel sounds, abdominal distention, and failure to pass stool and gas.
- Evidence of GI dysfunction on admission to the ICU correlates with adverse outcomes, prolonged duration of mechanical ventilation, increased hospital length of stay, and reduced survival.
- Ileus and gastroparesis may be worsened by delays in initiating feeding, poor control of hyperglycemia, overly aggressive fluid resuscitation, use of a high-fat hyperosmolar formula, continuous infusion of nutrients, and prolonged bed rest.
- Considerations to facilitate delivery of EN in critical illness include early initiation of therapy, selection of an isosmolar small-peptide formula with medium-chain triglycerides and whey protein, correction of electrolytes, employing goal-directed fluid volume resuscitation, use of crystalloid over colloid, avoidance of decompressive nasogastric tubes, routine placement on a bowel regimen, use of prokinetic agents in select patients, and intermittent infusion of enteral nutrients.
- Diarrhea and GI bleeding should be investigated independently, may be unrelated to dysmotility or ileus, and should not be considered an automatic contraindication to continued enteral feeding.
- The presence of ileus or GI dysfunction in critical illness identifies a patient at higher nutritional risk with an increased likelihood for complications and adverse outcomes, whose delivery of enteral feeding will be more difficult and require greater caution with close monitoring.

Diarrhea

Christian J. Brown, Tyler J. Loftus, and Martin D. Rosenthal

Diarrhea is one of the most common manifestations of gastrointestinal (GI) dysfunction in the intensive care unit (ICU); the reported incidence is between 2% and 63%.[1] *Diarrhea* is best defined as bowel movements that, because of increased frequency, abnormal consistency, or increased volume, cause discomfort to the patient or the caregiver. This definition demonstrates the subjectivity in diagnosing diarrhea, which complicates interpretation of the literature and limits applicability of guidelines. The National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) defines diarrhea more objectively as having loose, watery stools three or more times a day, further classified by chronicity:

- **Acute diarrhea** is a common problem that typically lasts 1 or 2 days and goes away on its own.
- **Persistent diarrhea** lasts longer than 2 weeks and less than 4 weeks.
- **Chronic diarrhea** lasts at least 4 weeks. Chronic diarrhea symptoms may be continual or may come and go.

The impact of diarrhea on patient care in the ICU, including its cost in morbidity and mortality, is unknown. However, it is undeniable that diarrhea remains a persistent problem in many ICUs not just for the patient but also for the care team (especially the bedside nurse).

CRITERIA

Several criteria diagnose diarrhea:

1. Abnormal frequency. Normal frequency is one or two bowel movements per day and is influenced by the amount of fiber in the diet. Three or more bowel movements per day is abnormal.[1]
2. Abnormal consistency. Abnormal consistency is described as either nonformed stool or stool having excessive fluid content that causes inconvenience to the patient, nursing staff, or caregiver. Normal stool water content is 60%–85% of the total weight.[1]
3. Abnormal amount. Stool amount and volume vary significantly with the amount and type of enteral intake. Insoluble fiber adds a significant amount of bulk volume. A normal amount is approximately 200 grams per day (g/d).[1] Abnormal amounts are greater than 300 g/d or volumes greater than 250 mL/d.[1,2]

To date, clinicians lack a consistent scale or index that allows a reliable and practical way of measuring stool volume, consistency, and frequency. In its absence, the bedside nurse remains the most reliable person to identify the presence of diarrhea.

PATHOPHYSIOLOGY

Bowel movements with normal physiologic volume, consistency, and frequency are the result of a GI tract that integrates motility, secretion, and absorption of fluids and adapts to the quality of the food bolus given. The result is a fecal bolus that is produced once or twice every 24 hours and has normal consistency and fluidity.

Diarrhea results when there is a disorder of GI physiology or when GI tract function is incapable of handling the food bolus (Fig. 27.1). There are several classifications of diarrhea, suggesting that no single classification is ideal for helping the clinician make patient care decisions. Perhaps the most useful approach is to classify diarrhea according to physiology:

1. Increased fluid secretion that overwhelms absorption. On average, up to 9 L of fluid is secreted into the GI lumen in addition to oral intake. Less than 1% of that fluid is contained in stool because of the amazingly large absorptive capacity of the small and large bowel. Within the intestinal mucosa, passive and active transport of sodium determines the amount of water that is absorbed. Stimulation of the active secretion of fluids into the GI lumen occurs when intracellular levels of the second messenger, cyclic adenosine monophosphate (cAMP), increases within enterocytes. Increased intracellular cAMP concentration promotes chloride secretion.[3] Thus diarrhea caused by excessive secretion of fluids is termed *secretory diarrhea*. Secretory diarrhea characteristically contains large amounts of fluid and is described as watery. Secretory diarrhea is observed in certain infectious diseases such as cholera and rotavirus infections. Secretory diarrhea also can be observed in endocrine disturbances associated with carcinoid syndrome or vasoactive intestinal peptide (VIP)–secreting tumors.
2. Gastroenteritis or infectious diarrhea occurs from GI tract inflammation with resultant increase in mucus secretion from the large bowel, leading to development of diarrhea. Excessive mucus secretion is observed in colonic infections such as bacterial (*Clostridium difficile* colitis), viral (norovirus), or parasitic (amebiasis).[4] The incidence of infectious diarrhea in the ICU is unknown, but increases with contaminated food products. Of particular concern is the contamination of the food being given in the ICU. Contamination of enteral formulas can occur at multiple levels, including preparation of the enteral product, use of open feeding systems, addition of modular dietary components, and contamination of the enteral access port (i.e., feeding tube, gastrostomy tube). The incidence of diarrhea resulting from contaminated feeding tubes is unknown.
3. Diarrhea resulting from increased osmotic load. Many substances taken orally are not fully absorbed and exert significant osmotic force, overwhelming the absorptive capacity of the GI tract. Many patients with diarrhea in the ICU fall into this category.
   A. Osmotic diarrhea caused by medications: Sorbitol is frequently and inadvertently given to patients in the ICU as a means of preparing many medications for delivery via feeding tubes and is an often-overlooked culprit causing diarrhea.[5] Other osmotic agents include GoLYTELY and magnesium-containing medications and electrolyte replacement formulations.

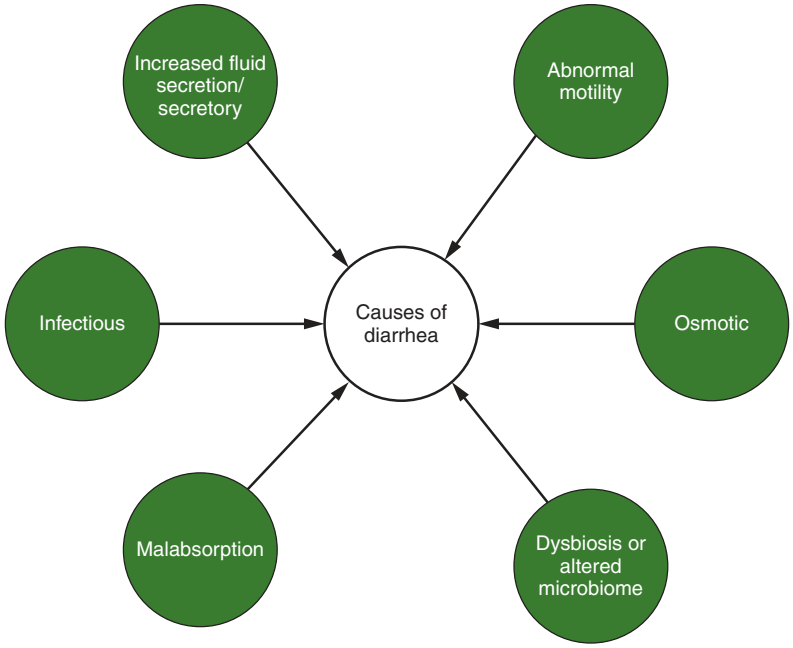

Fig. 27.1 Diarrhea: Abnormal Frequency, Consistency, and Amount. Acute diarrhea is a common problem that typically lasts 1 or 2 days and goes away on its own. Persistent diarrhea lasts longer than 2 weeks and less than 4 weeks. Chronic diarrhea lasts at least 4 weeks. Chronic diarrhea symptoms may be continual or may come and go. Consequences of diarrhea include wound breakdown, malnutrition, electrolyte imbalance, patient discomfort, and increased workload for nurses or caregivers.

B. Incomplete digestion and malabsorption: The incidence of malabsorption in the ICU is unknown. However, there are many instances where malabsorption should be considered the cause of diarrhea in the critically ill patient. These include:
   i. Incomplete protein digestion (azotorrhea): Protein digestion occurs mainly in the stomach by pepsin (only activated at low pH) and hydrochloric acid. In the ICU, many patients receive medications that raise gastric pH, such as histamine receptor type 2 (H_2) blockers and proton pump inhibitors.[6,7] In addition, feeding tubes frequently bypass the stomach, eliminating both gastric acid and gastric proteolytic digestion. Less frequent causes of azotorrhea are protein-losing enteropathies resulting from amyloidosis, sarcoidosis, inflammatory bowel disease, neoplasm, Ménétrier disease, and Zollinger-Ellison syndrome, to name a few.
   ii. Undigested carbohydrates: In addition to sorbitol (see earlier discussion), excessive glucose, lactose, or fructose in tube-feeding formulas can overwhelm the absorptive capacity of the small bowel, causing an osmotic influx into the gut lumen.[8]
   iii. Undigested fats: Steatorrhea (diarrhea caused by undigested fats) is characteristically observed in patients with pancreatic insufficiency. Inadvertent lack of mixing pancreatic enzymes with the food bolus can occur in patients with intestinal bypass or pancreatic fistulas or in patients who have large-volume gland necrosis from pancreatitis or a history of pancreatectomy. It is also observed in patients with incomplete bile production, such as patients with a biliary diversion.
   iv. Excessive dietary load: Diarrhea resulting from excessive load (overfeeding) of any of the main dietary components (protein, carbohydrate, or fat) can occur in the ICU. Iatrogenic overfeeding occurs in up to 33% of patients in the ICU and is a result of inappropriate estimations of caloric and protein needs or inadequate metabolic surveillance.[9] Excessive loads of protein, carbohydrate, or fat also occur with specialized formulas that contain altered amounts of one or more of these components. For example, certain diets are high in fat, overwhelming digestive and absorptive processes.
   v. Atrophy of the GI tract: Atrophy of the intestinal brush border is associated with decreased capacity of digestion and absorption. Atrophy occurs in malnourished patients; thus diarrhea commonly occurs in patients with hypoalbuminemia. Atrophy also occurs when enteral intake is interrupted for more than a few days. This is a particular problem in surgical patients when prolonged "bowel rest" results in disuse atrophy. A similar phenomenon occurs distal to an enterocutaneous fistula or ostomy, which, upon reversal, can result in diarrhea that slowly resolves as villous height returns to baseline.
4. Abnormal motility: Intestinal dysmotility is a frequent problem in the ICU. The use of promotility agents (e.g., erythromycin) can inadvertently cause diarrhea in these patients.
5. Abnormal gut flora: Normal colonic flora is essential for normal absorption and function of the large bowel. Antibiotics create massive disruptions in colonic flora and can sometimes lead to nosocomial infections with resultant diarrhea. Currently, *C. difficile* is the leading cause of nosocomial diarrhea, accounting for 30% of all antibiotic-associated diarrhea.[10] The gut microflora can be modulated through the use of probiotic agents, but this topic is under intense investigation, and no current guidelines exist regarding their use to treat or prevent diarrhea in ICU patients.[11]

CLINICAL CONSEQUENCES OF DIARRHEA

Untreated, diarrhea can lead to multiple problems. These include:
1. Wound breakdown and secondary soft tissue infection: Diarrhea can cause a moist, contaminated environment; if left untreated, this can

lead to skin breakdown and eventual soft tissue infection. Particularly concerning is the presence of decubitus ulcers; diarrhea can be either a causative factor or can worsen and complicate management.
2. Fluid and electrolyte disturbances are particularly frequent in patients with secretory diarrhea. In these patients, clinicians must pay attention to fluid replacement to avoid dehydration and correct metabolic acidosis and hypokalemia as needed.
3. Malnutrition: Inadequate nutrient absorption can lead to poor nutrient utilization. Malabsorptive diarrhea can be classified by stool enzyme and nutritional by-product measurements, such as fecal elastase and fecal fats.
4. Increased workload for nurses and caregivers: Diarrhea imposes a substantial burden on nurses and other caregivers. In addition, the presence of a soiled patient evokes a sense of poor quality of care. Maintaining a clean patient with diarrhea requires additional ICU personnel time and resources. The use of fecal management systems provides one strategy, but incurs the risk of ulceration. As with all clinical decisions, patient-specific risks and benefits must be weighed.

DIAGNOSIS

Careful and complete evaluation of diarrhea is necessary for good patient care. Unfortunately, diarrhea is often ignored or hastily treated while clinicians focus on other organ systems. Diagnostic laboratory tests are sparse, making it difficult to identify and treat the patient. The following diagnostic approach is suggested:

1. Does the patient really have diarrhea? It is important to question the accuracy of the diagnosis. The NIDDK definition of three or more loose stools a day should be applied. A concerted effort to diagnose diarrhea by all members of the ICU staff is essential. The creation of scales or indices could become particularly useful as a means of communication and could aid in assessing the effectiveness of treatment.
2. Can an iatrogenic cause explain the presence of diarrhea?
   A. Is the patient receiving prokinetic agents or stool softeners?
   B. Is the patient receiving medications with high concentrations of sorbitol?
   C. Is the patient being overfed?
   D. Is the patient intolerant to any of the components of the prescribed diet?
   E. Is a specialized diet providing an excessive amount of a substance (e.g., fat) that the patient is having difficulty digesting?
   F. Is bypassing the stomach or inhibiting acid secretion affecting the digestion of protein?
   G. Is the patient receiving any other medication that causes diarrhea?
3. Assessing the patient's absorptive or digestive capacity:
   A. Does the patient have gut atrophy, as seen with prolonged bowel rest, proximal fistula takedown, or ileostomy reversal? Would this patient benefit from an intestinal rehabilitation strategy?
   B. Is the patient malnourished?
   C. Does the patient have a condition (e.g., pancreatitis) that alters the secretion of digestive enzymes?
   D. Does the patient have a chronic disease process (e.g., short gut syndrome) that alters absorption?
4. Does the patient have an infection?
   A. Is there any evidence of contamination of feeding tubes? Is the feeding system a closed system? How often is it being changed?
   B. Is there cause for nosocomial bowel infection? Is the patient's *C. difficile* toxin negative?
   C. Has colonic flora been altered significantly with antibiotics?

TREATMENT

Treatment must address the underlying cause or causes. One or several reasons for the presence of diarrhea generally can be identified. Eliminating an infectious cause first has significant implications for treatment algorithms that use medications to slow fecal transit time. Slowing the progression of stool is not recommended for patients with *C. difficile* infection. Additionally, iatrogenic causes of diarrhea should be identified and corrected whenever feasible. For example, promotility and prokinetic agents should be discontinued. Treating teams must maintain good antibiotic stewardship and de-escalate and discontinue antibiotics as soon as possible.[12,13] Through appropriate use of antibiotics, the gut microbiome can be preserved, thus reducing chances of altered GI disturbances.

Once infectious sources and iatrogenic causes are excluded, clinicians should modify diets if the GI tract is being overwhelmed with high quantities of a particular nutrient. This is particularly important for patients receiving formulas that deliver excessive fat. In this circumstance, digestive enzymes such as pancreatic enzymes or bile substitutes should be supplemented when the disease process (or treatment) is associated with decreased production of these enzymes.

Bulk-forming agents can improve the consistency of the fecal bolus. These agents must be administered in appropriate amounts, because they can also cause diarrhea.[14] Agents that inhibit GI motility, such as loperamide or diphenoxylate and atropine, should be used with caution. These drugs are often ordered empirically and may worsen underlying pathology, especially when the causative agent is infectious, but can be very effective in appropriately selected critically ill patients.

Antibiotics for treating infectious diarrhea should be used with caution. If the diarrhea is causing minimal discomfort and is of no physiologic consequence, waiting for the results of tests for *C. difficile* is advised.[15]

Restoring normal colonic flora has become an increasingly frequent practice in the ICU. Provision of prebiotics and probiotics may have utility for treatment and prevention of common causes of diarrhea. Hempel et al. suggested in a 2012 meta-analysis that probiotics effectively treat antibiotic-associated diarrhea ($P < .001$ number needed to treat [NNT] 13), referencing 82 randomized controlled trials with over 11,000 patients.[17] Goldenberg et al. performed a Cochrane review and found that there was a significant correlation with the use of probiotics and prevention of *C. difficile* infection among 4200 patients.[18] The literature is evolving, but the most consistent signal is that microbiome diversity is important for treating and preventing these two forms of diarrhea. The strain of probiotic used in studies and reviewed in these meta-analyses is poorly documented. More research is needed to understand which probiotics confer the greatest benefits for distinct patient populations.

Stopping or decreasing the rate of enteral nutrition is only advisable if the patient is being overfed or exhibits intolerance to the diet. Only under exceptional circumstances should stopping oral intake and giving total parenteral nutrition be advocated as a treatment for diarrhea.

CONCLUSION

Diarrhea is a clinical manifestation of GI dysfunction in the ICU. The true incidence of diarrhea in ICU patients is unknown because of the lack of a universally accepted definition or concerted, systematic effort to study the problem. Despite these limitations, diarrhea can be effectively treated with careful clinical evaluation and simple therapeutic measures.

KEY POINTS

- Diarrhea is one of the most common GI dysfunctions that plague ICU patients and caregivers.
- Diarrhea has several causes in the ICU, of which infectious, malabsorptive, and secretory remain at large.
- Once the etiology is diagnosed, a treatment algorithm can be instituted.
- Infectious sources of diarrhea should be considered before using agents that decrease fecal transit time.
- Commonly used medications that reduce diarrhea are loperamide, diphenoxylate and atropine, fiber, and tincture of opium, which should be administered only after prokinetic/promotility and stool softener agents are discontinued.

Chest Pain

Daniel J. Rowan and David T. Huang

INITIAL APPROACH

Several life-threatening conditions can cause chest pain in the critically ill, and the initial approach should focus on prompt evaluation and resuscitation of the airway, breathing, and circulation. Assess the patient's level of consciousness, palpate the pulse, and listen to the breath sounds and heart. Obtain vital signs, including oxygen saturation by pulse oximetry, and ensure that the patient is attached to a cardiac monitor and has adequate intravenous (IV) access. Such measures will help ensure that critical abnormalities such as hypoxemia, hypotension, and unstable dysrhythmias are quickly identified and treated. These conditions, as well as the life-threatening causes of chest pain discussed here, are covered in greater detail in other chapters in this textbook.

HISTORY

After initial evaluation and stabilization, obtain a more detailed history. If the patient can communicate, start with an open-ended question like "What's going on, Mr. Jones?" Physicians often neglect to ask basic questions about the quality of chest pain, as was shown in a study of patients with aortic dissection (AD), and this omission is associated with a delay in diagnosis.[1] The use of a history-taking mnemonic can help avoid this mistake (see online supplemental table for further detail: eTable 28.1). Ask the bedside nurse about recent changes in the patient's condition. As an important subsequent step, a quick "chart dissection" should be performed, focusing on the findings at presentation, reason for intensive care unit (ICU) admission, past history, and progress notes. Attention should be given to recent procedures, previous diagnostic imaging such as chest computed tomography (CT), coronary angiography, or echocardiogram, in addition to electrocardiograms (ECGs). Much of the chest pain literature focuses on management in the emergency department (ED), and although the principles provided apply in both ED and ICU areas, there are also differences. Most notably, ICU patients are already admitted to the hospital and identified as critically ill, whereas ED patients are not. Key differences between assessment of chest pain in the ICU and ED are enumerated in Table 28.1.

PHYSICAL EXAMINATION

Inspect the chest for asymmetric excursions, rashes, or obvious sources of pain, such as chest tubes. Palpate the chest and neck for crepitus, which can result from a pneumothorax or pneumomediastinum. Check for pulsus paradoxus and jugular venous distention (JVD). Assess for asymmetry in the carotid, femoral, or radial pulses, which can be a sign of AD. If breath sounds are asymmetric, hyperresonance to percussion may confirm a pneumothorax. Cardiac auscultation may reveal a friction rub from pericarditis, "crunching" sounds from mediastinal emphysema (Hamman sign), a systolic murmur of aortic stenosis (AS), or an aortic insufficiency murmur from a proximal AD. A focused examination should include the abdomen to avoid missing an abdominal catastrophe masquerading as chest pain. Evaluate for evidence of shock, as demonstrated by coolness or mottling of the lower extremities, decreased urine output, or encephalopathy.

DIAGNOSTIC ADJUNCTS

In the absence of an obvious cause of chest pain (e.g., shingles), a portable chest x-ray (CXR) and ECG should be obtained. Serial cardiac enzymes (particularly high-sensitivity troponin) should be considered to exclude a myocardial infarction (MI). The ECG is often nonspecific but occasionally shows evidence suggestive of acute coronary syndrome (ACS), pericarditis, or pulmonary embolism (PE). The CXR is a useful screening tool for life-threatening causes of chest pain, such as pneumothorax or esophageal rupture. Both the ECG and CXR should be compared with those performed before the onset of pain.

IV contrast-enhanced CT can help diagnose a number of causes of chest pain, including PE, AD, esophageal rupture, pneumothorax, and pneumonia. The benefits of CT scanning, however, must be weighed against the risks of transporting a critically ill patient out of the ICU. Ultrasound (including echocardiography) can be rapidly performed at the bedside with minimal risk to the patient, and in the hands of a highly skilled clinician, can provide dynamic functional imaging and serve as a substitute for the CXR. Pericarditis with associated effusion, wall motion abnormality from MI, AS, AD, pneumothorax, or pleural effusions are all within the diagnostic scope of ultrasound. Ultrasound has the added benefit of providing information about cardiac function. Further discussion of the utility and implementation of bedside ultrasound can be found in greater detail in other chapters in this textbook. Diagnostic adjuncts should be used to augment pre-test probability for a particular diagnosis following a focused history and physical examination, as opposed to a "shotgun" approach to testing.

DIFFERENTIAL DIAGNOSES

1. Do not assume the admission diagnosis is correct or all-inclusive. Premature closure, that is, failing to consider alternative possibilities after a diagnosis has come to mind, is a common cause of medical error.[2] Premature closure likely contributes to the delay in diagnosis described in hospitalized patients with AD.[3]
2. Do not be biased by the type of ICU to which the patient is admitted. AD can present as a stroke, prompting admission to a neurologic ICU, or an acute abdomen can develop in a medical ICU patient.

ONLINE SUPPLEMENTAL eTABLE 28.1 OLDCAAR Mnemonic for Evaluating Pain

Domain	Suggested Questions
Onset	Sudden or gradual? Maximal pain at onset?
Location	Generalized or localized? Can you point with one finger to where it hurts?
Duration	When did it start? Just now, or did the pain occur earlier but you did not want to bother anyone? Is it constant or intermittent? If intermittent, is there a trigger, or is it random?
Character	Sharp? Dull? Ache? Indigestion? Pressure? Tearing? Ripping?
Associated symptoms	"Dizzy" (vertiginous or presyncopal)? Diaphoresis? Palpitations? Dyspnea? Nausea or vomiting?
Alleviating/aggravating	Position? Belching? Exertion? Deep breathing? Coughing?
Radiation	To the back? Jaw? Throat? Arm? Neck? Abdomen?

TABLE 28.1 Key Differences in the Assessment of Chest Pain in the Emergency Department vs. ICU

ED	ICU
History and Examination	
Evaluation aided by clinical decision rules, such as the HEART score, PERC, and Wells criteria	Most clinical decision rules are not validated in the ICU setting
Patients are generally participatory in history physical examination	History can be limited by comorbid conditions, and such as delirium or respiratory insufficiency
Assessment is often a first encounter, although prior visits increase the risk for representativeness	Evaluation often assisted by current course, creating the risk of premature closure of the loop bias
Workup and Management	
In the ED, management largely focuses on initial disposition, without the time for prolonged evaluation testing	In the ICU, workup is aided by continuous telemetry monitoring, serial reevaluation, and laboratory
Interpretation of cardiac biomarker elevation, ECG findings, and radiography more often clouded by intercurrent critical illness	

Evaluation in both the emergency department (*ED*) and the intensive care unit (*ICU*) relies upon a thorough history and physical examination and reasonable use of adjunctive testing, including laboratory assessment, electrocardiogram (*ECG*), chest x-ray (CXR), advanced imaging, and point-of-care ultrasound. Both initially focus on addressing and treating immediate life-threatening causes of chest pain. *PERC*, Pulmonary embolism rule-out criteria.

POTENTIALLY LIFE-THREATENING CAUSES OF CHEST PAIN

Acute Coronary Syndrome

ACS includes unstable angina, ST-segment elevation MI, and non-ST elevation myocardial infarction (NSTEMI). The classic symptoms include chest pressure radiating to the left arm, nausea, and diaphoresis, but this history has several diagnostic limitations. Although certain features (e.g., pain radiating down the left arm) are associated with a higher likelihood of ACS, and other characteristics (e.g., pleuritic, positional, or sharp pain) with a lesser likelihood, none can reliably confirm or exclude the diagnosis.[4,5] Reduction in pain after nitroglycerin is also not a reliable indicator of cardiac chest pain.[6] Conventional cardiovascular risk factors, including diabetes, smoking, dyslipidemia, hypertension, and a suggestive family history, predict the development of heart disease over years in asymptomatic patients but may be less useful in predicting ACS in patients with acute chest pain.[7] However, a recent cohort study of 1.3 million hospitalized patients identified a personal prior history of coronary disease, tachycardia, anemia, and leukocytosis to be associated with patients who developed in-hospital MI.[8]

There are no specific physical examination findings of ACS, but if the ACS is severe enough to induce left ventricular dysfunction, signs such as hypotension, JVD, and an S3 or S4 heart sound can be present. The ECG should be examined for ST-segment elevation or depression, Q waves, and T-wave inversions. An isolated ECG has limited sensitivity for diagnosing MI, but the yield increases with serial ECGs. Given the limitations of the ECG and of the history and examination findings, cardiac troponin should be measured in ICU patients with chest pain, and echocardiography provides complementary information by disclosing regional wall motion abnormalities.[9] Repeat measurement of troponin will help to further stratify patients.[10,11]

All patients suspected of having ACS should be treated with aspirin, if not contraindicated (e.g., AD also suspected), or alternatively prasugrel or ticagrelor if there is aspirin allergy. Dual antiplatelet therapy with a P2Y12 inhibitor (ticagrelor or prasugrel) should be considered in all, unless contraindicated.[12] Supplemental oxygen should only be applied to those patients with hypoxemia.[13] Sublingual nitroglycerin and IV morphine should be used to relieve pain if the systolic pressure exceeds 90 mm Hg and the patient has not recently taken a phosphodiesterase inhibitor (e.g., sildenafil). Further treatment of ACS is primarily dictated by ECG findings and the patient's clinical status, and in the setting of ST-segment elevation may include emergency percutaneous coronary intervention (preferred) or fibrinolysis when onsite interventional cardiac catheterization is unavailable. Depending on cardiac findings and the treatment administered, adjunctive therapies may include an anticoagulant, beta-blocker, statin, angiotensin-converting enzyme inhibitor or angiotensin receptor antagonist, and aldosterone receptor antagonist.[11]

Pulmonary Embolism

Approximately 1%–2% of ICU patients have been estimated to develop deep vein thrombosis (DVT) or PE, but the true incidence is probably higher, with autopsy studies identifying a significantly greater percentage.[14,15] ICU patients often have one or more risk factors for PE, including immobility, advanced age, obesity, recent surgery or trauma, mechanical ventilation, vasopressor use, advanced renal failure, sepsis, malignancy, and central venous catheterization.[16] Do not be deterred from evaluating for PE in patients receiving prophylactic anticoagulation, as risk of venous thromboembolism (VTE) persists despite its use, with various studies citing rates ranging from 5% to 10% in this cohort.[17] The burden of VTE in the ICU is high, with increased ICU length of stay and duration of mechanical ventilation associated with its diagnosis.[17,18]

Chest pain resulting from PE is often pleuritic and associated with dyspnea, hemoptysis, cough, or syncope.[19] Physical examination findings are generally nonspecific in PE. Unexplained tachypnea or tachycardia may be the only diagnostic clue. Hypoxia, though typical, is not a universal finding, and its absence cannot exclude PE. A large PE may present with hypotension or cardiovascular collapse. Signs of pulmonary hypertension and right heart failure, such as a loud second heart sound, JVD, or a right-sided S4 heart sound, may be present. Lung examination may reveal crackles, decreased breath sounds, wheezing, rhonchi, or a pleural friction rub. Physical evidence of concomitant DVT often includes unilateral lower extremity edema or erythema, but a significant percentage of diagnosed PEs are without associated DVT.[20]

The ECG is often normal, but may show sinus tachycardia (the most common finding), Brugada pattern, atrial fibrillation, or the classically reported S1Q3T3 pattern.[21] ST depressions and/or T-wave inversions in the precordial or inferior leads, ST elevation in aVr, qR pattern in V1, and right-axis deviation or right bundle branch block suggest increased right ventricular (RV) strain.[22] CXR can be normal

or reveal nonspecific findings such as pleural effusion, infiltrates, or atelectasis, and is only useful for ruling out alternative pathology.[23] Although D-dimer testing has been used to rule out VTE in outpatients with a low likelihood of this diagnosis, the D-dimer assay is less useful in the ICU setting.[17,24] Traditional risk stratification tools for PE, such as the Wells and Geneva scores, have also proven less sensitive in the ICU.[25]

CT pulmonary angiography can be rapidly performed and is the diagnostic test of choice for stable patients in whom there is moderate to high suspicion of PE, given its high sensitivity and specificity. A ventilation/perfusion scan can be time consuming and difficult to perform in mechanically ventilated patients, and interpretation is challenging in the presence of other lung pathology.[26] For patients with unstable hemodynamics, bedside transthoracic echocardiography (TTE), in addition to compressive ultrasound (CUS) of the lower extremities, may be used in tandem to assess for DVT and evidence of RV pressure overload.[27] Elevated troponin and B-type natriuretic peptide (BNP) are associated with a higher risk of mortality in PE.

Initial treatment of low-risk patients with PE involves anticoagulation with subcutaneous low-molecular-weight heparin or fondaparinux, IV unfractionated heparin, or direct oral anticoagulants. High-risk patients with hemodynamic instability and RV dysfunction resulting from PE may require systemic thrombolysis, with surgical embolectomy or catheter-directed thrombolysis recommended for those who have a contraindication to systemic thrombolytics.[26]

Thoracic Aortic Dissection

AD results from a tear in the aortic intima, allowing blood to dissect between the intimal and medial layers, generating a false lumen. This event has an incidence of 6–15/100,000.[28] The Stanford system classifies dissections as type A (involving the ascending aorta) or type B (involving the aorta distal to the left subclavian artery). Risk factors include hypertension, male sex, pregnancy, advanced age, atherosclerosis, diabetes mellitus, cocaine use, preexisting aortic and valvular disease, prior cardiac surgery, family history, Ehlers-Danlos syndrome, Turner syndrome, and giant cell arteritis. Patients younger than 40 years are more likely to have Marfan syndrome, Loeys-Dietz syndrome, bicuspid aortic valve, prior aortic surgery, or aortic aneurysm. The mortality rate is as high as 1%–2% per hour from symptom onset. A directed history remains critical to early diagnosis, with a particular focus on quality, radiation, and intensity of pain to ensure an accurate diagnosis.[1]

Many patients who complain of sudden onset of chest, back, or abdominal pain that radiates to the back often describe the pain as sharp, rather than tearing. AD can also present in a painless fashion, manifesting as syncope, stroke, or evolving heart failure.[29] Dissection can extend into any of the major aortic branches, causing a multitude of clinical presentations that arise in ischemia of the brain, heart, kidney, spinal cord, or gut.

Certain physical examination findings should raise the suspicion of AD. About one-quarter of patients have pulse deficits in the carotid, radial, or femoral arteries, and some have focal neurologic deficits related to cerebral or spinal cord ischemia and therefore can present as having a stroke or paraplegia.[30] Hypotension often occurs with type A dissection, whereas hypertension is more commonly seen in type B dissection. A significant difference in systolic blood pressure (>20 mm Hg) between the upper extremities may be detected, but this finding is not pathognomonic. A diastolic murmur of aortic insufficiency can result from retrograde dissection into the aortic valve, whereas a friction rub may be appreciated with concomitant large pericardial effusion or tamponade.

The ECG may be normal or show nonspecific ST-segment or T-wave changes or left ventricular hypertrophy secondary to hypertension. Rarely, the ECG reveals evidence of an MI from retrograde dissection into a coronary artery. Although patients may have an abnormality on CXR, such as widening of the mediastinum, an abnormal aortic contour, or displacement of intimal aortic calcification from the outer border of the aortic knob, this is not universal, and its absence can lead to delays in diagnosis.[31,32] The vast majority of patients undergo either CT angiography or transesophageal echocardiography for diagnosis, both of which have high sensitivity and specificity. Magnetic resonance imaging (MRI) may also have a limited role, although given its lack of generalized availability and lengthy examination duration, its use in this setting is less appealing.[33]

Initial management should focus on heart rate and blood pressure control, usually with beta-blockers, typically the rapidly titratable agent esmolol, and the use of a potent vasodilator such as nicardipine or clevidipine.[33,34] Emergent cardiothoracic surgical consultation is imperative. Further discussion of surgical operative strategy is beyond the scope of this chapter.

Pneumothorax

Pneumothorax is caused by air from the alveoli or the surrounding atmosphere entering the potential space between the parietal and visceral pleura. Pneumothorax in the ICU is often iatrogenic, resulting from mechanical ventilation (particularly with acute respiratory distress syndrome) and procedural attempts at central venous catheterization, thoracentesis, tracheostomy, transbronchial lung biopsy, or bronchoscopy.[35] Almost any lung pathology can contribute to the risk for pneumothorax, but a ruptured bleb from chronic obstructive pulmonary disease is most common. Patients with pneumothorax often complain of a sudden onset of ipsilateral pleuritic chest pain and dyspnea.

Chest examination may reveal palpable crepitus, decreased breath sounds, decreased chest wall excursion, or hyperresonance to percussion. Vital signs may be significant for tachycardia, hypoxia, or tachypnea. Patients with a tension pneumothorax classically have tracheal deviation, JVD, and hypotension. Patients receiving mechanical ventilation often, but not invariably, have increased peak inspiratory airway pressures. Signs of pneumothorax are nonspecific, and any worrisome deterioration of vital signs in a ventilated patient should prompt a diagnostic evaluation for pneumothorax.

CXRs are often performed in the semi-upright or supine position in the ICU, whereas the signature finding of pneumothorax, a visceral pleural line, is often seen only on an upright CXR. In supine patients, a deep sulcus sign may be seen where the costophrenic angle extends more inferiorly than normal, as air collects in this space. Alternatively, a sharp delineation of the cardiac silhouette from the lucency of an anteromedial pneumothorax may be seen. In an experienced operator's hands, ultrasound can rule out a pneumothorax with high sensitivity.[36] A CT scan is usually definitive.

Treatment of pneumothorax is contingent on its size, the patient's hemodynamic and respiratory status, and concurrent use of mechanical ventilation. Because of concern for conversion to tension pneumothorax in patients on mechanical ventilation, evacuation of air from the pleural space is often required with a tube thoracostomy. In patients with hemodynamic compromise from a suspected tension pneumothorax, treatment with immediate needle thoracostomy, followed by tube thoracostomy, should not be delayed while waiting for a CXR. For the vast majority of patients, a small-bore catheter placed via the Seldinger technique is as efficacious as standard chest tube placement in those with primary spontaneous pneumothorax.[37,38]

Esophageal Rupture

A full-thickness tear of the esophagus carries a high mortality risk, because of the intense inflammatory response to gastric contents in the mediastinum and pleural space, resulting in a chemical and bacterial mediastinitis, with development of sepsis and multisystem organ failure. Most cases of esophageal perforation are caused by upper gastrointestinal tract instrumentation. The risk of esophageal injury from a diagnostic endoscopy is low but increases dramatically when interventions such as dilation or stent placement are performed.[39] Esophageal rupture may be caused by other procedures commonly performed in the ICU, including nasogastric or tracheal intubation. Spontaneous rupture of the esophagus (Boerhaave syndrome) occurs from a sudden increase in intraluminal pressure, usually from vomiting or retching. Patients with esophageal disease such as cancer, Barrett esophagus, strictures, prior radiation, and varices are particularly vulnerable to rupture, most commonly at the left posterolateral aspect of the distal esophagus. With thoracic esophageal perforations, the pain localizes to the substernal or epigastric area, but it may occur in the neck with cervical perforations. Other associated symptoms include dysphagia, odynophagia, and dyspnea.

The patient is often febrile. Crepitus can be felt in the neck with perforation of the cervical esophagus. Mediastinal emphysema can be detected by a crunching sound on cardiac auscultation (Hamman sign). A CXR often reveals subcutaneous emphysema, pneumomediastinum, pneumothorax, or pleural effusion. The CXR is abnormal in almost 90% of cases, usually demonstrating left-sided infiltrate or effusion. A water-soluble contrast study of the esophagus or a CT scan of the chest and abdomen can be performed in cases where there is a high clinical suspicion and the CXR is nondiagnostic. Mortality increases with delays in treatment beyond 24 hours, and urgent diagnosis is imperative.[40]

Treatment may involve operative repair, endoscopic therapy, or conservative management, depending on the location of the leak, its containment, and the presence of sepsis. Conservative management consists of broad-spectrum antibiotics, ensuring coverage of both anaerobic and aerobic species (augmented by antifungal treatment in patients with relevant risk factors) and observation.[41,42]

Aortic Stenosis

AS causes left ventricular outflow obstruction, which leads to left ventricular hypertrophy. AS may result from a congenitally abnormal (bicuspid) valve, rheumatic heart disease, or valvular calcification. Clinical manifestations of AS, including angina, congestive heart failure, and syncope, occur when the hypertrophied left ventricle can no longer overcome the stenosis or when the hypertrophy itself causes diastolic dysfunction or excessive myocardial oxygen demand that predisposes to ischemia.

Physical examination features of AS include narrow pulse pressure, a delayed and slow rise of the carotid pulse (pulsus tardus et parvus), a systolic murmur at the right second intercostal space often radiating to the carotid arteries, and an S4 heart sound (if patients are in sinus rhythm). CXR and ECG may show signs of left ventricular hypertrophy, but the diagnostic study of choice is the echocardiogram.[43]

Definitive therapy involves valve replacement, either by conventional surgical approaches or, in well-selected cases, via transcatheter aortic valve replacement. Temporizing management focuses on cautiously decreasing afterload with vasodilators. Close hemodynamic monitoring is essential when using vasodilators because of the risk of hypotension and dysrhythmias, which are poorly tolerated. Angina and congestive heart failure are treated with oxygen and the careful administration of nitrates, morphine, and diuretics. Occasionally, balloon aortic valvuloplasty may be used to bridge patients until they can undergo surgical or transcatheter valve replacement.[44]

Miscellaneous

Other causes of potentially life-threatening chest pain in the ICU include pneumonia and acute abdominal processes. Pneumonia is often accompanied by pleuritic chest pain or shoulder pain referred from diaphragmatic irritation. Upper gastrointestinal pathology, such as cholecystitis, choledocholithiasis, cholangitis, or pancreatitis, may present with chest and abdominal pain radiating toward the back. A perforated ulcer can present with chest pain, and the diagnosis is often made when free air is incidentally discovered under the diaphragm on an upright CXR.

NON–LIFE-THREATENING CAUSES OF CHEST PAIN

The following causes of chest pain should be considered only after life-threatening causes have been excluded.

Pericarditis

Pericarditis is a relatively rare cause of chest pain in the inpatient setting.[45] The condition commonly results from viral or idiopathic causes, but other etiologies include bacterial infection, malignancy, tuberculosis, uremia, autoimmune diseases, transmural MI (Dressler syndrome), and cardiac surgery (postpericardiotomy syndrome). Chest pain from pericarditis is often retrosternal, pleuritic, and sharp, radiating to the back or arms and exacerbated when lying flat.

A pericardial friction rub is highly specific for pericarditis and is present in the majority of cases, heard best over the left sternal border with the patient sitting forward. Common ECG findings in pericarditis include diffuse ST-segment elevation without reciprocal ST depressions, absence of Q waves, and PR depressions.[45] Electrical alternans and low voltage on the ECG, coupled with cardiomegaly on CXR, strongly favor the concomitant presence of a large pericardial effusion. Although the ECG and CXR findings of pericardial effusion can be useful, echocardiography should be performed to confirm the diagnosis.

Treatment is aimed at the underlying etiology. Nonsteroidal antiinflammatory drugs (NSAIDs) relieve pain and inflammation in viral or idiopathic pericarditis. Colchicine may be used as an adjunct in reducing bouts of recurrent pericarditis.[46] Pericardiocentesis is performed for therapeutic purposes in the case of tamponade and for diagnostic purposes if tuberculosis, bacterial infection, or malignancy is suspected.

Esophageal Disorders

In patients with noncardiac chest pain, gastroesophageal reflux disorder and esophageal motility disorders (e.g., esophageal spasm) are commonly responsible. Esophageal disease is associated with pain precipitated by lying flat, postprandial pain, heartburn, or dysphagia. Because of the shared innervation of the heart and esophagus, visceral pain originating from these two organs can be similar in character. Empiric treatment with proton pump inhibitor or H_2 blocker may be considered. Additionally, a nasogastric tube with the distal tip in the esophagus can produce chest pain; this is easily remedied by advancing the tube distally into the stomach.

Musculoskeletal, Skin, and Psychiatric Disorders

Pain from costochondritis is often reproduced by direct palpation of the affected region or by arm movement and can be treated with NSAIDs. ICU patients may have other causes of chest wall pain, including rib fractures, chest tubes, postoperative pain after cardiothoracic surgery, or an intercostal muscle strain from vigorous coughing.

Herpes zoster should also be considered, which results from reactivation of the varicella-zoster virus within thoracic sensory ganglia, causing a painful, dermatomal rash on the chest. This pain of shingles may precede the rash by several days, often delaying its diagnosis. Treatment consists of antiviral medications, such as acyclovir or valaciclovir. Finally, it is imperative to rule out life-threatening causes of chest pain before attributing its etiology to anxiety. Psychiatric patients with cardiac or pulmonary disease can be challenging to diagnose, and a thorough approach is essential.

CONCLUSION

Attention to immediate life-threatening conditions and a thorough history and physical examination after initial stabilization are fundamental to managing chest pain in the ICU. A CXR, ECG, and serial cardiac enzymes should be ordered liberally, but intelligently. Focused ultrasound to assess the lungs, pleura, and heart can be helpful. A high index of suspicion for occult disease is necessary for complex ICU patients.

KEY POINTS

- Attention to detail with a brief but thorough history and physical examination are fundamental to managing chest pain in the ICU.
- A logical evaluation plan must simultaneously assess for and empirically treat immediately life-threatening etiologies of chest pain.
- Useful adjunctive testing includes ECG, CXR, cardiac enzymes, and focused ultrasound of the heart and lungs.
- Non–life-threatening causes of chest pain in the ICU are numerous, but should be diagnoses of exclusion.

This executive summary comprises the AHA guidelines for the appropriate diagnosis and management of patients with NSTEMI.

Contou D, Razazi K, Katsahian S, et al. Small-bore catheter versus chest tube drainage for pneumothorax. *J Emerg Med*. 2012;30(8):1407–1413.
This retrospective cohort study compared ≈200 patients treated with traditional chest tube with small-bore catheters for pneumothorax over an 8-year period, finding a similar rate of primary treatment failure but a decreased duration of tube placement and hospitalization in those with small-bore catheters. This supports the practice of placing smaller catheters in patients with primary pneumothorax in the ICU.

Evangelista A, Isselbacher EM, Bossone E. Insights from the International Registry of Acute Aortic Dissection: a 20-year experience of collaborative clinical research. *Circulation*. 2018;137(17):1846–1860.
The IRAAD is composed of more than 51 centers in 12 countries, enrolling more than 7000 patients diagnosed with acute aortic dissection since 1996. Epidemiology, typical symptomatology, diagnosis, management, and outcomes are evaluated over this period. This represents the largest registry of patients diagnosed with acute aortic dissection and is a tremendous repository of information for clinicians in the appropriate evaluation and treatment of the condition.

Girardi AM, Bettiol RS, Garcia TS, et al. Wells and Geneva scores are not reliable predictors of pulmonary embolism in critically ill patients: a retrospective study. *J Intensive Care Med.* 2018;35:1112–1117.
In this retrospective cohort study of ICU patients who underwent CT evaluation for pulmonary embolism, both the Geneva and Wells scores inappropriately stratified patients as low risk for PE as confirmed by CT. This highlights the importance of understanding that these risk scores have not been validated in the ICU setting, diligent evaluation for PE in ICU patients remains paramount, and further study is merited to clarify additional risk factors present in this cohort.

Graber ML, Franklin N, Gordon R. Diagnostic error in internal medicine. *Arch Intern Med.* 2005;165(13):1493–1499.
An analysis of 100 cases identified premature closure—that is, failing to consider alternatives once an initial diagnosis was made—as the most common cause of diagnostic error by internists. This study underscores the importance of not assuming that the admission diagnosis is necessarily correct or the only problem.

Biochemical or Electrocardiographic Evidence of Acute Myocardial Injury

Fabien Picard and Steven M. Hollenberg

The identification of myocardial injury is an important problem in the critical care setting. Biomarkers have been used to detect myocardial injury since 1954.[1] Since then, the sensitivity of serologic techniques has increased dramatically. Although increased sensitivity has allowed clinicians to detect smaller amounts of myocardial necrosis, this has also posed several interpretive challenges. What constitutes significant myocardial damage? How should evidence of myocardial necrosis be interpreted in the absence of classical clinical criteria for myocardial infarction? In response to some of these challenges, a task force has formulated a universal definition of myocardial infarction, updated in 2018 (Table 29.1).[2] These definitions rely on both electrocardiographic and biochemical information and stress that, in addition to biochemical findings, the diagnosis of myocardial infarction (MI) requires symptoms *or* characteristic electrocardiogram (ECG) changes *or* findings from imaging, angiography, or autopsy. The most important distinction for the clinician is between type 1 MIs (plaque rupture) and type 2 MIs (demand ischemia leading to infarction).

ELECTROCARDIOGRAPHIC EVIDENCE

Acute coronary syndromes (ACSs) are a group of conditions characterized by acute myocardial ischemia resulting from inadequacy of myocardial blood flow. The ACSs are classified by clinical, biochemical, and electrocardiographic data, initially dividing patients by ECG into those with ST elevation myocardial infarction (STEMI), who should be considered for immediate revascularization, and those without (non-ST elevation [NSTE-ACS]).[3] Patients with suspected ACS must have an ECG obtained and interpreted within 10 minutes of presentation.[4] Criteria for the diagnosis of STEMI include new ST elevation ≥0.1 mV at the J-point in at least two contiguous leads (except $V_{2–3}$) or new left bundle branch block (LBBB).[2,5] (In leads $V_{2–3}$ cut points are higher: ≥0.15 mV in women, ≥0.2 mV in men ≥40, and ≥0.25 mV in men <40.)

Many conditions that mimic STEMI lead to false positives.[2] An early repolarization pattern with up to 3-mm ST elevation in leads $V_{1–3}$ can be seen in some healthy individuals, typically in young men. Preexcitation, bundle branch block, pericarditis, pulmonary embolism, subarachnoid hemorrhage, metabolic disturbances (e.g., hyperkalemia and hypothermia), and left ventricular aneurysms can be associated with ST elevation in the absence of acute myocardial ischemia. On the other hand, some conditions can lead to false negatives, including prior MI, paced rhythm, and LBBB when acute ischemia is not recognized. These pitfalls are common, both in the real world and in large clinical trials.[6]

"Nondiagnostic" ECGs are common in the setting of true acute MI, characterizing up to 8% of such patients, with nonspecific changes occurring in another third.[7] These nondiagnostic ECG findings may be the result of occlusion of only small vessels or insensitivity of the 12-lead ECG to ischemia in the lateral or posterior myocardial territory. Supplemental leads, such as $V_{7–9}$, can improve sensitivity.[8] If ischemia is strongly suspected without ECG changes, serial ECGs or ECGs with additional leads should be performed[4] to increase the sensitivity of MI detection relative to single ECGs.[9]

ST-segment depression on an ECG identifies patients with ACS at high risk, as this is associated with the severity of coronary artery disease (CAD).[10] T-wave changes can also be prognostic. Patients presenting to the emergency department with ACS and isolated T-wave changes have a lower risk for adverse outcomes than those with ST depression but are at higher risk than those with a normal ECG.[11] In asymptomatic patients, most T-wave changes are nonspecific. However, in the intensive care unit (ICU), some patterns are strongly associated with myocardial ischemia. Marked symmetric precordial T-wave inversions ≥2 mm suggest acute ischemia, usually the result of a critical stenosis of the left anterior descending artery.[12]

CK-MB, TROPONIN, AND HIGH-SENSITIVITY TROPONIN

With cardiac cell death, proteins are released into the blood, and detection of these proteins has played a key role in establishing the diagnosis of ACS, predicting its outcome, and directing treatment. Creatine kinase (CK) and its isoenzyme MB (CK-MB) became the biomarkers of choice to establish myocardial injury and infarction in the 1970s, but have been superseded by troponin T and I, parts of the troponin-tropomyosin complex in cardiac myocytes, because of their increased sensitivity and specificity. Troponin elevations are much more sensitive and are highly specific for myocardial cellular injury; false positives because of fibrin interference or cross-reacting antibodies are infrequent.[13] Even minor increases in circulating troponin values correlate with adverse short-term and long-term outcomes in NSTE-ACS[13] and also identify the patients most likely to benefit from more aggressive antiplatelet strategies and from early coronary angiography and revascularization.[4]

The challenge for the clinician, and particularly for the intensivist, is that although the elevation of serum troponin is highly specific for myocardial cell damage, not all of the damage is a consequence of the rupture of an atherosclerotic plaque. Demand ischemia (type 2 MI) can also lead to troponin release. Other causes of elevated troponin, many of which are common in the ICU, are listed in Table 29.2.[2] This spectrum of troponin-associated conditions highlights the fact that MI should only be diagnosed in the appropriate clinical setting.[2] Troponin release in critically ill patients may not always represent myocardial cell death. Endotoxin, cytokines, and other inflammatory mediators, along with catecholamines and conditions such as hypotension, inotropes, or

TABLE 29.1 Clinical Classification and Definition of Different Types of Myocardial Infarctions

Type 1: MI Caused by Atherothrombotic CAD and Usually Precipitated by Atherosclerotic Plaque Disruption (Rupture or Erosion)

Detection of a rise and/or fall of cTn values with at least one value above the 99th percentile URL and with at least one of the following:

- Symptoms of acute myocardial ischemia
- New ischemic ECG changes
- Development of pathologic Q waves
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischemic etiology
- Identification of a coronary thrombus by angiography, including intracoronary imaging or by autopsy

Type 2: Myocardial Injury in the Context of a Mismatch Between Oxygen Supply and Demand

Detection of a rise and/or fall of cTn values with at least one value above the 99th percentile URL and evidence of an imbalance between myocardial oxygen supply and demand unrelated to acute coronary atherothrombosis, requiring at least one of the following:

- Symptoms of acute myocardial ischemia
- New ischemic ECG changes
- Development of pathologic Q waves
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischemic etiology

TYPE 3: Cardiac Death in Patients with Symptoms Suggestive of Myocardial Ischemia and Presumed New Ischemic ECG Changes Before Ctn Values Become Available or Abnormal

Patients who suffer cardiac death, with symptoms suggestive of myocardial ischemia accompanied by presumed new ischemic ECG changes or ventricular fibrillation, but die before blood samples for biomarkers can be obtained, or before increases in cardiac biomarkers can be identified, or MI is detected by autopsy examination.

Type 4a: MI Associated with Percutaneous Coronary Intervention (≤48 Hours After the Index Procedure)

Coronary intervention–related MI is arbitrarily defined by an elevation of cTn values more than five times the 99th percentile URL in patients with normal baseline values. In patients with elevated preprocedure cTn in whom the cTn levels are stable (<20% variation) or falling, the postprocedure cTn must rise by >20%. However, the absolute postprocedural value must still be at least five times the 99th percentile URL. In addition, one of the following elements is required:

- New ischemic ECG changes
- Development of new pathologic Q waves
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischemic etiology
- Angiographic findings consistent with a procedural flow-limiting complication such as coronary dissection, occlusion of a major epicardial artery or a side branch occlusion/thrombus, disruption of collateral flow, or distal embolization

TYPE 4b: Stent/Scaffold Thrombosis Associated with Percutaneous Coronary Intervention

TYPE 4c: Restenosis Associated with Percutaneous Coronary Intervention

TYPE 5: MI Associated with CABG (≤48 Hours After the Index Procedure)

CABG-related MI is arbitrarily defined as elevation of cTn values >10 times the 99th percentile URL in patients with normal baseline cTn values. In patients with elevated preprocedure cTn in whom cTn levels are stable (<20% variation) or falling, the postprocedure cTn must rise by >20%. However, the absolute postprocedural value still must be >10 times the 99th percentile URL. In addition, one of the following elements is required:

- Development of new pathologic Q waves
- Angiographic-documented new graft occlusion or new native coronary artery occlusion
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality in a pattern consistent with an ischemic etiology

CABG, Coronary artery bypass grafting; *cTn*, cardiac troponin; *ECG*, electrocardiogram; *MI*, myocardial infarction; *URL*, upper reference limit.

hypoxia, may cause the breakdown of cytoplasmic troponin into smaller fragments that can pass through endothelial monolayers and subsequently be detected by sensitive troponin assays.[14] Although detectable troponin levels usually emanate from myocardial cells, they may not always represent either irreversible cell death or myocardial ischemia. Renal dysfunction is another factor associated with elevated troponin levels, and both the sensitivity and specificity of this biomarker are decreased in that population.

Regardless of the cause, it is clear that elevation of serum troponin levels is associated with a worsened outcome both in and out of the ICU, even after adjustment for severity of the disease.[15] What is less clear is whether myocardial dysfunction represents the proximate cause of the worsened prognosis. It is often difficult to exclude ischemia in critically ill patients, but in a study of patients with septic shock, troponin predicted mortality risk even in patients in whom flow-limiting lesions were excluded either by stress echocardiography or by direct examination at autopsy.[16]

These challenges are likely to be compounded by the wider use of high-sensitivity troponin (hs-cTn) assays.[17] Two large prospective multicenter studies have demonstrated that high-sensitivity cTn and hs-cTn assays have a higher diagnostic accuracy for the diagnosis of MI than less-sensitive cTn assays, especially in patients presenting early after chest pain onset.[18,19] The clinical introduction of hs-cTn assays is a trade-off: on one hand allowing earlier detection and exclusion of acute MI (AMI) in the first hours, but on the other, the detection of myocardial cell death associated with multiple

TABLE 29.2 Causes of Elevation of Cardiac Troponin Values

Myocardial Injury Related to Acute Myocardial Ischemia

Atherosclerotic plaque disruption with thrombosis.

Myocardial Injury Related to Acute Myocardial Ischemia Because of Oxygen Supply/Demand Imbalance

Reduced myocardial perfusion, for example:

- Coronary artery spasm, microvascular dysfunction
- Coronary embolism
  - Coronary artery dissection
  - Sustained bradyarrhythmia
- Hypotension or shock

Respiratory failure

- Severe anemia

Increased myocardial oxygen demand, for example:

- Sustained tachyarrhythmia
- Severe hypertension with or without left ventricular hypertrophy

Other Causes of Myocardial Injury

Cardiac conditions, for example:

- Heart failure
  - Myocarditis
  - Cardiomyopathy (any type)
  - Takotsubo syndrome
  - Coronary revascularization procedure
  - Cardiac procedure other than revascularization

Catheter ablation

- Defibrillator shocks
- Cardiac contusion

Systemic conditions, for example:

- Sepsis, infectious disease
  - Chronic kidney disease
  - Stroke, subarachnoid hemorrhage
  - Pulmonary embolism, pulmonary hypertension
  - Infiltrative diseases (e.g., amyloidosis, sarcoidosis)

Chemotherapeutic agents

- Critically ill patients
- Strenuous exercise

From Thygesen K, Alpert JS, Jaffe AS, et al. Fourth universal definition of myocardial infarction. *Circulation.* 2018;138(20):e618–e651.

noninfarction pathophysiologic conditions. That enhanced sensitivity challenges the clinician to differentiate them.[20] A further difficulty in the ICU is that patients may not experience classic symptoms of ischemia or may be unable to report them. Despite this potentially confounding factor, it is useful for the clinician to recall that an MI is diagnosed when biomarkers are elevated in a suggestive clinical setting.[2] A characteristic rise and subsequent fall should be seen, as an isolated high troponin value may not result from persisting ischemia.[21] Troponin levels should be repeated to define the clinical course. In addition, it is important to note that the diagnostic performance of hs-cTn assays is currently not established outside the setting of the patient presenting to the emergency department with chest pain.[20]

OTHER BIOMARKERS

Although some emerging biomarkers provide good sensitivity or specificity for the diagnosis of MI, others may provide useful information regarding prognosis.

Cardiac myosin-binding protein C (cMyC) is a cardiac-restricted protein that rapidly enters the systemic circulation after myocardial injury, is relatively more abundant than troponin, and has been recently identified as a new candidate biomarker of cardiac injury.[22] cMyC rises more rapidly in the systemic circulation than hs-cTnT, perhaps as a result of its higher myocardial concentration.[23] In a recent analysis of unselected patients presenting to the emergency department with symptoms suggestive of AMI, discriminatory power for MI was comparable for cMyC and other biomarkers, but the combination of cMyC with standard-sensitivity cTn led to an increase in area under the diagnostic curve and more accurately classified patients with a single blood test into rule-out or rule-in categories.[24] Validation in larger and more varied cohorts is needed.

The N-terminus portion of human albumin binds to transition metal ions. Under ischemic and oxidative conditions, this binding is inhibited, and detection of this ischemia-modified albumin (IMA) has been described as a marker of oxidative stress and hypoperfusion.[25] In MI, IMA levels rise within 6 hours and remain elevated for 12 hours, and a combination of IMA, ECG, and contemporary troponin assays was reported to have a negative predictive value of 97% for MI.[26] In patients with severe sepsis, IMA was a strong predictor of short-term mortality.[27] Its use, however, has not yet been confirmed to add value to contemporary hs-TnT assays,[25] and detection of high IMA levels in patients with cancer, infection, brain ischemia, liver disease, and end-stage renal disease limits the specificity of this test for the diagnosis of MI.

MicroRNAs (mi-RNAs), short, noncoding RNAs that regulate gene expression at the post-transcriptional level, are novel markers that may prove clinically useful. Three mi-RNAs (miR-133a, miR-208b, and miR-499) demonstrated high sensitivity and specificity for detecting AMI,[28] but a recent study demonstrated that sensitivity of current mi-RNA detection was inferior to troponin.[29] A multibiomarker combination of muscle-enriched mi-RNAs with cMyBP-C and cardiac troponins could open a new path of integrating complementary characteristics of different biomarker types.

The prohormone proBNP is released by the heart in response to stretching of the wall and after ischemia. Subsequently, it is cleaved into active B-type natriuretic peptide (BNP) and N-terminal proBNP (NT-proBNP), both of which can be measured in blood. Higher BNP levels in ACS patients correlate with an increased risk of death, and BNP appears to confer information independent of other clinical markers, adding prognostic value to the Global Registry of Acute Coronary Events (GRACE) risk score.[30] Use of BNP in the ICU is complex, however; women and older individuals have higher BNP levels, and so age- and gender-specific cutoffs may be needed.[31] Whereas obese individuals have lower values, renal dysfunction increases BNP serum levels, sometimes dramatically.[32,33] BNP levels can also be increased in the setting of right ventricular strain. Consequently, in patients with pulmonary embolism, both elevated BNP and elevated troponin levels carry a worsened prognosis.[34] BNP remains a good indicator of ventricular dysfunction and myocardial wall stress, but which cutoff levels should be used in the ICU and what the clinician should do when the BNP exceeds those levels remain unclear.

KEY POINTS

- Of the five MI types, those most pertinent to the critical care setting are type 1 (plaque rupture) and type 2 (demand ischemia leading to infarction).
- "Nondiagnostic" ECGs are common in the setting of AMI.
- Troponin elevations are highly specific for myocardial cellular injury, but their release may not always indicate myocardial plaque rupture.
- High-sensitivity troponin assays have allowed clinicians to detect smaller amounts of myocardial necrosis, but this has also posed several interpretive challenges.
- Renal dysfunction is another factor associated with elevated troponin levels, decreasing both the sensitivity and specificity of this biomarker in this population.
- Emerging biomarkers have been shown to provide good sensitivity or specificity for the diagnosis of MI and may provide information regarding prognosis.

Point-of-Care Ultrasound

Sumit P. Singh and Davinder Ramsingh

Recent advances in ultrasound technology have allowed ultrasound instruments to become smaller, more portable, and less expensive, so that this powerful imaging tool can be readily and repeatedly used in everyday intensive care unit (ICU) care.[1] The concept of point-of-care ultrasound (POCUS) refers to the use of portable ultrasonography at the patient's bedside for diagnostic and therapeutic purposes.[2] The provider acquires and interprets all images in real time and then uses that information to diagnose and direct therapy. Although comprehensive imaging can also be performed and interpreted at the point of care, the term POCUS typically refers to an ultrasound examination that is simple, rapid, and goal-oriented. It is a tool used most often to provide answers to acute "yes or no" clinical questions, but interpretations can be more nuanced, depending on the provider's qualifications, experience, and skill. Indeed, POCUS has been identified as a separate imaging modality with defined routes for training, reporting, and billing.[3,4]

In the acute care setting, this modality has demonstrated utility for nearly every component of bedside assessment, including cardiac, pulmonary, hemodynamic, vascular, neurologic, and gastrointestinal status. Recent evidence has demonstrated improved diagnostic accuracy for each of these systems after the operator receives training from a cost-free online curriculum (www.foresightultrasound.com).[5]

This chapter seeks to review the current use of POCUS in the critical care setting. Specifically this chapter will discuss the following areas: (1) ultrasound physics and probe selection, (2) assessment of pulmonary status, (3) advanced vascular access, and (4) additional areas of assessment. Chapter 31 provides a thorough discussion of echocardiography, including the echocardiographic assessment of intravascular volume status (preload responsiveness) and the use of echocardiography to diagnose shock and monitor response to treatment. Training on these topics using a model simulation–based educational curriculum has been shown be effective and to positively affect patient care.[6]

ULTRASOUND PHYSICS, PROBE SELECTION, AND MANIPULATION

Clinical ultrasound systems use transducers that emit and detect sound waves with a frequency between 2 and 27 MHz. Image production depends on the strength of the returning ultrasound signal and relates directly to the angle at which the ultrasonic beam strikes the acoustic interface. The ultrasound signal is described by its frequency and wavelength. A shorter wavelength (i.e., a higher frequency) provides better resolution but less penetration into tissues. Therefore higher-frequency probes (5–10 MHz) provide better resolution but are useful only for imaging superficial structures. Lower-frequency probes (2–5 MHz) provide better penetration but have lower resolution. Probe selection is based on matching the properties of the ultrasound probe with the particular structure that one is trying to image. Besides frequency, additional properties of the probe include the footprint (area emitting the ultrasound) and shape. Typical phased-array probes emit at 3–5 MHz, have a small footprint, and produce a wide ultrasound image by sending out packets of ultrasound that are stitched together. Curved linear probes emit at 4–7 MHz, have a large footprint, and are ideal for imaging of abdominal structures. These probes generate a wide image because of the way the ultrasound waves are emitted. Linear probes emit at 10–27 MHz and are used for imaging superficial structures (Fig. 30.1).

Acoustic gel is used to minimize the difference in acoustic impendence from the probe to the skin. Standard 2D image creation is called *B-mode (brightness mode)*. In this mode, there is a change in spot brightness for each ultrasound signal received by the transducer. M-mode (motion mode) is a graphic B-mode pattern that is a single screen line of ultrasound signal displayed over time and is used primarily to assess the motion of structures along the ultrasound beam. Doppler ultrasound is a modality that is used to determine direction and intensity of vascular flow by assessing the change in velocities secondary to the motion of the structure of interest (usually red blood cells). It is important to remember that Doppler signals are more accurate when the ultrasound signal is parallel to the direction of flow. With color Doppler, the Doppler echoes are displayed with colors corresponding to the direction of flow. With continuous wave Doppler, one assesses the summation of velocities of flow along a line of the ultrasound signal. With pulse wave Doppler, one is able to assess flow velocity in an exact location, but with the limitation of only being able to assess a restricted range of velocities. From each transducer position, the targeted structure is characterized by five major probe movements: (1) *slide* refers to motion in the long axis of the probe along the body, (2) *rock* refers to motion along the long axis of probe at a fixed point of the body, (3) *sweep* refers to motion in the short axis of the probe along the body, (4) *fan* refers to motion along the short axis of the probe at a fixed point of the body, and (5) *rotation* refers to moving the probe in a clockwise or counterclockwise direction.[7]

ASSESSMENT OF PULMONARY DISORDERS

When applicable to the condition or problem at hand, ultrasound assessment of pulmonary disorders holds potential value for the critical care physician. Ultrasound may provide noninvasive, immediate bedside

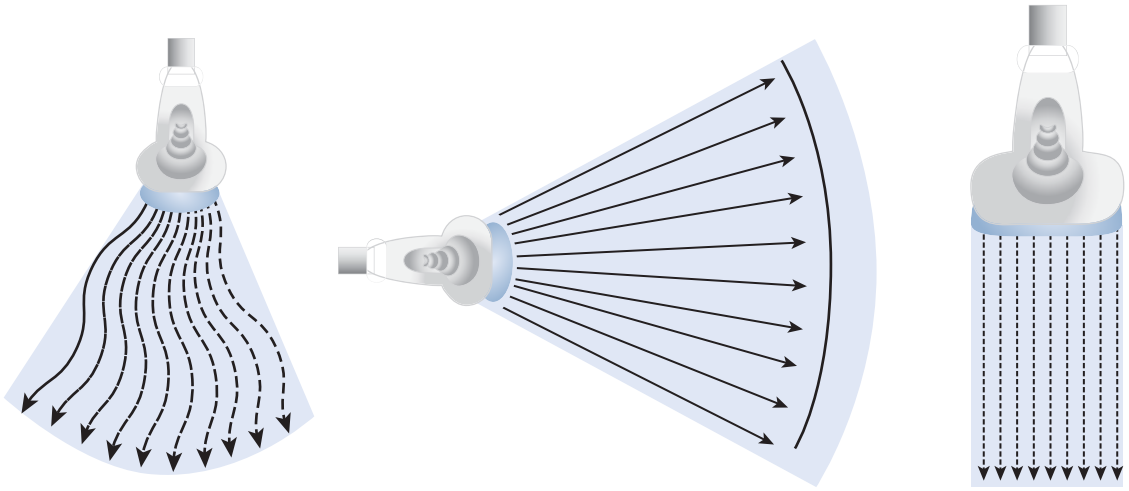

Fig. 30.1 Ultrasound Probe Types.

diagnosis, unlike a computed tomography (CT) scan, which requires transporting the patient. Ultrasound is especially useful in pregnant and pediatric patients, where minimizing radiation exposure is important. However, lung ultrasound does have some limitations. Central lung pathologies and areas under the ribs or scapula cannot be visualized. Examination of obese patients is difficult. Examination of trauma patients with subcutaneous emphysema is difficult or impossible.

Performing an ultrasound for detection of pneumothorax is a simple, easily learned technique. Studies showed that inexperienced, recently trained personnel produced high detection rates for pneumothorax.[8,9] Ultrasound of the lung relies on the physical principle that fluid collects in gravitationally dependent areas, whereas gas collects superiorly. Therefore positioning the patient appropriately for the examination is critical. In reporting the findings, the physician should specify both the patient's position (e.g., sitting, supine, right side down, or left side down) and the location of the probe. Probe placement should be posterior and inferior for detection of fluid but anterior and superior for detection of air. Although the probe can be placed transversely between two ribs, longitudinal placement with a view of the ribs is recommended because of the enhanced orientation provided by the rib shadows.

The curvilinear probe provides the best visualization of the pleural cavity. Although the lower frequency of 4–5 MHz does not allow the distinction of visceral from parietal pleura, it does permit visualization of normal lung "sliding" along the pleural surface and detection of air artifacts.

One of the initial steps in performing ultrasound of the lung is to visualize the diaphragm, which is a curvilinear hyperechoic structure that descends with every breath. The liver on the right side and the spleen on the left side serve as landmarks during this initial visualization.

A subcostal or transdiaphragmatic abdominal approach can also be used to visualize the pleural cavity, but a potential difficulty of this view is that "concave" organs, such as the spleen, may reverberate, producing artifacts that appear to be dense lesions in the pleural cavity.

A normal ultrasound image of the lung will have the following features:

1. Lung sliding: As the lung inflates or deflates, the visceral pleura moves against the parietal pleural. The ultrasound images show this to-and-fro pleural movement, called *lung sliding.* Lung sliding is more prominent at the lung bases than at the apex. It is absent in the presence of intervening pleural air (pneumothorax) or fluid (pleural effusion). Inflammation that causes adherence of the two pleural membranes will also lead to absence of lung sliding. In M-mode, lung sliding can be best seen with the muscle and parietal pleura represented as static horizontal lines above the to-and-fro movement of the visceral pleura and lung, which appears granular. This appearance on M-mode is called the *seashore sign* (Fig. 30.2).
2. A-lines: These are motionless horizontal reverberations of the pleural lining that give a regularly spaced, hyperechoic artifact on the ultrasound image.
3. B-lines: Also called *ultrasound lung comets,* B-lines may be considered the ultrasonic equivalent of radiologic Kerley B-lines that indicate lung edema. These artifacts have seven features: (1) have a "hydroaeric" comet tail, (2) are hyperechoic, (3) are well-defined, (4) arise from the pleural lining, (5) are associated with disappearance of A-lines, (6) move with lung sliding when present, and (7) feature a pattern of indefinite spreading in a cephalad direction.[10] B-lines are artifacts of water-thickened interlobular septa and indicate increasing amounts of extravascular pulmonary edema, such as occurs in congestive heart failure (Fig. 30.3).

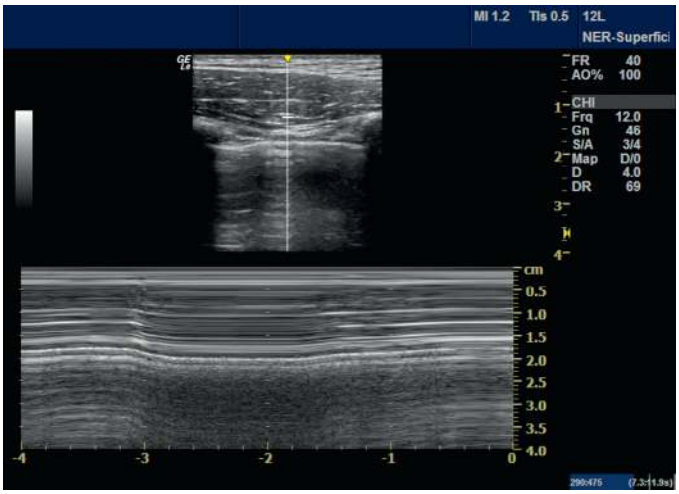

Fig. 30.2 Seashore Sign. M-mode ultrasound of normal lung.

Pleural Effusion

The pleural cavity is quite accessible to ultrasound visualization. Pleural effusions are best seen in dependent areas of the chest: that is,

Fig. 30.3 B-line.

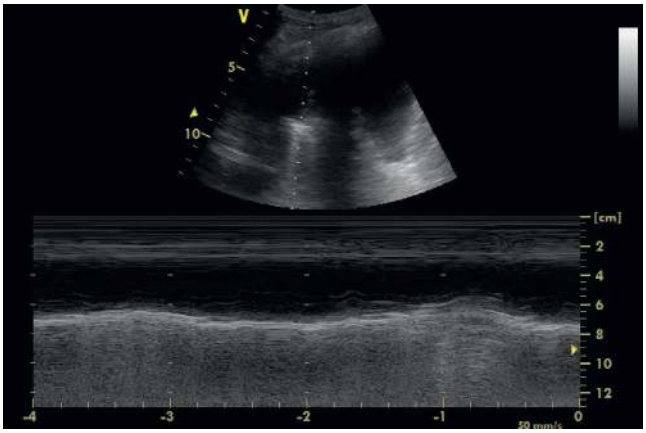

Fig. 30.4 Sinusoid Sign. The visceral pleura moves toward the parietal pleura with lung expansion, giving a sinusoidal sign on M-mode.

posterior or inferior areas. The fluid is bounded inferiorly by the diaphragm and peripherally by the visceral and parietal pleural margins. With respiration, the visceral pleura should move toward the parietal pleura, producing a sinusoid sign with M-mode, which is highly specific (97%) for the presence of a pleural effusion[11] (Fig. 30.4). At times, the lung may appear to be floating in the pleural liquid. A positive sinusoid sign can detect the presence of a low-viscosity pleural effusion, but it may be falsely negative if the pleural fluid is highly viscous.

Ultrasound is more sensitive and specific than either auscultation or chest x-ray and therefore is the method of choice to evaluate pleural effusions.[12,13] Effusions that produce a 1-cm thickness in dependent zones are easily detected, with accuracy exceeding 90%.[13] Anterior presentation of an effusion suggests that it is abundant. When large effusions are present, deeper structures can be visualized, such as a consolidated lung or the mediastinal contents. A large effusion may reveal air artifacts in the lung and allow the examiner to differentiate consolidated from aerated lung.

With experience, the examiner can estimate the volume of effusion as mild, moderate, or large. The echogenicity of an exudate allows the examiner to make an educated guess as to whether it is a transudate or an exudate; all transudates are anechoic, whereas exudative effusions are usually echogenic.

Hemothorax and purulent pleurisy present similar ultrasound patterns. Hemothorax produces an echogenic signal, indicating numerous particles floating within the effusion. In rare cases, the entire pleural cavity might be hypoechoic, mirroring the accompanying "whiteout" seen on chest x-ray. CT will be diagnostically helpful in these cases.

Ultrasound can facilitate thoracentesis. The patient should be positioned in a sitting or lateral decubitus position. It is important that the patient remain in the same position throughout the localization of the lesion and the subsequent procedure. Before performing thoracentesis, the operator should verify that the effusion is at least 1.5 cm thick and is visible over at least three intercostal spaces.[11] The operator should identify the most dependent part of the pleural cavity and carefully insert the needle under direct (real-time) ultrasound visualization, making every effort to avoid accidental puncture of other structures during the process. Ultrasound-guided thoracentesis is safe in mechanically ventilated patients.[11] After aspiration or biopsy, small pigtail catheters can be inserted and left in place for continuous drainage of the effusion.

Pulmonary Edema

Common practice in POCUS of the lung parenchyma is the evaluation of B-lines. The number of B-lines correlates with the amount of extracellular lung water and the pulmonary wedge pressure ($P < .001$).[10] Three or more B-lines in a single view are called *B+ lines* and represent interstitial edema.[14] The presence of B-lines in a patient with acute dyspnea, evaluated together with measurement of circulating N-terminal pro B-type natriuretic peptide and the Framingham criteria, helps distinguish between cardiogenic and noncardiogenic pulmonary edema ($P < .001$).[15] The presence of nine or more B-lines has been reported as 100% specific for cardiogenic dyspnea.[15] Ultrasound may be more than 90% sensitive and specific for acute cardiogenic pulmonary edema. Therefore when combined with bedside echocardiography to evaluate cardiac function, the diagnosis of congestive heart failure can be confirmed before administering a diuretic.

Lung Consolidation

Lung consolidation is associated radiographically with air bronchograms and is visualized on ultrasound as lenticular air pockets within hypodense areas of consolidated lung.

Lung ultrasound has been found to be comparable to chest x-ray in making a diagnosis of pneumonia.[16,17] The signal characteristics of pneumonic ultrasound depend on the stage of the infection. Subpleural consolidation with a treelike vascular pattern on Doppler might be present in the initial hepatization phase of lobar pneumonia. Lung sliding may be absent in the involved lobe secondary to inflammatory exudates. Later, during the resolution phase, ultrasound can detect the appearance of B-lines, which indicate increased aeration of the lung. Lung ultrasound can therefore be used to monitor the progression of pneumonia. Lung CT and ultrasound correlate closely as methods for evaluating reaeration.[18]

Pneumothorax

Ultrasound is highly accurate for detecting pneumothorax. The primary ultrasound feature is abolition of lung sliding, occasionally associated with A-lines and the absence of B-lines. In M-mode, this would give the appearance of multiple horizontal lines similar to a bar code. This nonspecific finding is seen in a number of other conditions, such as malignancy, chronic obstructive pulmonary disease (COPD), and pneumonia. More specific is the visualization of a lung point: that is, a point at which the lung and air can easily be visualized in the same M-mode image (Fig. 30.5). Moving the probe along the anterior, lateral, and posterior intercostal spaces and observation during an entire respiratory cycle at each locale can help locate a lung point. Additionally, evaluation for the absence of the lung pulse, which is an anteroposterior-directed pleural motion that is secondary to the transmission of cardiac movement across the thorax, can also help identify pneumothorax from

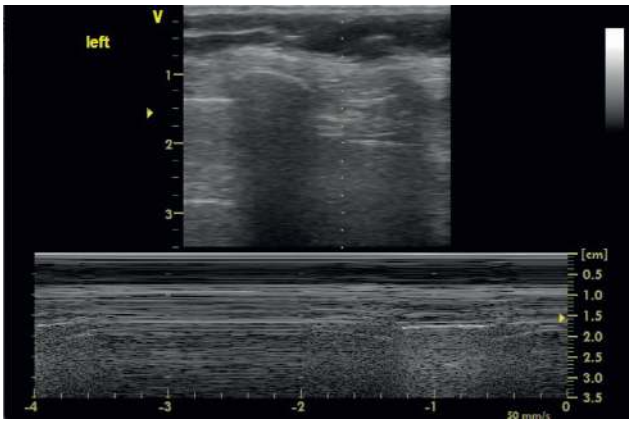

Fig. 30.5 Lung Point in M-mode. Both the bar code and seashore signs are seen as the lung point moves across the image.

other phenomena that can result in the absence of lung sliding (e.g., apnea, mainstem intubation, airway obstruction).

Chronic Obstructive Pulmonary Disease

Lung ultrasound in patients with COPD shows predominant A-lines with or without lung sliding but without a lung point. Ultrasound has an 89% sensitivity and 97% specificity for COPD.[10]

When using ultrasound to evaluate patients with dyspnea, it is advisable to first check for lung sliding and then for a lung point. The absence of lung sliding in association with the presence of a lung point indicates a diagnosis of pneumothorax. The presence of lung sliding with prominent B-lines (>3/field) indicates a diagnosis of pulmonary edema or pneumonia. The next steps are to check for the presence or absence of a dependent pleural effusion and evaluate for the presence or absence of lung consolidation. An exudative effusion, indicated by the absence of a sinusoidal sign in association with lung consolidation, favors the diagnosis of pneumonia. Absence of prominent B-lines and predominance of A-lines indicate either pulmonary embolism, worsening COPD, or pneumonia. Deep venous thrombosis (DVT) can be ruled out at this time by performing a venous examination of the lower and upper extremities. Absence of DVT and absence of any lung consolidation or pleural effusion favor the diagnosis of an exacerbation of COPD to explain the dyspnea. In patients with unclear or equivocal findings, further imaging modalities such as CT should be used.[10]

ADVANCED VASCULAR ACCESS

The use of ultrasound to aid in vascular access has advanced beyond its now-widespread use for central venous access. Specifically, ultrasound has proven to reliably aid the placement of difficult intravenous[19,20] and intraarterial catheters.[21,22] Use of ultrasound for peripheral venous access has been shown to significantly increase success rates as well.[23] A recent meta-analysis was conducted to compare an ultrasound guidance technique for central venous access with an anatomic landmark technique. That analysis indicated that ultrasound use decreased the risks of cannulation failure, arterial puncture, hematoma, and hemothorax.[24] However, it is important to emphasize that good anatomic knowledge and dynamic hand-eye-probe coordination to follow the needle tip are keys to success and avoidance of inadvertent arterial puncture.[25] Use of ultrasound has not eliminated complications related to injury of deeper structures (subclavian or vertebral artery) during insertion of internal jugular central lines.[25] This observation underlines the importance of formal training in ultrasound and simulated practice of central line placement, as supported by recently published guidelines.[25]

ADDITIONAL AREAS OF ASSESSMENT

POCUS is useful in assessing several other areas relevant to the issues faced by the critical care physician.

Deep Venous Thrombosis and Pulmonary Embolus

The current standard for evaluation of patients suspected to have DVT or pulmonary embolus involves CT pulmonary angiography and lower extremity compression ultrasonography. These tests are often performed despite a low pretest probability, and obtaining them potentially delays diagnosis.[26] A study in patients with a moderate to high probability of pulmonary embolus evaluated multiorgan ultrasound that was performed by intensivists, involved lung ultrasonography to search for subpleural infarcts, transthoracic echocardiography to detect right ventricular dilatation, and leg vein ultrasonography to detect DVT. The study reported that multiorgan ultrasound had a high sensitivity (90%) and specificity (86.2%) for the detection of pulmonary embolus.[27]

Airway Management

1. Endotracheal tube placement
   A report suggested the utility of ultrasound for verification of successful endotracheal intubation, reporting a sensitivity and specificity of 100% for the detection of successful endotracheal intubation versus esophageal intubation.[28] An evaluation of POCUS examination that included assessment for tracheal dilation with endotracheal tube cuff inflation and bilateral pleural lung sliding demonstrated a high degree of sensitivity (93%) and specificity (96%) to detect endobronchial versus tracheal intubation.[29]
2. Emergency cricothyroidotomy
   Surface landmarks for identification are often not reliable for the identification of the cricothyroid membrane, especially in obese and female patients.[30,31] Bedside ultrasound is a reliable modality for rapid identification of the anatomy for emergency cricothyrotomy (Fig. 30.6).[32]
3. Percutaneous tracheostomy placement
   Ultrasound improved success rates in accessing the trachea, with more than 90% correct placement with the first-pass attempt in a cadaveric study.[33] Real-time ultrasound has been used for percutaneous tracheostomies, with improved accuracy for midline placement of the needle.[34,35]

Gastric Volume Assessment

POCUS has also been used to assess gastric content and volume.[36,37] A grading system has been proposed based exclusively on qualitative sonographic assessment of the gastric antrum and has shown a strong correlation with predicted gastric volume (Fig. 30.7).[37] The presence of fluid in the antrum identified by ultrasound in both the supine and right lateral decubitus positions correlates with a large, clinically significant amount of gastric contents. This ability to detect gastric volume by POCUS may be useful in assessing aspiration risk.

Intracranial Pressure Estimation

POCUS has the potential to provide rapid assessment of elevated intracranial pressure (ICP), based on the measurement of the optic nerve sheath diameter. The optic nerve sheath is contiguous with the dura mater and has a trabeculated subarachnoid space through which cerebrospinal fluid circulates. The relationship between the optic nerve sheath diameter and ICP has been well established.[38,39] The sensitivity of ultrasonography in detecting elevated ICP was 100% (95% confidence interval [CI] 68%–100%), and specificity was 63% (95% CI 50%–76%).[38] An optic nerve sheath diameter of greater than 5 mm at a point approximately 2 mm from the retina suggests elevated ICP (Fig. 30.8).

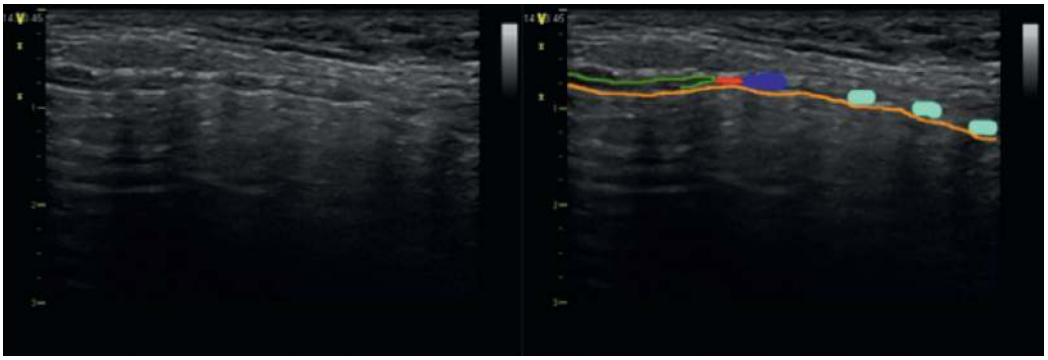

Fig. 30.6 Longitudinal Ultrasound View of the Trachea. Longitudinal midline-scan view of the neck shows the cricothyroid membrane in *red*. *Green* and *dark blue* represent the thyroid and the cricoid cartilages, respectively. The *orange lining* shows the air–tissue border between the trachea and air. *Light blue* indicates the tracheal cartilages.

KEY POINTS

- Ultrasound instruments have steadily become less expensive and more portable, resulting in wider bedside application during physical examination to aid in clinical decision making. For this reason POCUS use and knowledge are becoming basic clinical skills for the critical care physician.
- Probe selection depends on the organ to be examined. Deeper structures need a lower-frequency probe, which allows better penetration.
- Doppler signals are more accurate when ultrasound signals are parallel to the direction of flow. Pulse wave Doppler can assess the flow velocity in an exact location, whereas continuous Doppler assesses for a summation of velocities along the line of ultrasound signal.
- Lung ultrasound allows comprehensive assessment of the pulmonary system, offering high degrees of sensitivity and specificity for the detection of pneumothorax, quantification of pleural effusion, and characterization of parenchymal air-space disease. Bedside ultrasound-guided thoracentesis is usually safe, even in mechanically ventilated patients.
- Successful and safe POCUS use for vascular access involves excellent anatomic knowledge and dynamic hand-eye-probe coordination to follow the needle tip at all times to prevent inadvertent arterial punctures and other complications.
- Evaluation for pulmonary embolus by POCUS involves a multiorgan examination including lung ultrasonography, echocardiography, and lower extremity assessment to detect DVT.
- POCUS has high sensitivity and specificity for the detection of successful endotracheal intubation in addition to identification of anatomic structures and landmarks for cricothyroidotomy and percutaneous bedside tracheostomy.
- POCUS is increasingly being used for the assessment of gastric volume and content, especially before intubation for assessing aspiration risk.

Echocardiography

Wolf Benjamin Kratzert, Pierre N. Tawfik, and Aman Mahajan

Over the past 60 years, echocardiography has undergone substantial developments to become one of the most common modalities in the field of cardiovascular imaging. Starting in the 1980s, technologic advancements and the recognition of its potential moved echocardiographic imaging quickly into the operating room, emergency room, and intensive care unit (ICU). Today, it is fully integrated into medical subspecialties, such as anesthesiology, emergency medicine, critical care, and others.[1–3]

Several aspects differentiate critical care echocardiography from the comprehensive cardiology echocardiographic examination. Critical care echocardiography is focused on the immediate integration of diagnostic information into clinical management. In ICU patients, the interaction of heart and lung function and the presence of multiple medical interventions can make the interpretation of findings more complex. The ability to obtain adequate images can be limited. The hemodynamic profiles of patients tend to change continuously. Therefore 24-hour access to echocardiography is important.

INDICATIONS, CONTRAINDICATIONS, AND SAFETY

Indications for echocardiography, including the critical care and perioperative settings, are well established in the literature.[4–7] Although applications for echocardiography in the ICU continue to expand, the main indication remains the evaluation of hemodynamic instability and guidance of its clinical management (Table 31.1). Transthoracic echocardiography (TTE) represents the standard modality in the ICU, as it is noninvasive, readily available, and easy to use. Although TTE presents minimal risk to patients, acquiring satisfactory images is often problematic. In particular, surgical dressings, obesity, chronic obstructive pulmonary disease (COPD), and the requirement for mechanical ventilation can make imaging difficult. Problems associated with obtaining satisfactory images using TTE are the most common indication for transesophageal echocardiography (TEE) in the critical care setting, especially when patients are already intubated and sedated. Other less frequent indications are the need to diagnose cardiac valvular pathologies, endocarditis, or intracardiac thrombi or shunts. TEE requires advanced expertise and is an invasive procedure. As it carries increased risks of complications, absolute and relative contraindications are defined (Table 31.2), and risks and benefits must be considered before performing TEE.

IMPACT OF ECHOCARDIOGRAPHY IN THE ICU

Echocardiography is a valuable tool to identify the etiology of hemodynamic instability and to guide clinical management in a critical care setting.[8,9] Although some results support the view that echocardiography can affect the management of ICU patients,[10–12] definitive data regarding the impact of echocardiography on patient outcomes remain sparse.[13–15] One small study showed that using TEE to diagnose nonventricular pathologies as the etiology of hypotension was associated with improved ICU survival.[16] In a study of 220 ICU patients, Kanji and colleagues showed that therapy in subacute shock guided by limited TTE was associated with an improved 28-day survival and reduced the incidence of acute kidney injury (AKI) requiring renal replacement therapy (RRT).[17] Critical care echocardiography is increasingly accepted as a valuable tool for expedited diagnosis of emergent pathologies (i.e., cardiac tamponade, pneumothorax), serves as a noninvasive adjunct to workups of critical illness (i.e., shock etiology, fluid responsiveness), and may be informative when implementing mechanical ventilation (i.e., positive end-expiratory pressure [PEEP] titration).[1]

TRAINING, ACCREDITATION, AND INVESTIGATION

Although guidelines for training and accreditation for comprehensive echocardiography by cardiologists are well defined, similar guidelines are still evolving concerning the use of focused echocardiography by noncardiologists. Since about 2005, professional societies all over the world have been developing specific pathways and recommendations for training and accreditation requirements for focused critical care ultrasound. The first document on training and accreditation of echocardiography in intensive care developed by an international group of experts was published by the World Interactive Network Focused on Critical Ultrasound (WINFOCUS) in 2008.[18] In 2009 a working group formed by the American College of Chest Physicians and La Société de Réanimation de Langue Française published a consensus statement about competency for performing critical care ultrasonography.[19] Subsequently, an international expert group led by the European Society of Intensive Care Medicine proposed training guidelines and standardization of competency assessment for critical care ultrasonography, including echocardiography.[20] The same group published a consensus statement on the standards for advanced echocardiography in the ICU in 2014 and, recognizing heterogeneity in the existing literature, has recently emphasized the need for standardization in study design and reporting of research investigations.[21,22]

Billing

With the growing use of point-of-care (POC) echocardiography in the ICU, the question of reimbursement has been a topic of ongoing discussion. Several components of the focused critical care echocardiographic examination differ from the classic comprehensive echocardiographic examination. Physicians not fully accredited in echocardiography often perform the focused echocardiographic examination in critically ill patients, and the liability of interpretation only extends to the specific focus of the assessment. Images commonly are not stored for further clinical use. In the United States, Medicare uses the Current Procedural

TABLE 31.1 Indications for Echocardiography in the ICU

- Circulatory failure (hypotension, shock)
- Sepsis
- Low cardiac output state
- Cardiac arrest
- ACS
- Pulmonary embolism
- Suspected cardiac etiology of respiratory failure
- Aortic dissection
- Cardiac trauma
- Endocarditis
- Suspected cardiac etiology of systemic embolism
- Cardiac evaluation for potential organ donation
- Guidance and assessment of circulatory assist devices (TVPM, IABP, ECMO, VAD)

ACS, Acute coronary syndrome; *ECMO,* extracorporeal membrane oxygenator; *IABP,* intraaortic balloon pump; *TVPM,* transvenous pacemaker; *VAD,* ventricular assist device.

TABLE 31.2 Indications and Contraindications for TEE in the ICU

Indications	Contraindications
• Poor image quality in acute hemodynamic instability • Poor image quality second to severe obesity, emphysema, surgical drains/dressing • Comprehensive assessment of aortic dissection, endocarditis, valvular pathologies, prosthetic valves, intracardiac thrombus • Assessment of circulatory assist devices • Assessment of intracardiac shunt	Absolute: • Perforated viscus • Esophageal pathology (stricture, tumor, trauma, diverticulum, varices) • Recent esophageal or gastric surgery, status post esophagectomy or esophagogastrostomy • Active upper GIB • Cervical spine injury Relative: • Recent upper GIB • PUD • Coagulopathy, thrombocytopenia • Hiatal hernia

GIB, Gastrointestinal bleed; *PUD,* peptic ulcer disease.
TEE is mandatory for the comprehensive assessment of certain cardiac pathologies. In hemodynamic instability, when TTE imaging results in insufficient image quality, the intensivist has to weigh risk and benefits of performing an invasive TEE examination.

Terminology (CPT) code for the reimbursement of medical, surgical, and diagnostic services. Currently, the CPT coding does not incorporate an individual code for focused critical care ultrasound examinations, and its components do not fulfill the requirements of the standard diagnostic TTE examinations or the limited/follow-up examination, as described in their coding system. TEE requires specific competence and is performed by physicians with advanced training. When performed in the ICU, these examinations are commonly accepted using existing CPT codes for TEE examinations.[23]

POC echocardiography has the potential to reduce overall ICU costs considerably. By adding a noninvasive, less expensive diagnostic and monitoring technology, it can expedite and focus clinical management and decrease the risk to patients significantly. With standardization of critical care echocardiography training, its differentiation from the classic comprehensive training, and the increasing evidence of the benefits of POC echocardiography, a specific billing code for the focused examination is warranted.[24–26]

BASICS

Equipment

Typically, echocardiography equipment used in echocardiography laboratories and cardiac operating rooms features the newest and most advanced technologies. The most advanced equipment is not needed for use in a critical care setting. Several companies now offer machines with specific features geared toward use in emergency departments, trauma bays, or ICUs. These machines are used for the broad spectrum of critical care applications, including lung, vascular, and abdominal ultrasonography. The machines can be equipped with multiple software programs, including those useful for TTE and TEE. The ideal ICU ultrasound system is compact, portable, and durable. It requires minimal start-up time and has an easy-to-use operator interface. For routine daily use, it should have an extended battery life and internal storage capacity.

The transducers used for TTE and TEE examinations are typically phased-array transducers. They provide a frequency ranging from 1 to 10 MHz, which offers the optimal balance of penetration and resolution required to image the heart.

Knobology

Echocardiography machines have a collection of knobs and buttons to adjust image quality, use different modalities, and store images. As each manufacturer has a set arrangement of knobs, sliders, and buttons, it is essential for each operator to become familiar with the layout of the machine that he or she will use on a regular basis. The most important controls and their function are as follows:

GAIN: Adjusts overall image brightness
TIME-GAIN-COMPENSATION (TGC): Selectively adjusts sector image brightness
DEPTH: Adjusts depth of view
ZOOM: Selects specific image sector
FOCUS: Adjusts focal zone
DYNAMIC RANGE: Adjusts gray-scale to filter out background noise

Ultrasound Modalities

More so than during the examination of anatomic structures other than the heart, the use of multiple ultrasound modalities is essential for echocardiography. The most commonly used modalities in the ICU are two-dimensional (2D) imaging, motion mode (M-mode), color flow Doppler (CFD), pulsed wave Doppler (PWD), and continuous wave Doppler (CWD). 2D remains the initial and most commonly used mode of anatomic imaging and qualitative assessment of gross pathologies in the ICU. A modality less frequently used is M-mode. M-Mode represents a one-dimensional image against time and has the advantage of excellent temporal resolution, which is useful for the imaging of fast-moving structures like valvular leaflets.

When assessing hemodynamic profiles, the use of Doppler echocardiography, in addition to classic 2D imaging, provides the information needed for quantitative measurements. CFD displays blood flow velocity and direction of flow by color mapping. It combines qualitative 2D imaging with semiquantitative information about blood flow. CFD is useful for diagnosing intracardiac shunts or valvular pathologies and for seeking evidence of obstructions to blood flow. When a quantitative assessment is needed for the calculation of stroke volume (SV), cardiac output (CO), and pulmonary artery pressures (PAP), PWD and CWD are the modalities of choice. Both modes

provide information about blood flow direction and numeric estimates of blood flow velocity at the interrogated anatomic site. Whereas PWD measures blood flow velocity at the specific site of the sample volume and is limited by a certain velocity threshold called the Nyquist limit, CWD displays the maximum velocity along the whole interrogation beam without a velocity threshold. Both modalities require alignment of the interrogation beam with the direction of blood flow to minimize the underestimation of velocity caused by a suboptimal incidence angle. As with 2D imaging, several interventions can be applied to enhance Doppler quality and prevent artifacts as a result of the Nyquist limit. Most importantly, adjustment of the transducer location and frequency, sample volume depth, and movement of the baseline can maximize peak velocities with PWD.[27,28]

STANDARD VIEWS AND ANATOMY

When performing echocardiographic examinations, the position of the transducer in relationship to the body is called the *acoustic window,* and the image plane is defined as the *view*. Image planes are in reference to the point of focus, which most commonly is the left ventricle (LV).

Image Acquisition and Optimization

Following a consistent order of image acquisition minimizes the risk of missing images and pathologies and facilitates learning. Clockwise positioning and rotation of the transducer provides a simple and logical approach to the focused examination (Fig. 31.1).

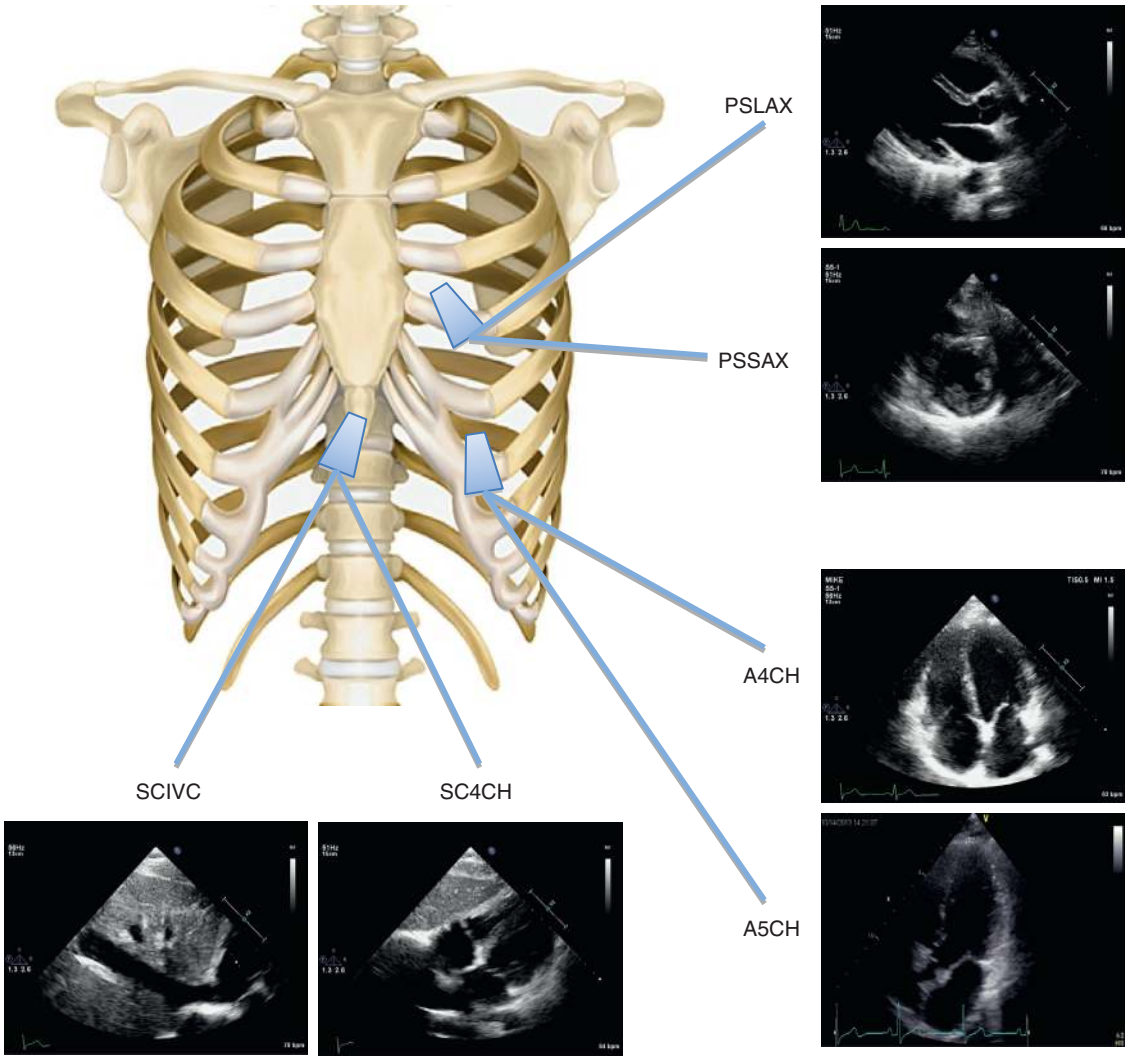

Fig. 31.1 TTE transducer position and imaging windows. Starting with the PS LAX and the probe marker toward 11 o'clock, the clockwise movement and rotation of the transducer will provide a systematic approach to obtaining acoustic windows and imaging views. Rotation of the transducer from the PS LAX view by 90 degrees clockwise will show the PS SAX view. In the PS SAX view, tilting the transducer cephalad or caudad will visualize the short axis of the AV, LV midpapillary, and LV apical. Further rotation of the transducer from 1 o'clock to 3 o'clock and movement to the apical position visualizes the A4CH view. Flattening of the transducer will show the LVOT and A5CH views. Counterclockwise rotation in the apical view will show the A2CH and A3CH views. Maintaining the probe marker in the 3 o'clock position visualizes the SC4CH view in the SC position. The slight rightward angle of the transducer provides the LAX of the IVC. *A2CH,* Apical two chamber; *A3CH,* apical three chamber; *A4CH,* apical four chamber; *A5CH,* apical five chamber; *AV,* aortic valve; *IVC,* inferior vena cava; *LAX,* long axis; *LV,* left ventricle; *LVOT,* left ventricular outflow tract; *PS LAX,* parasternal long axis; *PS SAX,* parasternal short axis.

Whether with TTE or TEE, standardized views are based on anatomic landmarks, which can be obtained at defined acoustic windows with specific transducer positions and angles. To avoid inadequate imaging and the risk of misinterpretation, knowledge of the specific anatomic landmarks defining each view is pertinent. In addition, the following techniques should always be used to optimize imaging. Body position: Extension of the left arm opens up the parasternal windows, and a slight left-side tilt can bring the cardiac apex closer to the chest wall. Flexing the legs at the hip facilitates the acquisition of subcostal windows. Image acquisition: Small changes in transducer position and angle, a change in the intercostal space above or below, and the use of TEE can provide improved imaging. Machine setting: Aside from adjusting gain, TGC, and dynamic range, precisely adjusting the focus and depth to the region of interest (ROI) is critical. In addition, using the zoom feature can be helpful. Especially in Doppler modes, these adjustments can improve measurements and avoid Doppler aliasing. Another option for improving image quality is contrasted echocardiography.[29] Even though not commonly used by intensivists when performing focused ICU examinations, injection of contrast media can significantly enhance opacification of the right and left ventricular chambers and enhance the definition of the endocardial border.[30]

Transthoracic Echocardiography

In TTE, three standard acoustic windows are used: the parasternal, apical, and subcostal positions (see Fig. 31.1). A fourth position called *suprasternal* is additionally used during comprehensive examinations and in the pediatric population.

Standard Transthoracic Views

The focused echocardiographic examination in the ICU commonly includes five major views: (1) the parasternal long-axis (PS LAX), (2) the parasternal short-axis (PS SAX), (3) the apical four-chamber (A4CH), (4) apical five-chamber (A5CH), and (5) the subcostal long-axis (SC LAX) (Table 31.3).[18,21]

PS LAX is obtained by positioning the transducer in the left third or fourth intercostal space (ICS), along the anterior midclavicular line, with the transducer marker directed toward the right shoulder (see Fig. 31.1). This view is primarily used to evaluate LV and right ventricle (RV) size and systolic function and to obtain quantitative measurements of ventricular size and wall thickness by the M-mode. The mitral valve (MV) and aortic valve (AV), including the left-ventricular outflow tract (LVOT) and aortic root, can be assessed with 2D and CFD for regurgitation, stenosis, or dynamic outflow obstruction. Additionally, this view can be used for the visualization of pericardial pathologies.

PARASTERNAL SHORT-AXIS VIEWS are obtained in the same transducer position as the parasternal long-axis view, with the transducer rotated 90 degrees clockwise and the marker directed toward the left shoulder (see Fig. 31.1). Within this view, multiple planes of the heart can be imaged depending on the tilt of the transducer. When tilting the probe from superiorly to inferiorly, visualization starting with the short axis of the AV over the basal and mid-SAX of the LV down to the apical segment of the LV is possible. This view is best used for the evaluation of LV size and systolic function. It is optimal for describing regional wall motion abnormalities, as all territories of coronary perfusion can be visualized simultaneously. In addition, the basal AV SAX view can provide information about the tricuspid valve (TV), including measurements of right ventricular systolic pressure (RVSP) by CWD.

APICAL VIEWS provide images of all four chambers (see Fig. 31.1). Most commonly used in the ICU are the A4CH and A5CH views. With the transducer positioned at the apex of the heart, commonly in the sixth or seventh ICS along the anterior axillary line, the probe marker is directed toward the left axilla. With tilting of the probe superiorly, the 4CH and 5CH views are obtained.

The 4CH view is used for the assessment of atrial and ventricular chamber sizes, biventricular systolic function, and regional wall motion abnormalities. Because of the optimal incidence angle and visualization of the TV, MV, and AV in the 4CH and 5CH views, quantitative

TABLE 31.3 Standard TTE Views, Anatomic Structures Seen, and Their Common Use

Standard TTE Views	Structures	Common Assessment
PS LAX	LA, LV, RV, MV, AV, LVOT, Desc Ao	LV and RV size, LV and RV systolic function, RWMA, AV and MV pathologies, LVOT obstructions (SAM), pericardial effusion/clot/tamponade, pleural effusion, LVOT diameter for SV calculation, aortic dissection and aneurysm
PS SAX AV	LA, RA, RV, PA, AV, TV, PV	AV pathologies, RV size and systolic function, TV pathologies, RVSP, intracardiac shunts, catheters/PM leads/cannulas
*PS SAX MID-PAP	LV, RV	LV size and systolic function, RWMA, pericardial effusion/clot/tamponade
*A4CH	LA, RA, LV, RV, MV, TV	LV and RV size, LV and RV systolic function, RWMA, LA and RA size, MV and TV pathologies, RVSP, TAPSE
A5CH	LA, RA, LV, RV, LVOT, AV, MV	LVOT obstructions (SAM), VTI LVOT and AV, AV pathologies
A2CH	LA, LV, MV	RWMA, MV pathologies
*SC SAX	RA, LA, RV, LV, diaphragm	Pericardial effusion/clot/tamponade, RV size and systolic function, RA size, catheters/PM leads/cannulas
*SC IVC LAX	IVC	Volume status, pericardial effusion/clot/tamponade
SC IVC SAX	IVC, Desc Ao	Volume status, pericardial effusion/clot/tamponade, aortic dissection and aneurysm, IABP

2CH, Two chamber; *4CH,* four chamber; *5CH,* five chamber; *A,* apical; *AV,* aortic valve; *Desc Ao,* descending aorta; *IABP,* intraaortic balloon pump; *IVC,* inferior vena cava; *LA,* left atrium; *LAX,* long axis; *LV,* left ventricle; *LVOT,* left ventricular outflow tract; *MV,* mitral valve; *PM,* pacemaker; *PS,* parasternal; *RA,* right atrium; *RV,* right ventricle; *RWMA,* regional wall motion abnormalities; *SAM,* systolic anterior mitral valve leaflet motion; *SAX,* short axis; *SC,* subcostal; *TV,* tricuspid valve; *VTI,* velocity-time interval.
As seen, the PS SAX, A4CH, and SC SAX in combination provide most information needed in the acute situation. Additional views for hemodynamic assessment are added to show the most common views used in the ICU.

measures by M-mode, CFD, CWD, and PWD are best obtained from the apical position. These views are mostly used by intensivists for quantitative evaluation of RV function and RVSP, LV cardiac output, and diastolic function, in addition to the evaluation of valvular pathologies by spectral-Doppler echocardiography.

From the 4CH position, a counterclockwise rotation of the transducer by 90 and 110 degrees will visualize the apical two-chamber (A2CH) and three-chamber views (A3CH), which completes the visualization of all LV wall segments when combined with the 4CH view.

SUBCOSTAL VIEWS are obtained by positioning the transducer in the subxiphoid or subcostal position while maintaining the marker directed toward the left lateral side of the patient. Aiming the probe toward the left shoulder and maintaining it flat on the abdomen, the heart is cut in a horizontal plane, showing all four chambers and particularly the RV free wall (see Fig. 31.1). A 90-degree rotation of the transducer counterclockwise while slightly aiming the probe toward the right shoulder will visualize the inferior vena cava (IVC) and its junction into the RA. These views can provide information about pericardial pathologies, such as pericardial effusion and tamponade. When angled slightly toward the right and caudad, global volume status can be assessed by measuring IVC diameter and dynamic collapse with respiratory variation (see Fig. 31.1).

Transesophageal Echocardiography

In the past, the use of TEE in a critical care setting was restricted by availability, technical issues, and the need for operator expertise. With improvements in equipment and growing expertise among intensivists, the use of this modality is increasing. Superior image quality and the ability to evaluate for certain pathologies remain the advantages of TEE over TTE.[31]

Safety of Transesophageal Echocardiography

TEE in ambulatory and nonoperative settings has an incidence of adverse events of between 0.2% and 0.5% and a mortality rate of <0.01%.[32] TEE in the ICU has slightly higher morbidity and mortality. Multiple studies show that the incidence of adverse events ranges from 1.6% to 5%.[16,33–35] In a review of 20 studies, Hüttemann and colleagues reported that the incidence of TEE-related complications in the ICU was 2.6%; there were no TEE-related deaths.[36] The main complications associated with TEE are arrhythmias, hypotension, airway compromise, and bleeding. These complications are more likely to occur in critically ill patients as compared with relatively healthier subjects because ICU patients often are hemodynamically unstable or already prone to hemorrhage. Nevertheless, if the operator is cognizant of the potential complications and takes pains to weigh the risks versus the benefits carefully, TEE can be performed safely in the ICU. Preparation of the patient before TEE is important. First, the indications for and specific questions to be answered by the examination have to be defined. Second, potential contraindications to TEE, such as recent esophageal or gastric surgery or active upper gastrointestinal bleeding, must be ruled out. Third, coagulation status must be assessed and abnormalities corrected, if possible. Fourth, nil per os (NPO) status must be assured. Fifth, the mode of sedation, the need for administration of paralytic agents, and airway protection have to be addressed. When performing the examination, insertion and manipulation of the probe should be tailored to the patient's condition and coexisting risk factors.

Standard Transesophageal Views

The TEE examination in the perioperative setting includes 20 standard views.[37] TEE in the ICU rarely requires a comprehensive examination. Several different protocols have been proposed for the focused TEE examination in critically ill patients, emergency room patients, or acute intraoperative emergencies.[38,39] The goal of the focused examination remains the same as with TTE, and unless prohibited by the severity of the situation, acquisition of standardized views should be obtained.

Although a comprehensive TEE examination uses views at four levels of the esophagogastric tract, the two main depths used during the focused examination are the midesophageal and transgastric planes. The midesophageal level provides optimal views for specific anatomic evaluation of cardiac structures, as the transducer is near the heart. Transgastric views are mainly used for quick evaluations of LV size, systolic function, and wall motion abnormalities. In addition, spectral-Doppler of the AV is performed in the deep transgastric view, as the incidence alignment angle is best in this location. The transgastric view can also show loculated or dependent pericardial effusions, which may be difficult to see in the midesophageal views.

HEMODYNAMIC ASSESSMENT

Echocardiography represents a method for the immediate diagnosis, management, and monitoring of hemodynamic profiles in critically ill patients. With an examination that rarely takes more than a few minutes to complete, echocardiography can provide the intensivist with anatomic information about the critically ill patient's intravascular volume status, the presence or absence of various forms of cardiac pathologies (e.g., pericardial effusion and tamponade; regional wall motion abnormalities), myocardial contractility, and ventricular dimensions. For the subsequent interpretation and use of this information, it is pertinent to incorporate the influence of concurrent pathologies and medical treatments on echocardiography findings. Especially common factors, such as arrhythmias, vasopressor or inotropic support, and mechanical ventilation, need to be considered during the qualitative and quantitative hemodynamic assessment.[40]

Cardiac Preload and Fluid Responsiveness

As the management of the critically ill patient has evolved, the question of volume (i.e., preload) responsiveness has taken priority over static parameters like central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP).[9] Many experts are skeptical about the clinical utility of static pressures for guiding the hemodynamic management of critically ill patients. Neither CVP nor PAOP is a good predictor of preload responsiveness (i.e., an increase in CO or SV after bolus administration of intravenous crystalloid or colloid solutions). With the validation of echocardiography, bedside examination is increasingly replacing invasive monitoring in the contemporary evaluation of cardiac preload and prediction of volume responsiveness.[9,41] While visualizing with echocardiography, a passive leg-raise maneuver (rapidly changing patient position for head of the bed from 30–45 degrees to 0 degrees while elevating the lower limbs to 30–45 degrees, thus moving 250–350 mL of blood from the leg to the heart) has proven to be a reliable technique to assess fluid responsiveness.[42,43] One meta-analysis of 23 studies and 1013 patients calculated a pooled sensitivity of 86%, specificity of 92%, and a summary Area under the curve receiver operating characteristics (AUROC) of 0.95 for the passive leg raise.[44] Cardiac output changes can be assessed after 1–2 minutes after the maneuver.[45] Assessment of IVC diameter and the collapsibility, cardiac chamber size, and ventricular outflow tract stroke volume (LVOT SV) measurements are among the most common methods used for qualitative and quantitative evaluation of these parameters.[46] Vignon and colleagues performed a multicenter prospective trial using passive leg raise and various echocardiographic indices to assess fluid responsiveness. Respiratory variation of the maximal Doppler velocity in the LVOT was the most sensitive indicator, and respiratory variation

of the superior vena cava diameter was the most specific in predicting fluid responsiveness.[47] However, both require the semi-invasive TEE.

Assessment of IVC size and its dynamic variation during changes in intrathoracic pressure with mechanical ventilation is the least laborious and the most common way for using echocardiography to evaluate cardiac preload and volume responsiveness in ICU patients. The average diameter of the IVC is 17 mm. The absolute IVC diameter by itself, unless <10 mm or >20 mm, does not correlate well with right atrial pressure (RAP) or preload responsiveness.[48] However, dynamic changes in the IVC diameter because of respiration can provide information about preload responsiveness.[46,48,49] Barbier and colleagues showed that dynamic changes in IVC diameter of >18% predict fluid responsiveness with a sensitivity and specificity of 90%–93%.[50] Feissel and colleagues confirmed these findings with a slightly different index of IVC collapsibility, showing a sensitivity and specificity of 90%–92%, respectively.[48] At the subcostal acoustic window, optimal measurements of the IVC diameter are made using the M-mode in the short-axis view. When interpreting information derived from IVC diameter measurements, it is important to incorporate the effects of atrial arrhythmias, significant tricuspid regurgitation, atrial shunting, or increased intraabdominal pressure on the appearance of the IVC.

Imaging of cardiac chamber size is routinely used in conjunction with other measurements to assess qualitatively intravascular volume status. The most common measurements are LV end-diastolic diameter (LVEDD) and the left ventricular end-diastolic area (LVEDA) using the SAX view of the LV (Fig. 31.2). Attention should be paid to poor image quality and foreshortening of the chamber, as these worsen endocardial border definition and lead to false calculations. Although the measurement of LVEDA provides a reliable estimation of left-ventricular volume in most patients,[51] low LVEDA does not necessarily indicate systemic hypovolemia; other causes of low LV preload must be considered. Other potential causes of impaired LV diastolic filling include loss

FS = [(EDD– ESD) / EDD] x 100

FAC = [(EDA – ESA) / EDA] x 100

Example:

FS_{LV} = *[(6.0 – 4.5) / 6.0] x 100*
= *25 %*

FAC_{LV} = *[(18.5 – 7.3) / 18.5] x 100*
= *60 %*

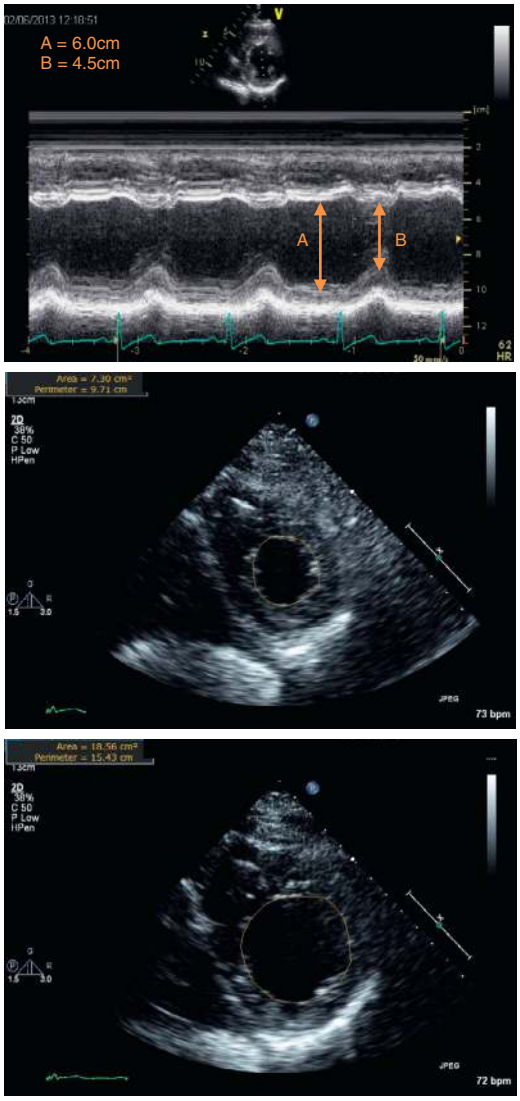

Fig. 31.2 Chamber size and semiquantitative calculation of left ventricular function. Fractional shortening methods used LV end-diastolic and end-systolic diameter from PS LAX or PS SAX midpapillary to calculate percentage value. Normal FS values are 25%–45%, correlating to normal ejection fraction. Fractional-area-change values correlate directly with ejection fraction. Measurements of area are taken from PS SAX midpapillary view. *EDA,* End-diastolic area; *EDD,* end-diastolic diameter; *ESA,* end-systolic area; *ESD,* end-systolic diameter; *FAC,* fractional area change; *FS,* fractional shortening; *PS LAX,* parasternal long axis; *PS SAX,* parasternal short axis.

of atrial contraction caused by arrhythmias, right ventricular dysfunction, and MV dysfunction. Apart from situations of severe hypovolemia,[52,53] quantitative measurements of left or right ventricular chamber size have not been shown to correlate reliably with cardiac preload and volume responsiveness.[54] Dynamic changes in LVEDA, however, correlate with volume responsiveness.[55]

Stroke Volume and Cardiac Output

Left-ventricular stroke volume (LV SV) and CO can be calculated using echocardiography.[56,57] Whereas CO measured by thermodilution is a reflection of right-sided CO, measurements with echocardiography use left-sided inflow and outflow at the level of the , LVOT, and AV. In addition, newer noninvasive modalities are based on PWD of aortic blood flow to assess cardiac output.[36] Although all of these anatomic locations have been validated in the literature, calculations using LVOT and AV are the most accurate when compared with the thermodilution method.[56,58] The continuity equation is used to calculate LV stroke volume by measuring LVOT diameter and LVOT velocity-time interval (VTI). Moreover, measurements by TTE are best obtained in the PSLAX and A5CH views. Once LV SV is calculated, multiplication by the heart rate (HR) provides CO (Fig. 31.3). As LV SV is dependent on the LV preload, limitations affecting LV filling, as mentioned earlier, have to be considered when calculating SV and CO.[59]

Right and Left Ventricular Afterload

With the ability to determine pressure gradients and flow in the heart by echocardiography, pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR) can be indirectly calculated using the following equation:

$$\text{Resistance} = \Delta P/CO$$

Based on this concept, several small studies have shown an adequate correlation using transvalvular gradients at the TV and MV to calculate pulmonary and systemic vascular resistance. Clinically cumbersome and without broad validation in the literature, these methods are not used on a routine basis in the ICU. In clinical practice, qualitative aspects seen on echocardiography are used to assess SVR. Best seen in the LV SAX view, a hyperdynamic ventricle in the setting of normovolemia suggests a low SVR. From this view, measurement of LVEDD and visual estimation of LV contractility can be used for fast and easy qualitative SVR estimation.[60]

For the assessment of PVR at the bedside, indirect calculation of PAP by tricuspid regurgitation (TR) jet, when present, is commonly achieved using the modified Bernoulli equation (Fig. 31.4). Measurement of peak TR_{vel}, when added to RAP, provides an estimate of RVSP that correlates well with systolic pulmonary artery pressure (SPAP) in the absence of tricuspid or pulmonary valve pathology.

Left Ventricular Systolic Function

Assessment of LV systolic function is one of the key elements of the ICU echocardiographic examination. Not only can an assessment of LV systolic function provide information about the etiology of circulatory or respiratory failure, but it also can be used to guide and monitor ensuing medical management. Multiple methods are available for the echocardiographic evaluation of LV function (Table 31.4). In an acute setting, the fastest and easiest assessment of myocardial function and ejection fraction uses qualitative or semiquantitative methods. For the qualitative assessment, thickening of the myocardium and endocardial inward motion in the LV SAX view are used to estimate systolic function. Caution must be taken when the LV is small or there is significant LV hypertrophy (LVH), as LV function appears different depending on the intracavitary size. A simplified classification scheme for LV function

$$A_{LVOT} = D_{LVOT}^2 \times 0.785$$

$$SV_{LVOT} = A_{LVOT} \times VTI_{LVOT}$$

$$CO = SV \times HR$$

Example:

A_{LVOT} = $(1.9\ cm)^2 \times 0.785$
= $2.8\ cm^2$

SV_{LVOT} = $2.8\ cm^2 \times 25\ cm$
= $70\ cm^3$

CO = $70\ mL \times 80\ bpm$
= $5600\ mL/min$

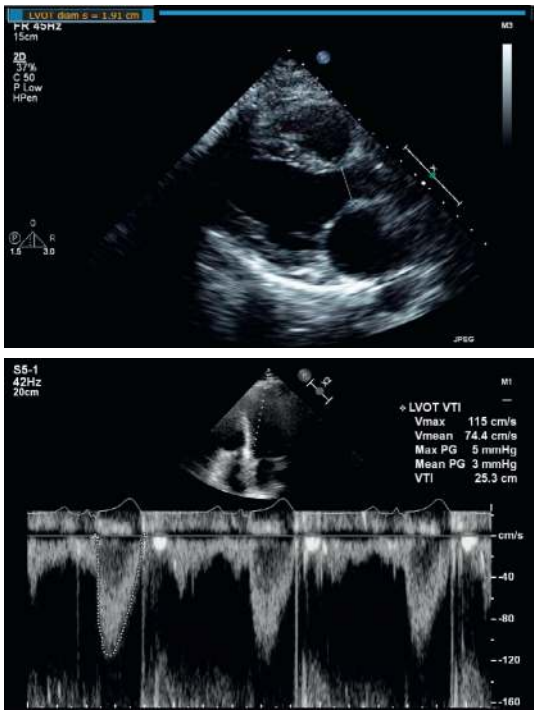

Fig. 31.3 LV SV and CO calculation. When LVOT diameter is measured in the PS LAX view, the LVOT area can be calculated. LVOT VTI is measured using PWD in the A5CH view. As seen in this example, the LV SV is 70 mL. When multiplying with an HR of 80 bpm, a CO of 5.6 L/min is estimated. A_{LVOT}, LVOT area; *CO,* cardiac output; D_{LVOT}, LVOT diameter; *HR,* heart rate; *LVOT,* left ventricular outflow tract; *SV,* stroke volume; *VTI,* velocity-time interval.

$$RVSP = (TR_{PEAK})^2 + RAP$$

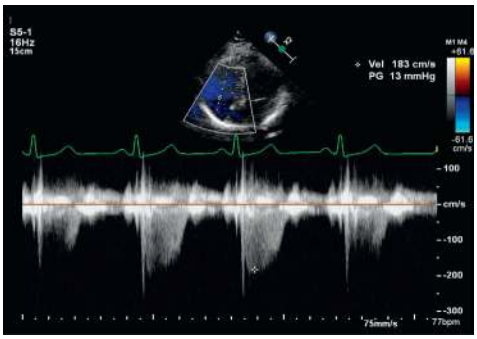

Fig. 31.4 RVSP measurement using the TR jet. After optimal alignment of the Doppler beam with the TR jet in the A4CH view, RVSP can be calculated by adding the square of the TR peak velocity in m/s to the RAP. When estimating an RAP of 10 mm Hg, RVSP in this example would be 23 mm Hg. *RAP,* Right atrial pressure; *RVSP,* right ventricular systolic pressure; *TR,* tricuspid regurgitation; TR_{PEAK}, peak velocity of TR jet.

TABLE 31.5 Echocardiographic Signs Suggestive of Pericardial Tamponade

PERICARDIAL TAMPONADE

- Effusion/clot on echo
- Dynamic collapse of RA ÔÇ± RV
- IVC plethora
- Exaggerated transvalvular flow patterns of tricuspid and mitral valve >25% with respiration
- Increase in interventricular dependence with respiration

IVC, Inferior vena cava; *RA,* right atrium; *RV,* right ventricle. Respiratory-induced pulsus paradoxus with exaggerated changes in flow >25% is seen in mitral or tricuspid valve Doppler flow.

(i.e., hyperdynamic, normal, moderately depressed, or severely depressed) is usually sufficient in a critical care setting, and several authors have shown that little training is required to make this assessment reliably.[61,62] When performed by an experienced echocardiographer, estimates of LVEF correlate well with quantitative measurements.[63,64]

Semiquantitative measurements can be obtained using the LV SAX view by calculating fractional shortening (FS) or fractional area change (FAC) (see Fig. 31.2). Because this view only visualizes one plane of the myocardium, additional qualitative assessments of the complete LV should be performed to avoid errors resulting from coexisting regional wall motion abnormalities (RWMAs).

A more accurate (but more time-consuming) assessment of LV systolic function can be made by volumetric measurements. Both the area-length formula and Simpson's method reliably estimate LVEF.[65]

Right Ventricular Systolic Function

Compared with the assessment of LV function, assessment of RV function is more complex, as ventricular compliance, wall thickness, systolic function, and TV function are more closely linked.[66,67] Significant RV systolic dysfunction often presents with RV dilation and TV regurgitation. Simultaneously, normal RV function can be observed with RV dilation and significant TV regurgitation when the RV has time to adjust to chronically increased afterload by wall hypertrophy. Additionally, the RV has a complex geometric structure, making volumetric measurements and imaging difficult. For these reasons, an assessment of RV function is currently done using a combination of qualitative and semiquantitative measures (Table 31.5). Image acquisition is best using the PS LAX and A4CH views. Semiquantitative measures only assess certain regions of the ventricle, and caution must be taken not to extrapolate these findings. FAC is

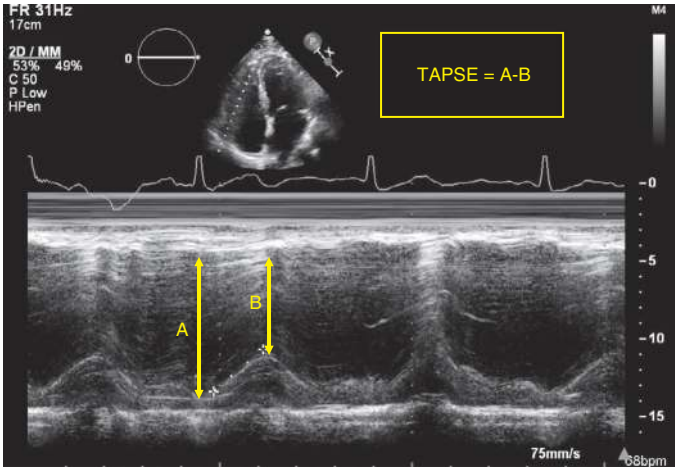

Fig. 31.5 Tricuspid annular plane systolic excursion (TAPSE). The distance of the tricuspid annulus from the apex is measured in the A4CH view. Subtraction of systolic from diastolic distance results in the TAPSE value. Normal values are greater than 20 mm.

currently recommended for semiquantitative calculation of RVEF, as traditional 2D methods assume symmetry of the ventricular structure,[68,69] and 3D methods are still being validated. Tricuspid annular plane systolic excursion (TAPSE) is easily obtained by TTE and is commonly used in combination with other methods (Fig. 31.5). RVSP, as described earlier, can reflect the ability of the RV to generate pressure and indirectly provides information about RV function. It is important to correlate measurements with factors that affect RV preload, PVR, and valvular function before making clinical judgments. Conditions that are commonly encountered in the ICU, such as acute respiratory distress syndrome (ARDS), acute pulmonary edema, volume overload, and arrhythmias, influence measured RVSP and often render it otherwise uninterpretable.[69,70]

CIRCULATORY FAILURE

Systematic Approach to Circulatory Failure

Circulatory failure is one of the most common indications for echocardiography in the ICU.[5,71] Several algorithms for hemodynamic assessment and management of circulatory failure by echocardiography have been described.[72–74] The algorithm should include the following steps: (1) seek to identify gross pathologies, such as cardiac tamponade, abnormal myocardial function, or marked hypovolemia or hypervolemia; (2) determine volume responsiveness and signs of low SVR; and (3) look for more subtle etiologies for hemodynamic instability like valvular pathologies (Fig. 31.6). Even though the clinical context will initially prompt evaluation for specific pathologies, it is important to perform a systematic assessment to avoid overlooking coexisting or complicating pathologies that need to be addressed or managed. When patients are being treated with inotropic agents or vasopressors, the echocardiographic findings must be interpreted in this context. The

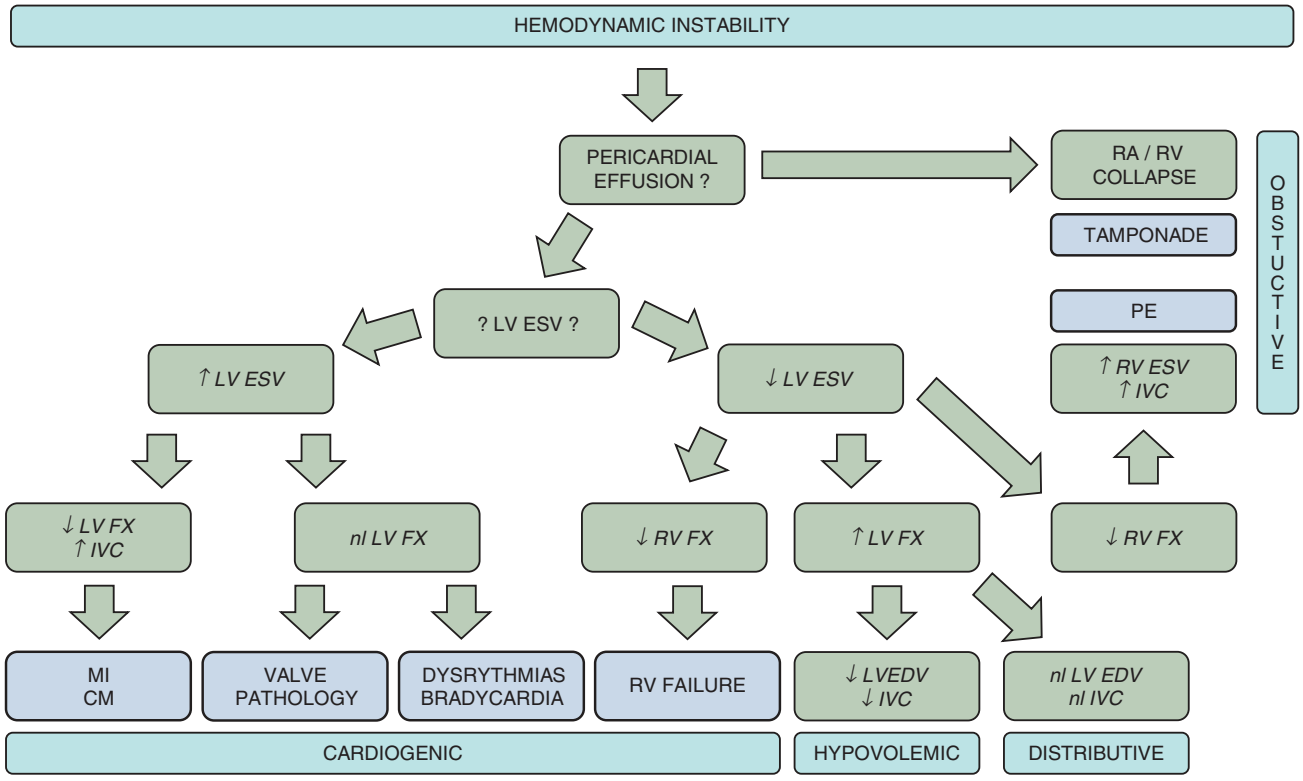

Fig. 31.6 Algorithm for the echocardiographic assessment of hemodynamic instability. After initial 2D assessment for hemodynamic-compromising pericardial effusion, evaluation of LV and RV size in systole and diastole and LV and RV systolic function is performed. Differentiation in cardiogenic, distributive, hypovolemic, or obstructive etiology of shock is often possible by following this algorithm. *CM,* Cardiomyopathy; *EDV,* end-diastolic volume; *ESV,* end-systolic volume; *FX,* systolic function; *IVC,* inferior vena cava; *LV,* left ventricle; *MI,* myocardial ischemia; *nl,* normal; *RA,* right atrium; *RV,* right ventricle; ↑, increased/hyperdynamic; ↓, decreased/depressed.

concurrent presence of different types of shock can complicate the hemodynamic assessment and the interpretation of echocardiographic findings. As myocardial function and SVR are pharmacologically altered, the underlying etiology for hemodynamic dysfunction may be obscured. Apparently normal ventricular function in the setting of sepsis can be observed with concomitant myocardial depression. Moreover, hyperdynamic ventricular function can be seen in both sepsis and hypovolemia. Therefore it is essential to correlate echocardiographic findings with the overall clinical picture. Table 31.6 shows the integration of echocardiographic findings and invasively measured values in different states of shock.

When monitoring clinical management, serial imaging must be performed and findings compared with previous ones. Additionally, management should be correlated to the overall picture, as not every patient with a certain hemodynamic disorder benefits from the same specific treatment.

Hypovolemic Shock

Hypovolemic shock is the result of an absolute or relative decrease in circulating volume secondary to volume loss or maldistribution. Echocardiography can identify intravascular hypovolemia and volume responsiveness using several approaches.[9] As described earlier, the IVC, LVEDD or LVEDA, and variation in LV SV are among the most used indicators (Fig. 31.7). An IVC diameter of <10 mm and significant changes in the IVC diameter with positive-pressure ventilation reflect systemic hypovolemia and suggest volume responsiveness.[48,50] If the EDD is <25 mm with hyperdynamic LV systolic function and "kissing" papillary muscles are seen during systole, then significant LV hypovolemia is present (Video 31.1).[52] Variations in LV SV reflected by changes in LVOT velocity predict the volume responsiveness. A change in LVOT V_{MAX} of >12% and a change in VTI_{LVOT} of >20% is seen in fluid responders.[75]

Cardiogenic Shock

Left heart failure resulting from systolic dysfunction is usually associated with low LVEF, low CO, systemic volume overload, and signs of pulmonary and hepatic congestion. Echocardiography can evaluate pathognomonic findings for heart failure and cardiogenic shock and possibly provide insights regarding etiology. Global myocardial dysfunction causing cardiogenic shock can be recognized when combining qualitative with supporting echocardiographic and clinical findings. Strong indicators for cardiogenic etiology of shock include enlarged LV size, qualitatively depressed LV function, FS <25%, low ejection fraction by FAC, and low CO by LVOT Doppler measurements.[76]

When assessing specific etiologies of cardiogenic shock, significant new RWMA and new or worsening mitral regurgitation can suggest acute myocardial ischemia (Video 31.2). Valvular pathologies, dynamic LVOT obstruction, and cardiac tamponade can cause hemodynamic instability, and these problems can be diagnosed using

TABLE 31.6 Echocardiographic and Hemodynamic Profiles in Different Shock States

	ECHO					INVASIVE MONITORING			
Type of Shock	Cardiac Function	LVESA	LVEDA	IVC	2D	Pulse Pressure	PAP	RAP CVP	SVO_2

Different types of shock present with specific echocardiographic and hemodynamic findings.

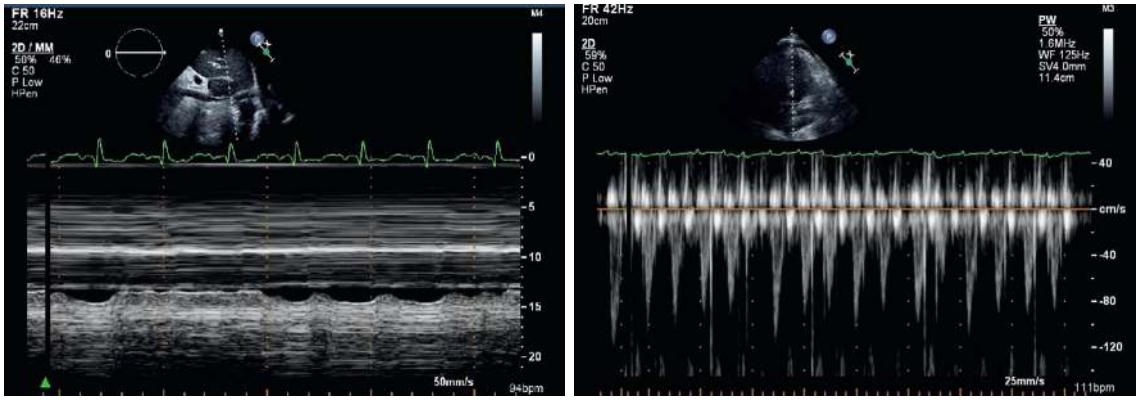

Fig. 31.7 IVC and LVOT velocities in hypovolemia. An IVC <1.5 cm with >50% respiratory collapse suggests intravascular hypovolemia. PWD of the LVOT shows respiratory variation in velocities. *IVC,* inferior vena cava; *LVOT,* left ventricular outflow tract; *PWD,* pulse wave Doppler.

echocardiography. Another important etiology of cardiogenic shock in the ICU is stress-induced cardiomyopathy (SCM). The incidence of this problem in ICU patients could be as high as 28%, and early diagnosis is facilitated using echocardiography.[77] Typical echocardiographic findings are apical ballooning with global LV dysfunction and compensatory hyperdynamic function of the basal segments (Video 31.3).

Right-sided heart failure, isolated or in the setting of biventricular failure, presents with slightly different echocardiographic findings. Mainly qualitative findings are depressed RV contractility, decreased ejection fraction by FAC, a TAPSE <16 mm in combination with RV dilation, RV/LV ratio of >0.8, and severe TV regurgitation (Video 31.4).[68] In this setting, low RVSP in conjunction with increased RAP, suggested by an IVC diameter >20 mm, can be the result of the inability of the myocardium to create adequate pressure. Evaluation of the LV often shows signs of hypovolemia with isolated RV failure caused by decreased LV preload.

The most common pathologies causing RV failure leading to acute cardiogenic shock are acute volume or pressure overload, new valvular pathologies, or acute ischemia. Chronic RV dysfunction predisposes patients to RV failure during critical illness from noncardiogenic causes. RV dilation, TV regurgitation, ventricular septal shifts, abnormal RVSP, and IVC dilation all help to inform the clinician about the etiology of acute RV failure. In particular, ventricular septal shifts have to be interpreted in this context, as they are commonly present in chronic valvular or pulmonary disease states and do not necessarily indicate the presence of acute RV failure (Fig. 31.8).

Distributive Shock

Septic shock can present with a highly variable clinical picture, and dynamic changes in the appearance of shock can occur within hours with or without intervention. The clinical picture of septic shock can range from aspects of a pure distributive shock to combinations of hypovolemic, cardiogenic, and distributive shock.[78,79] For this reason, echocardiography aids in the assessment and management of septic patients, and serial reevaluation is imperative to adapt to the dynamic evolution of the disease. Bedside echocardiography in the septic patient is focused on the systematic evaluation of volume status and fluid responsiveness, SVR, and ventricular function. Early echocardiographic signs supporting the diagnosis of septic shock are hyperdynamic LV systolic function and high CO levels in conjunction with small or normal LVEDA (Video 31.5). However, the findings will depend on intravascular volume status and RV function. It is important to differentiate between hypovolemia and low SVR in this situation, as the only distinction may be the difference in LVEDA (Video 31.1 vs. Video 31.5).

There are some caveats specific to the evaluation and monitoring of distributive shock. Fluid resuscitation often eliminates signs of hypovolemia, and vasopressors may depress the hyperdynamic appearance of the LV. If myocardial dysfunction is present, the ventricular function may appear normal or hyperdynamic on initial or follow-up imaging as opposed to the classic hyperdynamic shock picture. Inotropic support can alter echocardiographic findings even further.[80–82]

Obstructive Shock

Circulatory collapse caused by mechanical interference with ventricular filling or emptying is classified as an obstructive shock.[83] Potential

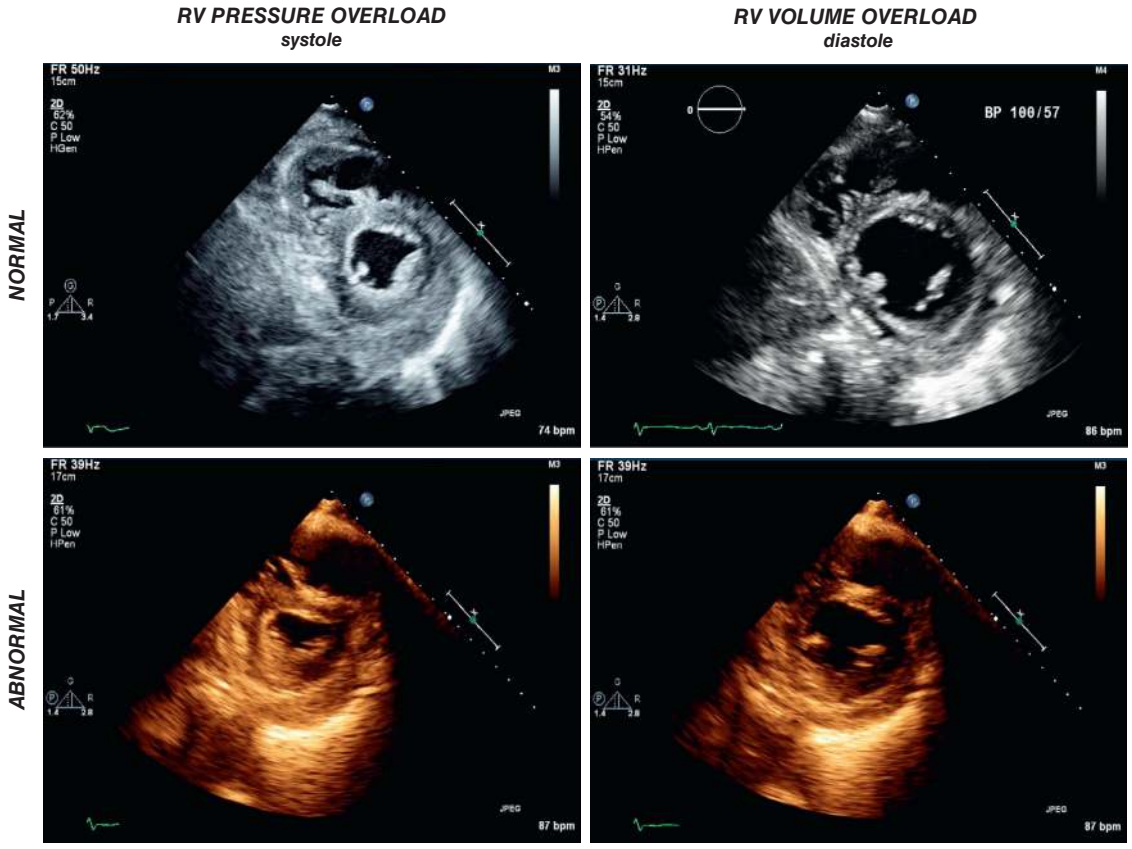

Fig. 31.8 Paradoxical interventricular septal shift. Pathologies causing RV pressure overload such as pulmonary hypertension will result in septal flattening during systole. With RV volume overload, a septal shift occurs in diastole. In acute RV failure, commonly both pathognomonic findings are seen. *RV,* Right ventricle.

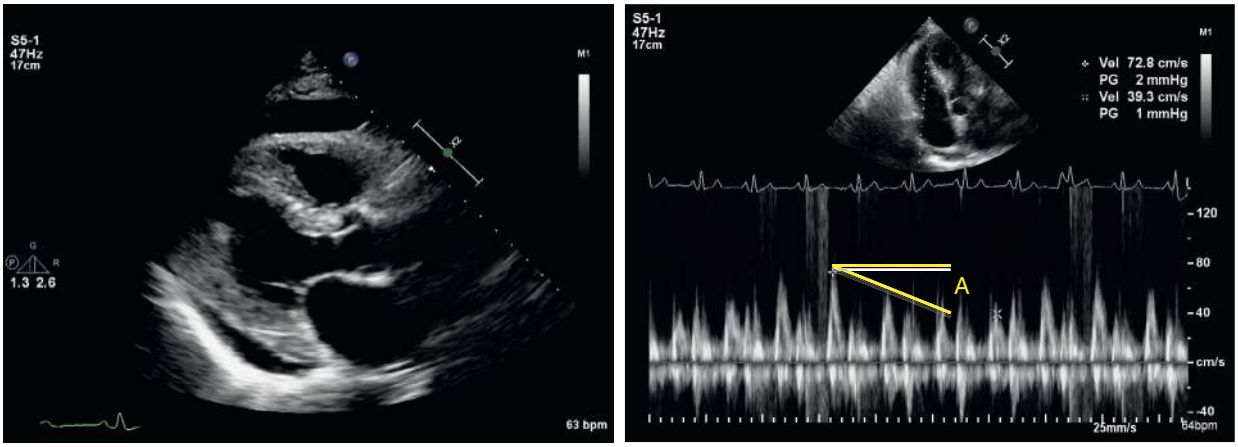

Fig. 31.9 Hemodynamic-compromising pericardial effusion/tamponade. Respiratory variation in TV inflow of >25% is suggestive of hemodynamic-compromising pericardial effusion and tamponade. It is important to differentiate a pericardial from a pleural effusion. The arrow marks the descending thoracic aorta. A pericardial effusion does not extend superiorly (leftward) past the descending thoracic aorta, whereas a pleural effusion projects more distal to the aorta with extension past the vessel toward the left of the image. Circumferential effusion, the diastolic collapse of RA or RV, and IVC plethora are additional signs suggestive of tamponade physiology, as seen in Video 31.6.

causes of obstructive shock include pericardial effusion and tamponade, tension pneumothorax, and pulmonary embolism, in addition to less common entities, such as intracardiac tumors or vena cava compression. As these processes are mechanical, echocardiography has the potential of visualizing the source of shock pathology directly aside from identifying the hemodynamic profile.

Pericardial effusion and cardiac tamponade are dynamic diseases closely linked to changes in intravascular volume status, intrathoracic pressures, and patient position. Although the etiology of an effusion cannot be defined by echocardiography, certain findings such as clot formation or stranding can hint toward hemorrhagic or purulent effusions of serous fluid (Fig. 31.9). When evaluating cardiac tamponade, echocardiography can exhibit signs suggestive of hemodynamically significant pericardial effusion or clot[84,85] (see Table 31.6 and Video 31.6). In postcardiac surgery patients, tamponade may not always be present with the classic circumferential effusion, and echocardiographic imaging should include an assessment for the localized clot or fluid collections in uncommon locations, such as the IVC-RA (right atrium) junction or posterior to the left atrium (LA).

A pulmonary embolism causes the obstruction of blood flow from the right side of the heart to the left. It commonly presents with signs of right-sided pressure overload and RV failure, in conjunction with a hypovolemic and hyperdynamic LV (Table 31.7 and Video 31.7).[86] The McConnell sign with akinesis of the RV free wall and normal function of the RV apex is pathognomonic but not always observed (see Video 31.7).[87] Occasionally, the obstructing embolism can be seen in the very proximal pulmonary vasculature. Additionally, it is pertinent to evaluate patients for intracardiac shunts, as these present a risk for paradoxical embolism and hypoxia and have a worse short-term prognosis.[88,89]

Tension pneumothorax can cause decreased cardiac preload, and echocardiographic findings show hypovolemia and possible mechanical cardiac compression or shift. Further imaging via chest ultrasound or radiography is necessary for the diagnosis. Other pathologies, such as extracardiac or intracardiac masses causing obstruction to ventricular filling, are uncommon. However, when these problems are present, echocardiography can be helpful for making the diagnosis and evaluating the hemodynamic significance.

TABLE 31.7 Echocardiographic Signs Seen With a Significant Pulmonary Embolism (PE)

PULMONARY EMBOLISM
• Clot in proximal pulmonary vasculature
• Depressed RV systolic function ± hypovolemic and hyperdynamic LV
• Interventricular septum shifts consistent with RV pressure overload
• McConnell sign
• Tricuspid regurgitation
• IVC plethora
• Intraatrial shunt

IVC, Inferior vena cava; *LV,* left ventricle; *RV,* right ventricle; *TR,* tricuspid valve.
Dependent on the extent of RV compromise, the LV will exhibit signs of hypovolemia. Classic sign of RV pressure overload shows a systolic shift of interventricular septum. Evaluation for intraarterial communication with right-to-left shunting is pertinent in patients with significantly increased right-sided pressures because of PE.

Echocardiography During Cardiopulmonary Resuscitation

Echocardiography is one important application of ultrasound in cardiac arrest. It focuses on identifying the immediate causes of cardiac arrest, such as cardiac tamponade, pulmonary embolism, hypovolemia, or myocardial failure, and can guide and follow resuscitation efforts.[90,91] Additionally, Salen and colleagues and Blyth and colleagues showed that the echocardiographic identification of cardiac activity can predict recovery of spontaneous circulation.[92,93] The best view for immediate evaluation in cardiac arrest is the LV SAX view. This is because it can provide information about extreme changes in volume status, myocardial function, and pericardial tamponade simultaneously. Additionally, it is easy to obtain and interpret. In the acute setting, TEE can often

provide better continuous imaging when chest compressions are ongoing, but it may interfere initially with intubation attempts.

SPECIFIC EVALUATION

Valvular Pathologies

A detailed assessment of valvular pathologies requires comprehensive echocardiographic skills and is performed by cardiologists or cardiothoracic anesthesiologists with advanced echocardiographic training. During limited ICU echocardiographic examinations, the operator should seek to identify gross valvular pathologies, as their presence can alter management. Aside from the immediate adjustment in hemodynamic management, any valvular pathology found on the basic bedside examination warrants further subsequent evaluation by a comprehensive examination.

Basic components of valve assessment include gross anatomic evaluation for obvious pathologies, such as calcifications or ruptured leaflets and papillary muscles (Table 31.8). CFD is used to recognize significant transvalvular flow acceleration suggestive of stenotic lesions or patterns of valvular regurgitation of hemodynamic significance. Basic quantitative measurements of transvalvular gradients by CWD can be obtained through AV and MV for grading of stenotic lesions and calculation of valve area, but this is part of the in-depth examination.[94,95] The five most common valvular pathologies are seen in Videos 31.8–31.12.

Cardiomyopathies and Dynamic Outflow Obstruction

Primary disease of the heart muscle plays a significant part in the overall morbidity and mortality of cardiovascular disease. Echocardiography provides information about the magnitude of systolic and diastolic heart failure, in addition to the etiology of cardiomyopathy. Echocardiography permits the assessment of immediate and long-term prognosis. As cardiomyopathies can alter the hemodynamic response to acute illnesses and their management in the ICU, it is important for the intensivist to know the echocardiographic patterns that are characteristic of these chronic disorders.[96]

Cardiomyopathies are commonly differentiated into three main types: (1) dilated cardiomyopathy, (2) hypertrophic cardiomyopathy, and (3) restrictive cardiomyopathy.[97] Dilated cardiomyopathy presents with echocardiographic findings of dilated ventricles and reduced ventricular systolic function (Video 31.13). Hypertrophic cardiomyopathy is characterized by symmetric or asymmetric concentric hypertrophy of the myocardium (Video 31.14). It is important to recognize a dynamic obstruction of the LVOT in hypertrophic obstructive cardiomyopathy (HOCM). This is because the presence of this problem alters the usual management of cardiogenic shock management because the administration of inotropic agents can be detrimental in patients with HOCM. Dynamic outflow obstruction in these cases is caused by the systolic anterior motion (SAM) of the mitral valve leaflet (Video 31.15).[98] As in HOCM, SAM can also be present after mitral valve surgery.[99]

Restrictive cardiomyopathy is more difficult to diagnose, as it presents with diastolic dysfunction of the ventricles, and echocardiographic findings require an evaluation of diastolic function. For the intensivist, if evaluation for diastolic dysfunction is difficult, findings of atrial enlargement with small ventricles and subjective restricted ventricular function are often the best supportive indicators for restrictive cardiomyopathies.[96]

Infectious Pathologies and Embolic Sources

TEE is used in the evaluation of infectious and embolic sources in patients with unexplained sepsis or embolic strokes. In an acute setting, transthoracic findings of new regurgitant valvular lesions in the setting of bacteremia can be suggestive of infectious endocarditis. However, TEE is warranted for the optimal assessment when vegetations are anticipated (Video 31.16). As differentiation can be difficult and an evaluation for coexisting involvement of the valvular structures is pertinent for possible surgical management, comprehensive TEE is commonly performed by cardiologists.[100] When the etiology of a stroke in the absence of an infection is unclear, or in the event of planned cardioversion for prolonged supraventricular tachyarrhythmias in patients with a high risk of thrombus formation, TEE is performed to evaluate for the presence of a left atrial appendage clot.[101] Additionally, when evaluating for cardiac sources of thromboembolic events, the presence of intracardiac shunts as the source for paradoxical events should be ruled out. As these are not always detected by

TABLE 31.8 Common Valvular Pathologies and Their Echocardiographic Findings

Valve Pathologies		Findings
Aortic stenosis (AS)	2D	Calcification of leaflet and annulus, restrictive leaflet motion, LVH
	CFD	Transvalvular flow acceleration, AI
	CWD	Transvalvular flow acceleration, increased peak mean, and peak gradient rounded Doppler profile
Aortic insufficiency (AI)	2D	Leaflet disruption, LV enlargement
	CFD	Regurgitant diastolic flow, turbulent flow, regurgitant jet direction
	CWD	Regurgitant diastolic flow, Doppler profile density, diastolic flow reversal in proximal thoracic aorta
Mitral stenosis (MS)	2D	Calcification of leaflet and annulus, restrictive leaflet motion, dilated LA
	CFD	Transvalvular flow acceleration, PISA, MR
	CWD	Transvalvular flow acceleration increased peak mean and peak gradient
Mitral insufficiency (MR)	2D	Leaflet pathology, chordal tethering, dilated annulus, LA enlargement, LV enlargement
	CFD	Regurgitant systolic flow, turbulent flow, regurgitant jet severity and direction
	CWD	Regurgitant diastolic flow, Doppler profile density, diastolic flow reversal in proximal thoracic aorta
	PWD	Pulmonary vein flows blunting/reversal
Tricuspid regurgitation (TR)	2D	Dilated annulus, leaflet pathology, RA enlargement, RV enlargement
	CFD	Regurgitant systolic flow, turbulent flow, regurgitant jet severity and direction
	CWD	Regurgitant diastolic flow, Doppler profile density
	PWD	Hepatic vein flows blunting/reversal

LA, Left atrium; *LVH,* left ventricular hypertrophy; *PISA,* proximal isovolumetric flow acceleration.

simple CFD interrogation, a bubble study during a Valsalva maneuver is performed to aid in the detection of right-to-left shunting.[102]

Aortic Pathologies

Echocardiographic assessment of aortic disease in acute hemodynamic instability in critically ill patients mainly focuses on the evaluation of aortic dissection. As TTE is of limited utility for evaluation of the thoracic and abdominal aorta, TEE is the modality of choice.[103] TEE has been shown to be equally accurate when compared with computed tomography (CT) or magnetic resonance imaging (MRI) in the diagnosis and confirmation of thoracic aortic dissection.[104] The evaluation includes the visualization of the dissection flap, identification of the true and false lumens, estimation of blood flow, and determination of active extravasation. When the aortic root is involved, assessment includes evaluation for subsequent complications, including aortic insufficiency (AI), pericardial effusion, and acute ischemia secondary to coronary involvement.

Trauma

Echocardiography in critically ill patients after trauma can evaluate the hemodynamic status and anatomic pathologies after forceful injuries.[105] After blunt chest trauma, echocardiography is a useful tool in the initial evaluation.[106] Catastrophic structural injuries, such as cardiac tamponade, cardiac rupture, coronary artery thrombus, disruption of valvular structures, and traumatic aortic injury, can be identified quickly.[73] More commonly, patients only present with signs of cardiac contusion, and echocardiography can assist with identification of myocardial dysfunction in the acute setting. Specific TTE views are part of the standard algorithms for an emergency ultrasound, such as the focused assessment with sonography in trauma (FAST) or focused cardiac ultrasound (FOCUS) examinations.[107–109] When available and no contraindications are present, TEE can also diagnose aortic injury, although CT is preferred for rapid evaluation.[110,111]

Interventional Use of Echocardiography

Interventional procedures involving cardiac structures are common in the ICU, and basic ultrasound and echocardiography play important roles in the conduct of these interventions. TTE or TEE performed at the bedside alleviate the need for transporting patients to the cardiac catheterization laboratory or procedure room for fluoroscopic guidance. This eliminates the risks that are associated with moving critically ill patients. Use of echocardiography can also decrease exposure to radiation.[112] Although the basic ultrasound can assist significantly in multiple types of procedures, including venous and arterial vascular access and drainage of pleural effusions or other fluid collections, echocardiography can assist in more advanced procedures. TTE can assist with pericardiocentesis and with gross localization of a transvenous pacemaker lead.[113–115] TEE provides optimal image quality for specific cardiovascular interventions, such as an intraaortic balloon pump (IABP) placement and positioning of extracorporeal membrane oxygenation (ECMO or ventricular assist device (VAD) cannulas.[73,116–118] TEE best evaluates mechanical assist devices. Thromboembolic events, overt hemolysis, or fluctuation in device power or flow warrant the evaluation for thrombus formation, cannula position, and device function.[119,120]

Hypoxemia

Echocardiography can assist in the diagnosis and management of acute respiratory failure. In pulmonary edema, differentiation between cardiogenic and noncardiogenic etiology aids in medical management. Either by invasive measurements or echocardiographic evaluation, estimation of LA and LV filling pressures is pertinent for the diagnosis of hydrostatic pulmonary edema. When a regular rhythm is present, LV filling pressures can be estimated by transmitral and pulmonary venous Doppler studies and is the most commonly used parameter for an easy, reproducible assessment in the ICU.[121] Common cardiac causes for pulmonary congestion are volume overload, acute mitral or aortic valve regurgitation, mitral stenosis, and severe LV systolic and diastolic dysfunction. All these problems can be assessed using 2D, CFD, and spectral Doppler echocardiographic modalities. In noncardiogenic ARDS, echocardiography can allow the clinician to assess changes in RV function with adjustments of mechanical ventilation.[122] Severe ARDS with increased pulmonary resistance and the use of high levels of PEEP may lead to acute or pulmonary issues with sudden RV failure and subsequent hemodynamic and respiratory decompensation.[123] Similarly, acute increases in pulmonary vascular resistance caused by pulmonary embolus (PE) can cause RV failure.[124] In these cases, echocardiography is often used as a supportive tool for the diagnosis and assessment of hemodynamic significance.

Another common cause of hypoxemia in mechanically ventilated patients is the presence of intracardiac shunts. With a prevalence of >25% in the general population, intraatrial communications, such as patent foramen ovale (PFO) and atrial septum defects (ASDs), are frequently clinically silent.[125,126] In healthy patients with PFO or ASD, shunting typically is either absent or directed from left to right. During critical illness, however, increased right-sided pressure caused by pulmonary hypertension, RV failure, volume overload, or TV regurgitation is common and can lead to right-to-left shunting, resulting in hypoxemia from the admixture of nonoxygenated with oxygenated blood.[73] Echocardiographic evaluation focuses on detection of intracardiac shunting and directional flow of the shunt by 2D echocardiography and CFD.

FUTURE DIRECTIONS

Many miniaturized and TTE and TEE devices have been introduced recently into the critical care environment for the use by noncardiologists for goal-directed therapy of the hemodynamically unstable patient. Handheld TTE devices demonstrate usefulness in the clinical setting when used by intensivists after undergoing brief training.[127–130] Miniaturized, disposable TEE probes that provide monoplane images have been introduced for continuous use up to 72 hours. The initial experience has demonstrated good utility in the management of hemodynamically unstable patients.[131,132] These novel monitoring devices for continuous echocardiographic imaging have great potential for providing many features of a regular TEE while minimizing the risks and allowing for use over time.[133,134] Advanced echocardiographic modalities, such as contrast echocardiography and endocardial border tracking, can be valuable when available.[135–137]

On the operator side, more intensivists are becoming skilled in echocardiography, and ICU fellowship programs increasingly teach focused echocardiography. With the growing importance of critical care echocardiography, critical care societies across the world propose the further integration of formal echocardiographic training into ICU fellowship training. Specific criteria are being defined for the future trainees, and courses in focused ICU echocardiography are offered for the practicing intensivist.[18–20]

Despite significant advancements in the field over the past decade, a broader validation of echocardiographic use in the ICU is needed. Outcome-based studies looking at the use of focused echocardiography as a monitoring tool and integration into goal-directed therapy will be helpful in strengthening the broad use of this valuable modality.

KEY POINTS

- TTE and TEE are valuable diagnostic and monitoring tools in the critical care setting and can have a significant impact on the management and outcome of critically ill patients.
- Training, accreditation, and maintenance of expertise in focused echocardiography are essential, and further development of these areas by national societies is needed.
- An understanding of ultrasound physiology, the echocardiography machine, anatomy, and normal echocardiographic findings is essential for the appropriate use of echocardiography in the ICU.
- The most common use of bedside echocardiography is the evaluation of acute circulatory and respiratory failure.
- An algorithmic approach to the hemodynamically unstable patient is warranted, and repeated echocardiographic assessment to confirm and adjust medical management needs to ensue until the patient stabilizes.
- Interpretation of echocardiographic findings should take into account the patient's history, pathophysiology, and current medical interventions.
- Management based on echocardiographic information needs to follow the complete clinical picture of the critically ill patient.
- With rapid advancement in ultrasound technology, pocket-sized handheld TTE devices and miniaturized TEE probes for continuous monitoring are being developed and will further promote the integration of focused echocardiography in the daily critical care practice.

ANNOTATED REFERENCES

Cheitlin MD, Armstrong WF, Aurigemma GP, et al. ACC/AHA/ASE 2003 guideline update for the clinical application of echocardiography: Summary article. *Circulation.* 2003;108(9):1146–1162.
Updated ACC/AHA/ASE guidelines regarding the clinical application of echocardiography. Regarding critical care, the new guidelines highlight the utility of transthoracic echocardiography in the detection of central pulmonary emboli and emphasize the potentially superior utility of transesophageal echocardiography. The use of echocardiography in blunt thoracic trauma is also reviewed.

Grider D, Society of Critical Care Medicine. *Ultrasonography in Critical Care.* Society of Critical Care Medicine. Available at https://www.sccm.org/Communications/Critical-Connections/Archives/2018/Ultrasonography-in-Critical-Care.
Of particular importance to the practicing provider, this summary provided by the Society of Critical Care Medicine of common CPT codes used in the intensive care unit may facilitate appropriate billing for echocardiographic procedures.

Roshdy A. Echodynamics: Interpretation, limitations, and clinical integration. *J Intensive Care Med.* 2018;33(8):439–446.
Review of considerations, indications, and limitations of echocardiographic assessment in complex critical illness physiology. For example, the inferior vena cava is often used to assess volume status and fluid responsiveness. However, it is less reliable when low tidal volumes are delivered, when low lung compliance occurs, when a patient is spontaneously breathing, and when excessive probe pressure is applied to the abdomen.

Vieillard-Baron A, Millington SJ, Sanfilippo F. A decade of progress in critical care echocardiography: A narrative review. *Intensive Care Med.* 2019;45:770–788.
An updated report of the areas in critical care, emergency medicine, and perioperative care where echocardiography may have a potential benefit or impact. Key messages, including the need to perform echocardiography for any hemodynamically unstable patient and that each critical care unit should have some individuals trained in advanced echocardiography, highlight the now-ubiquitous use of echocardiography in intensive care medicine.

Zochios V, Parhar K, Tunnicliffe W, et al. The right ventricle in ARDS. *Chest.* 2017;152(1):181–193.
Review highlighting the impact of acute respiratory distress syndrome on the right ventricle and current knowledge gaps in relation to echocardiographic assessment.

Cardiovascular Monitoring

Arthur Pavot, Xavier Monnet, and Jean-Louis Teboul

INTRODUCTION

Over the last decades, cardiovascular monitoring techniques used in the intensive care unit (ICU) and operating room (OR) have progressively evolved from invasive toward less invasive approaches. In the 1990s, the pulmonary artery catheter (PAC) was at its apogee,[1] as it was the only method to assess and monitor hemodynamics at the bedside. The PAC has provided clinicians with measurements of cardiac output (CO), pulmonary artery pressure (PAP), cardiac filling pressures, and mixed venous blood gases. Modified versions of PAC provided continuous monitoring of CO and of mixed venous oxygen saturation (SvO_2). However, a progressive decline of use of the PAC has been observed since 1995.[1] In addition to invasiveness, there were multiple reasons for such a decline: (1) evidence of insufficient physician knowledge in measuring and interpretating the PAC data[2,3]; (2) a report from a nonrandomized outcome study showing increased mortality associated with PAC vs. no PAC[4]; (3) findings from randomized controlled trials showing no outcome benefits of using PAC in ICU patients[5,6]; (4) development of bedside echocardiography in the ICU that allows better assessment of cardiac function; (5) emergence of transpulmonary thermodilution (TPTD),[7] esophageal Doppler (ED),[8] and minimally invasive or noninvasive pulse wave analysis (PWA) CO monitors.[9–11] The latter monitoring systems, which provide real-time and continuous CO and fluid responsiveness variables, belong to the class of functional hemodynamic monitoring devices. Use of such devices in goal-directed therapy strategies in the perioperative period of high-risk surgical patients has been reported to improve outcome in comparison to standard management using central venous pressure (CVP) and mean arterial pressure (MAP).[12] During recent years, the importance of predicting fluid responsiveness has also been emphasized in the ICU setting. This can be explained by (1) the demonstration that approximately half of ICU patients are fluid nonresponders[13] and (2) the fact that fluid overload is associated with increased mortality of ICU patients.[14] Numerous studies have documented the superiority of dynamic over static variables to predict fluid responsiveness.[15] Accordingly, many intensivists and anesthesiologists prioritize the use of devices that provide dynamic variables such as pulse pressure variation (PPV) and stroke volume variation (SVV)[15] or that facilitate tests such as passive leg raising (PLR)[16,17] or end-expiratory occlusion (EEO).[17–20] Thus it is easy to understand why in this context, the place of the PAC, which cannot provide adequate assessment of fluid responsiveness, has decreased over time.

In this chapter, we review the most used hemodynamic monitoring devices in the ICU and the OR settings, ranging from the invasive to less invasive ones. We emphasize the clinical relevance of the hemodynamic information they provide and the advantages and limitations of their use, knowing that they generally gain in safety what they lose in precision. We also discuss the place of hemodynamic monitoring in patients with shock and in patients in the OR setting.

THE AVAILABLE HEMODYNAMIC MONITORING DEVICES

The Pulmonary Artery Catheter

Description

The most commonly used PAC model is a fluid-filled catheter of 7 or 7.5F external diameter and 80-cm length that connects to an electronic pressure transducer. The distal lumen, ending at the tip of the catheter, enables blood sampling and pressure measurement at the level of the pulmonary artery. A few millimeters before its termination, a latex balloon surrounds the catheter. Temporary balloon inflation totally occludes the pulmonary artery branch (10–15 mm diameter) into which the catheter has been placed and allows the measurement of the pulmonary occlusion artery pressure (PAOP). A proximal lumen at the level of the right atrium allows measuring the right atrial (central venous) pressure. A thermistor located close to the tip of the catheter continuously senses the changes in blood temperature induced by thermal injection via the proximal lumen. This allows calculating thermodilution CO according to the Stewart-Hamilton principle.

Based on this minimal configuration, alternative PAC models can be equipped with:

- An ultra-fast thermistor providing calculation of right ventricular (RV) ejection fraction and RV end-diastolic volume
- A thermal filament for continuous CO measurement
- A fiberoptic probe for reflectance photometry and continuous assessment of SvO_2

Pulmonary Artery Catheter–Derived Variables

The PAC provides the physician with hemodynamic variables (right atrial pressure, PAP, PAOP, and CO) and with tissue perfusion variables such as SvO_2 and the mixed venous carbon dioxide pressure ($PvCO_2$). Simultaneous acquisition of arterial blood gases allows calculation of oxygen consumption (VO_2) and oxygen delivery (DO_2), using the time-honored Fick principle.

Pulmonary artery occlusion pressure. The PAOP is obtained after inflation of the distal balloon with 1.5 mL of air. This temporarily occludes a branch of the pulmonary artery of around 13 mm diameter and thus interrupts flow through the column of blood linking the balloon with a pulmonary vein of similar diameter. The PAOP reflects the pressure in a large pulmonary vein and thus approximates both the left atrial pressure (LAP) and left ventricular (LV) end-diastolic pressures (LVEDP).

It is recommended to measure PAOP at the end of expiration, a time when intrathoracic pressure is closest to its value at atmospheric pressure. Positive end-expiratory pressure (PEEP) or auto-PEEP may lead to overestimation of PAOP at end expiration as a measure of LV filling pressure (LVFP). Obtaining transmural PAOP, a better marker

of LVFP, requires subtraction from the end-expiratory PAOP a value that estimates the transmitted PEEP or auto-PEEP into the thorax. This value can be obtained by the product of PEEP (or auto-PEEP) by the ratio of the difference between the PAOP values at end expiration, and at end inspiration over the driving pressure (difference between plateau pressure and PEEP).[21]

Even if it reflects LAP, PAOP overestimates LVEDP in cases of mitral stenosis or insufficiency and underestimates LVEDP in the case of severe aortic insufficiency or reduced LV compliance.

Although the main interest of the transmural PAOP is to estimate the LVFP, the intramural PAOP is also used to reflect the pulmonary capillary pressure (Pcp). However, because PAOP reflects the pressure in a large pulmonary vein, it underestimates Pcp, particularly when CO is high and when pulmonary venous resistance is elevated, as during acute respiratory distress syndrome (ARDS).[22,23] The Pcp could be estimated from the PAP trace decay during the seconds after the distal balloon inflation, after extrapolation back toward time zero of the slow component of the pressure decay. For adequate precision, this calculation requires a computerized mathematical method.[23] Because Pcp is not measured in routine practice, PAOP provides only a rough estimate of the Pcp needed to differentiate between hydrostatic and increased permeability pulmonary edema. However, authentic increased permeability pulmonary edema also can be associated with elevated PAOP.[24]

Cardiac output. The CO can be measured using the thermodilution principle. Two methods of measurement are currently used:

- The intermittent thermodilution method requires the injection of a cold saline bolus through the proximal lumen of the catheter. The decrease in blood temperature is recorded by the distal thermistor, and CO is calculated from the Stewart-Hamilton equation. At least three measurements must be averaged for a reliable estimation of CO. Severe tricuspid regurgitation leads to underestimation of CO.[25]
- The "continuous" thermodilution method is based on automatic heating of blood by means of a proximal thermal filament (located about 15 cm from the tip of the PAC). The external monitor activates the heating filament for 1–4 seconds in a pseudorandom sequence. The resulting series of heat signals from the distal thermistor are analyzed stochastically to determine a single thermodilution curve. This technique has the advantage of continuously displaying CO and avoiding repeated manipulations of the lines and bolus injections. However, it does not enable real-time CO monitoring, because the average of successive CO measurements is delayed as compared with the intermittent technique.[26] This limits the ability to detect rapid hemodynamic changes induced by therapy or to track hemodynamic instability during high-risk surgery.

Mixed venous blood oxygen saturation. Because pulmonary arterial blood blends the mix from all venous territories of the body, measuring SvO_2 with the PAC enables assessment of global tissue oxygenation.

Two techniques are currently available. The first one requires sampling of the pulmonary artery blood through the distal tip of the PAC. The second technique uses PAC models, which enable a continuous "in vivo" monitoring of SvO_2 through fiberoptic spectrophotometry. The latter method has the advantage of avoiding repeated blood samplings and provides real-time monitoring of SvO_2.

Physiologically, SvO_2 depends on arterial oxygen saturation (SaO_2), VO_2, CO, and hemoglobin concentration (Hb), according to the formula derived from the Fick equation applied to oxygen: $SvO_2 = SaO_2 - [VO_2 / (CO \times Hb \times 13.4)]$. Because CO, Hb, and SaO_2 are the key determinants of DO_2, SvO_2 is an integrative variable, which is considered a marker of the global balance between actual VO_2 and DO_2.[23] SvO_2 values range from 65% to 77% in healthy subjects.

Useful interpretation of SvO_2 presents several difficulties.[27] First, a low value of SaO_2 results in a decreased SvO_2, which is no longer considered a marker of the VO_2/DO_2 balance. Second, a normal or high SvO_2 value can be observed during certain shock states (e.g., sepsis) because of impaired oxygen extraction capability. This difficulty emphasizes that when SaO_2 is normal, SvO_2 is a marker of the balance between DO_2 and VO_2 but does not faithfully reflect oxygen demand. Third, for constant VO_2, Hb, and SaO_2, the relation between SvO_2 and CO is hyperbolic. Thus although changes in SvO_2 parallel changes in CO in low CO states, marked changes in CO do not significantly alter SvO_2 in hyperdynamic ones. Fourth, in shock states characterized by DO_2/VO_2 dependency, changes in CO result in parallel changes in VO_2 such that SvO_2 will not change if DO_2 is below its critical value. Fifth, SvO_2 is the flow-weighted average of the venous saturation values from all organs of the body. Organs having high blood flow and low oxygen extraction, such as the kidneys, have a greater influence on SvO_2 than organs with low blood flow and high oxygen extraction, such as the myocardium. In sepsis, interpretation of SvO_2 is further complicated by the local maldistribution of blood flow. Nevertheless, in any shock state, monitoring SvO_2 is helpful because a low value (<65%) should prompt clinicians to increase DO_2 in order to improve tissue oxygenation.[27] On the other hand, a high value of SvO_2 suggests that attempts to increase DO_2 have little chance to improve tissue oxygenation significantly or ultimately benefit outcome.[28]

Veno-arterial carbon dioxide tension difference. The veno-arterial carbon dioxide tension (PCO_2) difference (ΔPCO_2) is the difference between $PvCO_2$ and PCO_2 in arterial blood ($PaCO_2$). Its normal value ranges from 2 to 5 mm Hg.

The Fick equation applied to carbon dioxide (CO_2) indicates that the CO_2 excretion (equivalent to CO_2 production [VCO_2] in a steady state) equals the product of CO by the difference between the CO_2 content in the mixed venous blood and in the arterial blood. The normal relationship between CO_2 content and PCO_2 is almost linear over the usual physiologic range of the CO_2 contents. Thus by substituting PCO_2 for CO_2 content, $\Delta PCO_2 = k \times VCO_2 / CO$, where k is a constant. Accordingly, ΔPCO_2 would be linearly related to VCO_2 and inversely related to CO.

The ΔPCO_2 is considered a marker of the adequacy of venous blood flow to remove the total CO_2 produced by the peripheral tissues.[29] An increased ΔPCO_2 suggests that the CO is not high enough with respect to the global metabolic conditions. A high ΔPCO_2 should prompt clinicians to consider measures aimed at increasing CO so as to reduce tissue hypoxia. Conversely, a normal ΔPCO_2 suggests that increasing CO is not a priority.

Complications Associated With Pulmonary Artery Catheters

The complications associated with the use of a PAC are relatively rare and can be related to (1) PAC insertion (e.g., arterial puncture, bleeding, pneumothorax, ventricular extrasystoles), (2) PAC maintenance (e.g., bacterial colonization, infectious endocarditis, venous thromboembolism), (3) balloon inflation (e.g., rupture of a pulmonary artery branch, false aneurysm of the pulmonary artery), and (4) PAC withdrawal (e.g., transient ventricular arrhythmias, knotting of the catheter). Some of these complications relate to the poor experience of the user and to the PAC length of stay. The PAC should be carefully removed as soon as no longer needed, and its use should not be prolonged longer than 3 or 4 days.

Systems Integrating Transpulmonary Thermodilution and Pulse Wave Analysis

Description

Two commercialized devices integrate the TPTD and the PWA methods: the PiCCO (Pulsion, Germany) and the VolumeView (Edwards LifeSciences, USA). They require the insertion of a standard central

catheter in the superior vena cava and a specific thermistor-tipped arterial catheter, which is usually inserted in the femoral artery. The arterial catheter can also be inserted in the radial, brachial, and axillary arteries if site-specific catheters are used. In practice, a bolus of cold saline (15 mL) is injected through the venous catheter. The thermistor at the tip of the arterial catheter detects the change in blood temperature induced by the cold bolus injection. In addition to providing TPTD-derived variables,[30] cold bolus injections allow calibrating the PWA-based CO, which is derived from the analysis of the ABP waveform.

Transpulmonary Thermodilution–Derived Variables

Transpulmonary thermodilution cardiac output. Similar to the intermittent PAC thermodilution, the area under the TPTD is inversely related to CO according to the Stewart-Hamilton principle. Because the thermistor is located in a femoral artery and not in a pulmonary artery, the TPTD curve has a longer appearance time, a less negative peak value, and a longer return time to baseline temperature compared with the PAC thermodilution curve. Nevertheless, there is a good agreement between CO values measured by the two methods in humans.[31] Although the PAC thermodilution should theoretically provide more accurate CO measurements (less indicator loss between the injection and the sampling sites) than TPTD, the latter has the advantage of being less influenced by respiration and severe tricuspid regurgitation. Cold saline (<8°C) injection should be preferred to room-temperature saline injection to avoid multiplying the risks of errors of measurements and to avoid overestimating CO.[32] The result of three cold bolus injections performed at random should be averaged to obtain an acceptable precision.[33] The least significant change is around 12%, which is comparable with that of the PAC.[33]

Global end-diastolic volume. Through a combined analysis of the thermodilution curve and of its natural logarithmic transformation, TPTD can estimate several volumes of fluid inside the thorax[34] (Fig. 32.1). In the PiCCO device, the global end-diastolic volume (GEDV) equals the product of CO by the difference between mean transit time and downslope time. In the VolumeView device, the calculation of GEDV takes into account the ratio of the maximal ascending and descending slopes of the TPTD curve. The GEDV represents the sum of the maximal volume of the four cardiac chambers and thus represents a volumetric measure of global preload.[35] As such, it can be helpful for identifying the mechanism of shock and following the effects of therapies, but like every static preload marker, it cannot be used to assess preload responsiveness.[36]

Extravascular lung water and pulmonary vascular permeability index. The extravascular lung water (EVLW) reflects the amount of fluid contained in the lung interstitial space and in the alveoli (i.e., pulmonary edema). The EVLW is inferred from the analysis of the TPTD curve (see Fig. 32.1) and has been validated against a reference method in humans.[37] The normal range of EVLW values is between 3 and 10 mL/kg. The TPTD detects short-term and small changes in EVLW.[38] The value of EVLW is that it tracks an independent risk factor for mortality in patients with ARDS.[39]

The pulmonary vascular permeability index (PVPI) is automatically calculated as the ratio between EVLW and the total pulmonary blood volume and therefore could reflect the integrity of the alveolocapillary barrier. It enables one to distinguish increased permeability pulmonary edema from hydrostatic pulmonary edema.[40,41] An increased PVPI is the physiologic hallmark of ARDS and could be integrated in its definition.[42]

In clinical practice, the combination of EVLW and PVPI can help clinicians guide fluid management during ARDS in cases of therapeutic conflicts. High values of EVLW and PVPI may indicate a high risk of fluid administration and prompt clinicians to refrain from increasing the rate of fluid infusion. In addition, repetitive measurements of PVPI may help monitor improvement or worsening of patients with ARDS, as PVPI is correlated with the oxygenation-based severity of ARDS, according to the criteria of the Berlin definition.[43]

Cardiac function index and global ejection fraction. The TPTD also provides the cardiac function index (CFI), which is the ratio of TPTD CO and GEDV, and the global ejection fraction (GEF), which is the CFI divided by heart rate multiplied by 4. The CFI and GEF behave as markers of cardiac systolic function[44–46]: they increase with dobutamine and do not change with volume expansion,[45] and their changes with cardiovascular therapies are correlated with changes in echocardiographic LV systolic function indices.[44–46] Thus through CFI and GEF, TPTD enables a rapid and easy detection of a decreased systolic function, which needs to be further confirmed by echocardiography.

Pulse Wave Analysis–Derived Variables

Pulse wave analysis–based cardiac output. The PWA represents a method of continuous CO monitoring based on the ABP waveform recorded through an arterial catheter. The PiCCO and the VolumeView technologies use the femoral artery catheter also used for TPTD measurements. The original algorithm used by the PiCCO was based on the three-element Windkessel model. It calculated the stroke volume by determining the area of the systolic portion of the arterial blood pressure (ABP) curve and dividing it by the aortic impedance. The latter was automatically determined during a calibration process consisting of measuring stroke volume with an independent technique: namely, TPTD. The current algorithm takes into account not only the area under the systolic part of the ABP curve but also the shape of the curve, the dicrotic notch position, and certain mechanical properties of the arterial system, such as the compliance/resistance couple. At the time of calibration, arterial compliance is calculated as τ/vascular resistance, where τ is a constant quantifying the diastolic pressure decay. Vascular resistance is determined at the time of calibration from the MAP and the TPTD CO. Compliance and resistance are updated on a beat-to-beat basis according to a proprietary algorithm. In spite of this automatic updating, there is a potential drift with time, making recalibration mandatory. In septic patients receiving vasopressors, the agreement between PWA CO (before recalibration) and TPTD CO (after recalibration) has been reported to be acceptable when the time elapsed between two calibration processes was less than 2 hours.[47] The VolumeView device uses a slightly different algorithm that also requires frequent recalibration.

Pulse pressure variation and stroke volume variation. Among all the heart-lung interaction indices, PPV has attained the highest level of evidence.[48,49] The PiCCO calculates it automatically and displays its value in real time. The SVV can also be monitored by the PiCCO and the VolumeView devices. The PPV and SVV cannot be reliably interpreted in cases of spontaneous breathing activity, low V_T ventilation, cardiac arrhythmias, or intraabdominal hypertension.[50] In case of low V_T, the changes in PPV during a transient increase in V_T reliably predict fluid responsiveness.[51] Alternatively, measuring the changes in PWA-based CO during PLR[17] or EEO[18] is helpful in situations where PPV and SVV fail to predict fluid responsiveness.

Advantages and Limitations of Transpulmonary Thermodilution Devices

As it provides a number of hemodynamic variables, TPTD belongs to the advanced hemodynamic monitoring technologies that are recommended in patients with circulatory failure, along with the PAC.[52,53] It requires the insertion of a large-diameter arterial catheter, which may precipitate adverse events that occur most frequently during insertion and removal. Even though these events are uncommon,[54] TPTD is still an invasive technique, which should be used only in selected patients.[52,53]

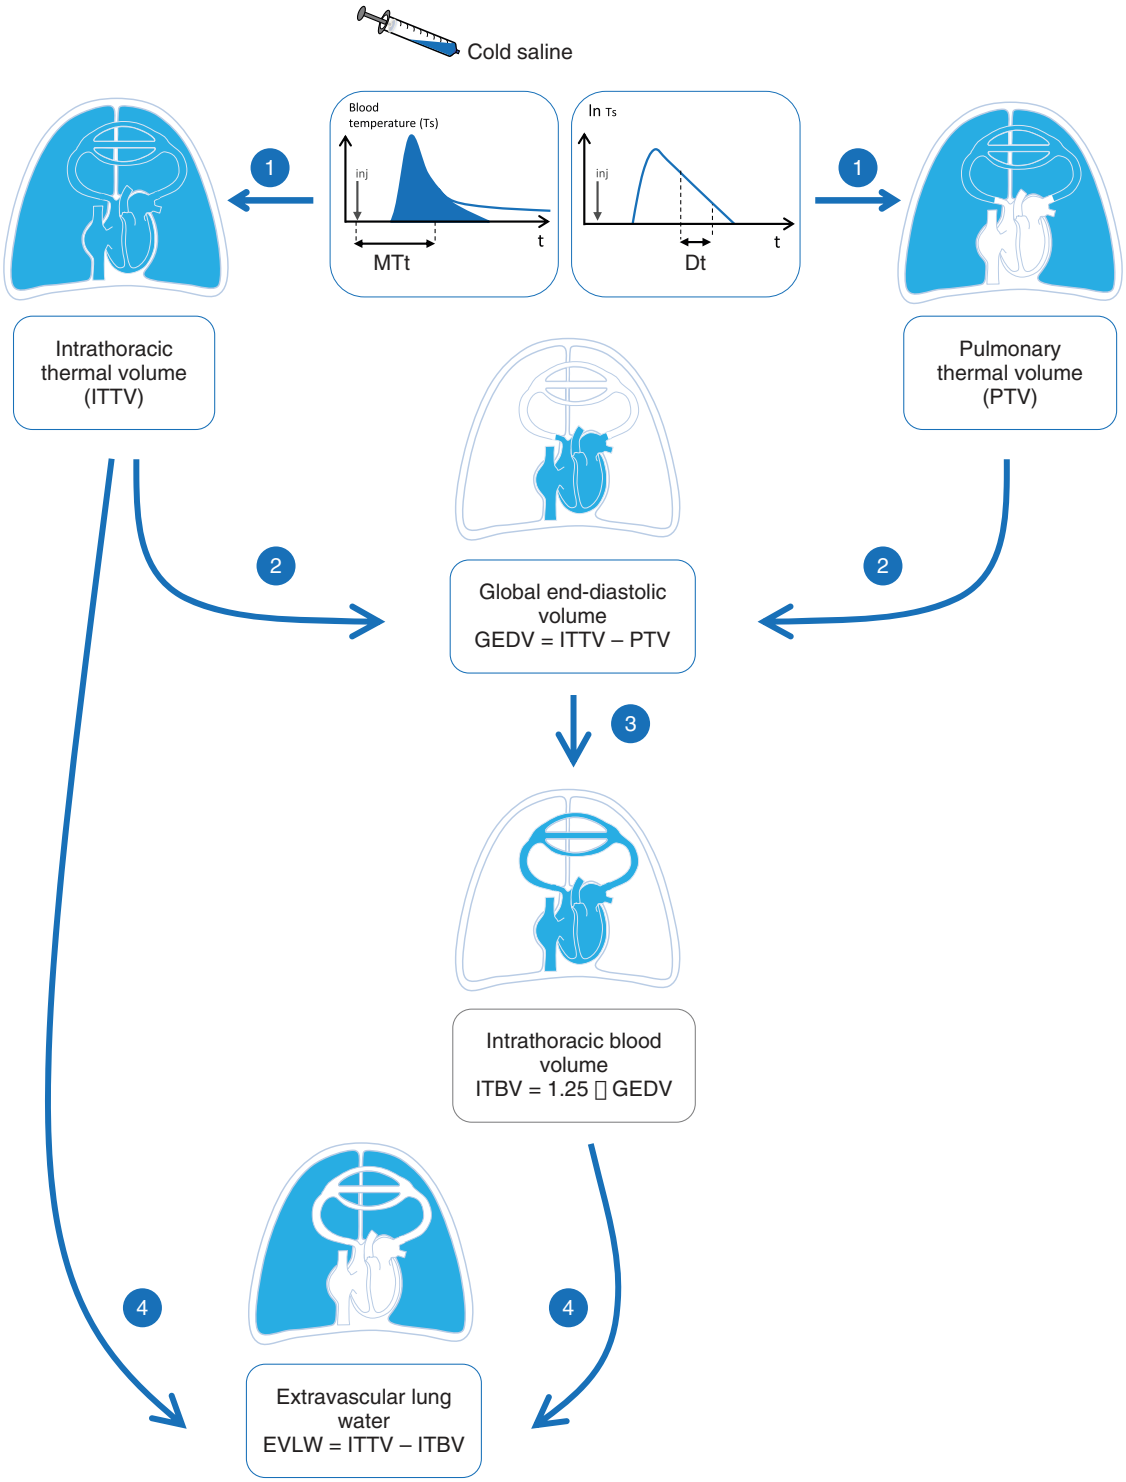

Fig. 32.1 Measurement of extravascular lung water by single thermal indicator dilution. *Dt,* Downslope time; *MTt,* mean transit time. (From Monnet X, Teboul JL. Transpulmonary thermodilution: Advantages and limits. *Crit Care.* 2017;21[1]:147.)

The TPTD remains valid during continuous venovenous hemofiltration at high flow rates.[55] By contrast, TPTD is unreliable during extracorporeal membrane oxygenation, because of the shunting of the cold indicator. Regarding preload and cardiac function TPTD-related indices, the main limitation is the impossibility to distinguish right ventricular (RV) from LV dysfunction. For instance, in case of isolated RV dysfunction, GEDV will increase and CFI (and GEF) will decrease, and the LV function can be normal.[44,45,56] It is recommended not to inject the cold bolus into a femoral vein because of the risk of overestimation of GEDV.[57] The EVLW measurements are less reliable in cases of large pulmonary vascular occlusions as a result of impeded distribution of the cold indicator through lung areas.[58] However, occlusions of small vessels that occur in ARDS or during hypoxic vasoconstriction have no consequences for EVLW monitoring.[59,60] PEEP decreases

EVLW to a small but systematic extent, which might be related to impeded drainage by lung lymphatics.[61] Pneumonectomy and lung resection decrease EVLW. The PVPI shares the same limitations as EVLW.

Lithium Dilution

The lithium dilution technique (LiDCOplus monitor, LiDCO Ltd., UK) provides intermittent CO measurements. A small amount of lithium chloride (0.002–0.004 mmoL/kg) is injected as a bolus through a central vein catheter. The changes in lithium concentrations are detected by blood being drawn out of a radial artery catheter over a specific lithium-selective sensor. Using the Stewart-Hamilton principle, CO can be thus calculated. Such CO measurements have been demonstrated to be reliable when compared with values obtained by PAC thermodilution.[62] To achieve an acceptable precision, three lithium dilution measurements should be averaged. This allows changes in CO ≥14% to be reliably detected.[63] The major inconvenience of LiDCOplus is the need for lithium injection, which cannot be repeated infinitely.

The LiDCOplus monitor also allows a beat-to-beat CO measurement with the pulse power analysis through a radial artery catheter. As the PiCCO monitor, the LiDCOplus monitor contains a proprietary algorithm (PulseCO) for converting a pressure-based signal into a flow measurement. The PulseCO algorithm is based on the physics of conservation of mass and energy. Manual calibration of the PulseCO is performed using the lithium dilution technique. The agreement between lithium dilution CO and the pulse power algorithm in the PulseCO monitor was reported to remain acceptable for up to 4 hours in ICU patients.[64] Using the PulseCO software, the LiDCOplus also allows PPV and SVV monitoring.[65]

Invasive Pulse Wave Analysis–Based Cardiac Output Monitoring Devices

Characteristics of the Devices

As they do not require external calibration by an indicator dilution method, these devices do not require any specific sensor-tipped catheter. They can be connected to any arterial line.[9–11]

The FloTrac device (Edwards LifeSciences, USA) estimates stroke volume as the product of pulsatility and a so-called "K" factor. Pulsatility is estimated from the standard deviation of arterial pulse pressure measurements. K quantifies arterial compliance and resistance and is estimated from the patient's morphometric data, which are compared with a large database of pressure waveform recordings. K is automatically adapted every 60 seconds by taking into account some geometric properties of the ABP curve, such as skewness and kurtosis.

With the ProAQT (Pulsion, Germany), the starting value of CO is not estimated from the Windkessel model, but through "auto-calibration" that uses the patient's own biometric data, MAP, and heart rate. After the initial auto-calibration, the ProAQT performs PWA with a method that is similar to that of the PiCCO. An automatic auto-calibration of CO can also be performed at any time. The ProAQT device can be "externally" calibrated using another technique (e.g., echocardiography), which is manually entered in the system.

With the LiDCOrapid (LiDCO Ltd., UK), the proprietary algorithm uses the patient's biometric characteristics to determine the starting CO value, which is then continuously updated according to the pulse power algorithm. Thus the LiDCOrapid cannot measure accurate values of CO but can only display trends. Nevertheless, external calibration can be performed on demand with an independent CO measurement.

The MostCare (Vygon, Italy) is the only currently available PWA monitor for which neither calibration nor adjustments based on user-entered data are required. This system is based on the pressure recording analytical method (PRAM) that performs a beat-to-beat analysis of the ABP waveform using the complex theory of perturbations.[66]

Advantages and Limitations

The uncalibrated PWA devices provide real-time CO monitoring, which allows early detection of hemodynamic instability and short-term effects of cardiovascular therapies. These monitors are helpful to assess fluid responsiveness by providing PPV and/or SVV and allowing performance of dynamic maneuvers such as PLR and EEO (changes in PWA-based CO) or V_T challenge (changes in PPV or SVV).[67] The absence of an external calibration requirement makes these devices easy to use. However, the absence of external calibration is also a disadvantage, as any drift of the ABP signal cannot be corrected and can lead to erroneous CO values. This can occur over time.[47] With the exception of the PRAM method,[10,11] acute changes in vascular tone may also result in inaccurate CO measurements, making such uncalibrated devices poorly reliable in cases of septic shock and/or use in vasopressors.[68–71] This is why uncalibrated PWA-based CO monitors are not recommended in ICU patients with shock.[52,53] However, they can have a place in the OR setting when CO monitoring is deemed to be necessary.[72] These conditions are suitable for such devices, as surgical procedures are generally short, seldom require vasopressors, and prioritize the detection of hypovolemia.

Esophageal Doppler

Principle

The use of ED is aimed at monitoring CO by continuously measuring the blood flow in the descending thoracic aorta. The device consists of a flexible probe introduced in the esophagus, which, in its thoracic portion, runs parallel to the descending aorta. At the tip of the probe, a Doppler transmitter/receiver records the velocity of red blood cells circulating in the thoracic aorta. Today, one single device (CardioQ, Deltex Medical, UK) is available on the market.

Measured Variables

Cardiac output. Blood flow in the descending aorta is assessed by measuring the velocity of blood passing the ED; the heart rate; and the estimation of the descending aorta diameter from the patient's weight, height, and age. From the value of aortic blood flow, the ED device infers the value of CO, based on the hypothesis that there is a constant distribution of the systemic blood flow between the upper territories and the descending aorta.

Clinical studies showed that ED CO agrees with PAC CO in ICU patients and in patients undergoing surgery.[73] ED CO monitoring has been reported to reliably track the CO changes caused by hemodynamic interventions.[74] The least significant change of ED CO is about 7%[75]

Respiratory variation of aortic blood flow and velocity. The CardioQ device automatically measures the respiratory variation of aortic velocity. The respiratory variation of blood flow in the descending aorta has been reported to reliably predict fluid responsiveness in mechanically ventilated patients,[76] but shares the same limitations as PPV and SVV.

Indicators of left ventricular systolic function and cardiac preload. Acceleration of the aortic blood flow and its maximal velocity have been demonstrated to reflect cardiac contractility.[77] The duration of the aortic blood flow corrected for heart rate (flow time corrected) is considered a marker of cardiac preload, but it also increases when LV afterload decreases. Despite its inclusion in several protocols of intraoperative fluid management, it cannot reliably predict fluid responsiveness.[76]

Advantages and Limitations

The ED monitoring is almost noninvasive, rapid to learn, and easy to use. It is indicated for the perioperative monitoring of high-risk surgical patients and is quite suitable for assessing the short-term effects of

PLR, for example.[78] However, its use in the ICU setting is limited, in part because the probe moves in the patient's esophagus if the patient is not deeply sedated. Another weakness of the currently commercialized device is the absence of measurement of the diameter of the descending aorta, which is an elastic structure that varies with ABP.[79] Considering it to be constant leads to underestimation of CO changes when ABP varies simultaneously.[79] Finally, the ED cannot estimate as many variables and thus provide as much useful information as PAC and TPTD do, which limits its interest in complex patients with shock.

Bioimpedance and Bioreactance

Bioimpedance

Principle. The bioimpedance technique uses the variation of thoracic impedance related to the fluid shift resulting from the ejection of the stroke volume throughout cardiac cycles.[80] An alternating electric current is applied to the thorax through voltage-generating electrodes, and using mathematical models, the stroke volume is calculated from the differences between inward and outward currents.[81]

Advantages and limitations. Despite being easy to use, this technique suffers from several major limitations. Reaching a correct signal/noise ratio can be challenging. The major limitations are the presence of intrathoracic extravascular fluids (pulmonary edema, pleural effusion), which attenuate the detected signal of arrhythmias, of motion, or of electrical interference. Accordingly, the reliability of this technique has been questioned in spite of several adjustments of its underlying mathematical algorithms.[82]

Bioreactance

Principle and information provided. To improve the signal/noise ratio, computing of the bioimpedance signal has been modified. The revisited technique, called *bioreactance,* focuses not only on the shift in amplitude but also on the phase between the inward and the outward current over the cardiac cycle. It relies only on the pulsatile flow (i.e., the aortic blood volume) and thus is free from potential extravascular thoracic fluids.[83] The Starling SV device (Baxter International, Inc., USA) uses four electrodes placed on the right and left upper and lower parts of the thorax, and the device displays a CO value calculated from the averaged values of the left and right sides.

Advantages and limitations. The major advantage of bioreactance is that it is totally noninvasive. When compared with PAC thermodilution, bioreactance apparently exhibits acceptable accuracy for assessing CO in patients after cardiac surgery.[83] However, its reliability has been seriously questioned in ICU patients,[84–86] including patients with sepsis[84] and cardiogenic shock.[86] The current version of the device (Starling SV) allows monitoring of CO closer to real time than did the previous one (NiCOM; Cheetah Medical, USA) and is able to assess the effects of the PLR test,[87] which the previous version did not.[85] Nevertheless, an important limitation of the bioreactance is that CO is the only value that it can provide.

Noninvasive Arterial Pressure Waveform–Based Cardiac Output Monitoring Devices

Principle and Information Provided

The Clearsight (Edwards Lifesciences, USA) and the NICCI (Pulsion, Germany) devices use the volume clamp method to obtain noninvasive ABP, PPV, and CO monitoring. The Clearsight includes an inflatable cuff, which is wrapped around a finger and a photoplethysmographic device that measures the diameter of the finger arteries at each systole. A fast servo-controlled system immediately inflates the cuff in order to keep the arteries' diameter constant. Therefore the counterpressure is equivalent to the finger ABP, and its continuous measurement allows estimating the finger ABP curve. A brachial ABP waveform is then reconstructed using a transfer correction and a level correction based on a clinical database. The Clearsight includes a proprietary PWA software that computes CO from the systolic pressure area and a physiologic three-element Windkessel model.[88] The NICCI device also uses the volume clamp principle, but the sensor contains two finger cuffs and performs an automatically alternating continuous measurement at the patient's finger.

Advantages and Limitations

Such PWA-based CO monitors could be used in situations requiring hemodynamic intervention when more invasive monitoring modalities are not readily available.[72] As they can provide only CO, PPV, and/or SVV, they are more suitable for use in the OR setting than in the ICU. Relatively good agreement with CO PAC was reported in the perioperative period of cardiac surgery.[89–91] By contrast, a poor agreement between Clearsight CO and TPTD CO and between their changes after a fluid challenge was found in ICU patients.[92] A recent meta-analysis included 19 studies that compared CO obtained by either the Clearsight or the NICCI with thermodilution CO.[93] The percentage error was acceptable (<30%) in only 2/5 of the OR studies and in only 2/14 of the ICU studies.[94] Another study pooled the data of 342 patients and showed that volume clamp CO and bolus thermodilution CO were poorly interchangeable, not only for absolute values but also for the trends.[93] This was particularly true in cases of norepinephrine use and of low ABP.[93]

HEMODYNAMIC MONITORING STRATEGY IN PATIENTS WITH SHOCK (FIG. 32.2)

Careful clinical examination should first be performed in the early phase of shock, as it can provide useful information about the causative mechanism. Furthermore, particular attention should be paid to markers of skin perfusion. The presence of mottling or of prolonged capillary refill time (CRT) is suggestive of a low CO with an excellent specificity but a low sensitivity.[95] A strategy guided by CRT was demonstrated to be noninferior[96] and even better[97] than a strategy based on decrease in blood lactate concentration during early resuscitation of septic shock.

Insertion of an arterial catheter has been recommended in patients with shock.[52,53] In addition to providing real-time accurate measurement of ABP, it allows monitoring PPV. The arterial catheter also allows performing repeated blood sampling that enables arterial blood gas measurement.

Insertion of a central venous catheter has also been recommended in patients with shock.[52,53] It provides measurements of CVP. The transmural value of CVP is a reflection of RV filing pressure and can help to detect RV dysfunction, which then needs confirmation by echocardiography. The intramural value of CVP reflects the backpressure to the perfusion of most vital organs. In this sense, the perfusion pressure is better reflected by the MAP-CVP difference (also called the *mean perfusion pressure;* MPP) than by the MAP alone, especially when CVP is high. The MPP, and not the MAP, was demonstrated to be well associated with the progression of acute kidney injury in ICU patients with a cutoff value of 60 mm Hg.[98] However, neither CVP[13,15] nor its changes during PLR[99] should be used to predict fluid responsiveness. The central venous catheter also provides oxygen saturation ($ScvO_2$), which is considered a reasonable surrogate of SvO_2.[52,53] Specific fiberoptic catheters measure $ScvO_2$ in real time, avoiding any manipulation. However, they are costly, and it is generally considered that intermittent blood sampling is sufficient in practice to obtain $ScvO_2$. In cases of shock, a low $ScvO_2$ (e.g.,

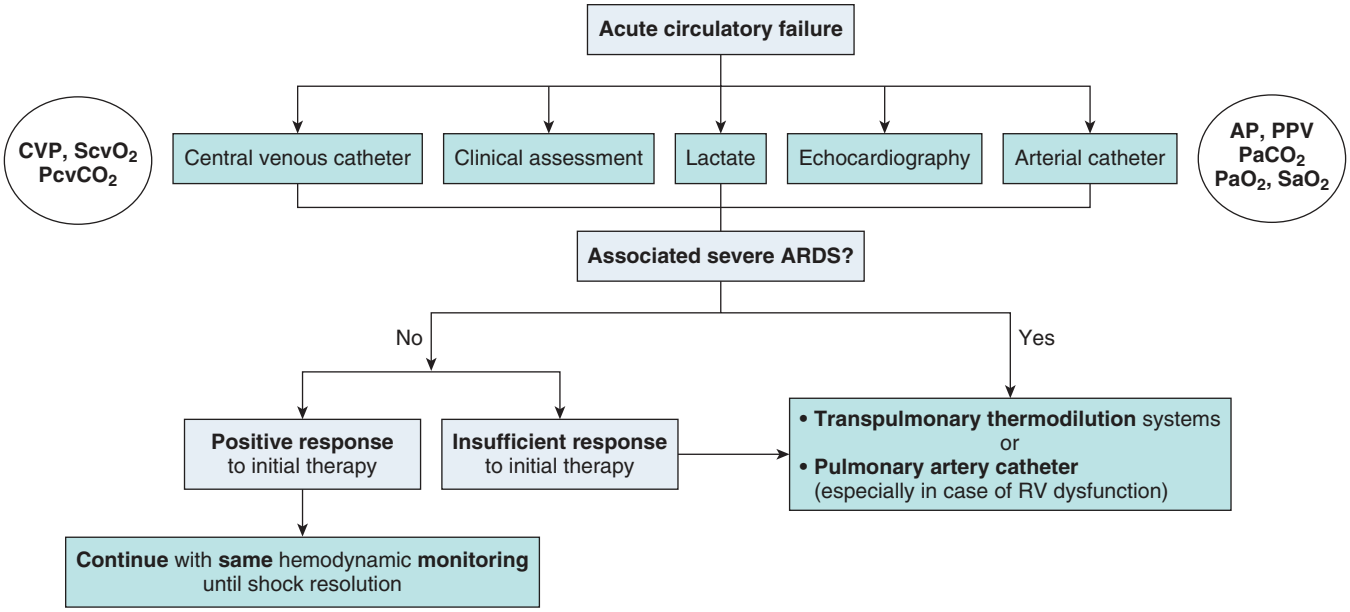

Fig. 32.2 Simplified algorithm for the choice of hemodynamic monitoring in patients with acute circulatory failure. *AP,* Arterial pressure; *ARDS,* acute respiratory distress syndrome; *CVP,* central venous pressure; *$PaCO_2$,* carbon dioxide pressure in the arterial blood; *PaO_2,* oxygen pressure in the arterial blood; *$PcvCO_2$,* carbon dioxide pressure in the central venous blood; *PPV,* pulse pressure variation; *RV,* right ventricular; *SaO_2,* arterial blood oxygen saturation; *$ScvO_2$,* central venous blood oxygen saturation. (From Teboul JL, Saugel B, Cecconi M, et al. Less invasive hemodynamic monitoring in critically ill patients. *Intensive Care Med.* 2016;42[9]:1350–1359.)

<70%) is suggestive of insufficient DO_2 and should prompt clinicians to increase DO_2.[52,53] Conversely, a high value of $ScvO_2$ (e.g., >80%) is suggestive of altered oxygen extraction capabilities. Finally, the central venous catheter provides the central venous carbon dioxide pressure ($PvCO_2$). The difference between $PcvCO_2$ and $PaCO_2$ is generally accepted as a reasonable surrogate of ΔPCO_2[53] and thus may be a good indicator of the adequacy of CO to the global metabolic conditions. In conditions where oxygen extraction is altered and $ScvO_2$ lies within the normal range, an abnormally high $PcvCO_2$-$PaCO_2$ difference (>6 mm Hg) suggests that CO may need to be raised to improve tissue oxygenation.[53] A normal $PcvCO_2$-$PaCO_2$ difference suggests that increase in CO is not a prioritized therapeutic option.

Echocardiography, which is not a monitoring device per se, is the best tool to assess cardiac function at the bedside. It is recommended to be performed as soon as possible in patients with shock.[52,53]

Therefore in the early phase of shock states, several pieces of useful information can be obtained from basic hemodynamic monitoring. In the majority of cases, a logical therapeutic decision based on this information can be made. If the hemodynamic condition improves with the initial therapy, such basic hemodynamic monitoring should be continued until shock resolution. If the hemodynamic response is absent or insufficient, it is recommended to use an advanced monitoring technology such as the PAC or the TPTD system (see Fig. 32.2). The PAC can be useful in the case of severe RV dysfunction diagnosed by echocardiography. The TPTD system is potentially helpful in cases of associated ARDS, as it offers the advantage of reliably assessing the benefit/risk ratio of fluid management: the expected benefit can be assessed by fluid responsiveness indices (obtained from PWA), and the risk can be assessed by EVLW and PVPI. In cases of severe ARDS associated with shock, it has been recommended to use advanced monitoring devices at an earlier phase.[52,53]

In patients with shock, there is a consensus to not use devices such as minimally invasive or noninvasive PWA-based CO monitors.[52,53] First, their validity has been seriously questioned under conditions of alteration of the vascular tone and/or use of vasopressors, and second, they provide intensivists with hemodynamic variables other than CO and fluid responsiveness indices.

It should be emphasized that no monitoring device can change the outcome by itself. The outcome can be improved only if the information provided by the device is appropriately collected and interpreted.

HEMODYNAMIC MONITORING STRATEGY IN THE OPERATING ROOM SETTING

Uncalibrated PWA monitors and ED monitoring have a place in the OR setting when CO monitoring is judged to be helpful for the patient's management. Use of such monitors in goal-directed therapy strategies in the perioperative period of high-risk surgical patients was demonstrated to potentially improve outcome.[12] The choice of ED vs. minimally invasive vs. noninvasive device is not fully codified. It depends on the local policies, the type of surgery (high vs. intermediate vs. low risk), and the patient's clinical condition (high vs. low risk). Some teams use pulse oximeters that can display the variation of the plethysmographic signal—used as a surrogate of PPV—for guiding fluid administration. Doing so is an important issue during surgery,[100] although its relevance has been recently questioned by a meta-analysis.[101] In some specific high-risk procedures (e.g., liver transplantation, esophagectomy, cardiac surgery), some teams monitor hemodynamics using advanced technologies (PAC, TPTD), which can be continued during the postoperative period. Transesophageal echocardiography can also be used in cardiac surgery patients either alone or along with invasive technologies.

THE FUTURE OF HEMODYNAMIC MONITORING

In an ideal world, the future of hemodynamic monitoring should be the addition of what we already have plus what we do not have so far but what we need. Today, we have essentially hemodynamic monitoring devices able to monitor traditional macrocirculatory variables. The two main characteristics of the most valuable current hemodynamic monitoring systems are (1) their invasiveness, even if the terms "minimally invasive" or "less invasive" are often used, and (2) their inability to precisely assess the microcirculation: adequacy of tissue perfusion and oxygenation. Is noninvasiveness the future that we expect? The answer should be positive only if noninvasiveness is associated with accuracy and precision. The current noninvasive CO monitors are used in the OR setting not for their numerical accuracy, but for their theoretical ability to track *changes* in CO. This can be enough in this setting because patients—even high-risk ones—are usually not sick before starting surgery, so that their starting CO is generally normal. What is important in this situation is to reliably track any abrupt decreases in CO. By contrast, in ICU patients, one needs both to measure accurate and precise CO values and to reliably track CO changes. To date, no noninvasive continuous hemodynamic system is able to do this. Hopefully, future technologic advances will provide ICU doctors and nurses with reliable noninvasive hemodynamic monitoring systems.

Another important aspect is to be able to monitor microcirculation and tissue perfusion. We know that correcting macrocirculatory variables cannot guarantee that tissue hypoperfusion has been fully reversed, too. Over the last decade, some technologies have been developed to monitor microcirculation (e.g., sublingual microcirculation) or tissue oxygenation. However, these techniques are still used for research purposes and not for routine practice.[52] We can expect in the near future a technologic jump in this field, allowing ICU caregivers to monitor microcirculation in real time. This would be a first step to integrate new microcirculatory variables in therapeutic strategies.

In addition, progress in technology and data processing that will inevitably occur should make this field very different in the near future from what we currently know. One can expect advances in terms of graphical displays, computerization, miniaturization, connectivity, data transfer from bedside monitors to personal interfaces, and implementation of novel sensors using micro- and nano-electromechanical systems. Finally, advances in artificial intelligence (predictive analytics, machine learning) should certainly help with integrated analysis of many hemodynamic variables collected by the monitoring systems. This should allow clinicians to better analyze the patient's true hemodynamic status and needs and/or to anticipate hemodynamic instability. There are currently devices that use machine learning to predict hypotension in the OR setting.[102] Numerous applications of artificial intelligence will undoubtedly occur in the next few years for hemodynamic monitoring and for therapeutic decision-making processes.[103] The challenge for the intensivist will be to intelligently use artificial intelligence for the benefit of their patients.[103]

KEY POINTS

- Pulmonary arterial catheter use has decreased since the mid-1990s, not only because of its invasiveness but mostly because of the development of bedside echocardiography and the emergence of other hemodynamic monitoring devices.
- Transpulmonary thermodilution coupled with pulse wave analysis provides a reliable measure of cardiac output, extravascular lung water, and preload responsiveness indices.
- Uncalibrated invasive pulse wave analysis monitoring devices provide hemodynamic information from a simple arterial catheter. They belong to the class of functional hemodynamic monitoring devices and could prove helpful to assess fluid responsiveness. However, their ability to accurately estimate cardiac output has been questioned in cases of altered vascular tone, limiting their interest for patients with shock and/or who receive vasopressors.
- Esophageal Doppler monitoring is a minimally invasive method to estimate cardiac output and indices of fluid responsiveness. It is better indicated in high-risk surgery patients than for patients with shock.
- The bioreactance method estimates cardiac output noninvasively. It uses skin surface electrodes delivering a low-amplitude and high-frequency current traversing the thorax. It has a limited place in severe, critically ill patients. More validation studies are necessary to clarify its place in other settings, such as the emergency room.
- Volume clamp methods uses the finger blood pressure to estimate cardiac output noninvasively using pulse wave analysis. However, their reliability has been questioned in critically ill patients. They are not recommended for patients in shock.
- The hemodynamic monitoring strategy to be employed in patients with shock is not strictly codified. Nevertheless, it is logical to take into account clinical information, data obtained from arterial central venous catheters, and, if possible, echocardiographic findings before making therapeutic decisions. In cases of insufficient response to the initial therapy, the use of a pulmonary artery catheter or transpulmonary thermodilution should be considered.

Bedside Monitoring of Pulmonary Function

John D. Davies and Amanda M. Dexter

PULSE OXIMETRY

Pulse oximetry is a microprocessor-based measurement that incorporates both oximetry and plethysmography to provide continuous noninvasive monitoring of the oxygen saturation of arterial blood (SpO_2). Often considered the "fifth vital sign," pulse oximetry is one of the most important technologic advances for monitoring patients during anesthesia, in the intensive care unit (ICU), on the general ward, in the emergency department, and during a wide variety of procedures. It can quickly detect even small changes in the effectiveness of oxygen uptake from the lung and how efficiently oxygen is carried to the tissues. Common applications for pulse oximetry may include mechanical ventilation, surgical monitoring, sleep evaluations, and effectiveness of certain clinical interventions.

The most common pulse oximeter probe is embedded into either a reusable clip probe or a single-patient adhesive probe and consists of two light-emitting diodes on one side and a light-detecting photodiode on the opposite side. Advantages of the reusable clip probe include utilization rapidity, ease of sampling different sites, and cost-effectiveness.[1] Advantages of the single-patient adhesive probe include less potential for infection transmission, more secure placement, and the ability to monitor at more body sites.[1] The most appropriate type of probe depends on the clinical situation. Either a finger, toe, or earlobe serves as the sample "cuvette" because the skin in these areas has a high vascular density. Pulse oximetry targets the signal arising from the arterial bed as light absorbance fluctuates with changing blood volume. Arterial blood flow causes signal changes in light absorption (the pulsatile component called *photoplethysmography*) that can be distinguished from venous and capillary blood in the surrounding tissues (the baseline, or direct current, component; Fig. 33.1).

According to the Beer-Lambert law, the concentration of a substance can be determined by its ability to transmit light.[2] Oxygenated hemoglobin (HbO_2) and deoxygenated or "reduced" hemoglobin (HbR) species absorb light differently, so the ratio of their absorbencies can be used to calculate HbO_2 saturation. The standard pulse oximeter emits two wavelengths of red light (660 nm and 940 nm) from the light-emitting diode on one side of the probe, through the capillary bed, to a light-detecting photodiode on the other side. Red light emitted at 940 nm is mainly absorbed by HbO_2, whereas red emitted at 660 nm is mainly absorbed by HbR. The difference between the transmitted light and unabsorbed light represents the amount of hemoglobin-bound oxygen and is expressed as a percentage.

In addition, there are two minor hemoglobin (Hb) species: **carboxyhemoglobin** (COHb) and **methemoglobin** (MetHb). Fractional SaO_2 is the proportion of HbO_2 relative to all four hemoglobin species:

$$HbO_2 = HbR + COHb + MetHb$$

Measuring fractional hemoglobin requires a co-oximeter that incorporates four wavelengths to distinguish each species (Fig. 33.2). In contrast, oxygen saturation as determined by pulse oximeter (SpO_2) uses two wavelengths, so that it measures functional SaO_2:

$$HbO_2 + HbR$$

Accuracy and Precision

The accuracy of pulse oximeters has improved over the years. In critically ill patients with an arterial oxygen saturation (SaO_2) >90%, it is now estimated that the mean difference between SpO_2 and SaO_2 is less than 2%.[3,4] Also, the standard deviation of the differences between the measurements represents the precision and has been estimated to be less than 3%.[3,4] However, when the SaO_2 drops below 90%, the accuracy of SpO_2 measurements decreases.[2]

The oxyhemoglobin dissociation curve must be taken into account when interpreting the SpO_2 (Fig. 33.3). If the curve is in a normal position, then high SpO_2 values (96%–98%) represent a PaO_2 in the range of 80–100 mm Hg, whereas SpO_2 values in the low to mid 90s represent a PaO_2 in the range of 60–80 mm Hg. An SpO_2 <90% indicates PaO_2 values that enter into the hypoxemic range. If the curve shifts to the left, a lower PaO_2 will produce a higher SpO_2, whereas the reverse is true if the curve is shifted to the right. Although a left shift in the oxyhemoglobin dissociation curve increases the affinity of Hgb for oxygen, it also makes it more difficult for the Hgb to release oxygen molecules. A right shift in the curve makes it more difficult for the Hgb to load oxygen molecules (see Fig. 33.3).

Dynamic Response

Because pulse oximeters detect very small optical signals (and reject a variety of artifacts), data must be averaged over several seconds, thus affecting the response time.[5,6] A prolonged lag time is more common with finger probes than with ear probes and is attributed to hypoxia-related peripheral vasoconstriction.[5–7] Bradycardia is also associated with a prolonged response time.

Sources of Error

Despite recent technologic advances, there still are a number of factors that may affect the accuracy of the pulse oximeter. Table 33.1 lists the most common ones.

Motion Artifact and Poor Perfusion

Motion artifact and poor perfusion are the most common sources of SpO_2 inaccuracies, which occur because the photoplethysmographic pulse signal is very low in these settings compared with the total

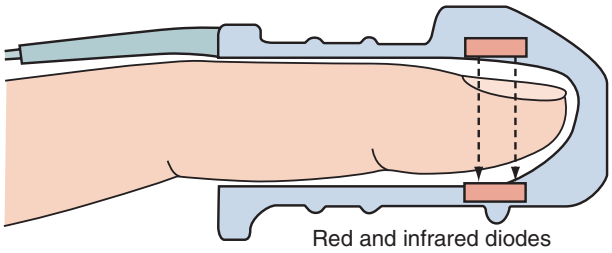

Fig. 33.1 Schematic depiction of the pulse oximeter light absorption signal. (Adapted with permission from Phillips Medical Systems, Carlsbad, California.)

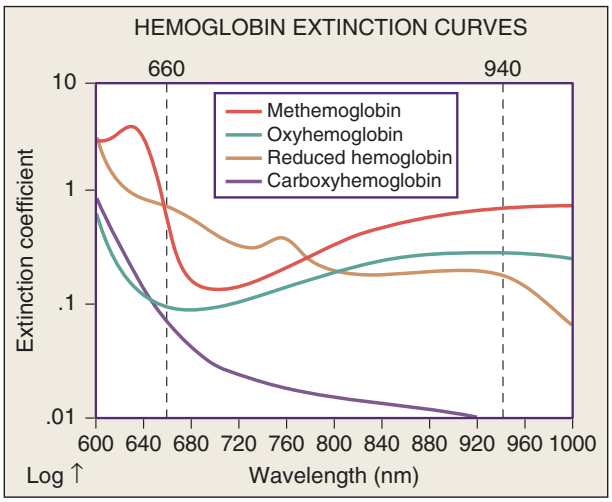

Fig. 33.2 Extinction coefficients of the four types of hemoglobin at the red and infrared wavelengths. Methemoglobin absorbs light at both wavelengths to an equal extent; absorption of red light by carboxyhemoglobin is similar to that of oxyhemoglobin. (From Tremper KK, Barker SJ. Pulse oximetry. *Anesthesiology.* 1989;70:98–108.)

TABLE 33.1 Common Factors Affecting Pulse Oximetry Measurements

Factor	Effect
Carboxyhemoglobin (COHb)	Slight reduction in accuracy of the assessment of oxygen saturation (SaO_2) by pulse oximetry (SpO_2) (i.e., overestimates the fraction of hemoglobin available for O_2 transport)
Methemoglobin (MetHb)	At high levels of MetHb, SpO_2 approaches 85%, independent of actual SaO_2
Methylene blue	Transient, marked decrease in SpO_2 lasting up to several minutes; possible secondary effects as a result of effects on hemodynamics
Anemia	If SaO_2 is normal, no effect; during hypoxemia with Hb values less than 14.5 g/dL, progressive underestimation of actual SaO_2
Ambient light interference	Bright light, particularly if flicker frequency is close to a harmonic of the light-emitting diode switching frequency, can falsely elevate the SpO_2 reading
Blood flow	Reduced amplitude of pulsations can hinder obtaining a reading or cause a falsely low reading
Motion	Movement, especially shivering, may depress the SpO_2 reading
Nail polish	Slight decrease in SpO_2 reading, with greatest effect using blue nail polish, or no change
Sensor contact	"Optical shunting" of light from source to detector directly or by reflection from skin results in falsely low SpO_2 reading
Skin pigmentation	Small errors or no significant effect reported; deep pigmentation can result in reduced signal
Tape	Transparent tape between sensor and skin has little effect; falsely low SpO_2 has been reported when smeared adhesive is in the optical path
Vasodilation	Slight decrease in SpO_2
Venous pulsation	Artifactual decrease in SpO_2

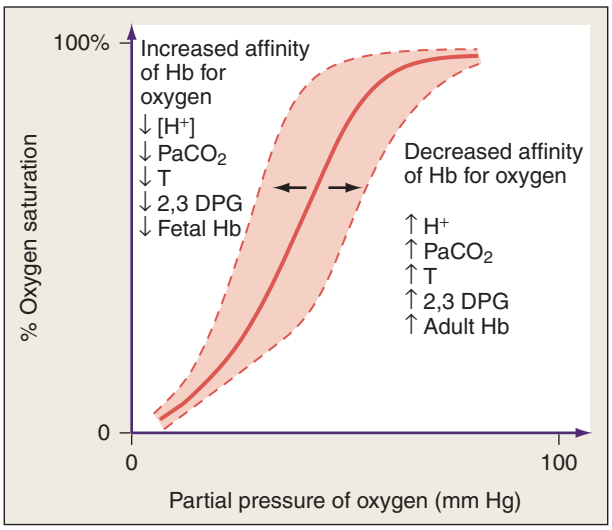

Fig. 33.3 Oxyhemoglobin dissociation curve relates oxygen saturation and partial pressure of oxygen in the blood. The curve is affected by many variables. *2,3 DPG,* 2,3-Diphosphoglycerate; *Hb,* haemoglobin; *$PaCO_2$,* partial pressure of carbon dioxide.

absorption signal.[8,9] The combination of motion artifact and poor perfusion substantially lowers SpO_2 accuracy compared with either artifact alone.[10] Causes of motion artifact include shivering, twitching, agitation, intraaortic balloon pump assistance, and patient transport.[11,12] Signs of motion artifact include a false or erratic pulse rate reading or an abnormal plethysmographic waveform. Peripheral hypoperfusion from hypothermia, low cardiac output, or vasoconstrictive drugs may increase bias, reduce precision, and prolong the time to detect a hypoxic event.[12]

Newer technologies have helped reduce the incidence of these problems, but have not eliminated them as sources of error. Relocation of the probe may be required to obtain a more accurate signal.

Dyshemoglobins and Vascular Dyes

Significant amounts of COHb or MetHb can cause errors in SpO_2 measurements. COHb and HbO_2 absorb equivalent amounts of red light. Because the amount of COHb is elevated in the setting of carbon monoxide poisoning, this results in a falsely elevated SpO_2 value because the pulse oximeter reports on total Hb saturation and not just HbO_2 saturation. The patient, however, could be experiencing profound hypoxemia. In contrast, MetHb causes substantial absorption of both red and infrared light, so the ratio approaches 1 (estimated SpO_2

of 85%).[2] Significant levels of MetHb falsely lower SpO_2 values even when the actual SaO_2 exceeds 85% and falsely elevates values when the true SaO_2 is less than 85%.[2] Additionally, the administration of methylene blue or indocyanine green dyes for diagnostic tests causes a false, transient (1- to 2-minute) drop in SpO_2 to as low as 65%.[13,14]

There are some newer pulse oximeters that claim to measure actual hemoglobin concentration, but validation study results have yielded mixed results.[15,16]

Nail Polish and Skin Pigmentation

Both dark skin pigmentation and dark nail polish interfere with absorption of the wavelengths used by pulse oximetry. Pulse oximeters thus have greater bias and less precision in dark-skinned patients.[8] Whereas an SpO_2 of 92% is sufficient to predict adequate oxygenation in light-skinned patients, a saturation of at least 95% is required in dark-skinned patients.[17] Also, dark nail polish colors can falsely lower SpO_2 values, whereas red polish tends not to affect pulse oximetry accuracy.[18] However, with newer technology, the negative effects of nail polish have been lessened. A study conducted with modern equipment showed an effect of dark nail polish on pulse oximetry readings, but the error was not clinically relevant.[19] When nail polish cannot be removed, mounting the oximeter probe sideways on the finger may yield a more accurate reading.[20]

Ambient Light, Anemia, and Hyperbilirubinemia

Although pulse oximeters compensate for the presence of ambient light, the sensor should be shielded from intense light sources with an opaque material. Falsely low SpO_2 readings occur when even minor gaps exist between the probe and skin, allowing light reflected off the skin's surface to "shunt" directly to the photodiode.[21] Xenon surgical lamps and fluorescent lighting can also cause falsely low SpO_2 values.[22] Under conditions of moderate to severe anemia (e.g., Hb 8 g/dL) and severe hypoxemia (SaO_2 54%), SpO_2 bias is markedly increased (by approximately −14%).[23] Hyperbilirubinemia does not affect SpO_2 directly.[24] However, carbon monoxide is a by-product of heme metabolism, and deeply icteric patients tend to have higher levels of COHb,[24] so SpO_2 may be falsely elevated under those conditions.

Pulsus Paradoxus

Pulsus paradoxus refers to an exaggerated fall in a patient's blood pressure during inspiration. A recent meta-analysis evaluated the relationship between pulsus paradoxus and pulse oximetry. The findings suggested that pulse oximetry plethysmograms can also be used as a noninvasive method for estimating pulsus paradoxus.[25] The authors further suggested that earlier recognition and improved management of elevated pulsus paradoxus may be achievable through the use of a pulse oximeter.[25]

Reflectance Pulse Oximetry

Reflectance pulse oximetry was designed to counter signal-detection problems associated with finger probes during hypoperfusion. The reflectance sensor is designed for placement on the forehead just above the orbital area, where superficial blood flow is abundant and less susceptible to vasconstriction.[26] Whereas traditional probes work by transilluminating a tissue bed and measuring the forward-scattered light on the opposite side of the finger, toe, or earlobe, reflectance probes are constructed with the light-emitting diodes and the photodetector located along the same surface. The photodetector measures the back-scattered light from the skin.[26] In addition, tolerance to site of placement for reflectance pulse oximetry has allowed fetal monitoring during labor.[27] Intraesophageal SpO_2 monitoring is currently under investigation.[28] Anasarca, excessive head movement, and difficulty in securing the probe site are some of the common problems encountered with reflectance pulse oximetry.[29] Light "shunting" from poor skin contact and direct sensor placement over a superficial artery are associated with artifacts.[30] However, recent studies have shown reflectance pulse oximetry to be as effective as phalanx finger sensors in many situations.[31–34]

Clinical Applications

Continuous pulse oximetry provides an early warning sign of evolving hypoxemia. A large single-center randomized controlled trial of perioperative patients found reported incidence rates of hypoxemia (SpO_2 less than 90%) to be 7.9% in patients monitored with pulse oximetry and only 0.4% in patients monitored without an oximeter.[35] From a surgical perspective, a study reported that continuous monitoring of SpO_2 revealed episodic and severe hypoxemic events, with some desaturations lasting as long as 21 ± 15 minutes.[36] Pulse oximetry has also been shown to aid in titrating FiO_2 in patients receiving mechanical ventilation. Two large clinical trials investigated whether or not the SpO_2/FiO_2 (S/F) ratio could be a reliable proxy for the PaO_2/FiO_2 (P/F) ratio in patients with acute lung injury (ALI) or acute respiratory distress syndrome (ARDS). The S/F ratio was reported to be a dependable surrogate in patients undergoing surgery, patients requiring increased levels of positive end-expiratory pressure (PEEP), and in calculating the sequential organ failure assessment scores.[37]

CAPNOMETRY

Capnometry affords the measurement and numeric display of expired carbon dioxide (CO_2) at the patient's airway opening. When a waveform plotting CO_2 against time or volume is also displayed, the process is referred to as **capnography**, and the waveform is referred to as a **capnogram**. Capnometry is most commonly used on patients receiving mechanical ventilation and uses infrared light projected through a gas sampling chamber to a detector on the opposite side. CO_2 absorbs infrared light at a peak wavelength of approximately 4.27 μm.[38,39] More infrared light passing through the sample chamber (i.e., less CO_2) causes a larger signal in the detector relative to the infrared light passing through a reference cell. The sample chamber is either connected directly to the Y-adapter of the ventilator circuit (mainstream) or by a sampling line at the Y-adapter that continuously aspirates gas into a sampling chamber located inside the monitor (sidestream). A colorimetric CO_2 detector is an example of a mainstream capnograph. This device has a pH-sensitive indicator that changes color in response to varying CO_2 concentrations during inspiration and expiration. A normal capnograph has a square-wave pattern with four different phases, which begins during the inspiratory phase and will continue through the entire expiratory phase (Fig. 33.4).[39] Phase I is the inspiratory baseline, which is caused by inspired gas with low levels of CO_2. Phase II is the exhalation of mixed fresh and alveolar gas, resulting in a very rapid increase in CO_2 levels. Phase III is the alveolar plateau, where the last of the alveolar gas is sampled; this is commonly the **end-tidal exhaled gas concentration** (P_{ETCO_2}). Phase IV reflects the reversal of gas flow direction (the expiratory downstroke) and the beginning of inspiration.

Abnormal Capnographs

The expired CO_2 waveform can distinguish a variety of pulmonary and airway pathologies. An esophageal intubation is discernible when the end-tidal waveform becomes lower and lower with subsequent breaths and the patient becomes more hypoxic. Other reasons for a flat tracing include capnograph disconnection, near-complete airway obstruction, endotracheal tube perforation, or cardiac arrest.[39,40] An asthmatic

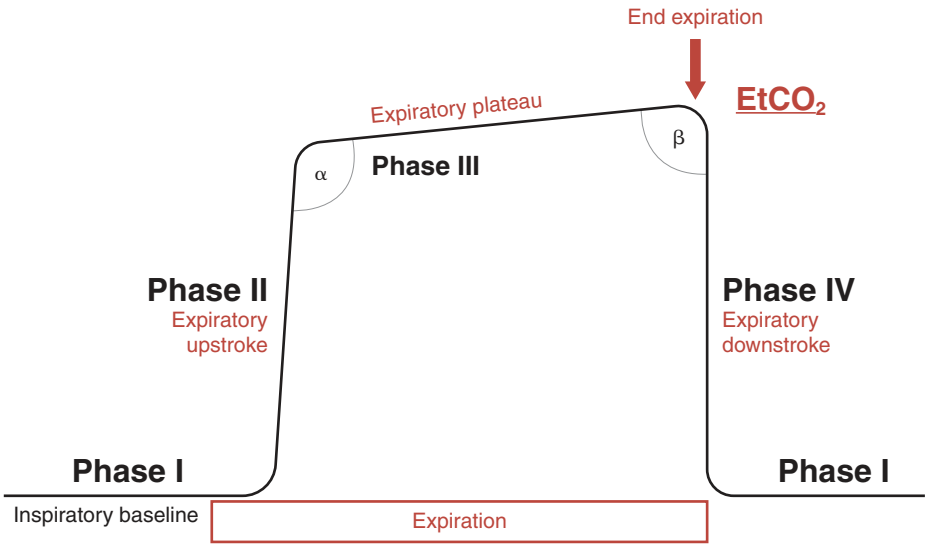

Fig. 33.4 Normal capnography trace. (From Kerslake I, Kelly F. Uses of capnography in the critical care unit. *BJA Education*. 2017;17:178–183.)

patient experiencing a bronchospasm would exhibit the classical sawtooth slope waveform. As the airway obstruction worsens, the slope of the transitional phase becomes more gradual. In patients with emphysema, the alveolar slope would be reversed. Because of a reduced gas exchanging surface and an abnormally increased lung compliance, alveolar gas exchange occurs quite rapidly; thus the waveform peak represents arterial CO_2. A "pigtail" capnograph pattern is typically seen in patients with poor lung compliance. A sudden peak of expired CO_2 occurs because of sudden airway closure.

Clinical Applications

Unlike PO_2 concentrations, venous and arterial blood have PCO_2 values that differ by a relatively small amount. Capnometric determination of the partial pressure of CO_2 in end-tidal exhaled gas (P_{ETCO_2}) is often used during mechanical ventilation as a surrogate with which to monitor changes in the partial pressure of CO_2 in the alveolar gas and (with less precision) in the arterial blood ($PaCO_2$). Although widely available today, how best to use P_{ETCO_2} as a representation of $PaCO_2$ remains unclear in ICU practice. Although perhaps not an exact match for $PaCO_2$, P_{ETCO_2} does provide a valuable trending tool. Also, with newer technologies, the accuracy of P_{ETCO_2} measurements is improving. A recent study reported strong correlations between P_{ETCO_2} and $PaCO_2$ across a wide range of dead-space conditions.[41] Capnometry is used for a variety of purposes, such as in the diagnosis of a pulmonary embolism, determination of lung recruitment response to PEEP, detection of auto (or intrinsic) PEEP (PEEPi), evaluation of weaning progress, and as an indirect marker of elevated dead-space ventilation. Other uses include the assessment of cardiopulmonary resuscitation, indirect determination of cardiac output through partial CO_2 rebreathing, verification of endotracheal cannulation, detection of airway accidents, and even determination of feeding tube placement. Guidelines for the use of capnometry/capnography are outlined by the American Association for Respiratory Care (AARC) (Box 33.1).[42]

$PaCO_2$-P_{ETCO_2} Gradient

Normal subjects have a $PaCO_2$-P_{ETCO_2} gradient of 4–5 mm Hg.[43,44] In critically ill patients, the $PaCO_2$-P_{ETCO_2} gradient can be markedly elevated, with a tendency toward wider gradients in obstructive lung diseases (7–16 mm Hg) than in ALI or cardiogenic pulmonary edema (4–12 mm Hg).[38,41,44–46] The strong correlation between ΔP_{ETCO_2} and $\Delta PaCO_2$ ($r = 0.82$), along with minor bias and reasonable precision between P_{ETCO_2} and $PaCO_2$, suggests that arterial blood gas monitoring may not be needed to assess ventilation unless the ΔP_{ETCO_2} exceeds 5 mm Hg.[47] Nevertheless, several studies have found that the ΔP_{ETCO_2} often falsely predicts the degree and direction of $\Delta PaCO_2$.[45–49] Therefore despite P_{ETCO_2} monitoring, routine arterial blood gas analysis is still required in critically ill patients.

Several factors determine the $PaCO_2$-P_{ETCO_2} gradient. Whereas $PaCO_2$ reflects the mean partial pressure of CO_2 in alveolar gas ($PaCO_2$), P_{ETCO_2} approximates the peak $PaCO_2$. During expiration, lung regions with high ventilation-to-perfusion ratios dilute the mixed CO_2 concentration so that P_{ETCO_2} is usually lower than $PaCO_2$. However, when CO_2 production is elevated (or expiration is prolonged), P_{ETCO_2} more closely resembles mixed venous PCO_2, as a higher amount of CO_2 diffuses into a progressively smaller lung volume. Thus the $PaCO_2$-P_{ETCO_2} gradient can be affected by changes in respiratory rate and tidal volume (VT) because of alterations in expiratory time and by CO_2 production and mixed venous CO_2 content. In fact, it is not uncommon for P_{ETCO_2} to marginally exceed $PaCO_2$. Inotropic or vasoactive drugs may affect the $PaCO_2$-P_{ETCO_2} gradient in an unpredictable manner, either by increasing cardiac output and pulmonary perfusion (thereby reducing alveolar dead space) or by reducing pulmonary vascular resistance and magnifying intrapulmonary shunt by countering hypoxic pulmonary vasoconstriction.

Certain mechanical factors can cause either inconsistencies or inaccuracies in P_{ETCO_2}. The sample tubing length and aspirating flow rates used in sidestream capnometers affect the time required to measure changes in tidal CO_2 concentration. At respiratory frequencies above 30 breaths/min, capnometers tend to underreport the true P_{ETCO_2}. This may occur because of gas mixing between adjacent breaths during transport down the sampling line and in the analysis chamber.[50] This problem can be avoided with mainstream analyzers, which provide near-instantaneous CO_2 measurement (less than 250 msec).[51]

$PaCO_2$-P_{ETCO_2} Gradient, PEEP, and Lung Recruitment

PEEP may recruit collapsed alveoli, improve ventilation-perfusion matching, and reduce alveolar dead space, but excessive levels cause overdistention and increased alveolar dead space. Because the

Box 33.1 American Association for Respiratory Care (AARC) Clinical Practice Guideline: Capnography/Capnometry During Mechanical Ventilation

Indications

- There are three broad categories of indications for capnography/capnometry: verification of artificial airway placement, assessment of pulmonary circulation and respiratory status, and optimization of mechanical ventilation.
  - Verification of artificial airway placement. Even when the endotracheal tube is seen to pass through the vocal cords and tube position is verified by chest expansion and auscultation during mechanical ventilation, providers should obtain additional confirmation of airway placement with waveform capnography or an exhaled CO_2 or esophageal detector device.
  - Assessment of pulmonary circulation and respiratory status. Capnography assists in:
    - Determining changes in pulmonary circulation and respiratory status sooner than pulse oximetry. In patients without lung disease, substantial hypercarbia may present before pulse oximetry notifies the clinician of a change in ventilation.
    - Monitoring the adequacy of pulmonary, systemic, and coronary blood flow, in addition to estimation of the effective (nonshunted) pulmonary capillary blood flow by a partial rebreathing method.
    - Evaluating the partial pressure of exhaled CO_2, especially P_{ETCO_2}.
    - Screening for pulmonary embolism.
  - Optimization of mechanical ventilation. Capnography during mechanical ventilation allows:
    - Continuous monitoring of the integrity of the ventilator circuit, including the artificial airway or bag mask ventilation, in addition to potentially detecting mechanical ventilation malfunctions.
    - Decreasing the duration of ventilatory support.
    - Adjustment of the trigger sensitivity.
    - Evaluation of the efficiency of mechanical ventilation by the difference between $PaCO_2$ and P_{ETCO_2}.
    - Monitoring of the severity of pulmonary disease and evaluating the response to therapy, especially therapies intended to improve the ratio of dead space to tidal volume (VD/VT) and ventilation-perfusion matching ($\dot{V}/\dot{Q}$).
    - Monitoring of $\dot{V}/\dot{Q}$ during independent lung ventilation.
    - Monitoring of inspired CO_2 when it is being therapeutically administered.
- Graphic evaluation of the ventilator-patient interface. Evaluation of the capnogram may be useful in detecting rebreathing of CO_2, obstructive pulmonary disease, the presence of inspiratory effort during neuromuscular blockade, cardiogenic oscillations, esophageal intubation, and cardiac arrest.
- Measurement of the volume of CO_2 elimination to assess metabolic rate and/or alveolar ventilation.
- Monitoring of VD/VT to determine eligibility for extubation in children.
- There is a relationship between VD/VT and survival in patients with acute respiratory distress syndrome.

Contraindications

- There are no absolute contraindications to capnography in mechanically ventilated patients, provided the data obtained are evaluated with consideration given to the patient's clinical condition.

Hazards/Complications

- Hazards/complications are different for the two types of capnographic devices.
  - Mainstream:
    - Dead space. Adapters inserted into the airway between the airway and the ventilator circuit should have a minimal amount of dead space. This effect is inversely proportional to the size of the patient being monitored.
    - The addition of the weight of a mainstream adapter can increase the risk of accidental extubation in neonates and small children.
  - Sidestream:
    - The gas sampling rate from some sidestream analyzers may be high enough to cause auto-triggering when flow triggering of mechanical breaths is used. This effect is also inversely proportional to the size of the patient.
    - The gas sampling rate can diminish delivered VT in neonates and small patients while using volume-targeted or volume-controlled ventilation modes.

Assessment of Need

- Capnography is considered a standard of care during general anesthesia.
- The American Society of Anesthesiologists has suggested that capnography be available for patients with acute ventilatory failure on mechanical ventilatory support.
- The American College of Emergency Physicians recommends capnography as an adjunctive method to ensure proper endotracheal tube position.
- The 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care recommend capnography to verify endotracheal tube placement in all age groups.
- Assessment of the need to use capnography with a specific patient should be guided by the clinical situation. The patient's primary cause of respiratory failure and the severity of his or her condition should be considered.

Assessment of Outcome

- Results should reflect the patient's condition and should validate the basis for ordering the monitoring. Documentation of results (along with all ventilatory and hemodynamic variables available), therapeutic interventions, and/or clinical decisions made based on the capnogram should be included in the patient's chart.

Monitoring

- During capnography, the following should be considered and monitored:
  - Ventilatory variables: tidal volume, respiratory rate, positive end-expiratory pressure, inspiratory-to-expiratory time ratio (I:E), peak airway pressure, and concentrations of respiratory gas mixture.
  - Hemodynamic variables: systemic and pulmonary blood pressures, cardiac output, shunt, and ventilation-perfusion imbalances.

From AARC clinical practice guideline: Capnography/capnometry during mechanical ventilation. *Respir Care*. 2011;56:503–509.

$PaCO_2$-P_{ETCO_2} gradient correlates strongly with the physiologic dead space–to–tidal volume ratio (VD/VT), this gradient may be useful in titrating PEEP in patients with ALI or ARDS. An animal model of ARDS found that stepwise application of PEEP progressively reduced the $PaCO_2$-P_{ETCO_2} gradient and coincided with maximal or near-maximal improvements in oxygenation.[52] However, PEEP applied beyond the lowest $PaCO_2$-P_{ETCO_2} gradient caused a secondary rise in the gradient, along with decreased cardiac output. Another study found that the $PaCO_2$-P_{ETCO_2} gradient narrowed (from 14 to 8 mm Hg) and oxygenation improved when PEEP was set at the lower inflection point of the pressure-volume inflation curve of the respiratory system.[53] When PEEP was set 5 cm H_2O above the lower inflection point, the $PaCO_2$-P_{ETCO_2} gradient rose to 11 mm Hg and cardiac output trended downward. In patients without a clear lower inflection point, the

$PaCO_2$-P_{ETCO_2} gradient did not change in response to PEEP. Thus in a subset of ARDS patients, the $PaCO_2$-P_{ETCO_2} gradient may be an effective way to titrate PEEP.

Newer-generation ventilators have integrated mainstream "volumetric" CO_2 (Vcap) sensors that allow for simultaneous bedside measurements of physiologic and alveolar dead space.[54] Measurement of dead space could potentially provide a monitoring parameter to follow in assessing pulmonary function, as discussed later.[54] Although Vcap is a promising physiologic tool, further research is needed to define its diagnostic value.

P_{ETCO_2} Monitoring During Cardiopulmonary Resuscitation

Monitoring end-tidal CO_2 concentration is a reliable method for evaluating the effectiveness of cardiopulmonary resuscitation.[55] In animal models, P_{ETCO_2} is strongly correlated with coronary perfusion pressure and successful resuscitation,[56] whereas in humans, changes in P_{ETCO_2} are directly proportional to changes in cardiac output.[57] P_{ETCO_2} during precordial compressions can distinguish successful from unsuccessful resuscitation technique, with values greater than 10 mm Hg[58] or greater than 16 mm Hg[59] associated with successful resuscitation.

Measurement of Dead-Space Ventilation

Ventilation-perfusion abnormalities are the primary physiologic disturbance in nearly all pulmonary diseases and the principal mechanism for elevated $PaCO_2$.[60] Dead-space ventilation (VD), the portion of VT that does not encounter perfused alveoli, directly affects CO_2 excretion and is used as an indirect measure of ventilation-perfusion abnormalities. Physiologic VD represents the summation of dead-space components attributable to anatomic-conducting airways and underperfused alveoli.

Physiologic VD/VT historically has been measured during a 3- to 5-minute exhaled gas collection into a 30- to 60-L Douglas bag. An arterial blood gas reading is obtained during the midpoint of the collection. VD/VT is calculated using the Enghoff modification of the Bohr equation, whereby the difference between $PaCO_2$ (a surrogate for the mean $PaCO_2$) and mean expired CO_2 tension (P_{ECO_2}) is divided by $PaCO_2$:

$$\frac{VD}{VT} = \frac{(PaCO_2 - P_{ECO_2})}{(PaCO_2)}$$

The dead-space volume per breath or per minute can be determined by multiplying VD/VT by the simultaneously measured average VT or minute ventilation ($\dot{V}_E$)[61]:

$$VD = \frac{(PaCO_2 - P_{ECO_2})}{(PaCO_2)} \times VT \text{ or } VD = \frac{(PaCO_2 - P_{ECO_2})}{(PaCO_2)} \times \dot{V}_E$$

Alveolar minute ventilation is obtained by subtracting the physiologic VD per minute from the $\dot{V}_E$. It can also be calculated as the volume of CO_2 produced per minute ($\dot{V}CO_2$) divided by the $PaCO_2$[61]:

$$\dot{V}_A = \frac{(\dot{V}CO_2)}{(PaCO_2)} \times 0.863$$

Although expired gas collection with a Douglas bag is the classic method for measuring VD/VT, the gas collection system requires additional valving and connectors, making the procedure time-consuming and awkward. Metabolic monitors produce equally accurate, reliable results and are less cumbersome.[62,63] The Douglas bag method and metabolic monitors, however, do share a limitation when used on a mechanically ventilated patient. During mechanical ventilation, gas is compressed in the circuit, which dilutes the fractional expired CO_2 concentration. A correction factor can be used to offset the mathematical effects of gas compression. Volumetric capnography is a convenient alternative method of measuring P_{ECO_2} and VD/VT and has the advantage of being measured at the patient, thus eliminating the effects of compression volume contamination and the need to apply a correction factor.[64] In patients with ARDS, it has been shown that measurements of VD/VT using volumetric capnography are as accurate as those obtained through the use of a metabolic monitor.[65]

A significant source of measurement error for VD/VT is the contamination of expired gas with circuit compression volume. During positive-pressure ventilation, part of the VT is compressed in the circuit, and during expiration, this gas mixes with CO_2-laden gas from the lungs. The dilution of the expired CO_2 results in a falsely elevated VD/VT that is directly proportional to the peak inspiratory pressure and circuit compliance. Clinically, correcting VD/VT for compression volume is done by multiplying the measured P_{ECO_2} by the ratio of the ventilator-set VT to the VT delivered to the patient.[65]

Clinically, VD/VT may assist in the management of pulmonary disease in terms of both ventilator adjustments and diagnostic testing. VD/VT tends to decrease as lung units are recruited but increase with lung overdistention during PEEP titration in ARDS. A recent study involving the use of dead-space calculations in ARDS reported that increased dead space is associated with higher mortality in the early and intermediate phases of ARDS.[66] Fletcher and Jonson used VD/VT to optimize VT and inspiratory time settings during general anesthesia.[67] Measuring VD/VT may assist in identifying patients who can be removed from mechanical ventilation. Hubble and coworkers found that values less than 0.50 predicted successful extubation, and values greater than 0.65 identified patients at risk for postextubation respiratory failure.[68]

One of the main clinical uses of VD/VT is to aid in the diagnosis of acute pulmonary embolism. VD/VT is comparable to radioisotopic lung scanning in detecting acute pulmonary embolism, with a value less than 0.40 suggesting that a significant embolus is improbable.[69] Single-breath estimates of alveolar VD are also capable of identifying patients with a pulmonary embolus.[70] Increased physiologic VD/VT (greater than 0.60) was found to be significantly associated with mortality in patients with ARDS and in neonates with congenital diaphragmatic hernia.[71,72] The finding that VD/VT is elevated early in the course of ARDS and is associated with increased mortality risk may be particularly useful. The efficacy of new therapies for ARDS may be judged, in part, by their ability to reduce VD/VT.

Transcutaneous Monitoring

Transcutaneous blood gas monitoring involves the use of a skin surface sensor to provide continuous noninvasive estimates of arterial PO_2 and PCO_2 (TcO_2 and $TcCO_2$, respectively). The sensor warms the skin to promote "arterialization" and to increase the permeability of the skin to O_2 and CO_2. Elements of the sensor include a heating element, an O_2 electrode, and a CO_2 electrode. The electrodes measure the gas tensions in an electrolyte gel located between the sensor and the skin. Similar to end-tidal CO_2 ($ETCO_2$) monitoring and pulse oximetry, transcutaneous monitoring has the potential advantages over direct arterial blood gas sampling of reducing the amount of blood drawn, time spent for analysis, patient discomfort, and associated costs. $TcCO_2$ tends to be more reliable than $ETCO_2$, most likely because of the greater diffusion capacity of CO_2 through the skin and the skin's own O_2 consumption.[73] $TcCO_2$ has historically been used more frequently in neonatal and pediatric populations, but recent technologic advances have extended its utilization to adults, despite the blunting

effects of a thicker epidermis. Transcutaneous blood gas monitoring has been commonly used to provide a picture of PCO_2 trends in patients with acute and chronic respiratory failure.[74] It has been shown to be particularly accurate in neonates because of their thin, poorly keratinized skin, which has fewer barriers to diffusion of capillary gases.[75]

The gradient between $TcCO_2$ and $PaCO_2$ is influenced by skin perfusion and skin temperature. Thus factors affecting cutaneous vasoconstriction (e.g., vasopressors, cardiac output, cutaneous vascular resistance) could potentially influence $TcCO_2$ measurements. Technical factors that can affect the accuracy of $TcCO_2$ measurements are similar to those of $ETCO_2$ monitoring and center around the inevitable gradient with $PaCO_2$.

The accuracy of transcutaneous arterial blood gas measurement in adults remains a point of debate. A number of studies have reported that $TcCO_2$ monitoring is accurate in adult patients with respiratory disorders.[76–79] Some studies have even suggested that $TcCO_2$ monitoring may be more accurate than $ETCO_2$ monitoring owing, in part, to the elimination of dead space.[80–82] Transcutaneous monitoring has been used in several clinical settings to determine the presence of hypoventilation or respiratory depression, including sleep studies, ventilatory management, bronchoscopies, and pulmonary function studies. However, some reports suggest that $TcPO_2$ is not accurate enough to be used clinically for ICU applications in adult populations or even in preterm infants.[83,84]

ASSESSMENT OF PULMONARY MECHANICS

Assessment of basic pulmonary mechanics is crucial to monitoring pulmonary function during mechanical ventilation. Monitoring pulmonary mechanics assists the clinician in adjusting ventilator settings, diagnosing lung conditions, and assessing the severity of lung impairment. At the bedside, changes to these mechanics can occur rapidly, meriting a speedy response, or they may reveal as slow trends in pulmonary conditions, prompting care plan adjustments. Assessment of pulmonary mechanics during constant-flow controlled ventilation requires the measurement of VT, peak inspiratory flow rate, and four pressures: peak airway pressure (Paw); end-inspiratory plateau pressure; end-expiratory pressure in the circuit; and, if auto-PEEP is suspected, end-expiratory pressure measured during an end-expiratory pause maneuver. Static measurements of pulmonary mechanics rely on circuit occlusions to create a no-flow situation, whereas dynamic measurements assess mechanical properties of the respiratory system continuously during mechanical ventilation (including flow-related components). From these measured variables, the compliance and resistance of the respiratory system are determined.

Compliance

Under conditions of passive mechanical ventilation, peak airway pressure denotes the total force per unit area necessary to overcome the resistive and elastic recoil properties of the respiratory system (i.e., both lungs and chest wall) and is expressed as the ratio of volume added (tidal volume) to pressure increment applied. Compliance determined from airway pressure is a measure of the elastic properties of the respiratory system, including the series-coupled lung and the chest wall. In clinical practice, pulmonary compliance is separated into two different measurements, dynamic compliance and static compliance. Dynamic compliance is the ratio of volume added to the inflation Paw above PEEP and therefore includes the resistive forces in the tracheobronchial tree. A more useful measurement is that of static compliance. Static compliance requires the use of an end-inspiratory hold. During an end-inspiratory pause, peak airway pressure dissipates down to a stable plateau pressure. At the end of the inspiratory hold maneuver, "static" conditions usually exist (resistive forces have been dissipated), and the corresponding "plateau pressure" represents the elastic recoil pressure of the respiratory system (Fig. 33.5).

Dividing the VT by the plateau pressure (Pplat) minus the PEEP yields the static compliance of the respiratory system (Crs-stat). Mechanically ventilated patients with "normal" lung physiology have a static respiratory compliance of 50–100 mL/cm H_2O.[85] Even at moderate levels of VE (greater than 10 L/min), dynamic gas trapping can occur (creating auto-PEEP) and, if suspected, Crs-stat must be calculated using total PEEP (PEEPtot) measured during an end-expiratory pause, rather than the PEEP applied at the airways:

$$\text{Crs}-\text{stat}=\frac{\text{VT}}{(\text{Pplat}-\text{PEEPtot})}$$

During patient-triggered ventilation, the assessment of pulmonary mechanics becomes more difficult because of the patient's spontaneous efforts, which may falsely raise or lower the Pplat. Obtaining an accurate measurement requires that the clinician perform the inspiratory hold when spontaneous efforts are absent, and the applied pause will most likely be of shorter duration.

Resistance

Respiratory system resistance (Rrs) is the ratio of the airway to alveolar pressure difference (Paw – Pplat) to flow. It describes the opposition to air flow through the respiratory tract during inspiration, including frictional forces. It is calculated as the difference between Paw and Pplat divided by the preocclusion peak inspiratory flow rate ($\dot{V}_I$) and expressed as cm H_2O/L per second:

$$\text{Rrs}=\frac{(\text{Paw}-\text{Pplat})}{\dot{V}_I}$$

Graphically, that pressure overcoming Rrs can be depicted as the difference between Paw and Pplat (see Fig. 33.5). Resistance, however, is flow dependent, because the driving pressure necessary to overcome resistance increases disproportionately to flow (because of increased turbulence). Therefore Rrs can be accurately determined only for a specified inspiratory flow (square wave) pattern. The level of Rrs strongly depends on the diameter of the airways and whether airflow is laminar or turbulent. Turbulent flow is commonly present in large

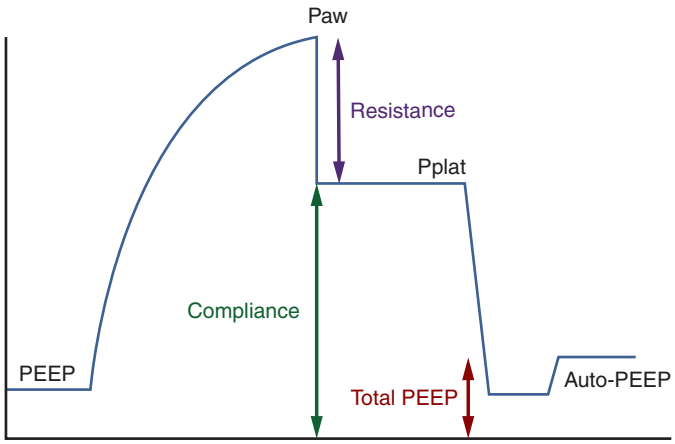

Fig. 33.5 Elements of an inspiratory pressure waveform. *Auto-PEEP,* Auto positive end-expiratory pressure; *Paw,* peak airway pressure; *PEEP,* positive end-expiratory pressure; *Pplat,* plateau pressure.

airways and at major bifurcations, whereas laminar flow is present at the slower velocities in the peripheral conducting airways. Poiseuille's law explains how relatively small changes in the radius of the airways cause large changes in airway resistance: $R = 8\ nl/\pi r^4$.[86]

Compliance and Resistance in Normal and Pathologic Conditions

In mechanically ventilated normal patients, compliance ranges from 50 to 100 mL/cm H_2O, and Rrs is 1–8 cm H_2O/L per second.[85,87] The effects of compliance and Rrs can also be displayed graphically from the monitor tracings of the mechanical ventilator. Fig. 33.5 illustrates where, during inspiration with an inspiratory pause, the effects of respiratory system compliance and resistance are visualized. In the face of decreasing compliance, an elevation in Pplat can be seen with little change to the Paw–Pplat differential. An increase in the Paw–Pplat differential with an unchanged Pplat represents an increased Rrs. Abnormalities in compliance and resistance in patients are dependent on both the cause and severity of the disease. Decreased compliance may occur in the case of ARDS, atelectasis, pneumothorax, lung fibrosis, or chest wall stiffness.[85–87] Assuming normal chest wall properties, monitoring compliance in ARDS patients can provide useful information about the volumetric capacity of aerated lung, as compliance reflects primarily the number rather than the stiffness of alveolar units. For this reason, compliance is also influenced by predicted lung size. An increase in compliance of individual lung units occurs in patients with emphysema. Increased Rrs may occur in the case of chronic obstructive pulmonary disease (COPD) or asthma, a narrow endotracheal tube, excessive secretions, use of a heat and moisture exchanger (HME), and incorrect positioning or kinking of the endotracheal tube.

Dynamic Gas Trapping and Intrinsic Positive End-Expiratory Pressure

At end expiration, if there is insufficient time for a patient to exhale completely to resting volume, gas gets trapped in the lungs, creating alveolar pressure that is above the set circuit baseline pressure. This phenomenon is referred to as *intrinsic PEEP (PEEPi)* or *auto-PEEP* (the terms are often used interchangeably). PEEPi can be measured by an end-expiratory circuit occlusion maneuver, whereby after a normal expiratory time elapses, both the inspiratory and expiratory ventilator valves close for 3–5 seconds, allowing alveolar pressure to equilibrate with the circuit pressure (see Fig. 33.5). This pressure represents the global average PEEPi through the airway channels that remain open at end expiration. The presence of PEEPi may also be detected by observing the expiratory flow graphic during tidal breathing. Fig. 33.6 shows the flow pattern from a patient who has normal exhalation mechanics (green tracing) contrasted with an expiratory flow waveform from a patient who had insufficient time for exhalation (red tracing). This graphical method of PEEPi identification does not quantify the amount of PEEPi. It is very important, however, to keep in mind that different degrees of PEEPi may coexist in the lungs because of regional variations in lung mechanics and differing time constants caused by the underlying pathology. PEEPi is more common in mechanically ventilated patients with COPD (in which dynamic hyperinflation slows elastic recoil) and patients who require high respiratory rates (which allow inadequate time for complete exhalation). There is evidence associating ventilator-triggering asynchrony (including missed, untriggered efforts) to PEEPi.[88,89] Trigger asynchrony may manifest itself as delayed triggering (in which there is a significant time lag between the initial patient effort to get a breath and the ventilator recognizing the effort) or as a missed trigger (the ventilator doesn't recognize patient effort and doesn't respond at all to the effort). PEEPi can predispose the patient to increased work of breathing, barotrauma, hemodynamic instability, and difficulty in triggering the ventilator.

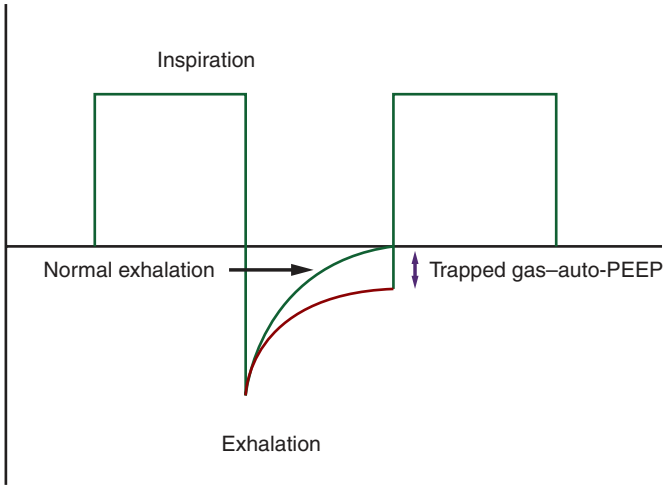

Fig. 33.6 Expiratory flow. *Green,* normal expiration; *red,* expiratory flow leading to auto-PEEP.

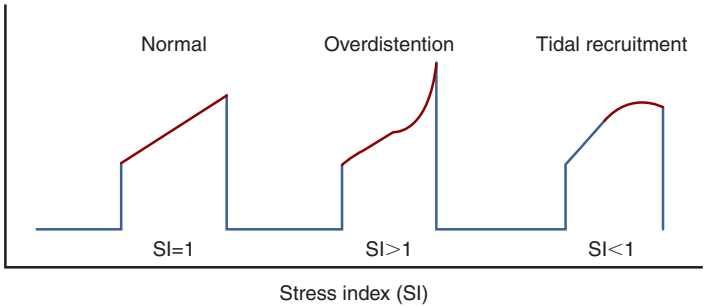

Fig. 33.7 Graphic representation of the stress index concept. The stress index is the coefficient b of a power equation (airway pressure = a · inspiratory time^b + c).

Stress Index

An alternative ventilatory measurement has been described in the literature to assist in lung protective management strategies. The visualization and assessment of a constant slope or "straight line" in the pressure-time ventilator waveform during inflation with constant ("square wave") flow, also known as the *stress index (SI),* has been used as a tool to help lessen the incidence of ventilator-induced lung injury (VILI) in mechanically ventilated patients.[90–93] Under such conditions, time is a linear analog of volume, so that the inflation Paw vs. time slope represents the inverse of compliance or elastance. To perform the SI, the patient must be placed on volume assist control ventilation with a square wave of flow and then the pressure-time waveform is observed (Fig. 33.7). The patient must also be passive during this maneuver. Any patient effort will distort the pressure-time waveform, thus preventing proper interpretation. The SI can be characterized by three profiles: (1) linear (normal), (2) upward convexity (overdistention), and (3) downward concavity (tidal recruitment). If an upward convexity is present, clinicians should consider lowering either the Vt or PEEP level to relieve overdistention. A downward concavity indicates improving respiratory system compliance. In this situation, PEEP could be added to take up some of the recruitment that occurs during the tidal breath. A linear SI is thought to be more optimal.[90–92,94]

Pressure-Volume Curves

A pressure-volume (P-V) curve traces changes in pressures and corresponding changes in volume. The static or quasi-static pressure-volume relationship can be used to analyze the elastic properties of the respiratory system and help guide mechanical ventilation.[95,96] P-V curves usually have a sigmoidal shape (Fig. 33.8). When inflation begins below functional residual capacity (FRC), there is relatively little volume change as transpulmonary pressure increases. This is referred to as the *starting compliance* and corresponds to the first 250 mL of volume change.[97] It reflects either the relatively high pressure required to overcome small airway closure in the dependent lung zones or the relatively small volume of aerated lung tissue as inflation commences. Typically, this low-compliance segment in the P-V curve is followed by an abrupt slope change with an appearance convex to the horizontal pressure axis that is termed the **lower inflection zone**, or Pflex. A common interpretation of the lower inflection "point" (actually a range) is that it signifies the pressure at which there is rather abrupt reopening of collapsed peripheral airways and alveoli.[98–100] Above the lower inflection point, the P-V curve becomes more linear, even though recruitment continues to occur to a limited extent.[101] As the total lung capacity is approached, compliance decreases and the P-V curve becomes concave to the pressure axis (bow-shaped). This appearance is thought to signify the loss of distensibility at maximal inflation. This change "point" (actually a zone) is termed the **upper inflection point.**[101]

As the lung is deflated, the linear portion of the curve is referred to as the *deflation compliance,* or true physiologic compliance, as it represents the elastic properties of the lung after full recruitment.[102] As lung deflation proceeds below FRC, an inflection point often occurs on the deflation limb that represents small-airway closure.[102] This airway closure tends to occur at a lower pressure than the lower inflection point on the inflation limb because the minimal force necessary to maintain patent airways is less than the pressure needed to recruit collapsed ones. Ideally a P-V curve should be constructed under static conditions (no flow) to eliminate the flow-resistive effects, which would distort the curve (super syringe method). However, because of the long duration required to construct the curve and the fact that the patient needs to be removed from the ventilator (risking derecruitment), this is unrealistic in the clinical arena. Most newer-generation ventilations employ a constant flow technique using extremely low inspiratory and expiratory flows (minimal flow-resistive effects) to accurately construct a P-V curve.[103] With either of these methods, the patient cannot make any spontaneous efforts, as that will render appropriate interpretation of the curve impossible.

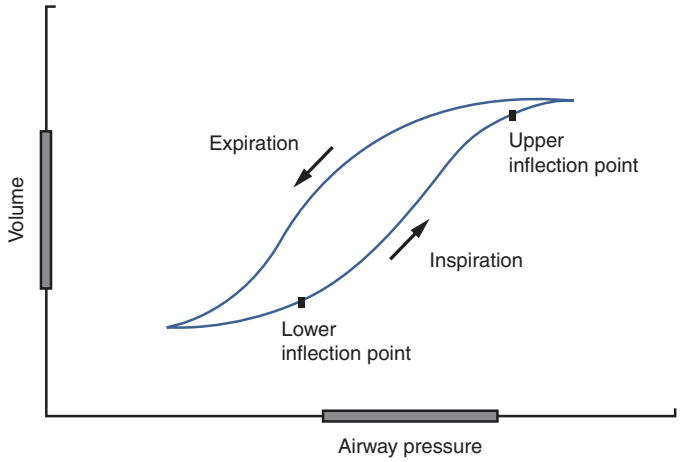

Fig. 33.8 Pressure-volume curve.

Hysteresis

Hysteresis refers to the difference in pressures necessary to achieve the same volume during inflation versus deflation. Compliance tends to be higher during deflation than inflation because higher pressures may be required during inspiration to overcome surface forces and recruit collapsed alveoli. This "extra" pressure is not required during deflation to prevent derecruitment. Ultimately then, the deflation limb may be more important for setting PEEP, as prevention of alveolar collapse—not reopening—is PEEP's primary purpose.[104]

ASSESSMENT OF BREATHING PATTERN AND CENTRAL DRIVE

Rate and Tidal Volume

Basic assessment of the respiratory pattern includes the measurement of respiratory rate and tidal volume (VT). A normal respiratory rate is 12–24 breaths/min, and mechanical ventilation is generally indicated when the rate exceeds 30 breaths/min.[105] A VT of 5 mL/kg is considered sufficient to maintain unassisted breathing.[106] Tachypnea is often the earliest sign of impending respiratory failure, even when arterial blood gases remain within normal limits. This may reflect the fact that muscle fatigue (which results from a mechanical workload that exceeds the power capacity of the ventilatory muscles) occurs before overt ventilatory pump failure. If untreated, a rapid, shallow breathing pattern can develop that will be progressively ineffective in maintaining acceptable arterial blood gas values.

Of particular interest is the utility of breathing pattern in assessing the feasibility of weaning from mechanical ventilation. Typically, patients who fail to wean are more tachypneic (respiratory rate greater than 30 breaths/min) and have an abnormally low VT (less than 200 mL). The respiratory rate–VT ratio, also known as the rapid shallow breathing index (RSBI), is a method that helps in evaluating readiness to wean. The RSBI is thought to be an accurate predictor of breathing effort.[107,108] An RSBI threshold of less than 105 has both a high positive predictive value (0.78) and high negative predictive value (0.95) for the ability to maintain unassisted breathing.[109] Although not an absolute predictor in and of itself, RSBI can be a valuable tool in helping to predict readiness to wean.

Central Ventilatory Drive

In some situations, clinicians may want to assess the central ventilatory drive. A heightened drive will increase the patient's work of breathing during mechanical ventilation.[110] Measuring the respiratory rate corresponding to the minute ventilation gives the clinician an indication of the central ventilatory drive, but it is influenced by respiratory system compliance and does not reflect the depth of the drive. Depth of the drive can be measured by a brief (100 msec) inspiratory occlusion shortly after the onset of an effort, called $P_{0.1}$. Briefly occluding the airway at the onset of inspiratory effort results in isometric contraction of the inspiratory muscles, so $P_{0.1}$ is relatively independent of respiratory system mechanics.[111] Measuring airway pressure at 100 msec indirectly reflects efferent motor neuron output. An increasing stimulus to the inspiratory muscles causes a more forceful contraction, with a proportional increase in pressure development. The selection of 100 msec is based on the fact that conscious or nonconscious perception of (and response to) sudden load changes requires approximately 250 msec.[112] During mechanical ventilation, the lag associated with the trigger phase provides sufficient time to measure $P_{0.1}$. Many of the newer ventilators now incorporate an automated $P_{0.1}$ maneuver.

In a healthy adult at rest, $P_{0.1}$ tends to range between 0.5 and 1.5 cm H_2O. In adult patients receiving mechanical ventilation, values exceeding 3.5 cm H_2O are considered elevated respiratory effort.[112]

A limitation of the $P_{0.1}$ is that it dissociates from ventilatory drive when muscle weakness is present or hyperinflation alters the force-length relationship of the inspiratory muscles.

KEY POINTS

- Pulse oximetry is a noninvasive and painless assessment tool that rapidly measures even small changes in oxygen saturation levels.
- Oxyhemoglobin and carboxyhemoglobin absorb equivalent amounts of red light, so carbon monoxide poisoning can result in falsely elevated oxygen saturation as measured by the pulse oximeter (SpO_2).
- Motion artifact and low perfusion are the most common sources of SpO_2 inaccuracies.
- Capnometry is an intensive care monitoring tool that displays the partial pressure concentration of carbon dioxide exhaled from the lungs both numerically and as a graphical waveform.
- In normal subjects the gradient between the partial pressure of carbon dioxide in arterial blood and the partial pressure of carbon dioxide in end-tidal exhaled gas ($PaCO_2$-P_{ETCO_2} gradient) is approximately 4–5 mm Hg, whereas in critically ill patients, the $PaCO_2$-P_{ETCO_2} gradient can be markedly elevated and inconsistent, particularly in those with obstructive lung disease (7–16 mm Hg).
- The $PaCO_2$-P_{ETCO_2} gradient is affected by changes in respiratory rate, tidal volume, CO_2 production, and mixed venous CO_2 content.
- Respiratory system compliance can be determined by applying an end-inspiratory hold (plateau pressure) during static conditions (no flow or patient spontaneous efforts).
- Intrinsic PEEP is measured by performing an expiratory hold, allowing the pressure in the patient's lungs to equilibrate with the circuit.
- When using the pressure-volume curve of the respiratory system (during quasi-static conditions) for lung protection in patients with ARDS, PEEP is set 2 cm H_2O above the lower inflection point to maintain lung recruitment, and tidal volume is set below the upper inflection point to prevent lung injury from excessive stretch.
- The stress index is used to assess the shape of the pressure waveform during constant-flow volume control.
- A threshold value of less than 105 for the respiratory rate/tidal volume ratio (RSBI) has both a high positive predictive value (0.78) and a high negative predictive value (0.95) for the ability to maintain unassisted breathing.
- Occlusion pressure at 100 msec ($P_{0.1}$), defined as the negative pressure measured 100 msec after the initiation of an inspiratory effort performed against a closed valve, is correlated with central respiratory drive and respiratory effort.

Arterial Blood Gas Interpretation

A. Murat Kaynar

Although arterial blood gas (ABG) data provide critical information to the practitioners of critical care medicine, ABG analysis is among the most frequently ordered test in the intensive care unit (ICU), is overused, and is associated with burdens to our patients (discomfort, blood loss) and healthcare systems.[1–5] Therefore appropriate understanding and use of this clinical test is important for optimal care. There are no randomized trials performed on data; however, studies looking at the utility of ABG in relation to clinical outcomes have given mixed results and collectively underscore the need to use ABG information obtained in the ICU within a specific and appropriate clinical context.[6–8] Since the 1950s, the development of polarographic electrodes by Clark for oxygen (O_2) and Severinghaus and Bradley and Stow and coworkers for carbon dioxide (CO_2) has permitted measurement of the partial pressures of oxygen (PaO_2) and carbon dioxide ($PaCO_2$) in arterial blood.[9–11] Cremer, Haber, and Klemensiewicz developed the pH electrode in the early 20th century. ABG remains the definitive method to diagnose, categorize, and quantitate respiratory and metabolic failure.[12]

WHY AM I OBTAINING THE ARTERIAL BLOOD GAS?

Acute metabolic acidosis is common among critically ill and results from complex causes. Unfortunately, the clinical focus often shifts from treating the underlying causes to correcting the pH itself. Thus the primary question to ask ourselves before reflexively ordering the next ABG should be "Why am I ordering this test?"

A pH value less than 7.38 defines acidemia, whereas severe acidosis is a pH of 7.20 or lower.[13] In acute severe metabolic acidemia, where the pH is <7.20, the incidence is 6% among the critically ill and carries an associated ICU mortality rate of almost 60%.[14] Interestingly, studies suggest that the presence of an arterial line is the most powerful predictor for obtaining an arterial blood sample for ABG, regardless of the PaO_2, $PaCO_2$, Acute Physiology and Chronic Health Evaluation (APACHE) II score, or presence of a ventilator.[1,15] In addition, there are no published guidelines and only limited trials that provide guidance to clinicians regarding the indications for sampling ABGs.[16] Protocolized care may be able to reduce the number of unnecessary ABGs without negative effects on patient outcomes.[1,4]

The indications for ABG analysis have to be guided by the clinical context. Already deployed technologies, such as pulse oximetry and transcutaneous CO_2 detection, decrease the frequency of using ABGs.[17,18] Yet we still need to give clinicians a "rule of thumb" for sampling ABGs. One attempt at constructing such an "ABG indications" list might be:

- After initiation of mechanical (invasive/noninvasive) ventilation
- Tracking the acute respiratory distress syndrome (ARDS) clinical course
- Presence of hypoxemic and/or hypercapnic respiratory failure
- Presence of acute circulatory failure
- Management of complex acid-base disorders

ARTERIAL BLOOD GAS SAMPLING

The ABG samples are either obtained from an arterial catheter or direct arterial puncture into a heparinized syringe. It used to be customary to flush a syringe with heparin and then use that syringe to sample ABGs; however, work in both adult and pediatric patients showed that excess heparin decreased the $PaCO_2$, PaO_2, HCO_3^-, and base excess, while the pH remained unchanged. Thus excess liquid heparin tends to promote the interpretation of metabolic acidosis with respiratory compensation.[19,20]

While the most common site for arterial puncture is the radial artery, femoral and brachial arteries are also commonly used to sample arterial blood. Risks associated with arterial punctures are hematoma formation, ischemia to the hand or lower extremity, arterial injury, pseudoaneurysms, and arteriovenous fistulae.[16,21–24] Once obtained, the arterial blood sample must be processed immediately and in accordance with the best laboratory practices. In addition to differences between laboratories, calibration discrepancies and contamination of electrodes with protein or other fluids may alter results.[25,26]

Using the polarographic electrodes, PaO_2, $PaCO_2$, and pH are directly measured; oxygen saturation is calculated from standard O_2 dissociation curves and may be directly measured with a co-oximeter.[9–12,27] A co-oximeter is a blood gas analyzer that measures not just the partial pressure of gases but also the concentration of oxygen associated with different types of hemoglobin based on their absorption spectra (Beer-Lambert law). The use of co-oximetry is usually indicated when:

- A toxin such as cyanide is suspected
- Hypoxia fails to improve with the administration of oxygen
- There is a discrepancy between the PaO_2 on a blood gas determination and the oxygen saturation on pulse oximetry (SpO_2)
- The clinician suspects dyshemoglobinemias such as methemoglobinemia (Met-Hb) or carboxyhemoglobinemia (CO-Hb)[28]

Pulse oximetry, unfortunately, does not differentiate among the different types of hemoglobin. For example, in the case of Met-Hb, the SpO_2 may read 86%, but desaturation can be demonstrated with co-oximetry, recording 68% oxyhemoglobin and 32% Met-Hb.[28,29]

The bicarbonate (HCO_3^-) concentration is then calculated using the Henderson-Hasselbalch equation:

$$pH = pK_A + \log([HCO_3^-]/[CO_2])$$

where pK_A is the negative log of the dissociation constant of carbonic acid (HCO_3^-).

The *base excess* is the quantity of strong acid required to titrate blood to pH 7.40 with a $PaCO_2$ of 40 mm Hg at 37°C. In reality, acid is not titrated but calculated using a variety of normograms.[30–34] Such

calculations focus only on the metabolic sources for pH and $[H^+]$ changes. Similarly, bicarbonate is a calculated value that assumes $PaCO_2$ to be 40 mm Hg.

The following are some of the details that contribute to erroneous readings and interpretations.

Steady State

The ABG has to be collected when a patient reaches a steady state during the clinical course, allowing for the arterial and alveolar gases to equilibrate. Equilibration may take up to 20 or 30 minutes in the case of patients with chronic obstructive pulmonary diseases (COPDs).[35]

Anticoagulants

As mentioned in the Arterial Blood Gas Sampling section, excess heparin may affect the $PaCO_2$, PaO_2, HCO_3^-, and base excess, while not interfering with the pH. Only 0.05 mL is required to anticoagulate 1 mL of blood. Knowing that the "dead space" volume of a standard 5-mL syringe is approximately 0.02 mL, it is safe to assume that just having heparin in that dead space would suffice to provide anticoagulation up to 2 mL of blood sample. New prefilled syringes (sodium or lithium heparin) overcome these problems.[19]

Processing Delay

Although the blood sample resides in the syringe until analyzed, it does consume O_2 and produce CO_2. Red blood cell glycolysis could generate more lactic acid through the aerobic glycolysis and lower the pH.[36,37] If the sample remains unanalyzed at room temperature for more than 15 minutes, there would be significant increases in $PaCO_2$ and decreases in pH. When the sample is stored on ice, however, it can be processed up to 2 hours after collection without affecting the blood gas values, even on Mt. Everest.[38–41]

Venous Sampling

If no arterial blood sample is obtained, venous blood gas analyses would be of limited help; however, venous samples do yield estimates for $PaCO_2$ and lactatemia.[42,43] This is discussed later in the chapter.

At times the intended arterial puncture results in inadvertent venous sampling. One can recognize venous sampling when:

- The practitioner fails to observe a flash of blood during syringe filling
- The blood gas analyses clearly are not compatible with the clinical condition
- There is unexpectedly low PaO_2 and high $PaCO_2$
- SpO_2 by simultaneous pulse oximetry exceeds the SaO_2 in the measured ABG

Collection Equipment and Technique

If the dead space were high in the syringe, it would lower the $PaCO_2$. Additionally, a needle smaller than a 25-gauge may cause hemolysis.

If an arterial line is in place, one must minimize the dead space of the system (priming the volume from sampling port to catheter tip) to prevent dilution; the safe upper limit would be two times the dead space.[3]

Hyperventilation

Hyperventilation resulting from anxiety and/or pain may acutely alter results from baseline values.

Leukocytosis

Leukocytosis decreases the PaO_2 and pH and elevates $PaCO_2$ in stored samples. Such PaO_2 decreases are most noticeable at higher PaO_2 levels, are attributable to cellular oxygen consumption, and may be attenuated when samples are stored at colder temperatures.

Hypothermia

Blood gas values are temperature dependent, and as the temperature decreases, solubility of CO_2 increases and partial pressures decline. Thus if blood samples are warmed to 37°C before analysis (as is common in most laboratories), PaO_2 and $PaCO_2$ will be overestimated and pH underestimated in hypothermic patients. The following correction formulas can be used:

- Subtract 5 mm Hg PO_2 per 1°C that the patient's temperature is less than 37°C.
- Subtract 2 mm Hg $PaCO_2$ per 1°C that the patient's temperature is less than 37°C.
- Add 0.012 pH units per 1°C that the patient's temperature is less than 37°C.

Although there is an extensive literature on the so-called "pH-stat" and "alpha-stat" assessment of ABGs, in summary the *pH-stat* acid-base approach aims at maintaining the patient's pH in a constant range via managing pH at the patient's temperature. As in the formulas provided earlier, *pH-stat* is temperature corrected. On the other hand, *alpha-stat* aims at the ionization state of histidine, and it is maintained by managing a standardized pH (measured at 37°C). Alpha (normally about 0.55) is the ratio of protonated imidazole to total imidazole on the histidine moieties of proteins. *Alpha-stat* is not temperature corrected; as the patient's temperature falls, the partial pressure of CO_2 decreases and solubility increases. Thus a hypothermic patient with a pH of 7.40 and a PCO_2 of 40 mm Hg (measured at 37°C) will actually have a lower $PaCO_2$ because of its lower partial pressure, and this will manifest as a *relative respiratory alkalosis. pH-stat,* with its goal of maintaining $PaCO_2$ of 40 mm Hg and pH of 7.40 at the patient's actual temperature, results in higher $PaCO_2$ *(respiratory acidosis)*.[44–46]

HYPOXEMIA, HYPOXIA, AND ARTERIAL BLOOD GAS ANALYSIS

The PaO_2 is primarily used to assess oxygenation, and it is reliable within a dynamic range between 30 and 200 mm Hg; however, the reliability of the reported oxygen saturation of blood (SaO_2) ranges within a much narrower range: between 30 and 60 mm Hg.[47] The noninvasive method of measuring oxygen saturation by pulse oximetry (SpO_2) or by ABG analysis (SaO_2) is a better indicator of arterial oxygen content than PaO_2, because only ~2% of the oxygen is carried in dissolved form, and the greatest amount (98%) is carried by Hb. When using SpO_2, one has to be cognizant about its shortcomings, including interference by indicator dyes used during procedures.[48,49]

Hypoxemia is defined as a PaO_2 of less than 80 mm Hg in adults breathing room air; *hypoxia* denotes tissue- or cell-level decreases in oxygen availability. Thus tissue or end-organ hypoxia in patients with hypoxemia depends on the severity of the hypoxemia and the ability of the cardiovascular system to compensate. Hypoxia is unlikely to occur in response to mild hypoxemia itself (PaO_2 = 60–79 mm Hg) when cardiovascular reflexes and integrity remain intact. Moderate hypoxemia (PaO_2 = 45–59 mm Hg) may be associated with hypoxia in patients with anemia or cardiovascular dysfunction. Hypoxia is almost always present with severe hypoxemia at levels of PaO_2 <45 mm Hg. Although the PaO_2 might be low at 45 mm Hg, the mitochondrial oxygen partial pressure necessary to complete oxidative phosphorylation is around 0.5–3 mm Hg (i.e., several orders of magnitude lower), suggesting that this buffer may be a reason why some accommodated patients with cyanotic diseases and elite Everest climbers without supplemental oxygen might have an average PaO_2 of 26 mm Hg and yet survive without significant end-organ injury.[50–57]

Acute respiratory insufficiency occurs when the lungs no longer meet the metabolic demands of the body, which by tradition is divided into two types:

- Type I, hypoxemic respiratory insufficiency: PaO_2 ≤60 mm Hg when breathing room air at 1 atm.
- Type II, hypercapnic respiratory insufficiency: $PaCO_2$ ≥50 mm Hg.

The tripartite information that can be gathered from ABG analyses are (1) oxygen saturation and content, (2) CO_2 as a marker of ventilation, and (3) acid-base status. Here we discuss all three components.

Alveolar Ventilation

The arterial CO_2 partial pressure ($PaCO_2$) reflects the CO_2 content of the sample. The CO_2 content basically is the balance between the quantity of CO_2 produced and its excretion through alveolar ventilation (VA). This relationship can be expressed by the expression:

$$PaCO_2 \sim CO_2/VA$$

The alveolar ventilation is that portion of total ventilation that participates in gas exchange with pulmonary blood. If the metabolic rate remains unchanged and CO_2 production is assumed to be in steady state, then:

$$1/VA \sim PaCO_2$$

Therefore when steady state is reached, $PaCO_2$ becomes a useful tool assessing alveolar ventilation. If $PaCO_2$ is >45 mm Hg, it is *alveolar hypoventilation*, and if $PaCO_2$ is <35 mm Hg, it is called *alveolar hyperventilation* (primary or compensatory for metabolic disturbance).

Oxygenation

Tissue oxygenation depends on the delivery of oxygenated blood (both dissolved and bound to hemoglobin). The PaO_2 is the partial pressure of oxygen in the blood, and this dissolved fraction makes a very small direct contribution to oxygen delivery (<2%); yet even this quantity may be useful in the setting of severe anemia.[58,59] The PaO_2 is dependent on the fraction of inspired oxygen (FiO_2), ventilation and perfusion matching (V ~ Q), and the mixed venous oxygen saturation ($SmvO_2$). The PaO_2 must be assessed within a clinical context along with the inspired oxygen and age of the patient.

Relationship Between PaO_2 and FiO_2

The PaO_2 alone provides limited information about the efficiency of alveolar-capillary oxygen exchange unless FiO_2 is also considered in the interpretation. In addition to the FiO_2, the other major determinant of PaO_2 is the degree of intrapulmonary venous admixture and shunting (Fig. 34.1). Although PaO_2 and FiO_2 alone do not quantitate the intrapulmonary shunt in the diagnosis and management of lung diseases nor in themselves guide the approach to respiratory support, they provide an overall indication regarding the category and severity of diagnosis, after which various formulas could be used for calculating the intrapulmonary shunt.

The classic "shunt equation" requires mixed venous sampling through a pulmonary artery catheter and the alveolar-arterial oxygen gradient equation (Table 34.1):

$$Q_s/Q_t = (C_cO_2 - C_aO_2)/(C_cO_2 - C_vO_2),$$

where:

Q_s is blood flow through the shunt
Q_t is total cardiac output
C_cO_2 is pulmonary end-capillary O_2 content
C_aO_2 is arterial O_2 content
C_vO_2 is mixed venous O_2 content

Clinically the so-called "P/F ratio" (PaO_2/FiO_2) is most commonly used to approximately quantitate the degree of venous admixture,

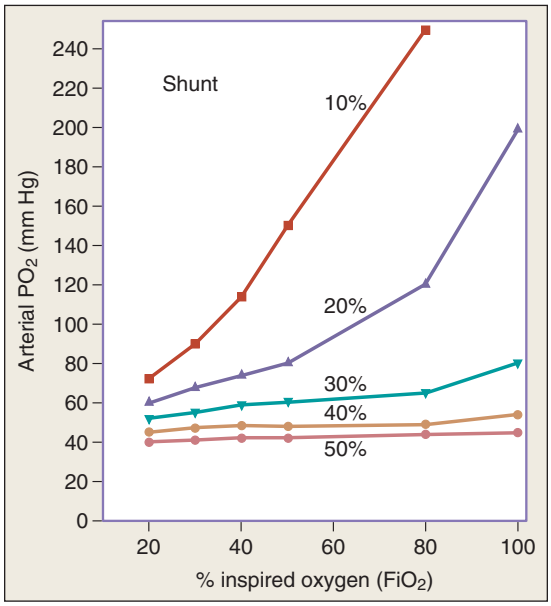

Fig. 34.1 The Effect on PaO_2 on Increasing FiO_2 According to Shunt Fraction.

TABLE 34.1 Formulas for Evaluating Gas Exchange in Patients

Age-adjusted PaO_2: Expected PaO_2 − 0.3 (age − 25)
Expected PaO_2 at 1 Torr is ~ 100 mg/Hb; an approximation could be done as: Expected PaO_2 ~ FiO_2 (%) * 5
The alveolar-arterial gradient: $AaDO_2 = (FiO_2 * (\text{barometric pressure} - 47)) - (PaO_2 + PaCO_2)$
Oxygenation index = ((mean airway pressure * FiO_2)/PaO_2) * 100
Dead space to tidal volume ratio: $Vd/Vt = (PaCO_2 - P_ECO_2)/PaCO_2$
The normal range is 20%–40%

composed of ventilation/perfusion mismatching (V/Q) and true shunt. Because the normal PaO_2 in an adult breathing room air with an FiO_2 21% is 80–100 mm Hg, the normal value for PaO_2/FiO_2 ranges between 400 and 500 mm Hg. A PaO_2/FiO_2 ratio of less than 200 most often indicates a shunt of greater than 20% of total cardiac output. This ratio has also been incorporated since 1994 into the ARDS definition.[60–62] When used in an unqualified fashion, a notable limitation of the PaO_2/FiO_2 ratio is that it does not take into account changes in $PaCO_2$ at low FiO_2, nor the influences of positive end-expiratory pressure (PEEP) and body position.

Age

Arterial oxygen tension decreases with age (see Table 34.1). For example, at age 60 years, FiO_2 21%, and 1 atmospheric pressure, the PaO_2 is 85–90 mm Hg; this value decreases to 80–85 mm Hg at the age of 80 years.

Acid-Base Balance

The normal diet generates volatile acid (from CO_2 production), primarily because of carbohydrate metabolism, and nonvolatile acids (e.g., phosphates and sulfates) from protein metabolism. The function of the homeostatic system is to maintain pH within a narrow range, and pH homeostasis is accomplished through the interaction of the lungs, kidneys, and blood buffers. Alveolar ventilation allows for excretion of CO_2, while the kidneys reclaim filtered bicarbonate (HCO_3^-)

excrete the daily acid load generated from dietary protein intake. Less than half of this acid load is excreted as *titratable acids* (i.e., phosphoric and sulfuric acids); the remaining acid load is excreted as ammonium. The blood pH is determined by the balance of these processes.[63]

The current mainstream understanding of the acid-base system dates back to the 1950s, when the concepts of the Henderson-Hasselbalch equation were combined with the Brønsted-Lowry theory, toward the *bicarbonate ion*–centered approach.[64,65] Stewart repackaged the pre-1950 ideas of acid-base in the late 1970s, including the Van Slyke definition of an acid. Using physical chemistry, Stewart promoted a new understanding of acid-base balance.[64,66] The resultant strong ion difference (SID) and the concentration of weak acids (particularly albumin) pushes bicarbonate into a minor role as an acid-base indicator rather than as an important mechanism:

$$SID = ([Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}]) - [Cl^-] + [lactate])$$

Although the SID is not the anion gap (AG), it does share a number of parameters, and the trends will often be close. The normal SID has not been well established, but the quoted range is 40–42 mEq/L. As the SID approaches zero, anions accumulate and the balance tilts towards acidity. This model makes it easier for clinicians to understand the commonly observed "hyperchloremic acidosis" after 0.9% saline administration and the systemic alkalosis of hypoalbuminemia (regarded as a weak acid).[67,68]

For practical reasons, the HCO_3^--centered approach is still more commonly used than the Stewart approach to understand and manage acid-base balance.[69] The Henderson-Hasselbalch equation describes the $pH = pK + \log (HCO_3^-/H_2CO_3)$. If all the constants are removed, the equation can be simplified to $pH = HCO_3^-/PaCO_2$. The HCO_3^- is controlled mainly by the kidney and blood buffers, whereas $PaCO_2$ is regulated by the lung adjustment of the blood level of volatile acid and carbonic acid. Buffer systems can act within a fraction of a second to prevent excessive changes in pH. The respiratory system takes about 1–15 minutes and the kidneys many minutes to days to readjust H^+ ion concentration. However, according to the Stewart approach, the use of bicarbonate increases the pH by increasing the sodium concentration of the plasma compared with chloride and not by simple addition of bicarbonate ions, as many of the latter rapidly convert to CO_2.[70] Although the use of bicarbonate is attractive and commonly practiced, we must use restraint in using bicarbonate in the critically ill without good justification. For example, a prospective study of 1700 patients with sepsis and acidosis who received bicarbonate in the first 2 days of hospital admission did not detect improved outcome.[71] Similarly, in a prospective randomized trial including 400 ICU patients with severe acidemia (pH <7.2, $PaCO_2$ 45 mm Hg, lactate >2 mM), early bicarbonate infusion with a pH goal >7.30 did not improve 28-day mortality or reduce the incidence of organ insufficiency.[72]

The Anion Gap

According to the principle of electrochemical neutrality, total **cations** must equal total **anions**, and so in considering the commonly measured cations and anions, a fixed number should be derived from their numeric difference. The measured cations are in excess; mathematically, this "gap" is automatically filled with unmeasured anions to preserve electrochemical neutrality. There is never a "real" AG; rather, it is an expression of nonroutinely measured anions. The AG is calculated using the following formula[73]:

$$AG = ([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-]) \text{ (Normal: } 10 \pm 2 \text{ mEq/L)*}$$

*Due to low concentration of K^+, it is not usually included in the calculation of AG.

During critical illness, albumin typically decreases rapidly, which is an important contributor to the "normal" AG. Therefore as the albumin concentration falls, it tends to reduce the size of the AG, or have an alkalinizing effect. Various corrections are available; however, Figge's AG correction (AG_{corr}) is most commonly used[73]:

$$\text{Albumin gap} = 40 - \text{measured albumin (normal albumin} \sim 40 \text{ g/L)}$$

$$AG_{corr} = AG + (\text{albumin gap}/4)$$

A STEPWISE APPROACH TO ACID-BASE DISORDERS

Step 1: Do a Comprehensive History and Physical Examination

The history and physical examination can often give clues as to the underlying acid-base disorder (Table 34.2). For example, severe diarrhea could lead to loss of HCO_3^- with subsequent *non–anion gap metabolic acidosis*. Patients with COPD would have chronic respiratory acidosis because of CO_2 accumulation counterbalanced by metabolic alkalosis, resulting in a normal pH.

Step 2: Order Simultaneous Arterial Blood Gas Measurement and Chemistry Profile

As mentioned in the previous section, the HCO_3^- is calculated in the ABG; therefore it is important to obtain a chemistry panel to have data that are actually measured. In addition, Na^+ and Cl^- provide additional information about the volume status and strong ion difference.[74–77]

Step 3: Check the Consistency and Validity of the Results

Normal ABG results are provided in Table 34.3.

Step 4: Identify the Primary Disturbance

With the ABG results in hand, the practitioner then has to determine whether the patient is significantly acidemic (pH <7.35) or alkalemic

TABLE 34.2 Common Clinical Presentations and Associated Acid-Base Disorders

Phenotype	Acid-Base Status
Pulmonary embolism	Respiratory alkalosis
Shock	Lactic acidosis (metabolic)
Sepsis	Metabolic acidosis and respiratory alkalosis
Vomiting	Metabolic alkalosis
Diarrhea	Metabolic acidosis
Acute kidney injury	Metabolic acidosis
Cirrhosis	Respiratory alkalosis
Pregnancy	Respiratory alkalosis
Diuretics	Metabolic alkalosis unless thiazides are used
COPD	Respiratory acidosis
Diabetic ketosis	Metabolic acidosis (ketoacidosis)
Ethylene glycol poisoning (antifreeze)	Metabolic acidosis
Excessive 0.9% saline use	Metabolic non-anion gap acidosis

COPD, Chronic obstructive pulmonary disease.

TABLE 34.3 Normal Acid-Base Values

	Mean	1 ± SD	2 ± SD
$PaCO_2$ (mm Hg)	40	38–42	35–45
pH	7.4	7.38–7.42	7.35–7.45
HCO_3^-	24	23–25	22–26

TABLE 34.4 Acid-Base Disorders

Phenotype	Diagnostic Criteria
Respiratory acidosis	$PaCO_2$ >45 mm Hg
Respiratory alkalosis	$PaCO_2$ <35 mm Hg
Acute respiratory acidosis	$PaCO_2$ >45 mm Hg and pH <7.35
Chronic respiratory acidosis	$PaCO_2$ >45 mm Hg and pH = 7.36–7.44
Acute respiratory alkalosis	$PaCO_2$ <35 mm Hg and pH >7.45
Chronic respiratory alkalosis	$PaCO_2$ <35 mm Hg and pH = 7.36–7.44
Acidemia	pH <7.35
Alkalemia	pH >7.45
Acidosis	HCO_3^- < 22 mEq/L
Alkalosis	HCO_3^- >26 mEq/L

TABLE 34.5 Compensation Formulas for Simple Acid-Base Disorders

Acid-Base Disorder	Compensation
Metabolic acidosis	Change in $PaCO_2$ = 1.2 × change in HCO_3^-
Metabolic alkalosis	Change in $PaCO_2$ = 0.6 × change in HCO_3^-
Acute respiratory acidosis	Change in HCO_3^- = 0.1 × change in $PaCO_2$
Chronic respiratory acidosis	Change in HCO_3^- = 0.35 × change in $PaCO_2$
Acute respiratory alkalosis	Change in HCO_3^- = 0.2 × change in $PaCO_2$
Chronic respiratory alkalosis	Change in HCO_3^- = 0.5 × change in $PaCO_2$

(pH >7.45) and what the primary cause is (metabolic, driven by HCO_3^-, or respiratory, driven by CO_2) (Table 34.4).

Step 5: Calculate the Expected Compensation

Any alteration in acid-base equilibrium sets into motion a compensatory response by either the lungs or the kidneys. The compensatory response attempts to return the ratio between $PaCO_2$ and HCO_3^- to normal with subsequent normalization of pH. Compensation is usually predictable; the adaptive responses for the simple acid-base disorders have been quantified experimentally[78] (Table 34.5). One then has to evaluate the compensatory responses and any secondary (uncompensated) acid-base disturbances.

Step 6. Calculate the "Gaps"

Calculate the Anion Gap

In high-AG metabolic acidosis, acid dissociates into H^+ and an unmeasured anion. H^+ is buffered by HCO_3^-, and the unmeasured anion accumulates in the serum, resulting in an increase in AG. In non–AG metabolic acidosis, H^+ is accompanied by Cl^- (a measured anion); therefore there is no change in AG. Acid-base disorders may present as two or three coexisting disorders. It is possible for a patient to have an acid-base disorder with normal pH, $PaCO_2$, and HCO_3^-, the only clue to an acid-base disorder being an increased AG. If the AG is increased by more than 5 mEq/L (i.e., an AG >15 mEq/L), the patient most likely has a metabolic acidosis. Compare the fall in plasma HCO_3^- ($25 - HCO_3^-$) with the increase in the plasma AG (ΔAG); these should be of similar magnitude. If there is a gross discrepancy (>5 mEq/L), then a mixed disturbance is present.

The **anion gap** is calculated by subtracting the serum concentrations of chloride and bicarbonate (**anions**) from the concentrations of sodium (**cations**):

$$([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-])^*$$

- If increase in the AG exceeds the fall in HCO_3^-, it suggests that a component of the metabolic acidosis is a result of HCO_3^- loss.
- If the increase in AG is less than the fall in HCO_3^-, this suggests coexisting metabolic alkalosis.

TABLE 34.6 Causes of an Increased Osmolal Gap

Ethylene glycol	Alcohol
Methanol	Isopropyl alcohol (nongap)
Mannitol	Sorbitol
Paraldehyde	Acetone

Osmolar Gap

Calculate the osmolar gap in patients with an unexplained AG metabolic acidosis to exclude ethylene glycol or methanol toxicity (Table 34.6). The serum osmolality is calculated as:

$$2 \times [Na^+] + [\text{Glucose}]/18 + [\text{BUN}]/2.8$$

with normal levels ranging around 280–290 mOsm/kgH_2O

The osmolal gap is defined as the difference between measured and calculated osmolality:

$$\text{Osmolar gap} = \text{Osmolality}_{\text{measured}} - \text{Osmolality}_{\text{calculated}}$$

(normal value less than or equal to 10 mOsm/kg H_2O)

COMMON ACID-BASE DISTURBANCES IN THE ICU

Metabolic Acidosis

The rate and degree of metabolic acidosis mainly depend on the underlying cause and the rapidity with which the causative condition develops. An acute, severe metabolic acidosis results in myocardial depression with a reduction in cardiac output, decreased blood pressure, and decreased hepatic and renal blood flows; the cardiovascular system also becomes less responsive to vasopressor agents.[79] Reentrant arrhythmias and a reduction in the ventricular fibrillation threshold can occur.[80]

The acute correction of metabolic acidosis has been a standard of care for intractable metabolic acidosis during acute coronary events; however, clinical trials did not show improved outcomes and led to paradoxical central nervous system acidosis, leading subsequently to its removal from current advanced cardiovascular life support (ACLS) algorithms.[81–83]

A metabolic acidosis in the critically ill patient requires an aggressive approach to the diagnosis and management of the underlying causes (Fig. 34.2 and Table 34.7). In most patients the causes are

*Because of the low concentration of K^+, it is not usually included in the calculation of AG.

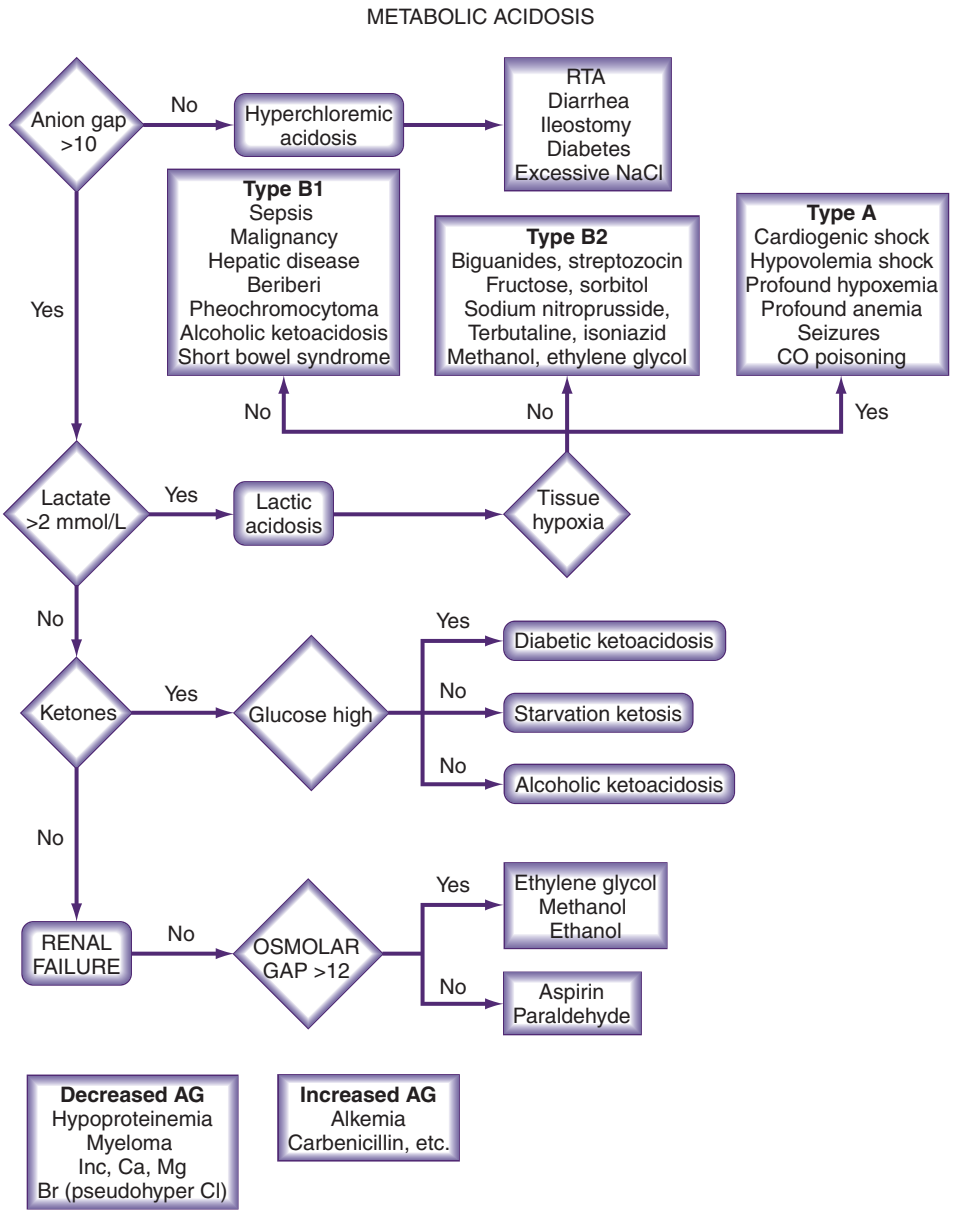

Fig. 34.2 Algorithm for Diagnosing Metabolic Acidosis.

TABLE 34.7 Causes of Metabolic Acidosis

Increased Anion Gap	Normal Anion Gap
Acute kidney injury	Hypokalemic acidosis
Rhabdomyolysis	Hyperkalemic acidosis
Ketoacidosis	
Lactic acidosis	
Toxins: 5-oxoproline	
Beriberi	

clinically obvious, with lactic acidosis (tissue hypoxia or sepsis), ketoacidosis, and acute kidney injury (AKI) being the most common.[84–86] In patients with an unexplained AG metabolic acidosis, drugs such as salicylates, methanol, or ethyleneglycol toxicity should always be considered.[87,88] Accumulation of 5-oxoproline related to the use of acetaminophen is a rare cause of an AG metabolic acidosis.[89] Long-term use of lorazepam can result in the accumulation of its vehicle, propylene glycol, resulting in worsening AKI, metabolic acidosis, and altered mental status.[90,91] Propylene glycol toxicity is typically observed after prolonged (>7 days), high-dose (average 14 mg/h), continuous lorazepam infusion and can be recognized by an increased osmolar gap.[92] Similarly, first reported in children and then recognized also in adults, prolonged high-dose propofol (>100 μg/kg/min) is occasionally associated with the "propofol infusion syndrome" characterized by rhabdomyolysis, metabolic acidosis, and renal and cardiac failure, requiring vigilance and early cessation of sedation and use of alternatives.[93,94] It has also been suggested that frequent assessment of creatinine kinase or lipid panels would alert the clinicians of an impending "propofol infusion syndrome."[95]

The prognosis is related to the underlying disorder causing the acidosis. In almost all circumstances, the treatment of a metabolic acidosis involves treatment of the underlying disorder. Except in specific

circumstances, there is no scientific evidence to support treating a metabolic or respiratory acidosis with sodium bicarbonate.[96] However, independent of the underlying cause, use of bicarbonate among critically ill patients may help restore cardiovascular responsiveness to vasoactive agents.[97] Bicarbonate increases hemoglobin-oxygen affinity, known as the *Bohr effect,* leading to potential tissue hypoxemia,[98] hypertonic state, and low plasma calcium concentrations because of albumin chelation.[99] Furthermore, the intracellular pH is a determinant of cellular function. The intracellular buffering system, including proteins, is much more effective in restoring pH to normal than are extracellular buffers.[100,101] Consequently, patients may tolerate a pH as low as 7.00 during sustained hypercapnia without obvious adverse effects. Paradoxically, sodium bicarbonate can decrease intracellular pH in circumstances where CO_2 elimination is fixed. In addition, infusion of bicarbonate can lead to a variety of problems in patients with acidosis, including fluid overload, hypernatremia, and postrecovery metabolic alkalosis. Furthermore, studies in both animals and humans suggest that alkali therapy may only transiently raise the plasma bicarbonate concentration. This finding appears to relate in part to CO_2 generated as the administered bicarbonate buffers excess hydrogen ions. Unless the minute ventilation (M_V) is increased in ventilated patients, CO_2 elimination will not increase and paradoxically may worsen the intracellular acidosis. Currently, there are no data to support the use of bicarbonate in patients with lactic acidosis.[96,102]

Bicarbonate is frequently administered to "correct the acidosis" in patients with diabetic ketoacidosis (DKA). However, paradoxically, bicarbonate has been demonstrated to increase ketone and lactate production.[103] Studies have demonstrated an increase in acetoacetate levels during alkali administration, followed by an increase in 3-hydroxybutyrate levels after its completion.[103,104] In pediatric patients, treatment with bicarbonate may prolong hospitalization.[105] In addition, bicarbonate may decrease cerebrospinal fluid (CSF) pH as increased CO_2 produced by buffering acid crosses the blood-brain barrier, combines with H_2O_2, and regenerates H^+. Therefore the general consensus is that adjunctive bicarbonate is unnecessary and potentially disadvantageous in severe DKA.[81]

Bicarbonate is considered "lifesaving," however, in patients with severe ethylene glycol and methanol toxicity. In hyperchloremic acidosis, endogenous regeneration of bicarbonate cannot occur (bicarbonate has been lost rather than buffered). Therefore even if the cause of the acidosis can be reversed, exogenous alkali is often required for prompt attenuation of *severe acidemia*. Bicarbonate therapy therefore is indicated in patients with severe *hyperchloremic acidosis* when the pH is less than 7.2; this includes patients with severe diarrhea, high-output fistulas, and renal tubular acidosis. To prevent hypernatremia, 3 × 50 mL ampules of $NaHCO_3^-$ (each containing 50 mmol of $NaHCO_3^-$) may be added to 1 L of 5% dextrose water and infused at a rate of 100–200 mL/h.

Lactic Acidosis

Lactate is the by-product of pyruvate use, and it is converted by lactate dehydrogenase. Either in hypoxia or during sepsis, lactic acid is preferentially produced. Lactic acid, like most substances with a pKa of less than 4 (pKa 3.78), circulates almost entirely as the freely dissociated anion, lactate (i.e., it releases its proton) at physiologic pH—strongly favoring the rightward diving of this equation:

$$CH_3CHOCOOH \leftrightarrow CH_3CHOCOO^- + H^+$$

Hyperlactatemia refers to an elevated plasma concentration of lactate anions. In clinical practice, *lactic acidemia* is defined as a pH less than 7.35 with a lactate concentration greater than 4 mmol/L. Lactic acidemia typically develops as a result of endogenously produced lactic acid, with lactate being measured as the dissociated base. During critical illness, the source of lactate is often believed to be ischemic anaerobically metabolizing tissues, such as the gut and muscle. In addition to ischemia, the Warburg effect with dysregulated glycolysis is a major nonischemic cause for lactatemia.[106,107] Furthermore, it should be noted that both the pH and AG are insensitive markers of an elevated lactate; patients with an elevated lactate level may have a normal pH and AG.[108] According to the Stewart interpretation, lactic acidosis occurs because of an increase in strong anions. As for other causes of metabolic acidosis, the Surviving Sepsis Campaign guidelines do not suggest the use of bicarbonate for plasma pH >7.15 among patients with lactic acidosis.[109]

D-Lactic Acidosis

Certain bacteria and viruses in the gastrointestinal (GI) tract may convert carbohydrates into organic acids or promote lactate dehydrogenase (LDH) activity.[110,111] The two factors that make this possible are slow GI transit (blind loops, obstruction) and change of the normal flora (usually with antibiotic therapy).[112] The most prevalent organic acid is D-lactic acid. Because humans metabolize this isomer more slowly than L-lactate and production rates can be very rapid, life-threatening acidosis can be produced.[113] The usual laboratory test for lactate is specific for the L-lactate isomer. Therefore to confirm the diagnosis, the plasma or more easily tested urinary D-lactate must be specifically requested.[114]

Metabolic Alkalosis

Metabolic alkalosis is a common acid-base disturbance in ICU patients characterized by an elevated serum pH (>7.45) secondary to plasma bicarbonate (HCO_3^-) retention. Metabolic alkalosis is usually the result of several therapeutic interventions in the critically ill patient (Table 34.8). Nasogastric drainage, diuretic-induced intravascular volume depletion, hypokalemia, and the use of corticosteroids are common causes of metabolic alkalosis in these patients. In addition, citrate in transfused blood is metabolized to bicarbonate, which may compound the metabolic alkalosis. Type II respiratory failure promotes compensatory retention of bicarbonate that may result in a posthypercapnic metabolic alkalosis when ventilation is normalized. In many

TABLE 34.8 Causes of Metabolic Alkalosis

Low Urine Chloride (Volume or Saline Responsive)	High Urine Chloride With Hypertension
Gastric volume loss	Primary and secondary hyperaldosteronism
Diuretics	Apparent mineralocorticoid excess
Posthypercapnia	Liddle's syndrome (autosomal dominant, pseudoaldosteronism)
Villous adenoma (rare)	Conn syndrome
Cystic fibrosis (if there has been excessive sweating)	Cushing disease
High Urine Chloride Without Hypertension	
Bartter syndrome	
Gitelman syndrome (autosomal recessive hypokalemic metabolic alkalosis)	
Excess bicarbonate administration	

patients, therefore, events that generated the metabolic alkalosis may not be present at the time of diagnosis.

Metabolic alkalosis may adversely affect cardiovascular, pulmonary, and metabolic function. It can decrease cardiac output, depress central ventilatory drive, shift the oxyhemoglobin saturation curve to the left (decreasing the offloading of hemoglobin-bound oxygen), worsen hypokalemia and hypophosphatemia, and negatively affect the ability to wean patients from mechanical ventilation. Rising serum pH has been shown to correlate with ICU mortality. Correction of metabolic alkalosis has been shown to increase minute ventilation, increase arterial oxygen tension and mixed venous oxygen tension, and decrease oxygen consumption. It is therefore important to correct significant metabolic alkalosis in the majority of critically ill patients. In the case of cardiac arrest, it is also challenging to correct metabolic alkalosis in a rapid fashion.[115–117]

The first therapeutic maneuver in patients with a metabolic alkalosis is to replace any volume deficit with normal saline (0.9% NaCl) and correct electrolyte deficiencies. Aggressive potassium supplementation is warranted to achieve a K^+ above 4.5 mEq/L. If these interventions fail, ammonium chloride, hydrochloric acid, or arginine hydrochloride may be given.[117,118] The disadvantage of these solutions is that they are difficult to use and require the administration of large volumes of hypotonic fluid. Extravasation of hydrochloric acid (even at 20–25 mmol/h) may result in severe tissue necrosis, mandating administration through a well-functioning central line. Acetazolamide is a carbonic anhydrase inhibitor promoting the renal excretion of bicarbonate and has been demonstrated to be effective in treating metabolic alkalosis in ICU patients. A single dose of 500 mg is recommended. The onset of action is within 1.5 hours, with duration of approximately 24 hours, and doses may be repeated.[117,119–121]

Respiratory Acidosis

Respiratory acidosis is also a common occurrence among the acutely ill, especially in those who are not mechanically ventilated, in addition to patients receiving lung-protective mechanical ventilation.[122] Failing respiratory muscles, pain preventing effective breathing, increased abdominal pressures, and centrally acting agents that suppress respiratory drive all depress ventilation, leading to increased CO_2 retention with subsequent respiratory acidosis. Among these patients, treating the underlying cause would lead to definite resolution, yet temporizing measures such as mechanical ventilation would be required.

In patients on lung-protective modes of mechanical ventilation, the so-called "permissive hypercapnia" itself has been suggested to have directly beneficial effects, yet later evidence did not support this contention.[123]

Respiratory Alkalosis

Respiratory alkalosis is induced by hyperventilation with causes originating from *central, hypoxemic, pulmonary,* and *iatrogenic* causes. Central causes include head injury, stroke, hyperthyroidism, anxiety-hyperventilation, pain, fear, stress, drugs, medications such as salicylates, and various toxins. In the case of medication-induced respiratory alkalosis, the ABG and further studies with toxicology panel would help to identify the causes. Hypoxia could lead to hyperventilation to correct hypoxia at the expense of CO_2 loss. Pulmonary causes include pulmonary embolisms, pneumothorax, pneumonia, and acute asthma or COPD exacerbations. Iatrogenic causes are almost universally induced by hyperventilation among intubated patients receiving mechanical ventilation support.[124]

Respiratory alkalosis may be an acute process or a chronic process. These are determined based on the level of metabolic compensation for the respiratory disease. Excess HCO_3^- levels are buffered to reduce levels and maintain a physiologic pH through the renal decrease of H^+ excretion and increasing HCO_3^- excretion; however, this metabolic process occurs over the course of days, whereas respiratory disease can adjust CO_2 levels in minutes to hours. Therefore acute respiratory alkalosis is associated with high bicarbonate levels because there has not been sufficient time to lower the HCO_3^- levels, and chronic respiratory alkalosis is associated with low to normal HCO_3^- levels.[1,8,9]

VENOUS BLOOD GAS ANALYSIS

There is a strong correlation between arterial and venous blood pH and HCO_3^- levels in patients with DKA and uremia.[120,121] In published studies, the difference between arterial and venous pH varied from 0.04 to 0.05, and the difference in bicarbonate levels varied from −1.72 to 1.88. However, the correlation between arterial and venous $PaCO_2$ was relatively poor.[125–127] Actually, this difference may be used to evaluate the adequacy of oxygen availability to the tissues (see later). Similarly, an excellent correlation has been demonstrated between mixed venous pH and HCO_3^- with arterial pH and HCO_3^- in critically ill patients.[128,129] Yet in shock states this tight association does not hold true; the correlation between arterial and venous pH, HCO_3^- and $PaCO_2$ is poor.[130,131] During cardiopulmonary resuscitation, the arterial blood vs. mixed venous blood pH were 7.41 vs. 7.15; likely $PaCO_2$ was 32 mm Hg vs. 74 mm Hg, respectively.[132,133]

Once shock is resolved, in patients without hypercarbia, ABG would not be necessary; pulse oximetry and venous blood gas analysis would be enough to make a clinical judgment. Furthermore, a venous blood gas can be useful to screen for arterial hypercarbia, with a venous $PvCO_2$ of >45 mm Hg being highly predictive of arterial hypercarbia.[134]

Mixed Venous/Central Venous Oxygen Saturation

Monitoring of SvO_2 has been used as a surrogate for the balance between systemic oxygen delivery and consumption during the treatment of critically ill patients.[135] An SvO_2 of less than 65% indicates inadequate oxygen delivery; however, this sample needs to be collected from the distal post of a pulmonary artery catheter (PAC), an invasive device whose use has not been shown to routinely improve patient outcome. Therefore most clinicians use the central venous oxygen saturation ($ScvO_2$) as a surrogate.[136,137]

There are multiple reasons why $ScvO_2$ and SvO_2 can differ. First of all, the vena caval blood streams into the right atrium and ventricle, and complete mixing occurs only during ventricular contraction. In addition, blood from the coronary sinus and Thebesian veins results in further discrepancies.[138,139] Thus SvO_2 is a better indicator of whole-body balance of oxygen supply and demand, whereas $ScvO_2$ more closely reflects the status of upper body tissues. In hemodynamically stable, healthy patients, $ScvO_2$ is usually 2%–5% less than SvO_2 because of the high oxygen content of effluent venous blood from the kidneys.[140] This changes during shock as blood is redistributed to the upper body at the expense of the splanchnic and renal circulations. In shock states, $ScvO_2$ may exceed that of SvO_2 by up to 20%.[141] This tendency also applies in patients with cardiogenic, septic, and hemorrhagic shock.[142] Therefore one has to assess these saturation values within the context of the clinical scenario.[137,141,143–147] In patients with sepsis and liver failure, a low $ScvO_2/SvO_2$ is usually indicative of decreased cardiac output, and normal values do not necessarily indicate resuscitation or adequate tissue oxygenation.[148–150] In liver failure, all pathologic collaterals may result in "arterialization" of the venous blood. In addition, cytopathic hypoxia (e.g., because of cyanide) may further decrease oxygen uptake and result in a

"spuriously high" $ScvO_2$.[151] Interestingly, patients dying of both sepsis and liver failure usually have a high $ScvO_2/SvO_2$.[152] In a recent goal-directed sepsis study, the mean $ScvO_2$ was 74% at enrollment, and less than 10% of patients required specific interventions to achieve values above 70%.[153]

In addition, a high mixed venous-to-arterial PCO_2 gradient is a predictor of decreased cardiac output and global tissue ischemia.[154–156] This observation has been confirmed by Adrogue et al, Mecher et al, Bakker et al, Levy et al, and Nassar et al, who demonstrated that a high mixed venous-to-arterial PCO_2 gradient is a sensitive marker of global tissue ischemia and fluid responsiveness during cardiogenic and septic shock.[133,157–160] Recent work suggests that central venous-to-arterial PCO_2 gradient (>6 mm Hg) reliably indicates success of resuscitation in septic shock.[161]

In summary, for hemodynamically unstable patients and those with complex acid-base disorders, as a rule of thumb, venous blood gas cannot be substituted for an ABG analysis. In these situations, both arterial and mixed venous/central venous blood gas analyses provide useful information.

KEY POINTS

- ABG analysis is the gold standard for the assessment of oxygenation, ventilation, and acid-base status for critically ill patients as long as it is obtained and interpreted within the clinical context.
- Pulse oximetry can provide a surrogate measure of arterial oxygen tension (PaO_2). Venous pH and bicarbonate (HCO_3^-) allow for the estimation of arterial pH and HCO_3^- in hemodynamically stable patients, yet one needs to be cautious during shock states. Venous carbon dioxide tension is a poor proxy of arterial $PaCO_2$. Venous blood gas analysis can be useful to screen for arterial hypercarbia, with a venous PCO_2 level above 45 mm Hg being highly predictive of arterial hypercarbia.
- The indications for ABG sampling have not been well defined; however, an ABG should generally be performed on admission to the ICU, after endotracheal intubation, and as the clinical context changes.
- ABG sampling does not have to be performed after each ventilator change or after each step during liberation from the ventilator.
- Because metabolic acidosis may have serious hemodynamic consequences, its etiology has to be determined and treatment initiated immediately.
- In most clinical situations, sodium bicarbonate ($NaHCO_3$) is of no therapeutic utility during metabolic acidosis.
- In patients with a metabolic alkalosis, correct any volume and potassium deficits first, then consider initiating acetazolamide and/or HCl infusions.
- The central venous oxygen saturation ($ScvO_2$) and the central venous-to-arterial $PaCO_2$ gap have utility in assessing the adequacy of resuscitation and oxygen delivery.

ANNOTATED REFERENCES

The traditional vs. the new perspective on acid-base balance:

Although the bedside clinician needs a handy tool to understand the acid-base balance to diagnose and manage their patients appropriately, the academic disagreements are still viable on the topic of acid-base balance. In summary, the traditional approach suggests that activity of H^+ in a biologic space is determined by the mass balance of H^+; proton transfer reactions via proton donors (weak acids) and proton acceptors (weak bases); and mass balance of proton donors and proton acceptors (Arrhenius, Sørenson, Henderson, Hasselbalch, Brønsted and Lowry, Van Slyke, Lewis, Severinghaus, Astrup, Siggard-Anderson, Schwartz, and Relman).

In 1978 Stewart questioned the traditional dogma by proposing that a complex mixture of ions regulates the activity of H^+ over the physiologic pH range (Na^+, K^+, Ca^{2+}); nonvolatile proton donators/acceptors transfer H^+ within the physiologic pH range (albumin, phosphate, hemoglobin, metabolizable organic compounds); and the volatile bicarbonate-CO_2 buffer system is composed of CO_2, HCO_3^-, H_2CO_2, and CO_3^{2-}. The following are useful literature articles on the topic.

Elbers PW, Van Regenmortel N, Gatz R. Over ten thousand cases and counting: acidbase.org is serving the critical care community. *Anaesthesiol Intensive Ther*. 2015;47(5):441–448.

A new reference of a handy online web tool to understand acid-base balance and the freely available textbook of Dr. Stewart. The web tool helps calculate the strong ion difference.

Kurtz I, Kraut J, Ornekian V, et al. Acid-base analysis: A critique of the Stewart and bicarbonate-centered approaches. *Am J Physiol Renal Physiol*. 2008;294(5):F1009–F1031.

The authors support the idea that the H^+/HCO_3^- approach based on the Henderson-Hasselbalch equation is mechanistically more robust than the Stewart or strong ion approach. Accordingly, CO_2/HCO_3^- is useful in the hands of the clinicians to approach all the acid-base derangements seen clinically; however, it is qualitative in nature and cannot quantify acid or base loads that result in metabolic acid-base disorders despite the concomitant use of base excess information—all leading to the argument for a more quantitative measurement: the Stewart approach. However, both are "equilibrium equations" and have similar predictive value for clinical acid-base disorders, suggesting the favorite approach by the authors is the Henderson-Hasselbalch equation.

Oxygen tension: From a global perspective to a regional assessment

The concept of partial pressure of oxygen measured in arterial blood gas analyses could be easily applied to oxygen tension measurements in regional perfusion. A recent work on brain tissue oxygen tension is relevant to the intensivist.

Rosenthal G, Hemphill III JC, Sorani M, et al. Brain tissue oxygen tension is more indicative of oxygen diffusion than oxygen delivery and metabolism in patients with traumatic brain injury. *Crit Care Med*. 2008;36(6):1917–1924.

The specific determinants of low brain tissue oxygen tension ($P_{bt}O_2$) after severe traumatic brain injury (TBI) remain poorly defined as to whether it reflects cerebral oxygen diffusion or cerebral oxygen delivery and metabolism. The group measured $P_{bt}O_2$ directly and the cerebral venous blood gases from a jugular bulb venous catheter. After multiple models of logistic regression, there is a strong association between brain tissue oxygen tension and diffusion of dissolved plasma oxygen across the blood-brain barrier, suggesting that $P_{bt}O_2$ represents the cerebral blood flow and cerebral arteriovenous O_2.

Other uses of CO_2 measurements: Evidence is suggesting that CO_2 could be used as endpoints for resuscitation in sepsis

Al Duhailib Z, Hegazy AF, Lalli R, et al. The use of central venous to arterial carbon dioxide tension gap for outcome prediction in critically ill patients: A systematic review and meta-analysis. *Crit Care Med*. 2020;48(12):1855–1861.

This review included 21 studies (n = 2155 patients) from medical (n = 925), cardiovascular (n = 685), surgical (n = 483), and mixed (n = 62) ICUs

comparing central CO_2 gap. A high CO_2 gap was associated with higher lactate levels (mean difference 0.44 mmol/L; 95% confidence interval [CI], 0.20–0.68 mmol/L; P = .0004), lower cardiac index (mean difference, −0.76 L/min/m; 95% CI, −1.04 to −0.49 L/min/m; P = .0001), central venous oxygen saturation (mean difference, −5.07; 95% CI, −7.78 to −2.37; P = .0002), and increased mortality (odds ratio, 2.22; 95% CI, 1.30–3.82; P = .004) in patients with shock. Yet it was not associated with longer ICU or hospital length of stay, requirement for renal replacement therapy, longer duration of mechanical ventilation, or higher vasopressors and inotropes use. The working hypothesis for the increased CO_2 gap is decreased cardiac output, yet this has to be tested further.

Guzman JA, Dikin MS, Kruse JA. Lingual, splanchnic, and systemic hemodynamic and carbon dioxide tension changes during endotoxic shock and resuscitation. *J Appl Physiol.* 2005;98(1):108–113.

The authors studied LPS-induced circulatory shock and resuscitation sublingual and intestinal mucosal blood flow and PCO_2 in a canine model. The shock did induce increased sublingual and splanchnic PCO_2, and the levels were nearly reversed after fluid resuscitation while the systemic hypotension persisted. Changes in sublingual and splanchnic PCO_2 paralleled gastric and intestinal PCO_2 changes during shock but not during resuscitation. This and other work suggest the utility of PCO_2 in estimating tissue perfusion.

Mesquida J, Saludes P, Gruartmoner G, et al. Central venous-to-arterial carbon dioxide difference combined with arterial-to-venous oxygen content difference is associated with lactate evolution in the hemodynamic resuscitation process in early septic shock. *Crit Care.* 2015;19:126.

Because normal or high central venous oxygen saturation $ScvO_2$ values cannot discriminate if tissue perfusion is adequate, other markers of tissue hypoxia are required. The authors studied the ratio of central venous-to-arterial carbon dioxide difference ($PcvaCO_2$ gap) to arterial-venous oxygen content difference ($CavO_2$) ratio to predict lactate evolution in septic shock. The high $PcvaCO_2/CavO_2$ ratio had a high predictive power towards no improvement in lactate clearance. The regional oxygen concentration (ROC) had an area under the curve (AUC) of 0.82, and when the $PcvaCO_2/CavO_2$ ratio was set at 1.4 mm Hg ⋮ dL/mL O_2, it carried a sensitivity of 0.80 and specificity of 0.75 for lactate improvement. This ratio and the use of PCO_2 could be used towards predicting the outcome from sepsis.

Tracheal Intubation

June M. Chae, John D. Davies, and Alexander S. Niven

INTRODUCTION

Tracheal intubation is a commonly performed, high-risk procedure in critically ill patients. There are important differences between elective intubation in the operating room compared with emergency intubation in the intensive care unit (ICU). Risks associated with emergent intubation in the critically ill include hypoxemia, hemodynamic instability, cardiac arrest, and death, underlining the importance of a systematic approach to optimize physiologic conditions and maximize first-attempt success. Although a wide variety of advanced airway devices are now available to help overcome anatomic difficulties and deliver rescue oxygenation, the best evidence-based approach for utilizing these tools in the ICU patient remains poorly defined. The goal of this chapter is to provide a systematic approach using best evidence to maximize the success and safety of tracheal intubation in the ICU.

PATIENT FACTORS AND AIRWAY ASSESSMENT

Reported complication rates from tracheal intubation in the critically ill range from 4.2% to 22% and remain unacceptably high in comparison with operating room procedures.[1–5] The Fourth National Audit Project of the Royal College of Anaesthetists and the Difficult Airway Society (NAP4) reported that 25% of adverse airway events occurred in the ICU and emergency department (ED). Inadequate identification of high-risk patients combined with poor planning, inadequate preparation, and ineffective teamwork were the primary causal and contributing factors to these adverse events.[6]

Physiologic Assessment

Decompensated cardiopulmonary disease and shunt physiology make preoxygenation more difficult in the critically ill, shortening the safe apnea time during intubation before hypoxemia develops.[7] Hemodynamic instability is an independent predictor of death after intubation, underscoring the importance of an individualized approach to high-risk patients, including those with severe valvular disease, pulmonary hypertension, right ventricular failure, and high shock index.[8–10] The combination of desaturation and hypotension increases the likelihood of cardiac arrest.[8]

Anatomic Assessment

Emergent airway management leaves little time to perform a thorough airway assessment and less time to plan the approach when high-risk features are present. In conscious and cooperative patients, an inability to bite the upper lip with the lower incisors may be the single best predictor of difficult laryngoscopy.[11] Other features predict difficult laryngoscopy. These include those that limit the ability to open the airway (interincisor distance, large tongue), displace the tongue into the submental space (large tongue, short mandible, short thyromental and hyomental distances), and/or impair alignment of the visual axes (cervical mobility).[12] Features that predict difficult bag-valve-mask ventilation (BMV) include obesity, facial hair, advanced age, history of sleep apnea, and being edentulous. Features that predict difficult supraglottic device use include restricted mouth opening, a distorted airway, reduced lung compliance, and upper airway obstruction.

Common methods of airway assessment are limited in their ability to correctly identify patients with a difficult airway (positive predictive value, 4%–27%).[13,14] The MACOCHA score, a seven-item prediction scale for the critically ill, is the only validated tool for identifying high-risk patients.[15,16]

OPTIMIZING AIRWAY MANAGEMENT IN THE CRITICALLY ILL

Positioning

Optimal patient positioning is important to maximize the success of both preoxygenation and laryngoscopy attempts. Upright positioning can optimize functional residual capacity (FRC), especially in obese and pregnant patients, which combined with careful preoxygenation, can prolong the safe apnea time during intubation.[12] A recent randomized trial showed increased difficulty with direct laryngoscopy using the "ramped" position (head of bed elevated 25 degrees, face parallel to the floor) compared with the "sniffing" position (supine, neck flexed, head extended).[17] Combining ramped with sniffing positions may improve first-pass intubation success, especially in obese patients.

Preoxygenation and Apneic Oxygenation

Critically ill patients run higher risks of life-threatening hypoxemia. Preoxygenation is generally limited by the size of the FRC and the ability to denitrogenate this space. In the critically ill, the degree of physiologic shunting is a major limiting factor to preoxygenation. Rapid-sequence intubation has an inherent delay of 45–90 seconds between medication administration and laryngoscopy.[18] A recent multicenter trial demonstrated that mask ventilation during the apneic period after induction reduced the incidence of severe hypoxemia without increased aspiration risk.[19] Noninvasive positive pressure ventilation (NIV) and high-flow nasal cannula (HFNC) have been shown to improve preoxygenation. A randomized trial failed to demonstrate clear benefit with routine apneic oxygenation in the critically ill, and this practice remains controversial.[20] In patients with refractory hypoxemia there is no safe apnea time, and awake intubation should be strongly considered when oxygenation can be assured during the procedure.

Rescue Oxygenation

Avoiding hypoxemia is essential to preserve safe patient conditions during intubation. If oxygen saturations drop significantly during this

procedure, the first rescue maneuver is the two-person BMV technique using an oropharyngeal airway and meticulous attention to patient positioning. If this maneuver proves inadequate, a second-generation supraglottic airway should be used expediently.[12,21,22] Airway managers must also be prepared to perform an emergent cricothyrotomy when a definitive airway cannot be secured and life-threatening hypoxemia persists after such maneuvers.

Hemodynamics

Critically ill patients are at risk for periprocedural hypotension, which can lead to cardiac arrest.[8] Hypotension during intubation occurs commonly, often the result of decreased circulating catecholamines, the physiologic effects of many induction medications such as increased venous capacitance after their administration, and decreased venous return from positive pressure ventilation.[23] Push-dose vasopressors with phenylephrine, ephedrine, and epinephrine can be considered; norepinephrine and epinephrine are more commonly used for continuous infusion.[24] Although a routine intravenous fluid bolus before induction as part of an "intubation bundle" has been shown to reduce the incidence of associated cardiovascular collapse in a single-center quality improvement intervention, this practice remains controversial because of a recent multicenter trial that demonstrated no attributable benefit.[3,23]

Soiled Airway

A soiled airway increases the risk for aspiration complications and decreases first-pass success. Emesis, hematemesis, and hemoptysis are more often encountered during emergency airway management. Training in the management of soiled airways is also limited. Although poorly studied, the suction-assisted laryngoscopy and airway decontamination (SALAD) technique has proved popular with many emergency airway managers. This technique involves passing the tip of a rigid (Yankauer) suction catheter from the left side of the mouth into the proximal esophagus after the upper airway is cleared to control further airway soilage during the intubation attempt.[25]

RAPID-SEQUENCE INTUBATION AND AIRWAY PHARMACOLOGY

Rapid-sequence intubation (RSI) is the standard of care in most emergency airway management settings because of its high rate of success.[26] The goal of RSI is to rapidly optimize conditions for intubation before desaturation and to prevent aspiration.[12] Medication administration in critically ill patients is challenging because of preexisting cardiopulmonary derangements and the concern for failed airway attempts. Except when a pulseless or unresponsive patient demands immediate intervention or does not require them, selecting and preparing appropriate medications should be a routine part of intubation preparation and planning. Common agents, indications, and doses are summarized in Table 35.1.[27] Drugs administered before induction are particularly useful in the setting of severe exacerbations of obstructive lung disease and significant intraocular or intracranial hypertension.

Initial induction agent doses should be reduced by 25%–50% in the elderly and in patients with hypotension, hypovolemia, or significantly impaired cardiac function. Propofol tends to provide for glottic visualization at full induction doses but causes significant hypotension. Etomidate has less associated hypotension and myocardial depression. It reduces adrenal steroidogenesis, but single doses do not appear to increase mortality even in septic patients.[28] Ketamine increases heart rate, blood pressure, and cardiac output and has been shown to provide similar intubating conditions and outcomes as etomidate in a large, prospective randomized trial.[29] Its use in the setting of increased intracranial pressure (ICP) is controversial.[30,31] Caution should be taken in the catecholamine-depleted patient, as ketamine can act as a negative inotrope.[32–34] Although ketamine can relieve bronchospasm, it may also increase orotracheal secretions and promote laryngospasm.[32,33]

TABLE 35.1 Common Medications Used During Tracheal Intubation

PREINDUCTION MEDICATIONS

Drug	Dose, Common Indications	Cautions
Fentanyl	2–3 micrograms/kg IV, 1–2 min CAD, aneurysm, increased ICP	Hypotension Masseter, chest wall rigidity
Esmolol	2–3 mg/kg IV Neurosurgery, head injury	Bradycardia Hypotension, bronchospasm
Lidocaine	1.5 mg/kg IV, 2–3 min Asthma, COPD, increased ICP	Hypotension

INDUCTION MEDICATIONS

Agent	Onset (seconds)	Duration (minutes)	Dose
Propofol	9–50	3–10	0.5–2 mg/kg
Etomidate	30–60	3–5	0.2–0.3 mg/kg
Ketamine	60–120	5–15	2 mg/kg

NEUROMUSCULAR BLOCKERS

Agent	Onset (seconds)	Duration (minutes)	Dose	Off-Label Dosing
Succinylcholine	30–60	5–15	1.0–1.5 mg/kg	Manufacturer's recommendation 0.6 mg/kg
Rocuronium	45–60	45–70	0.6–1.2 mg/kg	
Atracurium	60–90	35–70	0.4–0.5 mg/kg	

CAD, Coronary artery disease; *COPD*, chronic obstructive pulmonary disease; *ICP*, intracranial pressure; *IV*, intravenous. From Reynolds SF, Heffner J. Airway management of the critically ill patient. *Chest*. 2005;127:1397–1412.

The combination of an induction agent such as propofol with a paralytic reliably produces optimal intubating conditions.[35,36] Historically, succinylcholine has been one of the most commonly used depolarizing muscle relaxants because of its rapid onset of action and very short duration. In situations where succinylcholine may be considered unsafe (Box 35.1), rocuronium or atracurium will provide a similar onset of action but a much longer duration of paralysis.

In recent years, the availability of sugammadex, a drug that rapidly reverses the effects of the steroidal neuromuscular blocking agents (NMBAs), has prompted increased rocuronium use, especially if paralytic choice is limited by contraindications to succinylcholine.[24,37] Caution is recommended in patients with renal impairment. When required, the rocuronium–sugammadex complex can be removed by hemodialysis.[38]

LARYNGOSCOPY

Recent years have seen the development of a wide array of commercially available airway equipment, with mixed availability and familiarity in many ICUs.[39] Most experts recommend the selection of a limited list of airway tools most appropriate for a given ICU population to facilitate familiarity and training.

Direct Laryngoscopy

Macintosh and Miller blades are designed for rapid endotracheal tube (ETT) placement. The Macintosh blade is broad, curved, and includes a flange to displace the tongue to the left when the blade is introduced into the mouth from the right side (paraglossal approach). The blade is advanced toward midline, and the tip is directed into the vallecula once the epiglottis comes into view. Gentle blade traction will lift the epiglottis and expose the glottic aperture. The Miller blade is longer and straighter, with a slightly curved tip. It is generally inserted using a midline approach, and the distal end is used to directly lift the tip of the epiglottis. Care must be taken with both blades to apply caudal and anterior force, holding the laryngoscope handle near its base and keeping its angle less than 45 degrees to the patient to avoid dental damage. Blade sizes 3 or 4 are appropriate for most adult procedures. The broader surface of the Macintosh blade may provide better upward displacement of excess upper airway soft tissue, and the longer and narrower profile of the Miller blade may assist in the setting of narrow mouth opening or a long epiglottis. When using any blade, a stylet is generally used to help guide the ETT through the vocal cords and can be shaped with a distal bend to aid in tracheal placement.

Indirect Laryngoscopy

Indirect laryngoscopy devices provide video or optical imaging using mirrors and prisms to improve glottic visualization in individuals in whom alignment of the airway axes is difficult. Some devices incorporate an acutely angulated blade (i.e., GlideScope, McGrath, C-MAC), whereas others incorporate a channel (i.e., Airtraq, Pentax) to facilitate ETT placement through a more anterior glottis with the head in a neutral position.[40]

Confidently interpreting research that compares direct and indirect laryngoscopy is difficult. Some literature suggests that indirect laryngoscopy offers little advantage in the average patient, but affords high rates of intubation success in patients with difficult airway risk factors, obesity, or failed direct laryngoscopy attempts.[41–45] Videolaryngoscopy (VL) can accelerate training performance with novices and provides a high rate of first-time success in the hands of less experienced intubators.[46–48]

Several trials have demonstrated improved glottic visualization but no clear benefit in the rate of first-pass success using indirect laryngoscopy for emergency airway management.[49–54] Lascarrou and colleagues compared VL with direct laryngoscopy (DL) without excluding predicted or historically difficult intubations and not only found no difference in success but also found an increase in severe complications with McGrath Mac VL. DL failure is frequently associated with the inability to visualize the glottis, whereas failure in VL is often related to the inability to pass the ETT.[53] Each device has unique technical considerations with which operators must become familiar to maximize their potential benefit.

BOX 35.1 Contraindications to Succinylcholine

History of malignant hyperthermia
Hyperkalemia
Upper, lower motor neuron lesions
Myopathy
Crush injury
Severe burns (>24 hours)
Prolonged immobility

DIFFICULT AIRWAY MANAGEMENT

A difficult airway is defined as the presence of clinical factors that complicate ventilation or intubation.[55] The incidence of difficult airways encountered during emergent intubations is reported to be 10%.[4,56] Although the best management approach to a difficult airway in the ICU is not well studied, a recent systematic review of published guidelines found substantial similarities. The algorithms analyzed recommended a stepwise approach to airway management, using tracheal intubation, face mask ventilation, and supraglottic airway devices, followed by an early emergency surgical airway if these attempts are unsuccessful and a life-threatening situation exists.[57]

In the setting of a predicted difficult airway, indirect optical devices and VLs provide better glottic visualization and maximize the likelihood of intubation success. In one large single-institution study, a gum elastic bougie was the preferred method to successfully manage patients with incomplete glottic visualization and those for whom glottic intubation is not possible.[4] Although controversial, one large single-institution study reported that use of a bougie combined with either DL or VL as a primary intubation strategy was associated with a significantly higher rate of first-pass success compared with using an ETT and stylet.[58] This strategy requires further study in the critical care setting before widespread adoption.

An intubating supraglottic device (SGD) is also an appropriate primary or rescue strategy. SGDs, such as the laryngeal mask airway and King tube, can be placed into the upper airway to reestablish adequate oxygenation and ventilation without significant technical expertise in many cases. Intubation through SGDs has proven successful after failed direct laryngoscopy and usually provides a rapid primary approach in patients with a predicted difficult airway.[59,60] A number of current SGDs also provide the option of one-step intubation through the device (Ambu Aura-i, CookGas LLC, Air-Q/ILA, LMA Fastrach, and Classic Excel, i-Gel).

Surgical cricothyroidotomy is reserved for the emergency airway situation when an extraglottic airway cannot be effectively employed because of upper airway abnormalities, blood, or secretions that obviate proper placement and function. Cricothyroidotomy can be performed most rapidly using a rapid four-step technique.[61] Passing a bougie through the neck incision to serve as an ETT guide has been reported successful even in the hands of the novice nonsurgeon.[62] A cricothyroidotomy kit that uses a Seldinger approach is also available

but has been associated with longer time to placement.[63] Major complications include esophageal perforation, subcutaneous emphysema, and bleeding.

Cooperative patients with slowly progressive respiratory failure and predicted difficult airways can be considered for awake intubation. Awake intubation provides the opportunity to preserve spontaneous respiration and prolong the available time for intubation attempts. Upright fiber-optic–assisted intubation through a Williams or Ovassapian intubating airway is a common and effective approach. Preinsertion, patient candidates typically require a combination of nebulized or atomized lidocaine directed at the base of tongue and tonsillar pillars. Low-dose narcotics such as remifentanil appear to be superior to dexmedetomidine when combined with low-dose midazolam for sedation.[64] Unfortunately, the time required for appropriate airway preparation can be challenging in critical care practice, limiting broad-based application of this technique.

HUMAN FACTORS

Training

Current airway management training is highly variable, even among anesthesia providers.[65–68] A recent meta-analysis suggested that the level of training, as opposed to specialty type, was the key factor for optimizing proper airway management.[69,70] The appropriate volume and scope of airway training required, however, remains a topic in need of further research. Novices can attain reasonable competence with direct laryngoscopy after 30–50 cases and may accelerate their skills using video-assisted instruction, but performance continues to improve even after 100 intubations.[71–73] Box 35.2 provides a suggested list of airway management topics for training, but these recommendations are based only on expert opinion.[74] The development of a vast array of advanced airway management devices has only complicated efforts to standardize training and approaches to ICU airway management. In a national survey of 180 American ICU and anesthesiology directors, only 70% had a difficult airway cart in their ICU, and 60% of the respondents reported that they had not been trained in the use of such equipment.[39]

Preparation

NAP4 found that preparation, equipment, and communication errors were the most common causes of complications during airway management in ICUs and EDs in the United Kingdom.[6] These data underline the importance of deliberate planning and preparation to maximize patient safety and procedure success.

BOX 35.2 Fundamental Airway Knowledge and Skills

Face mask ventilation, airway positioning
Laryngeal mask airway (LMA, including intubating devices)
Oral endotracheal intubation (direct laryngoscopy [DL])
Simple maneuvers (positioning, BURP*) to improve DL
Use of stylet, gum elastic bougie
Rapid-sequence induction
Fiber-optic intubation via conduit (oropharyngeal airway, LMA)
Percutaneous cricothyrotomy

* *BURP*, Backwards, upwards, and rightwards positioning.
From Goldmann K, Ferson DZ. Education and training in airway management. *Best Pract Res Clin Anaesthesiol.* 2005;19(4):717–732.

Resource management principles important for an efficient airway management team include explicit role assignments, closed loop communication, and standardized guidelines for equipment, medication preparation, and positioning. Clear articulation of the primary and backup airway management plans and discrete oxygen cutoffs (which should prompt termination of intubation efforts and resumption of BMV ventilation) provide shared situational awareness and guidance to maintain quality control and safety throughout the procedure.

Checklists and Maximizing Patient Safety

The American Society of Anesthesiologists recommends that an airway assessment be performed before all intubations and emphasizes a systematic approach that maximizes oxygen delivery and considers an awake procedure, a variety of noninvasive techniques, and preservation of spontaneous ventilation.[55] Other recent studies have also underlined the importance of having a systematic approach to airway assessment, patient and equipment preparation, and procedure planning in order to maximize intubation success. Jaber and colleagues demonstrated that implementation of a protocolized ICU intubation bundle (Box 35.3) reduced complications by 25%.[3]

Improved patient safety and reduced need for emergent surgical airways have been achieved through implementation of a standardized, team-based approach that includes proactive identification of patients with known difficult airways, ready availability of advanced airway equipment, simulation-based airway skills and teamwork training, a mandatory bedside procedure checklist, and postevent debriefs.[75,76] The APPROACH mnemonic (Box 35.4) is one structured checklist tool aimed at ensuring that these standardized interventions are consistently performed.[77]

CONCLUSION

Tracheal intubation in the ICU remains a high-risk procedure, and a systematic approach that emphasizes planning, preparation, and teamwork is necessary to maximize its outcome and safety.

Although intensivists should maintain facility with DL, there are growing data supporting the use of indirect laryngoscopy as both a primary and rescue technique in the ICU. In the setting of an emergency airway, an extraglottic airway or surgical airway should be rapidly employed. If oxygenation and ventilation can be reestablished, a wider variety of techniques can be considered.

Airway management in the critically ill patient goes beyond performing laryngoscopy; it is about preventing hypoxemia and cardiovascular collapse through preparation; consideration of difficult anatomic, physiologic and situational factors; and optimizing the chances of first-pass success.

KEY POINTS

- A systematic approach that emphasizes planning, preparation, and teamwork is the best proven method to reduce risks associated with airway management in the ICU.
- An extraglottic airway should be employed early in the patient with inadequate oxygenation and ventilation.
- Optimizing difficult anatomic, physiologic, and situational factors will enhance the chances of first-pass success.

BOX 35.3 ICU Intubation Bundle Used in a Large Multicenter Study to Improve Patient Outcomes

Preintubation

1. Presence of two operators
2. Fluid loading (isotonic saline [500 mL]) in the absence of cardiogenic pulmonary edema
3. Preparation of long-term sedation
4. Preoxygenation for 3 minutes with NIPPV in case of acute respiratory failure (Fio_2 100%, pressure support ventilation level between 5 and 15 cm H_2O to obtain an expiratory tidal volume between 6 and 8 mL/kg and PEEP of 5 cm H_2O)

During Intubation

5. Rapid-sequence induction: etomidate (0.2–0.3 mg/kg) or ketamine (1–3 mg/kg) combined with succinylcholine (1–1.5 mg/kg) in the absence of allergy, hyperkalemia, severe acidosis, acute or chronic neuromuscular disease, burn patients for more than 48 hours, and major crush injury
6. Sellick maneuver

Postintubation

7. Immediate confirmation of tube placement by capnography
8. Norepinephrine if diastolic blood pressure remains <35 mm Hg
9. Initiate long-term sedation
10. Initial "protective ventilation": tidal volume 6–8 mL/kg of ideal body weight for a plateau pressure <30 cm H_2O

Fio_2, Inspired oxygen fraction; *NIPPV*, noninvasive positive pressure ventilation; *PEEP*, positive end expiratory pressure.
From Jaber S, Jung B, Corne P, et al. An intervention to decrease complications related to endotracheal intubation in the intensive care unit: a prospective, multiple-center study. *Intensive Care Med.* 2010;36:248–255.

BOX 35.4 The CHEST APPROACH to Airway Management

Assess the airway—it's all in your **HAND**
History of difficult intubation
Anatomic considerations
- 3-3-2 rule
- Modified Mallampati Classification
- Other risk factors for airway distortion, obstruction

Neck mobility
Difficult airway should be considered if concerns with any of the factors noted earlier
Preoxygenate using 100% oxygen, bag-valve-mask with PEEP valve
Prepare
Patient: Sniffing position, headboard off and patient head just below the intubator's xiphoid process
Medications: Free-flowing IV, premedication, induction, paralytic, and vasopressor agents
Right side: Suction, endotracheal tube with stylet and syringe attached
Left side: Laryngoscope handle, blades, oral and nasal airways, end-tidal CO_2 detector
Review team member roles, primary and backup intubation plans
Oxygen cutoffs: Identify signals to abort, reinitiate bag-valve-mask ventilation
Administer medication, if indicated
Confirm endotracheal tube placement using two indicators (including end-tidal CO_2)
Hold endotracheal tube until secured

IV, Intravenous; *PEEP*, positive end expiratory pressure. From American College of Chest Physicians Airway Management Program Curriculum, 2013.

Tracheostomy

Pierpaolo Terragni, Daniela Pasero, Chiara Faggiano, and V. Marco Ranieri

INDICATIONS

Airway access for the treatment of upper airway obstruction or mechanical ventilation (MV) can be obtained by either orotracheal intubation (OTI) or placement of a tracheostomy tube. During general anesthesia or after episodes of acute respiratory failure, patients are usually mechanically ventilated through an orotracheal tube, which can be easily and rapidly inserted as an initial airway device. When prolonged MV is provided or protection from tracheal aspiration is needed, a conversion to tracheostomy is mandatory and offers several potential advantages.

The introduction of the percutaneous tracheostomy (PT) by Ciaglia in 1985 as an alternative to surgical tracheostomy (ST) attracted interest regarding its indications.[1] Initially, PT was reserved for patients with few risk factors and favorable neck anatomy; however, with wider use, the indications expanded and PT has largely replaced surgical procedures. During the past decade, use of PT has increased, both for prolonged ventilation and in case of upper airway obstruction secondary to trauma or surgery of the face and neck region.[2] Although an improvement of survival rates in intensive care units (ICUs) among patients receiving tracheostomy has been reported, the hospital mortality rate was similar between patients with or without tracheostomy. However, patients who required tracheostomy and were discharged at home had double the mortality of nontracheostomized patients.[3]

More recent studies report further data on long-term outcomes in patients with tracheostomy and a better outcome among patients <65 years of age, although the overall 1-year mortality is still high (46.5%), whereas, not surprisingly, in patients >65 years of age a 50% higher mortality is observed. These data show trends toward earlier tracheostomies, shorter hospital length of stay, and increased discharges to long-term facilities versus home, with a stable and high long-term mortality rate. Therefore what has really changed is the location of death that has been shifted to post–acute care facilities.[4]

According to these outcome data, and considering its invasiveness and procedural risks, tracheostomy should be considered only when prolonged MV is expected or the upper airway cannot be secured safely by other means.

Advantages of Tracheostomy

European surveys investigating the use of tracheostomy in critically ill patients reveal heterogeneity regarding techniques, timing, operator experience, and settings.[5] Tracheostomy offers many clinical benefits for patients with respiratory failure or individuals requiring prolonged MV or airway protection because of neurologic dysfunction. Compared with OTI, it provides safer airway protection and increases patient mobility by decreasing the risk of accidental extubation because of more effective securing of the tracheal cannula: patients with tracheostomy have a 1% incidence of accidental decannulation, compared with a rate of 8%–21% of accidental orotracheal tube dislocation.[6] Moreover, because the internal cannula is not affected by head and neck movement, the occurrence of lesions resulting from tracheal mucosal abrasion and laryngeal damage is low.[5]

Additionally, easier airway suctioning and secretions management improve pulmonary secretion management and oral hygiene; therefore tracheostomy allows better patient comfort that might facilitate communication with family members and nurses. Patients can be mobilized earlier and more easily, with faster return to oral feeding, shorter nasogastric tube dwell time,[7,8] and reduced risk of tracheoesophageal fistula occurrence.

Use of a tracheostomy tube can aid in weaning from MV, because the direct approach to the trachea (with an internal diameter greater than in the translaryngeal approach) and reduced length all reduce airflow resistance; it also allows faster resumption of autonomous respiration, with less use of sedative agents, fewer days on the ventilator, shorter length of stay in the ICU, and reduced use of resources.[3,9,10] Although PT continues to gain acceptance as the method of choice, no single technique has been shown to be superior to another in any clinical situation. Furthermore, PT has a steep learning curve and requires mastery of procedural skills and extensive expertise.

TRACHEOSTOMY TECHNIQUES

Percutaneous Dilational Tracheostomy vs. Surgical Tracheostomy

Tracheostomy techniques are evolving and improving. Two basic methods are available: PT and ST. The choice of whether to use one or the other depends on available resources, operator experience, and degree of patient complexity.

ST presents a similar risk of operative complications (minor or major hemorrhage, tracheo-innominate fistula, subglottic stenosis, oxygen desaturation, subcutaneous emphysema, pneumothorax, accidental decannulation, and airway loss) compared with PT.

Several meta-analyses (Delaney and colleagues on 1212 patients, Higgins and Punthakee on 1000 patients enrolled in 15 prospective randomized controlled trials [RCTs], and more recently, Putensen and colleagues who tested 14 RCTs on different PT techniques versus ST in 973 patients) reported a significant reduction in wound infection and stoma inflammation in PT; the latter is also performed faster even if associated with increased technical difficulties, although the benefits were found in studies using the multiple dilators technique (MDT), which is now replaced by the single-step dilation tracheostomy (SSDT) technique.[11–13]

Based on the analysis of different European surveys about the use of tracheostomy in critically ill patients, a wide heterogeneity regarding techniques, timing, operator, and structures used to perform the procedure can be observed.[5]

Surgical Techniques

ST in European ICUs is less common than PT; meanwhile, elsewhere it is equally distributed.

ST is prevalent in surgical ICUs: surgeons performed 61% of STs in Germany and 44% of all tracheostomies in the Netherlands. In an Italian survey, a dedicated team involving more than one intensivist and a nurse performed 62.6% of all tracheostomies.

Most STs were performed in operating rooms. In Germany, 28% of STs were performed in the ICU, whereas in the Netherlands the percentage was lower. In 42% of French ICUs, surgeons always performed tracheostomies (in France, ST remains largely preferred).[5]

Although PT has become a common procedure in patients undergoing elective tracheostomy, in the case of long-term MV, ST remains the method of choice in selected critically ill patients presenting with distortion of neck anatomy, prior neck surgery, cervical irradiation, maxillofacial or neck trauma, morbid obesity, difficult airway, or marked coagulopathy (e.g., patients undergoing heparin treatment during extracorporeal membrane oxygenation support). ST can be also safer when anatomic landmarks are difficult to palpate, the patient presents with a malignancy at the site of insertion, or if emergency tracheostomy placement is required.

Usually physicians are more likely to perform ST to explore the airway anatomy in the operative setting and then proceed to the PT where the airway is less well visualized (some PT procedures such as the Griggs technique can be easily converted to ST in cases of difficult anatomic landmarks).

Otolaryngologists or general surgeons perform ST in the operating room in selected challenging cases involving patients presenting with complex anatomy (short neck, morbid obesity, neck stiffness, local malignancy, tracheal deviation) or coagulopathy, in addition to patients with neck, esophageal, and cardiovascular surgeries.

ST procedures can be performed under general anesthesia with propofol, fentanyl, and muscle relaxant administration. The surgical treatment of the tracheal window can be either mini-invasive similar to PT (with an open access without sutures) or invasive, realizing a true stoma and removing the anterior part of the tracheal wall with a ring flap sutured to the skin; the tracheostomy tube must be inserted between the first and third tracheal rings and fixed with two sutures: in this case, the surgical treatment involves a full dissection of the pretracheal tissues and insertion of the tracheostomy tube into the trachea under direct vision.

Because morbidity has been observed related to the transport of critically ill patients, to further reduce the rate of inadvertent mishaps, alternative techniques and surgical procedures such as ST should be considered and performed by anesthesiologists or surgeons at the bedside in the ICU.[14] Even if it can be more difficult because of suboptimal conditions of lighting, suction, sterility, and cautery, bedside tracheostomy avoids transferring the patient to the operating room, making it ideal for selected cases.

ST presents a similar risk of complications or death compared with PT, except stoma infections. The proportion of patients receiving PT or ST varies across different settings: ST is largely performed in ICUs managed by surgeons, PT is preferred in ICUs managed by intensivists, and both techniques are adopted in medical/surgical ICUs.[15–20]

Percutaneous Tracheostomy

Various PT devices have been developed to minimize risk and simplify the procedure.

Evolution in terms of technique, introduction of new percutaneous devices, and support tools such as fiber-optic bronchoscopy and ultrasound during the procedure have made this tracheostomy technique easier and safer.

Since PT was first described by Ciaglia and colleagues (using a guide wire),[1] new methods have been developed by combining the percutaneous nephrostomy multiple-dilator procedure and a variant of the vascular access described by Seldinger in 1953. In 1990 Griggs described the guide wire dilator forceps technique (GWDF) (Portex Limited, Hythe, Kent, UK), an improvement on the Rapitrach method in which the forceps was inserted along the guide wire and opened to the size of the skin incision to dilate the trachea[21,22] (Fig. 36.1). Ciaglia's initial serial MDT was revised in 1999 for use with a single tapered dilator (SSDT) with a hydrophilic coating: it allowed, in a single step, achieving complete dilation of pretracheal tissues with a technique known as the Blue Rhino technique (Cook Critical Care, Bloomington, IN, USA).[23] In 1997 Fantoni described the translaryngeal technique (TLT) (Mallinckrodt, Mirandola, Italy) in which the dilator passed from inside to outside the tracheal wall without requiring external compression of the tracheal tissues.[24] In 2003, a screwlike device was designed to open the tracheal stoma (rotational dilation technique), which was useful in case of loss of view of the tracheal lumen during bronchoscopy and to minimize the risk of posterior tracheal wall injury (PercTwist method, Rüsch GmbH, Kernen, Germany).[25]

The Ciaglia Blue Dolphin system (balloon dilatational tracheostomy method) was introduced in 2008. It represents the most recent technique derived from the Fogarty balloon embolectomy catheter used in vascular surgery. This device generates a radial force to widen the tracheostoma in a single-step dilation, minimizing bleeding and tracheal ring injury, while achieving good cosmetic results after decannulation.[26]

The success of PT rests on the expertise of the intensivist or surgeon in ICU settings (mixed medical/surgical, only medical or surgical). Moreover, the availability of different PT techniques should enable physicians to optimize the procedure and thus challenge the need for ST in clinical scenarios of primary surgical technique competence such as obesity, neurotrauma, or vascular abnormalities with high risk of bleeding.

Today we see an extensive use of PT in ICU, thanks to the easy execution of procedure at the bedside, avoiding high risk in patient transfer to the operating room.[14,27–29]

At present, there is no evidence supporting the recommendation of one PT technique over the others. A method can be selected on the basis of clinical criteria, operator experience, local practice, and availability.[30]

Fig. 36.1 Guide wire dilator forceps technique (Portex Limited, Hythe, Kent, UK). The operator shows the surgical forceps.

A systematic review and meta-analysis of PT in critically ill patients recently investigated the advantages of PT versus ST in relation to major and minor intraprocedural complications.[31] The review included 13 RCTs on tracheostomy in medical, neurologic, or surgical ICU settings published in the past 10 years. Results demonstrated the equivalence of all techniques in terms of incidence of side effects and rate of procedure success, except for **percutaneous** TLT, which was associated with more severe complications and a greater need to convert to another tracheostomy technique compared with GWDF and SSDT techniques.[31]

In a more recent systematic review of 14 randomized comparative studies published between 1985 and 2013, the authors suggested that the SSDT technique is less difficult and most likely associated with a greater frequency of minor hemorrhagic events, but might be preferable because clinicians have greater experience using this technique, which is the most widespread in clinical practice.[32]

Comparing ST with PT, results of the most recent meta-analysis by Putensen et al. focused on lower risks of stoma inflammation and infectious complications using PT, but as a limitation of analysis, the benefit was mostly the result of studies using the MDT, which has largely fallen out of use in favor of the SSDT technique; no advantages were found in terms of hemorrhagic complications between ST and PT.[13]

COMPLICATIONS

PT in critically ill patients is considered a relatively safe procedure, with a low frequency of major complications even in patients with severe coagulation disorders.

Complications arising from tracheostomy maneuvers based on the time between the procedure and their onset can be classified as intraoperative and postoperative (early and late complications, respectively). The frequency and severity of complications depend on tracheostomy technique, operator experience, patient anatomy, and pathophysiologic factors related to the degree of organ dysfunction, especially respiratory and coagulation deficits.

Procedure-related complications include oxygen desaturation and difficult cannula placement because of acute tracheostomy tube occlusion (generally because of the formation of a blood clot or mucus plug) or tube insertion into the wrong tract. Other early complications include hemorrhage, with bleeding controlled by local pressure or requiring exploration (with conversion from PT to another dilational technique or surgery in some cases), or desaturation because of subcutaneous emphysema with or without evidence of pneumothorax. Patients with severe bleeding should undergo bronchoscopy for suspected tracheoesophageal fistula, but this occurrence is normally characteristic of late complications.

Common adverse events in the postoperative period or later include slight bleeding, controlled by local pressure; accidental cannula removal and/or displacement (dislodged tracheal tubes within 7 days of insertion should be replaced with a tube the same size or smaller); and airway obstruction resulting from granuloma formation or stoma infection/inflammation.

Several uncontrolled case series have reported PT complications, but there are few prospective comparative studies of complications associated with PT and surgical tracheostomy or between different PT methods. A meta-analysis by Freeman and colleagues. found that, compared with surgical tracheostomy, Ciaglia's and Grigg's techniques were generally associated with lower rates of stomal bleeding, infection, and postoperative complications.[33] In a randomized trial, with double-blind follow-up comparing the outcomes and the short- and long-term complications of TLT versus surgical tracheostomy, Antonelli and colleagues demonstrated lower bleeding rates with TLT, no increase in the risk of bacteremia caused by the spread of upper respiratory tract microbes, and similar long-term effects (physical and emotional) of the two procedures.[34]

The recent implementation of extracorporeal circuits, such as venovenous extracorporeal membrane oxygenation (VV-ECMO) to improve ventilatory support, has increased the complexity of critically ill patients. ECMO circuit–blood interaction activates the coagulation cascade, with increased risk of thrombotic and hemorrhagic events. This condition might increase the risk of hemorrhagic complication during PT; however, recent retrospective data showed that PT is a safe procedure even during ECMO support when skilled operators, with careful optimization of the coagulation state, perform it.[35,36] A recent retrospective observational study reported a consistent risk of major complications (15%), which is much higher when compared with that of non-ECMO patients, where only 3% had early severe complications.[35,37,38] The most commonly described complication was major bleeding requiring blood transfusion, occurring in 11% of the studied population, and it corresponded to two-thirds of all major complications. Moreover, two posterior tracheal wall injuries, one bronchial mucosal injury, thyroid isthmus, external jugular vein injury, and one case of tension pneumothorax were described. ECMO circuit change was required in five cases because of either oxygenator failure or bleeding and circuit-related disseminated intravascular coagulation (DIC).[35] A previous retrospective study reporting data from two different German centers showed a lower incidence of major complications in five patients (4.2%) out of 118 PTs performed in a 6-year period.[36] The main difference between the two studies was the heparin management strategy: in the previous study heparin had been stopped 1 hour before PT, whereas in the more recent study it was based on the clinician's decision; as the median time of suspension of heparin was longer than 1 hour, more coagulation disorders were observed. In addition, in the previous study, clinicians performed PT earlier compared with the more recent study. However, the number of cases is too small to draw conclusions on the safety of PT during ECMO support and suggest performing PT after weaning from ECMO whenever possible.[35,36]

TIMING OF TRACHEOSTOMY

Older guidelines recommended tracheostomy after 3 weeks of endotracheal intubation only if extubation did not occur by 21 days.[39] But defining and predicting the need for prolonged MV continues to pose a major methodologic challenge. Except in emergency procedures, the timing of tracheostomy in patients requiring prolonged MV is controversial. But the real issue behind the debate is how to measure the effectiveness of early tracheostomy and its effects on outcome.

A meta-analysis published in 2005 reported that early tracheostomy shortened the duration of MV and the length of ICU stay.[40] In their study involving 1044 patients, Wang and colleagues suggested that tracheostomy timing did not significantly alter major clinical outcomes in critically ill patients.[41] Two Italian and French RCTs published by Terragni and colleagues and Trouillet and colleagues, respectively, evaluated the benefits and risks of tracheostomy and the ability to identify early patients requiring prolonged MV.[42,43] Both trials enrolled candidates for tracheostomy. In the first study, respiratory function improved in 43.3% of patients randomized to the late tracheostomy group so that tracheostomy was no longer necessary. Likewise, in the French study, only 27% of patients in the prolonged MV group underwent late tracheostomy.

The TracMan UK randomized trial analyzed survival in early versus late tracheostomy and confirmed the results of the previous trials.[44] In the early group, 91.9% of the patients enrolled received a tracheostomy, whereas only 44.9% in the late tracheostomy group underwent

tracheostomy. No significant differences in mortality or other major secondary outcomes between the two groups were found. These results convinced clinicians that routine early tracheostomy does not necessarily reduce the incidence of ventilator-associated pneumonia (VAP), shorten hospital stay, or lead to lower mortality. In general, tracheostomy should not be performed earlier than 13–15 days of OTI.[45]

Ten years after the most representative large RCT on tracheostomy timing in critically ill patients,[42] delaying the procedure for roughly 2 weeks after translaryngeal intubation is the recommended practice, and the decision is mostly influenced by the patient's overall clinical condition, prognosis, and ability to wean.

However, these trials have not strongly explored the effects of timing on mortality, which requires a large sample size.[46] Siempos Ilias and colleagues analyzed the incidence of mortality and pneumonia in 13 RCTs (2434 patients, 648 deaths) comparing early tracheostomy (within a week after OTI) with late (done any time after the first week of MV) or no tracheostomy in critically ill patients under MV.

The authors demonstrated that all-cause mortality in the ICU was not significantly lower in patients assigned to the early vs. the late or no tracheostomy group, and the incidence of VAP was lower in patients assigned to the early vs. the late or no tracheostomy group without evidence of a difference between the compared groups for 1-year mortality. Currently, if the common practice of delaying tracheostomy can be supported by the lack of effects on long-term mortality and the potential complications applying early tracheostomy timing, further studies are warranted on long-term outcomes.

Because data on patient outcomes related to the timing of tracheostomy are heterogeneous, selected patients with neurologic injury can benefit from prolonged intubation because of their limited ability to clear secretions. Prolonged intubation in traumatic brain injury, however, is associated with a high incidence of pneumonia. Conversely, early tracheostomy after trauma reduces the length of ICU stay, days on MV, and incidence of VAP. In patients with infratentorial lesions, Qureshi and colleagues suggested an aggressive policy regarding tracheostomy, which was justified by the low rate of successful extubation.[47–50] Although early tracheostomy in selected neurologic patients may reduce the length of ICU stay and pulmonary morbidity, the first 7–10 days after acute brain injury coincide with the highest incidence of intracranial hypertension; therefore the appropriate timing for tracheostomy in those patients must be related to the risk of severe intracranial hypertension.[51]

TRACHEOSTOMY AND SAFETY

Adult tracheostomy can be performed in the operating room or at the bedside in the ICU. To improve PT safety in different scenarios, suggested procedures to confirm tracheal puncture include (1) ultrasound for preoperative evaluation of the neck or during the intraoperative stage for monitoring needle progression through the trachea and (2) bronchoscopy surveillance during the procedure, which is increasingly performed by intensivists in critical care. In our experience, PT is a safe and easy procedure to perform at the bedside, even in difficult situations, by skilled intensivists with full technical support to minimize complications. For selected patients (e.g., individuals with distorted neck anatomy or history of prior neck surgery), a surgeon skilled in the conventional open technique should be readily available, even if the team is well trained in PT.[52]

Bronchoscopy

Safety during the PT procedure can be enhanced with bronchoscopy guidance to minimize complications. Several authors have recommended the use of bronchoscopy during PT because it provides direct visualization of the airway during tracheostomy tube placement. A previous retrospective study evaluating the safety and efficacy of PT procedures with or without bronchoscopy showed that the use of bronchoscopy did not give any advantage in the number of complications, except a higher conversion rate to surgical tracheostomy in the procedures performed without tracheostomy, whereas survival rate, ventilator-free days, and the length of ICU and hospital stay were similar among the analyzed trauma patients.[53] More recently an RCT showed that PT performed with fiber-optic bronchoscopy is superior to PT without bronchoscopy control by reducing the rate of major and minor complications (40% vs. 20%) and the duration of the procedure.[54]

Intraoperative endoscopic control has been shown to reduce complications associated with tracheostomy. Bronchoscopy guidance can improve safety and efficiency by monitoring placement of the tracheal puncture, the dilational procedure (preventing damage to the posterior tracheal wall and visualizing progression through the interannular membrane without breaking the tracheal rings), insertion of the tracheal cannula, and postprocedure control to detect intratracheal lesions and confirm correct endotracheal placement[55] (see Fig. 36.3).

Ultrasound and Percutaneous Tracheostomy

Although fiber-optic endoscopic control reduced some major complications during PT, in selected cases, there might be serious hemorrhagic complications because of puncturing of venous or arterial vessels in patients with aberrant vascular anatomy. Muhammad and colleagues reviewed the incidence and sequelae of bleeding events as a complication of PT.[56] They found that variations in venous (inferior thyroid vein) and arterial anatomy (thyroid artery) can lead to serious bleeding events that required investigation with diagnostic ultrasound and/or radiologic examination before proceeding with PT.

The presence of an abnormal branch of the innominate artery passing in front of the trachea near the area of a tracheostomy procedure can be detected by clinical evaluation (pulsatile swelling at the base of the neck); however, an additional ultrasound evaluation could be useful to confirm the complexity of the tracheostomy procedure and may warrant switching to a surgical approach in some cases[5] (Fig. 36.2).

Ultrasound alone cannot replace bronchoscopy. Nonetheless, it might help to identify vascular structures when evaluating the anterior neck region and guide to the best area to perform PT, avoiding major bleeding complications. Several observational studies showed the usefulness of ultrasound before tracheostomy to prevent vascular complications, and in a selected population with acute brain injury and morbid obesity, where prolonged bronchoscopy might increase intracranial pressure, ultrasound-guided PT proved successful.[57,58]

Recently, an RCT showed that ultrasound-guided PT is a safe procedure for critically ill patients and has some advantages compared with bronchoscopy-guided PT because it reduced the major bleeding complications. The trial showed that the real advantage of the ultrasound technique is the possibility of exploring the neck area to study the vascular structure; in fact, in six patients of the ultrasound–PT group, the entry location was changed after neck examination with ultrasound. The ultrasound-guided technique was performed with a transverse probe position in the out-of-plane mode to follow needle entry during puncture.[59]

In conclusion, for a safer procedure, the best option is to use ultrasound to explore the neck area to study the vascular structure and eventually to guide the percutaneous incision, but the procedure should be controlled using an optical fiber bronchoscopy, at least at the end of the procedure, to exclude any mechanical complication on tracheal structures.

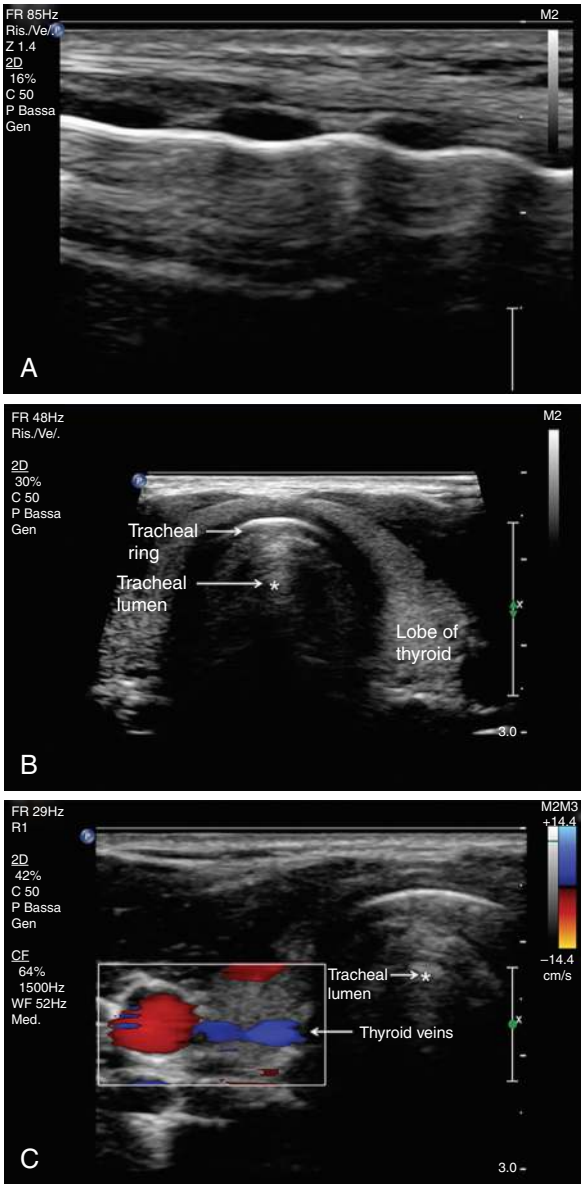

Fig. 36.2 Use of ultrasound to evaluate the anterior neck region may be a valid and economic support to improve preoperative assessment and identify potential bleeding complications during the procedure. **A,** Sagittal ultrasound image showing the upper four tracheal rings. **B,** Transverse ultrasound image showing the anterior tracheal wall, tracheal lumen shadow, and thyroid gland. **C,** Axial image of trachea and surrounding structures with vascular structures depicted (thyroid veins).

TRACHEOSTOMY IN NEUROCRITICAL PATIENTS

In patients with severe acute brain injury, tracheostomy represents an easy way to reduce the time under sedation and on MV, ICU length of stay, and to allow faster rehabilitation.[60] The decision to perform a tracheostomy in patients affected by severe acute brain injury is usually made in a phase when the prognosis is uncertain in order to give more time for a clearer prognosis to emerge.[61] A large retrospective cohort study exploring trends in tracheostomy over time conducted in the United States showed an increase from 28% to 32% over a decade. The major increase was reported in teaching and urban hospitals. After this increase in tracheostomy rate, discharge to home was relatively stable, but in-hospital mortality was significantly reduced, from 19.3% to 9.1%, whereas discharge to long-term acute facilities was increased.[62] Time to tracheostomy in patients with severe acute brain injury should be short. The limited data available from a randomized trial suggest that performing an early tracheostomy, within the first 10 days after tracheal intubation, may reduce long-term and ICU mortality and reduce the duration of MV and ICU length of stay.[63]

MANAGEMENT AND CARE OF THE TRACHEOSTOMIZED PATIENT

Another important step is the management of the tracheostomized patient. There is increasing evidence that specialist tracheostomy teams improve patient outcome and enhance the weaning process.

To improve the quality of care provided to tracheostomized patients and to support staff involved in the delivery of routine tracheostomy care, the development of a quality improvement project was performed, funded by the NHS Wales Critical Care and Trauma Network. The project consisted of formal tracheostomy teaching that was delivered by a tracheostomy team to 165 clinicians involved in tracheostomy care: 75.8% were nurses, 7.3% physiotherapists, 8.5% speech and language therapists, 7.3% medical, and 1.2% other healthcare professionals.[64]

The results of the project showed an improvement in self-assessed confidence, with knowledge and skills observed for all aspects of tracheostomy care, with greatest improvement for "methods of insertion" and "communication and swallow." Moreover, there was increased use of speaking valves to facilitate verbal communication for patients receiving ventilation. Furthermore, eating and drinking practice for patients with tracheostomy with or without MV was variable, and speech and language therapy (SLT) assessment before commencing oral intake was not occurring. After teaching sessions, all patients were assessed by SLT before commencing oral intake, and 100% of those appropriate managed to eat and drink safely during MV.[64]

In conclusion, with the increase in the number of tracheostomized patients over time, it is important to implement a program of education provided to patients and to clinical staff, to improve the management of tracheostomy and the quality of life of the patients.

TRACHEOSTOMY EMERGENCY

Emergency tracheostomy is rarely necessary because new techniques of OTI are available in critical care areas. On rare occasions, however, intubation via the oral or nasal route is unsuccessful or hazardous: foreign bodies in the larynx or extrinsic airway compression (Fig. 36.3A and B) or tracheal stenosis (more frequently as a consequence of prolonged laryngeal intubation) involving the subglottic region represent a major therapeutic challenge precluding, in some cases, OTI for establishment of an airway.

Although in laryngotracheal stenosis, surgery is considered a first-line treatment, preservation of the recurrent laryngeal nerves results in technical problems.[65]

The use of tracheal prostheses and permanent tracheostomy for establishment of an airway have been alternatives to surgery, but in recent years, the interest in endoscopic procedures such as laser-assisted endoscopy, with or without stenting, has promoted their use in subglottic stenosis to allow stabilization of the tracheal wall, with or without airways control by temporary tracheostomy (Figs. 36.4A and B and 36.5A and B).

TRACHEOSTOMY TRAINING

A learning curve for PT has been identified.[66,67] The American Thoracic Society and the European Respiratory Society recommend 5–10 procedures, whereas the American College of Chest Physicians recommends 20 procedures.

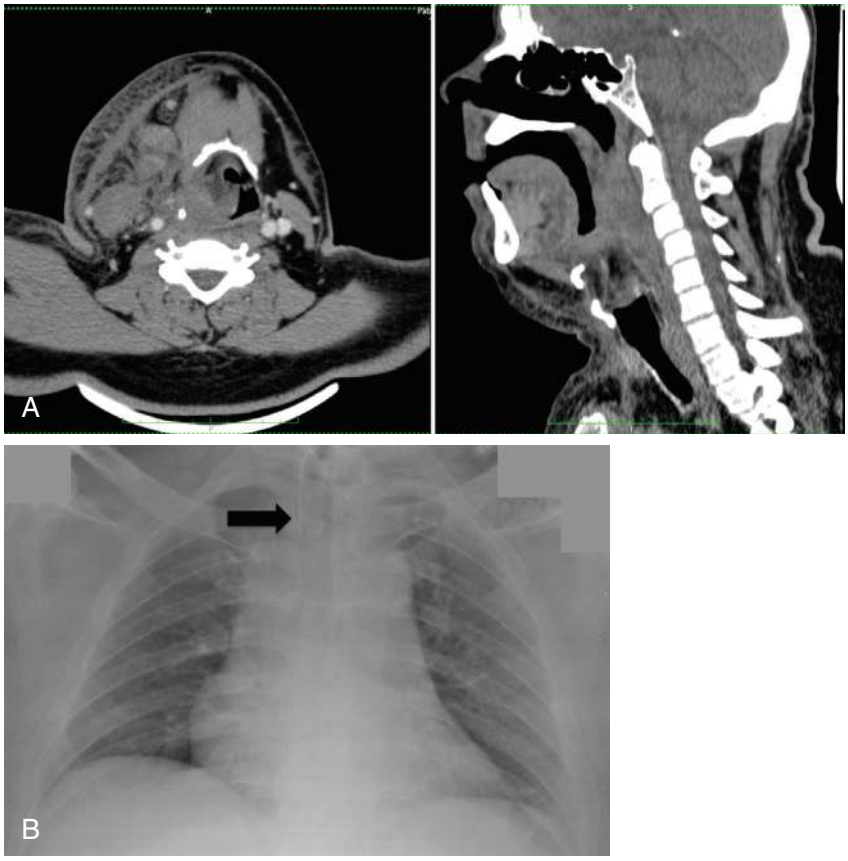

Fig. 36.3 **A,** CT scan of very severe airway obstruction as a consequence of posttraumatic oropharyngeal hematoma. **B,** Chest x-ray image after airways control by temporary tracheostomy in perioperative assessment.

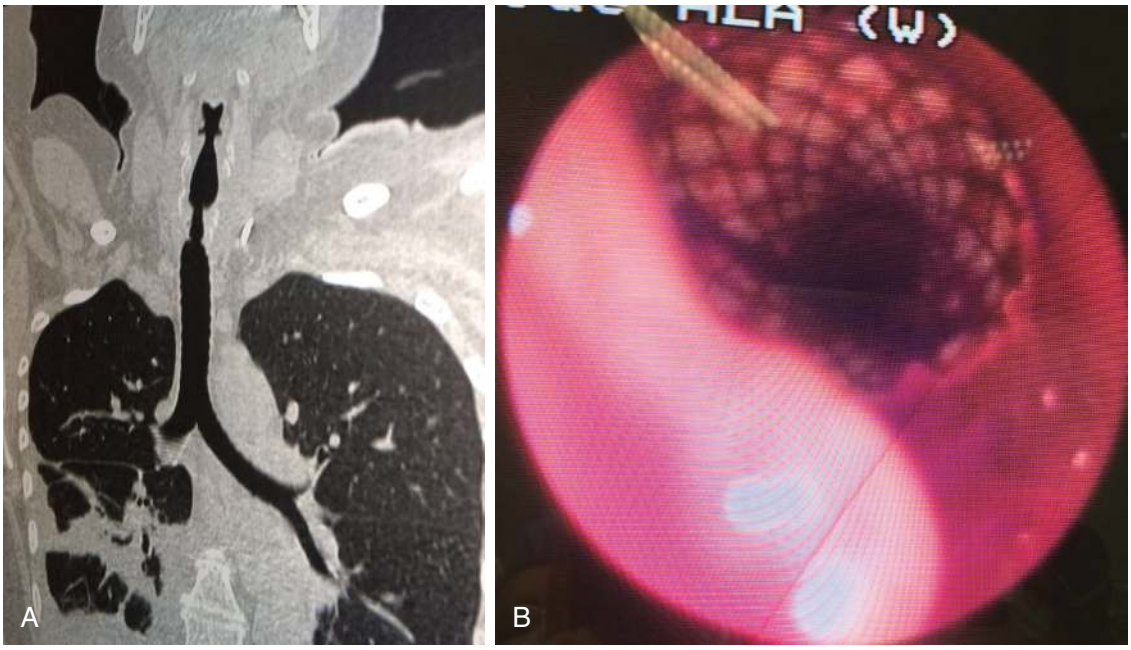

Fig. 36.4 **A,** CT scan of moderate stenosis as a consequence of prolonged laryngeal intubation involving the subglottic region. **B,** Laser-assisted endoscopy with stenting to allow stabilization of the tracheal wall without airway control by temporary tracheostomy.

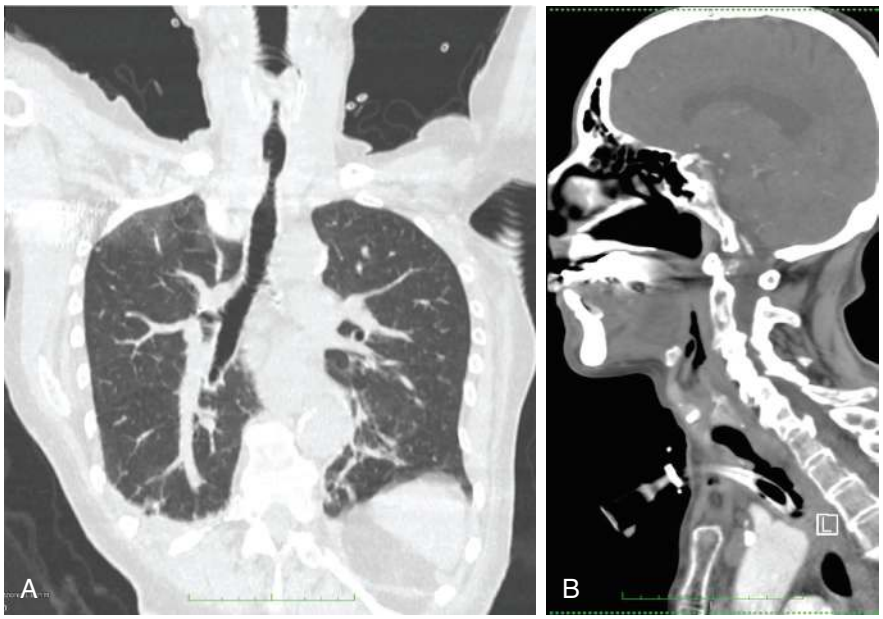

Fig. 36.5 **A,** CT scan of very severe subglottic stenosis as a consequence of prolonged laryngeal intubation in a patient after cardiac arrest because of acute airway obstruction. **B,** CT scan of airway control by temporary tracheostomy in preoperative assessment.

During initial training, practice on manikins, animal models, or biologic tissues (because of ethical and economic concerns) can improve skills and minimize complications.[68–71] The pig model may provide a more realistic approach.[72] An Italian group tested the efficacy of the porcine model in developing the skills that residents require for successful PT. The model consisted of a larynx and trachea free from perilaryngeal and peritracheal tissues. The resulting tissue block was then placed on a backing with an overlapping of sponge and plastic wrapping (simulating the skin) before being inserted into the manikin's neck.[73]

Recently a new training approach in endoscopic PT using a simulation model based on biologic tissue was performed.[71] Adult sheep heads and necks bought from the slaughterhouse were used for training (Fig. 36.6). Tracheostomy training stations for different PTs were available, with an orotracheal tube correctly positioned through the larynx of the sheep necks. The necks were cut so as to preserve all the tracheal rings. A single-use flexible video-endoscope was available in each training station to allow the participant performing PT procedures to see manipulation results and for teachers to monitor and advise as they proceeded. With the same training model, cricothyrotomy was always performed through the cricothyroid membrane.

Simulation models based on animal tissue for training in PT seem to be more realistic than manikins in terms of reality of the skin and landmark recognition. Moreover, they provide a particular "tactile feeling" in trainees and allow better monitoring of skill acquisition in endoscopic PT settings.

Fig. 36.6 Tracheostomy training station for single-step dilation tracheostomy (SSDT) with a simulation model based on biologic tissue (adult sheep neck). A detail of the Blue Rhino Ciaglia introducer (Cook Critical Care, Bloomington, IN, USA) among tracheal rings during insertion into the trachea of the sheep model.

ACKNOWLEDGMENTS

The authors wish to thank Pierpaolo Mura, MD (anesthesiologist), Davide Piredda, MD (anesthesiologist), Olindo Massarelli, MD (maxilla-facial surgeon), Cristiano Mereu, MD (anesthesiologist), Francesco Riu, MD (otolaryngologist surgeon), and Alessandra Meloni, MD (anesthesiologist) of AOU Sassari for providing computed tomography scans and chest x-ray images.

KEY POINTS

- Surveys on tracheostomy show wide heterogeneity in techniques (PT or surgical), timing, operator experience, and settings.
- PT continues to gain acceptance as the method of choice, though no single technique has been shown to be superior to another.
- PT has become the procedure of choice in patients undergoing elective tracheostomy; however, ST remains the method of choice in selected critically ill patients presenting with distorted neck anatomy, prior neck surgery, cervical irradiation, maxillofacial or neck trauma, morbid obesity, difficult airways, or marked coagulopathy.
- The optimal timing of tracheostomy in patients requiring prolonged MV remains controversial. After results of large RCTs in critically ill patients on tracheostomy timing, the delay of the procedure for roughly 2 weeks after translaryngeal intubation is the recommended practice, and the decision is mostly influenced by the patient's overall clinical condition, prognosis, and tolerance to weaning.
- PT is not without complications; it has a steep learning curve and requires mastery of procedural skills and extensive expertise. During initial training, practice on manikins, animal models, or biologic tissues (because of ethical and economic concerns) can improve the skills and minimize complications.

Basic Principles of Mechanical Ventilation

Neil R. MacIntyre

Mechanical ventilatory support provides pressure and flow to the airways to help accomplish oxygen (O_2) and carbon dioxide (CO_2) transport between the environment and the pulmonary capillary bed. The overall clinical goal of mechanical ventilation is to maintain appropriate levels of O_2 and CO_2 content in the arterial blood while unloading the ventilatory muscles. An equally important goal is to provide this support without harming the lungs. Positive-pressure mechanical ventilation can be applied through either an artificial airway or a tight-fitting mask (noninvasive ventilation, discussed in detail in Chapter 55).

DESIGN FEATURES OF MODERN MECHANICAL VENTILATORS

Most modern ventilators use high-pressure gas sources to drive gas flow. Tidal breaths are generated by metering this gas flow and can be classified regarding what initiates the breath (trigger variable), what controls gas delivery during the breath (target or limit variable), and what terminates the breath (cycle variable).[1] In general, breaths can be initiated (triggered) by patient effort (assisted breaths) or by the machine timer (controlled breaths). Target or limit variables are either a set flow or a set inspiratory pressure. With flow targeting, the ventilator regulates the airway pressure to maintain a clinician-determined flow pattern. In contrast, for pressure targeting, the ventilator adjusts flow to maintain a clinician-determined inspiratory pressure. Cycle variables are a set volume, flow, or set inspiratory time. Breaths can also be cycled if pressure limits are exceeded. Using this approach, standard breath delivery algorithms from modern mechanical ventilators can be classified into five basic breath categories based upon trigger, target, and cycle criteria: (1) volume control (VC), (2) volume assist (VA), (3) pressure control (PC), (4) pressure assist (PA), and (5) pressure support (PS) (Fig. 37.1).[1]

The availability and delivery logic of the different breath types define the mode of mechanical ventilatory support. The mode controller is an electronic, pneumatic, or microprocessor-based system designed to provide the desired combination of breaths according to set algorithms and feedback data (conditional variables). The five most common modes are volume assist-control (VACV), pressure assist-control (PACV), volume synchronized intermittent mandatory ventilation (V-SIMV), pressure synchronized intermittent mandatory ventilation (P-SIMV), and standalone pressure support ventilation (PSV). It is important to note that a technique using pressure-targeted IMV set in a long inspiratory:expiratory configuration *(airway pressure release ventilation)* has often been labeled a "new mode" when it can be viewed simply as a modification of P-SIMV that extends the inflation period and allows tidal breaths superimposed on the higher pressure level.

Current ventilator designs incorporate advanced monitoring and feedback functions to allow continuous adjustments in the breath delivery patterns.[2,3] An early approach involved adding flow to the end of a pressure-targeted inflation if a target volume was not achieved *(volume-assured pressure support)*. A similar concept involves a feedback mechanism during volume-assist breaths that adds inspiratory flow to assure airway pressure does not fall below zero in the presence of vigorous inspiratory efforts.

Today, however, the most common of these feedback control mechanisms provides additional inspiratory pressure during pressure-targeted breaths to assure that the targeted average tidal volume is achieved. This mechanism makes adjustments based on previous tidal volumes and is commonly termed *pressure-regulated volume control* (pressure assist-control breaths) or *volume support* (pressure support breath). Inspiratory pressure feedback control features can incorporate additional inputs (e.g., exhaled CO_2, minute ventilation, respiratory rate) to "fine-tune" breath delivery. A more sophisticated and advanced form of these feedback control systems incorporates a minute volume target and adjusts inspiratory pressure, respiratory rate, and inspiratory:expiratory timing to minimize the calculated work per breath and avoid air trapping *(adaptive support ventilation)*.

Finally, over the last three decades, two truly novel assist modes have been introduced: proportional assist ventilation (PAV) and neutrally adjusted ventilatory assistance (NAVA).[4] The former calculates respiratory system mechanics and adjusts flow and inspiratory pressure to proportionately unload inspiratory muscles; the latter uses the diaphragmatic electromyographic (EMG) signal to adjust flow and pressure delivery in accordance with patient effort. These modes are discussed in more detail elsewhere in this text.

PHYSIOLOGIC EFFECTS OF MECHANICAL VENTILATION

Alveolar Ventilation and the Equation of Motion

Alveolar ventilation denotes fresh gas delivery to the gas-exchanging regions of the lungs. Mathematically this is expressed as:

$$VA = f \times (VT - VD)$$

where VA = alveolar ventilation per minute, f = breathing frequency, VT = tidal volume, and VD = wasted ventilation or dead space per breath. Alveolar ventilation needs to be adequate for the rates of tissue oxygen consumption (VO_2) and carbon dioxide production (VCO_2). By convention, CO_2 transport, as expressed by the relationship between VCO_2 and the steady-state arterial PCO_2, is used to quantify VA:

$$VA = 800 \times (VCO_2 \ / \ PaCO_2)$$

The difference between total ventilation (f × VT) and VA is VD.

The lungs are inflated by mechanical ventilation when a dynamic pressure increment or flow is applied at the airway opening. These applied forces interact with respiratory system compliance (both lung and chest wall components), airway resistance, and, to a lesser extent,

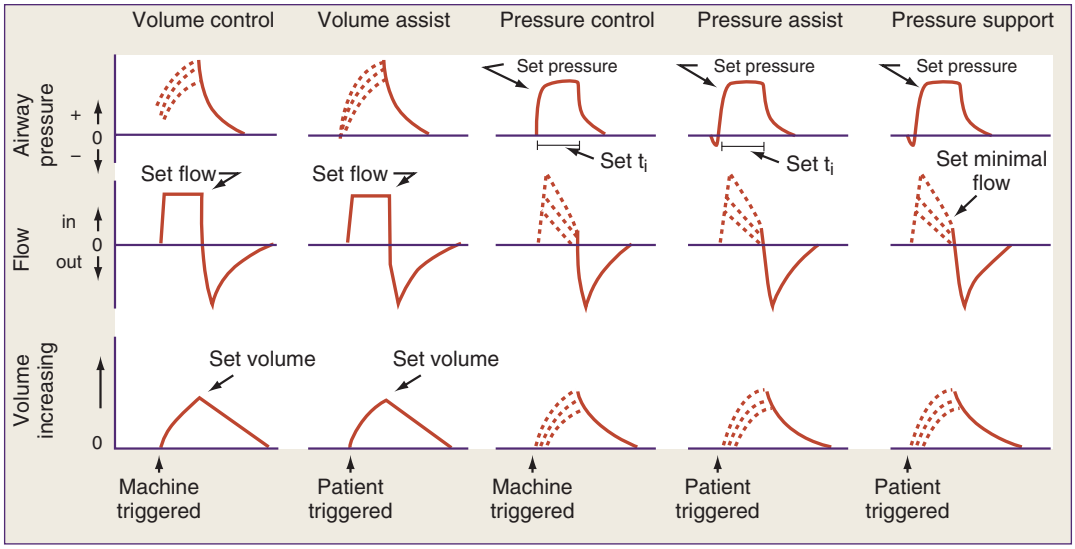

Fig. 37.1 Airway pressure, flow, and volume tracings over time depicting the five basic breaths are available on most modern mechanical ventilators. Breaths are classified by their trigger, target or limit, and cycle variables. (Adapted from MacIntyre NR. Mechanical ventilatory support. In Dantzker D, MacIntyre NR, Bakow E, eds. *Comprehensive Respiratory Care*. Philadelphia: Saunders; 1995, p. 2335.)

respiratory system inertance and lung tissue resistance to effect gas flow.[5–8] For simplicity, inertance and tissue resistance are relatively small and for clinical purposes can be ignored, so that the interactions of pressure, flow, and volume with respiratory system mechanics can be expressed by the simplified equation of motion:

$$\text{Pressure across the respiratory system in excess of the end-expiratory pressure} = (\text{flow} \times \text{resistance}) + (\text{tidal volume/compliance})$$

In the mechanically ventilated patient, this relationship is expressed as:

$$\Delta Pcir + \Delta Pmus = (\dot{V} \times R) + (VT / Crs)$$

where ΔPcir is the change in ventilator circuit pressure above baseline (peak pressure minus end-expiratory pressure: Ppeak − PEEP); ΔPmus is inspiratory muscle pressure generated by the patient (if present); $\dot{V}$ is the flow into the patient's lungs; R is the resistance of the external circuit, artificial airway, and natural airways combined; V_T is the tidal volume; and C_{RS} is the respiratory system compliance. If intrinsic or auto-PEEP (PEEPi) is present, muscle and circuit pressure must overcome this end-expiratory bias before flow and volume can be delivered, and thus PEEPi will add to the pressure requirement.

When flow is paused and pressure is held constant at end inspiration ($\dot{V} = 0$, Pmus = 0), the ventilator circuit pressure levels off at a pressure commonly referred to as the "plateau" pressure (Pplat). By use of this inspiratory hold, the components of Pcir required for flow and for respiratory system distention can be separated to describe R and Crs:

$$R = (Ppeak - Pplat)/\dot{V}$$

$$Crs = VT / (Pplat - PEEP)$$

Importantly, airway pressure measurements made under no-flow conditions are alveolar pressures and are determined by the pressure needed to distend the lung and the chest wall at that volume (Pplat at end inspiration, PEEP at end expiration). However, it is only the pressure across the lungs (transpulmonary pressure [TPP]) that affects alveolar stretch, drives regional ventilation, and maintains end-expiratory lung volume. TPP can be directly measured if an estimate of average pleural pressure (approximated by esophageal pressure) is available. Thus TPP = alveolar pressure minus pleural pressure = Paw − Ppl.[9]

In practice, because chest wall compliance (the major determinant of Ppl) is generally high, Ppl changes over the respiratory cycle are usually small, and measurements of airway Pplat and PEEP are reasonable approximations of TPP. In contrast, under conditions of very low chest wall compliance (e.g., obesity, anasarca, abdominal compartment syndrome, tight bandages), Ppl may be quite high, and thus the measured Pplat and PEEP will markedly overestimate the actual TPP.[9] This influence needs to be considered when setting the upper limits of ventilator settings in such patients and may require actual measurements of Ppl (Pes) to be safe.

In situations where spontaneous efforts occur, no-flow conditions at end inspiration are difficult to obtain, and consequently Pplat may be impossible to measure in real time. One solution to approximate Pplat under these conditions would be to deliver a controlled (i.e., passive) breath with an inspiratory pause using a similar VT and PEEP. Alternatively, there are proprietary monitors that can analyze the expiratory flow pattern during a passive exhalation to calculate respiratory system compliance and resistance and then determine a Pplat.[10]

Flow-Targeted vs. Pressure-Targeted Breaths

As noted earlier, there are two basic approaches to delivering positive-pressure breaths: flow targeting and pressure targeting. With flow targeting, the clinician sets inspiratory flow so that circuit pressure is the dependent variable. With pressure targeting, the clinician sets an inspiratory pressure target (with either time or flow as the cycling criterion) so that flow and volume are dependent variables (i.e., varying with lung mechanics and patient effort). With a flow-targeted breath, changes in compliance, resistance, or patient effort will change Pcir (but not flow); in contrast, with a pressure-targeted breath, similar changes in compliance, resistance, or effort will cause a change of tidal volume (but not Pcir).

Each strategy has advantages and disadvantages.[1,11] For flow-targeted breaths, a minimal tidal volume can be guaranteed. For pressure-targeted breaths, the rapid initial flow and subsequent declining flow of pressure targeting may enhance gas mixing and patient synchrony. As noted earlier, on modern ventilators, a variety of feedback mechanisms can combine features of flow- and pressure-targeted breaths.

Intrinsic (Auto) PEEP

PEEPi is the positive end-expiratory pressure that develops within alveoli because of insufficient expiration time, either because of inadequate time allowed between breaths by the ventilator or patient or because of increased expiratory resistance and collapse (flow limitation).[6–8,12–15] PEEPi depends on three factors: the minute ventilation, the expiratory time fraction, and the respiratory system's expiratory time constant (the product of resistance and compliance). The potential for developing PEEPi rises with increases in the minute ventilation, decreases in the expiratory time fraction, or increases in the expiratory time constant (i.e., with higher R or C_{RS} values).

The development of PEEPi will have different effects during pressure-targeted compared with flow-targeted ventilation. In flow-targeted ventilation, the constant delivered flow and volume (and thus ΔP_{cir}) means that a rising PEEPi will increase both the Ppeak and the Pplat. In contrast, in pressure-targeted ventilation, the set P_{cir} limit coupled with a rising PEEPi level will decrease ΔP_{cir} and, with it, the delivered tidal volume (and minute ventilation). Importantly, this accommodation may help limit the buildup of PEEPi.

In the patient without respiratory effort, PEEPi can be recognized in two ways. First, when an inadequate expiratory time produces PEEPi, analysis of the flow graphic will show that expiratory flow has not returned to zero before the next breath is given. Second, PEEPi in alveoli with patent airways can be quantified during an expiratory hold maneuver that permits equilibration of the end-expiratory pressure with Pcir. Note that total end-expiratory pressure is the sum of applied PEEP and PEEPi. Importantly, in patients with airway collapse, the expiratory hold maneuver will not detect the presence of PEEPi in units peripheral to the zone of closure.

In the patient with respiratory efforts, PEEPi can function as an inspiratory threshold load that produces delayed or even missed triggering of the desired breath.[12–14] In those cases with tidal flow limitation, this load can be counterbalanced with the judicious application of applied PEEP, guided either clinically or with Pes measurements.[13]

Distribution of Ventilation

A positive-pressure tidal breath must be distributed among the millions of alveolar units in the lung.[16–18] Factors affecting this distribution include regional resistances, compliances, functional residual capacities, the delivered flow pattern (including inspiratory pause), and the presence or absence of patient inspiratory efforts. In general, positive-pressure breaths will tend to distribute more to units with high compliance and low resistance and away from obstructed or stiff units (Fig. 37.2). This creates the potential for regional overdistention of healthier lung units, even in the face of "normal"-sized tidal volumes (see "Ventilator-Induced Lung Injury" later).

The flow pattern influences ventilation distribution. For example, when there are obstructive inhomogeneities, slow and constant flows will tend to distribute gas more evenly (although consequent shorter expiratory times may worsen air trapping). In addition, end-inspiratory pauses can also allow a gas shifting *pendelluft* action to help fill disadvantaged alveoli (see Fig. 37.2). In contrast, when there is parenchymal lung injury without obstructive airway inhomogeneity, initially rapid flows with subsequent deceleration (typically seen in pressure-targeted breaths) may distribute gas more evenly and will pressurize lung units rapidly, producing a higher mean inspiratory alveolar pressure for a given breath volume.

Finally, the presence or absence of patient efforts will affect this distribution. A passive positive-pressure breath without diaphragmatic contraction will distribute to more nondependent regions. In contrast, an active diaphragm will facilitate distribution of gas to more dependent zones. Importantly, in lungs with severe mechanical heterogeneity, an active diaphragm may promote regional overinflation (see "Ventilator-Induced Lung Injury" later).[19,20]

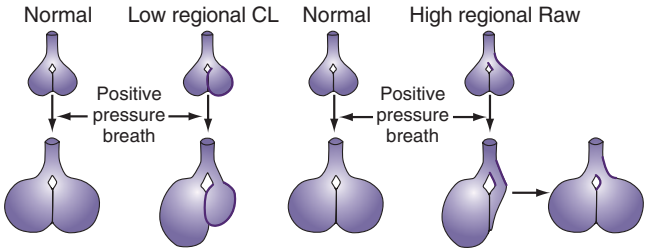

Fig. 37.2 Schematic effects of the ventilation distribution in two-unit lung models with homogeneous mechanical properties, abnormal compliance distribution, and abnormal resistance distribution. Note that in situations involving inhomogeneous lung mechanics, positive-pressure breaths are preferentially distributed to "healthier" regions of the lung and can produce regional overdistention even when a normal-sized global tidal volume is delivered. *CL,* lung compliance; *Raw,* airway resistance. (Adapted from MacIntyre NR. Mechanical ventilatory support. In Dantzker D, MacIntyre NR, Bakow E, eds. *Comprehensive Respiratory Care.* Philadelphia: Saunders; 1995, p.453)

It should be noted that more uniform ventilation distribution does not necessarily mean better $\dot{V}/\dot{Q}$ matching (i.e., more homogeneous ventilation distribution may actually worsen $\dot{V}/\dot{Q}$ matching in a lung with inhomogeneous perfusion). Because of all these considerations, predicting which flow pattern will optimize ventilation-perfusion matching is difficult, often inconsequential, and usually an exercise of empirical trial and error.

Alveolar Recruitment and Gas Exchange

Because of alveolar flooding, inflammatory exudates, and collapse, lung injury usually leads to $\dot{V}/\dot{Q}$ mismatching and intrapulmonary shunt.[21] In many (but not all) of these disease processes, substantial numbers of collapsed alveoli can be recruited during a positive-pressure ventilatory cycle. The ongoing opening and closure may be effectively countered by adequate end-expiratory pressure (PEEP or continuous positive airway pressure [CPAP]).[22–25] Alveoli prevented from collapsing, or "derecruiting," by PEEP receive several potential benefits. First, alveolar recruitment improves $\dot{V}/\dot{Q}$ matching and gas exchange throughout the ventilatory cycle. Second, as discussed in more detail later, continually patent alveoli are not exposed to the risk of injury from the shear stress of repeated opening and closing. Third, open alveoli increase generation of surfactant monolayers that improve lung compliance.

PEEP, however, can also be detrimental. Because the tidal breath is delivered on top of the baseline PEEP, end-inspiratory pressures are usually raised by the application of PEEP (although this increase may be less than the actual added PEEP because of recruitment-improved compliance). This increase must be considered if the lung is at risk for regional overdistention (see "Ventilator-Induced Lung Injury" later). Moreover, because parenchymal lung injury is often quite heterogeneous, appropriate PEEP in one region may be suboptimal in another and excessive in yet another. Optimizing PEEP is thus a balance between recruiting the recruitable alveoli in diseased regions without overdistending already recruited alveoli in healthier regions. Another potential detrimental effect of PEEP is that it raises mean intrathoracic pressure, with the potential in susceptible patients to impede venous return and compromise cardiac filling (see "Cardiac Effects" later).

Because diseased lung units require higher pressures to open than to keep open, additional recruitment can sometimes be provided by the use of recruitment maneuvers (RMs) that apply pressures in excess of the tidal values.[26–29] RMs are often performed using sustained inflations

(e.g., 30–40 cm H_2O) for up to 2 minutes. Alternative approaches use transient elevations of the PEEP–tidal volume setting and single or multiple "sigh breaths" that take the lung briefly to near-total lung capacity. Importantly, these transient pressure elevations can themselves have adverse hemodynamic consequences and, to avoid undesired patient efforts, the patient may require additional sedation (or even neuromuscular blockade).[26–29] It also must be pointed out that RMs provide initial alveolar recruitment only—the maintenance of recruitment depends on an appropriate setting of PEEP to prevent subsequent derecruitment.

Inspiratory time prolongations may also improve recruitment.[30–32] Prolonging inspiratory time, generally by adding a pause, often in conjunction with a rapid decelerating flow (i.e., pressure-targeted breath), has several physiologic effects. First, the longer inflation period may recruit more alveoli because recruitment depends not only on the pressure applied but also on its duration. Second, increased gas mixing time may improve $\dot{V}/\dot{Q}$ matching in parenchymal lung injury. Third, the development of PEEPi consequent to shorter expiratory times can have effects similar to those of applied PEEP. It should be noted, however, that the distribution of PEEPi (most pronounced in lung units with long time constants) may be less uniform than that of applied PEEP; thus the effects on $\dot{V}/\dot{Q}$ may also be different. Fourth, because these long inspiratory times significantly increase total intrathoracic pressures, cardiac output may be reduced (see "Cardiac Effects" later). And finally, inspiratory-to-expiratory ratios that exceed 1:1 (so-called inverse-ratio ventilation) are uncomfortable, and patient sedation/paralysis is often required unless a gating mechanism allows spontaneous breathing during the inflation period (airway pressure release ventilation).[31]

Mechanical Unloading

Mechanical loads describe the physical demands placed on respiratory muscles to breathe.[33,34] Loads are often expressed as the pressure–time product (PTP—the integral of pressure over time), work (W—the integral of pressure over volume), or power (W / time). Because mechanical loads correlate with inspiratory muscle oxygen demands, the concept of load is useful in considering inspiratory muscle energy requirements during spontaneous or interactive ventilatory support. More recently, the concept of mechanical loads (especially power) have been used to describe mechanical forces on the lungs that might be implicated in producing injury (see "Ventilator-Induced Lung Injury" later).[35]

Compliance and resistance, coupled with delivered flow and volume, each contribute to the magnitude of the load per breath (see "Alveolar Ventilation and the Equation of Motion" earlier). During spontaneous breaths, Pcir is zero, and integrating Pes over time or volume (in reference to the passive inflation pressure) describes the load borne by the inspiratory muscles to inflate the lungs. During a controlled passive breath, integrating Pcir over time or volume describes the load borne by the ventilator to inflate the entire respiratory system (lungs and chest wall), and integrating Pes over time or volume describes the loads imposed by the chest wall only. During interactive breaths, the load is shared between patient and ventilator.

Inspiratory muscle overload is one of the major determinants of continuing ventilator dependency and can result either from excessive mechanical loads or from inspiratory muscle dysfunction. Loads can be increased either by disease or by inappropriate ventilatory assistance (see "Patient-Ventilator Dyssynchrony" later). Inspiratory muscle dysfunction can be a result of the systemic inflammatory response syndrome, metabolic disturbances, drugs (e.g., steroids, previous use of neuromuscular blockers), malnutrition, or malpositioning (i.e., diaphragm flattening from lung overinflation).[36] Mathematically, inspiratory muscle fatigue and failure can be expected when the Pressure Time Index (PTI) exceeds 0.15[33]:

$$\text{PTI} = \text{Inspiratory pressure} / (\text{max diaphragmatic pressure}) \times (\text{inspiratory time} / \text{breath cycle time})$$

Clinically, inspiratory muscle overload is manifested by rapid, shallow breathing patterns; paradoxical abdominal motion; and patient distress.

Insufficient loading may also affect inspiratory muscles. Specifically, controlled mechanical ventilation that occurs without any patient effort, perhaps for as little as 24 hours, may produce muscle changes similar to disuse atrophy—a condition described as "ventilator-induced diaphragmatic dysfunction" (VIDD).[37–39]

ADVERSE EFFECTS OF POSITIVE-PRESSURE MECHANICAL VENTILATION

Ventilator-Induced Lung Injury

The lung can be injured when it is stretched excessively by positive-pressure ventilation. Historically, the most well-recognized injury was alveolar rupture, presenting as extraalveolar air in the mediastinum (pneumomediastinum), pericardium (pneumopericardium), subcutaneous tissue (subcutaneous emphysema), pleura (pneumothorax), and vasculature (air emboli). The risk of extraalveolar air increases as a function of the magnitude and duration of alveolar overdistention. Thus interactions of the respiratory system mechanics and mechanical ventilation strategies (e.g., high regional tidal volume and PEEP—both applied and intrinsic) that produce regions of excessive alveolar stretch for prolonged periods create alveolar units that are at risk for rupture.

Over the last half-century, it has become increasingly clear that repeatedly excessive alveolar stretch (i.e., beyond physiologic limits) can produce significant lung injury even without frank alveolar rupture (ventilator-induced lung injury [VILI])[40] Excessive stretching is induced by excessive "stress" (transpulmonary pressure) producing excessive "strain" (volume change) at end inspiration (static strain) and during tidal breath delivery (tidal strain).[40–46] A similar phenomenon occurs at the interfaces of collapsed and open alveoli when the collapsed alveoli are repetitively opened and closed. VILI may be worsened by increasing the frequency of excessive lung tidal stretching (reflected in measurements of the mechanical power to breathe) and from acceleration forces associated with rapid initial gas flow into the lung.[35] Pathologically, VILI manifests as diffuse alveolar damage and is associated with cytokine release[47,48] and bacterial translocation.[49]

VILI is often a regional phenomenon that occurs when low-resistance/high-compliance units receive a disproportionately high regional tidal volume (see Fig. 37.2) or when collapsed lung regions are repeatedly opened and closed. Importantly, vigorous spontaneous efforts, although sometimes improving ventilation distribution as described earlier, can also produce regional overdistention in severely damaged lungs. This can be especially harmful if spontaneous efforts result in excessive tidal volumes (self-induced lung injury [SILI]).[19,20]

Concern about VILI development is the rationale for using "lung-protective" ventilator strategies that include tidal volumes in the physiologic range (e.g., 4–8 mL/kg ideal body weight [IBW]), maximal end inspiratory TPP below the physiologic maximum (i.e., <25–30 cm H_2O), and PEEP strategies that minimize the collapse-reopening phenomenon without overdistending patent lung units.[25,50–52]

More recently, analyses of pressure changes during tidal volume delivery have helped "fine-tune" these recommendations. For example, the driving pressure to distend alveoli (DP = Pplat − PEEP) reflects the compliance characteristics of the lung during tidal breath delivery

(DP = VT / C).[45] From retrospective analyses of several mechanical ventilation trials, elevations in DP (e.g., >13–19 cm H_2O) would suggest either excessive regional tidal distention (in spite of an acceptable "global VT") or inadequate recruitment (in spite of acceptable gas exchange). A similar strategy analyzes the pressure profile during tidal breath delivery with a constant flow (stress index).[53] Under these conditions, an airway pressure waveform with a progressively increasing slope suggests overdistention; an airway pressure waveform with a progressively decreasing slope suggests inadequate recruitment; and an airway pressure waveform with a diagonal straight line suggests less hazardous VT and PEEP settings. Importantly, lung protective strategies may require acceptance of less-than-optimal values for pH, PaO_2, and PCO_2 in exchange for lower (and safer) distending pressures and volumes.

Cardiac Effects

In addition to affecting ventilation and ventilation distribution, intrathoracic pressure changes resulting from positive-pressure ventilation can affect cardiovascular function.[54–58] In general, as the mean intrathoracic pressure is increased, the right ventricular filling is decreased. This is the rationale for using volume repletion to maintain cardiac output in the setting of high intrathoracic pressure. In addition, lung distention can increase the right ventricular afterload, further compromising cardiac output. Conversely, elevations in intrathoracic pressure can improve left ventricular function because of an effective reduction in its afterload. Indeed, the sudden release of intrathoracic pressure (e.g., during a ventilator disconnect or spontaneous breathing trial) has the potential to precipitate flash pulmonary edema because of the acute increase in afterload coupled with increased venous return.

Intrathoracic pressures can also influence the distribution of perfusion. Although an oversimplification of the actual dynamics, the relationship between alveolar and perfusion pressures in the three-zone lung model can help explain this.[59] Specifically, the supine human lung is generally in a zone 3 (vascular distention) state. However, as the intraalveolar pressures rise, the zone 2 and zone 1 regions can appear, creating high $\dot{V}/\dot{Q}$ units. Indeed, increases in dead space (occurring in zones 1 or 2 of the lung) can be a consequence of ventilatory strategies using high ventilatory pressures or in the setting of high PEEP (either intrinsic or applied).

Positive-pressure mechanical ventilation can affect other aspects of cardiovascular function. Specifically, dyspnea, anxiety, and discomfort from inadequate ventilatory support can lead to stress-related catechol release, with subsequent increases in myocardial O_2 demands and risk of dysrhythmias. In addition, coronary blood vessel O_2 delivery can be compromised by inadequate gas exchange from lung injury coupled with low mixed venous O_2 partial pressure, resulting in part from high O_2 consumption demands by the ventilatory muscles.

Patient-Ventilator Dyssynchrony

Patients can interact with all three phases of an assisted breath: (1) trigger, (2) flow delivery, and (3) cycle.[60–62] Triggering dyssynchronies that manifest as unrecognized or delayed responses to patient effort can be attributed to insensitive or unresponsive triggering mechanisms or PEEPi. These impose a triggering load on the respiratory muscles. Premature triggering ("double triggering") may be derived from circuit motion artifacts, premature breath cycling, or the recently described "reverse" triggering observed during controlled breaths. Flow dyssynchrony occurs when the ventilator's flow delivery algorithm is not well matched to patient effort and is more likely to occur during fixed-flow breaths (i.e., flow targeted). Cycle dyssynchrony occurs when the breath cycling criteria are either inappropriately short or long for the duration of effort. Patients dyssynchronous in any phase will have unnecessary loads placed on their respiratory muscles, thereby increasing the risk of muscle fatigue. Moreover, dyssynchronous interactions produce discomfort and dyspnea.

There is no doubt that many dyssynchronies are subtle and of little clinical relevance. However, significant dyssynchronies that produce severe patient discomfort are frequently cited indications for the administration of sedatives in many intensive care units (ICUs). Therefore this may affect the duration of intubation, as high sedation usage is linked to longer ventilator use.

Managing dyssynchronies can be a significant clinical challenge. Setting trigger sensitivity to be as sensitive as possible without autotriggering is crucial. Judiciously applied PEEP in the setting of a triggering load from PEEPi can be helpful. Careful adjustments of flow magnitude, timing, and patterns (especially the use of pressure-targeted, variable-flow breaths) may help optimize flow and cycle synchrony. Finally, the newer interactive modes of PAV and NAVA described earlier may offer help to optimize synchrony in the future.

Oxygen Toxicity

Oxygen concentrations approaching 100% are known to cause oxidant injury to the airways and lung parenchyma.[63,64] The majority of the data supporting this concept, however, are derived from animal studies, and animals and humans often have different O_2 tolerances. It is unclear what the "safe" O_2 concentration or duration of exposure is in sick humans. Most consensus groups have argued that fraction of inspired oxygen (Fio_2) values less than 0.4 are safe for prolonged periods and that Fio_2 values greater than 0.8 should be avoided if possible.

Ventilator-Related Infections

Mechanically ventilated patients are at an increased risk of pulmonary infections for several reasons[2]: (1) The natural protective mechanism of glottic closure is compromised by an endotracheal tube. This permits the continuous low-grade seepage of oropharyngeal material into the airways. (2) The endotracheal tube impairs the cough reflex and in itself serves as a potential portal for pathogens to enter the lungs. This route is particularly important if the external circuit is contaminated. (3) Airway and parenchymal injury from both the underlying disease and management complications may predispose the lung to infections. (4) The ICU environment, with its heavy antibiotic use and the presence of very sick patients in close proximity, heightens risk for a variety of nosocomial infections, often from antibiotic-resistant organisms.

Preventing ventilator-associated tracheobronchitis and pneumonia is of great importance because the length of stay and mortality are heavily influenced by their development.[65–67] Handwashing and carefully chosen antibiotic regimens for other infections confer important benefits. Management strategies that avoid breaking the integrity of the circuit (e.g., circuit changes only when visibly contaminated) also appear to be helpful. Finally, the continuous drainage of subglottic secretions may be a simple way of reducing lung contamination by oropharyngeal material.

CONCLUSION

Positive-pressure mechanical ventilatory support is an essential component in the life support of patients with respiratory failure. However, it is important to note that this technology is supportive, not therapeutic, and it cannot cure lung injury. Indeed, the best we can hope for is to "buy time" by supporting gas exchange without harming the lungs.

The major goals of mechanical ventilation with positive pressure are to unload the ventilatory muscles and to optimize ventilation-perfusion matching so as to ensure adequate pulmonary gas exchange. Important complications include VILI, cardiac compromise, oxygen

toxicity, and patient discomfort. Applying ventilatory support often requires trade-offs as clinicians attempt to balance gas exchange needs with the risk of these complications. Future innovations cannot focus simply on physiologic endpoints. Rather, innovations should demonstrate benefits in clinically relevant outcomes, such as mortality, ventilator-free days, barotrauma, and costs. Only then can we properly assess the often bewildering array of new approaches to this vital life-support technology.

KEY POINTS

- Ventilator breath delivery is characterized by the trigger, target, and cycle variables.
- The interaction of a positive-pressure breath and respiratory system mechanics is summarized by the equation of motion:

Airway Pressure = (Flow × Resistance)
+ (Tidal Volume/Respiratory System Compliance)
+ PEEP

- The goal of positive-pressure mechanical ventilation is to provide adequate gas exchange while protecting the lung from overdistention and recruitment–derecruitment injuries.
- Positive-pressure mechanical ventilation in obstructive lung disease poses the additional risk of producing overdistention from air trapping.

ANNOTATED REFERENCES

Beitler JR, Malhotra A, Thompson BT. Ventilator-induced lung injury. *Clin Chest Med.* 2016;37(4):633–646.
An excellent review attempting to link important data from animal studies of ventilator-induced lung injury to the clinical setting, with an emphasis on how ventilator strategies can produce both lung and systemic injury.

Briel M, Meade M, Mercat A, et al. Higher vs. lower positive end-expiratory pressure in patients with acute lung injury and acute respiratory distress syndrome: systematic review and meta-analysis. *JAMA.* 2010;303:865–873.
This is a meta-analysis of the three large trials conducted in the past decade examining high- versus low-PEEP strategies in the setting of low-VT ventilation. The results indicate that in acute respiratory distress syndrome (ARDS) patients, a high-PEEP strategy offers a mortality benefit. However, in the less severe acute lung injury (ALI) patients, a high-PEEP strategy trended toward a worse mortality.

Gilstrap D, MacIntyre N. Patient–ventilator interactions. Implications for clinical management. *Am J Respir Crit Care Med.* 2013;188(9):1058.
This is a comprehensive review of all of the important interactions between patients and ventilators during the triggering, flow delivery, and cycling phases of assisted breath delivery. It also provides practical information on how to manage clinically important dyssynchronies.

NIH ARDS Network. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *N Engl J Med.* 2000;342(18):1301–1308.
This landmark study clearly established the link between excessive lung stretching during mechanical ventilation and worse survival in patients with acute lung injury. The message from this paper is very clear: Although large tidal volumes may improve gas exchange, they ultimately cause harm by overstretching healthier regions of the lung.

Pinsky MR, Guimond JG. The effects of positive end-expiratory pressure on heart-lung interactions. *J Crit Care.* 1991;6(1):1–15.
An excellent overview of the complex interactions of intrathoracic positive pressure and cardiac function. The fact that the dual effects of decreased right heart filling and decreased left ventricular afterload can have both positive and negative effects is carefully explained.

Truwit JD, Marini JJ. Evaluation of thoracic mechanics in the ventilated patient. Part I. Primary measurements. *J Crit Care.* 1988;3:133–150; Part II. Applied mechanics. *J Crit Care.* 1988;3:192–213.
This two-part report comprehensively reviews all aspects of respiratory system mechanics as they apply to mechanical ventilation. Both theory and practical applicability are provided.

Basic Principles of Renal Replacement Therapy

Eric A.J. Hoste and Floris Vanommeslaeghe

Acute kidney injury (AKI) is a common complication in critically ill patients admitted to the intensive care unit (ICU).[1–3] Epidemiologic data suggest that over 50% of ICU patients suffer from AKI, and up to 13.5% will be treated with renal replacement therapy (RRT).[1–3] Change in patient characteristics, with admission of older patients with more comorbidities such as diabetes, cardiovascular disease, and hypertension, resulted over the last decade in a marked increase of the proportion of patients treated with RRT.[4,5] RRT has therefore become an essential and often used treatment option for ICU patients, involving a spectrum of treatment modalities, with various advantages and disadvantages depending on the situation. RRT is most often delivered via extracorporeal techniques, but the COVID-19 pandemic caused renewed interest in peritoneal dialysis (PD), a technique using the peritoneum of the patient as a semipermeable exchange membrane.

TECHNICAL ASPECTS OF RRT

Extracorporeal techniques can be done with different modalities (Table 38.1). These are named according to the duration of RRT and the technique used for exchange of solutes and water: diffusion or convection.

Diffusion and Convection

Exchange of waste products over the semipermeable membrane can be via diffusion (hemodialysis) or convection (hemofiltration) (Fig. 38.1). In diffusion, blood and dialysate flow countercurrent on both sides of the semipermeable membrane of the hemofilter. The driving force that moves solutes over the semipermeable membrane is the solute concentration gradient. Uremic toxins such as blood urea nitrogen and creatinine will have high blood concentrations and are absent in the dialysate. Other factors that determine the movement of solutes from blood to dialysate are the diffusion coefficient of the membrane, its thickness, and its surface area. Diffusion is very efficient in the removal of small molecules such as potassium, ammonium, and creatinine (<500 Da); it is less efficient in the removal of larger solutes.

In hemofiltration, solutes and water are transported over the membrane by a difference in pressure between both sides of the membrane. Water and solutes are pressed from the blood compartment to the so-called effluent. The permeability coefficient of the membrane and the difference in pressure between both sides of the membrane determine the amount of fluid and solutes transported over the membrane. The effluent rate is controlled by a pump. Hemofiltration is more efficient for removal of larger molecules. In hemodiafiltration, both convection and diffusion are combined.

There are currently no data to suggest the superiority of diffusion over convection.

Duration of RRT

Intermittent hemodialysis (IHD) is a very efficient dialysis technique performed during a 3- to 4-hour period; continuous renal replacement therapy (CRRT) is less efficient, but done 24 hours a day; and hybrid techniques, alternatively termed *sustained low-efficiency daily dialysis* or *extended daily dialysis* (SLEDD or EDD), have intermediate efficacy and are used 6–12 hours per day.[6,7]

Intermittent and hybrid therapies will be performed with the use of dialysis machines that are also used for chronic dialysis patients. These monitors typically have more complicated interfaces and are therefore often managed by dialysis nurses. CRRT is most often performed with specifically designed monitors with a relatively easy interface and are managed by ICU nurses. Some centers also use these RRT machines for hybrid therapy.

Specifics Aspects of a CRRT Circuit

Fig. 38.2 shows the different aspects of CRRT performed as continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF).

Dose of RRT

The dose of CRRT is by convention expressed as the clearance of urea, a small molecule that both in hemodialysis and hemofiltration is not retained by the membrane. The effluent rate—the volume of fluid produced by hemofiltration and/or hemodialysis—therefore equals the clearance of urea, and when corrected for body weight, can be used to express the dose of CRRT: dose of CRRT = effluent rate per hour per kg body weight (mL/kg/h). For a desired dose of 25 mL/kg/h for a 60-kg patient, the effluent rate will be 25 × 60 = 1500 mL/h. This effluent needs to be partly or completely replaced by a replacement fluid; otherwise, fluid losses will be too high. The amount of effluent that is replaced will determine the fluid balance of the patient. This replacement fluid can be given prefilter (predilution), postfilter (postdilution), or in a combination of both. When given in postdilution mode, blood will concentrate while passing through the capillaries of the hemofilter. This may lead to clogging (partial clotting) and clotting of the capillaries, leading to decreased efficacy because fewer capillaries are available. To prevent this, a filtration fraction—the proportion of effluent over plasma flow—of less than 25% is advised. The filtration fraction is indicated on the dashboard of present-day CRRT machines.

In CRRT, the delivered dose should be 20–25 mL/kg/h of effluent. Two large prospective randomized studies compared this dose to a higher dose and found that outcomes were similar.[8,9] Treatment interruptions often lead to a lower delivered dialysis dose. Therefore it is advised to prescribe a dose of 25–30 mL/kg/h.[10]

TABLE 38.1 Renal Replacement Therapy Modalities

Modality	Abbreviation	Treatment Duration (per day)	Blood Flow (mL/h)	Dialysate Flow (mL/min)
Intermittent hemodialysis	IHD	2–4 h	200–450	
Hybrid techniques		6–12 h	150–200	One and a half times blood flow
• Slow low-efficiency daily dialysis	SLEDD			
• Extended daily dialysis	EDD			
• Prolonged intermittent renal replacement therapy	PIRRT			
Continuous renal replacement therapy	CRRT	24 h	100–250	
• Continuous venovenous hemofiltration	CVVH			
• Continuous venovenous hemodialysis	CVVHD			
• Continuous venovenous hemodiafiltration	CVVHDF			
Peritoneal dialysis	PD	Solution: dextrose 1.5% or glucose 1.36% to start, higher glucose concentration according to ultrafiltration needs		
• Manual exchanges	CAPD	Fill volume 1500–2000 mL		
• Automated PD (cycler)	APD	Dwell time per exchange: 2 h, consider change to 4 h once acidosis, pulmonary edema, and hyperkalemia are resolved		

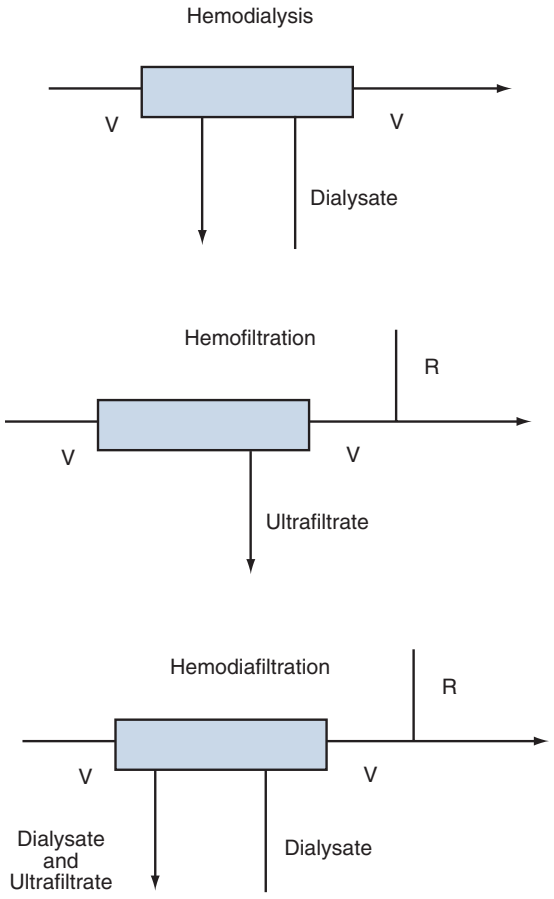

Fig. 38.1 Diffusion (as in hemodialysis) and convection (as in hemofiltration). *R,* Replacement fluid; *V,* venous blood prefilter and postfilter.

In intermittent RRT, the minimum delivered dose of dialysis should be three sessions of at least 3 hours per week, with a blood flow of >200 mL/min and a dialysate flow of >500 mL.[11]

Anticoagulation

During RRT, the patient's blood is purified by circulating it through an extracorporeal circuit containing a hemodialyzer, consisting of about 10,000 semipermeable capillary fibers. Disordered blood flow and contact of the blood with the bioincompatible material of the fibers activate the coagulation cascade, leading to clotting and subsequent blocking of the capillary fibers. This results in a reduction of the efficiency of the dialysis procedure, as fewer fibers remain available for solute exchange. When more pronounced, coagulation can even cause loss of extracorporeal blood volume by complete clotting of the extracorporeal circuit, so blood can no longer be returned to the patient.[12] Anticoagulation for RRT should be tailored according to patient characteristics and the modality chosen. Capturing the end result of the rebalanced hemostatic system in ICU patients with AKI is challenging, but new laboratory testing methods, including thromboelastography/rotational thromboelastometry (TEG/ROTEM) and thrombin generation assays, potentially yield vital information. The first technique assesses development, strength, and dissolution of clots by viscoelastic testing and does not take long before providing results. It offers information on the contribution of both enzymatic and cellular components in whole blood. Thromboelastometry analysis progressively finds acceptance in the care of patients undergoing high-risk surgery.[13] The second, thrombin generation (TG), mirrors a significant part of the overall hemostatic system, reflecting contributions of natural procoagulants and anticoagulants to hemostasis and the effect of drugs. Many semiautomated and fully automated assays are on the market today, although regrettably still lacking interlaboratory standardization.[14]

Special attention is required for nonanticoagulant strategies to avoid coagulation of the circuit. Patients with a high hematocrit are at higher risk for clotting of the extracorporeal/dialysis circuit because of the higher viscosity of the blood. Blood products should be administered separate from RRT as much as possible. Prompt reaction to pump alarms is important, avoiding interruption of the blood flow. In this regard, well-functioning vascular access is fundamental. Circuits with a lot of blood-air contact because of the use of drip chambers are especially prone to clotting. There is no evidence pointing towards the efficacy of intermittently rinsing the circuit with saline flushes to prevent clotting.[15]

No Anticoagulation Strategy

Several authors described large series of patients treated without any form of anticoagulation during RRT for AKI (in up to 50%–60%).[8,9] Especially in patients with coagulopathy, an acceptable treatment length can be reached even without anticoagulant.[16] Risking circuit clotting—in the worst case implying the loss of approximately 200 mL

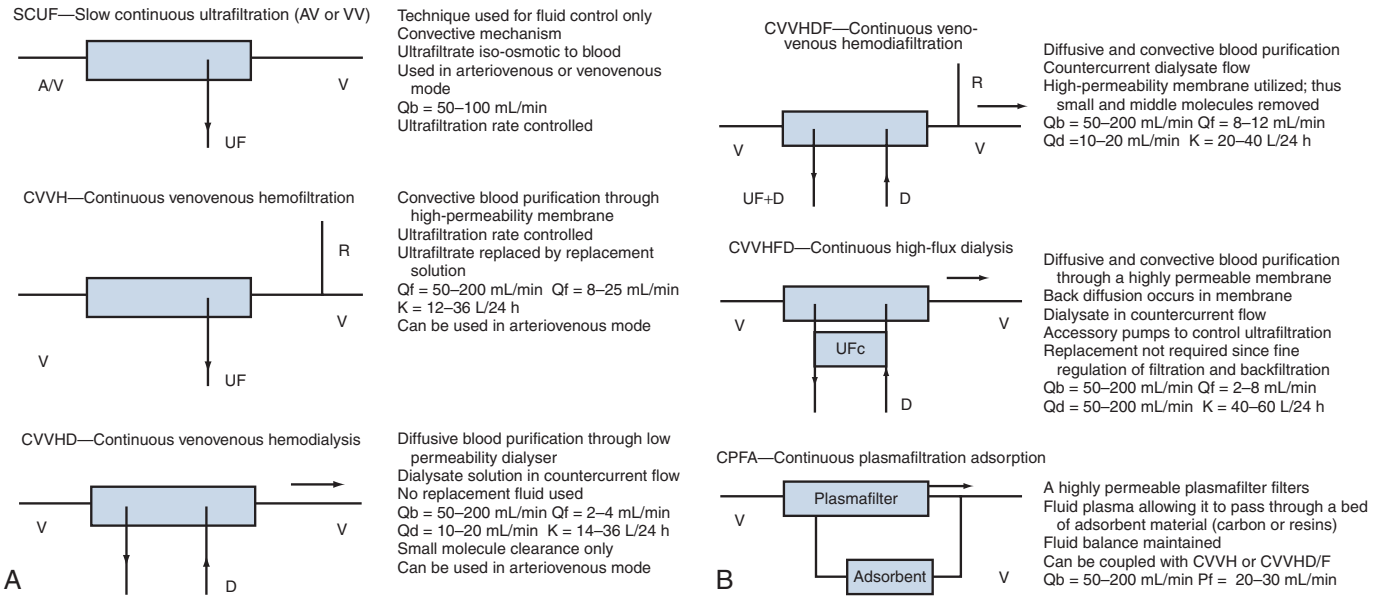

Fig. 38.2 Schematic representation and definitions of the different continuous renal replacement therapies according to standard nomenclature. of extracorporeal blood and eventually also the venous access—may be defensible in patients with high bleeding risk. Neither the effect of clogging on filter performance nor the consumption of coagulation factors in RRT without anticoagulation are well studied.

Unfractionated Heparin (UFH)

Current guidelines suggest using UFH for intermittent RRT in patients without increased bleeding risk and in the case of contraindications for citrate in continuous RRT. It has a half-life between 0.5 and 3.0 hours in patients receiving dialysis.[17] It has a rapid action time of approximately 3–5 minutes. UFH acts by potentiating thrombin and inhibiting activated factor Xa. A variety of infusion schemas exists, including single dose, repeated bolus, or continuous infusion. An example of a standard dosing regimen is a bolus of 500–1000 units at the start of treatment, followed by 500–750 units/h. Other authors suggest adapting the dose to the body weight, starting with a bolus of 10–20 units/kg/h, followed by a maintenance infusion of 10–20 units/kg/h that typically would be stopped 30 minutes before the end of treatment. UFH treatment needs to be individualized according to the clinical setting. It can be monitored with routine laboratory tests as activated partial thromboplastin time (aPTT) or activated coagulation time (ACT), but many centers move to anti–factor Xa assays for monitoring UFH because it reflects the anticoagulant activity more adequately, especially during inflammatory conditions.[18,19] Anti–factor Xa level–guided anticoagulation protocols yield important potential in decreasing filter clotting.[20] If routine laboratory tests are used, typical anticoagulation targets in ICU patients are 1.5–2 times prolongation of the aPTT and 40% increase of ACT. If needed, UFH can be reversed with protamine. Heparin failure, resulting in clotting of the circuit, can be the result of antithrombin deficiency or UFH neutralization by binding to plasma proteins. During treatment, the thrombocyte count should be monitored, allowing timely detection of heparin-induced thrombocytopenia (HIT).

Low-Molecular-Weight Heparin (LMWH)

Low-molecular-weight heparins are effective and can safely be used for anticoagulation during RRT in critically ill patients.[21] LMWHs are mostly administered as a single bolus in the beginning of the dialysis, immediately after the start in the case of postfilter administration, or prefilter after 5 minutes.[22] They have a weight-based dosing and are frequently used without therapeutic monitoring in case of short treatment sessions, but especially in the setting of prolonged daily use, periodic measurement of anti–factor Xa levels is mandatory, because LMWHs are only partially cleared during hemodialysis (especially with high-flux membranes).

Citrate

The 2012 Kidney Disease Improving Global Outcomes (KDIGO) Clinical Practice Guidelines for Acute Kidney Injury have recommended regional citrate anticoagulation as the preferred anticoagulation modality for CRRT in critically ill patients for whom it is not contraindicated.[10] Citrate chelates calcium, an essential cofactor of many steps of the coagulation cascade. A whole range of protocols exist, applying various dialysate/replacement fluids for different RRT modalities. Prefilter infusion of citrate, either as a separate trisodium citrate solution or added to a calcium-free predilution replacement fluid, lowers the ionized calcium levels in the extracorporeal circuit to a level that achieves full blood anticoagulation (i.e., 0.3–0.4 mmol/L). In most of the protocols, the citrate dose is adapted according to the result of postfilter circuit ionized calcium measurements, although there is some concern about the reliability of blood gas analyzers at the point of care for this purpose.[23] Having a low molecular weight (198 and 258, respectively) and high sieving coefficient, citrate and citrate complexes are partially removed in the effluent. Citrate clearance is higher with dialysis than with CVVH, with extraction ratios from 20% to 60% depending on the modality and dose of the RRT. In most of the treatment protocols calcium infusion is needed to replace calcium losses and maintain systemic ionized calcium levels within the normal range. Remaining citrate is metabolized in the liver, muscle, and kidney, producing bicarbonate and eventually leading to metabolic alkalosis; therefore most of the commercially available replacement fluids contain a lowered bicarbonate concentration. In patients with impaired citrate metabolism, acidosis can ensue. Other potential

metabolic derangements include hypernatremia (metabolization of trisodium citrate), hypomagnesaemia (effluent losses in the form of citrate complexes), and hypocalcemia. Citrate accumulation can occur in patients with a profound shock or severe liver failure, although studies argued that citrate can be used safely in patients with liver dysfunction.[24] In case of citrate accumulation, there is a simultaneous increase of the total calcium and fall of the ionized calcium. The total calcium to ionized calcium ratio is the best marker for citrate intoxication. When this ratio exceeds 2.5, citrate administration must be stopped. Unintended rapid infusion of a hypertonic citrate solution, causing life-threatening hypocalcemia, is the main risk of citrate anticoagulation. In this case, it is recommended to stop the citrate infusion while continuing dialysis with a calcium-containing dialysate. In experienced hands, severe hypocalcemia-related complications seldom occur, and regional citrate anticoagulation has been shown to be safe. Treatment protocols should describe how to adjust flows under different conditions to prevent metabolic derangements. Compared with heparin, citrate is associated with lower risk of circuit loss, lower incidences of filter failure, less bleeding, and lower transfusion rates. Furthermore, citrate is a source of energy and has potential antiinflammatory effects.

UFH and Protamine

Regional anticoagulation can also be accomplished by the combination of UFH and protamine. Its use has decreased in parallel with the increasing popularity of citrate. Protamine has several side effects such as anaphylaxis, hypotension, cardiac depression, leukopenia, and thrombocytopenia. Further, there may be a risk for a rebound anticoagulant effect because of the shorter half-life of protamine compared with heparin. Regional anticoagulation with heparin-protamine is therefore no longer recommended.[10,25,26]

Platelet-Inhibiting Agents

Prostacyclin (PGI_2) and its analogue (nafamostat) inhibit platelet aggregation and adhesion. They have been used alone or in combination with heparin to improve filter survival, but several guidance documents do not recommend their use in RRT. In addition, these drugs are expensive, and there are safety concerns over hemodynamic stability with the use of prostacyclin, and anaphylaxis, agranulocytosis, and hyperkalemia with the use of nafamostat.

Dialysis Access

Central venous access is with a double-lumen catheter, preferably in the right jugular vein or a femoral vein. Use of the subclavian vein is not recommended, because contact of the catheter with the vessel wall may lead to thrombosis and ensuing stenosis, jeopardizing the possibility for an arteriovenous fistula in case there is no recovery of kidney function and the patient remains dialysis dependent. This will more likely occur when the catheter has a trajectory with angulations, such as when inserted in the left jugular vein or the subclavian veins.

For optimal blood flow rates, the tip of the catheter should be located in a large vein (i.e., the inferior or superior vena cava). For an adult, the optimal length of a catheter in the right jugular vein is therefore 12–15 cm; the left jugular vein 15–20 cm; and for the femoral approach, this is 19–24 cm. There are several different designs of dialysis catheters. At present it is not clear which design is preferable. The outer diameters of catheters vary between 11 and 14 French; larger catheter diameters will result in better blood flow rates.[27]

Temporary, noncuffed, nontunneled dialysis catheters are preferred in case of sepsis, lack of image guidance, and uncorrectable coagulopathy. However, in the absence of these contraindications, placement of a cuffed tunneled catheter may be considered immediately or after 2 weeks of using a temporary catheter.[28,29]

Like hemodialysis catheters, the insertion of Tenckhoff catheters for peritoneal dialysis can be done bedside using a Seldinger technique. In challenging cases, ultrasound or fluoroscopic guidance may be of added value. In patients with previous midline surgical scars or suspicion of intraabdominal adhesions, a surgical approach (laparoscopy or laparotomy) that offers direct vision is preferred. In experienced teams, start of peritoneal dialysis within 24–48 hours of catheter placement comes with low rates of PD fluid leaks, and rapid escalation in dwell volumes is possible. Tenckhoff catheters placed using the percutaneous technique or surgically with a purse-string suture can be removed easily, or might serve as a long-term access in case patients fail to recover from the AKI episode.

INITIATION OF RRT

The kidneys are crucial for removal of water and homeostasis of electrolytes and acid-base. Volume overload in an anuric patient and severe electrolyte and acid-base abnormalities are therefore absolute criteria for initiation of RRT (Table 38.2).[30,31] Unlike HD or CRRT, ultrafiltration and clearance cannot be exactly predicted in PD treatment. High-glucose-containing PD solutions can remove up to 1 L of fluid in 4 hours. Standard PD solutions do not contain potassium, but because solute removal is slower during PD, it may take a one day of high-volume PD to achieve serum potassium control, and later on the treatment potassium administration (intravenous or via the PD solution) may be necessary.

The exact timing of initiation of RRT in ICU patients has been the topic of fierce debates for decades. If exposure to RRT was without risks, we would not wait until occurrence of absolute criteria. But very

TABLE 38.2 Criteria for Initiation of RRT for AKI

Indication	Characteristic
ABSOLUTE CRITERIA	
Metabolic abnormality	BUN >100 mg/dL (35.7 mmol/L)
	Hyperkalemia >6 mmol/L with ECG abnormalities
	Hypermagnesemia >8 mEq/L (4 mmol/L) with anuria and absence of deep tendon reflexes
Acidosis	pH <7.15
	Lactic acidosis related to metformin use
Fluid overload	Diuretic resistant
RELATIVE CRITERIA	
Metabolic abnormality	BUN >76 mg/dL (27 mmol/L)
	Hyperkalemia >6 mmol/L
	Dysnatremia
	Hypermagnesemia >8 mEq/L (4 mmol/L)
Acidosis	pH >7.15
Anuria/oliguria	AKI stage 1
	AKI stage 2
	AKI stage 3
Fluid overload	Diuretic sensitive

AKI, Acute kidney injury; *BUN,* blood urea nitrogen; *ECG,* electrocardiogram.

Modified from Gibney N, Hoste E, Burdmann EA, et al. Timing of initiation and discontinuation of renal replacement therapy in AKI: unanswered key questions. *Clin J Am Soc Nephrol.* 2008;3:876–880.

early initiation of RRT in patients will expose these patients to potential hazards associated with insertion of the catheter (blood loss, thrombosis, catheter infection) and exposure to the extracorporeal circuit (air embolism, hypotension, etc.).[32] If RRT offers support in patients with only mild or moderate AKI, early initiation may be beneficial. However, available data suggest no benefit in, for instance, modulation of the inflammatory response,[33,34] and one study even showed harm when RRT was started very early in patients with severe sepsis or septic shock.[35]

Cohort studies on timing of RRT showed a benefit for early initiation of RRT.[36,37] However, the few small prospective randomized studies that evaluated early initiation of RRT could not show a benefit for early initiation of RRT.[31,38,39] On the other hand, cohort studies also showed that late initiation is associated with worse outcomes.[40–42] Recently, four large prospective randomized studies have addressed this in different types of cohorts. Of these, the ELAIN study, a single-center study in predominantly surgical ICU patients, found initiation at AKI KDIGO stage 2 led to reduced 90-day mortality when compared with initiating CRRT at AKI KDIGO stage 3.[43] The three other studies in general ICU and septic ICU patients could not show a mortality difference between early or accelerated initiation at KDIGO stage 2 or 3 compared with standard of care.[44–46] Moreover, they noticed that approximately 40% of patients in the standard group were not treated with RRT. Finally, the largest of the three studies, the STARRT-AKI study that included 3019 patients, found that accelerated initiation was associated with a higher proportion of patients dependent on RRT at 90 days.[46] A meta-analysis in which all prospective studies except STARRT-AKI were included showed that there is no benefit for an accelerated initiation of RRT when there are no urgent indications for RRT, and this strategy may lead to less use of RRT and thus costs.[47]

The decision to initiate RRT is therefore based on clinical criteria. These should incorporate the "demand" for RRT, which includes overload of fluid and solutes, but also severity of acute disease and chronic comorbidities.[48] Knowledge on the deterioration or recovery of kidney function within a certain period would help us in the timing of RRT, especially when there are only relative criteria for initiation of RRT (see Table 38.2). A clinical risk assessment may identify patients at greater risk for further deterioration of kidney function. This may take into account risk factors such as age, chronic kidney disease, and severity of illness of the patient. Other tools that have been explored are measurement of specific kidney biomarkers[49] such as C-C motif chemokine ligand 14 (CCL14)[50] and the furosemide stress test[51]

CHOICE OF RRT MODALITY

Since the introduction of CRRT in the mid-1980s, there has been debate on the optimal modality of RRT. Several relatively small studies and meta-analyses showed that CRRT and IHD are associated with similar patient outcomes.[52,53] However, the number of patients included in individual studies was relatively low, the baseline characteristics of patients were different, and the techniques used (modalities, dose, initiation criteria) varied between studies, making comparisons difficult. Renal outcomes may, however, be better when CRRT is used. Cohort studies and also comparison of the large prospective randomized studies on dose—the ATN and RENAL studies—suggest that CRRT is associated with better renal recovery and less end-stage kidney disease in survivors.[8,9,54–56]

CRRT is performed with a lower extracorporeal blood flow and allows removal of fluid over a longer time and a lower ultrafiltration rate, characteristics that enhance the hemodynamic tolerability of this technique. Hence, CRRT is often recommended for hemodynamically unstable patients,[10] although studies in specialized centers could not demonstrate that IHD was tolerated worse compared with CRRT in shock patients.[57]

Intermittent techniques, however, use fewer resources because they allow for several treatments with one machine per day, and dialysate and replacement fluid is produced by the dialysis machines instead of having to buy these special solutions for CRRT. It will depend on the specific setting on whether the cost of CRRT is greater than that of IHD or vice versa.[58,59] An important argument in favor of IHD and hybrid therapy is that these modalities will allow for mobilization of the patient during the off period. A recent meta-analysis suggests that hybrid therapies are associated with the same outcomes as CRRT, suggesting that increasing the length of intermittent treatment may combine the best of IHD and CRRT.[60] However, these data were compiled on a limited number of patients and most in cohort studies, making this conclusion prone to bias.

SPECIAL INDICATIONS

Heparin-Induced Thrombocytopenia

Up to 3% of heparin-exposed patients develop antibodies directed against the complex of heparin and platelet factor 4, resulting in thrombocytopenia with or without thrombosis. If HIT is likely, all heparin administration, including LMWHs, heparin-coated dialyzer membranes, and catheter locks containing heparin, must be stopped. Guidance documents recommend various options for anticoagulation during RRT in this circumstance: regional citrate anticoagulation or the use of direct thrombin inhibitors (such as argatroban or bivalirudin) or factor Xa inhibitors (such as fondaparinux).[10] Argatroban has a rapid onset of action and an elimination half-life of less than 1 hour. Its clearance is mainly hepatic (it is contraindicated in cases of severe liver failure) and independent of kidney function. Bivalirudin is renally cleared to a small extent (20%) and partially (25%) removed by dialysis.[61] Fondaparinux is excreted exclusively by the kidney[61] and can be removed using high-flux dialysis membranes.[62]

Patients with High Serum Urea Concentration

When applying acute RRT to a highly uremic patient (typically >175 mg/dL), precautions should be taken to prevent disequilibrium syndrome. This neurologic condition is characterized by nausea, vomiting, restlessness, and headache and may occasionally progress to seizures, coma, or death. The syndrome is believed to be primarily related to the decreasing osmolarity of the blood after the initiation of RRT, creating an osmotic gradient between the blood and the brain, which is compensated for by an influx of water into the brain compartment. To avoid brain edema caused by large variations in osmolality, several preventive measures can be taken, targeting a reduction in the plasma urea nitrogen of, at most, 40%. The dialysis dose can be reduced by lowering blood flow and dialysate flow, using a small dialyzer, and limiting the length of the treatment. The use of a sodium-enriched dialysate may further reduce the risk.[63]

Patients with Intracranial Hypertension or Cerebral Edema

In patients with acute brain injury, AKI requiring RRT may worsen the neurologic status in several ways. The accumulated urea and solutes diffuse from the blood compartment to the brain cells, thereby increasing water uptake by the brain cells. Dysfunction in the blood-brain barrier reinforces this process. The shift of water into brain tissue as a result of lowered tonicity of plasma with respect to the brain cells (as described in disequilibrium syndrome) may lead to increased intracranial pressure causing cerebral hypoperfusion. This is pronounced by the decreased or absent autoregulation of the cerebral blood flow and eventual hypotension during RRT. Both

hypotension and disequilibrium can be avoided by the slow progressive removal of fluids and solutes during CRRT, which in this setting is preferred over intermittent RRT. If the patient is also at increased risk for intracranial bleeding, locoregional citrate anticoagulation is recommended.[26] Gradual solute removal during peritoneal dialysis lowers the potential for disequilibrium syndrome and intracranial fluid shifts, making this a treatment modality to consider in patients with increased intracranial pressure. In case of cerebral edema because of an acute rise of ammonia, prompt RRT is mandatory. In adults, hyperammonemia is defined as a serum concentration above 50 μmol/L or 85 μg/dL, and RRT is generally indicated at ammonia levels exceeding 150 μmol/L or 255 μg/dL. When rapid ammonia clearance is needed, HD or high-dose CRRT are the preferred treatment modalities; PD is less efficient.[64,65]

Patients with Hyponatremia

If patients with severe chronic hyponatremia are treated with conventional RRT, the serum sodium concentration can be expected to increase rapidly, exposing patients to the risk of developing osmotic demyelination. High serum urea concentration may protect the brain against this.[66,67] To avoid osmotic demyelination in patients with chronic hyponatremia, the treatment during a single dialysis session has to be adjusted to provide a rate of correction that does not exceed the generally recommended rate. The easiest way to do this is to choosing low-efficiency RRT such as CVVH and to maintain sodium concentration of the replacement fluid slightly higher than the serum sodium concentration. In the routinely available dialysate/replacement solutions, the variability in sodium content is limited. Adapting the sodium concentration can be established by adding sterile water to the replacement fluid bag. Diluting replacement fluid will also result in decreased potassium and bicarbonate concentrations, and therefore may induce hypokalemia and acidosis. When applying HD treatment, one can make use of the lowest-available sodium setting (130 mmol/L), reduce the blood flow rate markedly (to 2 mL/kg/min), and shorten the dialysis time.[68]

Prevention of Contrast-Induced Nephropathy

A single dialysis session removes 60%–90% of contrast media from the blood,[69,70] and one study argued that periprocedural CRRT may be beneficial in patients with chronic kidney disease.[71] However, meta-analyses including studies in patients without severe chronic kidney disease, could not show a benefit for this strategy.[69,72] Considering the possible complications, cost, logistical difficulties, and uncertain benefit, several guidelines do not recommend RRT for the prevention of contrast-induced nephropathy.[10,73,74]

Patients with Severe Hemodynamic Instability

CVVHD, sustained low-efficiency daily dialysis, or continuous HD[10,26,73–76] seem to be equivalent treatment strategies in terms of mortality, kidney recovery, and fluid removal for hemodynamically unstable patients.[75–78] Treating those patients requires some precautions: less-aggressive ultrafiltration; increasing dialysate sodium and calcium concentrations to 145 mmol/L and 1.5 mmol/L, respectively; adapting the dialysate temperature to obtain isothermal dialysis; connecting afferent and efferent bloodlines simultaneously at the start of the procedure; and raising the blood flow slowly.

Patients with Severe Lactate Acidosis

The key issue in the management of lactic acidosis is to treat the underlying cause. CRRT can be performed in critically ill patients with severe lactic acidosis and AKI.[79] Using continuous hemodialysis with bicarbonate dialysate, lactate concentrations can be lowered and the pH can be corrected. However, no adequately powered randomized clinical trial with clinical outcome endpoints has yet evaluated RRT in this setting.[80] Severe lactate acidosis may preclude PD with lactate-buffered solutions.[81]

CONCLUSION

RRT for AKI is used in up to 10%–15% of ICU patients. Urgent indications include severe hyperkalemia and fluid overload not responsive to diuretic therapy. In the absence of urgent indications, initiation of RRT should be based on clinical judgment, which should include the demand for RRT and the capacity of the kidneys. Early initiation of RRT at AKI stage 2 or 3 does not offer a survival benefit. The modality of RRT chosen will be determined by the availability of modalities, the expertise of the team in handling these, and patient characteristics that may change during the course of illness. Continuous therapies are the most used modality in many ICUs. Intermittent hemodialysis can cause hemodynamic instability and is so preferably used in hemodynamically stable patients. Specialized units also use intermittent hemodialysis and hybrid therapies for hemodynamically unstable patients. PD is used in low- and middle-income countries as a first-choice therapy but can be used also in specific patients in case of a capacity surge, such as during the COVID-19 pandemic. Extracorporeal therapies can be performed without anticoagulation. Anticoagulation strategies most often used are regional citrate anticoagulation, UFH, and LMWHs. For continuous RRT a delivered dose of 20–25 mL/kg/h is recommended. To account for downtime, a prescribed dose of 25–30 mL/kg/h is advised.

KEY POINTS

- Urgent indications for initiation of RRT for AKI include severe hyperkalemia and fluid overload not responsive on diuretic therapy.
  - In the absence of urgent indications, early initiation of RRT does not offer a survival benefit.
  - In the absence of urgent indications, RRT is started on clinical judgment and the balance between the capacity of the kidneys to remove fluid and metabolites and the demand of the patient, which includes comorbidities, severity of acute illness, and retention of fluid and metabolites.
- The choice of the modality of RRT will be determined by the availability of modalities, the familiarity of the team to handle these, and patient characteristics. In hemodynamically unstable patients, continuous therapies will be used more often.
- RRT can be performed without anticoagulation in patients with impaired coagulation or increased bleeding risk. Citrate, UFH, and LMWHs are the most often used anticoagulation strategies.

Target Temperature Management in Critically Ill Patients

Filippo Annoni, Lorenzo Peluso, and Fabio Silvio Taccone

DEFINITIONS

Hypothermia is defined as a core body temperature lower than 36°C, regardless of the cause.[1] Within hypothermia we can still distinguish mild (i.e., between 35°C and 32°C), moderate (i.e., between 32°C and 28°C), severe (i.e., between 28°C and 24°C), and profound (i.e., <24°C) hypothermia.[2]

The concept of target temperature management (TTM) includes the use of induced hypothermia (i.e., cooling procedures initiated to provide brain and/or organ protection in different clinical scenarios), followed by or combined with an active control of temperature (i.e., normothermia and avoidance of fever) after hypothermia over a defined period.[3]

PHYSIOLOGY AND PATHOPHYSIOLOGY

Hypothermia has been considered over decades as a potential therapeutic strategy for different purposes, including pain management, hemorrhagic control, tetanus treatment, and neuroprotection; however, its applicability remained limited by the difficulties in achieving and maintaining a given temperature threshold (in particular for nonsedated patients) and in managing related adverse effects. As a matter of fact, only "moderate hypothermia" was initially considered to be effective[4]; nevertheless, in the last few decades, the report of beneficial effects of "mild hypothermia" in some clinical settings, together with the advances in medical technologies providing adequate temperature management, has significantly contributed to spread the research and implementation of TTM worldwide.

Most studies have focused on the effects of hypothermia/TTM on the brain, considering its high sensitivity to ischemic injury. When the brain temperature is reduced, its metabolic rate slows down by 6%–10% for each degree, thereby diminishing oxygen consumption and carbon dioxide (CO_2) production and the reperfusion injury.[5] Indeed, after a period of blood flow reduction, a complex cascade of events triggered by the reperfusion starts within minutes and can persist up to 72 hours, increasing the degree of ischemic injury.[6] These mechanisms include (1) an increase of the inflammatory response accompanied by increased cerebral blood flow (hyperemic phase); (2) an increase in cellular Ca^{2+} influx that is responsible, along with the cellular metabolic failure, for mitochondrial dysfunction; (3) a decrease in intracellular pH; (4) the release of glutamate in the extracellular space in the brain, determining a state of persistent neuronal hyperexcitability; (5) blood-brain barrier disruption with augmented permeability; (6) augmented production of free radicals; and (7) increase in programmed cell death (apoptosis).[4] Moreover, hyperthermia, which is either caused by the inflammation after reperfusion or by direct hypothalamic damage, which is involved in the tight temperature regulation in humans, occurs frequently in the postreperfusion phase; as hyperthermia is independently associated with worse outcome[7] and can also exacerbate the magnitude of the secondary brain damage,[8,9] it sounds logical to control body and brain temperature in brain-injured patients.

In particular, hypothermia can mitigate several of these phenomena, thus limiting the installation of a vicious circle by which the organ damage can further progress despite optimal medical treatment. In particular, in the acute phase (i.e., first minutes to hours), hypothermia would contribute to reducing reperfusion injuries by reducing the cerebral metabolic rate[10] and the release of excitatory amino acids,[11] decreasing free radical production[5] and inflammation,[12] and attenuating pro-apoptotic signals.[13] Subsequently, in the subacute phase, hypothermia can counteract the occurrence of brain edema[14] (i.e., hours to days), and it can favor neuronal repair[15] (i.e., following days and weeks). As body temperature is a major determinant of all biochemical reactions and interactions in the human organism, inducing hypothermia modifies the entirety of the biologic processes thorough the body (Table 39.1).

The first effect triggered by the temperature drop is the appearance of shivering, which generally manifests as the core temperature becomes lower than 35.5°C[4]: that is, one degree below the vasoconstriction threshold.[16] Shivering is the physiologic attempt to restore core temperature by causing an increase in heat production by involuntary movements, but also determines increase in work of breathing, heart rate, and myocardial oxygen consumption.[17] These effects could complicate the induction phase of hypothermia (i.e., prolonged time to target temperature) and should be treated promptly to avoid an undesired increase in the metabolic rate in injured organs.[5] Several options could be considered, including pharmacologic therapy and direct surface counter-warming,[18] as summarized in Table 39.2.

The induction of hypothermia can induce some cardiovascular alterations, including an increase in cardiac systolic function associated with a mild impairment in diastolic function despite a reduction in heart rate.[19] However, the cardiovascular effects of hypothermia could be different in critical illness: In survivors after cardiac arrest, cooling to 33°C has been shown to increase contractility[20] and improve recovery from cardiac arrest–related dysfunction when applied for more than 48 hours.[21] Pulmonary effects of TTM are tightly related to the decrease in oxygen demand and CO_2 production by the entire body. These variations must be taken into account to adequately adjust ventilatory parameters in order to avoid deleterious shifts in arterial partial pressure of CO_2 (PCO_2) or pH.[5] Several aspects of the immunologic response are also modified by hypothermia, raising concerns about a higher incidence of infections.[22] Fortunately, large trials using mild TTM did not show any difference in the rate of infections.[23–25] Nevertheless, perioperative hypothermia has been associated with an increased risk for surgical wound infection when compared with normothermia.[26] Also, platelet count and function appear to be decreased

when core temperature decreases below 35°C, whereas coagulation appears to be affected significantly only for temperatures below 33°C.[5,27] Reassuringly, despite these alterations no significant increase in spontaneous bleeding or hemorrhage rate has been found in large trials on the use of mild TTM in comatose survivors after cardiac arrest[23] or after traumatic brain injury (TBI).[28,29] Hypothermia can induce electrolyte abnormalities and increase the sensitivity to them. Specifically, potassium, magnesium, and phosphate depletion could cause serious adverse effects, including life-threatening arrhythmias, both during the induction and the rewarming phase and must then be monitored closely.[30] Hyperglycemia, caused by decreased insulin sensitivity occurring during hypothermia, is common particularly in the induction phase and is associated with poor neurologic outcome,[31] whereas hypoglycemia caused by increased insulin sensitivity may occur during the rewarming phase, especially if the rewarming rate is too fast.[5] The overall changes in enzymatic (i.e., liver) and tubular (i.e., kidney) functionality can reduce the blood clearance of several medications during hypothermia[32]; thus when TTM is applied, possible alteration in drug pharmacodynamics must be taken into account. Lastly, TTM can slow bowel and gastric function, promoting ileus and delayed gastric emptying,[33] which in turn must not be considered a contraindication to nasogastric feeding when indicated.

TABLE 39.1 Main Physiologic Effects of Mild Hypothermia

Physiologic Variables	Observed Effect
Cerebral metabolism	Decreased
Cerebral blood flow	Decreased
Fat metabolism	Increased
Lactate production	Increased
Oxygen consumption and carbon dioxide production	Decreased
Insulin secretion and sensitivity	Decreased
Inflammatory response	Decreased
Shivering	Increased
Cutaneous vasoconstriction	Increased
Renal electrolyte excretion (Mg, K, P)	Increased
Heart rate (if euvolemia)	Decreased
Myocardial contractility	Increased
Myocardial sensitivity to mechanical manipulation	Increased
Response to antiarrhythmic drugs	Decreased
Platelet function	Decreased
Drug clearance	Decreased
Bowel function	Decreased

CLINICAL APPLICATION OF HYPOTHERMIA/TTM IN CARDIAC ARREST

Experimental Evidence

Experimental evidence in different animal models has shown that body temperature may play a critical role in determining the extent of brain injuries after transient global ischemia.[34–36] Specifically, induced hypothermia was associated with a protective effect on brain damage, whereas hyperthermia or fever was associated with a deleterious effect.[35,37,38] In a recent comprehensive systematic review and meta-analysis of TTM in animal cardiac arrest models, TTM was found to be beneficial in most experimental conditions for all outcomes, despite the fact that the majority of the studies were conducted in small

TABLE 39.2 Therapeutic Options to Treat Shivering During Hypothermia (Not Exhaustive)

Drug or Strategy	Pros	Cons
Passive cutaneous counter-warming (i.e., blanket, room temperature)	Inexpensive, widely available	Unprecise, might require time to be effective
Active cutaneous counter-warming (i.e., heated forced-air blanket)	Relatively cheap, fast, evidence supported	Requires specific material
Selected cutaneous counter-warming (i.e., face, hands)	Fast; the patient remains accessible all the time	Unprecise, may be less effective than full-body surface counter-warming
Acetaminophen	Well tolerated, widely available	Liver toxicity; might mask fever Limited usefulness to treat shivering
Magnesium sulfate (IV)	Well tolerated, efficient with surface cooling technique	Risks of hypermagnesemia
Serotonin modulators (i.e., buspirone, ondansetron)	Effective for shivering prevention	Often ineffective for moderate and severe shivering
Opioids (i.e., morphine, sufentanil, meperidine)	Widely available, often already part of the treatment in patients requiring TTM	Might increase the risk of seizures, respiratory depression, dependency
Alpha-agonists (i.e., dexmedetomidine, clonidine)	Fast acting, widely available, effective for mild and intermittent shivering	Bradycardia, hypotension
Ketamine	Effective as bolus to prevent and treat shivering	Hypertension, lack of evidence for continuous infusion, hallucinations
Sedatives (i.e., propofol, midazolam, thiopental)	Widely available, often part of the treatment in patients requiring TTM	Risk of hypotension and propofol-related infusion syndrome Increased delirium incidence (midazolam) Long-lasting sedation (thiopental, midazolam)
Neuromuscular blockers	Effective for moderate and severe shivering, widely available	Increase necessity for sedation, prolonged ICU stay Increase risk of ventilator-associated pneumonia

ICU, Intensive care unit; *IV*, intravenous; *TTM*, target temperature management.

animals (i.e., rodents) and not entirely replicated in all species, were profoundly heterogeneous (i.e., intra-arrest cooling vs. early/delayed cooling), and many were biased by small cohorts or not clinically relevant outcomes (i.e., histologic effects on dying neurons or apoptosis, circulating biomarkers of brain injury, short-term survival).[39] The difficulty in translating experimental results into clinical practice is common to other fields of research and is further increased by the profound differences in etiology, comorbidities, and recovery capacities along different life periods in humans, requiring an even greater amount of scientific evidence.

Newborns

Neonatal encephalopathy (NE) is a clinically defined syndrome of impaired neurologic function in the earliest hours/days of life in infants born at or beyond the 35th week of gestation.[40] Among different causes of NE, hypoxic ischemic encephalopathy (HIE) is a subtype caused by the limitation of oxygen delivery in the newborn and is responsible for high mortality and neurodevelopmental impairment.[41,42] It remains challenging for the clinician to diagnose and classify the severity of NE in newborns[43,44]; the Sarnat staging system (and its modified version, excluding heart rate) is a neurologic physical examination–based tool useful to classify newborns with suspected HIE into three categories of severity (i.e., mild, moderate, and severe).[45] In moderate and severe HIE, therapeutic hypothermia administered for 72 hours at a core temperature of 33°C–34°C was associated with reduced brain injury and improved survival in several clinical trials,[46–50] providing clear long-term neurocognitive benefit.[51] Time to initiation of TTM in newborns appears to be of critical importance, meaning the highest benefit is to be expected with the earliest initiation.[52] Whether the treatment should be applied also to neonates of more than 6 hours of age remains disputable.[53,54] Given the large amount of evidence available, TTM at 33°C–34°C initiated within 6 hours of age and continued for 72 hours is now considered the standard of care for moderate to severe HIE in newborns with at least 36 weeks of gestation, but it remains controversial in more premature infants or in mild HIE.

Pediatric

Evidence extrapolated from neonatal HIE or adult studies may not fit with the heterogeneous pediatric population. Peculiar characteristics such as the respiratory rather than the etiology of cardiac arrest in children and the different comorbidities might shift the balance of applying TTM after global ischemic brain injury to harm, and hence it needs to be studied in a specific manner.[55,56] Recently, two large randomized controlled trials (RCTs) addressing both the population of out-of-hospital cardiac arrest (OHCA) and in-hospital cardiac arrest (IHCA) did not find a benefit in survival with good neurologic outcome at 1 year between TTM maintained for 48 hours at 33°C compared with therapeutic normothermia (i.e., 36.5°C target temperature) in children of age between 2 days and 18 years.[57,58] In a recent meta-analysis evaluating available evidence for TTM 32°C–36°C compared with no target or other different temperature targets in comatose children after the return of spontaneous circulation (ROSC) including eight observational cohort studies and one pilot study, no clear benefit or harm could be identified.[59] The evidence to support the use of TTM in comatose children after ROSC remains inconclusive, and its application remains largely derived from adult evidence.

Adults

Mild hypothermia (i.e., 32°C–34°C) was implemented globally following the publication of two RCTs regarding OHCA comatose survivors of presumed cardiac origin with initial shockable rhythm conducted in Australia and Europe, which showed significant benefit on survival and neurologic outcome when TTM was continued for 12–24 hours,[60,61] when compared with standard of care. In 2013 the TTM trial showed that two different "doses" of TTM (i.e., 33°C or 36°C for 24 hours) resulted in similar mortality and neurologic outcome when applied to comatose survivors resuscitated from OHCA of presumed cardiac origin, irrespective of the initial rhythm.[23] Since then, several centers around the globe have adopted 36°C as the target core temperature in the postresuscitation phase; however, this shift from mild hypothermia to controlled normothermia has often produced greater difficulties in maintaining optimal target temperature, resulting in a higher incidence of early fever and potentially in a reduced probability of good neurologic recovery.[62,63]

Recently, in a mixed population of OHCA and IHCA patients with an initial nonshockable rhythm and mainly hypoxic causes of arrest, mild hypothermia at 33°C was found to significantly increase the number of patients with favorable neurologic outcome when compared with normothermia at 36.5°C–37.5°C,[25] in particular within the IHCA group. However, a large randomized trial involving more than 1800 patients reported that hypothermia at 33°C for 24 hours did not result in improved survival or neurologic outcome when compared with normothermia (i.e., 37.5°C), although half of normothermic patients required a specific device to actively maintain body temperature within this value.[64]

All these results suggest the following statements: (1) TTM is not effective in all comatose survivors after cardiac arrest; (2) TTM at 33°C might be used in nonshockable rhythms, in particular in the presence of "respiratory" causes or occurring in the hospital; and (3) subgroup analyses to understand which patients might benefit from this intervention are necessary.

Moreover, because animal experiments showed an even greater benefit of TTM when it was started during resuscitation maneuvers, intra-arrest cooling was studied with large amounts of cold fluid and failed to provide any additional benefits in humans, while decreasing the ROSC rate in patients with initial shockable rhythm.[65] Conversely, transnasal evaporative intra-arrest cooling appeared to be feasible and safe and was associated with a positive trend of increased favorable neurologic outcome in OHCA with initial shockable rhythm.[66] More studies are necessary to demonstrate the effectiveness of this approach in large patient cohorts.

OTHER CLINICAL APPLICATIONS OF HYPOTHERMIA/TTM IN BRAIN INJURY

Traumatic Brain Injury

Increased intracranial pressure (ICP) is a common complication of TBI because of the mass effect of the hemorrhage), the inflammatory edema accompanying the blood-brain barrier disruption, and the disturbed cerebrospinal fluid drainage. A rise in ICP often results in a decrease in cerebral perfusion pressure, coupled with the disturbed autoregulation of the cerebrovascular system, and this can lead to secondary ischemic damage and thus worsen prognosis.[67]

One large study evaluated the use of TTM as first-line treatment for elevated ICP (i.e., vs. osmotic therapy) and found a higher mortality rate and worse neurologic outcome than in the control group; hence the study was prematurely stopped.[28] Another recently published RCT investigated the use of early prophylactic TTM for 72 hours at 33°C in association with slow rewarming and did not find any difference in favorable neurologic outcomes.[29] At this stage, the widespread use of TTM is not indicated in the early phases of severe TBI, but can remain effective to reduce ICP in case of refractory

intracranial hypertension.[68] Of note, the control group in all these studies was kept at "strict normothermia" (i.e., 37°C), which should be therefore considered "standard of care" in this setting.

Intracerebral Hemorrhage and Subarachnoid Hemorrhage

In patients suffering from intracerebral hemorrhage (ICH), increased ICP caused by cerebral edema and hematoma expansion can represent a life-threatening complication; in addition, early brain edema or delayed cerebral ischemia after subarachnoid hemorrhage (SAH) might result in secondary ischemic brain damage. In a series of patients with large intracerebral hemorrhage (>25 mL), long-lasting mild TTM (35°C for up to 10 days) has shown promising results in terms of neurologic outcome and decrease in peri-hemorrhagic edema when compared with an historical cohort.[69] Similar results were observed with hypothermia in a series of 100 patients with persistently elevated ICP after ICH.[70] More recently, excellent outcome was described in a small case series of patients with severe vasospasm and elevated ICP treated with TTM after SAH, although there was no control group.[71] Hence, TTM should only be considered an adjunct therapy in cases of refractory ICP in this setting and should be further evaluated in clinical trials. Although unproven, "strict normothermia" (i.e., 37°C) should be considered the standard of care in ICH and SAH patients with severe neurologic impairment and/or elevated ICP.

Ischemic Stroke

Ideally, the neuroprotective role of TTM could limit the extension of the core ischemic area after an acute ischemic stroke and therefore limit the burden of neurologic disability. Evidence to support the use of TTM is based on relatively small and heterogeneous trials with different TTM strategies, indications, and outcome assessment.[72] One large randomized ongoing trial, the IcTUS2/3 trial (NCT01123161), is actually investigating whether the combination of thrombolysis and TTM is superior to thrombolysis alone. However, the EuroHYP-1 trial, which enrolled 98 patients, showed no benefit from mild TTM plus medical treatment on the functional outcomes of ischemic stroke patients treated with the best-available medical care.[73]

OTHER POTENTIAL APPLICATIONS

In acute myocardial infarction, therapeutic hypothermia has been investigated in both experimental and clinical settings with the purpose to limit ischemia reperfusion injuries and thereby reduce the infarct size.[74] No consistent findings were found in a series of small randomized trials and their pooled data analysis, despite a promising possible application of TTM for infarction with a large myocardium at risk and localized within the anterior wall of the left ventricle.[75]

In spinal cord injury, TTM has been not studied by any RCTs yet, despite some experimental evidence and some clinical reports of possible beneficial effects.[76]

In the context of hepatic liver failure and hepatic encephalopathy, TTM was used as an adjunctive therapy in the case of increased ICP for patients who were subsequently transplanted, with beneficial effects on both hemodynamic variables and ammonia levels[77]; however, because of the weak evidence available, it is not considered yet the standard of care.

In mechanically ventilated patients with septic shock, induced hypothermia (target 32°C–34°C for 24 hours) followed by 48 hours of normothermia (i.e., 36°C–38°C) resulted in a similar overall mortality rate than a control normothermic group; moreover, in the hypothermia group, 30-day mortality was higher (44.2% vs. 35.8%) than the normothermic group.[78] Hence, induced hypothermia should not be used in patients with septic shock. Whether normothermia might improve hemodynamics and outcome in these patients when compared with no fever control remains to be evaluated.[79]

PRACTICAL ASPECTS

Three different phases can be identified in the process of applying TTM (induction, maintenance, and rewarming), during which several "phase-specific" physiologic phenomena could be observed in response to a decrease in body temperature. A practical algorithm for the application of TTM is provided in Fig. 39.1. Ideally a rapid induction, a precise target temperature during maintenance, and a slow and constant rewarming should be achieved to provide the most effective treatment and avoid side effects at best.[80]

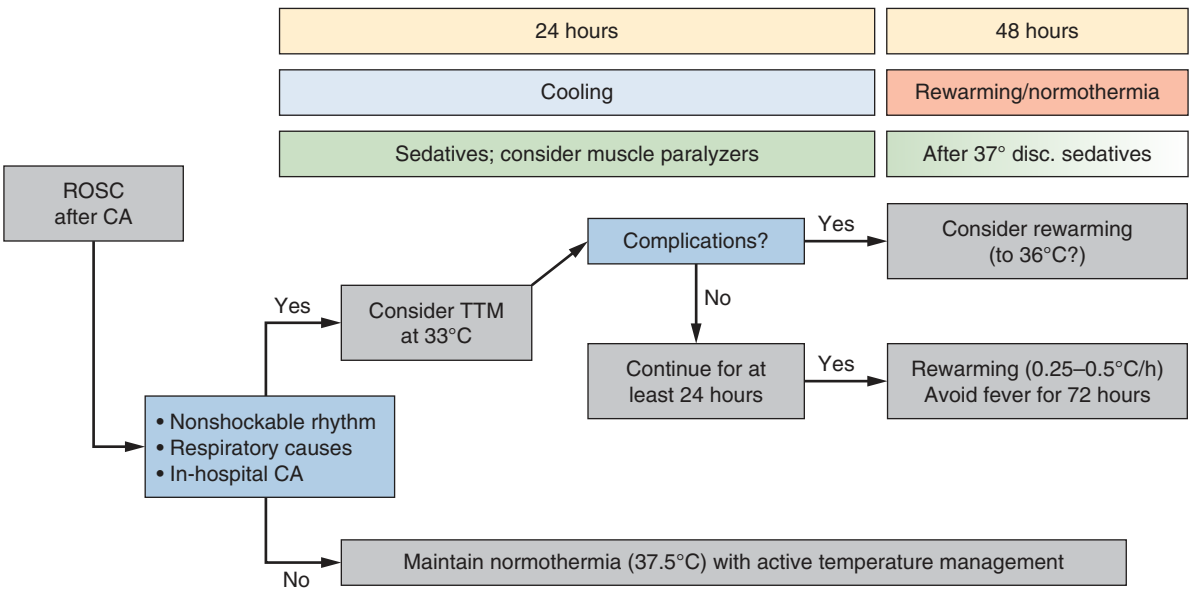

Fig. 39.1 Example of TTM Algorithm in Cardiac Arrest Patients. Consider TTM at 33°C if the arrest is associated with nonshockable rhythm, in particular for respiratory causes and if developed in hospital. *CA,* Cardiac arrest; *ROSC,* return of spontaneous circulation; *TTM,* target temperature management.

Initiation of TTM should be started as soon as possible, in particular after cardiac arrest, and maintained for a minimum period of 24 hours or longer, according to the underlying disease. As soon as the decision to apply TTM is made, a continuous measurement of the core temperature by an intravascular, bladder, or esophageal probe should be started to ensure an optimal temperature management. The appropriate device to induce and maintain the selected temperature is also of importance: several methods exist, including ice packs, cold fluids, cold blankets, automated skin pad systems, intravascular devices, and intranasal gas cooling devices; consistent differences exist among them, which are outlined in Table 39.3. Moreover, automated temperature feedback systems, both intravascular and external, were associated with better neurologic outcomes[81] and should therefore be considered, at least for cardiac arrest patients. Adverse secondary effects, including shivering, electrolyte disorders, ventilatory adjustments, and the presence of life-threatening hemorrhage, should be promptly recognized and treated.

The subsequent rewarming phase should be slow (0.15°C–0.25°C/h) to minimize adverse events and potentially minimize the burden of secondary brain damage.[82,83] Sedation must be titrated wisely according to the comfort of patients, their hemodynamic status, and the need to perform a comprehensive neurologic assessment.

TABLE 39.3 Different Cooling Methods

Drug or Strategy	Pros	Cons
IV fluids	Easily feasible in different locations Not expensive Low workload for healthcare providers	Difficult to maintain constant temperature Not specific to brain cooling Slow induction No feedback control Risk of fluid overload
Surface devices without temperature feedback	Easily feasible in different locations	Difficult to maintain temperature Not specific to brain cooling Slow induction No feedback control Risk of skin lesions Expensive
Surface devices with temperature feedback	Precise temperature induction and maintenance Fast induction Presence of feedback control Low workload for healthcare providers	Only feasible in ICU setting Not specific to brain cooling Risk of skin lesions Expensive
IVC	Precise temperature induction and maintenance Fast induction Presence of feedback control Low workload for healthcare providers	Only feasible in ICU setting Not specific to brain cooling Risk of infections and/or thrombosis Expensive
TNEC	Easily feasible in different locations Specific to brain cooling Very few side effects	Difficult to maintain temperature Slow induction No feedback control Risk of fluid overload

ICU, Intensive care unit; IV, intravenous; *IVC,* intravascular catheter; *TNEC,* transnasal evaporative cooling.

CONCLUSIONS

The application of TTM during critical illness remains controversial and still associated with unanswered issues, such as which patient populations might benefit the most. Clinically relevant effects of hypothermia have been observed in newborns suffering from HIW and in some—at the moment poorly characterized—adult cardiac arrest survivors. Future research is needed to clarify the exact role of TTM after cardiac arrest and other critical illnesses.

KEY POINTS

- TTM has been shown to minimize or reduce the severity of cerebral damage in different models of experimental brain injury, in particular of anoxic origin.
- When hypothermia is used, several side effects, including shivering, altered diastolic ventricular function, moderate immunosuppression, reduced platelet function, electrolyte imbalance, and hyperglycemia, may occur. All these phenomena should be adequately monitored and treated whenever necessary.
- In newborns suffering from HIE, the use of TTM at 33°C for 72 hours is recommended as the standard of care in the management of such patients.
- In cardiac arrest in pediatric patients, there is no evidence for a beneficial effect of TTM.
- In adult victims of cardiac arrest, the use of TTM remains extremely controversial; if the application of hypothermia at 33°C should not be considered standard of care any more in such patients, there are some patients (i.e., nonshockable rhythms, in particular if of respiratory origin and/or occurring in hospital) who might still benefit from such intervention.
- In traumatic brain-injured patients, hypothermia at 33°C should be avoided as first-line therapy; its role as "salvage therapy" in the case of refractory intracranial hypertension is still accepted in current recommendations.
- In other forms of brain injury, the benefits of TTM remain poorly demonstrated; however, in severe patients, aiming at normothermia appears the most widely used approach.
- There is no indication for regular use of hypothermia or strict normothermia in other critically ill patients

Extracorporeal Membrane Oxygenation (Venovenous and Venoarterial ECMO)

Ali B.V. McMichael, Mehul A. Desai, Melissa E. Brunsvold, and Heidi J. Dalton

INTRODUCTION

Use of extracorporeal life support (ECLS) for respiratory and/or cardiac failure continues to increase, with almost 500 Extracorporeal Life Support Organization (ELSO) centers worldwide and almost 100,000 patients now added to the ELSO registry.[1] In actuality, ECLS use is likely much higher, as many centers do not report data to ELSO or any other international registry. The survival rate for ECLS varies significantly by indication for support and age.[2] Table 40.1 lists the survival rates reported to ELSO for neonates, pediatric, and adult patients. ECLS complications continue to be common and are most frequently the result of bleeding or clotting. As ECLS technology improves and global experience increases, the indications for ECLS continue to expand.

MODES OF ECMO

Extracorporeal membrane oxygenation (ECMO) modes are conventionally named for the sites from which the blood is drained and returned. Fig. 40.1 depicts typical cannula placement for neonates, pediatric, and adult patients. There are two major technical types of ECLS: venoarterial (VA) and venovenous (VV). Hybrid modes that incorporate VA and VV together are also used in specific circumstances.

Venoarterial Cannulation

In the VA mode, deoxygenated blood is removed from the venous system and pumped to a membrane lung, which removes carbon dioxide and adds oxygen. Oxygenated blood is then returned to the patient via the arterial system. Use of the venous and arterial vessels depends on the patient size and condition and is divided into peripheral and central cannulation.

Venous drainage in older children and adults is either from the internal jugular or femoral vein. As femoral vessel size limits the adequacy of venous and arterial cannulation in neonates and small children, usually up to the age of 2 years, the right or left internal jugular vein is most commonly accessed. Oxygenated blood is usually returned to the patient via the carotid or femoral artery. The femoral artery is the preferred method in adolescents and adults to prevent need to repair or sacrifice the carotid artery at the time of decannulation. An increase in adverse neurologic events resulting from restricted cerebral blood flow secondary to loss of the right carotid artery and from emboli returning from the ECMO circuit to the left carotid are also reasons why carotid access is often avoided.[3] Cerebral venous congestion from internal jugular cannulas is also theorized to add to the risk of neurologic events, although there are no definitive studies that have adequately researched this. Some neonatal centers advocate placement of a distal jugular bulb drainage cannula (also known as a *cephalad cannula*), which is then Y'ed into the ECMO venous drainage line to increase venous flow and decrease intracranial venous pressure. This technique, however, is rarely described in adult care.[4] If the femoral artery is used, a reperfusion cannula may need to be employed to provide adequate perfusion distal to the cannula site and thereby mitigate limb ischemia.[5] Continuous noninvasive monitoring by pulse oximetry or near-infrared spectroscopy on lower extremities during femoral VA access may help with earlier identification of limb ischemia if changes in blood flow and oxygenation develop post-cannulation.[5–7] A side-graft on the femoral artery can also be placed that does not totally occlude distal blood flow, but this process cannot be accomplished via a percutaneous approach and requires surgical intervention. Other arterial access possibilities include cannulation of the subclavian and innominate vessels, facilitated by advances in cannula technology and growing experience. If these arteries are cannulated, care must be taken to avoid either hyperemia of the distal limb (which may require a ligature to restrict distal blood flow) or ischemia that develops after occlusion of distal flow. Side grafts have also been used in subclavian arterial access.

Hypoxemia Differential

In patients with severe respiratory failure who are cannulated via the femoral artery, development of differential oxygen saturation of the upper and lower extremities can occur because of competing native cardiac output and returning ECMO circuit flow directed retrograde up the aorta. Where the native cardiac output, which is likely desaturated in patients with severe pulmonary gas exchange problems, meets the oxygenated ECMO return flow is often termed the "mixing zone." Higher native cardiac output and lower ECMO return will move the mixing zone more distal in the aorta, whereas increased ECMO flow may push oxygenated blood farther up the aorta. If desaturated blood from the left heart is primarily perfusing the upper body, including the brain and coronaries, this results in a cyanotic upper body with a well-perfused lower body, a condition for which the terms "harlequin" or "north-south" syndrome is used. Methods to improve upper body oxygenation include placing another venous cannula into the right atrium (RA) which is Y'ed into the arterial ECMO return to direct some oxygenated blood to the RA and improve cardiac oxygen delivery. Care must be taken to ensure that both ECMO return cannulas—especially the femoral cannula—achieve adequate flow to prevent stasis and thrombosis.

TABLE 40.1 Survival to Decannulation and Discharge or Transfer for Neonatal, Pediatric, and Adult Extracorporeal Membrane Oxygenation (ECMO)

	Total Runs	Survival to Decannulation, *N* (%)	Survival to Hospital Discharge or Transfer, *N* (%)

ECPR, Extracorporeal pulmonary resuscitation. Data from the ELSO International Registry Report, July 2020.

For patients cannulated via the femoral artery, use of pulse oximetry or arterial blood gas data from the right hand or use of cerebral near-infrared spectroscopy (NIRS) may help follow oxygen saturation levels. Although there is controversy as to when adequate oxygen is reaching the upper body and brain, most centers use as guidelines the achieving of arterial saturations >80% (sometimes lower) or, conversely, avoidance of signs of inadequate oxygenation, such as mental confusion, electrocardiogram (ECG) changes of ischemia, or high blood lactate levels. These help to determine whether the cannulation strategy needs to be altered to improve upper body oxygenation. If unable to adequately provide respiratory and cardiac support with this configuration, movement of the femoral artery cannula to an upper body site or central cannulation should be established.

Central Cannulation

Central cannulation is accomplished via a median sternotomy with cannulation of the RA as the venous drainage and ascending aorta as the arterial return. Advantages of central VA-ECMO include increased venous drainage and antegrade return of oxygenated blood flow to the proximal aorta. Central cannulation is most commonly used for postcardiotomy patients but may benefit septic shock patients when higher flow is required. Disadvantages to central cannulation include increased risk of bleeding and infection and decreased patient mobility.

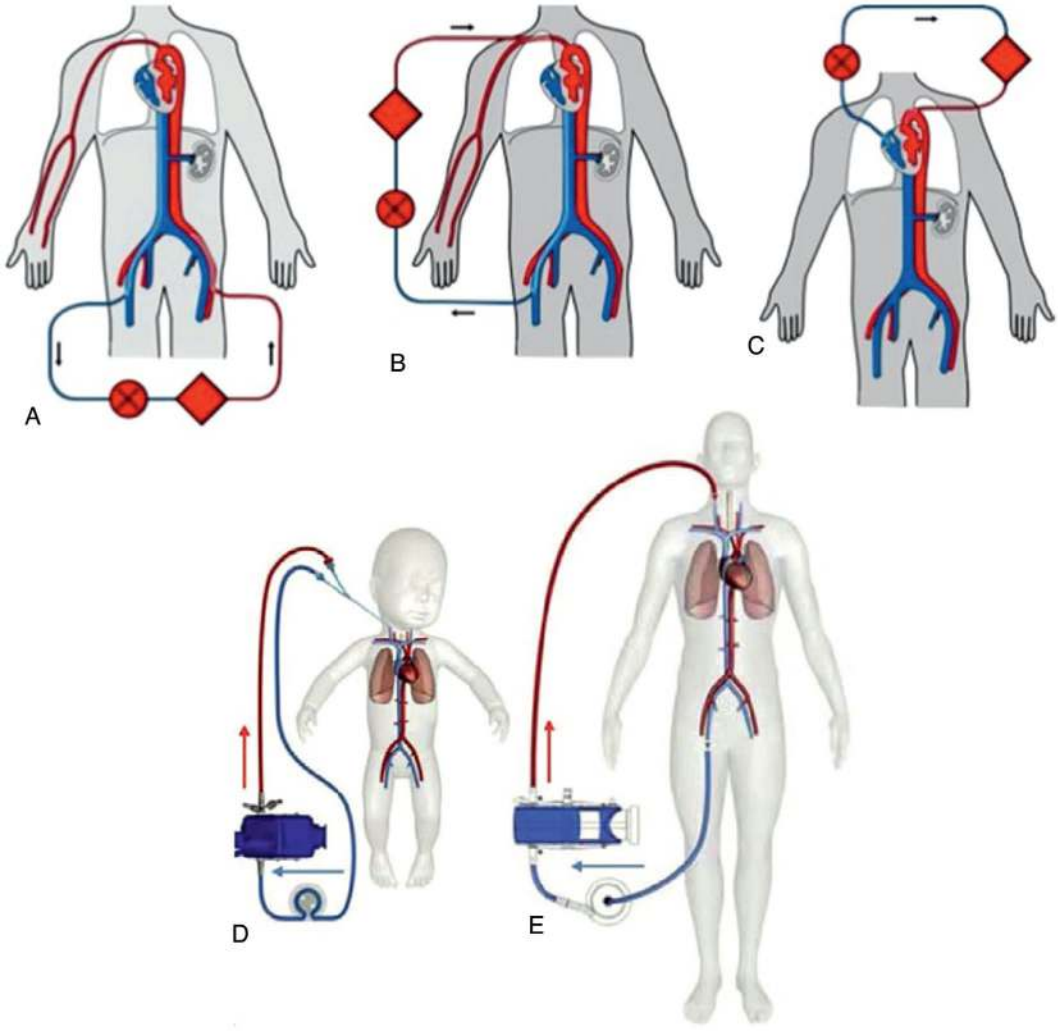

Fig. 40.1 Schematic of possible venoarterial **(A–C)** and venovenous **(D, E)** ECMO circuit configuration. **(A)** VA, peripheral, femorofemoral. **(B)** VA, peripheral, femoro-axillary cannulation. **(C)** VA, central cannulation. **(D)** VV, single, double-lumen cannula. **(E)** VV, two single-lumen cannulas. *ECMO,* Extracorporeal life support; *VA,* veno-arterial; *VV,* venovenous. (Adapted from Sangalli F, Patroniti N, Pesenti A. *ECMO—Extracorporeal Life Support in Adults.* New York: Springer; 2014: Figs. 3-9 and 6-6.)

Venovenous Cannulation

In the VV mode, deoxygenated blood is removed from the venous system and sent via an external pump to the membrane lung where oxygen is added and carbon dioxide removed. Oxygenated blood is then returned to the venous system. As the native heart must deliver oxygenated ECMO flow to the systemic circulation, VV requires adequate cardiac function. Venous blood is externally diverted from the patient, commonly by the inferior vena cava (IVC) and usually via the femoral vein, and then reinfused to the RA after gas exchange via the internal jugular vein. The drainage cannula is optimally placed in the hepatic IVC/RA region, as the largest volume of flowing blood for drainage exists here, and this vessel is less prone to collapse than those farther down in the abdomen. The internal jugular reinfusion cannula should be placed in the RA. The two cannulas should be separated by a few centimeters to reduce recirculation of ECMO return being drained back into the ECMO intake circuit without traversing the systemic circulation. Dual-lumen cannulas now exist that drain both the IVC and superior vena cava (SVC) and reinfuse oxygenated blood into the RA. When placed properly, these catheters direct oxygenated return through the tricuspid valve and into the right ventricle, thus reducing recirculation. As it is somewhat difficult to achieve proper placement of the dual-lumen cannula, placement under fluoroscopic or echocardiographic guidance is recommended. Unfortunately, dual-lumen cannulas appropriate for neonates are not readily available; those that are available have concerns regarding cardiac perforation or placement, which limit their use.[8]

In patients cannulated for respiratory failure via VV-ECMO, sudden right ventricular failure can occur, often after days to a week on ECMO support. Although causation of such events is unclear, etiologies may include development of progressive pulmonary fibrosis and associated increased pulmonary vascular resistance, pulmonary emboli, fluid overload, or failure of the right ventricle from constant exposure to the relatively high-pressure jet returning from the ECMO circuit. Deterioration can occur rapidly, and if not medically managed successfully or the patient is not transitioned to VA support, right ventricular failure may lead to cardiac arrest.[9] Periodic echocardiographic evaluation of right ventricular function coupled with clinical examination aimed at detecting venous distention or other evidence of right heart failure are advisable.

PHYSICAL SYSTEMS FOR ECMO

The ECLS circuity is composed of cannulas, a pump, an oxygenator (which is also referred to as the *membrane lung*), and tubing. Several technologic changes have been made to the ECLS circuit, including creation of centrifugal pumps with streamlined circuity and decreased priming volume; advancements in artificial membrane technology; and integrated systems that allow for ongoing assessment of venous saturations, blood gas values, temperature, hemoglobin, ECMO flow, ECMO pressures, and alarms. Newer systems also have enhanced portability and improved safety.[10,11]

Two pump types exist for ECLS: centrifugal and roller-head. With the advent of newer centrifugal systems that are not associated with the severe hemolysis and plasma leakage issues of the past, most centers now use centrifugal pump and hollow-fiber/polymethylpentene membrane lung systems. Roller-pump devices generate high return pressure that poses justified concern for circuit rupture. Given this hazard and their dependence on gravity for venous drainage, many centers now have abandoned them. Centrifugal systems are also easier to set up, require less priming volume, may be safer, are easier to move, and facilitate patient mobility. In addition, centrifugal systems tend to require less immediate bedside technician monitoring, which reduces staffing needs and costs.[11–13] Moreover, newer systems are thought to minimize the hemolysis encountered with earlier versions of centrifugal pumps.[14] At this writing, newer centrifugal and membrane lung systems are appearing on the market, each with potential advantages and more miniaturization; however, whether these innovations truly affect outcome is yet unknown. Of interest, use of roller-pump devices continues in the United States for neonatal patients, whereas the rest of the world has changed to centrifugal setups. Several reports of an increase in hemolysis, hyperbilirubinemia, renal injury, and a decrease in survival in children with centrifugal pumps compared with roller devices have appeared, although whether these events are related to lack of experience with centrifugal systems or to other factors is unclear.[15–17]

Much like the pumps, oxygenator technology has improved over time. Use of the silicone membrane lung, the workhorse for ECMO for many years, provided good gas exchange but was cumbersome to prime, stimulated a large inflammatory response because of its large surface area, and promoted thrombosis which required replacement. Its use has almost disappeared, and most centers have transitioned to microporous hollow-fiber oxygenators that employ polymethylpentene fiber technology. Hollow-fiber oxygenators are also advantageous because of their lower priming volume, smaller surface area, and improved gas exchange. These devices now exist in a variety of sizes, which makes them applicable to patients of varying size—neonates through adults.

Most ECMO systems also incorporate measurement of flow, revolutions per minute, pressure and alarm limits, and a variety of other indicators. Devices to measure flow, blood gases, and other parameters can also be placed on the circuit noninvasively. These even afford remote monitoring and adjustments in flow, which may allow multiple patients to be managed at distant sites. One new recently Food and Drug Administration (FDA)–approved system by Abiomed provides an oxygen concentrator, which obviates need for an external oxygen source, and a battery life of 3 hours, which may allow ambulation and facilitate care of patients outside the intensive care environment.

MANAGEMENT OF ANTICOAGULATION AND BLOOD TRANSFUSION

During ECMO initiation, a massive inflammatory response occurs because of contact of patient blood with the foreign ECMO circuit, upregulating the coagulation system. Both activation and consumption of platelets occur, which induce changes in the coagulation cascade and promote a prothrombotic state.[18–20] Anticoagulation is administered during cannulation and is continued throughout the ECMO run to mitigate the risk of thrombosis in both the circuit and the patient. Unfractionated heparin (UFH) remains the standard anticoagulant for ECLS patients, although newer anticoagulants, including direct thrombin inhibitors such as bivalirudin and argatroban, have been used successfully as well. No randomized trial exists currently to compare UFH with these newer anticoagulants to demonstrate if the anticoagulants are equivalent or if one approach is better than another. In a pilot single-center adult study, use of an algorithm-based heparin titration based on activated partial thromboplastin time (aPTT) was compared with a weight-dosed arm of 10 units/kg/hour with no titration for 10 patients on VV-ECMO. No differences were noted in need for circuit exchange, bleeding events, or amount of transfused blood.[21] Other case series in patients with high risk for bleeding, including trauma or postcardiotomy, have shown that low-dose or no heparin during ECMO may be safe, but continuous monitoring of the circuit for thrombus formation is warranted.[22] Other means of reducing platelet activation, aggregation, and circuit thrombosis such as surface coatings on the ECMO tubing, administering nitric oxide across the

membrane lung, and use of antiplatelet agents, are areas of clinical and bench research.

Laboratory monitoring for UFH on ECLS varies among centers, and no single test or combination of tests has been found to be superior to another regarding bleeding or thrombosis. Although much effort and research have occurred and continue to try to define the optimal anticoagulation testing regimen for patients receiving ECLS, the answer is not currently known. Activated clotting time (ACT) is historically the most common laboratory test for monitoring UFH, but other tests, such as anti–factor Xa and viscoelastic assays, are being employed at many ECLS institutions. ACT is a whole-blood test that measures the time of whole blood to form a fibrin clot. It can be performed at the bedside and is simple to do, but its accuracy is affected by several factors, including thrombocytopenia, platelet dysfunction, hemodilution, hypofibrinogenemia, temperature, and technical factors. Anti–factor Xa assay is a chromogenic assay that measures the UFH inhibition of the factor Xa activity, and thus should be a better test for providing information specific to heparin effect. Viscoelastic testing methods such as thromboelastography (TEG) and rotational thromboelastometry (ROTEM) are whole-blood tests that measure the viscoelastic properties of a clot, including time to initiate clot formation, extent of fibrin formation, clot strength, and clot lysis. Although viscoelastic tests seem to provide a more comprehensive view of the quantity and function of coagulation factors, platelets, and fibrinogen, there currently are minimal data to support their use in ECLS, although more data are emerging. Bedside viscoelastic testing is now available at many centers, but it is currently unknown if it will improve anticoagulation management or if it will decrease the incidence of thrombotic or bleeding events. An understanding of what each anticoagulant test measures and its limitations is crucial to manage ECMO anticoagulation. Many studies suggest that a combination of probes, including a clotting time test such as ACT or TEG/ROTEM, plus a plasma-based test such as anti–factor Xa or aPTT, present a more comprehensive picture of the coagulation status and anticoagulant effect in ECLS patients.[23]

Blood product transfusion thresholds vary based on patient age and type of ECLS (VV versus VA). Table 40.2 displays common transfusion thresholds recommended by ELSO. Other more detailed manuscripts on this topic are included in the references.[24,25] Adult patients tend to have lower hemoglobin goals than children, although reasons for this are unclear. Red blood cells are transfused with the primary goal to increase oxygen-carrying capacity and augment tissue oxygenation, but study results vary as to whether increasing hemoglobin improves clinical status or if the potential adverse effects of transfusion outweigh any potential benefit.[26–31] Similar issues with adverse effects of platelet transfusion to achieve goal platelet count have been documented in ECMO patients.[28,32,33] One common agreement regards the mandate to maintain normal fibrinogen levels during ECMO.

TABLE 40.2 Transfusion Thresholds for Blood Products in Adults and Children

	Adult	Pediatric
Hemoglobin	7 g/dL	8–10* g/dL
Platelet	Nonbleeding patients: >50–100,000 cells/mm^3 Bleeding patients >100,000 cells/mm^3	Nonbleeding patients: >50–100,000 cells/mm^3 Bleeding patients >100,000 cells/mm^3
FFP	>1.5–2.0 if bleeding	>1.5–2.0 if bleeding
Fibrinogen	<100–150 mg/dL	<100–150 mg/dL

FFP: Fresh frozen plasma.
*Consider higher hemoglobin goal for cyanotic congenital heart disease.

COMPLICATIONS

Among the most common complications for ECLS patients are hemorrhage and thrombosis. A summary of the most frequent complications reported to the ELSO registry are listed in Tables 40.3 and 40.4. Development of secondary infection while being supported by ECMO, need for a long duration of support, mediastinal cannulation, lack of correction in lactate or pH over the first 24 hours of support, and quantity of administered blood products are all factors that have been associated with outcome.[34,35]

Several neurologic complications, including seizures, ischemic stroke, intracranial hemorrhage, and brain death, may occur during ECMO.[36,37] The cause of neurologic injury during ECMO is complex and likely multifactorial. Predispositions include patient pre-ECMO factors such as hypoxia, acidosis, low cardiac output, impaired cerebral autoregulation, and alterations in cerebral blood flow.[38] Cannulation site can increase the risk of neurologic complications; ligation of the carotid artery is associated with the highest risk of injury.[39] Noninva-

TABLE 40.3 Common Complications for Adult and Pediatric Patients Placed on ECMO for Primary Respiratory Indication

	Adult (%)	Neonatal (%)	Pediatric (%)

sive monitoring, including NIRS, transcranial Doppler, and electroencephalogram (EEG), may help detect acute brain injury.[40–42] Initial studies employing multimodal neurologic monitoring are promising, but further study and standardization are needed.[43,44]

Vascular complications are also common and occurred in 29% of patients in a systematic review of 6583 adult ECMO patients.[45] Access of the femoral artery for VA-ECMO can lead to lower extremity ischemia, pseudoaneurysm formation, dissection, and retroperitoneal bleeding. As mentioned previously, a distal perfusion cannula can be placed to mitigate limb ischemia. In addition, at the time of decannulation, a repair of the femoral artery can be performed to prevent arterial stenosis.[46] Dissection and retroperitoneal hematoma may occur during cannulation, but the risk can be minimized by using ultrasound guidance during percutaneous access of the femoral vessels. Thromboembolism and pseudoaneurysm are usually late vascular complications that occur in approximately 6% and 1.3% of patients, respectively.[45] Pseudoaneurysms present with a pulsatile, palpable bulge and if small generally can be managed with injection of thrombin. If large or rapidly expanding, however, these defects will usually require surgical intervention.[47] Because injury to the right ventricle, coronary sinus, and hepatic vein can occur during placement of dual-lumen VV-ECMO cannulas, their placement under fluoroscopy is recommended.

Although pump or circuit failure is an uncommon event, sudden deterioration of performance can result in lack of adequate patient support, leading to adverse events or fatality. Air embolus in centrifugal pumps can also occur, and centers transitioning from roller-head to centrifugal systems often see a rise in air events, as the "suction" provided by the centrifugal pump can rapidly pull air from any open stopcock. For this reason, most centers limit any access on the "negative" or prepump head side of the ECMO circuit, and systems that can stop forward flow of air bubbles are often employed. Centrifugal pumps require a thorough understanding of how patient physiology affects them, as they are very sensitive to "preload" (adequate venous drainage) and "afterload" that may impede forward ECMO flow from the pump.

ECMO FOR RESPIRATORY FAILURE

Use of ECLS for respiratory failure is supported by the rationale that ECLS provides time for lung recovery while simultaneously allowing implementation of effective lung protective ventilation. The ELSO guidelines for acute respiratory failure consider ECLS as a rescue therapy for hypoxic respiratory failure with high mortality risk, hypercarbia despite plateau pressures >30 cm H_2O, severe air leak syndrome, need for intubation for a patient on a lung transplant list, or immediate cardiac or respiratory collapse.[48] Each center may develop their own criteria, but these general rules exist. Use of scoring systems to predict ECMO outcome or candidacy are appearing but require further refinement. Descriptions of these scores, including PRESET, PRESERVE, and RESP, can be found in the references.[49–52] Table 40.5 lists the most common adult respiratory indications for ECLS.

ARDS

Severe acute respiratory distress syndrome (ARDS) continues to have a high associated mortality rate, in spite of the use of lung protective strategies that include ventilation with relatively low tidal volumes and pressures.[53–55] Per ELSO guidelines, ECLS should be considered for patients in hypoxic respiratory failure if the mortality risk exceeds 50%, and ECLS is indicated if risk of death is 80% or greater.[48] Mortality of 50% is associated with a PaO_2/FiO_2 <150 mm Hg on FiO_2 of 90% and/or a Murray score of 2 to 3. Mortality rates of ~80% are associated with a PaO_2/FiO_2 <100 on FiO_2 >90% and/or a Murray score of 3 to 4.

Two recent randomized controlled trials that evaluated ECLS in adult ARDS patients are CESAR and EOLIA. In the CESAR trial, 180 adult patients with refractory ARDS were randomized 1:1 to transfer to a ECMO center for VV-ECMO consideration versus conventional care using a lung protective strategy.[56] Respiratory support of patients in the conventional arm who were not transferred to the ECMO center was suggested to follow general lung protective guidelines, but specific ventilator management was not mandated. Of the 90 patients transferred to the ECMO center, 68 (75%) received ECMO and 57 (63%) survived to 6 months without disability, compared with the 41 (47%) patients who survived to 6 months and received conventional management. Although these results seem to demonstrate the efficacy of ECMO, limitations to data interpretation include the fact that 22 of the patients randomized for transfer to the ECMO center did not receive ECMO and 5 patients died during transport.[57] Critics of the study noted that the major finding was that care in an ECMO-capable center was associated with improved outcome, not necessarily the use of ECMO. The EOLIA trial was undertaken to overcome some limitations noted in the CESAR trial. This randomized controlled trial

included 240 adult patients randomized by center and length of mechanical ventilation to VV-ECMO or conventional ventilator treatment according to the published Express trial of positive end-expiratory pressure (PEEP) that used a tidal volume of 6 mL/kg and PEEP set so as to not exceed a plateau pressure of 28–30 cm H_2O.[58] Early use of neuromuscular blocking agents and prone positioning were also recommended. The primary endpoint was 60-day mortality. Although there was no significant difference in mortality rate between groups (35% in the ECMO groups versus 46% in the control group, $P = .09$), patients in the most severe group of respiratory failure based on PaO_2/FiO_2 did experience benefit from ECMO. Further, if data of patients who suffered a sudden cardiac arrest that necessitated the VA-ECMO were excluded from the analysis, ECMO also appeared to confer benefit. Last, the study was powered to see a reduction of 20% in mortality in the ECMO group. As mortality in the control group was less than expected, this may have contributed to the inability to detect a statistically significant difference between groups. Despite not having definitive evidence favoring ECMO for acute respiratory failure, it should be considered for severe ARDS patients but requires judicious patient selection, early initiation of ECLS, and use of lung protective strategies while on ECMO.

ECMO Use in Lung Transplantation

The number of lung transplants in the United States per year is increasing. In 2018 2562 lung transplants were performed in the United States. However, despite this increase, 365 adult lung transplant candidates remained who died or became too sick to undergo transplant.[59] The mortality rate for waitlisted patients with acute end-stage exacerbations persists as high as 50%. If patients do not require support for oxygenation but do need decarboxylation, extracorporeal carbon dioxide removal ($ECCO_2R$) can be employed. In one report of 121 patients who underwent ECMO (VA, VV, and central ECMO) as a bridge to lung transplant, 70 (59%) received a transplant and 64 (91%)) survived to discharge. One predictor of successful bridge to transplant was the ability to rehabilitate to ambulation (odds ratio, 7.579; 95% confidence interval, 2.158–26.615; $P = .002$).[60] As a result of ECMO support, 82 (68%) patients were able to achieve ambulation. Therefore any lung transplant candidate who requires so much support that it interferes with rehabilitation, such as prone positioning or paralysis, should be considered for ECMO as a bridge to transplant. Contraindications to ECMO as a bridge to transplant include severe second organ dysfunction, sepsis, and removal from transplant listing.

For patients with primary graft dysfunction (PGD) after transplantation, ECMO can be used to support patients until lung recovery.[61] Although survival is improved by ECMO, the long-term graft outcomes may be negatively affected, as patients with PGD who require ECMO have been found to have impaired maximum allograft function compared with those who do not require ECMO.[62]

ECMO Use in Refractory Hypercapnia

For patients with severe hypercapnia with obstructive lung disease, including asthma and chronic obstructive pulmonary disease (COPD), ECLS and a similar technique that is directed at mainly carbon dioxide removal ($ECCO_2R$) may be considered. Although ECLS and $ECCO_2R$ are applied to patients on conventional mechanical ventilation with hypercarbia, they may simultaneously offer advantages over unassisted mechanical ventilation by reducing ventilator-associated lung injury risk, including oxygen toxicity and hyperinflation. As membrane lungs are highly efficient at removing carbon dioxide, much less flow is needed to achieve decarboxylation than is required for oxygenation. This allows for use of smaller drainage cannulas, single dual-lumen cannulas, and even systems where the patient's own cardiac output provides flow without need for an ECMO pump in the system. During $ECCO_2R$, blood is removed from a venous drainage cannula and pumped via an ECMO pump or the patient's own cardiac output through a membrane lung where carbon dioxide is removed via diffusion and then returned to the body. Employing either $ECCO_2R$ or ECMO can rapidly reverse acidosis related to acute hypercapnia. If acidosis is detrimental to cardiac or neurologic performance, ECMO or $ECCO_2R$ can reduce risk of death. As many acutely hypercapnic states (such as severe asthma) are self-limited, providing support may require very short ECMO/$ECCO_2R$ runs. Use of these techniques has also been employed before intubation as a means of avoiding intubation and sedation.

A systematic review of 142 adult $ECCO_2R$ patients from six studies demonstrated a reduced need for endotracheal intubation but no improvement on outcomes, including duration of mechanical ventilation, intensive care unit (ICU) length of stay, and mortality.[63] Several trials are currently ongoing to further evaluate $ECCO_2R$ in adult respiratory failure, and new devices that require flow rates of <500 mL/min are also in clinical trials.

ECLS IN HEART FAILURE

The use of VA extracorporeal support for heart failure has increased, motivated by the ongoing improvements in technology and management. The reversibility of the etiology of heart failure is key to survival, unless the patient is under consideration for destination therapy, short-term ventricular assist device (VAD) placement, or transplant. Commonly held contraindications for VA-ECMO in heart failure include uncontrollable bleeding, irreversible neurologic or end-organ impairment, incurable malignancy, and end-stage cardiac disease when not a candidate for transplant or destination therapy of VAD. VA-ECMO can be considered for a variety of cardiogenic shock states, some of which are highlighted here. Table 40.6 demonstrates the most common adult cardiac indications for ECLS.

Postoperative Cardiogenic Shock

ECMO may be considered postoperatively as a temporary support for patients unable to wean from cardiopulmonary bypass. Whereas approximately 50% of postoperative cardiogenic shock patients can be weaned off of ECMO, survival to hospital discharge only approximates 30%. Predictors of adverse outcome associated with mortality include advanced age (>70 years old), prolonged ECMO support, renal failure, high EuroSCORE, diabetes mellitus, obesity, and lack of improvement of lactate while receiving ECMO assistance.[64] Duration of ECMO support compared with other ECMO indications is generally shorter, and if cardiac recovery has not occurred within 48–72 hours, some institutions recommended transition to more durable assist devices.[65] Early evaluation of residual repairable lesions should be undertaken by means of ECG or cardiac catheterization laboratory investigation.

Acute Myocardial Infarction

Although implementation of ECMO after acute myocardial infarction (AMI) is rare, its use has increased significantly over the last two decades.[66] VA-ECMO may benefit patients with AMI with refractory cardiogenic shock in order to prevent further end-organ injury and potentially facilitate percutaneous coronary intervention. Patients with severely depressed left ventricular function should also undergo continuous evaluation for need for venting or unloading of the left ventricle (LV). Many centers have developed "shock teams" to identify patients in a timely fashion who require device or interventional procedures, often using algorithms for the deployment of ECMO, stents, intraaortic balloon pump (IABP), Impella, and other aspects of care to aid in rapid decision making.[67,68]

Acute Fulminant Myocarditis

Acute fulminant myocarditis (AFM) is characterized by a refractory and rapid onset of severe hemodynamic compromise and usually is secondary to a viral illness. Patients with AFM require aggressive pharmacologic therapy and often mechanical circulatory support until native cardiac function recovers. Although transplant or VAD may be required, myocarditis is one cardiac entity in which recovery with ECMO may occur even after several weeks. In a multiinstitutional review of 57 adult patients with AFM, 43 (75%) patients recovered function in 9 days (standard deviation [SD] ± 10.6) and 41 (72%) patients survived to discharge.[69]

LEFT VENTRICULAR UNLOADING

Because of the higher risk of bleeding and infectious complications with open surgical access, percutaneous cannulation is preferred for VA-ECMO. As mentioned previously, the most common cannulation method remains femoral access, which introduces retrograde flow to the aorta. The presence of retrograde flow introduces variable afterload that can potentially impair recovery of the LV. In the absence of LV recovery, rising left atrial pressures may result in pulmonary vascular congestion and pulmonary hemorrhage. Impaired oxygenation by the native lung may then result in ejection of hypoxemic blood into the aortic root and arch, resulting in coronary ischemia and cerebral ischemia, respectively. These events increase the risk of death. Although universal agreement on when to employ ventricular offloading does not exist, most centers use a pulse pressure of <10 mm Hg, development of pulmonary edema, and echocardiographic evaluation of aortic outflow as markers for intervention. Pulmonary artery catheter data, which are infrequently available these days, may be informative. Although low-dose inotropes or afterload reduction can sometimes be helpful, the impact of increasing calciotropic support on a failing ischemic heart may accentuate harm. An akinetic or hypokinetic heart in the presence of high afterload can produce inadequate ventricular contraction with a relatively immobile aortic valve. Thrombi mat, then form above the valve or within the LV, despite therapeutic anticoagulation. Upon recovery of cardiac function, this can place the patient at risk for coronary or cerebral infarction. Similarly, in patients with a mechanical mitral valve, the presence of low flow and pressure can potentiate clot formation. This vicious cycle places the heart at risk of impaired recovery, remodeling, and progressive heart failure.

Several observational studies have demonstrated decreased mortality with LV unloading in patients on VA-ECMO for cardiogenic shock.[70] LV unloading options currently consist of surgical techniques (surgical LV vent), transaortic LV unloading (cannula or peripheral VAD such as Impella), transseptal venting (atrial septostomy or percutaneous transseptal atrial vent), indirect LV unloading (via IABP), and use of positive inotropic agents. The decision for mode of LV unloading requires understanding of the myocardial physiology, valvular function, and potential for recovery. Because of the dynamic environment and potential implications on recovery, constant assessment and evaluation are required to determine the optimal method and timing of initiating LV unloading.

ECPR

Extracorporeal pulmonary resuscitation (ECPR) continues to be a rescue therapy for cardiac arrest refractory to conventional cardiopulmonary resuscitation (CPR). A review of over 1700 adult patients who had received ECPR from 2003 to 2014 in the ELSO registry found that the survival to hospital discharge had remained stagnant over the 12-year period at 27%–30%.[71] The use of ECPR during that same period significantly increased from 35 to over 400 cases per year. Although survival had not significantly improved, the same review found that ECLS-related complications, including acute renal failure, pulmonary hemorrhage, surgical site bleeding, and nosocomial infections, have decreased over time. Neurologic complications continue to be common, but in comparison with conventional CPR, ECPR has a higher favorable neurologic outcome.[72–74]

Most studies have found that a longer interval from CPR onset to establishment of ECLS is associated with poorer results, including unfavorable neurologic outcomes. Delay varies with location (out-of-hospital versus in-hospital arrest), age, adequacy of CPR, and etiology of arrest.[75–79] In a single-center review of 55 out-of-hospital-cardiac-arrest (OHCA) patients with coronary artery disease and an initial rhythm of ventricular fibrillation or ventricular tachycardia, a protocolized resuscitation strategy including mechanical CPR, initiation of ECLS upon arrival to hospital followed by coronary angiography, and percutaneous coronary intervention (if appropriate) demonstrated survival to discharge with good neurologic outcome in 36 (42%) patients, compared with 26 (15%) in a historical control group.[80] This review highlights both the importance of the initial rhythm on survival outcome and need for a dedicated multiprofessional team of first responders, ECLS, and interventional cardiologists. The CHEER study, a single-center prospective observational study of 26 OHCA and in-hospital-cardiac arrest (IHCA) adult patients, employed a

multipronged resuscitation protocol using a mechanical CPR device, therapeutic hypothermia, and two-physician percutaneous femoral vein and artery cannulation.[81] Time from cardiac arrest to ECMO initiation was notably quick, with a median time of 56 minutes for all patients and 40 minutes for survivors. Nonsurvivors had a longer time to ECMO initiation, with a median time of 70 minutes, highlighting the importance of decreasing time to ECMO initiation. Fifty-four percent of patients survived to hospital discharge, with all survivors having good neurologic outcomes. A recent study, ARREST, randomized 30 adults with OHCA and refractory ventricular fibrillation to standard ACLS treatment or ECMO. The phase II open-label, single-center trial found that 6 of the 14 patients (43%) treated with ECMO survived to discharge, compared with only 1 of 15 (7%) patients treated with standard ACLS.[82] However, whether ECPR should be employed for all OHCA patients is still controversial, given the significant barriers to out-of-hospital ECPR implementation that include cost and resource availability. A recent large registry study showed that ECPR did not improve mortality or outcome.[83] ECPR may be more successful in OHCA for patients with a shockable rhythm, who receive immediate bystander CPR, and have a CPR duration less than 60–90 minutes. Improving center outcomes for all ECPR patients should focus on appropriate patient selection and quality of CPR and team training (including simulation if able), with the primary goal of minimizing time to cannulation.[84,85]

NEW INDICATIONS

The emergence of the COVID-19 pandemic created a new indication for respiratory ECLS in the setting of overwhelmed ICUs and diminishing supply of protective personal equipment. As the knowledge of the respiratory virus continues to evolve, recommendations were created by ELSO to help guide decision making for provision and clinical management of COVID-19 ECLS patients. Data from the ELSO COVID dashboard currently show 3668 adult COVID-19 patients treated with ECMO from January to November 2020, with a mortality rate of 45% for patients with a final disposition of hospital discharge or death.

A disturbance in the coagulation pathway for COVID-19 patients has now been well described in the literature that is characterized by increased risk of arterial and venous thromboembolism. Consequently, higher levels of anticoagulation may be required.[86] However, some ECMO patients may have an increased risk of bleeding later in the ECMO course because of transition from a procoagulant state to an anticoagulant state secondary to a disseminated intravascular coagulation (DIC)–like picture, decreased platelet adhesion, and hyperfibrinolysis.[87] The increased rate of thrombosis but a concomitant increased potential for later bleeding adds to the general confusion regarding anticoagulation during ECMO. Use of viscoelastic testing in this population may be especially useful. One intriguing new finding from the international COVID Consortium noted that use of prone positioning during ECMO in COVID patients was associated with improved outcome. More study in this area is clearly required.

WEANING FROM ECMO

Weaning from ECLS depends on the mode. For VV mode, the extracorporeal gas flow should be reduced stepwise to zero and then gas flow clamped off from the membrane lung with close monitoring of the patient's arterial oxygenation and carbon dioxide levels. Initially, circuit flow is continued. The patient is generally monitored for several hours to a few days while monitoring hemodynamic parameters and signs of adequate tissue oxygenation such as lactate. Ventilator support may need to be increased while still keeping below injurious setting guidelines that address tidal volume, airway pressures, ventilation frequency rate, and fraction of inspired oxygen. Note that many patients with respiratory failure will have return of adequate oxygenation before the ability to maintain adequate ventilation. Monitoring of respiratory rate and work of breathing during the trial off ECMO are important aspects. In patients who remain intubated, use of end-tidal CO_2 monitoring may identify rapid increases in $PaCO_2$ during weaning or trial off support. Although reduction of blood flow is not mandatory during VV ECMO weaning as blood is leaving and entering the same side of the heart, most centers do reduce blood flow to 1–2 L/min before decannulation.

For VA patients, the ECMO blood flow is reduced either over a predetermined time frame set by the clinical team or fairly rapidly with echocardiographic guidance at the bedside. Often referred to as a "ramp trial," reduction of flow is lowered to 1 L/min or 40–50 cc/kg in pediatric patients and cardiac patients while performance is assessed via hemodynamics, gas exchange, and echocardiographic evaluation. Length of time spent at low flow should be carefully considered, because of the risk of thrombus formation. If the patient tolerates lower flow, assessed by stable hemodynamics with minimal need to increase vasoactive support and maintenance of stable oxygenation and ventilation, then consideration for decannulation may be appropriate. Especially in infants and children, even the low flow provided during this phase may be enough to maintain clinical stability; when all support is removed, however, some patients rapidly fail. Thus to adequately assess if the patient can tolerate the absence of ECMO support, clamping of both circuit cannulas is required. To prevent clotting from stasis in the cannulas, they should be opened and flushed every 10–15 minutes. Adult patients may not require total clamping of the circuit if they exhibit good performance at low flow. Alternatively, patients who are recovering but not yet able to independently maintain adequate unassisted hemodynamic support may be transitioned to other devices such as Impella until full recovery occurs.

PEDIATRIC ECMO

According to the most recent ELSO registry report from July 2020, the number of neonatal and pediatric patients in the registry who received ECLS is 72,178, with an overall survival rate to hospital discharge of 61%.[88] Historically, ECLS was used mainly as a rescue therapy for neonatal respiratory and cardiac failure. As the indications for ECLS have expanded in older groups, an increase in pediatric cases, especially cardiac, has simultaneously occurred. Improvements in perinatal and neonatal care have reduced the need for ECMO in the newborn.

The most common indication for neonatal respiratory ECLS is congenital diaphragmatic hernia, which also has the lowest associated rate of survival. Infectious lung disease, including bronchiolitis, pneumonia, and pertussis, is the most common etiology for pediatric respiratory failure[89] (see Table 40.5). VV cannulation use had increased substantially over the last decade. However, given current lack of appropriate VV cannulas for neonates, there has been a relative recent decline in VV-ECMO.

Table 40.6 lists the most common cardiac etiologies for neonates and pediatric patients. A recent review from the Pediatric Cardiac Critical Care Consortium (PC[4]) registry described the epidemiology and outcomes for pediatric ECLS cardiac patients.[90] That review of over 14,000 hospitalizations found that pediatric cardiac ECLS was used most often for systemic circulatory failure and cardiac arrest. Surgical patients were more likely to need ECMO postoperatively if they were younger, had been sicker preoperatively, had longer operative bypass time, or required more complex repairs. Surgical patients had a slightly lower in-hospital mortality rate of 49% compared with

63% for medical patients. Mortality rate for patients who received ECPR was 83% for medical patients and compared with a mortality rate of 50% for medical patients.

The most common complications for neonatal and pediatric ECLS stem from mechanical issues or bleeding and thrombotic events. Neurologic complications continue to contribute to significant morbidity and mortality, with 5%–11% of neonatal and pediatric patients suffering from an intracranial hemorrhage. Many recent reviews of neonatal and pediatric ECLS have highlighted the importance of long-term follow-up after hospital discharge with neurodevelopmental screening to assess for any neuropsychologic deficiencies that may impair learning, communication, and behavior.[91]

Similar to adult ECMO, scoring systems have been developed to predict mortality for pediatric ECLS patients. Several scores composed of different variables have been created for neonatal and pediatric respiratory patients. A score system by Barbaro and colleagues based on ELSO registry data divides patients into neonatal (neo-RESCUERS) and pediatric (ped-RESCUERS).[92,93] Maul and colleagues developed the neonatal respiratory score PIPER (Pittsburgh Index for Pre-ECMO Risk), as a tool to compare neonatal VA respiratory patients.[94] Lastly, the P-PREP score for patients aged 7 days to less than 18 years with respiratory failure by Bailly and colleagues was also derived from the ELSO registry and then externally validated.[95] These scores should not be used as selection tools to deny ECLS to individual patients or for management, but rather to help counsel families of the possible mortality risks and for research and quality improvement.[96] Further refinement and validation of these scores are needed. Detailed pediatric ECMO information is also provided within the references.

ETHICAL CONSIDERATIONS

As the number of centers that provide ECLS and the indications for ECLS continue to increase, there are several ethical considerations confronting its use. The final goal for any ECLS patient should be recovery or transplantation, for which ECLS serves as a temporizing bridge. For some patients, recovery or transplant prove not achievable, requiring withdrawal or limitation of ECLS support. Clear communication before initiation of ECLS regarding risk of complications, possible failure, overall goals of care, and limitations of ECLS can help mitigate some of the family distress in the event that withdrawal is deemed necessary by the caregivers. Palliative care teams can help with these difficult conversations, facilitating alignment of goals of the family and care team. In times of pandemic situations such as COVID-19, lack of available staff, equipment, and hospital beds and lack of in-person family discussions also raise new ethical concerns of how best to triage patients, provide ECMO care, establish appropriate informed consent when emergent discussions are held over the phone, and provide understanding of the patient's clinical course without family bedside presence. The ability to maintain ECMO over months with newer technology also raises issues of when to withdraw or limit care. All these challenges will require careful conversation and thought as the field moves forward.

FUTURE CONSIDERATIONS

Given the rapid extension of ECMO to many clinical settings previously excluded or unexplored, it is likely that the use of this modality will continue to rise. How, when, and where to offer it to well-qualified patients will remain key issues to resolve. How to assure access to such care is also problematic, especially in resource-poor environments or in regions with no nearby ECMO center. Guidelines for credentialing for ECMO centers and providers also need further discussion. Use of telemedicine or remote monitoring systems to augment patient management may assist in care. The continued evaluation of quality of life after ECMO, risk/benefit, and healthcare expenditures are also areas of mandatory research. With recent reports that ECMO techniques may improve outcome in cardiac arrest and can be effectively applied outside the hospital environment, the question of how this innovation will affect emergency care is another discussion likely to become a focal point in the near future. Only with well-intentioned collaboration among clinicians, researchers, and administrators will we improve ECMO outcomes at the center, regional, national, and international levels.

KEY POINTS

- There are two modes of ECMO: venovenous and venoarterial. Venovenous ECMO is used for isolated respiratory failure, whereas venoarterial ECMO provides both respiratory and cardiovascular support.
- Venovenous ECMO is used for diverse pediatric and adult indications, including severe ARDS, refractory hypercapnia, bridging to lung transplantation, and severe PGD after lung transplant.
- Venoarterial ECMO is used for certain cardiogenic shock states, including postoperative cardiogenic shock, AMI, and acute myocarditis. This methodology also serves as a bridge to deploying a VAD or heart transplantation.
- ECPR can be used for refractory cardiac arrest, but high rates of morbidity and mortality in this setting continue to require judicious patient selection.
- Anticoagulation is necessary during most ECMO runs to prevent patient and circuit clotting. Management of anticoagulation continues to be challenging, and more research is needed to define optimal laboratory testing and anticoagulation strategies.
- Complications occur commonly during ECMO and include infection, bleeding, clotting, and cerebrovascular events such as ischemic stroke and hemorrhage.

Brunetti MA, Gaynor JW, Retzloff LB, et al. Characteristics, risk factors, and outcomes of extracorporeal membrane oxygenation use in pediatric cardiac ICUs: a report from the Pediatric Cardiac Critical Care Consortium Registry. *Pediatr Crit Care Med.* 2018;19:544–552.
This review is the first multicenter study describing outcomes of pediatric cardiac patients requiring ECMO. Data were obtained from the Pediatric Cardiac Critical Care Consortium (PC⁴) registry. Of 449 ECMO runs, the mortality rate was 49% in the surgical group and 63% in the medical group. High-risk subgroups were identified among both medical and surgical cohorts to create or improve quality initiatives that affect patient outcome.

Combes A, Hajage D, Capellier G, et al. Extracorporeal membrane oxygenation for severe acute respiratory distress syndrome. *N Engl J Med.* 2018;378:1965–1975.
The EOLIA trial followed the CESAR trial and attempted to determine if early initiation of ECMO for severe ARDS patients reduced 60-day mortality. No statistical difference in mortality was seen between the control group who received conventional mechanical ventilation and the ECMO group. The power calculation was based on a high expected mortality of 60%, which was a major critique of the study.

Lorusso R, Gelsomino S, Parise O, et al. Neurologic injury in adults supported with veno-venous extracorporeal membrane oxygenation for respiratory failure: findings from the Extracorporeal Life Support Organization Database. *Crit Care Med.* 2017;45:1389–1397.
This observational study of 4988 VV-ECMO adult patients describes the neurologic complications reported to ELSO from approximately 350 centers.

Neurologic complications occurred in 7% of the patients, with intracranial events being the most common (181 of the 426 complications, 42.5%). This review emphasizes that the mortality rate for patients with neurologic complications was high, with 76% of patients dying compared with 38% of patients who did not have neurologic complications.

Nutritional Support

Arthur R.H. van Zanten

Critically ill patients typically have anorexia and are frequently unable to take oral diets. Therefore micronutrients and macronutrients should be prescribed as enteral or parenteral nutrition.[1]

The catabolic response of critical illness is characterized by inflammatory and endocrine stress responses that may induce variations in resting energy expenditure (REE) and urinary nitrogen excretion.[2]

Nutritional intake may be insufficient and lead to accumulated energy and protein deficits. This can result in a reduction of the lean body mass (LBM) to an extent of 1 kg per day.[3] Low-admission LBM, severe skeletal muscle wasting, and intensive care unit (ICU)–acquired weakness are all associated with a prolonged need for mechanical ventilation and increased infectious morbidity and mortality rates.[4,5]

Anorexia is likely a temporary adaptive response, as animal and human studies have shown trophic effects of enteral nutrients on gut mucosa integrity and improved outcomes.[6]

Nutritional support for adult ICU patients aims at reducing energy and protein deficits without inducing overfeeding, providing sufficient micronutrient intake, and preserving gut integrity. Several large nutrition trials with high-quality data have led to some consensus. However, many controversies persist.[6,7]

NUTRITIONAL RISK ASSESSMENT

Most nutritional assessment instruments, such as the MNA, SGA, SNAQ, NRS-2002, and MUST scores, have not been developed for ICU patients and rarely have been specifically validated.[8]

The (modified) NUTrition Risk in the Critically ill (mNUTRIC score) has been made available.[9] A conceptual model links starvation, inflammation, nutritional status, and outcomes. Low scores (0–4) predict a low malnutrition risk, and high scores (5–9) identify patients with increased ventilation duration and mortality that are most likely to benefit from nutrition therapy (Table 41.1).

Patients with a higher body mass index (BMI; kg/m^2) demonstrate better ICU and hospital survival because of poorly understood mechanisms.[10] Low skeletal muscle area, as assessed by computed tomography (CT) scan, is a risk factor for mortality in ventilated patients independent of gender and APACHE-II score. Moreover, muscle mass was a primary predictor of mortality, whereas BMI was not.[11] Preserving LBM is a primary target of nutritional therapy.

REFEEDING SYNDROME

Refeeding syndrome refers to biochemical and clinical symptoms, in addition to metabolic abnormalities caused by shifts in electrolytes and fluid imbalance in malnourished patients undergoing refeeding by oral, enteral, and/or parenteral feeding.[12]

It is characterized by low concentrations of predominantly intracellular ions: phosphate, magnesium, and potassium, in addition to abnormalities in glucose metabolism, sodium levels, and water balance associated with morbidity and mortality.[13] Thiamine deficiency can also occur.[14]

The incidence of refeeding syndrome can be up to one-third of patients in longer-ventilated ICU patients when a nutrition-induced drop in plasma phosphate levels <0.65 mmol/L is used as the definition.[15] Plasma electrolytes—in particular phosphate—and glucose should be measured before feeding and any deficiencies corrected during feeding. Whenever marked hypophosphatemia occurs after the start of feeding, intake should be reduced to 500 kcal per day for 48 hours.[16,17]

ENTERAL NUTRITION

Tube feeding, or enteral nutrition (EN), is administered as a special liquid food mixture containing proteins, carbohydrates, fats, vitamins, and minerals through a tube into the stomach or small bowel.

Feeding Tubes

Nasogastric or nasoenteral tubes are placed into the stomach or bowel through the nose. To prevent sinusitis or nasal decubital ulceration, orogastric and oroenteral tubes are also used. A tube placed directly through the skin into the stomach or bowel is called a *gastrostomy* or *jejunostomy*.

Nasogastric tubes may be used depending on composition: polyvinyl chloride (PVC) tubes up to 10 days, polyurethane (PUR) up to 6–8 weeks, and silicone tubes for 6 weeks to 3 months.

Blenderized Tube Feeds

Low-cost blenderized tube feeds ("home brew") are used in some parts of the world. Macronutrient content is usually highly variable, often conflicting with daily recommendations.[18] Moreover, there is a high contamination risk, physical and chemical instability, and high osmolarity and viscosity, potentially enhancing intolerance.

Commercially Available Tube Feeds

Tube feeds are available as canned powder to dissolve, liquid-containing glass bottles, or self-collapsible packages. Closed feeding systems involve the use of sterile feeding containers that are spiked with feeding sets. Closed feeding systems use connectors that prevent a connection to intravenous lines and reduce the contamination risk, and the hanging time can be increased up to 24 hours. Higher contract price and increased waste of closed systems lead to higher daily costs. However, after adjusting for nursing time and feed contamination costs, the total costs are lower.[19]

TABLE 41.1 Modified* NUTRIC Score Variables

The NUTRIC score is designed to quantify the risk of critically ill patients developing adverse events that may be modified by aggressive nutrition therapy. The score of 1–9 is based on five variables that are explained here.

Variable	Range	Points
Age (years)	<50	0
	50 to <75	1
	>75	2
APACHE-II score (points)	<15	0
	15 to <20	1
	20 to 28	2
	>28	3
SOFA score (points)	<6	0
	6 to <10	1
	>10	2
Number of comorbidities	0 to 1	0
	>2	1
Days from hospital to ICU admission	0 to <1	0
	>1	1

*Interleukin-6 (IL-6) was part of the original scoring system (acute inflammation); however, it was often not routinely available, as it contributed very little to the overall prediction of the NUTRIC score. The modified score is depicted.

From Heyland DK, Dhaliwal R, Jiang X, et al. Identifying critically ill patients who benefit the most from nutrition therapy: The development and initial validation of a novel risk assessment tool. *Crit Care*. 2011;15(6):R268.

Compositions of Tube Feeding

Nutrient concentrations of formulas vary from 1.0 to 2.0 kcal/mL. Calorically dense formulas are used in patients requiring fluid restriction. Polymeric high-protein formulas have higher protein to nonprotein energy ratios and aid in achieving protein requirements in obese patients while preventing energy overfeeding. There is no evidence that hydrolyzed protein (peptide-based) formulas are superior with respect to tolerance, absorption, or outcome.[20]

Fibers

There are feeds with and without fibers. Sources of fiber in EN include soluble and insoluble fibers. Soluble fibers (e.g., pectin and guar) are fermented by colonic bacteria and enhance colonic sodium and water absorption to treat EN-associated diarrhea. Insoluble fibers (e.g., soy polysaccharide) increase fecal weight and peristalsis and decrease the fecal transit time.[21] Frequently, mixtures of fibers are used.

Disease-Specific Feeding Formulas

Renal formulas have lower protein concentrations and lower potassium and phosphate levels. Hepatic formulas have increased amounts of branched-chain amino acids (e.g., valine, leucine, and isoleucine) and reduced amounts of aromatic amino acids (e.g., phenylalanine, tyrosine, and tryptophan). Diabetic formulas have lower carbohydrate, higher fat content, and variable types of carbohydrates (e.g., oligosaccharides, fructose, cornstarch, and fiber). In pulmonary formulas, some carbohydrate calories are substituted with fat calories to limit carbon dioxide (CO_2) production and improve ventilation. Acute respiratory distress syndrome (ARDS) formulas combine antioxidants with borage and fish oils to supplement gamma-linoleic acid (GLA), and eicosapentaenoic acid (EPA).

In patients with chyle leakage, low-fat or medium-chain triglycerides (MCTs) or enriched feeds are recommended. MCTs do not require lymphatic transport.

Overall, for all disease-specific feeding formulas, strong evidence to improve outcome is lacking.[22]

Allergies

The majority of adverse reactions to foods are nonimmunologic in origin, with lactose intolerance being the most common. Documented food allergies in adults are likely lower than 8%–10%, and most enteral feeds are gluten-free. For specific allergies, soy-free, casein-free, whey-free, and egg-free feeds are available.

Contraindications to Enteral Nutrition

In general, EN is safe when contraindications are carefully reviewed (Table 41.2). They are related to obstruction, bowel perforation, and ischemia. Many critically ill patients are at risk of splanchnic hypoperfusion caused by circulatory redistribution. It is essential to provide adequate fluid therapy before commencing EN. There is no definition of hemodynamic stability associated with safe enteral feeding. Retrospective data show that early EN in patients on vasopressor treatment is safe and improves outcome.[23] However, aggressive feeding up to target in the phase of shock resuscitation induces bowel ischemia.[24] Patients should have stable blood pressures without the need to increase vasopressors, with acceptable central venous oxygen saturation ($ScVO_2$) and/or plasma lactate levels or other indicators of adequate blood flow. For most patients this will be within 12–24 hours after admission, still meeting the window of early EN (24–28 hours).

Timing of Initiation

By definition, early EN is initiated within the first 24–48 hours after hospital admission. Admission is considered to be the starting moment for ICU patients. Observational studies show that early EN is superior to late initiation (>48 hours) and is therefore recommended in the guidelines.[25] The practical inability to initiate early EN may reflect the severity of illness.

Trophic or Permissive Underfeeding Versus Full Enteral Nutrition

The optimal dose of nutritional support is heavily debated. Permissive underfeeding, trophic, trickle, and hypocaloric feeding are frequently used and confusing.

Permissive underfeeding suggests a lower nutritional intake (e.g., calories, proteins, and micronutrients) is acceptable. Hypocaloric feeding implies that only energy intake is lower. Trophic feeding has no clear definition, although it is accepted to represent an enteral intake of 10–20 mL/h or 500–1000 kcal/day.

Recent trials on trophic, permissive underfeeding and full nutritional support did not demonstrate benefits of either strategy, suggesting that trophic feeding or permissive underfeeding (PERMIT trial)could be sufficient; however, gastrointestinal tolerance was better in the trophic feeding arm in the EDEN trial.[26–28] Most studies included relatively young, well-nourished (high BMI) patients with low nutritional risk (NUTRIC score <5). In the only trial with a higher nutritional risk, trophic feeding was associated with more infections. Functional outcomes in all studies were not investigated, although long-term outcomes have been shown to be associated with feeding adequacy.[29]

Energy-Dense Versus Routine Enteral Nutrition

In 3957 patients undergoing mechanical ventilation, the rate of survival at 90 days associated with the use of an energy-dense formulation

TABLE 41.2 Recommendations to Start and Delay Early Enteral Nutrition

Recommendations	Rationale
Recommendation 1: Start early enteral nutrition in all critically ill patients within 48 hours, preferably within 24 hours when there is no reason to delay enteral nutrition (see the following recommendations).	Early enteral nutrition is associated with lower risk of infections and preserves the gut function, immunity, and absorptive capacity.
Recommendation 2: Delay early enteral nutrition in case of enteral obstruction.	Feeding proximal of an obstruction will lead to blow-out or perforation.
Recommendation 3: Delay early enteral nutrition in case of compromised splanchnic circulation such as uncontrolled shock, overt bowel ischemia, abdominal compartment syndrome, and during intraabdominal hypertension when feeding increases abdominal pressures.	Absorption of nutrients demands energy and oxygen. In states of low flow or ischemia, forcing feeding into the ischemic gut may aggravate ischemia and lead to necrosis or perforation.
Recommendation 4: Delay early enteral nutrition in case of high-output fistula that cannot be bypassed.	Enteral feeding will be spilled into the peritoneal space or increase the fistula production.
Recommendation 5: Delay early enteral nutrition in case of active gastrointestinal bleeding.	Enteral feeding will limit the visualization of the upper gastrointestinal tract during endoscopy.
Recommendation 6: Delay early enteral nutrition in case of high gastrointestinal residual volume (> 500 mL in 6 hours).	This threshold is associated with poor gastric emptying and may increase the risk of aspiration. Prokinetics and postpyloric feeding can circumvent this problem.

From Van Zanten ARH, De Waele E, Wischmeyer PE. Nutrition therapy and critical illness: Practical guidance for the ICU, post-ICU, and long-term convalescence phases. *Crit Care*. 2019;23(1):368.

(1.5 kcal/mL) for enteral delivery of nutrition was not higher than that with routine EN (1.0 kcal/mL). Higher calorie delivery did not affect survival time, receipt of organ support, number of days alive and out of the ICU and hospital or free of organ support, or the incidence of infective complications or adverse events.[30]

Stoppages

Interruptions in enteral feeding for various reasons are frequent, resulting in intakes less than the prescribed amounts. Administering target volumes over 20 hours to circumvent this problem or to increase the infusion rate after stoppages can be recommended.[31]

Gastric Residual Volume

The increased gastric residual volume (GRV) amount aspirated from the stomach after administration of feed represents feeding intolerance. Risk factors for delayed gastric emptying include gastroparesis, diabetes mellitus, gastric outlet obstruction, (postoperative) ileus, trauma, or sepsis, and medications affecting gastric motor function (e.g., opioids). Aspiration of gastric contents should be prevented, although the GRV thresholds are non–evidence based. Recommendations have gradually increased up to 500 mL in 6 hours and GRV can be reinfused or discarded. Discarded GRV reduces feeding efficacy.

Proton pump inhibitors reduce gastric secretions.[32] Prokinetic medications are used to improve gastric emptying, such as metoclopramide (e.g., 4 × 10 mg and erythromycin 2 × 200 mg) either alone or combined. They are safe when QTC intervals are monitored and used for up to 7 days, and tachyphylaxis is common.[33] Two trials demonstrated that the omission of GRV measurement does not increase the aspiration incidence. Moreover, allowing a large GRV increases the amount of feeding administered. To abandon the GRV measurement is debated, and if all strategies fail, a postpyloric feeding tube can be inserted as often as small intestinal functions are normal.[34]

Postpyloric Feeding

Immediate postpyloric feeding may facilitate the early increase of EN, although evidence of superiority is lacking. However, reduced aspiration risk has been clearly demonstrated.[35] Postpyloric tubes are placed by duodenal endoscopy or disposable tubes with fish-eye lenses, using electromagnetic tube placement or self-advancing nasal-jejunal devices. Selection of modality, timing, and success of positioning are related to patient factors, operator experience, and logistics. Criteria to monitor postpyloric feeding are provided (Box 41.1), as monitoring jejunal feeding is complex.

Complications of Enteral Nutrition

Most complications associated with EN are minor, but some can be serious. Complications can be categorized into problems encountered during the placement of tubes (e.g., tracheal/pulmonary misplacement and epistaxis) and during delivery: clinical and metabolic problems (e.g., refeeding syndrome, high GRV, vomiting, aspiration, diarrhea, azotemia, hypernatremia, and dehydration or hyperglycemia), and nutritional problems (e.g., tube obstruction and bacterial contamination).

Aspiration

There is no consistent relationship between GRVs and aspiration. Aspiration may occur with low GRV; it occurs significantly more often when the volumes are high.[36] Head-of-bed elevation can be recommended, although whether 45 degrees head-of-bed elevation is superior to 25 to 30 degrees elevation remains unproven.

Routine GRV monitoring in ventilated patients to prevent aspiration is debatable, as omitting measurements does not transfer into higher ventilator-associated pneumonia rates.[37]

Diarrhea

Critically ill patients may develop diarrhea for various reasons (Box 41.2). During the first 14 ICU days, at least 1 day of diarrhea was observed in 14% of patients. Delivering >60% of the energy target by EN, antibiotics, and antifungal drugs are risk factors.[38] Of the diarrhea episodes, 89% last 4 days or less. EN per se was not a risk factor, although anecdotal improvements have been reported when using fiber-enriched nutrition or hydrolyzed protein formulas.[39]

Constipation

The prevalence of lower gastrointestinal tract paralysis leads to an increased fecal transit time; >5 days is common, and in some series up to 90% is seen. Opioid administration is associated with delayed defecation. Prophylactic or therapeutic laxatives and/or fiber-enriched EN (prebiotics) is recommended. Both lactulose and polyethylene glycol are more effective in promoting defecation than the placebo. Early defecation is associated with a shorter length of stay.[40]

Box 41.1 Monitoring Postpyloric Feeding*

Monitor
GRV volume and aspect
Abdominal distention
Fecal transit time
Intraabdominal pressure (optional)

Criteria to Stop Postpyloric Feeding
Major feeding admixture in gastric aspirate suggesting backflow (NB: gastric aspirate without tube feed admixture is not a reason to stop irrespective of volume)
Major abdominal distention
Uncontrolled vomiting
Obstruction ileus
Intraabdominal pressure >20 cm H_2O
Severe diarrhea

GRV, Gastric residual volume.
*Before starting postpyloric feeding, check for general recommendations to delay enteral nutrition (see Table 41.2).

BOX 41.2 Common Causes of Diarrhea in Critically Ill Patients

Medication
Antibiotics
H_2-recepter antagonists, antacids
Drugs: significant amounts of sorbitol, magnesium, or hypertonic medications
Laxative use (unintended)

Gastrointestinal Dysfunction
Gastric or small bowel resection
Inflammatory bowel disease
Pancreatic insufficiency
Radiation enteritis
Sprue
Protein-losing gastroenteropathies
Bowel impaction (paradoxical)

Malnutrition
Hypoproteinemia
Micronutrient deficiencies

Enteral Nutrition–Associated
Excessive feeding rate, concentration, volume, or osmolality
Adaptation in malnourished patients or those whose gastrointestinal tract has not been used recently
Intolerance or allergy to feeding formula

Infection
Clostridium difficile enterocolitis
Opportunistic gastrointestinal infection
Significant amounts of contaminated feeding formula
Altered gastrointestinal flora

Endocrine Dysfunction
Diabetes mellitus
Hyperthyroidism
Hypocortisolism

Protocols

Evidence-based nutrition protocols designed to improve enteral feeding have been shown to improve feeding adequacy and outcome.[41,42] Developing a protocol is recommended (Fig. 41.1).

PARENTERAL NUTRITION

Total parenteral nutrition (TPN) supplies all daily nutritional requirements by the parenteral route (via a central venous catheter or venous peripherally inserted central catheter [PICC] line). Partial or supplemental parenteral nutrition (SPN) aims to close the gap in the intake when EN does not reach the targets.

Composition

The optimal PN composition depends on the clinical situation, energy, and protein needs, in addition to electrolyte abnormalities and the risk of fluid overload.

The liquid food mixture of standard PN comprises amino acids (apart from glutamine for reasons of stability), carbohydrates (e.g., dextrose/glucose), and lipid emulsions (e.g., soybean oil–, olive oil–, or fish oil–based) and is infused from multichamber or single-chamber sterile infusion bags.[43] Trace elements are added to meet daily recommended allowances. In the absence of EN, vitamin K supplementation, among other vitamins, is important. In the case of hepatic complications (hyperbilirubinemia) interruption of lipid emulsion is recommended, and the optimal lipid emulsion still is debated. The omega-3 fatty acids in fish oil have antiinflammatory effects, omega-9 fatty acids in olive oil have neutral immune effects, and omega-6 fatty acids in soybean oil are proinflammatory. Soybean-based emulsions should be avoided.[6]

Timing of SPN Initiation

Nutrition guidelines present divergent advice regarding the timing of SPN, ranging from early SPN (<48 hours after admission) to postponing SPN until day 8 after ICU admission. Others have studied starting SPN after 3 days (timely; Fig. 41.2).

One randomized controlled trial (RCT) found a higher percentage of living ICU discharge at day 8 in the late SPN group, but there were no differences in ICU and in-hospital mortality. No other RCT found differences in ICU or in-hospital mortality rates. Contradicting results were found for ICU and hospital length of stay, infection rates, nutrition targets, duration of ventilation, glucose control, duration of renal replacement therapy, muscle wasting, and fat loss.

It is reasonable to assume that there are no clinically relevant benefits of early SPN. Considering infectious morbidity and potential slower organ failure resolution and higher acquisition costs, the early administration of SPN cannot be recommended.[44]

In severely malnourished patients, early SPN should be considered, and initiation can be delayed for 5–8 days in others.[25,45]

Complications

Several complications are related to PN use (Box 41.3), and most can be prevented by catheter sepsis prevention and the close monitoring of glucose and electrolytes, fluid status, triglycerides, and liver and renal laboratory tests.[46]

Parenteral Nutrition Versus Enteral Nutrition

EN was considered to be superior to PN. The CALORIES trial that compared 2400 patients randomized into EN or PN changed this assumption.[47] No differences in infections and mortality were found, and less vomiting and hypoglycemia were observed during PN. No differences in caloric intake were found to be the result of the

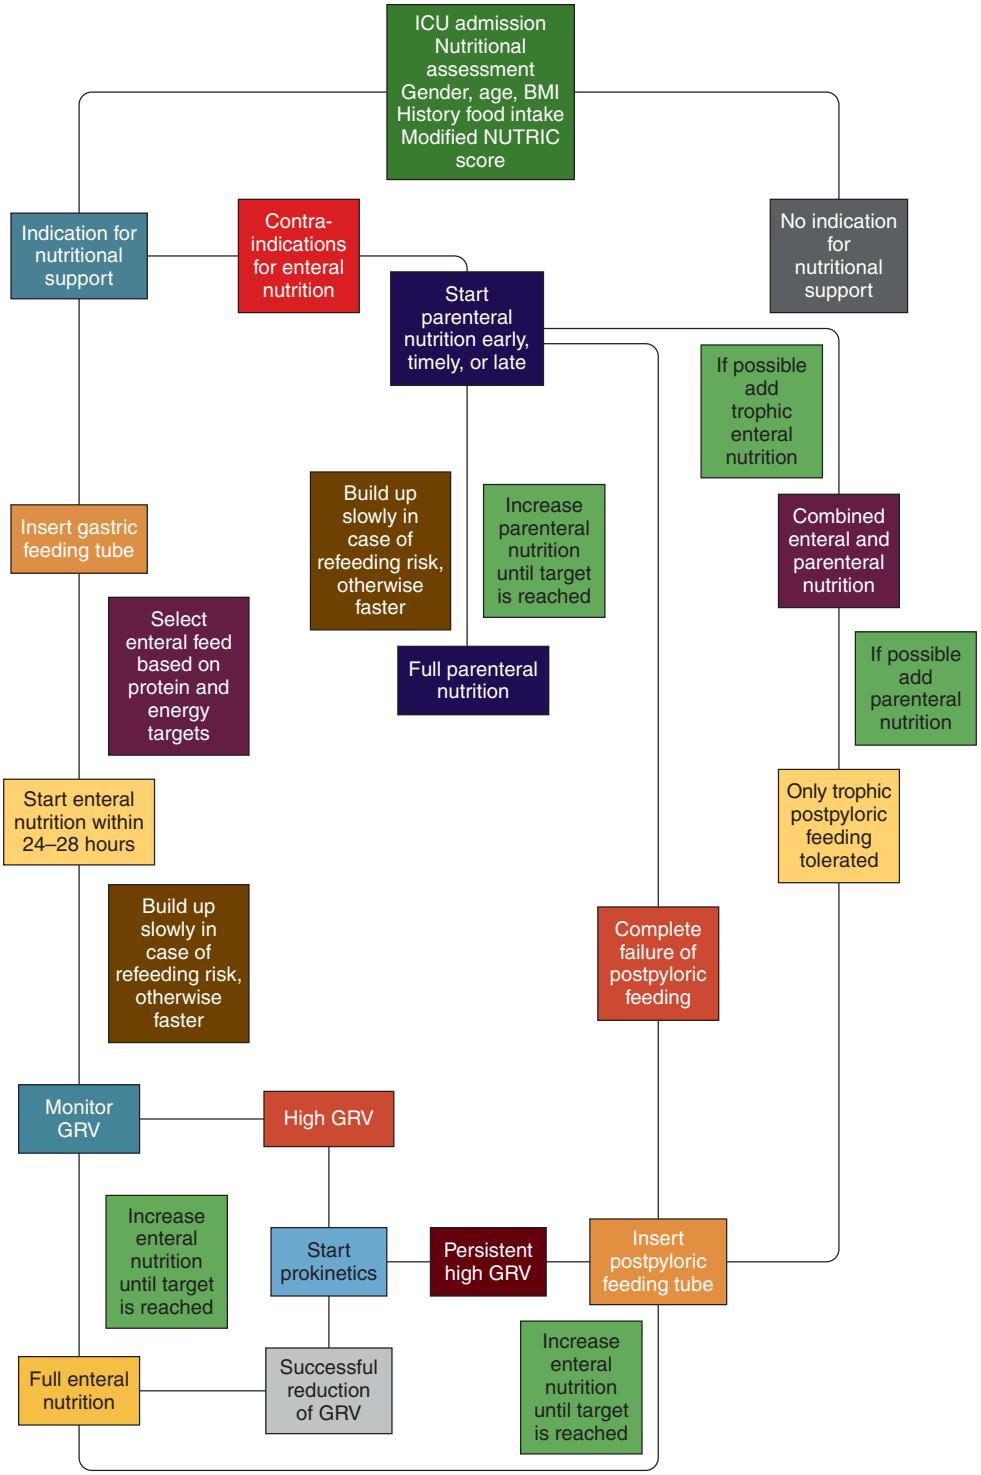

Fig. 41.1 Nutritional support flow chart. *BMI*, Body mass index; *GRV*, gastric residual volume; *ICU*, intensive care unit.

buildup of parenteral intake. Possibly because of better glucose control, preventing overfeeding, and better central catheter care, complications were similar to EN. EN remains a first-line therapy, but in cases where targets cannot be reached, it is safe to commence PN.

CALORIC REQUIREMENTS

Energy requirements in critical illness are unknown. Underfeeding (<80% of energy target) and cumulative energy deficit and overfeeding (>110% of target) are associated with increased morbidity (e.g., infections) and mortality. An optimum energy intake is estimated at 70%–85% of the REE target.[25,48] This lower optimum may result from endogenous energy production that cannot be abolished by providing energy.

Formulas to Estimate Energy Expenditure

Energy requirements are estimated based on patient characteristics before admission. However, requirements differ for each patient and day and should be preferably adjusted according to indirect calorimetry,

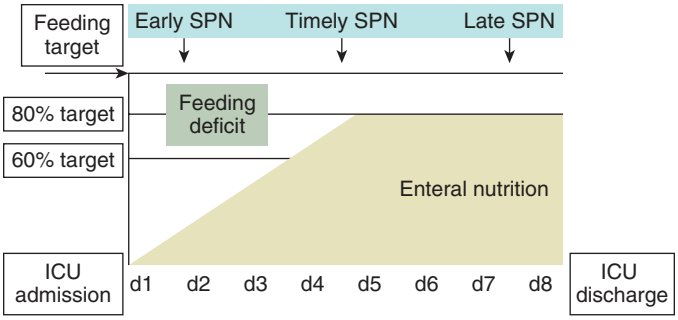

Fig. 41.2 Timing of supplemental parenteral nutrition (*SPN*) to prevent feeding deficit in the intensive care unit (*ICU*).

BOX 41.3 Complications of Parenteral Nutrition

Catheter-Related
Bleeding
Pneumothorax
Central line–associated bloodstream infection
Obstruction
Thrombosis, embolism

Metabolic
Refeeding syndrome
Overfeeding
Glucose abnormalities (hyperglycemia or hypoglycemia)
Hyperlipidemia (hypertriglyceridemia)
Liver dysfunction (increased transaminases, bilirubin, and alkaline phosphatase)
Hepatomegaly
Hyperammonemia
Abnormalities of serum electrolytes and minerals
Vitamin and mineral deficiencies
Elevated BUN

Circulatory
Volume overload

Adverse Reactions
Dyspnea

Nausea
Headache
Back pain
Sweating
Dizziness

Gallbladder-Associated
Cholelithiasis
Gallbladder sludge
Cholecystitis (acalculous)

BUN, Blood urea nitrogen.

although not widely available and often technically difficult or impossible to apply. Data from 160 variations of 13 predictive equations compared with indirect calorimetry measurements demonstrated 38% underestimated and 12% overestimated energy expenditure (>10%). Differences from −43% to 66% above indirect calorimetry values in individual patients were observed.[49]

Guideline Recommendations for Daily Energy Intake

International societies have recommended intakes ranging from 20 to 25 kcal/kg per day in the acute phase and from 25 to 30 kcal/kg in the recovery phase. Additionally, it was suggested to prescribe hypocaloric feeding in critically ill obese (BMI >30 kg/m^2) patients, 60%–70% of the target energy requirements, or 11–14 kcal/kg of the actual body weight or 22–25 kcal/kg of the ideal body weight.[1,25,50]

Indirect Calorimetry

Using a metabolic cart, REE can be measured with indirect calorimetry by measuring oxygen consumption (VO_2) and carbon dioxide production (VCO_2). Every liter of oxygen consumed is equivalent to 5 kcal. Weir introduced an equation to calculate REE:

$$\text{REE} = [\text{VO}_2\ (3.941) + \text{VCO}_2\ (1.11)]\,1440\ \text{min/day}$$

REE provides better energy targets than formulas, and the respiratory quotient (RQ) (CO_2 production/O_2 consumption) is indicative of substrate use. RQ is 1.0 when the fuel is a carbohydrate, 0.8 for protein, and 0.7 for fat; normal RQ is 0.80–0.85. RQ >1.0 may indicate overfeeding. Inaccuracies can arise from air leaks (e.g., circuit or pneumothorax). As O_2 sensors are inaccurate at the higher fraction of inspired oxygen (FiO_2) levels (>0.6–0.7), application in pulmonary failure is limited. Additionally, high positive end-expiratory pressure (PEEP) levels of circuit compressibility cause volume changes and measurement errors.

The evidence that strategies of energy provision based on indirect calorimetry results in improved outcomes is limited.[50] However, the application of indirect calorimetry is now recommended.[25]

Nonnutritional Calories

Typically, nutritional calories are evaluated; however, some calories may go unnoticed. Glucose- and dextrose-containing infusions and drugs, propofol (lipid-based), and trisodium citrate used for extracorporeal circuit anticoagulation during renal replacement therapy provide nonnutritional caloric intake, potentially inducing overfeeding.[51]

PROTEIN REQUIREMENTS

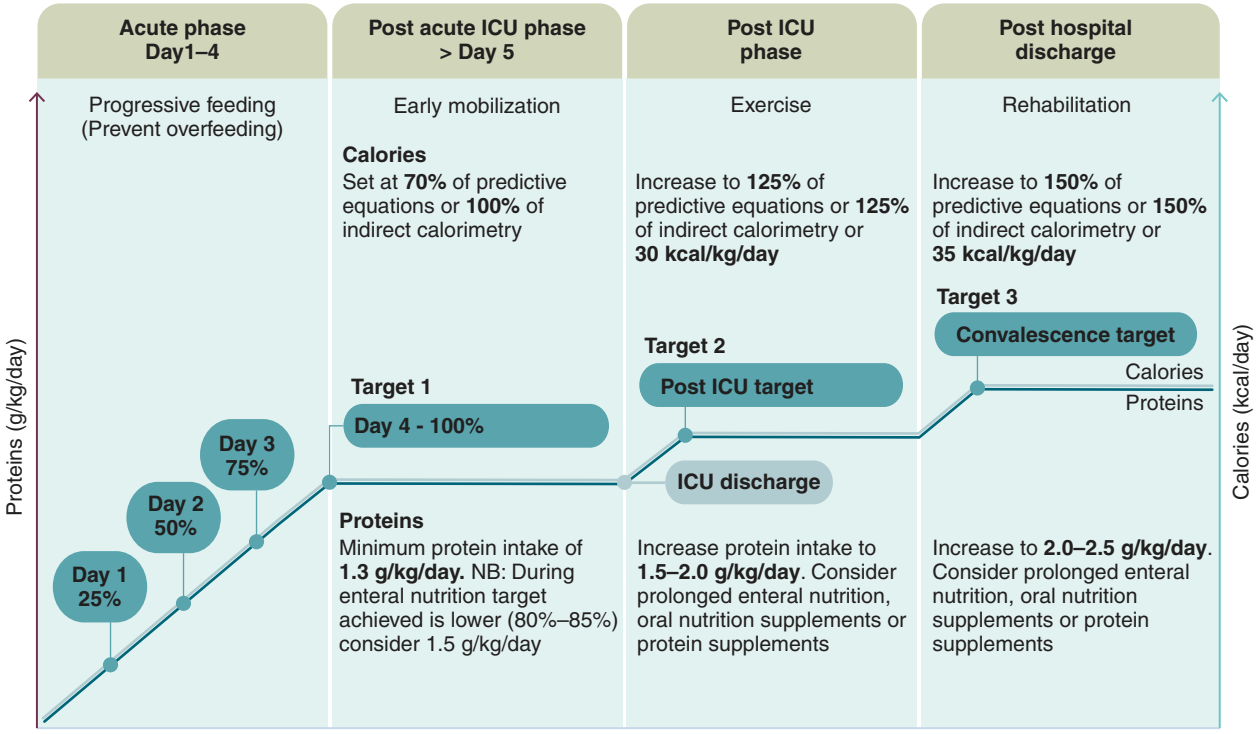
Critical illness causes increased protein turnover and the loss of LBM. There is growing evidence demonstrating the importance of protein and amino acid provisions, and it is likely that nutritional proteins have an impact on the preservation of muscle mass, resulting in better patient outcomes.[48]

Guideline Recommendations for Daily Protein Intake

Several nutritional societies provide slightly different recommendations; however, they can be summarized as to provide at least 1.3 g/kg per day or 1.2–2.0 g protein/kg if the BMI is <30 kg/m^2, 2.0 g/kg ideal body weight if the BMI is 30–40 kg/m^2, and 2.5 g/kg ideal body weight if the BMI is >40 kg/m^2.[1,21,25] Recent studies have suggested that early (day 1–3) very high protein administration may confer harm.[52,53] Therefore gradual progression to protein targets is recommended over 3–4 days.[25,54]

RECOMMENDATIONS FOR CALORIES AND PROTEINS DURING DISEASE AND RECOVERY PHASES

In the early phase, gradual progression of calories and proteins to target is recommended while monitoring phosphate for refeeding hypophosphatemia.[54] During the further patient journey, more calories and



Recommendations			
	Adjust caloric intake for nonnutritional calories from glucose, propofol, and citrate	Patients are at risk for reductions in caloric intake after cessation of enteral nutrition	Patients are at risk for prolonged reduced caloric intake; consider the use of oral nutrition supplements
	When feeding is reduced to prevent overfeeding due to nonnutritional calories, use very-high protein feeds or protein supplements	Patients are at risk for reductions in protein intake after cessation of enteral nutrition and feeding tube removal	Patients are at risk for prolonged reduced protein intake; consider the use of oral nutrition supplements
Monitoring			
Monitor phosphate. Stay at 25% of caloric for 48 h when phosphate drops	Indirect calorimetry (every 48 h) and adjust target accordingly	Monitor oral intake; do not remove feeding tube early	Monitor oral intake and oral nutrition supplement intake
Prevent very early high protein intake	Consider to monitor nitrogen balance	Consider use of muscle ultrasound, BIA, DEXA or CT for body composition	Consider functional muscle tests and follow-up of body composition

Fig. 41.3 Practical Approach to Provide Proteins and Calories During the Phases of Critical Illness and Convalescence. During the first 3 days, calories and proteins are gradually progressed to target 1 on day 4 in steps of 25% daily increase. Target 1 is 1.3 g/kg/day for proteins and for calories, 70% of calculated targets, or 100% of the target when measured by indirect calorimetry. Target 2 should be met during chronic critical illness and after intensive care unit (*ICU*) discharge on general wards. For target 2, calories are increased to 125% of predictive equations or indirect calorimetry, or 30 kcal/kg/day, and for proteins 1.5–2.0 g/kg/day should be targeted. After hospital discharge, target 3 recommends a higher caloric target (150% of predictive equations or 35 kcal/kg/day) and a higher protein intake of 2.0–2.5 g/kg/day. *BIA,* Bioelectrical impedance analysis; *CT,* computed tomography; *DEXA,* dual-energy x-ray absorptiometry; *g/kg/day,* grams of proteins per kilogram per day; *kcal/day,* total kilocalories per day. (From Van Zanten ARH, De Waele E, Wischmeyer PE. Nutrition therapy and critical illness: Practical guidance for the ICU, post-ICU, and long-term convalescence phases. *Crit Care.* 2019;23[1]:368.)

proteins should be prescribed (Fig. 41.3). Even after ICU and hospital discharge, increased levels of calories and proteins are necessary to recover, probably for prolonged periods.[54]

SPECIFIC MACRONUTRIENTS

Enriched or supplemented (par)enteral nutrition with supposed immune-modulating macronutrients (e.g., glutamine, arginine, and fish oil) have frequently been studied.[37] Pharmaconutrition suggests that specific nutritional components may exert pharmacologic effects to modulate the immune response.

Contrasting earlier international recommendations, the MetaPlus trial demonstrated no effect of a cocktail of macronutrients (e.g., glutamine and fish oil) and micronutrients (e.g., selenium, vitamins C and E, and zinc) on the primary endpoint of infections.[53] Moreover, increased long-term mortality among medical patients was observed.

In the REDOXS trial, no clinical benefit of glutamine and antioxidants was found and a trend toward increased mortality at 28 days, in addition to significant increases in in-hospital and 6-month mortality in glutamine-supplemented patients, were found.[55]

Since then, the safety of immune-modulating ingredients has been questioned. Benefits are limited or absent, and potential harm is involved. Use of unbalanced compositions is not recommended.[56]

Glutamine

Glutamine is the most abundant plasma amino acid. In critical illness, plasma levels can be low. However, this is not always the case. Nonessential amino acids can be synthesized from other amino acids. Low levels in ICU patients are considered to be conditionally deficient, too low for the actual condition or disease state. As low-admission plasma glutamine was associated with increased mortality, supplementation was considered.

Positive effects are based on results from older, smaller, and mainly single-center studies. Recent studies have challenged the conditional deficiency hypothesis, both in mechanistic studies and in recent randomized trials (MetaPlus and REDOXS). Low levels could potentially reflect an adaptive response. Glutamine supplementation may only be considered while monitoring plasma levels and should be avoided, as serious safety issues are involved.[57]

Arginine

Another amino acid considered to be conditionally deficient is arginine. Data from 30 trials in 3000 patients after major surgery exhibited reduced infectious morbidity of arginine supplementation and a reduced length of stay. Before surgery, 5–7 days of arginine (12–15 g/day) may be beneficial. However, harm was observed in severe sepsis patients. Excessive nitric oxide production increasing mortality risk was the suggested mechanism. For sepsis patients, arginine-supplemented EN should be avoided.[39]

Fish Oil

There is a lack of studies showing associations of low baseline EPA and docosahexaenoic acid (DHA) levels and outcome. Smaller studies combined borage and fish oils (GLA/EPA) with antioxidants in ARDS, suggesting a benefit.[22] The large OMEGA-EN trial (e.g., omega-3 fatty acids, EPA, DHA, GLA, and antioxidants) in ARDS patients was prematurely terminated for not reducing ventilator-free days and a higher 60-day in-hospital mortality trend ($P = .054$).[58] At present, based on a meta-analysis, the effect of fish oil seems limited or absent.[59]

SPECIFIC MICRONUTRIENTS

The exact recommended daily allowances (RDAs) for antioxidants, trace elements, and vitamins in ICU patients are not known. Many patients have low admission plasma levels. During the ICU stay, this may worsen, as RDAs are only available in 1500 mL (or 1500 kcal) of EN, and many patients have lower intakes. In PN, trace elements and vitamins must be added. However, whether supraphysiologic dosages should be prescribed is inconclusive.

Antioxidants and Trace Elements

A meta-analysis of 21 RCTs on combined antioxidant supplementation showed significant reductions in mortality, ventilation duration, and a trend toward reduction in infections with no effect on ICU or hospital length of stay. Most of the included RCTs were small studies (<100 patients), which were inadequate to detect important effects on mortality. The positive signal emerges only after statistically aggregating these smaller trials.[60]

Vitamins

Few data are available via vitamin supplementation in ICU patients; however, whether low plasma levels reflect deficiency is not known. Hyperlactatemia may reflect thiamine deficiency, and supplementation is recommended.[57] Supplementation may also be indicated in case of history of alcohol abuse, severe malnutrition, or refeeding hypophosphatemia.

Although initial studies on high-dose supplementation with vitamins C, D, and B_1 (and steroids) were promising, recent RCTs were unable to show benefits concerning relevant clinical endpoints.[61–65]

There is a lack of dose-finding studies for most vitamins in critically ill patients. Moreover, we do not know whether normalizing plasma levels translates into a better outcome.[57]

PREBIOTICS AND PROBIOTICS

The World Health Organization has defined probiotics as "live microorganisms, which confer a health benefit on the host."[66] Prebiotics (fibers) are food for probiotics that are nondigestible by humans. Prebiotics stimulate the growth of beneficial bacteria. Symbiotic supplements contain both probiotics and prebiotics.

Critical illness leads to alterations of the gut microbiota, leading to a loss of commensal flora and the overgrowth of potentially pathogenic bacteria. Probiotics restore the microbiota bacterial balance and improve the immune function, in addition to the gastrointestinal structure and function.[67]

Bacterial translocation of probiotics has been reported anecdotally. Since the PROPATRIA trial,[68] which showed increased mortality among probiotic-treated pancreatitis patients because of gut ischemia, safety concerns have been expressed.

A meta-analysis of 13 RCTs did not demonstrate a reduction in the ventilation duration or lower ICU or hospital mortality rates. However, a reduced incidence of ICU-acquired pneumonia and ICU length of stay was found.[69] In a recent Cochrane analysis, the effect on pneumonia was questioned because of the low-quality studies that were included.[70] Identification of which ICU patients could benefit from probiotics is unclear.

SPECIAL PEDIATRIC CONSIDERATIONS

This chapter has been written from the perspective of the adult ICU patient. However, with respect to many aspects, considerations for children are similar. Clinical nutritional support in children must minimize tissue loss, optimize tissue repair, and minimize metabolic overloading. Patients in the pediatric intensive care unit (PICU) should undergo detailed nutrition assessment within 48 hours of admission. Furthermore, as patients are at risk of nutrition deterioration during hospitalization, which can adversely affect clinical outcomes, it has been suggested that the nutrition status of patients be reevaluated at least weekly throughout hospitalization.[71,72]

Pushing nutritional intake beyond recommended levels may create additional metabolic stress. Also for children, indirect calorimetry is recommended to target the energy settings, as predictive equations have been shown to be unreliable. Overall, the pediatric critical care population is heterogeneous, and a nuanced approach to individualizing nutrition support with the aim of improving clinical outcomes is necessary. On the basis of evidence from RCTs and as supported by observational cohort studies, a minimum protein intake of 1.5 g/kg per day is recommended.[71,72]

EN support is generally considered the preferred route for nutrition; however, parenteral nutrition may be necessary to meet the needs of some critically ill children. Based on large cohort studies, early initiation

of EN (within 24–48 hours of PICU admission) and achievement of up to two-thirds of the nutrient goal in the first week of critical illness have been associated with improved clinical outcomes.[71,72]

In the recent PEPANIC trial it was clearly demonstrated that early SPN may induce harm in children. Early parenteral nutrition should be avoided in the early phase (first week) of critical illness unless the enteral route cannot be used.[73] The complexity of pediatric disease and the wide range of ages and body conditions, in addition to the multiple options for nutrient delivery, necessitate close collaboration between physicians and pediatric dietitians who are familiar with children's nutrition requirements during critical illness. In children, immunonutrition is not recommended.

KEY POINTS

- ICU admission LBM and cumulative protein and energy deficit are associated with outcome.
- Refeeding syndrome, as identified by hypophosphatemia occurring after resuming nutrition, should lead to caloric restriction for 2 days and gradual introduction of calories, while supplementing electrolytes and thiamine.
- Enteral feeding is preferred over parenteral nutrition and should be initiated early (24–48 hours after ICU admission) to preserve gut condition.
- Absolute contraindications for EN are intestinal obstruction, perforation, and ischemia.
- Hemodynamic instability is only a temporary contraindication for enteral feeding; feeding can commence when stable vasopressor infusion is achieved.
- In well-nourished patients, trophic feeding or permissive underfeeding is associated with similar outcomes as full nutritional support.
- Higher calorie delivery by energy-dense feeding is associated with similar outcomes as routine enteral feeding.
- Measuring GRV reduces feeding efficiency; therefore it should be abandoned, or high GRV up to 500 mL in 6 hours should be accepted.
- Critical care nutrition protocols improve feeding adequacy.
- Gastrointestinal symptoms such as diarrhea are common during an ICU stay; however, they are frequently the result of causes other than enteral feeding.
- There are no clear benefits of SPN within 5 days of ICU admission.
- Formulae to estimate energy expenditure are inaccurate; therefore indirect calorimetry is recommended.
- Caloric overfeeding should be prevented; therefore nonnutritional calories from propofol, dextrose, and citrate infusion should be considered as an energy source.
- Protein intake should be at least 1.3 g/kg per day (1.5 g/kg per day in children), with higher recommendations in patients with greater BMI and protein loss resulting from renal replacement therapy. Gradual progression to target over several days is recommended.
- Based on contradictory results from clinical trials, pharmaconutrition with glutamine, arginine, and fish oil cannot be recommended.
- RDAs for vitamins and trace elements in critical illness are unknown; however, supplementation should be considered in patients on parenteral nutrition or EN intake below 1500 kcal/day.
- High-dose supplementation of vitamins B_1, C, and D has not improved outcomes of critical illness.
- Although prebiotics and probiotics seem to be safe in most ICU patients, proven benefits in targeting gut microbiota with these strategies are lacking.
